INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Ultrapure Calcium Formate

A. A. Fakeev and A. I. Sukhanovskaya

State Research Institute of Chemicals and Ultrapure Chemical Substances, Moscow, Russia

Received April 15, 2005

Abstract—Crystallization of $Ca(HCOO)_2$ from aqueous solutions was studied and conditions under which an ultrapure product can be obtained were determined.

DOI: 10.1134/S1070427206010010

Calcium formate is a promising material for synthesis of high-temperature superconductors (HTSs) from bismuth, rare-earth elements, thallium, and mercury [1–3]. Substitution of oxides, nitrates, or carbonates by the corresponding formates in solid-phase synthesis markedly simplifies the process and ensures high chemical homogeneity and stoichiometry of the material obtained [4]. In [5], a high efficiency of metal formates in fabrication of films and ceramics from solutions was demonstrated.

In synthesis of HTSs, impurities can strongly affect their structure, phase composition, electrical properties, and strength. It has been shown for the example of the Y–Ba–Cu–O ceramics that particular attention should be given to control over the content of such impurities as ions of iron, nickel, manganese, cobalt, zinc, magnesium, etc. [6, 7].

Calcium formate of pure grades is not manufactured in Russia. Previously, minor amounts of a pure reagent (iron, heavy metals 1×10^{-3} wt % each, chlorides 5×10^{-3} wt %, sulfates 1×10^{-2} wt %) have been manufactured to order [8]. According to catalogs, calcium formate is manufactured in Italy, Germany, Switzerland, the United Kingdom, France, and the United States. Most of the products being manufactured are of the pure grade. Companies in Italy and Switzerland produce a higher-quality formate.

No reports describing synthesis of ultrapure calcium formate could be found in the literature. It has been suggested to obtain the product by the reaction of dilute formic acid with $CaCO_3$, with the subsequent recovery of crystals by evaporation on a water bath and drying in air [9]. A method for synthesis of $Ca(HCOO)_2$ by the reaction of $CaCO_3$ with concentrated HCOOH (90 wt %), evaporation, drying of the resulting crystals, and their triple recrystallization has been described [10], with the quality of the product not specified. A method is known for synthesis of calcium formate by dissolution of $CaCO_3$ is dilute HCOOH (15 wt %), taken in a 43% excess relative to the stoichiometry, with the subsequent evaporation of the solution on a steam bath, separation of the crystals formed, their washing with ethanol, and drying in air successively at room temperature and at 60°C [8].

Of most practical interest among the known methods for deep purification of inorganic substances [11], as applied to $Ca(HCOO)_2$, is its crystallization from aqueous solutions. The compound is comparatively well soluble in water, has a positive temperature coefficient of solubility, and the method for its crystallization from aqueous solutions may be one of the simplest among methods for production of ultrapure calcium formate.

The aim of this study was to develop a procedure for preparing ultrapure calcium formate.

The efficiency of the crystallization purification of calcium formate can be tentatively evaluated using data on phase equilibria in water–salt systems containing this compound. Analysis of the solubility diagrams in the systems $Ca(HCOO)_2$–$M^{n+}(HCOO)_n$–H_2O (M^{n+} is Li^+ [12], K^+ [13], Mg^{2+} [14], Zn^{2+} [15], Cd^{2+} [16], Pb^{2+} [17], Cu^{2+} [18], Y^{3+} [19], Mn^{2+} [20], Ni^{2+} [21], and Cu^{2+} [22]) at 25°C shows that there is no iso- or isodimorphism of the components, with the exception of the system with Cd(II), and, presumably, separation of $Ca(HCOO)_2$ and formates of the above-mentioned elements is possible. Solid solutions are not formed in the systems considered in the region of $Ca(HCOO)_2$ crystallization [12–22], and, consequently, formates of these element will be concentrated in the mother liquor. It would be expected that lithium, potassium, magnesium, zinc, cadmium, lead, cop-

per, manganese, nickel, and yttrium formates will be removed by the subsequent recrystallization of $Ca(HCOO)_2$. No data are available in the literature for water–salt systems containing Ca–Co and Ca–Fe, but, with the solubilities [23] and structure of these formates (Table 1) taken into account, it could be assumed that calcium and cobalt (iron) formates can be separated.

Analysis of published data on the structure of calcium formate and concomitant elements shows that only calcium formate crystallizes in the rhombic crystal system, whereas the other formates form monoclinic crystals. Comparison of the data in Table 1 with the results obtained in studies of the corresponding water–salt systems [14–22] confirms the suggestion that the crystallization method for $Ca(HCOO)_2$ purification is efficient.

With account of the aforesaid, we studied experimentally the crystallization of calcium formate from aqueous solutions. The influence exerted by the yield of $Ca(HCOO)_2$ and by washing of its crystals on the efficiency of the purification process was analyzed.

EXPERIMENTAL

An aqueous solution of $Ca(HCOO)_2$ (200 ml), saturated at 80–85°C, was evaporated on a water bath until crystals were obtained and cooled to 25°C under continuous agitation. The crystals formed were separated and thoroughly squeezed between sheets of a blue-band paper filter under a press to remove the mother liquor, and a sample was taken for analysis. The remaining $Ca(HCOO)_2$ crystals were transferred to a glass vessel for washing, poured over with a calcium formate solution saturated at 25°C (s : l = 1 : 2), the mixture was thoroughly agitated for about 30 min, and the washed crystals were separated and squeezed as described above. Crystals taken for analysis before and after washing were dried at 80°C for about 2 h.

Impurities can be captured in crystallization of $Ca(HCOO)_2$ via adsorption or occlusion of the mother liquor.

The starting $Ca(HCOO)_2$ and crystals before and after washing were analyzed by the atomic-emission method with excitation in an inductively coupled plasma (Baird plasma spectrometer, the United States). The determination error was 10–30%, depending on the properties of an impurity and its content [25].

The results of the analysis were used to calculate the purification coefficients K_p as a ratio of the impurity contents before and after crystallization (washing) [11].

Analysis of the results obtained (Table 2) shows that a change in the degree of crystallization from 0.2 to 0.7 affects only slightly the efficiency of $Ca(HCOO)_2$ purification. For impurities of iron, manganese, and copper ions, the efficiency of the crystallization is virtually the same (K_p = 35–60); additional washing of the crystals positively affects the purification coefficient. In view of the insufficient sensitivity of this analytical technique, it was impossible to determine K_p of $Ca(HCOO)_2$ crystals after washing for all of the impurities studied.

The efficiency of $Ca(HCOO)_2$ crystallization from aqueous solutions was determined using radioactive tracers ^{54}Mn and ^{63}Ni. The experimental procedure was supplemented with spiking of the starting solution with the tracer; the content of manganese and nickel varied from 10^{-3} to 10^{-5} wt %.

The activity of the solutions (crystals were preliminarily dissolved in distilled water) was measured

with a BDIS-3-05 transducer with a detector of ^{54}Mn γ-radiation. The accuracy of radiometric measurements of the activity was 2–3 rel %. In studying the behavior of the ^{63}Ni impurity (β-radiation), the activity was measured with a BDIS-3-05 transducer with scintillation grains; the accuracy of radiometric measurements of the activity was about 10 rel %.

The data obtained (Table 3) show that, in crystallization from aqueous solutions, the purification coefficients of $Ca(HCOO)_2$ crystals are about 40–60 for manganese and nickel ions. After washing of the crystals with a saturated solution of $Ca(HCOO)_2$, these coefficients increase to 260–300. In this case, the degree of crystallization (in the range 0.2–0.7) and the impurity content (10^{-3}–10^{-5} wt %) have no essential effect on the purification coefficients.

The purification coefficients obtained by various methods for manganese and nickel ions in $Ca(HCOO)_2$ crystallization are reasonably consistent (Tables 2, 3) and are in good agreement with the data on the structure of formates of the elements under consideration (Table 1).

Flowsheet for synthesis of ultrapure $Ca(HCOO)_2$: (*1*) reactor for production of a $Ca(HCOO)_2$ solution, (*2*) filter for filtration of the solution, (*3*) evaporator for evaporation of the solution, (*4*) filter for separation and washing of $Ca(HCOO)_2$ crystals, (*5*) reactor for preparation of washing $Ca(HCOO)_2$ solution, and (*6*) quartz furnace for drying of crystals.

Thus, the crystallization of calcium formate from aqueous solutions is an efficient method of its purification.

The results obtained in the study were used to develop a flowsheet of a process for synthesis of ultrapure calcium formate. The principal stages of the process are as follows: production of a calcium formate solution and its filtration, evaporation of the solution, crystallization, separation of $Ca(HCOO)_2$ crystals, washing of the crystals with a saturated solution of $Ca(HCOO)_2$, and drying.

Reagent-grade $Ca(HCOO)_2$ was obtained using $CaCO_3$ of analytically pure grade [GOST (State Standard) 4530–76], formic acid of the same grade (GOST 5848–73), and distilled water:

$$CaCO_{3(solid)} + 2HCOOH + H_2O = Ca(HCOO)_{2(solution)} + CO_2 + 2H_2O.$$

A reasonable excess of HCOOH (15% relative to the stoichiometry), necessary for complete dissolution of $CaCO_3$, was chosen empirically. With a lesser excess of HCOOH (5–10%), the dissolution of the $CaCO_3$ powder was incomplete. The solution obtained was filtered ("blue ribbon" paper filter), evaporated, and gradually cooled under vigorous agitation. The resulting crystals of $Ca(HCOO)_2$ were separated, thoroughly washed on the filter with its saturated solution prepared by dissolution of preliminarily purified crystals, squeezed, and dried at 80–90°C. All stages of the process for synthesis of ultrapure $Ca(HCOO)_2$ were tested on a laboratory installation (see figure). The mother liquor produced in the crystallization stage contained (wt %): $Ca(HCOO)_2$ about 13.9, HCOOH 11.9, and H_2O 74.2, according to the results of a chemical analysis. It was thrice recycled into the stage of preparation of the starting

Table 4. Quality of a laboratory sample of $Ca(HCOO)_2$ and best foreign analogs (according to catalogs)

Sample	Content, wt %							
	Fe	Mn	Ni	Co	Cu	Pb	Mg	Zn
Laboratory	0.5	0.5	0.5	0.2	0.1	5	50	5
Pure grade, TU (Technical Specifications) 6-09-11-1149–86, Russia	100							
RPE, C.Erba, Italy	50		25		25	25	200	25
Fluka, Switzerland	50	500	50	50	50	50	5000	50

$Ca(HCOO)_2$ solution and then was removed from the process by precipitation of calcium carbonate with a 10% solution of Na_2CO_3.

Performing the crystallization from acid solutions (~15 wt % excess of HCOOH relative to stoichiometry) ruled out adsorption of cation impurities by the crystals and somewhat raised the yield of the finished product [26].

Analysis of a laboratory sample of the product shows that the method developed yields ultrapure calcium formate of a better quality, compared with the best foreign analogs (Table 4).

CONCLUSIONS

(1) Calcium formate can be purified by crystallization from aqueous solutions.

(2) A procedure for synthesis of ultrapure $Ca(HCOO)_2$ was developed.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Behavior of Manganese(II) in Calcium Formate Solutions

A. A. Fakeev

State Research Institute of Chemicals and Ultrapure Chemical Substances, Moscow, Russia

Received February 9, 2005

Abstract—The solubility in the system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O at 25°C was studied by the isothermal method. The behavior of manganese in $Ca(HCOO)_2$ crystallization from aqueous solutions was examined with ^{54}Mn tracer in the concentration range 10^{-3}–10^{-5} wt %.

DOI: 10.1134/S1070427206010022

Practical use of high-temperature superconductors (HTS) is largely determined by the stability of their properties [1, 2]. Passing from the solid-phase technology to synthesis of HTS from aqueous solutions with the use of metal formates, acetates, and oxalates provides high chemical homogeneity and stoichiometry of compositions [3, 4].

Introduction of calcium into HTS based on compounds of bismuth, thallium, rare-earth elements, and mercury improves the properties of these superconductors [3–5].

Use of metal formates in production of HTS imposes stringent requirements upon the content of impurities (iron, manganese, nickel, copper, cobalt, chromium, etc.), which can strongly affect the microstructure, state of grain boundaries, and, in the end, the electrical and mechanical properties of HTS [6, 7].

Calcium formate of pure grades is not manufactured in Russia.

Calcium formate is fairly well soluble in water and has a positive temperature coefficient of solubility; therefore, its crystallization from aqueous solutions may be one of the simplest and most efficient techniques for synthesis of an ultrapure product.

The efficiency of crystallization as the purificaiton method can be tentatively evaluated by data obtained in a study of water–salt systems composed of calcium formate and ions whose content in HTS is limited. As the objects of study served water–salt systems $Ca(HCOO)_2$–$M^n(HCOO)_n$–H_2O at 25°C, where M^n is nickel [8], copper [9], lead [10], magnesium [11], lithium [12], potassium [13], zinc [14], cadmium [15], barium [16], and yttrium [17]. Systems with lithium, magnesium, lead, barium, nickel, zinc, and yttrium ions are of a simple eutonic type, and those with copper, potassium, and cadmium ions are complex systems in which double formates are formed. Analysis of the data obtained shows that there is no interaction between the components in the region of crystallization of calcium formate, and ions will be captured by the forming crystals via adsorption and occlusion of the mother liquor.

In this study, we examined the behavior of manganese(II) in a wide range of its concentrations in calcium formate solutions at 25°C.

EXPERIMENTAL

To judge how manganese(II) behaves in crystallization of calcium formate from aqueous solutions, the ranges of macro- and microconcentrations were examined.

Calcium formate and manganese(II) formate dihydrate were obtained by the reaction of calcium carbonate of ultrapure 7–3 grade [TU (Technical Specifications) 6-09-1990–75] or basic manganese carbonate of analytically pure grade [GOST (State Standard) 7205–77] with formic acid of analytically pure grade (GOST 5847–73). According to the results of chemical and X-ray phase analyses, the compounds obtained were of composition α-$Ca(HCOO)_2$ [18] and $Mn(HCOO)_2 \cdot 2H_2O$ [19].

The content of calcium and manganese jointly present in the macroconcentration range was determined by complexometric titration with a 0.05 M solution of Na_2EDTA with Eriochrome Black T as indicator: the sum of calcium and manganese, at pH 12, and separately manganese, upon precipitation of calcium with a 0.1 M solution of ammonium fluoride.

Table 1. Solubility in the system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O at 25°C

Point no.	Liquid phase, wt %		Solid residue, wt %		Composition of solid phase
	$Ca(HCOO)_2$	$Mn(HCOO)_2$	$Ca(HCOO)_2$	$Mn(HCOO)_2$	
1A	15.6	–	–	–	$Ca(HCOO)_2$
2	15.1	1.0	79.8	0.6	$Ca(HCOO)_2$
3	15.0	1.2	74.0	0.6	$Ca(HCOO)_2$
4E	14.0	2.9	70.0	5.5	$Ca(HCOO)_2$ + $Mn(HCOO)_2 \cdot 2H_2O$
	14.0	2.9	13.1	43.2	$Ca(HCOO)_2$ + $Mn(HCOO)_2 \cdot 2H_2O$
5	12.8	2.8	4.5	46.0	$Mn(HCOO)_2 \cdot 2H_2O$
6	12.6	3.0	4.4	46.6	$Mn(HCOO)_2 \cdot 2H_2O$
7	10.0	3.0	4.2	49.2	$Mn(HCOO)_2 \cdot 2H_2O$
8	9.4	3.5	3.6	51.4	$Mn(HCOO)_2 \cdot 2H_2O$
9	8.4	3.7	3.1	51.2	$Mn(HCOO)_2 \cdot 2H_2O$
10	4.9	4.6	1.7	54.2	$Mn(HCOO)_2 \cdot 2H_2O$
11	0.9	6.3	0.3	56.0	$Mn(HCOO)_2 \cdot 2H_2O$
12B	–	7.7	–	–	$Mn(HCOO)_2 \cdot 2H_2O$

To prevent hydrolysis of manganese(II), hydroxylamine hydrochloride was introduced into the solutions being analyzed [20]. The admissible discrepancy between two parallel determinations was 0.5 rel %, and the total error of analysis, 1.5 rel %.

An X-ray diffraction analysis of the samples was made on a DRON-4-13 diffractometer with CuK_α radiation and semiconductor-purity germanium as internal reference. The X-ray diffraction patterns obtained were processed using the Rapid software package; the reflections were assigned and the lattice constants refined by means of the Powtool software package.

As manganese(II) is susceptible to oxidation in air [21], we tested preliminarily the stability of 2–10% manganese(II) formate solutions in formic acid. The optical spectra of freshly prepared manganese(II) formate solutions in 2.0, 5.0, and 10.0 wt % formic acid and those after 20 days, measured at 350–700 nm on a Specord instrument (Germany) with cell thickness of 1 cm and solution concentration of ~10 wt %, were virtually identical. With account of the aforesaid, an HCOOH concentration of about 2.0 wt % is sufficient for oxidation and hydrolysis of manganese(II) formate to be prevented.

The system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O was studied at 25°C by the isothermal method in special hermetically sealed glass vessels with magnetic stirrers without any liquid seals. The temperature was maintained constant with an accuracy of ±0.1°C [22]. The HCOOH concentration was approximately 2.0 wt %. The starting substances were charged in accordance with the results of a preliminary calculation. The time in which equilibrium was attained was about two days.

The composition of the solid phases was graphically determined by the Schreinemakers method and confirmed by chemical and X-ray techniques.

The data on the solubility in binary systems $Ca(HCOO)_2$–H_2O and $Mn(HCOO)_2$–H_2O were taken from the literature [23, 24].

A study of the solubility in the system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O in a wide range of concentrations of the components at 25°C demonstrated (Table 1) that there is no interaction between the components. Construction of the solubility diagram and an analysis of the solid phases by chemical and X-ray diffraction techniques confirmed the presence of the starting components, $Ca(HCOO)_2$ [18] and $Mn(HCOO)_2$ [19], as solid phases. The composition of the eutonic solution was as follows (wt %): $Ca(HCOO)_2$ 14.0 and $Mn(HCOO)_2$ 2.9. Calcium formate exerts a salting-out effect on manganese(II) formate, reducing its solubility by a factor of nearly 3. The main part of the diagram is occupied by the crystallization branch of the least soluble component, manganese(II) formate.

In the region of crystallization of calcium formate, there is no interaction between the components to give new phases or solid solutions. The capture of manganese(II) ions by crystals of calcium formate may be due to their adsorption on the surface or to occlusion of the mother liquor, and, consequently, a considerable degree of product purification to remove manganese(II) ions would be expected.

Table 2. Distribution of the ^{54}Mn impurity in crystallization of calcium formate from aqueous solutions at 25°C

Initial content of impurity, wt %	Degree of crystallization of $Ca(HCOO)_2$	Purification coefficient of crystals	
		before washing	after washing
10^{-3}	0.2	50 ± 3	260 ± 7
10^{-4}		55 ± 4	260 ± 8
10^{-5}		58 ± 4	260 ± 7
10^{-3}	0.4	52 ± 4	260 ± 7
10^{-4}		55 ± 4	262 ± 7
10^{-5}		59 ± 3	268 ± 8
10^{-3}	0.7	60 ± 3	270 ± 7
10^{-4}		63 ± 4	268 ± 8
10^{-5}		66 ± 4	270 ± 8

The system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O was studied in the range of microconcentrations of manganese(II) by using a radioactive tracer, ^{54}Mn.

^{54}Mn was introduced into a concentrated aqueous solution of calcium formate at 75–80°C, formic acid was added in an amount necessary for creating a concentration of 2.0 wt %, and the mixture was vigorously agitated for 1.0 h. The precipitated $Ca(HCOO)_2$ crystals were separated on a funnel, thoroughly squeezed between sheets of a filter paper to remove the mother liquor, and a sample was taken to measure the activity of the crystals. The squeezed crystals of calcium formate were washed by decantation with an aqueous solution of calcium formate, saturated at room temperature and taken in a 1 : 2 ratio by mass, and the thus washed crystals were squeezed as described above. The content of manganese(II) in solution was varied from 10^{-3} to 10^{-5} wt %, and the degree of crystallization, from 0.2 to 0.7 [25].

The activity of the solutions preliminarily prepared by dissolving the crystals in distilled water was measured with a BDIS-3-05 transducer with a detector of γ-radiation. The accuracy of radiometric measurements was 2–3 rel %. The data obtained in these measurements were used to calculate the purification coefficient as a ratio of the activities before and after crystallization, related to unit mass of calcium formate [25].

As shown by the results obtained (Table 2), a microimpurity of manganese(II) is mainly concentrated in crystallization of calcium formate in the mother liquor. An additional washing of $Ca(HCOO)_2$ crystals with a saturated aqueous solution of calcium formate substantially enhances the purification effect. The concentration of the manganese(II) impurity and the degree of crystallization do not noticeably affect the purification coefficient.

A study of the distribution of manganese(II) in the microconcentration range in crystallization of $Ca(HCOO)_2$ (Table 2) demonstrated that there is no isodimorphism or isomorphism of calcium formate and manganese(II) formate dihydrate. Manganese(II) is captured by crystals of calcium formate via occlusion of the mother liquor [adsorption of manganese(II) on the surface of the crystals is reduced to a minimum in the case of crystallization in an acid medium, HCOOH].

Thus, the results of studying the behavior of manganese(II) in calcium formate solutions in a wide range of concentrations (micro- and macroranges) indicate that there is no interaction between the components, which is accounted for by the difference of the crystal structures of calcium formate and manganese(II) formate dihydrate. $Ca(HCOO)_2$ crystallizes in the rhombic crystal system (space group *Pbca*) [18]; according to refined data, $Mn(COOH)_2 \cdot 2H_2O$ crystallizes in the monoclinic crystal system (space group $P2_1/c$) [26].

According to the data presented above and published data, ions of manganese(II), nickel, copper, magnesium, lithium, potassium, zinc, cadmium, barium, and yttrium [8–17] can find their way into the crystals formed in synthesis of ultrapure calcium formate by crystallization via occlusion of the mother liquor or adsorption. Thorough washing of the precipitate is necessary for removing these impurities. Performing the crystallization of $Ca(HCOO)_2$ in formic acid (2–3 wt %) will virtually rule out adsorption of ions on the crystals.

CONCLUSIONS

(1) The solubility diagram of the system $Ca(HCOO)_2$–$Mn(HCOO)_2$–H_2O was studied in a wide range of concentrations of the components; the system is of a simple eutonic type. The composition of the solid phases was confirmed by the results of chemical and X-ray analyses.

(2) The behavior of ^{54}Mn in crystallization of $Ca(HCOO)_2$ was studied at concentrations in the range 10^{-3}–10^{-5} wt % and the occlusion nature of its capture by the crystals formed was established.

(3) Crystallization from aqueous solutions is a promising method for purification of $Ca(HCOO)_2$.

Abstract—Phase formation processes were studied and features of the crystallization of complex phosphates with a langbeinite structure from potassium phosphate melts were established. The compounds obtained were characterized by X-ray phase analysis, IR spectroscopy, diffuse reflection spectroscopy, and ESR spectroscopy.

DOI: 10.1134/S1070427206010034

Two structural types, Nasicon and langbeinite, are realized for complex phosphates with a three-dimensional crystal framework $[M_2(PO_4)_3]^{n-}$ [1]. At present phosphates with the Nasicon framework are the most studied, because they are of interest as superionic conductors [1–5] and high-temperature materials with low thermal expansion coefficients [6, 7]. Complex phosphates with the langbeinite-type lattice are first of all considered as promising crystal matrices for immobilization of radioactive and highly toxic wastes with the aim of their further disposal [8], thanks to high chemical and radiation resistance of phosphates with the langbeinite structure.

A three-dimensional anionic crystal framework $[M_2(PO_4)_3]^{n-}$ of the langbeinite type forms relatively large cationic cavities, which can retain cations of various sizes: Na^+, K^+, Rb^+, Cs^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}. Various elements or their pairs can play the role of framework-forming metals: Ti, Fe, Cr, Nb, Y, Zr, Hf, and REE [8–18]. Such a variety of possible combinations stimulates the further search for compounds with practically important and special properties among phosphates with the langbeinite structure.

Complex phosphates, which are structural analogs of langbeinite, were synthesized using various techniques, namely, solid-phase reactions [8–10, 14–16], melt crystallization [11, 18, 19], and hydrothermal synthesis [20]. At the same time, approaches to the target-oriented synthesis of phosphates of this structural type are in the stage of formation and coming into being.

We examined the main regular trends in the phase formation of complex phosphates with a langbeinite-type crystal framework in potassium phosphate melts. The compounds obtained were characterized by X-ray phase analysis (XPA), IR spectroscopy, diffuse reflection spectroscopy, and ESR spectroscopy. The influence of framework-forming different-valence metals on the formation of crystalline phosphates with the langbeinite structure from melts is discussed.

EXPERIMENTAL

We studied phase formation of complex phosphates with the langbeinite structure from melts of the systems K_2O–P_2O_5–TiO_2–$M^{II}O$ (M^{II} = Mn, Ni, Co, Cu, Zn), K_2O–P_2O_5–TiO_2–$M^{III}_2O_3$ (M^{III} = Al, Sc, Cr, Fe, In, Y), and K_2O–P_2O_5–$M^{V}_2O_5$–$M^{III}_2O_3$ (M^{V} = Nb, Ta; M^{III} = Fe, Cr, In, Y). The starting substances for preparing the melts were analytically pure grade KPO_3, $NH_4H_2PO_4$, $K_4P_2O_7 \cdot 4H_2O$, Al_2O_3, Cr_2O_3, In_2O_3, NiO, cobalt subcarbonate (containing 59.1 wt % CoO), CuO, ZnO, and also ultrapure grade TiO_2, Fe_2O_3, Y_2O_3, Nb_2O_5, and Ta_2O_5. In some cases, pure grade dihydrogen phosphates $Cu(H_2PO_4) \cdot 2H_2O$ and $Mn(H_2PO_4)_2 \cdot 2H_2O$ were used.

Potassium/phosphorus ratios (K/P) in the systems were set within the limits from 0.70 to 1.45; the M^{III}/Ti, M^{II}/Ti, and M^{II}/M^{V} ratios were varied discretely from 0.05 to 2.00. Ground charges of the starting components were heated in platinum crucibles

to 1000–1150°C. The resulting melts were kept with intermittent stirring for 3–8 h under isothermal conditions up to complete dissolution of the oxides. The temperature and dissolution time were determined empirically depending on the nature and content of oxides in the system. After homogenization of the melts, their crystallization was carried out by spontaneous cooling at a rate of 10–50 deg h^{-1} to 650–750°C. The solubility of oxides and the phase formation were monitored by intermittent sampling. Melt samples were dissolved in water, and the presence of oxides or crystalline phases was determined by optical microscopy. After the crystallization completion, we decanted the melts leaving the formed phases and washed them to remove the residual flux with hot solutions of inorganic acids. The resulting compounds were washed with double-distilled water and dried in air at 105–120°C.

We carried out the X-ray phase analysis of the crystallization products and recorded the X-ray patterns of the individual compounds on a DRON-3.0 diffractometer using CuK_α radiation (λ = 1.54178 Å). The IR spectra were recorded on Nexus 470 FTIR (Nicolet) and UR-20 spectrometers in the range 400–1500 cm^{-1}; the samples were pelletized with KBr. The ESR spectra of polycrystalline samples were recorded on a PS100.X instrument at room temperature, and the electronic diffuse reflection spectra, on a UV-VIS Specord M-40 spectrophotometer in the range 14000–36000 cm^{-1}.

Complex phosphates with the langbeinite structure in potassium phosphate melts are formed as crystals of tetrahedral or octahedral shape. In most cases, their composition and phase-formation area depend on both K/P and M^{III}/Ti (M^{II}/Ti, M^{III}/M^{V}) ratios in a system and also on particular metal. The optimized conditions of the crystallization of the phosphates isostructural to langbeinite are given in Table 1.

For the systems K_2O–P_2O_5–TiO_2– $M^{II}O$ (M^{II} = Mn, Ni, Co, Cu, Zn), the character and areas of the formation of $K_2Ti_{1.5}M^{II}_{0.5}(PO_4)_3$ phases are similar in the case of manganese, nickel, and cobalt (K/P = 0.9–1.1; M^{II}/Ti = 0.5–2.0, Ti/P = 0.15) and considerably differ for the copper- and zinc-containing systems. The complex phosphate $K_2Cu^{II}_{0.5}Ti_{1.5}(PO_4)_3$ isostructural to langbeinite can be isolated in the pure form only within a narrow temperatures range 900–720°C for the ratios K/P = 0.9–1.0, Cu^{II}/Ti = 0.7–1.5, and Ti/P = 0.12–0.14. Such limits are caused by partial reduction of copper(II) to copper(I) in the melts with ratios K/P < 0.9 and, consequently, by the formation of complex phosphates containing copper(I). At higher (K/P = 1.0–1.2) ratios, three complex phosphates $KTi_2(PO_4)_3$, $K_2Cu^{II}_{0.5}Ti_{1.5}(PO_4)_3$, and $KTiOPO_4$ crystallize simultaneously. A similar pattern is observed for melts of the system K_2O–P_2O_5–TiO_2–ZnO where crystals of the phosphate $K_2Zn_{0.5}Ti_{1.5}(PO_4)_3$ isostructural to langbeinite can be obtained in a mixture with $KTi_2(PO_4)_3$ or $KTiOPO_4$.

The crystallization of complex phosphates with the langbeinite structure in K_2O–P_2O_5–TiO_2–$M^{III}_2O_3$ (M^{III} = Al, Sc, Cr, Fe, In, Y) melts in a wide range of M^{III}/Ti ratios is accompanied by redox processes [19]. Generally, the composition of the resulting complex phosphates is described by the formula $K_{1+y}Ti_{2-x}\cdot M^{III}_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$), and the resulting compounds contain titanium(III). The formation of a compound with a fixed composition in the melts and the degree of reduction of titanium(IV) to titanium(III) primarily depend on the initial ratios K/P and M^{III}/Ti in the system. A series of compounds $K_{1+y}Ti_{2-x}Al_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$) obtained by spontaneous crystallization in the melts of the system K_2O–P_2O_5–TiO_2–Al_2O_3 were studied in detail in [21]. It was shown by X-ray photoelectron spectroscopy, X-ray fluorescence analysis, and ESR spectroscopy that the partial reduction $Ti^{4+} \rightarrow Ti^{3+}$ is caused by a rearrangement of the three-dimensional crystal framework with the formation of a langbeinite-type structure when Al^{3+} is incorporated in the double phosphate $KTi_2(PO_4)_3$. In this case, the Ti^{3+} content in the $K_{1+y}Ti_{2-x}Al_x(PO_4)_3$ compounds first increases as the initial Al/Ti ratio in the melt increases from 0.2 to 0.7, and then it decreases in the range of Al/Ti = 0.7–1.5. For Al/Ti ratios higher than 1.5, the phosphate $K_2TiAl(PO_4)_3$ isostructural to langbeinite and containing no titanium(III) crystallizes.

The formation of complex phosphates $K_{1+y}Ti_{2-x}\cdot M^{III}_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$) in the melts of the systems K_2O–P_2O_5–TiO_2–$M^{III}_2O_3$ (M^{III} = Sc, Cr, Fe, In, Y) occurs similarly. The amount of titanium(III) in the crystal phases first increases and then decreases as the M^{III}/Ti ratio in the melt increases, which is manifested in the intensity of color of the resulting compounds. On reaching a certain "critical" M^{III}/Ti ratio, colorless phosphates of the composition $K_2TiM^{III}(PO_4)_3$ are formed. Numerically this ratio depends on the nature of M(III) (Table 1). At the same time, it should be noted that $K_{1+y}Ti_{2-x}M^{III}_x(PO_4)_3$ phosphates (M^{III} = Cr, Fe, In, Y) can be obtained in the pure state within the limits of M^{III}/Ti ratios from 0.1 to 1.0. At $M^{III} > 1.0$, double diphosphates $KM^{III}P_2O_7$ are formed simultaneously in the melts.

Table 1. Areas and conditions of the crystallization of phosphates with a langbeinite structure from melts

Compound	Ratio of components in a melt	Temperature of crystal formation, °C	Habit and color of crystals
$K_2Ti_{1.5}Mn_{0.5}(PO_4)_3$	K/P = 0.9–1.1, Mn/Ti = 2.0–0.5, Ti/P = 0.25–0.3	950–700	Red-brown tetrahedra with bevel vertices
$K_2Ti_{1.5}Ni_{0.5}(PO_4)_3$	K/P = 0.9–1.1, Ni/Ti = 2.0–0.5, Ti/P = 0.27–0.32	1000–650	Green tetrahedra of regular shape
$K_2Ti_{1.5}Co_{0.5}(PO_4)_3$	K/P = 0.9–1.1, Co/Ti = 2.0–0.5, Ti/P = 0.25–0.3	950–700	Red tetrahedra with bevel vertices or regular octahedra
$K_2Ti_{1.5}Cu_{0.5}(PO_4)_3$	K/P = 0.85–0.95, Cu/Ti = 1.5–0.5, Ti/P = 0.25–0.32	900–720	Grey-blue tetrahedra with elongated vertices
$K_2Ti_{1.5}Zn_{0.5}(PO_4)_3$	K/P = 0.9, Zn/Ti = 2.0, Ti/P = 0.25–0.27	1000–800	Colorless tetrahedra with elongated vertices
$K_{1+y}Ti_{2-x}Al_x(PO_4)_3$ $(0<x\le1,\ 0\le y\le1,\ y\ge x)$	K/P = 0.8–1.15, Al/Ti = 0.2–1.5, Ti/P = 0.15–0.30	1000–750	Regular tetrahedra or octahedra with color from pale blue to dark blue
$K_{1+y}Ti_{2-x}Fe_x(PO_4)_3$ $(0<x\le1,\ 0\le y\le1,\ y\ge x)$	K/P = 1.0–1.2, Fe/Ti = 0.5–1.5, Ti/P = 0.15–0.26	1000–700	Regular tetrahedra with color from pale blue to dark blue
$K_{1+y}Ti_{2-x}Cr_x(PO_4)_3$ $(0<x\le1,\ 0\le y\le1,\ y\ge x)$	K/P = 1.0–1.2, Cr/Ti = 0.5–1.5, Ti/P = 0.15–0.22	1000–800	Gray-green regular tetrahedra
$K_{1+y}Ti_{2-x}In_x(PO_4)_3$ $(0<x\le1,\ 0\le y\le1,\ y\ge x)$	K/P = 1.0–1.15, In/Ti = 0.3–1.0, Ti/P = 0.17–0.26	1000–800	Regular tetrahedra with color from pale blue to dark blue
$K_{1+y}Ti_{2-x}Y_x(PO_4)_3$ $(0<x\le1,\ 0\le y\le1,\ y\ge x)$	K/P = 1.0–1.15, Y/Ti = 0.2–1.0, Ti/P = 0.17–0.25	1000–800	Regular tetrahedra with color from pale blue to dark blue
$K_2Nb_{0.5}Fe_{1.5}(PO_4)_3$	K/P = 0.7–1.1, Fe/Nb = 1.0, Fe/P = 0.28	820–780	Light pink regular tetrahedra
$K_2Ta_{0.5}Fe_{1.5}(PO_4)_3$	K/P = 1.0–1.1, Fe/Ta = 2.0–3.0, Fe/P = 0.37	1000–820	Yellow-brown regular tetrahedra or octahedra
$K_2Ta_{0.5}Cr_{1.5}(PO_4)_3$	K/P = 1.0–1.2, Cr/Ta = 1.0, Cr/P = 0.13	850–780	Dark green regular tetrahedra
$K_2Nb_{0.5}In_{1.5}(PO_4)_3$	K/P = 1.0–1.4, In/Nb = 1.0, In/P = 0.13	820–760	Colorless tetrahedra with bevel vertices
$K_2Ta_{0.5}In_{1.5}(PO_4)_3$	K/P = 1.0–1.4, In/Ta = 1.0, In/P = 0.044	820–760	Colorless tetrahedra with bevel vertices
$K_2Nb_{0.5}Y_{1.5}(PO_4)_3$	K/P = 1.2–1.5, Y/Nb = 1.0, Y/P = 0.19	920–860	Colorless regular tetrahedra
$K_2Ta_{0.5}Y_{1.5}(PO_4)_3$	K/P = 1.2–1.5, Y/Ta = 1.0, Y/P = 0.125	920–860	Colorless regular tetrahedra

The areas of the crystallization of phosphates isostructural to langbeinite correspond to rather narrow ranges of the K/P ratio in the system. In the case of scandium, indium, and yttrium, they are limited to K/P values from 1.00 to 1.15; for iron and chromium, the limits are somewhat wider (K/P = 1.00–1.20); and for aluminum, they are the widest (K/P = 0.9–1.15).

The presence of titanium(III) in the phosphates $K_{1+y}Ti_{2-x}M^{III}_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$; M^{III} = Sc, Cr, Fe, In, Y) isostructural to langbeinite was confirmed by diffuse reflection and ESR spectroscopy. The diffuse reflection spectra of a series of phosphates (Fig. 1) contain two bands. The first broad band in the region of 17 500–18 800 cm^{-1} corresponds to the one-electron transition $^2T_{2g} \rightarrow {}^2E_g$ in the $[Ti^{3+}O_6]$ chromophore, and the second strong band at 31 000 cm^{-1} is caused by the oxygen-to-metal charge transfer. Slight asymmetry of the first band suggests

possible trigonal distortion of the [TiO_6] polyhedron, resulting in the splitting of the T_{2g} term. The effect of trigonal splitting of the T_{2g} ground term is confirmed by the ESR data, as the ESR spectra of Ti^{3+} complexes are known to be observable at room temperature at an axial distortion in a trigonal-symmetry field [22]. In the case of the series of phosphates under study $K_{1+y}Ti_{2-x}M^{III}_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$) containing various metals(III) (aluminum, iron, scandium, indium, and yttrium), all ESR spectra at room temperature represent a symmetric singlet with equal parameters: g = 2.001 and ΔH = 110 G.

Regions and conditions of the formation of complex phosphate phases with the langbeinite structure for the melts of the systems K_2O–P_2O_5–$M^V_2O_5$–$M^{III}_2O_3$ (M^V = Nb, Ta; M^{III} = Fe, Cr, In, Y) substantially depend on particular M(III). It was found experimentally that the usual content of M(V) oxides in the systems required for the crystallization of phosphates of this structural type is 12–16 wt % for Nb_2O_5 and 5–10 wt % for Ta_2O_5. The content of M(III) oxides can vary in a rather wide range, 5–20 wt %. The phosphates isostructural to langbeinite are formed as transparent colorless or colored crystals of tetrahedral or octahedral habit (Table 1).

We failed to obtain phosphates isostructural to langbeinite from melts of the system K_2O–P_2O_5–Nb_2O_5–Cr_2O_3. This is caused by the primary formation of kinetically labile $KCrP_2O_7$ on the Cr_2O_3–melt phase boundary. It is practically insoluble and blocks the active oxide surface.

The X-ray patterns of the obtained double phosphates isostructural to langbeinite were analyzed using the least-squares iteration method applied to identity periods of structural models based on the structural data for the compounds $K_2Ti_2(PO_4)_3$ [10, 11, 20], $KBaFe_2(PO_4)_3$ [12], and $K_{1.388}Ti^{4+}_{1.612}Ti^{3+}_{0.273}Al_{0.115}(PO_4)_3$ [23]. The calculated parameters of cubic unit cells of the synthesized phosphates vary within 9.8–11.6 Å depending on the ionic radii of the framework-forming metals (Table 2).

The main absorption bands in the IR spectra of phosphates with the langbeinite structure (Fig. 2) are characteristic of double orthophosphates with a three-dimensional $[M_2(PO_4)_3]^{n-}$ crystal framework [24]. In the frequency range 400–700 cm^{-1}, five absorption bands are usually present, corresponding to δ_s and δ_{as} vibrations of O–P–O and MO_2 groups. The ν_s vibration of the P–O bond is manifested in the spectra as a strong broad band in the frequency range 850–970 cm^{-1}, and the ν_{as} vibration of this bond gives rise

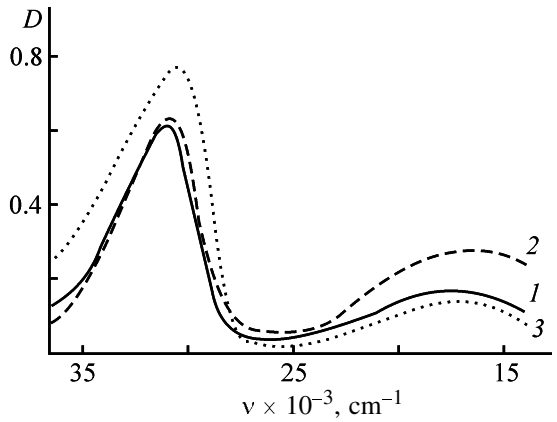

Fig. 1. Diffuse reflection electronic spectra of complex phosphates containing trivalent titanium, isostructural to langbeinite: (*D*) optical density and (ν) wavenumber. (*1*) $K_{1+x}Al_xTi_{1.3}(PO_4)_3$, (*2*) $K_{1.9}Sc_{0.9}Ti_{1.1}(PO_4)_3$, and (*3*) $K_{1.7}In_{0.7}Ti_{1.3}(PO_4)_3$.

to two bands at 1000–1020 and 1100–1130 cm^{-1}. In some cases, an additional band near 1050 cm^{-1} is also observed.

Generally, when considering the processes of the formation of phosphate phases with the langbeinite structure, we should note that the construction of $[M_2(PO_4)_3]^{n-}$ three-dimensional crystal frameworks can be realized with different-valence metals significantly differing in the ionic radius. The ionic radii of M(II) and M(III) for titanium-containing frameworks $[Ti_{1.5}M_{0.5}(PO_4)_3]^{2-}$ and $[Ti^{IV}M^{III}(PO_4)_3]^{2-}$

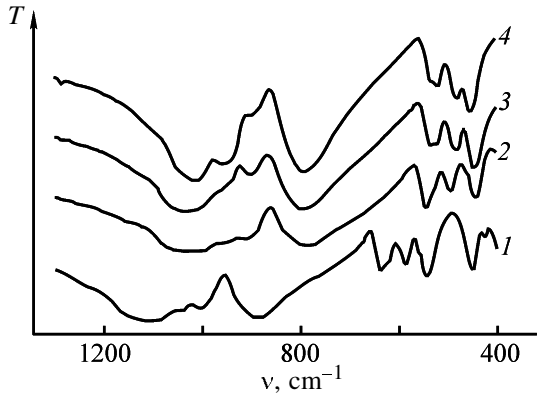

Fig. 2. IR spectra of phosphates isostructural to langbeinite: (*T*) transmittance and (ν) wavenumber. (*1*) $K_2Fe_{1.5}Nb_{0.5}(PO_4)_3$, (*2*) $K_2Cr_{1.5}Nb_{0.5}(PO_4)_3$, (*3*) $K_2In_{1.5}Nb_{0.5}(PO_4)_3$, and (*4*) $K_2Y_{1.5}Nb_{0.5}(PO_4)_3$.

can vary over a wide range: 0.74–0.91 Å from magnesium(II) to manganese(II) and 0.57–0.97 Å from aluminum(III) to yttrium(III) [25]. Correspondingly, the ratios of ionic radii M^{2+} (0.74–0.91)/Ti^{4+} (0.64) = 1.16–1.42 and M^{3+} (0.57–0.97)/Ti^{4+} (0.64) = 0.89–1.52 of the metals forming a three-dimensional framework can differ by a factor of more than 1.5. A similar pattern is also observed with the frameworks $M^{V}_{0.5}M^{III}_{1.5}(PO_4)_3]^{2-}$ (M^V = Nb, Ta) with the ratios M^{3+} (0.67–0.97)/M^{5+} (0.66) = 1.02–1.45. At the same time, the crystallization areas in potassium phosphate melts (ratios K/P, M^{III}/Ti, M^{II}/Ti, and M^{II}/M^V) in phosphates isostructural to langbeinite can considerably differ depending on the nature of different-valence framework-forming metals (Table 1).

CONCLUSIONS

(1) As a result of comprehensive studies of phase formation of complex phosphates with the langbeinite structure in potassium phosphate melts, the crystallization areas (K/P, M^{III}/Ti, M^{II}/Ti, and M^{II}/M^V ratios) and conditions were determined for the following complex phosphates: $K_2Ti_{1.5}M^{II}_{0.5}(PO_4)_3$ (M^{II} = Mn, Ni, Co, Cu, Zn), $K_{1+y}Ti_{2-x}M^{III}_x(PO_4)_3$ ($0 < x \le 1$, $0 \le y \le 1$, $y \ge x$; M^{III} = Al, Sc, Cr, Fe, In, Y), and $K_2M^{V}_{0.5}M^{III}_{1.5}(PO_4)_3$ (M^V = Nb, Ta; M^{III} = Fe, Cr, In, Y).

(2) The complex phosphates obtained were shown by X-ray phase analysis and powder X-ray diffraction to be isostructural; the parameters of their unit cells were calculated.

(3) The compounds synthesized were characterized by IR spectroscopy, diffuse reflection spectroscopy, and ESR spectroscopy.

(4) In the case of langbeinite structures, the ionic radii of different-valence metals forming the $[M_2(PO_4)_3]^{2-}$ three-dimensional crystal framework can differ by a factor of more than 1.5.

Abstract—The kinetics of titanium(IV) extraction from sphene with boiling 4–6 M sulfuric acid was studied. The rate constants of the sphene dissolution were determined. The influence of the particle size of the starting mineral on the rate of its dissolution was established. The feasibility of performing sphene dissolution by a liquid-phase procedure yielding stable titanium-containing sulfate solutions suitable for the synthesis of multifunctional composite materials was examined.

DOI: 10.1134/S1070427206010046

Sulfuric acid breakdown of sphene ($TiSiCaO_5$) is an operation determining the whole subsequent process cycle and, consequently, the ultimate goal of its processing. The conditions of carrying out the operation are most commonly chosen so as to attain the maximal degree of sphene breakdown, which is possible only if the process is carried out under rigid conditions: at a high H_2SO_4 concentration of 70–92 wt % and an elevated temperature of 140–200°C with continuous stirring of the reaction mixture [1–3]. However, in this case the service life of the process equipment becomes shorter and its safe maintenance is complicated. Moreover, the reagent expenditure and, correspondingly, the amount of wastes polluting the environment increase. Sphene reacts with a dilute acid (up to 3 M H_2SO_4) [4] very slowly, and its dissolution is accompanied by the formation of a finely dispersed mixed solid phase containing titanium(IV) and silicon(IV) hydroxides and calcium sulfate dihydrate.

We have chosen 4–6 M H_2SO_4 for this study. As the preliminary tests showed, such a choice, firstly, provides high stability of Ti(IV) in the liquid phase of the heated and cooled reaction mass, secondly, makes the operation of the process equipment easier, and, thridly, provides formation of a versatile titanium-containing intermediate product (as a solution), which serves as the basis for subsequent syntheses of various titanium-containing products [5–7].

To find optimal conditions for processing the mineral concentrate containing sphene, we have carried out a physicochemical study of the reaction of the mineral with H_2SO_4 solutions and have determined the kinetic features of this process.

The subject of the study was a crushed sphene concentrate with various particle size. It contained 94 wt % sphene mineral, which corresponds to the content of TiO_2 in the concentrate of 35–36 wt %. The process temperature was 108–115°C (boiling), and the weight ratio of sphene to sulfuric acid (calculated for monohydrate) in the starting mixture was s : 1 = 1 : (1.2–1.8).

A three-necked flask equipped with a stirrer, a reflux condenser, and a thermometer was charged with H_2SO_4 of a specified concentration, and then sphene was added under stirring. The suspension was heated to boil and stirred for 7 h. Samples of the reaction mixture were taken after heating for 30, 120, 180, 240, 300, and 420 min; in these samples, the liquid and solid phases were separated, and their composition was determined. In the liquid phase we determined the content of $Ti(IV)_{tot}$ and also of $Ti(IV)_{react}$ existing in the form of monomeric sulfate complexes or polymeric complexes with a low degree of polymerization. To determine $Ti(IV)_{tot}$, we boiled an aliquot of the solution with an addition of H_2O_2 and determined the optical density of the resulting colored solution [8–10]. The procedure of determining $Ti(IV)_{react}$ was as follows: 1 ml of H_2O_2 (30 wt %) was added into a volumetric flask filled with H_2SO_4 (5 wt %) almost to a mark, then an aliquot of the test solution was added, and the mixture was brought to the mark with H_2SO_4 (5 wt %) [11]. The optical density of the colored solution of Ti(IV) was determined with a

KFK-2 photocolorimeter. The first colorimetric determination was carried out 1 min after the contact between the analyzed solution and H_2O_2. A cell with the colored solution remained in the device, and the optical density was determined in 2, 4, 6, 8, and 10 min. The TiO_2 content (g l^{-1}) was plotted vs. time (min). The initial linear portion of the curve was extrapolated to the *x*-axis (zero time). The value found by the extrapolation corresponds to the content of $Ti(IV)_{react}$. The changes in its content in the liquid phase of the suspension on its keeping at the boiling point are given in the table. These data almost completely coincide with the $Ti(IV)_{tot}$ concentrations. The solid phase was washed with water and alcohol, and its phase composition was determined with a DRON-2 diffractometer. The samples were examined with an electron microscope.

We ground the sphene concentrate in a ball mill in the dry mode. The ground product was separated into three fractions: <28, 28–63, and 63–100 μm. The specific pore volume determined with a Mikrometric-2000 device substantially increases as the sphene particle size decreases. The deterioration of the structural order of the sphene grains resulting from mechanical action (crushing) enhances the chemical activity of the particles and is accompanied by the ionization and amorphization of the surface [12]. The particle activity is the higher, the smaller are sphene particles. The IR spectra (a Perkin–Elmer FT spectrometer) of the sphene samples with various particle size *D* are not identical. Thus, for smaller particles a band appears in the region of 2500–2550 cm^{-1}, typical for silanol Si–OH groups, and intensification of the band in the region of 1412–1507 cm^{-1} suggests formation of calcium carbonate on the particle surface (Fig. 1). The appearance of new formations in the form of amorphous shells on the surface of the ground sphene particles is confirmed by a photomicrograph (Fig. 2).

The sphene activated by grinding reacts with sulfuric acid of the specified concentrations as follows:

$$CaSiTiO_5 + 2H_2SO_4 = TiOSO_4 + CaSO_4\downarrow + SiO_2 \cdot xH_2O\downarrow + H_2O.$$

In the process, Ti(IV) passes into the liquid phase, and solid reaction products, calcium sulfate and amor-

phous $SiO_2 \cdot xH_2O$, are formed. Titanium(IV) is concentrated in the liquid phase owing to its high solubility under the conditions outlined. Since the sphene dissolution is a heterogeneous process and occurs at the liquid (sulfuric acid solution)–solid (sphene particles) interface, its rate can depend not only on sulfuric acid concentration and temperature initiating the crystal disruption, but also on the interface area, i.e., on the particle size.

Figure 3a shows changes in the Ti(IV) content in the suspension liquid phase on its heating at various initial concentrations of sulfuric acid: 4, 5, and 6 M. Figure 3b shows the influence of the sphene particle size. These curves show that, initially, sphene dissolution and Ti(IV) extraction into the liquid phase occur rather actively (stage I). An increase in the H_2SO_4 concentration and, correspondingly, in the temperature accelerates the reaction. As the amount of solid products in the reaction mass increases, the process decelerates. Examination of the solid phase by X-ray phase analysis and electron microscopy shows that the reaction products (amorphous $SiO_2 \cdot xH_2O$ and crystalline $CaSO_4$) are formed as individual phases and also make a porous shell on the surface of sphene particles. The rate of the further Ti(IV) extraction from sphene is determined by the rate of the reagent diffusion through this shell (stage II). Approximately in 5 h, the degree of Ti(IV) passing into the liquid sulfuric acid phase ranges from 35 to 80% depending on the process conditions. The mechanism of dissolution is the same in both stages of the process. Only the rate of Ti(IV) transfer into the liquid phase changes.

To calculate the rate constant K of the sphene dissolution reaction (c = 5.5 M H_2SO_4), we used the known graphic procedure [1, 13, 14]. We constructed $\ln(c_{TiO_2}) = f(\tau)$ plots and determined from them the rate constants (stages I and II) in relation to the initial particle size of sphene. The results are given below:

D, μm	<28	28–63	63–100
K, min^{-1}:			
Stage I	1.8×10^{-2}	1.5×10^{-2}	1.2×10^{-2}
Stage II	5.52×10^{-4}	3.80×10^{-4}	2.29×10^{-4}

In the system under study, Ti(IV) mostly occurs in the form of monomeric titanium(IV) oxosulfate complexes which show a high resistance to polymerization and, consequently, to the solid phase formation.

The sphene particle size affects the kinetics of its dissolution to a greater extent than does variation of the acidity within the range under study. The reaction rate both in the first and in the second stages is the higher, the smaller are sphene particles. However, the rate constant in the first stage increases in total by 30% as the particle size decreases, whereas in the second stage it increases by a factor of almost 2.5. A substantial decrease in the dissolution rate is observed during the process, especially for sphene with larger particles (≥63 μm). This is caused not only by the formation of reaction products on the surface of mineral particles, but also by the necessity of destroying the mineral grains.

CONCLUSIONS

(1) In the range of sulfuric acid concentrations under study, sphene dissolution occurring at the boiling point of the reaction mass is accompanied by transfer of Ti(IV) into the liquid phase and formation of solid reaction products: anhydrous $CaSO_4$ and amorphous silica gel.

(2) Titanium(IV) concentrating in the liquid phase predominantly occurs in the form of monomeric titanium(IV) oxosulfate complexes ensuring high resistance of the system to the formation of a titanium-containing solid phase.

(3) The sphene dissolution in the heterogeneous system is controlled by the diffusion, i.e., by delivery of the reagent through a layer of reaction products on the sphene particle surface.

(4) The fact that the system kept for a long time undergoes no significant changes offers processing advantages; in particular, it allows separation of sphene components present in the liquid and solid phases.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Regular Trends in Uptake of Halogens by Alkali Silicate Glasses Containing Two Glass-Forming Components

A. A. Kiprianov

St. Petersburg State University, St. Petersburg, Russia

Received June 23, 2005

Abstract—Oxyhalide alkali silicate glasses M_2O–R_2O_3–SiO_2 + Hal (M = Li, Na, K; R = B, Al; Hal = F, Cl) containing two network-forming components were prepared, and their bulk thermal and electrical properties were studied.

DOI: 10.1134/S1070427206010058

Oxyhalide glasses attract growing interest of biologists [1], medicians [2], and optical [3] and electronics engineers [4]. The addition of halogen-containing components into the starting stock in synthesis of silicate glasses, which was done for a long time exclusively for process purposes [5], allows preparation of the materials with new unique properties.

At the same time, the structure of such glasses containing a mixed anionic constituent virtually is not studied. Simple and evident problems concerning the limiting content of halogen additives that does not cause glass opacification remain unclear. The same can be said about the components favoring fixation of fluorine and chlorine in the silicate network. Data concerning the influence of halide additives on the glass properties, obtained by different authors, are controversial. Most commonly, replacement of the bridging oxygen atom in the silicate tetrahedron by halogen, suggested by the polarization theory which has been proposed more than forty years ago [6], is not confirmed in experiments [7]. Active studies performed in the last years mostly by the high-resolution NMR spectroscopy {^{19}F, ^{27}Al, ^{29}Si MAS-NMR (magic angle spinning), ^{19}F–^{27}Al, ^{19}F–^{29}Si cross-polarization} [1, 8–12], and analysis of their results in particular, show that a variety of fluorine-containing groups derived from network-forming components (silicate, aluminate, and borate), in which the central cation is present in different coordination states, can be formed in the glass structure. At the same time, these and earlier experiments [13, 14] show that fluorine-containing aluminate groups are formed preferentially.

The type of the structural groups is the key parameter affecting the properties of electrode glasses: the character of ion-exchange centers determines the potentiometric behavior of pH- and pM-metric sensors. The halide additives exert a positive effect on the selectivity of cation-exchange glass membranes [15, 16]. This study was performed to interpret the previously obtained results and develop theoretical principles of controllable synthesis of oxyhalide glasses with preset characteristics, including electrode characteristics.

EXPERIMENTAL

As objects of study we chose alkali silicate glasses M_2O–R_2O_3–SiO_2 (M is Li, Na, K; R is Al, B) containing two network-forming components; in their preparation, a part of alkali metal oxides was replaced by the metal halides. In each series of the glasses studied, the ratio of the content of the modifier to the sum of the network-forming cations [M]/([R] + [Si]) (by synthesis) was kept constant. The compositions are given in terms of the known designation: glass-forming oxides and modifiers are given in molar percents and the metal halide, in weight percents. For example, the glass containing by synthesis 26 mol % $Li_2(O,F_2)$, 1 mol % Al_2O_3, and 63 mol % SiO_2, in which a part of alkali metal oxide is replaced by the alkali halide (one Li_2O unit by two LiF units) providing a fluorine content of 4 wt % (in terms of atomic fluorine), is designated as LiAl-2601 + 4 wt % F. This method of designation of the halogen content in glass is the most convenient [17]. The above designation simplifies comparison of the volatile fluorine content by both synthesis and analysis. Moreover, recalculation of the glass compositions in terms of atomic percents shows that the numerical values for fluorine in

weight and atomic percents are reasonably close, i.e., this method is the most useful source of information.

The glasses were synthesized in a laboratory electrical furnace equipped with Silit (silicon carbide) heaters in open platinum crucibles at 1550–1600°C. The total duration of the process including filling of the starting mixture and the synthesis itself was from 5 to 10 h. The glasses were made in the form of rods and pellets. This was done by casting a melt into cooled massive metallic molds with subsequent annealing in a muffle furnace.

The halide content was determined by specially developed methods in all glasses. The fluorine content was determined by the method described in [18] and the chlorine content, by the known Mohr's method [19]. The error of the analysis did not exceed 2–5%.

The thermal characteristics of the glasses (softening point T_w and glass-transition point T_g) were measured in a DBK-5AM vertical quartz dilatometer in the temperature range 20–900°C at a heating rate of 4 deg min^{-1}.

The resistance of the glass pellets (3 cm in diameter, 0.3 cm thick, Aquadag contact area 0.81 cm^2) was measured with an E8-2 ac bridge at a frequency of 100 Hz in the temperature range 100–350°C. The temperature in the cell was maintained constant to within ±0.5°C. The measurement error did not exceed 5%.

The compositions of the glasses synthesized and the results of determining the halide content in them are presented in the table. Most of the glasses synthesized are homogeneous, without visible evidence of phase separation and crystallization. In synthesis of certain compositions, the known opacification properties of fluorine [20] were, however, revealed by the marked opalescence. The opalescence was weak [see table, outward appearance (2)] or strong [(3)]; a portion of glasses synthesized from the starting mixture with the high content of fluorine was milk-white [(4)]. In the glasses synthesized from the starting mixture containing up to 10 wt % chlorides, even weak opacification was not observed. Glasses with a high content of chlorine, however, could not be prepared quantitatively because of spontaneous ejection of melt from the crucible [see table, (5)]; the results of analysis of the remaining glass melt are given in parentheses. The syntheses of these glasses under varied conditions from starting components prepared by different methods gave the same result.

The data of the table confirm the well-known conclusions that the silicate glass synthesis is accompanied by significant loss of halides: from 1/4 to 1/3 of their initial amount evolves into the gas phase. To assess the reproducibility of the results obtained, and, correspondingly, of the fluorine content in the glass,

the chosen compositions were synthesized again: the results of the analyses agreed to within ±0.1 wt % F.

Figures 1a and 1b present the dependences of the halogen content in the glass determined by analysis vs. its content introduced into the starting mixture in synthesis. In the case of fluoride additives, the dependences are linear (a), whereas in the case of chloride additives they tend to flatten out (b). These trends are qualitatively similar to those known from the literature [14, 17, 21].

Undoubtedly, the results obtained reflect certain regular trends responsible for the uptake of halogens by silicate glasses (the correlation coefficients *R* of the linear dependences are given in caption to Fig. 1). At the same time, the mechanism of this process and the type of the newly formed groups cannot be revealed from these dependences. To do this, we studied the bulk thermal and electrical properties of the glasses synthesized.

The dependences of the softening point T_w on the fluorine content taken up by the glass are presented in Fig. 2a. As seen, the known general trend consisting in that the characteristic temperatures of silicate glasses decrease with the introduction of fluorine [17, 21, 22] is observed with the majority of samples. At the same time, for a number of the compositions studied, the fluorine introduction produces an opposite effect, and for certain dependences a pronounced minimum is observed. Similar results reflecting ambiguity of the effect exerted by chlorine on the thermal characteristics of silicate glasses are presented in [23].

The electrical characteristics of the glasses synthesized are plotted in Fig. 2b. As in the previous case, the dependences describing the resistivity $\log \rho_{20}$ of glasses vs. the fluorine content in them show no common trend.

The data obtained do not principally differ from those known from the literature. However, the method of their presentation is purely demonstrational and does not reveal true effects exerted by halogens on the properties of silicate glasses. Undoubtedly, analysis of the dependences obtained is also complicated by the fact that the true compositions of the glasses studied (by analysis) do not coincide with those ascribed to them (by synthesis), because a portion of components in the form of halides actively vaporizes in the course of the synthesis.

The subsequent treatment of our results was largely formal. The oxyfluoride glasses synthesized were divided onto four groups according to the degree of opacification. The photographs of some samples are shown in Fig. 3.

The X-ray phase analysis of the chosen glasses revealed X-ray amorphous glassy phase in glasses (1) whose phase composition was homogeneous by visual observation. At the same time, the opacification of

sodium aluminosilicate glasses is due to the separation of sodium fluoride, whereas that of potassium aluminosilicate glasses, due to the separation of cryolite $3KF \cdot AlF_3$. The latter result is in line with the conclusions of [24] consisting in that the above fluorides are major components of the crystalline phase of opaque (opalescent) glasses. The photomicrographs of the glasses confirm the presence of this crystalline phase dispersed in the glass matrix [25].

The previously performed studies, including those

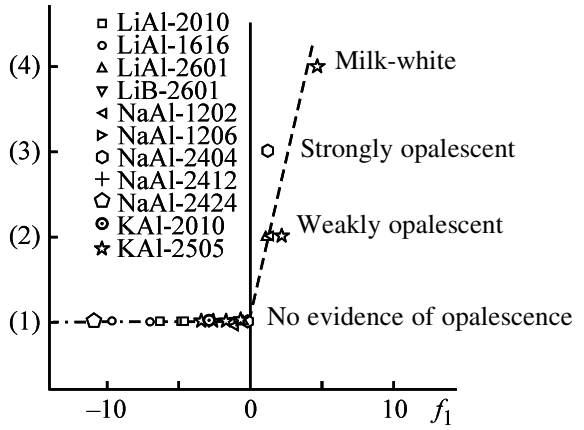

Fig. 4. Outward appearance of the glass as a function of the difference in the content of fluorine and second network-forming oxide f_1 = [F, at. %] – [R, at. %].

concerning the electrode properties of oxyhalide glasses containing two glass-forming components [15, 16], suggest that fluorine enters the aluminate constituent of the glass network with the formation of strong acid groups. To support this suggestion, in view of development of a formal semiquantitative method suitable for interpretation of the results obtained, we present the dependence of the degree of the glass opacification on the difference between the contents of fluorine and aluminum introduced in the glass synthesis (f_1 = [F, at. %] – [Al, at. %]) (Fig. 4). The vertical line at $f_1 = 0$ is a boundary where the contents of the aluminate groups and the halogen atoms are equal; on the left-hand side ($f_1 < 0$) are located glasses with excess sites and on the right-hand side, glasses with excess halide atoms. As seen, all glasses with the inhomogeneous phase composition are located in the right-hand side of the graphs at $f_1 > 1$. It may be suggested that glass opacification, i.e., formation of the separate fluoride phase from the evolution of excess fluorine, is typical of compositions wherein the substitution of one of bridging oxygens in each aluminate tetrahedra by nonbridging fluorine $[AlO_{4/2}]^- \rightarrow [AlO_{3/2}F]^-$ (first step) is complete in the course of melting and the second step $[AlO_{3/2}F]^- \rightarrow [AlO_{2/2}F_2]^-$ starts developing. The forming doubly substituted groups containing two bridging oxygen atoms lose their network-forming properties and serve as a source of the crystallization of the corresponding fluorides (MF or $3MF \cdot AlF_3$).

The results of studying the bulk thermal and electrical properties of the glasses, taking into account the revealed regular trends, are shown in Fig. 5. As argument was chosen the ratio of the fluorine and aluminum contents introduced in the glass synthesis; when their contents are equal, $f_2 = 1$. As seen, the softening point T_w decreases with the incorporation of fluorine into the glass structure (Fig. 5a). This is due to the substitution of one bridging oxygen by nonbridging fluorine, which weakens the glass framework. An increase in T_w at the high content of halogen

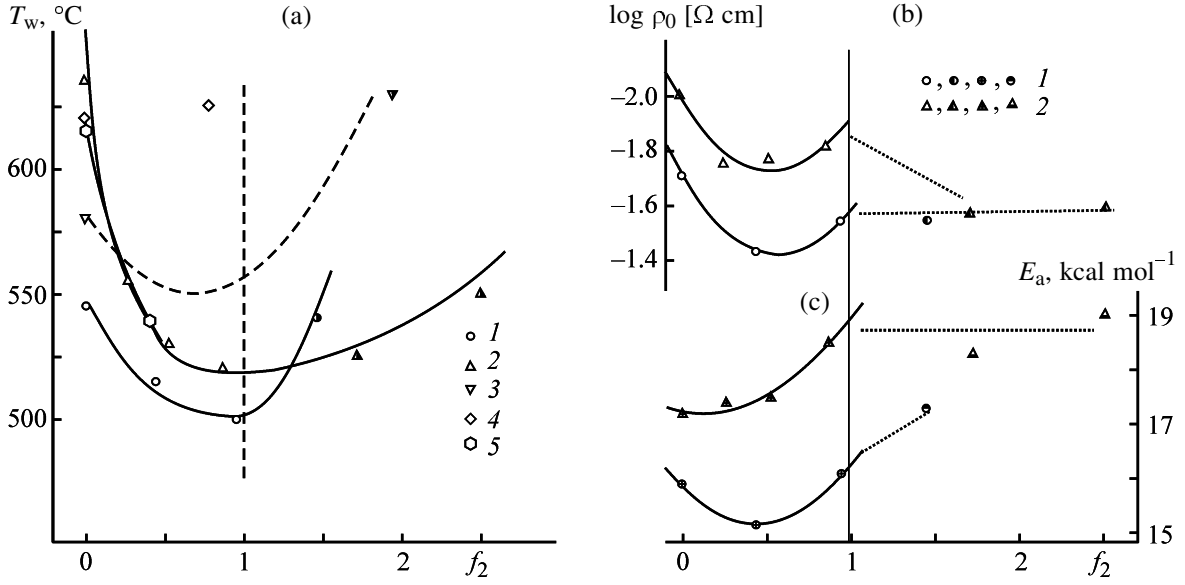

Fig. 5. Dependences of the (a) softening point T_w, (b) ogarithm of the preexponential term $\log \rho_0$, and (c) activation energy of electrical conductivity E_a on the ratio of the fluorine content introduced into the glass to the content of the second network-forming component f_2 = [F, at. %]/[R, at. %]. (c) Data of [26]. (*x*) Amount of F added.

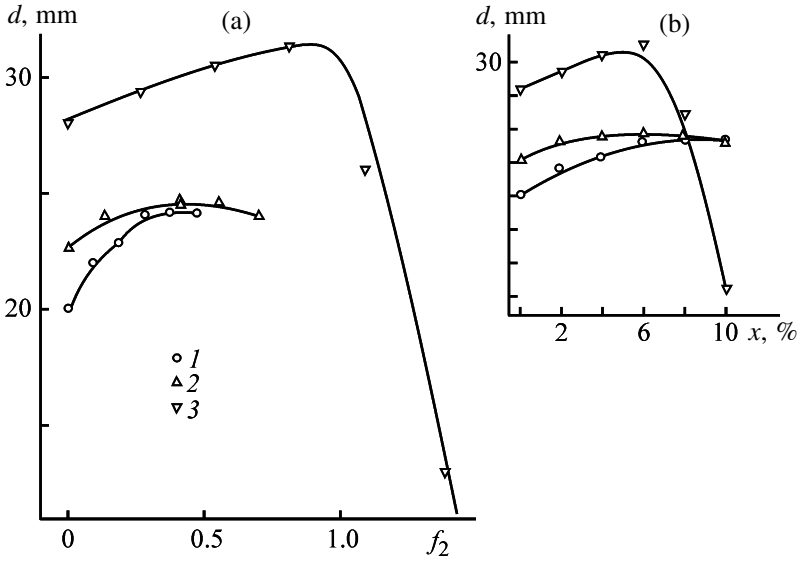

Fig. 7. (a) Flowability data from [27] for three series of yNa_2O–zB_2O_3–$(100 - y - z)SiO_2$ (mol %) glasses containing sodium fluoride, plotted vs. the ratio of the fluorine content introduced into the glass to the content of the second network-forming oxide f_2 = [F, at. %]/[B, at. %]), and (b) the same data plotted vs. fluorine content x. For explanations, see text. (*d*) Drop diameter. (*1*) Series I: y = 12.5, z = 37.5; (*2*) series II: $y = z$ = 25; (*3*) series III: y = 37.5, z = 12.5.

is due to the cardinal transformation of the glass structure owing to the crystallization of excess fluorides.

The electrical conductivity parameters, i.e., the logarithm of the preexponential term ρ_0 in the $\rho = \rho_0 \exp(E_a/RT)$ dependence, where ρ is the resistivity, and the activation energy of conductivity, presented in the new coordinates for different glasses, also became reasonable (Fig. 5b). Variations with the halogen content are regular at $f_2 < 1$, i.e., in the region of macrohomogeneous glass compositions; on passing to inhomogeneous compositions, the characteristics change, and this change is determined by the type of the crystallizing compound and by the phase ratio.

To confirm the common character of the suggested description, we have processed the available data obtained by other researchers (Figs. 6, 7). To a first ap-

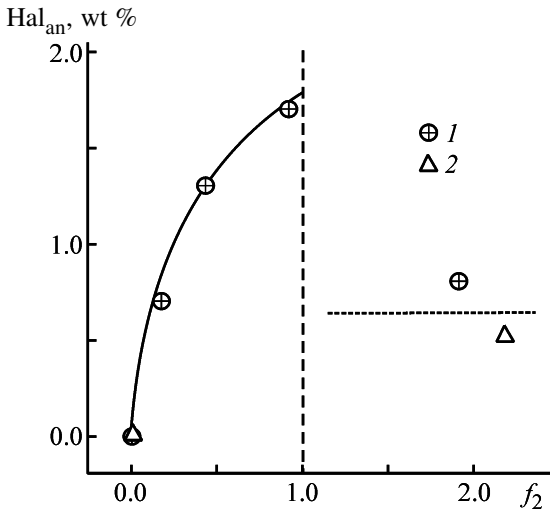

Fig. 8. Fluorine content by analysis Hal$_{an}$ in (*1*) NaAl-2705 + *x* wt % Cl and (*2*) KAl-2705 + *x* wt % Cl glasses as a function of the ratio of the chlorine content in the glass to the content of the second network-forming oxide f_2 = [Cl, at. %]/[R, at. %].

proximation, the dependences of the electrical conductivity parameters reported in [26] for the series of glasses containing (wt %): 20 Na_2O, 10 Al_2O_3, 9 ZnO, 6 B_2O_3, 55 SiO_2 + xF_2 (the composition NaAlZnB-21$_3$05$_2$07$_3$05$_7$ + *x* wt % F) (Fig. 6c) coincide with our dependences (Fig. 5b). It should be noted that, according to input data, to $f_2 > 1$ corresponds an opal glass containing 10.8 wt % fluorine.

Belyaev and Belyi [27] studied the fusibility and flowability of fusible enamel frits of various basicites containing fluorine (for compositions, see caption to Fig. 7). The target characteristics was determined from the diameter of drop formed by heating a small bar of glass powder (10 mm in diameter, 8 mm high) at 800°C for 5 min (the results are reproduced in Fig. 7b). The authors ascribed the observed decrease in fusibility of base glasses to their crystallization caused by surrounding of sodium with fluorine. The input data plotted in the new coordinates in Fig. 7a suggest that the crystallization and, consequently, the deteriorated flowability are revealed in compositions with $f_2 > 1$, i.e., in glasses formed from the melts, in which the substitution of bridging oxygens for fluorine in borate tetrahedra proceeded up to the formation of doubly substituted groups $[BO_{2/2}F_2]^-$.

The most convincing argument in favor of the concept proposed are results of processing of our data for glasses with the chloride additives. The data of Fig. 1b in the form of the dependences of the chlorine content taken up by glass on the structure-sensitive function f_2 are demonstrated in Fig. 8. It is seen that, as in the case of fluoride additives, fixation of chlorine in the glass-forming matrix occurs only as long as the content of the aluminate tetrahedra exceeds the content of the halogen atoms introduced into the melt. At the same time, contrary to the case of fluorine whose excess is separated into the crystalline phase, it is likely that the increased content of chlorine results in the formation of doubly substituted aluminum oxychloride groups $[AlO_{2/2}Cl_2]^-$, which easily lose oxygen atoms and release volatile $AlCl_3$.[1] The possibility of formation of these multiply substituted groups was predicted in [6] based on the fact that the polarizability of chloride anion is higher than that of fluoride anion and is comparable to that of oxygen. Therefore, the probability that chlorine replaces more than one oxygen in the aluminum coordination sphere is considerably higher than in the case of fluorine [6]. Apparently, it is the accumulation of a large amount of gaseous aluminum chloride that caused the above-noted ejection of the glass melt from the crucible [see table, (5)].

Our suggestions on the formation of $[RO_{3/2}Hal]^-$ groups by halogens with the second network-forming oxide do not contradict the conclusions made elsewhere. For example, Callow [17] noted a decrease in the opalescence with the replacement of a portion of SiO_2 by Al_2O_3, and Parker *et al.* [14] noted a slight increase in fixation of fluorine with increasing content of aluminum oxide in the alkali silicate glass. The latter fact is attributed in [14, 17] to an increase in the melt viscosity with the introduction of aluminum oxide, on the one hand, and to a decrease in the fluoride activity and, correspondingly, volatility, owing to fixation of alkali metal cation in the aluminate tetrahedron, on the other hand. According to the data of [29], agreement has been achieved concerning the formation of Al–F bond in aluminosilicate glasses. The fact that halogen forms bonds preferentially with aluminum (i.e., with the second network-forming oxide) is confirmed by a variety of the NMR spectra in which Si–F bonds are manifested only weakly [11] or are absent [1]. At the same time, the reason of this preference and the types of the groups formed remain unclear. Based on analysis of the high-resolution NMR spectra (^{19}F, ^{27}Al, ^{29}Si MAS-NMR, ^{19}F–^{27}Al, ^{19}F–^{29}Si cross-polarization) of the jadeite, cryolite, and albite glasses containing the fluoride additives, it is concluded in [1, 12] that fluorine forms bonds with the three main groups, [4]Al, [5]Al, and [6]Al, which differ in the coordination states of aluminum, with the AlF_6^{3-} octahedral complexes being major. Schaller

[1] $T_{subl}(AlCl_3)$ = 179.9°C, whereas $T_{boil}(AlF_3)$ = 1529°C [28].

et al. [12] also suggest that bridging Al–F–Al bonds, mixed octahedral aluminum complexes containing fluorine and oxygen [6] $Al(F,O)_n$, and tetrahedral complexes AlF_4^- can be formed. As a result of these structural transformations, aluminum loses network-forming properties and, according to the authors' data, converts into a modifying ion.

Liu and Nekvasil [29, 30] made a critical review supported by the model calculations, concerning the suggestions made in the literature on the formation of fluorine-containing groups in silicate glasses. It is convincingly demonstrated that the analysis of the above NMR spectra should be revised. For all the tetrahedral aluminum fragments, the calculated positions of the peaks are in good agreement with the experiment, demonstrating that any AlF_4^- group, $[AlF_3O_{1/2}]^-$, $[AlF_2O_{2/2}]^-$, or $[AlFO_{3/2}]$, or all these groups simultaneously, can be present in a glass. Moreover, the analysis showed that the experimental data [1, 12] do not distinguish the above groups. These conclusions coincide with those made in [8] that the four-coordinate aluminum groups $[AlO_xF_y]_n$ are major halogen-containing fragments in $CaO \cdot CaF_2 \cdot Al_2O_3 \cdot 2SiO_2$ glass. It should be noted that no data are available in the literature concerning the formation of oxychloride aluminate groups in a glass or melt.

Thus, the results obtained extend our views on the fixation of halogens (both fluorine and chlorine) in the groups involving the second network-forming oxide (both aluminum and boron) and clearly demonstrate that the groups formed are $[RO_{3/2}Hal]^-$ (R is Al or B and Hal, F or Cl).

CONCLUSIONS

(1) The results of a study of the bulk thermal and electrical characteristics of a series of alkali silicate oxyhalide glasses containing the second network-forming agent, with account made of the synthesis conditions and tendency to crystallize, showed that the halogen (F, Cl) is selectively fixed by the second network-forming oxide with the formation of mixed tetrahedra $[RO_{3/2}Hal]^-$, with substitution of one bridging oxygen.

(2) Exceess of the halide content introduced during the glass synthesis over the content of the second network-forming oxide results in the formation of doubly substituted groups $[RO_{2/2}Hal_2]^-$, which serve as source of crystallization of the corresponding fluorides in the case of fluorine or are converted into highly volatile $AlCl_3$ in the case of chlorine.

Abstract—A chemical analysis of aqueous extracts from shungite-III from the Zazhogino deposit (Republic of Karelia) and of natural water contacting with shungite rocks was made. The chemical composition and bactericide properties of "shungite water" were studied.

DOI: 10.1134/S107042720601006X

At present shungite-based preparations are widely used in cosmetology and medicine. In particular, evidence concerning the unique therapeutic-prophylactic properties of water infusion of shungite, shungite-based skin preparations, baths with shungite, and shungite rubble and pebble for massage is given in monographs [1, 2] and numerous advertising issues.

The aim of this study was to examine the chemical composition and selected properties of water that was brought in contact in both laboratory and natural conditions. Our study involved model experiments on leaching of shungite with distilled water, sampling and chemical analysis of samples of natural water that was in contact with shungite rock, and analysis of the chemical composition and bactericidal properties of "shungite water."

As the object of laboratory studies served shungite-III, a material based on shungite rock from the Zazhogino deposit (Republic of Karelia). Shungites (shungite rock) from the Zazhogino deposit are, on the average, composed of 30% carbon and 70% silicates [3]. As regards the content of carbon, they belong to a third variety of shungite rock (shungite-III) [3] or to maxovites [4]. The following microimpurities were found in these shungites: Fe, Ti, V, Ni, Cu, and Zn, mainly in the sulfide (pyrite, pyrrhotine, sphalerite) and oxide (e.g., rutile) mineral forms.

Table 1 lists the concentrations of a number of microelements in an averaged sample of shungite-III, determined by quantitative emission analysis (Central Analytical Laboratory, Karpinskii Russian Research Geological Institute). The content of the rock-forming oxides is as follows (wt %): Al_2O_3 3.5, MgO 4.0, CaO 0.12, Na_2O 0.3, K_2O 1.8, and TiO_2 0.4.

The aqueous extracts were prepared and chemically analyzed as follows. Model experiments on determination of water-soluble forms of shungite microcomponents were performed at room temperature under static conditions: weighed portions of three different fractions of shungite (<0.25 mm, 0.25–1 mm, and 1–3 mm) were poured over with distilled water in a 1 : 5 ratio and the resulting mixtures were thoroughly agitated for 1 h, were allowed to stand for three days (as shown in [5], this time is sufficient for the water-soluble fractions to virtually completely pass from shungite into water), and then were filtered through a "blue band" paper filter. The aqueous extracts, natural water, and shungite water were analyzed by the ICP ES technique at the Laboratory of the Center for Research and Water Quality Monitoring, Vodokanal State Unitary Enterprise. The results obtained are listed in Table 2. The concentrations of Na, Ti, Ag,

As, B, and Sb are below the detection limit. The concentrations of microelements in aqueous extracts, recalculated to their content in shungite, give notion of the fraction of water-soluble forms of separate components relative to their total content (Table 2). It can be seen from the data presented that some elements (Fe, Al, Zn) are present in the aqueous extracts in rather high concentrations; probably, their hydrolysis may be a reason for the substantial decrease in the pH of distilled water after its interaction with shungite.

The chemical elements contained in the shungite samples studied can be conditionally divided into three groups. To the first group belong elements that the least actively pass into an aqueous extract. For these elements, the fraction of water-soluble forms relative to their total content in a solid sample is exceedingly low: tenths of a percent for Na, Cr, Mo, V; hundredths of a percent for K, Pb; and even less for Ti, Ba. For these elements, either no changes at all with the degree of shungite grinding are observed in their concentrations in aqueous extracts or this dependence is very weak. The only exception is lead, but the difference revealed (nearly an order of magnitude) is due to some local contamination. For the second group of elements (Al, Ca, Mg, Fe, Mn, and Be), the fraction of water-soluble elements relative to their total content in shungite is several percents (10–12% at most). A clearly pronounced increase in their concentrations in aqueous extracts with the degree of shungite grinding is observed. The same dependence is preserved for elements belonging to the third group (Cu, Co, Ni, and Zn), but these elements differ in that they pass into an aqueous solution to a considerably greater extent than the others: The fraction of water-soluble forms relative to their total content in shungite is several tens of percent and reaches values of 60–90% in the case of leaching of the <0.25-mm fraction. Similarly to Fe, these elements are present in shungite mainly as sulfides, which turn into more soluble mineral forms under oxidizing conditions.

In addition to laboratory experiments, samples of natural water directly contacting with shungite rock or of water from reservoirs lying close to shungite deposits were taken. The results of their chemical analyses are listed in Table 3. Sample no. 1 was taken from a well at the Maksovo open pit, where under-

ground water is in direct contact with shungite rock. The water of this sample was distinguished by dark color, muddiness, and large content of a suspended shungite material. Sample no. 2 was taken on the territory of the Zazhogino deposit from a sedimentation tank for technical water used to wash shungite. The water was also distinguished by muddiness and rather large content of a suspended material. Finally, sample no. 3 was taken from the Tsarevka River at a distance of approximately 500 m from the Zazhogino deposit. The water was slightly muddy and yellowish. Sample nos. 4 and 5 were taken from rivers running close to the Maksovo deposit: Kelei River (about 4 km from Tolvuya settlement and 0.5 km from the Maksovo deposit) and at the mouth of the Tsarevka River (Lake Onega, near Tolvuya settlement). Both these rivers flow past several shungite bedrocks. It can be seen from Table 3 that the fundamental aspects revealed in analysis of aqueous extracts from shungite are only valid for sample no. 1, i.e., for water that has been in prolonged contact with shungite rock and contains a large amount of a suspended shungite material. Compared with the others, this sample is distinguished by an exceedingly high concentration of iron and very high content of aluminum, zinc, nickel, and copper. Sample no. 2 is also characterized by increased concentrations of a number of microcomponents (Al, Cd, Co, Mn, Ni, Zn), because this water basin lies in the industrial zone and is subject to a strong technological impact. In the rest of the samples, i.e., in water from small rivers running near Zazhogino and Maksovo deposits, the maximum permissible concentrations for potable and household water [6] are not exceeded. Thus, under natural conditions, water is not enriched with microelements from shungite to any noticeable extent without its direct and prolonged contact with ground shungite rock.

Table 5. Results of a microbiological analysis of shungite water

Sample	Coli index	Total microbe number, colony-forming units cm^{-3}
Water from the Neva River		
before treatment	2.4×10^6	4.4×10^5
after treatment	<10	<10

To analyze the chemical composition and properties of shungite water by the methods described in [2, 7], two samples were prepared. The first method consisted in the following: a well-washed 15-g shungite sample was poured over with 25 ml of ordinary tap water and the mixture was kept at room temperature for three days. After this time, the mixture was filtered. The second sample was prepared in the same way, but, prior to being kept for three days, the mixture was boiled for 20 min. The results of chemical analyses are listed in Table 4. The same table presents for comparison values of the upper permissible consumption level of some elements, which is "the highest daily consumption level that does not exert any unfavorable influence on the health of all members of a population. When the consumption exceeds this level, the risk of unfavorable consequences becomes higher" [8].

To study the bactericidal properties of shungite and shungite water, two samples were prepared. The first sample was taken from the Neva River for comparative analysis, and the second was composed of the same water subjected to treatment with shungite by the first of the two techniques described above. The bactericidal properties of shungite water prepared by the second technique (with preliminary boiling of shungites) were not studied because most of bacteria perish in boiling, irrespective of the influence exerted on them by shungite. The study was performed[1] using the method of sanitary-microbiological analysis of water from surface reservoirs (no. 2285–91; January 19, 1981), which included determination of two basic components: total microbial number (colony-forming units cm^{-3}) and Coli index.

The results obtained are listed in Table 5. It is clearly seen that, upon interaction with shungite, water that could be named "dirty" with confidence becomes microbiologically clean. In view of the previously obtained data on leaching-out of various chemical elements, including heavy metals, from shungite, it may be suggested that just the increased concentrations of these elements are among the reasons for the bactericidal properties of shungite and shungite water.

CONCLUSIONS

(1) The interaction of ground shungite with water gives a solution with rather high concentrations of a number of microelements, including heavy matals. The shungite water prepared in accordance with techniques described in the literature exhibits bactericidal properties.

(2) The concentrations of microcomponents in aqueous extracts from shungite-III are rather high and frequently exceed the maximum permissible concentrations for potable and household water.

[1] The study was performed at the St. Petersburg Certification Center, TEST-Sankt-Peterburg Federal State Institution.

ACKNOWLEDGMENTS

The study was supported by the Federal Scientific and Technical Target Program "Research and Development in Priority Areas of Science and Technology" for the years 2002–2006 (State Contract no. 0.2.467.11.7005 of May 23, 2005).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of Heat Capacity of Systems *n*-Alkanol–*n*-Alkane

Abstract—A method was suggested for calculating the molar heat capacity of *n*-alkanol–*n*-alkane solutions with account of the molecular association by the free-volume theory from data on the viscosity of these systems.

DOI: 10.1134/S1070427206010071

The heat capacity belongs to the most important thermodynamic properties of a solution. The study of heat capacity is urgent from both applied (to calculate the thermal regimes of reactors and choose heat carriers) and basic viewpoint (in view of the role of the heat capacity in solution thermodynamics) [1].

For *n*-alkanol–*n*-alkane mixtures, the heat capacity has been studied to a considerably lesser extent than other physicochemical properties. Therefore, the calculation of the heat capacity by using quantitative property–property relationships is an urgent problem. In our previous study [2], a method was suggested for calculating the viscosity of *n*-alkanol–*n*-alkane solutions with account of the molecular association by the free-volume theory. In this study, we used the data on viscosity of *n*-alkanol–*n*-alkane solutions to calculate their heat capacity with account of the molecular association by the free-volume theory. The calculation method was tested with the experimentally studied [3] 1-pentanol–*n*-decane system and with systems ethanol–*n*-heptane, 1-propanol–*n*-heptane, 1-propanol–*n*-hexane, 1-butanol–*n*-heptane, and 1-butanol–*n*-decane, for which the heat capacity and viscosity values required for the calculation are available from the literature [3–8].

One of the semiempirical methods for describing the viscosity of liquids that obviate fitting parameters is the free-volume theory relating the viscosity to the so-called reduced volume $\tilde{V}$ [9]:

$$\Delta\ln\eta = \frac{1}{\tilde{V} - 1} - \frac{x_A}{\tilde{V}_A - 1} - \frac{x_B}{\tilde{V}_B - 1}, \quad (1)$$

where $\Delta\ln\eta = \ln\eta - x_A\ln\eta_A - x_B\ln\eta_B$, η_A and η_B are the dynamic viscosities of components A and B, respectively; $\tilde{V} = V/V^*$, $\tilde{V}_A = V_A/V_A^*$, and $\tilde{V}_B = V_B/V_B^*$ are the reduced volumes of the solution and of components A and B, respectively; x_A and x_B are the mole fractions of components A and B, respectively; V, V_A, and V_B are the molar volumes of the solution and of components A and B, respectively; V^*, V_A^*, and V_B^* are the volumes of the solution occupied by the liquid molecule (the occupied volume) and of components A and B, respectively.

The free-volume concept, applicable to both thermodynamic and kinetic properties, makes it possible to find a quantitative relationship between the heat capacity and viscosity of liquid mixtures. The excess molar volume V^E($V^E = V - V_A x_A - V_B x_B$) incorporates the chemical term V^E_{chem} and the physical term V^E_{phys} [10].

$$V^E = V^E_{chem} - V^E_{phys}, \quad (2)$$

$$V^E_{chem} = \tilde{V}V^E_{assoc} = \tilde{V}\Delta V^0(1 - K\varphi_A)/S = H^E_{assoc}(\Delta V^0/\Delta H^0)\tilde{V}, \quad (3)$$

where S is the average degree of association; K, association constant of 1-alkanol; φ_A, volume fraction of 1-alkanol; and H^E, enthalpy of mixing.

The standard enthalpy of association ΔH^0 for *n*-alkanols is taken as –25.1 kJ mol^{-1}, and the change in the volume in association, as $\Delta V^0 = -5.6$ cm^3 mol^{-1} [10]. The subscript assoc at the excess thermodynamic quantity stands for the association processes.

In any accepted molecular association model, it is preferable to calculate the parameter

$$(\partial V^E_{assoc}/\partial T) = (C^E_p)_{assoc}(\Delta V^0/\Delta H^0) \quad (4)$$

from the experimental viscosity values rather than from those obtained from theoretical models. Analysis of a large body of the experimental data [11] showed that the dependences of C_p^E on the composition in *n*-alkanol–*n*-alkane solutions are determined solely by the chemical term $(C_p^E)_{assoc}$ (except for the areas with small *n*-alkane concentration); the same is true for $(\partial V^E/\partial T)$. Then,

$$(\partial V^E_{chem}/\partial T)_p = \tilde{V} C_p^E (\Delta V^0/\Delta H^0) + (\partial \tilde{V}^E_{chem}/\partial T) H^E_{assoc} (\Delta V^0/\Delta H^0). \quad (5)$$

Compared to the first term, the second term is smaller by an order of magnitude. As a result, we obtain

$$(\partial V^E_{chem}/\partial T)_p \cong \tilde{V} C_p^E (\Delta V^0/\Delta H^0). \quad (6)$$

For C_p^E with account of relation (6) we have

$$C_p^E = \frac{V^* \Delta H^0 [\alpha - V^{-1}(x_A \alpha_A V_A + x_B \alpha_B V_B)]}{\Delta V^0}, \quad (7)$$

where α, α_A, and α_B are the volume expansion coefficients of the solution, *n*-alkanol, and *n*-alkane, respectively.

For pure solvents, the α values are known, whereas for mixtures, as a rule, they are lacking. To calculate the volume expansion coefficient in terms of the Flory theory [12], it is necessary to know the reduced volume of solution $\tilde{V}$, which can be determined by substituting the dynamic viscosity values in formula (1). Then, from the known value of $\tilde{V}$ we can calculate α of the solution by the formula

$$\alpha = \frac{3(1 - \tilde{V}^{1/3})}{(3\tilde{V}^{1/3} - 4)T}. \quad (8)$$

To calculate the occupied volume of the solution V^* by formula (7), we used the Kretschmer–Wiebe's model of continuous association [10]. This model takes into account that the alcohol molecules form chains of associates $A_n + A_1 \rightleftarrows A_{n+1}$, where the length of the chain *n* can acquire infinitely large values ($n \div \infty$), with the association constant satisfying the relation $K_n = [(n + 1)/n]K$. In view of the fact that the occupied volume is physically an additive parameter, for the binary mixture, taking into account the 1-alkanol association, we obtain

$$V^* = (V^*_{A_1} + \Delta V^0 K \varphi_{A_1}) x_A + V^*_B x_B, \quad (9)$$

where V^*_A is the mole fraction of a hypothetical liquid of monomers and φ_{A_1} is the volume fraction of the monomers in the mixture, which is determined by the relation

$$\varphi_{A_1} = [2K\varphi_A + 1 - (4K\varphi_A + 1)^{1/2}]/2K^2\varphi_A. \quad (10)$$

The V^*_{A1} and K values were taken from [10]. They are presented in Table 1 along with other properties of 1-alkanols and *n*-alkanes.

Table 1. Properties and parameters of pure components at T = 298.15 K [10]

Component	K	V	$V^*_{A_1}$	V^*
		$cm^3\ mol^{-1}$		
Ethanol	317	58.66	52.19	46.90
1-Propanol	197	75.12	66.32	61.09
1-Butanol	175	91.98	80.89	75.70
1-Pentanol	153	108.7	95.27	90.10
n-Hexane	–	131.6	–	99.34
n-Heptane	–	144.5	–	111.5
n-Decane	–	195.9	–	155.9

Substituting the α and V^* values calculated by formulas (8) and (9), respectively, in formula (7), we will determine C_p^E of the solution and, from this quantity, the molar heat capacity:

$$C_p = C_p^E + C_{p_A} x_A + C_{p_B} x_B, \quad (11)$$

where C_{p_A} and C_{p_B} are the molar heat capacities of 1-alkanol and *n*-alkane, respectively.

As example, we will calculate the molar heat capacity for the system 1-propanol–*n*-hexane at the mole fraction x_A = 0.102.

(1) Using formula (10), we determine the mole fraction of 1-propanol monomers in the system φ_{A_1} (for 1-propanol K = 197 at T = 298.15 K [10], φ_A = 0.061):

$$\varphi_{A_1} = \frac{2K\varphi_A + 1 - (4K\varphi_A + 1)^{1/2}}{2K^2\varphi_A} = 0.004727.$$

(2) Using formula (9), we calculate the occupied volume of the binary mixture at T = 298.15 K (for 1-propanol, $V^*_{A_1}$ = 66.32 [10], ΔV^0 = –5.6 [10], V^*_B = 99.34 $cm^3\ mol^{-1}$ [10]):

$$V^* = (V^*_{A_1} + \Delta V^0 K \varphi_{A_1}) x_A + V^*_B x_B = 95.440\ cm^3\ mol^{-1}.$$

(3) Using formula (8), we determine the reduced

volumes of 1-propanol and *n*-hexane (the volume expansion coefficient taking into account the association is α_A = 0.000914 K^{-1} for 1-propanol [10] and α_B = 0.001385 K^{-1} for *n*-hexane [10]; T = 298.15 K):

$$\tilde{V}_A = [\alpha_A T/3(1 + \alpha_A T) + 1]^3 = 1.22980,$$

$$\tilde{V}_B = [\alpha_B T/3(1 + \alpha_B T) + 1]^3 = 1.32165.$$

(4) We determine the reduced volume of the solution by relationship (1) (for a given composition, $\Delta\ln\eta$ = –0.1224 [13]):

$$\tilde{V} = \frac{1 + \Delta\ln\eta + x_A/(\tilde{V}_A - 1) + x_B/(\tilde{V}_B - 1)}{\Delta\ln\eta + x_A/(\tilde{V}_A - 1) + x_B/(\tilde{V}_B - 1)} = 1.32120.$$

(5) Using relationship (8), we calculate the volume expansion coefficient of the solution:

$$\alpha = \frac{3(1 - \tilde{V}^{1/3})}{(3\tilde{V}^{1/3} - 4)T} = 0.0013825.$$

(6) Using formula (7), we determine C_p^E (J mol^{-1} K^{-1}) of the solution (ΔH^0 = –25.1 kJ mol^{-1} [10]; the 1-propanol–*n*-hexane solution of the given composition at T = 298.15 K has the molar volume V = 126.022 cm^3 mol^{-1} [13], α = 0.0013825 K^{-1}):

$$C_p^E = \frac{V^*\Delta H^0[\alpha - V^{-1}(x_A\alpha_A V_A + x_B\alpha_B V_B)]}{\Delta V^0}$$

$$= 12.055 \text{ J mol}^{-1}\text{ K}^{-1}.$$

(7) By formula (11), we determine the molar heat capacity of the given solution (at T = 298.15 K, 1-propanol has the molar heat capacity C_{pA} = 143.9 J mol^{-1} K^{-1} [6] and *n*-hexane, C_{pB} = 201.34 J mol^{-1} K^{-1} [6]):

$$C_p = C_p^E + C_{pA}x_A + C_{pB}x_B = 207.54 \text{ J mol}^{-1}\text{ K}^{-1}.$$

CONCLUSIONS

(1) The calculated heat capacities are in good agreement with the experimental data (Table 2). The average error in calculating the heat capacity is 0.046 and the maximum error, 0.31%. The relationship between the heat capacity and viscosity of nonelectrolyte systems was studied for the first time by the example of 1-alkanol–*n*-alkane solution. In other words, a method was suggested for calculating the heat capacity of 1-alkanol–*n*-alkane systems from data on their viscosity.

(2) For practical purposes, the heat capacity of nonelectrolyte systems can be calculated from data on their properties.

Abstract—Heats of solution of cyclohexane and squalane in mixtures of 1-octanol with acetone or 1,4-dioxane within the entire range of compositions were measured calorimetrically. The enthalpies of solution of cyclohexane, squalane, and hexadecane in the mixtures of acetone or 1,4-dioxane with 1-octanol show linear correlation. Enthalpies of solvation of propane, decane, and eicosane in these mixtures were calculated.

DOI: 10.1134/S1070427206010083

Alkanes are the simplest organic compounds. Only a few papers concern the thermochemistry of solution of alkanes in binary nonaqueous solvents [1–6]. In this study, we took a cyclic alkane, cyclohexane, and a branched alkane, squalane (2,6,10,15,19,23-hexamethyltetracosane), which is a liquid (mp 38°C) with a high molecular weight and a low volatility; this simplifies the calorimetric experiment. Squalane is widely used in gas–liquid chromatography as a stationary phase [7–9], in medicine for treatment of burns [10], and as a constituent of pharmaceuticals, perfumes, and cosmetics.

We took as one of solvents 1-octanol, which, along with octane, chloroform, and propylene glycol dipelargonate, constitutes the so-called "critical quartet" [11, 12] used to provide better correlation of the distribution coefficients of biologically active substances (including medicinal preparations) between water and nonaqueous solvent with their ability to penetrate through cell membranes. 1,4-Dioxane, similarly to ethers, has low dielectric constant and in this respect can be classed with low-polarity solvents. However, the standard heats of solution of alkanes in dioxane and ethers differ very strongly. For instance, for hexadecane in dibutyl ether it is as low as 1.80 kJ mol^{-1} [13], whereas in dioxane it is by an order of magnitude higher [4, 14, 15]. Thus, dioxane and ethers are located at the opposite ends of the solvency scale with respect to alkanes. Acetone as an object of the investigation was taken because of its wide application.

In this study, we measured the enthalpies of solution of cyclohexane and squalane in mixtures of acetone or 1,4-dioxane with 1-octanol.

EXPERIMENTAL

Integral heats of solution were measured on an ampule-type variable-temperature calorimeter equipped with an isothermal jacket and 60 cm^3 reaction vessel. The procedure of the calorimetric experiment was the same as in [16, 17]. The thermometric and thermal sensitivities of the device were 5×10^{-6} deg and 5×10^{-3} J per mm of the recorder scale, respectively.

The solvents used were purified as in [18]. The water content in 1-octanol was monitored by Fischer titration [19] and was no more than 0.03 wt %. Chromatographically pure grade cyclohexane and squalane (Merck) were used without additional purification.

The arithmetical mean heats of solution ($\Delta_s H^m$) were taken as standard enthalpies of solution of the compounds ($\Delta_s H^0$) (Table 1), because the difference between these values was within the limits of the experimental error, which was estimated at 2–3%.

The standard enthalpies of solution of cyclohexane in 1-octanol that we measured well coincide with the published value, 1.88 kJ mol^{-1} [20]. To check the squalane quality, we measured the enthalpy of its solution in chloroform and CCl_4. The data obtained are in good agreement with the published values [21] (in parentheses): 11.10 ± 0.08 (11.12 ± 0.05) and 4.84 ± 0.08 (4.67 ± 0.08) kJ mol^{-1}, respectively.

The data obtained are listed in Table 1. They were

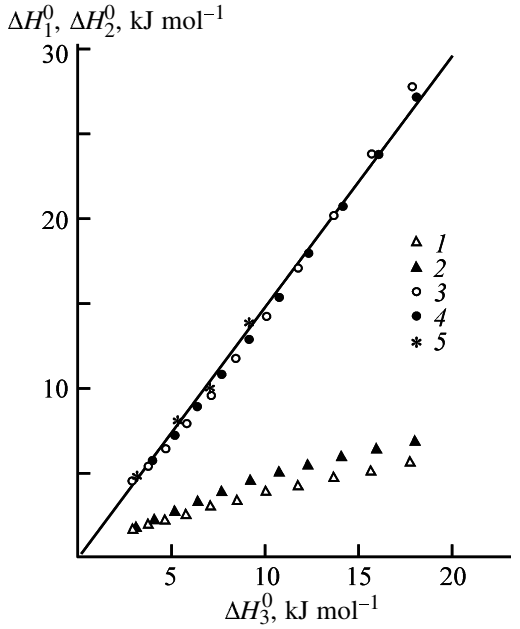
approximated by Eqs. (1)–(3):

$$\Delta_s H^0 = A_0 + A_1X_2 + A_2X_1X_2, \quad (1)$$

$$\Delta_s H^0 = A_0 + A_1X_2 + (A_2 + A_3X_1X_2)X_1X_2, \quad (2)$$

$$\Delta_s H^0 = B_0 + B_1\Phi_2 + B_2\Phi_1\Phi_2, \quad (3)$$

where X_2 and Φ_2 are mole and volume fractions of 1-octanol, respectively. The coefficients of these equations are listed in Tables 2 and 3.



In Eqs. (1)–(3), the sum of the first and second terms is equal to the additive value of the enthalpy of solution, and the third term is equal to excess enthalpy of solution, described by the Redlich–Kister equation [22]. Representation of the experimental data in the form of approximating function allows estimation of the smoothness of the experimental dependences, reproducibility of measurements, and random error; it also allows compact storage of the experimental data (22).

Table 3. Coefficients of polynomials $\Delta H^0 = B_0 + B_1\Phi_2 + B_2\Phi_1\Phi_2$ describing the enthalpies of solution of squalane in the mixed solvents at 25°C

System	B_0	B_1	B_2	S, kJ mol^{-1}
Acetone–1-octanol	27.14	–22.55	–11.40	0.29
1,4-Dioxane–1-octanol	27.83	–23.18	–17.53	0.13

As seen from Tables 2 and 3, transition from mole to volume fractions allows the power of the approximation function in the case of squalane to be decreased without noticeable worsening of the description. For hexadecane in the mixed solvents [5, 6], transition from X to Φ also leads to improvement of description and decrease in the polynomial power. However, for cyclohexane, probably because of small size or cyclic structure of its molecule, transition from mole to volume fractions does not improve the description of the experiment. Therefore, in further calculations, we used Eq. (1) for cyclohexane and Eq. (3) for squalane.

A linear correlation between the enthalpies of solution of squalane and cyclohexane in isomeric butanols and in 1-octanol was found in [23]. It is of interest to examine similar dependences for solvents considered in this study. The correlations of the enthalpies of solution of cyclohexane and squalane with those of hexadecane are shown in the figure. The enthalpies of solution of cyclohexane in the mixtures studied (including their separate components) were calculated by Eq. (1) with the coefficients taken in Table 2. The enthalpies of solution of squalane were calculated by Eq. (3) with the coefficients from Table 3. The enthalpies of solution of hexadecane in acetone–1-octanol and 1,4-dioxane–1-octanol mixtures (step 0.1 volume fraction), including separate components of the mixed solvent, were calculated by Eq. (3) with the coefficients taken from [5, 6]. As seen from the figure, the correlation between the enthalpies of solution of squalane and those of hexadecane in acetone–1-octanol and 1,4-dioxane–1-octanol mixtures is linear (correlation coefficient R 0.9974). The points corresponding to the enthalpies of solution of squalane in *n*-OctOH, *n*-BuOH, *i*-BuOH, and *t*-BuOH [23] also fall on this line. Data on the enthalpies of solution of hexadecane in the above alcohols were taken from [24, 25]. The linear correlations of the enthalpies of solution of cyclohexane in acetone–1-octanol (R = 0.942) and in 1-octanol–1,4-dioxane (R = 0.995) are different.

Correlation of the enthalpies of solution of cyclohexane ΔH_1^0 in (*1*) 1,4-dioxane–1-octanol and (*2*) acetone–1-octanol mixtures, squalane ΔH_2^0 in (*3*) 1,4-dioxane–1-octanol and (*4*) acetone–1-octanol mixtures, and (*5*) squalane in *n*-OctOH, *n*-BuOH, *i*-BuOH, and *t*-BuOH with those of hexadecane ΔH_3^0. (*1–4*) Calculated by Eqs. (1) and (3); (*5*) experimental.

Stephenson and Fuchs [13] found that the enthalpies of solvation ($\Delta_{solv}H^0$) of *n*-alkanes (C_5–C_{16}) in various solvents are linear functions of the number of carbon atoms in the alkane molecule (N_C). Using the experimental data from [13–15, 26], they obtained linear correlations (4)–(6) of the enthalpies of solvation (kJ mol^{-1}) of *n*-alkanes in acetone, 1,4-dioxane, and 1-octanol, respectively, with N_C of alkane:

$$\Delta_{solv}H^0 = -1.0 - 3.86N_C;\ R = 0.9999,\ S = 0.25, \quad (4)$$

$$\Delta_{solv}H^0 = -0.6 - 3.88N_C;\ R = 0.9999,\ S = 0.09, \quad (5)$$

$$\Delta_{solv}H^0 = -1.7 - 4.80N_C;\ R = 0.9999,\ S = 0.10. \quad (6)$$

We obtained linear correlations of the enthalpies of solution of two linear (C_{11} and C_{16}) and one branched (C_{30}) alkanes in acetone with those in 1,4-dioxane:

$$\Delta_s H^0(Me_2CO) = -0.98\Delta_s H^0(C_4H_8O_2);\ R = 0.9995,$$

$$S = 0.23. \quad (7)$$

* (Φ_2) Mole fraction of 1-octanol.

Using Eqs. (4)–(6), we calculated the enthalpies of solvation of propane, decane, and eicosane in acetone, 1,4-dioxane, and 1-octanol and then found linear correlations of the enthalpies of solvation of propane [Eq. (8)], decane [Eq. (9)], and eicosane [Eq. (10)] in acetone–1-octanol and 1,4-dioxane–1-octanol mixtures with the enthalpies of solution of hexadecane in the same mixtures:

$$\Delta_{solv}H^0 = -16.78 + 0.243\Delta_sH^0;\ R = 0.9941,\ S = 0.33; \quad (8)$$

$$\Delta_{solv}H^0 = -51.66 + 0.678\Delta_sH^0;\ R = 0.9990,\ S = 0.30; \quad (9)$$

$$\Delta_{solv}H^0 = -101.50 + 1.30\Delta_sH^0;\ R = 0.9998,\ S = 0.26. \quad (10)$$

Equations (4)–(6) and (8)–(10) allow calculation of the enthalpies of solvation of alkanes over the entire range of compositions of acetone–1-octanol and 1,4-dioxane–1-octanol mixtures without carrying out the experiment. The results of the calculation for propane, decane, and eicosane are listed in Table 4. Propane is a gas and eicosane (C_{20}) is solid under the common conditions, which complicates the comparative calorimetric experiment. Therefore, we calculated the enthalpies of solvation (but not solution). We calculated the enthalpies of solvation by Eq. (11)

$$\Delta_{solv}H^0 = \Delta_sH^0 - \Delta_vH^0, \quad (11)$$

where Δ_vH^0 is the enthalpy of vaporization. The required data on the heats of vaporization were taken from [27].

CONCLUSIONS

(1) Enthalpies of solution of cyclohexane and squalane in mixtures of acetone or 1,4-dioxane with 1-octanol were determined experimentally.

(2) Linear dependences between the enthalpies of solution of branched (squalane), cyclic (cyclohexane), and linear (hexadecane) alkanes in the above mixtures were found.

(3) Enthalpies of solvation of propane, decane, and eicosane in the mixtures studied were calculated.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Regular Trends in Distribution of Substituted Benzoic Acids between Organic Solvents and Water

Abstract—The influence of physicochemical properties of organic solvents on the distribution constants of aromatic carboxylic acids between the organic and aqueous phases was examined.

DOI: 10.1134/S1070427206010095

Substituted benzoic acids are intermediates in the synthesis of numerous organic compounds, including precursors of dyes and drugs. As a rule, syntheses of substituted benzoic acids or particular steps (nitration, reduction) are performed in the aqueous phase. Therefore, recovery of substituted benzoic acids from the aqueous phase with organic solvents is important from both technological and environmental viewpoints. Although available data on the distribution constants K_d of substituted benzoic acids between organic and aqueous phases are numerous, no reliable quantitative relationships between K_d and physicochemical characteristics of the extractants are known. Such relationships would allow prediction of K_d for other solvents, not tested experimentally, and thus would allow purposeful choice of appropriate solvents for the extraction.

We showed in [1, 2] that the logarithms of the distribution constants of substituted aliphatic acids between organic and aqueous phases, $\log K_d$, do not correlate with their dissociation constants, pK. It was appropriate to check whether such a correlation takes place with aromatic acids. The pK values for a series of substituted benzoic acids and their distribution constants ($\log K_d$) in the systems with the most extensively studied organic solvents (*n*-octanol, chloroform, toluene) [3, 4] are given in Table 1. It is seen that, whereas K of *ortho*-substituted benzoic acids is in most cases higher by an order of magnitude than K of their *meta* and *para* isomers, there are no definite trends in the distribution constants: the *meta* and *para* isomers are extracted in some cases better and in other cases worse than the *ortho* isomers.

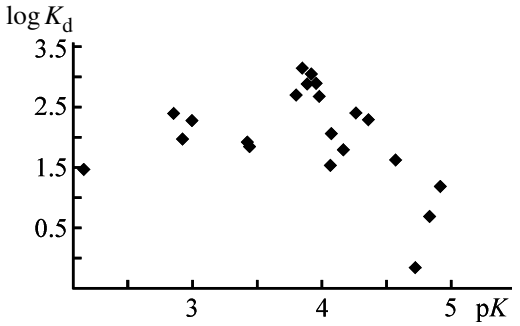

Fig. 1. log K_d of aromatic acids in the octanol–water system vs. their pK.

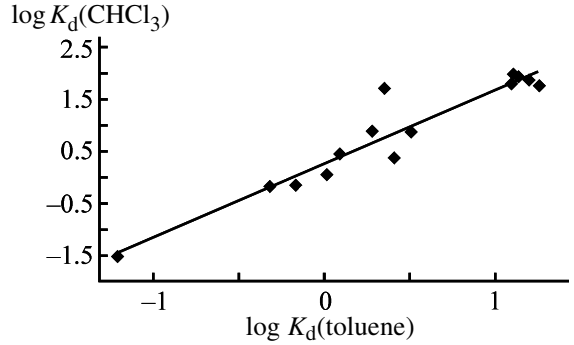

Fig. 2. Correlation between log K_d of carboxylic acids in the chloroform–water and toluene–water systems.

Figure 1 shows that there is no correlation between log K_d of acids in the octanol–water system and their pK. With other organic solvents, such correlation is lacking also. At the same time, it is interesting that, whereas the log K_d values in the systems with octanol and $CHCl_3$ do not correlate with each other, an approximate linear correlation does exist between the data for two aprotic solvents, toluene and $CHCl_3$ (Fig. 2).

We found in [1] that the correlation of K_d of aliphatic carboxylic acids between water and organic solvents with the properties of these solvents can be described by a five-parameter equation

$$\log K_d = a_0 + 4a_1\frac{n^2 - 1}{n^2 + 2} + a_2\frac{\varepsilon - 1}{2\varepsilon + 1} + a_3\delta^2 + a_4B + a_5E_T, \quad (1)$$

where n is the refractive index and ε, dielectric permittivity of the organic solvents (parameters determining their polarizability and polarity and responsible for the nonspecific solvation of a substrate); B, Palm basicity [5] and E_T, Reichardt electrophilicity [6] (parameters determining the capability of a solvent for acid–base interactions, i.e., for specific solvation); and δ^2, Hildebrand solubility parameter squared [parameter characterizing the cohesion (self-association) energy of a solvent, proportional to the energy required for penetration of a foreign molecule into the solvent structure, i.e., for formation of a cavity in the liquid].

We found that the major influence on log K_d of aliphatic acids is exerted by two characteristics of extractants: basicity B and polarity function $f(\varepsilon)$. The major solvation process controlling the transfer of an acid to the organic phase is its interaction with basic solvents with the formation of a complex; the solvent polarity positively affects this process. Formation of such complexes in extraction of phenols with basic solvents was confirmed by UV spectrophotometry and refractometry [7]. Therefore, the influence of properties of a solvent on its extraction power with respect to aliphatic carboxylic acids in most cases can be described with acceptable accuracy by a two-parameter equation

$$\log K_d = a_0 + a_2 f(\varepsilon) + a_4 B. \quad (2)$$

At the same time, we showed in [1] that the coefficients a_0, a_2, and a_4, characterizing the contribution of particular solvation processes to K_d of aliphatic acids, correlate with some of their parameters. Namely, a_4 linearly decreases, with a satisfactory accuracy, with an increase in pK; a_2 decreases with an increase in the Kirkwood parameter $(\varepsilon - 1)/(2\varepsilon + 1)$; a_0 grows with an increase in the molar volume of acids V_m (which is approximately proportional to their molar weight).

In the case of aromatic acids, the applicability of Eqs. (1) and (2) to K_d values with different extractants was proved for benzoic and salicylic acids [8, 9]; therefore, it was interesting to check the applicability of these equations to other aromatic acids and the existence of relationships like (2) with characteristics of the acids. The distribution of aminobenzoic acids was studied in most detail in [3, 4, 10, 11]. The distribution constants K_d of *o*-aminobenzoic acid between water and 38 organic solvents are given in Table 2. This data set can be described with a fairly high multiple correlation coefficient $R = 0.920$ by Eq. (1) supplemented with one more term taking into account the solvent molar volume V_m. Since for some extractants the K_d values given in different papers differ appreciably, we selected their optimal values best fitting the general equation. After such a selection, R increased insignificantly, to 0.927. To attain $R > 0.95$, which is considered as satisfactory level according to recommendations of the Group for Correlation Analysis in Chemistry (CAC IUPAC) [12], we excluded from the calculations the most deviating data for isopropyl

alcohol and dichloroethane. It should be noted here that, when constructing multiparameter equations describing the influence of various properties of solvents on an experimentally measured quantity (reaction rate constants, spectral shifts, or, as in our case, distribution constants), the adequacy of the equations obtained is commonly assessed by the multiple correlation coefficient R itself, rather than by R^2 [13]. Thus, we obtained an adequate equation for 36 extractants:

$$\log K_d = 1.72 - (4.44 \pm 2.18) f(n^2) + (4.21 \pm 1.13) f(\varepsilon) + (6.80 \pm 0.89) \times 10^{-3} B - (0.08 \pm 0.03) E_T + (1.64 \pm 1.67) \times 10^{-3} \delta^2 + (1.32 \pm 1.41) \times 10^{-3} V_m, \quad (3)$$

$$N = 36, \ R = 0.959, \ \text{rms error } s = \pm 0.235.$$

In this case, the decisive parameter is the solvent basicity B, with which $\log K_b$ correlates with the pair correlation coefficient $r = 0.910$ for 36 solvents. The coefficients at some terms of the regression equation (e.g., V_m, δ^2) have large rms deviations, sometimes exceeding their absolute values, which indicates that these terms are insignificant. Therefore, the significance of particular terms of the equation was checked, according to [12], by their alternate exclusion with the calculation of R for the equations with the smaller number of terms. By so doing, we found that V_m and δ^2 are insignificant and the significance of $f(n^2)$ is low. Finally, $\log K_d$ of *o*-aminobenzoic acid is adequately described by a three-parameter equation

$$\log K_d = 0.51 + (2.97 \pm 1.00) f(\varepsilon) + (7.62 \pm 0.66) \times 10^{-3} B - (0.05 \pm 0.02) E_T, \quad (4)$$

$$N = 36, \ R = 0.953, \ s = \pm 0.250.$$

The decisive influence of $f(\varepsilon)$, B, and, to a lesser extent, E_T is consistent with the relatively high coefficients r of correlations of $\log K_d$ with these parameters: 0.754, 0.910, and 0.704, respectively, whereas with the remaining parameters r is within 0.2–0.4. Generalization of the data with a two-parameter equation including the basicity and polarity parameters only is, however, unsatisfactory, because R becomes lower than 0.95 and the standard deviation of the coeficient at the Kirkwood parameter becomes larger than the absolute value of this coefficient, i.e., this factor becomes insignificant. However, the corresponding equation (5) allows comparison with the related two-parameter equations for other acids, including aliphatic acids [1]:

$$\log K_d = -0.54 + (0.65 \pm 0.72) f(\varepsilon) + (6.93 \pm 0.70) \times 10^{-3} B, \quad (5)$$

$$N = 36, \ R = 0.940, \ s = \pm 0.281.$$

The $\log K_d$ values calculated by Eq. (4) and their deviations from the experimental values, $\Delta \log K_d = \log K_{exp} - \log K_{calc}$, are given in Table 2. Except the data for the two excluded solvents, $\Delta \log K_d$ is within $s = \pm 0.250$ or only slightly exceeds this level.

Data on the distribution of other substituted benzoic acids for which the available data are sufficient for statistical treatment can also be satisfactorily fitted by an equation of type (1); as a rule, the decisive influence on $\log K_d$ is exerted by the solvent basicity. In what follows, we present the coefficients r_B of pair correlation of $\log K_d$ with the solvent basicity and also, for comparison with aliphatic acids, the two-parameter equations $\log K_d = f(\varepsilon, B)$, even when their coefficients R are lower than the value of 0.95 recommended in [12], i.e., when these equations are not quite adequate. Table 3 presents the $\log K_d$ values from [3, 4] for *p*- and *m*-amino- and *m*-hydroxybenzoic acids, and also for *m*-chloro- and *m*-nitrobenzoic acids, although the available K_d values for them are fewer.

For *p*-aminobenzoic acid, R for the whole set of 22 solvents is as low as 0.912, but after exclusion of data for dichloromethane and nitrobenzene we obtain an adequate equation:

$$\log K_d = -4.99 + (7.54 \pm 4.95) f(n^2) + (19.09 \pm 1.98) f(\varepsilon) + (4.53 \pm 1.34) \times 10^{-3} B - (0.02 \pm 0.04) E_T - (7.30 \pm 2.79) \times 10^{-3} \delta^2 - (9.33 \pm 2.90) \times 10^{-3} V_m, \quad (6)$$

$$N = 20, \ R = 0.969, \ s = \pm 0.267.$$

In this case, the polarizability and (in contrast to *m*-aminobenzoic acid) electrophilicity factors are insignificant:

$$\log K_d = -3.46 + (17.38 \pm 1.65) f(\varepsilon) + (2.91 \pm 1.15) \times 10^{-3} B - (6.41 \pm 1.10) \times 10^{-3} \delta^2 - (7.14 \pm 2.11) \times 10^{-3} V_m, \quad (7)$$

$$R = 0.962, \ s = \pm 0.298, \ r_B = 0.612.$$

Here the structural factors δ^2 and V_m are also significant; the correlation coefficient R of Eq. (8) obtained upon their exclusion is unacceptably low:

$$\log K_d = -4.46 + (11.30 \pm 1.98) f(\varepsilon) + (2.70 \pm 1.40) \times 10^{-3} B, \quad (8)$$

$$R = 0.878, \ s = \pm 0.519.$$

Tributyl phosphate	2.4900	2.3442	–0.1457

* Data for these solvents were excluded from further calculations.

With *m*-aminobenzoic acid, large number of factors should be taken into account also. For the whole set of 17 extractants, $R = 0.872$, and a satisfactory correlation is obtained after exclusion of data for $CHBr_3$ and benzene:

$$\log K_d = 6.17 - (47.16 \pm 5.81) f(n^2) + (24.31 \pm 1.68) f(\varepsilon) - (7.52 \pm 1.10) \times 10^{-3} B - (0.11 \pm 0.03) E_T + (0.32 \pm 2.05) \times 10^{-3} \delta^2 + (14.41 \pm 3.30) \times 10^{-3} V_m, \quad (9)$$

$$N = 15,\ R = 0.987,\ s = \pm 0.150,\ r_B = 0.680.$$

In contrast to other benzoic acids, here the coefficient at the basicity parameter B is negative and the coefficients at parameters of nonspecific solvation are very large in absolute values. As in the case of *p*-aminobenzoic acid, the electrophilicity parameter E_T is insignificant here, and the correlation coefficient of the five-parameter equation obtained after its exclusion remains essentially the same ($R = 0.987$), but further exclusion of any term makes the correlation inadequate (R becomes less than 0.95). For the two-parameter equation $\log K_d = f(\varepsilon, B)$, R is as low as 0.774. At the same time, the coefficient at B becomes positive, and the coefficient at $f(\varepsilon)$ drastically decreases:

$$\log K_d = -2.67 + (4.82 \pm 2.21) f(\varepsilon) + (3.85 \pm 1.68) \times 10^{-3} B, \quad (10)$$

$$R = 0.774,\ s = \pm 0.591.$$

With the other three acids, the results obtained were considerably better. The equation obtained for *m*-hydroxybenzoic acid resembles that obtained for *o*-aminobenzoic acid. For the whole set of 15 extractants, R of the five-parameter equation is 0.944, and exclusion of the most deviating data for *o*-nitrotoluene leads to a six-parameter equation with $R = 0.991$, with the desicive influence of the basicity factor ($r_B = 0.946$):

$$\log K_d = 1.33 + (4.91 \pm 3.13) f(n^2) + (9.12 \pm 1.48) f(\varepsilon) + (21.97 \pm 1.63) \times 10^{-3} B - (0.10 \pm 0.04) E_T - (7.46 \pm 2.07) \times 10^{-3} \delta^2 - (1.21 \pm 0.03) \times 10^{-3} V_m, \quad (11)$$

$$R = 0.991,\ s = \pm 0.178.$$

As in the previous case, the parameters $f(n^2)$ and V_m are essentially insignificant, as well as δ^2. The distribution of *m*-hydroxybenzoic acid can be satisfactorily described by simplified equations

$$\log K_d = 0.43 + (7.12 \pm 2.02) f(\varepsilon) + (18.41 \pm 0.02) \times 10^{-3} B - (0.13 \pm 0.06) E_T, \quad (12)$$

$$R = 0.976,\ s = \pm 0.30;$$

Table 3. Distribution constants of substituted benzoic acids between organic and aqueous phases [3, 4]

$$\log K_d = 0.76 + (2.93 \pm 1.08) f(\varepsilon) + (13.99 \pm 1.50) \times 10^{-3} B, \quad (13)$$

$$R = 0.966, \; s = \pm 0.36.$$

The distribution of *m*-chloro- and *m*-nitrobenzoic acids was studied with seven extractants only; therefore, the equations obtained for them are less reliable. Nevertheless, positive results were obtained. For *m*-chlorobenzoic acid, we obtained a six-parameter equation with $R = 0.999$, but a two-parameter equation is also quite adequate:

$$\log K_d = -0.85 + (3.20 \pm 1.13) f(\varepsilon) + (5.90 \pm 0.86) \times 10^{-3} B, \quad (14)$$

$$N = 7, \; R = 0.983, \; s = \pm 0.167.$$

The decisive effect is exerted by the basicity (pair correlation coefficient of $\log K_d$ with B $r_B = 0.960$).

Similar result was obtained for *m*-nitrobenzoic acid: for the six-parameter equation, $R = 0.999$; the polarizability and molar volume factors are essentially insignificant (for the four-parameter equation, $R = 0.996$); the two-parameter equation is also quite adequate:

$$\log K_d = -1.71 + (5.29 \pm 1.92) f(\varepsilon) + (6.43 \pm 1.55) \times 10^{-3} B, \quad (15)$$

$$N = 7, \; R = 0.964, \; s = \pm 0.297, \; r_B = 0.916.$$

For a number of other acids, K_d is known with 4–6 extractants only [3, 4], which makes construction of

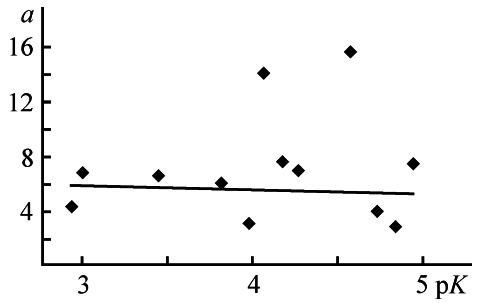

Fig. 3. Coefficient a_4 of equations of type (2) for distribution of aromatic acids vs. their dissociation constant pK.

an equation of type (1) impossible. However, the influence of the major factors, $f(\varepsilon)$ and B, can be evaluated by an equation of type (2), although such equations will be less reliable statistically. Below we give for each acid the K_d values with the examined solvents, the corresponding equation of type (2), and the coefficient r_B. For comparison, we also give two-parameter equations for unsubstituted benzoic and 2-hydroxybenzoic (salicylic) acids, calculated on the basis of data from [8, 9].

Benzoic acid, 36 solvents [8]:

$$\log K_d = -1.15 + (2.56 \pm 0.66) f(\varepsilon) + (7.54 \pm 0.68) \times 10^{-3} B, \quad (16)$$

$$N = 36,\ R = 0.957,\ s = \pm 0.277,\ r_B = 0.936.$$

o-Hydroxybenzoic (salicylic) acid, 28 solvents [9]:

$$\log K_d = -0.671 + (2.63 \pm 1.01) f(\varepsilon) + (6.57 \pm 0.95) \times 10^{-3} B, \quad (17)$$

$$N = 28,\ R = 0.931,\ s \pm 0.344,\ r_B = 0.911.$$

p-Hydroxybenzoic acid: K_d 0.6 (ethylbenzene), 0.01 (chloroform), 26.0 (diethyl ether), 27.0 (isobutanol), 38.0 (*n*-octanol):

$$\log K_d = -0.567 + (3.71 \pm 2.52) f(\varepsilon) + (15.56 \pm 1.82) \times 10^{-3} B, \quad (18)$$

$$N = 5,\ R = 0.979,\ s = \pm 0.349,\ r_B = 0.967.$$

o-Chlorobenzoic acid: K_d 0.41 (cyclohexane), 1.90 (toluene), 1.02 (*m*-xylene), 8.00 ($CHCl_3$), 94.00 (diethyl ether), 95.00 (*n*-octanol):

$$\log K_d = -1.67 + (6.60 \pm 1.22) f(\varepsilon) + (4.28 \pm 0.93) \times 10^{-3} B, \quad (19)$$

$$N = 6,\ R = 0.984,\ s = \pm 0.180,\ r_B = 0.885.$$

m-Chlorobenzoic acid: K_d 0.41 (*n*-hexane), 1.62 (benzene), 2.6 (chloroform), 1.23 (toluene), CCl_4 (1.42), 93.3 (diethyl ether), 67.6 (*n*-octanol):

$$\log K_d = -0.85 + (3.20 \pm 1.13) f(\varepsilon) + (5.90 \pm 0.86) \times 10^{-3} B, \quad (20)$$

$$N = 7,\ R = 0.983,\ s = \pm 0.276,\ r_B = 0.960.$$

p-Chlorobenzoic acid: K_d 2.09 (benzene), 7.58 (chloroform), 3.24 (toluene), 77.6 (*n*-octanol):

$$\log K_d = -0.86 + (4.73 \pm 0.38) f(\varepsilon) + (3.01 \pm 0.37) \times 10^{-3} B, \quad (21)$$

$$N = 4,\ R = 0.997,\ s = \pm 0.05,\ r_B = 0.873.$$

m-Toluic acid: K_d 4.5 (cyclohexane), 12.6 (toluene), 57 (chloroform), 235 (*n*-octanol):

$$\log K_d = -0.528 + (0.72 \pm 0.15) f(\varepsilon) + (6.49 \pm 0.15) \times 10^{-3} B, \quad (22)$$

$$N = 4,\ R = 0.999,\ s = \pm 0.02,\ r_B = 0.997.$$

These equations show that the distribution factors of aromatic acids between organic and aqueous phases can be satisfactorily described in most cases by two-parameter linear equations taking into account the polarity and basicity of the organic solvent, with the influence of basicity being decisive. Certain differences observed with aminobenzoic acids are probably caused by possible simultaneous solvation of the amino group capable of hydrogen bonding. The coefficients at both terms of the equation are positive (i.e., the extraction increases with an increase in the parameters) and vary depending on the acid in the following ranges: at $f(\varepsilon)$, 0.7–11; at $10^{-3}B$, 3–15.5 (for the majority of acids, 4–7). The absolute term a_0 is negative. However, we failed to obtain, as for aliphatic acids [1], explicit correlations of these coefficients with such characteristics of acids as the molar volume and ε. Aromatic acids are crystalline, and the ε values for them are, as a rule, unknown, as well as the densities required for determination of the molar volume. An attempt to construct a correlation of a_4 with pK of acids failed also (Fig. 3). This may be due to the occurrence in aromatic acids of some effects that are absent in aliphatic acids: conjugation of lone electron pairs of the carbonyl oxygen atom with the π-electron ring, possible hydrogen bonding with *o*-amino or *o*-hydroxy groups with the formation of an energetically favorable cyclic structure, steric effects, etc.

The conclusion that the acid–base interactions and extractant polarity are the decisive factors in the extraction of aromatic acids is consistent with the con-

clusions made by Okada *et al.* [10], who studied the distribution of *p*-aminobenzoic acid between the organic and aqueous phases. In experiments on the extraction of this acid with mixtures of cyclohexane with *n*-octanol, they confirmed the lack of linear correlation between $\log K_d$ and ε of the mixtures and concluded that the extraction is influenced by various solvation factors acting simultaneously.

CONCLUSIONS

(1) The distribution constants of substituted aromatic acids between organic and aqueous phases show no linear correlation with any extractant characteristic taken separately. These quantities can be satisfactorily generalized only with multiparameter equations taking into account various properties of the extractants.

(2) The major factor governing the degree of recovery of acids with organic extractants is the Palm basicity of the extractant.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Tetrazole on Ni(II) and Fe(III) Oxides

Abstract—Kinetics of evolution of the electrosurface (electrokinetic potential and pH at isoelectric point) and adsorption properties is studied in the systems aqueous tetrazole–metal oxide (NiO or Fe_2O_3) in long-term experiments with variation of the tetrazole concentration and solution pH.

DOI: 10.1134/S1070427206010101

This paper continues a series of studies considering the features of adsorption of azoles on the surface of transition metal oxides [1–5] and concerns adsorption of tetrazole on NiO and Fe_2O_3.

Previously we demonstrated [3, 4] that the electrokinetic potential ζ of NiO, Fe_2O_3, and $NiFeO_4$ surfaces in aqueous tetrazole solutions starts to change practically immediately after bringing the phases in contact, and its evolution in time is rather complex. We concluded that, first, the interaction between tetrazole molecules (both in the molecular and ionic forms) with surface sites of the oxide surface undoubtely occurs, and second, neither the Gouy–Chapman model (nonspecific adsorption), nor the theory of adsorption of organic surfactants can adequately reproduce this interaction. Our results revealed that adsorption of tetrazole and other ligands is caused primarily by the adsorbent–adsorbate donor–acceptor interaction. The facts that ζ changes over a long time and that the ζ vs. t_c dependence (t_c is the contacting time) is rather complex suggest several steps of transformation of the adsorbate in the adsorption layer. In this case, the mechanism of each step (naturally, except for the first one) does not necessarily involve the formation of donor–acceptor bonds.

In this study we examined the kinetics of evolution of the parameters referred to the bulk of the aqueous phase, such as the tetrazole concentration c and pH, and also of those characterizing the oxide surface (electrokinetic potential ζ and pH at the isoelectric point pH_{IEP}). The adsorption of tetrazole per unit surface area Γ was determined from the difference $\Delta c = c - c_0$, where c_0 is the tetrazole concentration in the initial solution, and the specific surface area of the adsorbent s_{sp}. In the experiments we varied the solution pH and c_0. For c_0, we selected two values, 1×10^{-3} and 1×10^{-4} M. For each of these concentrations, we selected two pH values, that established in the system naturally (solution no. 1) and pH 3 (solution no. 2). In the latter case, pH 3 was adjusted and then maintained throughout the experiment by adding an acid or an alkali. The initial pH in solution no. 1 was 3.9 and 5.3 at $c_0 = 1 \times 10^{-3}$ and 1×10^{-4} M, respectively. In addition to the working (tetrazole-containing) solutions we used reference (tetrazole-free) solutions with the same ionic strength, which was adjusted by adding HCl, KCl, and KOH.

All the chemicals used in the study were of analytically pure grade. The solutions were prepared in distilled water [conductivity $(1–2) \times 10^{-6}$ S cm^{-1}].

The metal oxides were prepared as fine powders. Their characteristics were the same as in the corresponding experiments described in [6].

Figure 1 shows the ζ vs. t_c dependence for NiO dispersions in tetrazole solutions of two different concentrations (1×10^{-3} and 1×10^{-4} M) and with different pH values. There was no way to depict data obtained at small t_c using the time scale acceptable for presentation of the data obtained in 7-day experiments. Therefore, in the plot, the ζ values corresponding to $t_c = 0$, in fact, correspond to $t_c = 0.02–0.2$ h. The exact initial ζ values ($t_c = 0$) are equal to those in the corresponding reference solutions (see caption to Fig. 1). Note that, in the reference solutions, ζ remained unchanged throughout prolonged experiments.

Data presented in Fig. 1 are consistent with those reported previously [3, 4]. In all the dispersions, after bringing the phases in contact, initially positive ζ

rapidly increases. Then it passes through a maximum and decreases during a long time. Finally, either ζ remains practically unchanged (in most cases) or increases again (NiO; $c_0 = 10^{-3}$ M) but at a lower rate than initially. The fact that some differences are observed between the results obtained in this study and those reported previously [3, 4], particularly, in the tetrazole concentration at which the characteristic trends are more clearly pronounced, can be attributed to high sensitivity of the electrokinetic properties to the batch of the adsorbent and phase ratio (in this study, both the batch of the oxide and phase ratio were different from those used previously).

Note also that the ζ values at $t_c = 0$ and $t_c = 0.02$–0.2 h, referred to NiO dispersions in solution no. 1, are close to those in the reference solutions at the same pH, while for the dispersions in solution no. 2, ζ in tetrazole-containing solutions is mostly considerably lower. Furthermore, in the NiO dispersions the factors of the tetrazole concentration and pH play certain role, which is not the case in the Fe_2O_3 dispersions. The pH_{IEP} values in tetrazole-containing dispersions ($c_0 = 10^{-3}$ M), measured at $t_c = 24$ h, are 5.4 and 5.7 for NiO and Fe_2O_3, respectively. In the reference solutions, the corresponding values are 7.5 and 6.1. Thus, introduction of tetrazole in concentration of 10^{-3} M shifts pH_{IEP} of both oxides toward lower values, the effect being more pronounced for NiO.

Figure 2 shows the Γ vs. t_c dependences obtained for the dispersions of both oxides at a tetrazole concentration of 10^{-3} M and pH of the liquid phase corresponding to solution nos. 1 and 2. Comparison of Figs. 1 and 2 (adsorbent NiO) shows that the corresponding dependences of ζ vs. t_c and Γ vs. t_c are close in shape. In solution no. 1, the parameters ζ and Γ rapidly increase at small t_c, then they increase at a lower rate, and, finally, flatten out at large t_c. In solution no. 2 the curves run more smoothly, but the similarity remains. In the case of Fe_2O_3, the corresponding curves are similar in shape also.

Note here that there is no need in analysis of the observed differences in the positions of the extrema in the ζ vs. t_c and Γ vs. t_c curves, since the phase ratios in the electrokinetic and adsorption experiments were different.

Figure 3 shows the Γ vs. t_c dependences obtained for the dispersions of both oxides, but at a tetrazole concentration of 10^{-4} M. At this lower tetrazole concentration, the trends in ζ and Γ remain similar, even being less pronounced than at $c_0 = 10^{-3}$ M.

It should be pointed out that the effect of adsorbent

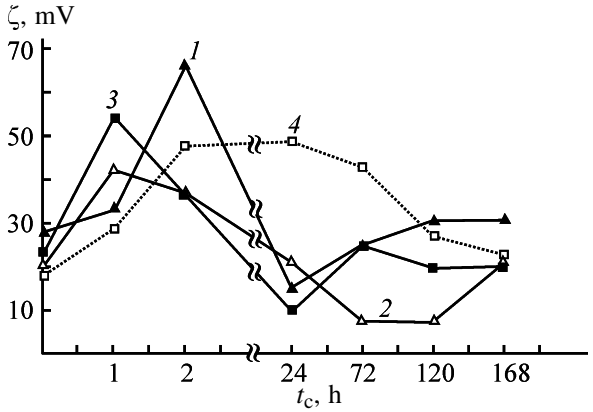

Fig. 1. Electrokinetic potential ζ of NiO as a function of the contacting time t_c. c_0 (M): (*1, 3*) 10^{-3} and (*2, 4*) 10^{-4}. (*1, 2*) Solution no. 1 and (*3, 4*) solution no. 2. ζ (mV) in the corresponding reference solutions: (*1*) +32, (*2*) +17, (*3*) +37, and (*4*) +39.

on the adsorption of tetrazole is clearly pronounced in the dispersions with an aqueous phase corresponding to solution no. 1 (Figs. 2 and 3), but not at pH 3 (Fig. 2), which can be attributed to the differences in the hydrolytic behavior of iron and nickel. The OH^- group occurring in the surface complex as a result of hydrolysis is a more tightly bound ligand as compared to tetrazole. In contrast to Ni(II), Fe(III) has a strong tendency to hydrolysis at pH realized in solution no. 1. At pH 3 neither surface Fe(III) nor Ni(II) are hydrolyzed.

Data on pH at various contacting times of the oxides with various tetrazole solutions are given in the table. Note here that, at the moment of contacting the oxides with tetrazole solutions, in all cases, pH is lower than pH_{IEP} of the oxides in the reference solutions. Thus, initially (at t_c of about several minutes), the oxide surface was positively charged in all the systems.

The table shows that significant changes in pH occurred only in the NiO dispersions. In the Fe_2O_3 dispersions, pH does not depend on t_c.

All the results obtained suggest specific nature of the processes initiated by introduction of tetrazole into the adsorption layer at the surface of both oxides: increase in the initially positive ζ after addition of tetrazole into the aqueous phase; shift of pH_{IEP}; nonmonotonic run of the kinetic curves of all the characteristic parameters; and long time required to establish the steady state.

Since the trends of the selected characteristic parameters were demonstrated to be more clearly pronounced in NiO dispersions, let us further analyze surface processes occurring on this adsorbent.

The rather complex kinetic curves of ζ and Γ obtained with tetrazole are qualitatively similar to those obtained previously [3, 4]. For example, the observed distinct growth of the initially positive ζ in the initial stage of the experiment is equally typical of both tetrazole and 1,3-diazole.

In the case of 1,3-diazole solutions with a high concentration of the cationic species, the increase in the initially positive ζ on the NiO surface was attributed to the adsorption of long chains of the cations having a large total positive charge. The same interpretation could be applied to the NiO dispersions in aqueous tetrazole solutions at pH 3 (solution no. 2), as containing sufficient amounts of tetrazole in the cationic form. Therefore, in this case, the mechanisms of the surface reactions are similar to those occurring in adsorption of diazole [3, 4].

However, it is clearly seen from even superficial comparison of the properties of the tetrazole and 1,3-diazole solutions that the adsorption mechanisms are significantly different for the dispersions in solution no. 1.

In this case, the fraction of the cationic form of 1,3-diazole is 10–40%, while for tetrazole, this fraction is very small or lacking at all. Furthermore, in this solution, 50–60% of tetrazole occurs in the anionic form (at $c = 1 \times 10^{-4}$ M). It is known that large associates are preferentially formed from cationic azole species, and anionic species do not form associates at all. Therefore, the observed initial growth of the positive ζ in solution no. 1 cannot be attributed to the adsorption of positively charged associates.

Figure 4 shows the suggested mechanisms of successive processes occurring with ionic and molecular species and with associates of tetrazole in the surface layer in the systems with solution no. 1.

As known [7–11], the π system of tetrazole consists of six delocalized π electrons (p_z electron of the carbon atom, p_z^2 lone pair of the pyrrole nitrogen, and p_z electrons of the pyridine nitrogen atoms). The pyridine nitrogens N^2, N^3, and N^4 have lone pairs potentially capable of forming donor–acceptor bonds, and the pyrrole nitrogen (N_1) is responsible for acid–base interactions. At the same time, the tetrazole molecule exhibits distinct aromaticity, which is considerably higher than that in 1,3-diazole. Formation of the

anionic form (deprotonation) increases the electron density on all the atoms of the tetrazole ring. Therefore, the aromaticity of the tetrazolate anion is even higher as compared to the neutral molecule, approaching that of the benzene ring.

When tetrazolate anions, neutral species, and their associates enter the surface layer under the action of Coulombic forces and also as a result of diffusion, they can be fixed on the positively charged oxide surface by virtue of their π-donor capacity (Fig. 4a). The anions add a negative charge, while neutral molecules and associates do not change the potential of the surface layer. In this first stage, the major amount of tetrazole is accumulated in the adsorption layer, and in the other stages, successive transformations of adsorbed tetrazole species take place.

Strong nonuniform surface field polarizes tetrazole, thus increasing the charge localization on separate atoms. In this case, the negative charge on an atom could be preferentially localized on the pyrrole nitrogen (N^1), resulting in electrostatic bonding between N^1 and the positively charged area of the oxide surface (Fig. 4b). In the next stage, all other nitrogen atoms are involved in donor–acceptor bonding with the surface nickel atom (Fig. 4c), which is accompanied by change in the spatial orientation of the adsorbed tetrazole molecule.

The increase in the positive charge in the period t_c = 0.2–2.0 h can be attributed to, e.g., decreasing contribution of the negative charge, i.e., relative increase of the positive charge, by virtue of the ligand exchange of a part of the OH^- groups for neutral tetrazole molecules, as demonstrated by the observed increase in pH (see table).

The increase in pH, in its turn, results in increasing content of tetrazole in the anionic form in the bulk of solution, thus increasing the adsorption of the anions and decreasing ζ potential.

Finally, the above-considered scheme refers to single "portion" of the substance that entered the adsorption layer. In fact, the system is in a dynamic equilibrium, and the experiment demonstrates some statistically averaged pattern. In the course of the experiment, this scheme is multiply realized in the system with successively altered contribution of separate stages.

Let us apply this scheme to analyze the ζ vs. t_c and Γ vs. t_c dependences obtained in the experiments with NiO at $c_0 = 10^{-3}$ M (solution no. 1). It follows from the aforementioned that pH of the initial tetrazole solution was 3.9. According to the speciation diagram

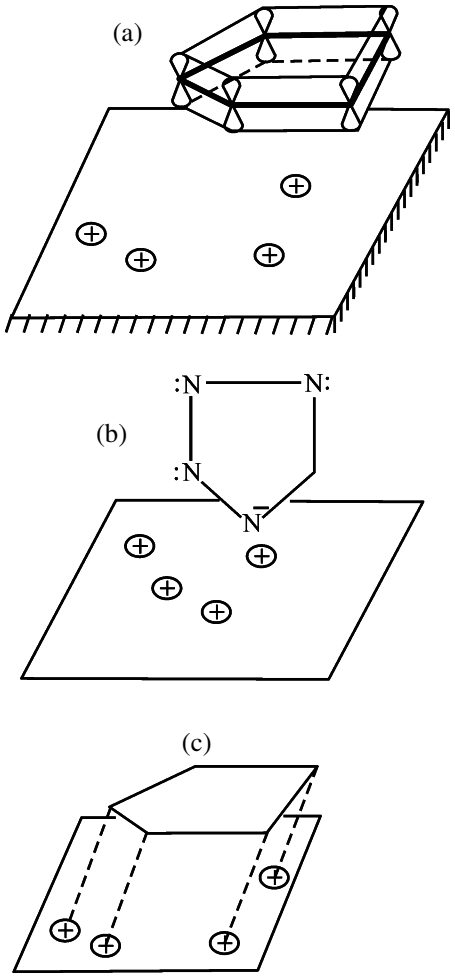

Fig. 4. Scheme of successive processes occurring in the surface layer upon adsorption of the tetrazole anion: (a) fixation on the surface via the π system of tetrazole, (b) electrostatic bonding with localization of the charge on the heterocycle, and (c) donor–acceptor bonding.

estimated from K_a and K_{BH^+} [12], the concentration of cationic species in this solution is extremely low. The surface potential is positive and rather high. It is obvious that, under these conditions, any significant adsorption of the cationic form is quite improbable. Noticeable amounts of neutral and anionic species could be adsorbed via π interaction and via π and Coulombic interactions, respectively. At small t_c, the concentration of the anionic species is low (even being somewhat higher than 7%), and that of the neutral species is high. It is known that introduction of a very low concentration of anions into the electrical double layer cannot significantly decrease the absolute value of ζ (in our experiments ζ remained practically unchanged at t_c < 1 h). The observed considerable growth of ζ at t_c from 1 to 2 h is due to the

fact that, in this period, reorientation and polarization of the adsorbed molecules contribute significantly. The subsequent decrease in ζ suggests that the bulk of solution contains large amount of anionic species (about 50% at pH 5.1) which are actively adsorbed on the surface. With increasing coverage of the surface with adsorbed anions, the further accumulation of the anionic species in the adsorption layer decelerates and then completely ceases after reaching the limiting coverage. The increase in ζ after passing the minimum, as was suggested above, is caused by the ligand exchange of the OH^- groups for the neutral tetrazole species, which is consistent with the increase in pH in this stage like that in the first stage.

The drift of pH_{IEP} to the left suggests that, at least at the final stage of the experiment, it is the anionic form of tetrazole that is adsorbed specifically.

The scheme suggested in this study is also applicable to the systems with $c_0 = 10^{-4}$ M. In this case we obtained the dependences characterized by the lack of the initial flat section and by considerably smoother other sections. The lack of the initial section is quite natural in the systems with a considerably lower concentration of the neutral form as compared to the systems with $c_0 = 10^{-3}$ M. The above-described scheme involving successive processes manifested in particular sections of the ζ vs. t_c curves can be equally used for interpretation of the Γ vs. t_c curves (Figs. 2 and 3).

The results obtained in the systems with Fe_2O_3 are consistent with the suggested scheme also. Generally, the ζ vs. t_c and Γ vs. t_c dependences are similar to those in the systems with NiO, although the positions of the maxima and minima in the curves as well as the levels of particular sections of the curves depend on the adsorbent. The shift of pH_{IEP} is considerably smaller in the Fe_2O_3 suspensions, which is consistent with our previous conclusions [3, 4] that, first, in the case of azoles as ligands, Fe(III) is a weaker acceptor than Ni(II), and second, that hydrolysis of iron increases with increasing pH, while nickel is not hydrolyzed at both pH values used in this study. The fact of considerably lower Γ in the system with Fe_2O_3 at $c_0 = 10^{-3}$ M (solution no. 1; Fig. 2, curve *1*') as compared to solution no. 2 (Fig. 2, curve *2*') also can be attributed to the features of hydrolytic behavior of Fe(III).

To conclude, as expected, the sorption mechanism is controlled primarily by the state of tetrazole molecules in solution.

CONCLUSIONS

(1) In NiO and Fe_2O_3 dispersions in aqueous tetrazole solutions with the initial tetrazole concentration $c_0 = 10^{-3}$ M, at the equilibrium (naturally established) solution pH, the dependences of the electrokinetic potential ζ on the contacting time t_c initially increase, pass through a maximum after a short time after bringing the phases in contact, and then pass through a minimum with increasing t_c. In the NiO dispersions, such an extremal run of the dependences is more clearly pronounced as compared to the Fe_2O_3 dispersions.

(2) The dependences of the tetrazole adsorption Γ on the contacting time are generally similar to the ζ vs. t_c dependences. The limiting Γ is considerably higher in the NiO suspensions.

(3) In the investigated dispersions in aqueous tetrazole solutions, pH_{IEP} shifts to more acidic range relative to the values obtained in HCl and KOH solutions. The shift is larger in the case of NiO (about 2 pH units) as compared to Fe_2O_3 (0.4 pH unit).

(4) The features of the ζ vs. t_c and Γ vs. t_c curves obtained at lower tetrazole concentration ($c_0 = 10^{-4}$ M) are generally the same, but less pronounced.

ACKNOWLEDGMENTS

The study was supported by the grant of the President of the Russian Federation for Support of Leading Scientific Schools (no. NSh-789.2003.3) and by the Russian Foundation for Basic Research (project no. 03-03-32418).

SORPTION AND ION-EXCHANGE PROCESSES

Packing for High-Performance Liquid Chromatography Based on Microspheric Particles of (Urea–Formaldehyde Resin)–Silica Gel Composite

L. S. Banyan

Yerevan State University, Yerevan, Armenia

Received June 7, 2005

Abstract—Preparation of uniform microspheric particles of the (urea–formaldehyde resin)–silica gel composite was studied. The suitability of this composite modified with C_{18} groups as packing for reversed-phase high-performance liquid chromatography was evaluated. The sorbent was modified using either octadecyldimethylchlorosilane or polymers containing C_{18} groups, and the columns packed with the resulting sorbent were studied. The experimental results showed that the polymeric modification allows efficient shielding of the surface silanol groups.

DOI: 10.1134/S1070427206010113

Uniform microspheric particles find expanding application in preparation of sorbents and supports for chromatography, and thus the reproducibility of their structural characteristics, primarily determined by reproducibility of the particle size, is of particular importance. Therefore, development of new procedures for preparing microspheric supports for high-performance liquid chromatography HPLC (both porous and non-porous) is an urgent problem [1–3].

Iler *et al*. [4, 5] suggested a new procedure for preparing uniform urea–formaldehyde resin microspheres based on formation of coacervates as liquid micrometer-size drops in the course of polymerization of urea and formaldehyde in acidic silica sol. Oligomers form coacervates bound by hydrogen bonds, which contain silica or other hydrophilic colloidal particles. Microspheric particles with the diameter varying from 0.2 to 20 μm (5–10 μm on the average) are prepared using colloidal silica particles (5–500 nm size) whose parameters are easily controlled. The advantages of the above procedure for preparing (urea–formaldehyde resin)–silica gel (UFR–SG) microspheres [4, 5] are as follows: (1) it yields uniform microspheric particles and thus eliminates fractionation problems and (2) it allows control of the particle size in the course of polycondensation by changing content of colloidal silica in the system.

Airapetyan *et al*. [6, 7] studied the effect of colloidal silica in the course of formation of uniform UFR–SG particles.

The resulting UFR–SG particles can be used as nonporous support for HPLC because they meet such chromatographic requirements as rigid silica skeleton and uniformity of the microspheric particle size (1.5–2.0 μm) typical for nonporous packing. The difference in the particle size does not exceed 10% [8–11].

The suitability of the urea–formaldehyde resin packing as HPLC sorbent was discussed in [12, 13]. Monolithic tube of urea–formaldehyde resin prepared *in situ* is used as a new support for affinity chromatography. This monolithic UFR tube consists of agglomerates of 2-μm particles of irregular shape and is characterized by biporosity. Cibacron Blue dye [12] is used as affine ligand grafted to the support surface [12].

A stationary phase for HPLC in which microspheric particles (3–5 μm in diameters) are formed by condensation of hexamethylenetetramine with urea in the presence of zirconyl chloride was reported in [13].

EXPERIMENTAL

Preparation of microspheric UFR–SG particles. Microspheric UFR–SG particles were prepared under the conditions presented in Table 1. First, urea was dissolved in concentrated hydrochloric acid. Then, the mixture was diluted with distilled water, and the required amounts of silica sol and formaldehyde (Table 1) were added. The volume of silica sol (20%

SiO_2) was varied in the 0–90 ml range. As colloidal silica, we used stabilized silica sol prepared by the procedure given elsewhere [14]. After addition of all the components, the reaction mixture was stirred for 20–30 s. Depending on the amount of silica sol, the microspheric particles with the particle size varied from 1.0 to 15 μm were obtained. After storage of the resulting particles in the mother liquor for approximately 1 h, they were decanted, washed with distilled water and acetone on the filter, and dried in an oven at 120°C for 2 h.

Modification of the microsphere surface with silanes. Modification of the packing with silanes such as octadecyldimethylchlorosilane (ODCS) and trimethylchlorosilane (TMCS) was performed in accordance with the procedure given in [14]. The microspheric support (10 g) after drying at 120°C for 2 h was placed in a three-necked flask equipped with a thermometer and a stirrer, toluene (250 ml) was added, and the mixture was heated with stirring to reflux (105°C). Then, ODCS (5 ml) and pyridine (2 ml, after refluxing for 30 min) were added, the mixture was refluxed for 8 h. The reaction mixture was cooled to room temperature, and the sorbent was decanted, washed with acetone, water–acetone (1 : 1 v/v) mixture, and acetone on the filter, and dried at 120°C in air. Additional silanization with TMCS was performed by the procedure given above.

Modification of the filler surface with polymers. Copolymers of octadecyl methacrylate (ODMA) and methyl methacrylate (MMA) were prepared by the procedure presented in [11]. Octadecyl methacrylate (3.0 g) was mixed with MMA (3 ml) and polymerization initiator dicumyl peroxide (DCP, 0.05 g). The mixture was heated to reflux in a flask equipped with a reflux condenser until a viscous mass formed, after which the heating was terminated. The resulting oligomer was dissolved in *n*-pentane. The polymeric coating was deposited on the sorbent surface by the following procedure. Microspheric particles (5 g) were added to the solution containing oligomer (1.25 g) and DCP (40 mg) in pentane (15 ml), and the solvent was removed on a rotary evaporator. The dried powder was placed in a sealed flask and exposed to thermal treatment in accordance with the following schedule: The sample was first heated to 100°C over a period of 1 h, then the temperature was increased to 130°C in 1 h, and the sample was kept at this temperature for 2 h. The resulting powder was washed with toluene : dioxane (1/1 v/v) and acetone and dried in an oven at 120°C. The pore characteristics were determined by sorption of benzene vapor.

The HPLC analysis was performed on an HPLC device equipped with a Waters 600S controller, Waters 427 pump, and UV–VIS detector.

Some chromatographic parameters of the columns packed with the UFR–SG and UFR microspheres obtained are listed in Table 2. As can be seen, in the case of microspheric UFR–SG particles with significant content of silica (45–60 wt %), both silanes and polymeric agents act as effective modifiers. It should be noted that polymeric modification provides complete shielding of all the silanol groups on the filler surface, which is confirmed by retention times of pyridine and phenol. The pyridine peak appears before the phenol peak, which confirms the absence of interaction of the silanol groups on the filler surface with pyridine molecules.

Certain decrease in the silica content in the system does not noticeably affect the modification. To obtain polymer-modified sorbents (e.g., sample no. 4), the sample first was modified with vinylchlorosilane and then the polymeric ODMA–MAA layer was de-

* Sample numbers are the same as in Table 1.

posited. The chromatographic parameters of the columns packed with microspheres modified with various agents are listed in Table 2.

In the case of polymeric modification, the effect of further decrease in the silica content is minor, which is confirmed by the data on polymeric coating of UFR microspheric particles (Table 2, sample nos. 6–8). Our chromatographic studies showed that these systems can be used as nonporous packing for reversed-phase HPLC (RP–HPLC).

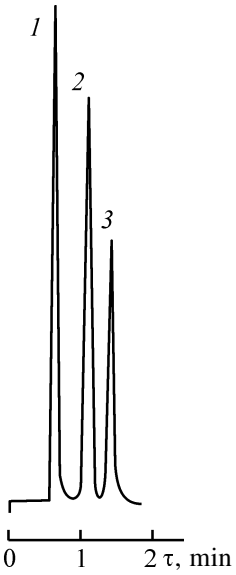

Fig. 1. Chromatographic pattern of the uracil–phenol–toluene model system obtained using the column packed with UFR–SG–C_{18}(TMCS) (Table 2, run no. 1). Components: (*1*) uracil, (*2*) phenol, and (*3*) toluene.

The chromatogram of the uracil–phenol–toluene model system, obtained using the column packed with UFR–SG–C_{18}(TMCS), is shown in Fig. 1. As can be seen, UFR–SG microspheres can be efficiently modified with silanes, i.e., the microsphere surface still contains significant amount of silanol groups capable of covalent bonding with alkyl groups. In the case of model solutions containing pyridine, strong tailing and delay of the pyridine peak are observed.

In the absence of silica, the results of modifying UFR microspheric particles with silanes were unsatisfactory. The resulting samples exhibited insufficient hydrophobic properties and the columns packed with them exhibited no features required of RP–HPLC (Table 2). After modification with trimethylchlorosilane, the retention times of toluene and uracil were 1.55 and 1.9 min, respectively; i.e., this sorbent is unsuitable for RP–HPLC. Similar results were obtained by modification with γ-aminopropyltriethoxysilane (γ-APTES); the toluene peak appeared before those of uracil and pyridine. However, after modification with the polymer (poly-ODMA–MMA), the column packed with the resulting microspheres became suitable for RP–HPLC.

The chromatographic pattern of the uracil–pyridine–phenol–toluene model system obtained using the column packed with UFR–SG–poly-ODMA–MMA is shown in Fig. 2. As can be seen, UFR–SG microspheres after polymeric modification exhibit no tailing and no strong retention of pyridine. This confirms that the polymeric modification provides complete shielding of all the silanol groups on the packing surface.

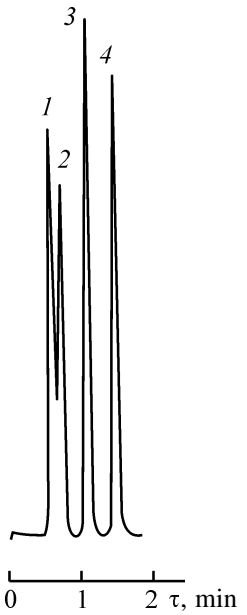

Fig. 2. Chromatographic pattern of the uracil–pyridine–phenol–toluene model system obtained using the column packed with UFR–SG–poly-ODMA–MMA (Table 2, run no. 4). Components: (*1*) uracil, (*2*) pyridine, (*3*) phenol, and (*4*) toluene.

Previously we showed that UFR microspheric particles are easily modified with polymers; this approach eliminates silanol interactions. In the case of UFR–SG, polymeric modification also eliminates silanol interaction (Table 2).

Moreover, the UFR and UFR–SG systems can be successfully used as nonporous packing for RP–HPLC. Comparison of the chromatographic parameters showed that after polymeric modification the retention time of toluene decreases. This is probably due to decreasing surface area of the sorbent (when the polymeric component fills the pores) or to insufficient amount of the C_{18} groups on the sorbent surface. However, our calculations showed that the amount of these groups on the surface is even greater than that at common modification with octadecyldimethylchlorosilane.

CONCLUSIONS

(1) Microspheric particles formed in the (urea–formaldehyde resin)–silica gel system after modification with octadecyldimethylchlorosilane and additional treatment with trimethylchlorosilane are suitable as packing for reversed-phase high-performance liquid chromatography.

(2) Modification with polymers provides efficient shielding of the surface of microspheres formed in the urea–formaldehyde resin system in the presence of silica gel and without it. Efficient shielding of the silanol groups is confirmed by the retention times of pyridine and phenol in the course of chromatographic analysis of the model system.

SORPTION AND ION-EXCHANGE PROCESSES

Hydrothermal Modification of Silica in the Form of a Hydrogel–Xerogel

V. V. Sidorchuk

Institute of Sorption and Problems of Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received May 18, 2005

Abstract—The influence exerted by the conditions of hydrothermal treatment of silicas in the form of a gel–xerogel on the pore structure and mechanical properties of the adsorbents obtained was studied.

DOI: 10.1134/S1070427206010125

Two methods for hydrothermal modification of silicas are known: in the form of (i) moist true gel or coagel (sediment) and (ii) dry xerogel [1–3]. Exhibiting common patterns in variation of the pore structure parameters (decrease in the specific surface area and expansion of pores with an increase in temperature [4]), both the methods have their own specific features. For example, treatment of moist gels leads to a significant increase in the pore volume (up to 3 $cm^3\ g^{-1}$), whereas in modification of dry xerogels, this quantity remains unchanged. As a result, the pore size increases to a considerably greater extent in the first case, compared with the second. This, in turn, leads to a poorer mechanical strength of silicas treated as moist gels, compared with those processed in the form of dry xerogels [1, 5–8].

It is known that the strength of a porous body is determined by the strength of unit contacts between primary particles, p_1, and their number on a unit cross-section area, Q_S, which directly depends on the pore volume [1, 9]. Sorption, catalysis, and chromatography frequently require supports that simultaneously have large volume and size of pores and a high mechanical strength [10]. In this study, an attempt was made to combine the advantages of the two above-mentioned alternatives of hydrothermal modification of silica gels: they were treated as a moist hydrogel during a part of time (to achieve a more pronounced increase in the volume and size of pores) and as a dry xerogel during the rest of the time (in order to strengthen the skeleton).

EXPERIMENTAL

As a model serve aerosilogel prepared by the procedure described in [8]: by dispersing an aerosil of A-300 brand in a dispersion medium (distilled water or 2% aqueous ammonia) at an s : l ratio equal to 0.20. The resulting gel was subjected to a hydrothermal treatment at 100–400°C for 5 h either in a moist state or as a dry xerogel (in both cases, an amount of water, necessary for creating an equilibrium pressure of its vapor, was introduced onto the bottom of an autoclave). In addition, a moist gel was modified as follows: it was introduced into the autoclave in an amount that contains a portion of water whose evaporation leads to establishment in the autoclave of an equilibrium pressure at a chosen temperature (modification in the form of a gel–xerogel). As a result, the gel was treated as a moist gel for a certain time (until water was completely evaporated) and as a dry xerogel during the rest of the time. A dry xerogel requiring no drying was discharged from the autoclave. It is known that, in the case of modification of a hydrogel and xerogel with introduction of water to the bottom of an autoclave, the result is determined exclusively by the duration of the isothermal period, being independent of the heating rate [4]. At the same time, when the treatment of a moist gel involves only water contained in the gel itself (treatment of a gel–xerogel), the rate at which the autoclave is heated to a prescribed temperature strongly affects the results obtained, because it predetermines the duration of modification in the form of a moist gel. Both fast (in 0.5 h) and slow (in 2 h) heating modes were used.

The specific surface area S ($m^2\ g^{-1}$) of aerosilogels was found by measuring the thermal desorption of argon with a GKh-1 gas meter, the total pore volume V_Σ ($cm^3\ g^{-1}$) was determined by impregnation with water, and the average pore diameter was calculated using the formula $d_p = 4V_\Sigma 10^3/S$ (nm). The mech-

anical strength of cylindrical grains, P_m (MPa) was measured with an MP-2S device.

The strength of unit contacts, p_1 (Pa), was calculated by the formula [9]

$$p_1 = P_m/Q_s, \quad (1)$$

and the number of contacts on a unit cross section, Q_s (cm^{-2}), by the formula [11]

$$Q_s = 7.32 \times 10^{10} S^2/V_\Sigma^{2/3}. \quad (2)$$

The manner in which the porous structure parameters of aerosilogels vary in different types of hydrothermal treatment, presented in Table 1, is well consistent with the patterns known for silica sorbents [1–4, 8, 11]: as temperature increases, the specific surface area decreases, pores expand, and the pore volume grows (for gels) or remains constant (for xerogels). As would be expected, tendencies characteristic of treatments in the form of a gel and a xerogel are combined in modification in the form of a gel–xerogel. The decrease in the specific surface area in combined treatment is the most pronounced at temperatures $T \geq 300$°C, and at $T \leq 250$°C the pore size exceeds the corresponding values in treatment of a gel and a xerogel. These experimental data are not quite understandable in terms of the commonly accepted mechanisms of changes in the porous structure in hydrothermal modification of silicas [4].

The most interesting results presented in Table 2 and Figs. 1–3 were obtained for changes in the mech-

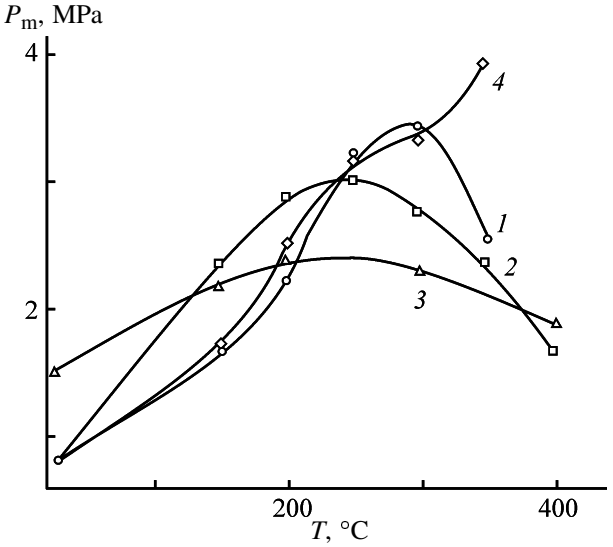

Fig. 1. Mechanical strength P_m of gels-xerogels vs. temperature T of hydrothermal treatment: (*1*) water, heating in 2 h; (*2*) water, heating in 0.5 h; and (*3*) 2% ammonia solution, heating in 0.5 h.

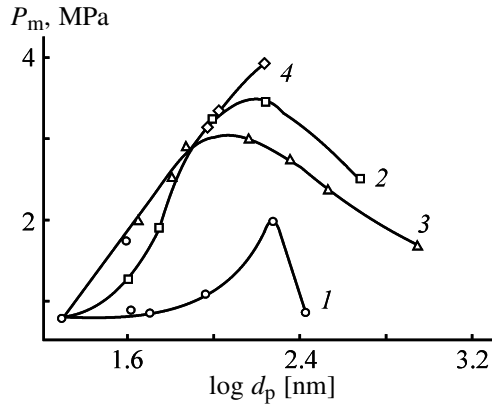

Fig. 2. Mechanical strength P_m of gels-xerogels vs. average pore size d_p in hydrothermal treatment of moist aerosilogels. (*1*) Gel, (*2*) gel–xerogel (heating in 2 h), (*3*) gel–xerogel (heating in 0.5 h), and (*4*) xerogel.

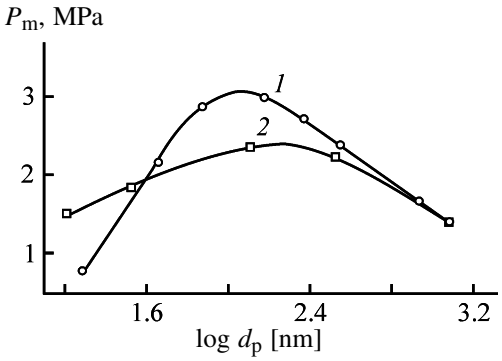

Fig. 3. Mechanical strength P_m of xerogels vs. average pore size d_p in hydrothermal treatment in the form of a gel–xerogel at fast heating (in 0.5 h). Medium: (*1*) water and (*2*) 2% ammonia solution.

anical strength of aerosilogels in the course of hydrothermal treatment by different methods. For example, the mechanical strength steadily increases with temperature only in treatment of a xerogel, whereas in all the other methods, the P_m–T dependence has an extremum, as also does the dependence of P_m on the pore size (Figs. 2, 3). A similar pattern has been observed in hydrothermal treatment of other silicas [1, 5–8] and was attributed to possible thinning of pore walls for very coarsely porous samples formed at high temperatures.

Only at temperatures exceeding 250–300°C (depending on the rate of autoclave heating), the mechanical strength of samples modified in the form of a xerogel exceeds the value of P_m for aerosilogels treated in the form of a gel–xerogel. In the case of fast heating and treatment in the range 150–200°C, the value of P_m for samples modified in the form of a gel–xerogel exceeds by 20–25% the similar parameter for samples processed as a xerogel. Figures 2 and 3 show that, up to a pore size of 100 nm, the silicas obtained by hydrothermal treatment of a gel–xerogel are as strong as the samples modified in the form of a xerogel and substantially exceed in strength the aerosilogels treated as a gel, even though having considerably larger V_Σ than xerogels (Table 1) and, accordingly, smaller Q_s.

In all cases, the strength of unit contacts (Table 2), calculated by formulas (1) and (2), steadily increases with temperature, but does so for the gel to the least extent, because the gel has the least close-packed structure and mass transfer in its treatment is predominantly directed from the surface of fine particles to that of coarse particles, rather than to places of their contact [2, 4]. Therefore, coagulation-type, i.e., the least strong contacts between particles exist in gels [2, 9].

The maximum rise in the strength of unit contacts was recorded in treatment as a gel–xerogel, especially for samples obtained with a 2% ammonia solution. In this case, mass transfer directed to places of contact between particles markedly exceeds that for the gel [3, 4, 8], which leads to formation of strong phase contacts between particles [9].

An unexpected result among those under consideration is the smaller value of p_1 for the most close-packed structure (xerogel), for which the intensity of mass transfer to places of contact between particles must be the highest. The strength of a porous body depends not only on the parameters appearing in formula (1), but also on the presence of mechanical stresses in the structure [9, 10]. Therefore, it may be assumed that the mode of hydrothermal treatment of a gel–xerogel, which, as already noted, is accompanied by mild drying (at a smaller humidity gradient between the gel and the medium), prevents build-up of stress at places of interparticle contacts. This is also confirmed by the data reported in [12].

CONCLUSIONS

(1) A new mode of hydrothermal treatment of silica adsorbents, modification in the form of a gel–xerogel, was considered. This mode enables the following. First, it is possible to combine hydrothermal treatment of a gel and a xerogel and sample drying in a single process. Second, thanks to this combining, the advantages of each separate modification method can be used and thereby it is possible to control in a substantially wider range the specific surface area and the volume and size of pores. As a result, samples

simultaneously having a large pore volume, small specific surface area, and sufficiently high mechanical strength can be obtained.

(2) A technical and economical disadvantage of this treatment technique consists in that the output capacity of the process at temperatures below 300°C is not high, because the filling of the autoclave with the gel does not exceed 25%. Therefore, it is better to use the hydrothermal modification of a gel–xerogel at temperatures $T \geq 300$°C.

SORPTION AND ION-EXCHANGE PROCESSES

Changes in the Pore Structure of Silica in Chemical Modification with Organic Compounds

V. V. Sidorchuk

Institute of Sorption and Problems of Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received May 18, 2005

Abstract—Changes in the pore structure of silica adsorbents in their chemical modification with organic compounds of various kinds by gas- and liquid-phase processes, as well as those under conditions of high pressure of the reagents, were studied.

DOI: 10.1134/S1070427206010137

It is believed that changes in the parameters of the pore structure of silicas in their chemical modification is determined by the degree of grafting, size of the molecule of a modifying reagent, and structure of a modifying bed [1, 2]. In the process, the specific surface area S, total pore volume V_Σ, and pore size d, as a rule, decrease. In [2], an equation is given for calculating the specific surface area of modified silica after chemisorption of aliphatic linear reagents. This equation can be used to calculate the decrease in the specific surface area, ΔS, upon modification via shileding of the surface of the starting silica. The calculated value of ΔS depends on the nature and structure of the modifier molecule. At the same time, the value of ΔS can be found from experimental data as the difference of the specific surface areas of the starting and modified silicas:

$$\Delta S = S_0 - S, \quad (1)$$

where S_0 is the specific surface area of the starting silica, and S, that of modified silica; both the quantities are experimentally measured.

In most cases, the calculated decrease in the specific surface area, ΔS, is markedly lower than that measured experimentally. This may be due to the fact that the influence exerted on the decrease in the specific surface area of silica by processes of mass transfer of silica itself, which are possible in pore bodies at elevated temperatures, is disregarded. For example, mass transfer is the main mechanism by which the pore structure of silicas of varied origin changes (primarily, this refers to the specific surface area) in treatment in aqueous media, especially under hydrothermal conditions [2–4].

Although the solubility of silicon dioxide in organic media is considerably lower than that in water [3], it is clearly impossible to disregard mass transfer of silica in its modification with organic compounds. This is so because many liquid-phase, and especially gas-phase, modification processes are performed at elevated temperatures (100–400°C and higher) [2, 5], when mass transfer via surface self-diffusion of silica is possible. It is not advisable to disregard the influence exerted on mass transfer processes by water desorbed from the surface in the course of modification and by that released in surface reactions. This is of particular importance in the presence of nitrogen-containing organic bases, which are frequently used as catalysts for modification processes [5]. It is necessary to primarily take into account the mass transfer of silica in modification under the conditions of a high pressure in the autoclave [6]. In view of the aforesaid, the total decrease in the specific surface area of silica, ΔS, in the course of its chemical modification should be, in the general case, a sum of at least two terms:

$$\Delta S = \Delta S_{chem} + \Delta S_{mass}, \quad (2)$$

where ΔS_{mass} is the change in the specific surface area associated with mass-transfer processes, and ΔS_{chem} is that associated with shielding of the surface by a grafted layer.

Equations (1), (2) and experimental data make it possible to evaluate each component of the change in the specific surface area in chemical modification. For example, ΔS_{chem} can be found if mass transfer of silica is excluded in modification.

In the authors' opinion, use of the specific surface area of silica in calculating the surface concentration

Table 1. Change in of the adsorption-structural characteristics of aerosilogel in relation to the modification conditions

20	P = 51 atm, 250°C, chlorobenzene	252	252	1.34	–

of grafted groups (μmol m^{-2}) is unjustified. If the modification processes occur without mass transfer of silica, the specific surface area of the starting silica should be used. If, however, the mass transfer of silica does occur in modification, it is necessary to use a corrected value of the specific surface area, which takes into account the decrease in the specific surface area of the starting silica via mass transfer:

$$S_{corr} = S_0 - \Delta S_{mass} \quad (3)$$

or, with account of Eqs. (1) and (2),

$$S_{corr} = S + \Delta S_{chem}. \quad (4)$$

It is just the quantity S_{corr}, rather than S_0 or S_{chem} (frequently suggested in the literature [2, 5]), that is preferable for calculation of the surface concentration μ (μM) of grafted groups:

$$\mu = c \times 10^3 / S_{corr}, \quad (5)$$

where c is the concentration of grafted groups (μmol g^{-1}).

EXPERIMENTAL

The study was concerned with changes in the pore structure parameters of a model silica, aerosilogel prepared using the procedure described in [7], in the course of its modification with organic compounds of varied nature by ordinary gas- and liquid-phase processes [5] and also under conditions of a high pressure of reagents in the autoclave [6]. The starting aerosilogel was preliminarily dried in air at 150°C for 4 h (for liquid-phase and autoclave processes) or thermally treated in a vacuum at 150°C for 2 h at a residual pressure of 10^{-3} Torr (for gas-phase processes).

All the compounds were purified and dried prior to being used for modification. The specific surface area of the starting (S_0) and modified (S) silicas was measured by the method based on thermal desorption of argon on a GKh-1 gas meter, the total pore volume V_Σ was found by impregnation with ethanol [8], and the pore size distribution was determined on a PA-3M mercury porosimeter. The course of surface reactions was monitored qualitatively by measuring IR spectra on an IKS-29 spectrophotometer in the range 4200–1400 cm^{-1}, and quantitatively, by derivatographic analysis on a Q-1500D instrument in the temperature range 20–1000°C and a heating rate of 10 deg min^{-1} [9, 10], and also by elemental analysis on a Carlo Erba CHN Mod 1106 elemental analyzer.

Table 1 lists data on modification of the aerosilogel with various organic compounds in several ways. It can be seen that, for ordinary gas-phase (g/ph) and

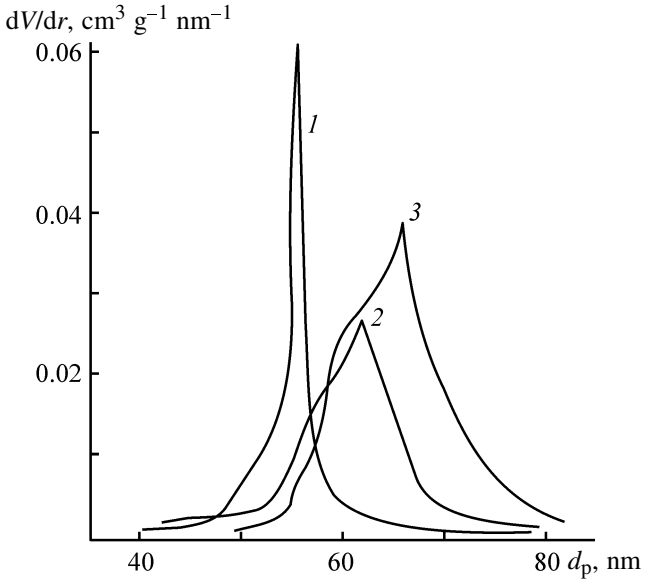

Fig. 1. Pore size distribution, according to data of mercury porosimetry, for (*1*) starting aerosilogel and (*2, 3*) aerosilogels treated in the autoclave with hexane at (*2*) 200 and (*3*) 300°C. (*V*) Pore volume, (d_p) pore diameter, and (*r*) pore radius.

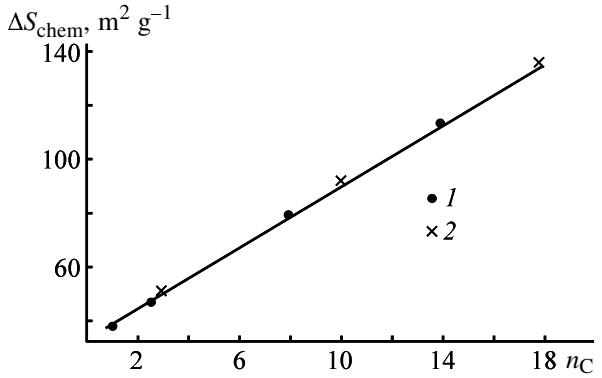

Fig. 2. Specific surface area ΔS_{chem} containing 1 mmol of a grafted substance vs. the length n_C of the hydrocarbon chain of the modifier. (*1*) Aliphatic alcohols and (*2*) alkylchlorosilanes according to [1].

liquid-phase (l/ph) processes, S and V_Σ decrease only in those cases when chemical modification of the surface occurs. When this is not the case, S and V_Σ remain virtually constant, despite the rather high treatment temperature, which is exemplified by gas-phase modification in a quartz cell (sample nos. 12–14; it should be noted that the pressure of modifier vapor in gas-phase processes did not exceed 100 mm Hg). At the same time, treatment in an autoclave even with such compounds, chemically inert toward the silica surface, as hexane, acetone, or chlorobenzene (sample nos. 18–20) leads to a rather significant decrease in the specific surface area at a constant V_Σ (modifier vapor pressure 40–100 atm). The change in the pore structure of the aerosilogel upon its modification with hexane is also indicated by the distribution curves of pore volume with pore size, measured using mercury porosimetry (Fig. 1): it can be seen that the curves are shifted into the region of larger pore radii. In this case, there is no grafting of organic fragments to the surface (according to the data furnished by IR spectroscopy and derivatography). Therefore, the decrease in S and also a change in the type of pore volume distribution respect to pore sizes should be attributed to rearrangement of the skeleton of silica via mass transfer. The strongest decrease in the specific surface area is observed when aerosilogel is modified with hexamethyldisilazane (sample nos. 4, 10, 17), whose interaction with silanol groups on the surface yields ammonia, which intensifies the mass transfer [3].

In order to rule out the mass transfer of silica, an aerosilogel sample preliminarily hydrothermally treated at 250°C was subjected to chemical modification in an autoclave at 250°C. It is known that treatment under more severe, in particular, hydrothermal, conditions precludes mass transfer in a subsequent treatment under milder conditions [11]. In this case, $\Delta S_{mass} = 0$ and $\Delta S_{chem} = S_0 - S$. As a result, we obtained the dependence of ΔS_{chem} per 1 mmol of a grafted alcohol on its chain length (C_1–C_{14}) (Fig. 2). The line constructed is also a good fit to the points calculated using the data of [1] for silicas modified with alkylchlorosilanes with a length of the hydrocarbon chain C_3, C_{10}, and C_{18}. Hence follows the conclusion that the plot in Fig. 2 can be used with a satisfactory accuracy for evaluating ΔS_{chem} in treatment of silica with any linear multifunctional modifier.

Similarly, experiments on modification of aerosilogel samples hydrothermally treated at 250°C with trimethylchlorosilane, trimethyliodosilane, hexamethyldisiloxane, and hexamethyldisilazane show that grafting of 1 mmol of trimethylsilyl groups to the silica surface leads to a decrease in the specific surface area of silica by 105 ± 5 $m^2\ g^{-1}$.

The resulting values of ΔS_{chem} were used to calculate S_{corr} and the concentration of grafted groups per unit surface area (Table 1). The values of μ calculated by Eq. (1) using the values of S_{corr} were 10–30% higher than those obtained using the specific surface area S_0 of the starting silica and 10–30% lower than those obtained with the specific surface area S of modified samples.

In order to verify the results of calculation of ΔS_{chem}, chemical modification in the autoclave was also performed for aerosilogels preliminarily treated

* HTT and TT are hydrothermal and thermal treatments, respectively.

under hydrothermal conditions at 150 and 200°C (Table 2). Butoxy groups were removed from the silica surface after chemical modification either by mild hydrolysis (by boiling in water in the presence of ammonia) or by thermal decomposition in air at 450°C. Trimethylsilyl groups were removed by thermal decomposition in air at 700°C (the temperatures of thermal decomposition were found from derivatographic measurements). In this way we restored the surface onto which the modifiers were grafted. The data obtained indicate the following.

(1) If the temperature of chemical modification with *n*-butanol does not exceed that of hydrothermal treatment by more than 50°C, then there is virtually no mass transfer of silica in the course of modification and, after removal of butoxy groups, the specific surface area virtually coincides with the value of S for the sample before modification (compare sample nos. 1, 3, 5, 6 and 10, 12, 13).

(2) If, however, the temperature of chemical modification exceeds that of preliminary hydrothermal treatment by 100°C, the former process may involve an additional decrease in the specific surface area via mass transfer of silicon (compare sample nos. 1, 8, 9, and 10, 17, 18).

(3) In chemical modification with hexamethyldisilazane, during which ammonia is liberated, mass transfer of silica apparently occurs at any of the temperatures studied (compare sample nos. 10, 15, 20).

The change in the most probable pore size (Table 2), calculated from porosimetric data, confirms the above reasoning.

The following experimental fact should be mentioned in conclusion: chemical modification is necessarily accompanied by a decrease in the pore volume (Tables 1, 2). At the same time, it is known that treatment in the absence of chemical modifiers does not change the pore volume of silica xerogels. The magnitude of the decrease in V_Σ is proportional to the degree of grafting and to the molar volume of modifier; however, an additional study is necessary for establishing a clearly pronounced relationship. It should only be added here that the decrease in the total pore volume of silicas is a good indicator of their chemical modification, and the V_Σ measurement itself is a simple express technique for establishing the fact of grafting of a modifier to the surface.

CONCLUSIONS

(1) The results obtained in the study point to an important contribution made by mass transfer of silica to the decrease in its specific surface area in chemical modification with organic compounds, especially under conditions of a high pressure of reagents.

(2) A more precise calculation of the concentration of grafted groups per unit surface area requires, in addition to measuring the specific surface area of modified silica, also estimating the extent to which the specific surface area decreases via shielding of the surface by the grafted layer. It is shown that the following support can be used for this purpose: silica treated under hydrothermal conditions at a temperature exceeding by 100–150°C that of the reaction of chemical modification.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Solvating Additives on Anion-Exchange Extraction of Trichloroacetate Anions from Aqueous Solutions with Trinonyloctadecylammonium Picrate in Toluene

Abstract—The solvation effect of trifluoroacetophenone derivatives on anion-exchange extraction of trichloroacetate anions from aqueous phase with trinonyloctadecylammonium picrate in toluene was studied.

DOI: 10.1134/S1070427206010149

Solutions of higher quaternary ammonium salts (QASs) in organic solvents immiscible with water efficiently extract various anions from aqueous phase by the anion-exchange mechanism [1]. The extractability of anions from aqueous solutions in these systems is quantitatively characterized by the concentration equilibrium constant $K_{Cl^-}^{An^-}$ of the anion-exchange reaction

$$R_4N^+Cl^-_{org} + An^-_{aq} \rightleftarrows R_4N^+An^-_{org} + Cl^-_{aq}.$$

It is known that the order of extractability of anions of various kinds with liquid anion exchangers does not depend on the organic solvent [1]. Therefore, the relative extractability of anions in their series can be changed either by going to another liquid anion exchanger [2] or by adding some additional solvating agent [3]. For example, even small additions of hexyl *p*-trifluoroacetylbenzoate (approximately 10^{-2} M) increase the extraction constant of carboxylate anions R–COO$^-$ with QASs in organic solvents by several orders of magnitude [4].

In this study we examined the effect of trifluoroacetophenone derivatives of various structures on anion-exchange extraction of trichloroacetate anions from aqueous phase with a quaternary ammonium picrate in toluene and determined the extraction and solvation constants and the average solvation numbers.

EXPERIMENTAL

We studied the extraction of trichloroacetate (TCA) anions from aqueous sodium trichloroacetate with a liquid anion exchanger, trinonyloctadecylammonim $[(C_9H_{19})_3C_{18}H_{37}N^+]$ picrate, TNODA Pic, in toluene. The extraction was carried out in test tubes with ground-glass stoppers at the volume ratio of the organic and aqueous phases of 1 : 1 at 293 ± 1 K. After completion of the extraction, the aqueous phase was separated and filtered. The content of picrate anions in the filtered solutions was determined spectrophotometrically on an SF-26 spectrophotometer [5].

The ion-exchange extraction of TCA$^-$ anions from aqueous phase with TNODA Pic in toluene can be described by equation of the following heterogeneous reaction:

$$R_4N^+Pic^-_{org} + TCA^-_{aq} \rightleftarrows R_4N^+TCA^-_{org} + Pic^-_{aq}. \quad (1)$$

The concentration constant of this reaction $K_{Pic^-}^{TCA^-}$ was calculated by the equation

$$K_{Pic^-}^{TCA^-} = \frac{[Pic^-]^2}{(c_{0,R_4N^+Pic^-} - [Pic^-])(c_{0,TCA^-} - [Pic^-])}, \quad (2)$$

where $c_{0,R_4N^+Pic^-}$ is the initial TNODA Pic concentration and c_{0,TCA^-}, the initial trichloroacetate anion concentration in the aqueous phase.

On addition of the solvating agent S to the organic phase, TNODA TCA is selectively solvated with S molecules by the reaction

$$R_4N^+TCA^- + pS \rightleftarrows R_4N^+TCA^-\cdots pS. \quad (3)$$

whereas TNODA Pic is not solvated [6].

The constant $K_{Pic^-}^{TCA^-}$ [Eq. (2)] does not take into account the solvation of the extracted TCA anions by reaction (3) (Eq. 1). Therefore, this constant is considered to be an apparent quantity and hereinafter is denoted as $\tilde{K}_{Pic^-}^{TCA^-}$.

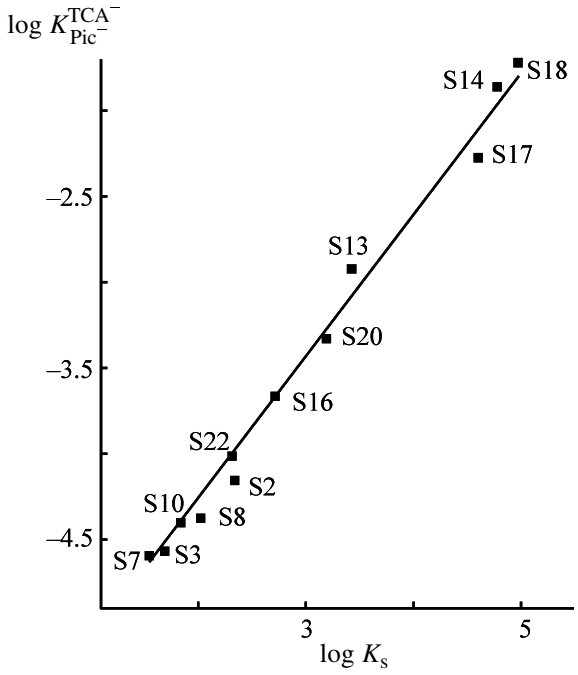

Fig. 1. Correlation between the logarithms of the anion-exchange extraction constants of TCA^- anions from the aqueous phase with TNODA Pic in toluene containing various organic additives and logarithms of the solvation constant K_s of TCA anions.

The relation between the concentration anion-exchange extraction constants $K_{Pic^-}^{TCA^-}$, the apparent anion-exchange extraction constants $\tilde{K}_{Pic^-}^{TCA^-}$, solvation constants K_s, and average solvation number p is described by the following bilogarithmic equation:

$$\log(\tilde{K}_{Cr^-}^{An^-}/K_{Cr^-}^{An^-} - 1) = \log K_s + p\log[S]. \quad (4)$$

The parameters K_s and p calculated by Eq. (4) using the special computer program [7] are listed in the table.

Analysis of the results listed in the table shows that the additives (trifluoroacetophenone derivatives) increasing the anion-exchange extraction of trichloroacetate anions are characterized by the following structural features.

(1) All the additives contain the CF_3 groups. This is seen from the fact that, in going from trifluoroacetophenone (structure S2) to tribromoacetophenone (structure S24), the effect of additive on the extraction completely disappears.

(2) The CF_3 group is a fragment of the trifluoroacetyl group –CO–CF_3. This requirement is confirmed by the fact that trifluoromethylbenzene (structure SI) does not affect the anion-exchange equilibrium. The molecules containing the carbonyl (structure S27) or ester (structures S25 and S26) groups only do not enhance the anion-exchange extraction either:

(3) The additives containing trifluoroacetyl group bound to saturated hydrocarbon radical directly (structure S6) or via the ester oxygen atom (S19 structure) do not affect the extraction constant.

(4) Di(trifluoroacetyl)acetylene containing two trifluoroacetyl groups linked by the C≡C group (structure S23) slightly increases the extraction constant (by 0.2 logarithmic units). This effect considerably increases (to 0.65 logarithmic units) if one of the trifluoacetyl groups is replaced by the benzene ring (structure S22). The binding of benzene ring directly to the trifluoroacetyl group (structure S2) does not noticeably change this effect ($\Delta\log K = 0.52$).

These results show that the organic additives increasing extraction of TCA anions must contain the trifluoroacetyl group and the benzene ring. The simplest molecule of this kind is trifluoroacetophenone (structure S2). The solvation efficiency of this additive can be increased by substituting the hydrogen atoms of the benzene ring by appropriate substituent.

We found that the complete substitution of hydrogen atoms in the trifluoroacetophenone benzene ring by the methyl and nitro groups (structure S15) results in disappearance of the solvation effect. This result shows that the hydrogen atoms of the benzene ring contribute to solvation of the trichloroaceate anion with trifluoroacetophenone. The similar effect was first reported in [8].

Table shows that, for all the additives, the average solvation number is approximately 1. These data also show (Fig. 1) that the logarithms of the apparent ion-exchange extraction constants linearly correlate with the logarithms of the solvation constants. This correlation is described by the equation

$$\log K_{Pic^-}^{TCA^-} = (-5.91 \pm 0.08) + (0.83 \pm 0.03)\log K_s,\ r = 0.994.$$

Figure 2 shows that the logarithms of the anion-exchange extraction constants linearly correlate with the sum of the Hammett σ-constants of substituents in solvating agents (*m*- and *p*-substituted trifluoroacetophenone). As expected, the maximal increase in extraction occurs for solvating agent of structure S18 having three substituens: *p*-chlorine and two *m*-nitro groups. In the presence of this additive, the extractive power of TNODA Pic with respect to TCA anions exceeds that in the presence of hexyl *p*-trifluoroacetylbenzoate, unsubstituted trifluoroacetophenone, and TNODA Pic in toluene by a factor of 1.61, 2.44, and 2.96, respectively.

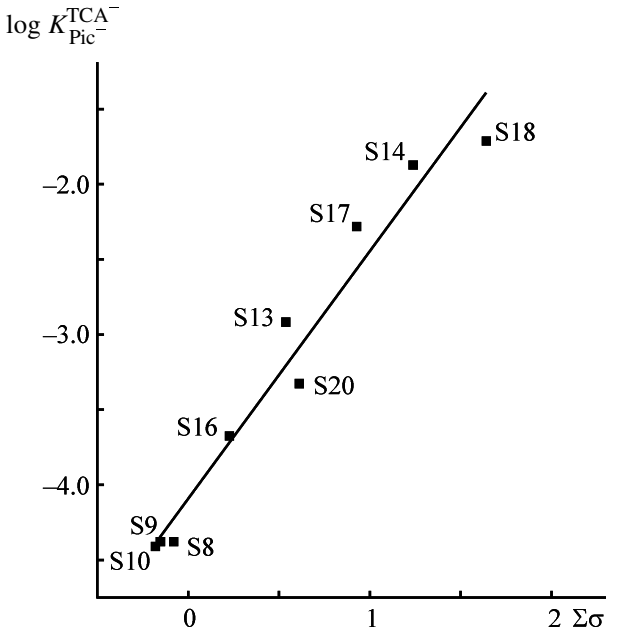

Fig. 2. Correlation between the logarithms of the anion-exchange extraction constants of TCA^- anions from the aqueous phase with TNODA Pic in toluene containing various organic additives and sum of the Hammett σ constants of substituents in the organic additives. Regression equation $\log K_{Pic^-}^{TCA^-} = 4.10 + 1.65\Sigma\sigma$.

The Hammett equation $\log K = \log K_0 + \rho\Sigma\sigma$ contains the parameter ρ reflecting the sensitivity of the anion-exchange equilibrium to variation in the trifluoroacethophenone electrophilicity. We found that, for the extraction systems under consideration, $\rho = 1.65 \pm 0.13$. We believe that high ρ value in our systems is caused by low toluene polarity; it is consistent with the data on ρ values for anion-exchange equilibria in chlorobenzene ($\rho = 1.89 \pm 0.04$) and methyl butyl ketone ($\rho = 1.71 \pm 0.06$) reported in [3].

The introduction of Cl and NO_2 electron-acceptor groups into the benzene ring of trifluoroacetophenone sharply increases the anion-exchange extraction of trichloroacetate anions. We believe that this effect is caused by the fact that the introduced substituents, exhibiting strong negative inductive effect (*–I*), increase the electrophilicity of the carbon atoms of the carbonyl groups in trifluoroacetophenone molecules and, as a result, enhance their solvating power with respect to TCA anions.

We found that substituted trifluoroacetophenones are strong solvating agents increasing the extraction of trichloroacetate by three orders of magnitude even at their low content (10^{-2} M). Taking into account that the anion-exchange extraction constant increases in the direct proportion with increasing concentration of the solvating additive, we can increase the anion-exchange extraction constant to five orders of magnitude by increasing the solvating agent concentration.

CONCLUSIONS

(1) Among 27 trifluoroacetophenone derivatives and related compounds tested as solvating additives in extraction of trifluoroacetate anions with trinonyloctadecylammonium picrate in toluene, only those containing the trichloroacetyl group bound to the benzene ring increase the extraction, provided that the benzene ring contains unsubstituted H atoms. The introduction of nitro groups and chlorine atoms into the benzene ring of the solvating additives increases this effect.

(2) Logarithms of anion-exchange extraction constants of trichloroacetate with trinonyloctadecylammonium picrate in toluene vary in direct proportion with the solvation constant of trichloroacetate with solvating additives.

(3) The apparent anion-exchange extraction constants of trichloroacetate with TNODA Pic in toluene linearly depend on the sum of the Hammett σ-constants of the solvating additives.

Abstract—The possibility of preparing gadolinium chelates of various compositions by electrolysis of a nonaqueous solution containing thenoyltrifluoroacetone was examined.

DOI: 10.1134/S1070427206010150

Anodic dissolution of rare-earth metals and alloys in nonaqueous media in the presence of β-diketones yields β-diketonates [1–10]. The advantages of the electrochemical procedure for preparing rare-earth chelates are as follows: the process is one-step, no by-products are formed, and hydration and hydrolysis are excluded. Anodic dissolution of *f* elements allows preparation of chelates of metals in various valence states [4–7, 9, 11, 12], which is particularly valuable, as it becomes possible to prepare under common conditions coordination compounds of rare-earth elements in lower oxidation states [4–7, 9].

The electrolyses performed in [1–12] involved no profound changes in the chemical composition of β-diketones. The cathodic reduction was accompanied only by transition of the β-diketone to the acido form due to elimination of the proton from the γ-position. At the same time, under certain conditions acetylacetone can be electrochemically converted into a tetraketone (3,4-diacetylhexane-2,5-dione) [13]. This reaction opens prospects for one-step electrochemical synthesis of complex metal chelates with tetraketones. One of typical β-diketones is thenoyltrifluoroacetone; electrochemical preparation of its complexes with such *d* elements as Cr, Co, and Cu was reported in [14–16]. At the same time, the behavior of thenoyltrifluoroacetone in the course of electrolysis with a uranium anode is not unambiguous. For example, Matassa *et al.* [11] failed to prepare electrochemically uranyl thenoyltrifluoroacetonate; this fact suggests that the β-diketone could undergo electrochemical transformations in the presence of an *f* element.

In this study we attempted one-step electrochemical synthesis of a gadolinium tetraketonate starting from thenoyltrifluoroacetone. The choice of Gd was governed by the stability of its trivalent state under the conditions of the anodic oxidation [6], which makes the reaction pathway more predictable.

EXPERIMENTAL

Tetraethylammonium bromide and thenoyltrifluoroacetone [1,1,1-trifluoro-4-(2-thienyl)-2,4-butanedione, HTTA] of analytically pure grade was recrystallized twice from ethanol and stored in a vacuum desiccator over phosphorus pentoxide. The IR absorption spectra were recorded on a Specord IR75 spectrophotometer in the range 4000–400 cm^{-1}; samples were taken as mulls in mineral oil or as films prepared from acetone solutions. The mass spectra were recorded with an MKh-1320 mass spectrometer. The metal content in the substances was determined gravimetrically after calcination of weighed portions to Gd_2O_3 [6].

Electrolysis of a 0.2 M solution of thenoyltrifluoroacetone in acetonitrile was performed in a diaphragmless cylindrical cell with direct current at a voltage of 3 V under argon. The initial current density was 10 mA cm^{-2}. The cathode (nickel foil) was arranged along the internal lateral surface of the cell. The gadolinium anode was arranged in the cell center. The ratio of the cathode and anode surface areas was 28 : 1. The electrochemical synthesis procedure is described in more detail elsewhere [1–12].

Devices for thermal studies [thermogravimetric (TG) analysis, isothermal heating] were described in [7]. Isothermal heating of samples was performed under argon.

During 180-min electrolysis, 420 C of the electricity was passed. The solution remained transparent

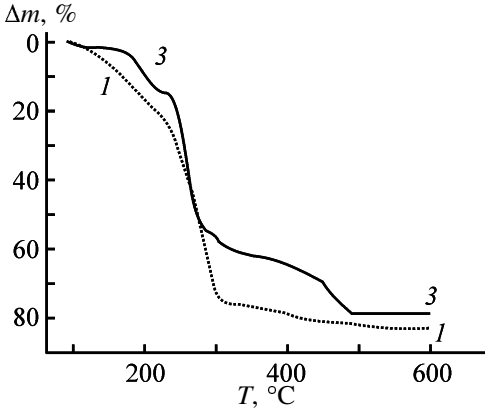
Substance no.	Chelate			Gd content, wt %	
	formula	weight, g	current efficiency, %	found	calculated
1	$[Gd\{(TTA^*)_2\}_3]$	1.85	85.8	10.6	10.59
2	$[(Gd\{(TTA^*)_2\}_{2.75}]$	0.4	21.8	11.6	11.45
3	$[Gd\{(TTA^*)_2\}_{2.25}]$	0.9	–	14.0	13.64

Note: $(TTA^*)_2$ denotes 1,1,1,6,6,6-hexafluoro-3,4-di(2-thienylcarbonyl)hexane-2,5-dione.



throughout the process. The current density decreased to 1.6 mA cm^{-2}, which is presumably caused by formation of weakly dissociating chelates in the solution. The anode weight loss was 0.609 g, which corresponded to 267% current efficiency by Gd(III) and suggests simultaneous chemical dissolution of Gd in the course of the electrolysis. Similar electrochemical behavior of some rare-earth metals was observed in other studies [7–10, 15].

The mother liquor obtained was evaporated to a slurry and treated with diethyl ether. The residue after evaporation of the ether was partially soluble in benzene. Thus, we obtained substance 1 insoluble in benzene and substance 2 soluble in benzene (after the solvent evaporation). Substance 3 was obtained by treatment of substance 1 with water. The analytical data, current efficiencies, and presumed compositions of the complexes are given in Table 1.

The gadolinium : thenoyltrifluoroacetone ratio in the first chelate is 1 : 6. If TTA remained unchanged in the course of electrolysis, such a ratio would correspond to the composition $Gd(TTA)_3 \cdot 3HTTA$. Weakly bound neutral β-diketone molecules are usually removed from complexes in the first step of thermolysis [1, 2, 4–10, 14, 15]. The TG curves of chelates 1 and 3 (Table 1) are shown in the figure. The curves have no pronounced plateaus that could be expected for adducts (stability of the intermediate desolvated form). The pattern of thermal decomposition is complex, with weak inflections in the TG curves, but the process occurs in one step. The most pronounced inflection is observed in the initial portion of the TG curves at 150–170°C. Therefore, we performed a series of isothermal heatings at 140, 145, 150, and 155°C. The weight loss was 1.3, 1.4, 1.6, and 2.2%, respectively. Thus, under isothermal conditions, we also failed to obtain a stable intermediate corresponding to elimination of a large neutral ligand.

The IR spectrum of $[Gd\{(TTA^*)_2\}_3]$ (Table 2) contains strong bands in the range of CO and CC stretching vibrations at 1700–1500 cm^{-1}. The absorption bands in the range 1560–1500 cm^{-1} suggest formation of a quasiaromatic chelate ring [17–23]. The bathochromic shift of the C=O bands caused by a decrease in the C=O bond multiplicity reaches 105–83 cm^{-1} (the C=O strecthing vibrations in HTTA are manifested at 1660 and 1638 cm^{-1}). The very strong band at 1595 cm^{-1} with a shoulder at 1630 cm^{-1} can be assigned to C=O groups of thenoyltrifluoroacetone coordinated without formation of a quasiaromatic chelate, i.e., without transformation of the ligand into the acido form [18, 20–23]. As expected, the bathochromic shift in this case is considerably smaller: 65–8 cm^{-1}. The complex shape of the band at 1595 cm^{-1} indicates that the neutral CO groups are coordinated to the central atom to a different extent. An alternative explanation of the weaker bathochromic shift may be hydrogen bonding of the carbonyl groups in the enol form of the β-diketone [24]. The presence of the enol form is confirmed by a broad strong band at 3650–3050 cm^{-1} (OH stretching vibrations, Table 2), taking into account that the synthesis was performed in acetonitrile under anhydrous conditions.

As noted above, substance 3 (Table 1) was obtained by treatment of $[Gd\{(TTA^*)_2\}_3]$ with water. Usually β-diketonates of *f* elements are susceptible to hydration and hydrolysis [25–27]. However, the IR

TG curves of gadolinium chelates (curve nos. are substance nos. in Table 1): (Δ*m*) weight loss and (*T*) temperature.

* L denotes TTA, and L_2^*, 1,1,1,6,6,6-hexafluoro-3,4-di(2-thienylcarbonyl)hexane-2,5-dione.

spectrum of $[Gd\{(TTA^*)_2\}_{2.25}]$ shows no absorption in the range 4000–3000 cm^{-1} (Table 2). In the range 1650–1580 cm^{-1}, there is a strong band with a maximum at 1597 cm^{-1} with a well-defined shoulder at 1605 cm^{-1}. On the whole, the IR spectrum of $[Gd\{(TTA^*)_2\}_{2.25}]$ in this range resembles the spectrum of $[Gd\{(TTA^*)_2\}_3]$ with the only difference that the shoulder at 1630 cm^{-1} in the spectrum of the latter is manifested as a very weak band in the spectrum of the former. The spectra of these two substances differ more significantly in the range 1560–1500 cm^{-1} corresponding to stretching vibrations of the CO and CC groups of the quasiaromatic ring. In the spectrum of $[Gd\{(TTA^*)_2\}_{2.25}]$, the bands are appreciably stronger than in the spectrum of $[Gd\{(TTA^*)_2\}_3]$, though their positions are essentially the same. The absorption patterns of these two compounds in the other ranges are virtually identical (Table 2).

Comparison of the IR spectra of $[Gd\{(TTA^*)_2\}_3]$ and $[Gd\{(TTA^*)_2\}_{2.25}]$ shows that treatment of the former chelate with water does not result in its hydration and hydrolysis but results in removal of a part of

the ligand occurring in the enol form. The strong CF_3 vibration bands at 1300–1100 cm^{-1} in the spectra of the complexes (Table 2) indicate that the electrochemical synthesis leaves the CF_3 groups intact. As judged from the spectra, the thienyl group remains intact also (bands at 1050, 850, 624 cm^{-1} [19]).

The mass spectra of $[Gd\{(TTA^*)_2\}_3]$ are given in Table 3. No metal-containing ions, which could be reliably identified by a characteristic isotopic pattern [28], were detected. The heaviest ions observed in the mass spectrum correspond to the doubled weight of thenoyltrifluoroacetone (minus two hydrogen atoms): 443, 442, and 441. These peaks indicate that thenoyltrifluoroacetone underwent dimerization in the course of electrolysis. The further fragmentation pattern of the dimer shows that it contains intact thienyl and CF_3 groups (Table 3), which is consistent with the IR data. The whole set of the data obtained (spectroscopy, elemental analysis, thermolysis) suggest that HTTA underwent dimerization by coupling of the γ-C atoms with elimination of γ-H atoms. The resulting 1,1,1,6,6,6-hexafluoro-3,4-di(2-thienylcarbonyl)hexane-2,5-dione $[(TTA^*)_2]$ can potentially form two chelate rings via enolization of the two remaining γ-H protons. However, apparently, the removal of the second proton will be hindered, in particular, because of the electrostatic effect of the arising negative charge. This assumption allows us to account for formation of complexes with lower ligand content and fractional ligand-to-metal ratios on treatment of $[Gd\{(TTA^*)_2\}_3]$ with various solvents (Table 1).

The lack of metal-containing fragments in the mass spectrum of $[Gd\{(TTA^*)_2\}_3]$ is due to the capability of the ligand for complexation in two opposite directions, which is confirmed by the IR data (strong donor–acceptor interaction without transition into the acido form). This should result in polymerization of the chelate due to strong binding of the metal with ligands of adjacent chelate fragments. Whereas a metal atom is bonded at least with four ligand molecules (three in the acido form and one from the surrounding of the adjacent metal by the donor–acceptor mechanism; in this case, the coordination number is 8, which is typical of rare-earth metals [25]), not all the ligands will be bonded with two metal atoms (excess coordination capacity, steric hindrance caused by branched structure), which is confirmed by detection of the enol form. Therefore, under conditions of the mass-spectrometric experiment, the complex will decompose with the elimination of the least bonded ligands, rather than pass into the gas phase.

CONCLUSIONS

(1) Electrolysis of an acetonitrile solution containing thenoyltrifluoroacetone with a gadolinium anode allows preparation of $[Gd\{(TTA^*)_2\}_3]$ and $[Gd\{(TTA^*)_2\}_{2.75}]$, where $(TTA^*)_2$ is 1,1,1,6,6,6-hexafluoro-3,4-di(2-thienylcarbonyl)hexane-2,5-dione. Treatment of the former compound with water yields $[Gd\{(TTA^*)_2\}_{2.25}]$.

(2) The compounds obtained contain no neutral ligands, and the peripheral CF_3 and thienyl groups remain intact. The ligand interacts with the metal with the formation of a quasiaromatic chelate ring, i.e., via transition into the acido form. The remaining neutral part of the tetraketone interacts with the adjacent Gd atoms.

(3) Not all the available carbonyl groups are involved in donor–acceptor interactions, because of steric hindrance and deficiency of metal atoms. Therefore, some of these groups are enolized. The compounds obtained, when treated with water, lose only a part of the ligand occurring in the enol form and are not hydrated or hydrolyzed; such a behavior is untypical of β-diketonates.

Abstract—Conductivity of the network polymer based on tetra(sulfonatophenyl)-*meta*-cyclophanoctol in the H^+, Na^+, Cu^{2+}, Zn^{2+}, and Ni^{2+} forms is studied, and the self-diffusion coefficients and activation energies of diffusion of the metal cations in the polymer phase are estimated.

DOI: 10.1134/S1070427206010162

High-performance fuel cells could be developed only on the basis of novel materials, which should be highly efficient and selective catalysts of cathodic oxidation of fuel and anodic reduction of oxygen. The use of such materials in fabricating electrodes should increase the exchange current and decrease the energy loss for polarization of the oxygen electrode. Finely dispersed Pt-group metals were suggested as catalysts of electrode reactions. Also it seems promising to use finely dispersed "soft" transition metals such as copper and nickel. Optimal distribution of a liquid and gas in the electrode material should also improve the performance of fuel cells. Therefore, its structure should be porous, and it should contain hydrophilic fragments in combination with hydrophobized active layers [1].

Network polymers based on calixarenes, particularly, *meta*-cyclophanoctols, show promise as the matrix in developing composite materials for electrodes of a new generation of fuel cells. Thanks to the presence of the hydrophobic belt formed by the arene fragments and also of the hydrophilic substituents in the immobilized *meta*-cyclophanoctols, the structure of the calixarene-containing polymers contains both hydrophilic and hydrophobic layers. It is known [2] that calixarene-based network polymers are cation exchangers. They can be charged with various metal ions, and the metal concentration in the polymer can be varied over a wide range. To determine the kinetic characteristics of redox reactions in the systems containing polymeric materials based on *meta*-cyclophanoctols, it is necessary to have available information on the electrochemical properties of immobilized *meta*-cyclophanoctols, particularly, on the dependences of the ionic conductivity of the polymers on their counterion composition and temperature.

In this study we measured the conductivity of the network polymer based on *cis*-tetra(sulfonatophenyl)-*meta*-cyclophanoctol

R = $PhSO_3H$,

and estimated the self-diffusion coefficients and activation energies of diffusion of Na^+, Cu^{2+}, Zn^{2+}, and Ni^{2+} in the polymer phase over the temperature range 298–333 K.

EXPERIMENTAL

The network polymer based on *cis*-tetra(sulfonatophenyl)-*meta*-cyclophanoctol was obtained as spherical granules 0.05–0.5 mm in diameter by catalytic resol polycondensation of *cis*-tetraphenyl-*meta*-cyclophanoctol with formaldehyde, followed by treatment with concentrated sulfuric acid [3]. The dynamic ion-exchange capacity of the polymer was determined by passing 0.1 N NaCl through a column packed with the polymer in the H form or of 0.05 N $CuCl_2$, $ZnCl_2$, and $NiCl_2$ through a bed of the polymer in the Na

Conductivity of the polymer $\bar{\chi}$ and self-diffusion coefficient $\bar{D}_i$, activation energy of diffusion $\bar{E}_a$, and entropy constituent of the free energy of diffusion $d\exp(\Delta S^{\neq}/2R)$ of cations in the polymer phase at 298 K

Cation	$\bar{\chi} \times 10^4$, Ω^{-1} cm^{-1}	$\bar{D}_i \times 10^6$, cm^2 s^{-1}	$\bar{E}_a$, kJ mol^{-1}	$d\exp(\Delta S^{\neq}/2R)$

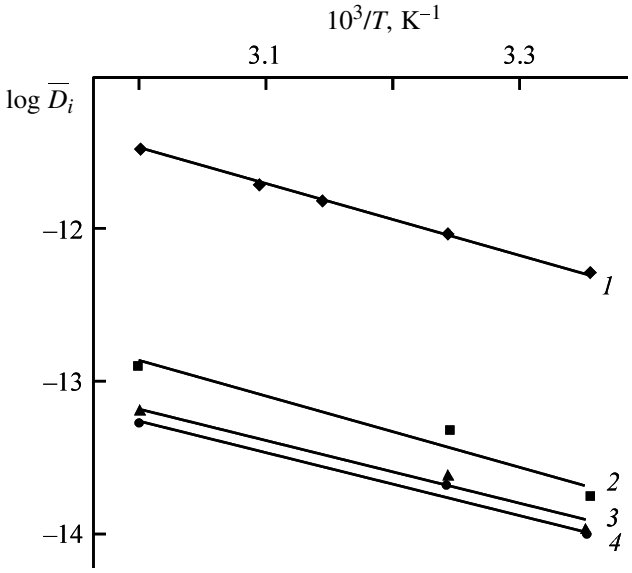
* (N. d.) Not determined. It is difficult to estimate t_i for H^+ because of possible penetration of a Donnan electrolyte to the polymer phase.

form (to 100% breakthrough of the metal ion). The volume dynamic ion-exchange capacity of the polymer in the H and Na forms was found to be 0.53 and 0.59 g-equiv l^{-1}, respectively, and in the Cu^{2+}, Ni^{2+}, and Zn^{2+} forms, 0.65 g-equiv l^{-1}.

The conductivity of the polymer itself was estimated from the experimental conductivity of the interface polymer/equilibrium electrolyte solution and that of the equilibrium electrolyte near the isoelectric point using the semiempirical relationship [5]. The concentration of the isoelectric HCl solution in equilibrium with the H form of the polymer approached 0.5 g-equiv l^{-1}. In the cases of cationic forms of the polymer, the concentration of the equilibrium solutions of the corresponding metal chlorides was no more than 0.1 g-equiv l^{-1}. The conductivities of the polymer/electrolyte interfacial layer and of the electrolyte solutions were measured at 1000 and 4000 Hz using a measuring system representing an ac bridge equipped with a dual-beam oscillograph as an amplitude-phase balance indicator, switched to the diagonal of the bridge. An audio-frequency oscillator, having a fine adjustment of the frequency and output voltage amplitude, equipped with an output transformer with a grounded point and fully balanced halfparts of the output winding, was switched to another diagonal of the bridge. The grade of accuracy of the devices constituting the measuring system is 0.2. The interfacial conductivity was measured using a specially designed cell with a mobile Pt electrode [6]. The conductivity of the equilibrium solution was measured separately using a conductometric sensor with platinized Pt electrodes. The conductometric cell and sensor were calibrated using standard KCl solutions.

The ionic conductivity of swollen cation exchangers, including the investigated polymer, strongly depends on the mobile counterion [7]. The table shows the conductivity of the network polymer based on *cis*-tetra(sulfonatophenyl)-*meta*-cyclophanoctol in the H^+, Na^+, Cu^{2+}, Ni^{2+}, and Zn^{2+} forms.



The conductivity of the investigated polymer is well comparable with that of nonaqueous electrolytes in lithium power sources [8], solid sodium aluminate proposed as an electrolyte for chemical power sources [1], and ordinary ion-exchange resins [6]. The conductivity of various cationic forms of the polymer increases in the order $Ni^{2+} < Cu^{2+} < Zn^{2+} < Na^+ \ll H^+$. The observed considerably higher conductivity of the H form can be attributed to the relay mechanism of charge transfer in the systems containing H^+. Furthermore, the conductivity of the H form could be significantly increased by virtue of the Donnan electrolyte as a result of rather high concentration of the isoconducting HCl solution in equilibrium with the polymer in the H form.

The conductivity of the polymer is directly related to the self-diffusion coefficient of the cation through the well-known Nernst–Einstein equation:

$$D_i = \frac{RT}{zF^2}\frac{\bar{\chi} t_i}{\bar{c}_R}, \quad (1)$$

where D_i is the self-diffusion coefficient of the ion; R, gas constant; T, temperature; z, ionic charge; F, Faraday number; $\bar{\chi}$, conductivity of the polymer phase; $\bar{c}_R$, volume ion-exchange capacity of the polymer; and t_i, transport number of the counterion.

In the polymer phase, the ionic groups are tightly bound to the polymer matrix and are not involved in charge transfer. Mobile species are counterions and ions penetrating to the polymer phase as a result of the Donnan effect. Since the salt concentration in the solutions in equilibrium with the polymer was no more than 0.1 g-equiv l^{-1}, charge transfer in the polymer studied proceeds essentially by the metal ions ($t_i \to 1$). The self-diffusion coefficient of the cations in the polymer phase (see table), estimated by Eq. (1), increases with decreasing cationic charge. The counterions are electrostatically attracted to the charges fixed on the polymer matrix. It is logical to suggest

Dependence of $\log \bar{D}_i$ vs. $1/T$ for self-diffusion of (*1*) Na^+, (*2*) Zn^{2+}, (*3*) Cu^{2+}, and (*4*) Ni^{2+} in the network polymer based on *cis*-tetra(sulfonatophenyl)-*meta*-cyclophanoctol.

that, with decreasing cationic charge, the electrostatic interaction between the fixed ion and counterion weakens, thus decreasing the activation energy and increasing the self-diffusion coefficient of the counterion in the polymer phase.

The figure shows the temperature dependences of the logarithms of the self-diffusion coefficients of the cations in the polymer phase. The dependences are linear (r 0.98–0.99), suggesting that the activation energies of diffusion of the cations can be estimated from the slope of the Arrhenius curves. As seen from the table, the activation energy of diffusion of Na^+, Cu^{2+}, Zn^{2+}, and Ni^{2+} in the polymer studied is 16–19 kJ mol^{-1} at 298–333 K, i.e., no clearly pronounced dependence on the cationic charge is observed.

The Eyring equation relates the diffusion coefficient to the activation energy E_a and activation entropy $\Delta S^{\neq}$ of the process:

$$\bar{D}_i = ea^2 \frac{kT}{h} \exp(\Delta S^{\neq}/R) \exp(-E_a/RT), \qquad (2)$$

where d is the jumping distance of the ion in diffusion; k, Boltzmann constant; and h, Planck constant.

Comparison of the self-diffusion coefficients of the cations with the entropy term (see table) shows that a decrease in $\bar{D}_i$ on passing from Na^+ to the double-charged cations is accompanied by a decrease in the entropy term, which is probably due to partial localization of the diffusing species in the vicinity of the ionic groups of the polymer.

CONCLUSIONS

(1) The conductivity at 298 K of the network polymer based on tetra(sulfonatophenyl)-*meta*-cyclophanoctol in the Cu^{2+}, Zn^{2+}, and Ni^{2+} forms is found to be 0.004–0.005 Ω^{-1} cm^{-1}, increasing to 0.01 and 0.115 Ω^{-1} cm^{-1} for the Na^+ and H^+ forms, respectively.

(2) The self-diffusion coefficient of the metal cations in the polymer phase increases on passing from the double-charged cations to Na^+, which is due to an increase in the entropy constituent of the free energy of activation of diffusion.

CATALYSIS

Influence of Concentration and Amount of Spent Sulfuric Acid on the Degree of Its Catalytic Decomposition

N. A. Dobrovinskaya, E. I. Dobkina, and S. M. Kuznetsova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 9, 2005

Abstract—The influence of the concentration, composition, and amount of spent sulfuric acid on final characteristics of its thermocatalytic decomposition was studied.

DOI: 10.1134/S1070427206010174

Spent sulfuric acid (SSA) containing small amounts of organic impurities (usually no more than 2–4 wt %) is formed in certain large-capacity processes, such as alkylation and production of synthetic alcohols [1]. Thermocatalytic decomposition in a fluidized bed at 750–850°C yielding sulfur dioxide suitable for the further processing into sulfuric acid by classic schemes [2] seems to be the most promising for the regeneration of such SSA.

Thus, the final aim of the SSA thermolysis is the production of commercial acid of standard concentrations, and the content of sulfur dioxide in the gases from the decomposition is the factor determining the feasibility of their further processing. To reach the maximal productivity of catalytic reactors of the SO_2 oxidation to SO_3, it is recommended [2] to maintain the 7.0–7.5 vol % concentration of sulfur dioxide at the reactor input in the case of single contact and 9–10 vol % in the case of double contact.

It was shown in [3] that it is appropriate to carry out the thermocatalytic decomposition on supported iron–copper oxide catalysts using silica-modified γ-Al_2O_3 as support.

EXPERIMENTAL

All experiments were carried out with the above-mentioned catalyst. The content of sulfur dioxide in the decomposition products of spent SSA from the production of methyl ethyl ketone (MEK) is plotted in Fig. 1 vs. SSA concentration. The starting acid containing 43 wt % monohydrate was evaporated to 63, 72, and 85 wt % monohydrate. The amount of organic impurities in the evaporated acid was 1.6, 1.7, and 1.8 wt %, respectively (1.5 wt % in the starting SSA); their effect on the sulfuric acid thermolysis is negligible [4].

It is seen from Fig. 1 that, in the range of loads with respect to SSA under study, the required concentration of sulfur dioxide is reached in thermolysis of the acid containing no less than 70 wt % monohydrate. To obtain a gas with an SO_2 content sufficient for the subsequent industrial oxidation, it is appropriate to carry out the thermocatalytic SSA decomposition at high loads with respect to the acid. However, an increase in these loads can lead to the catalyst deactivation owing to coking of its surface. Figure 2 shows that the decrease in the activity when the optimal load with respect to SSA is considerably exceeded is different for acid samples containing different amounts of organic impurities.

When SSA from alkylation, containing 3.0 wt % hydrocarbons, is decomposed, the degree of decomposition β gradually decreases as the specific load

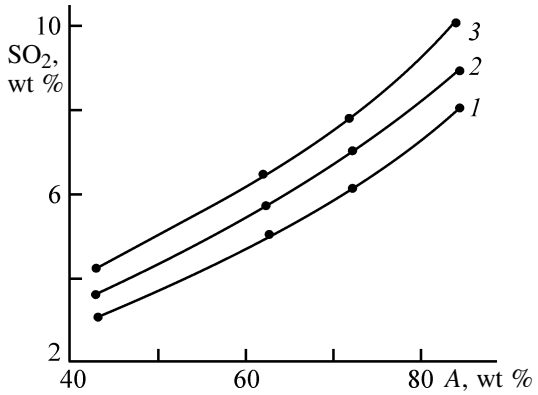

Fig. 1. SO_2 concentration in decomposition products of SSA from MEK production as a function of the monohydrate content A in the acid. Load with respect to SSA, kg h^{-1}: (*1*) 0.04, (*2*) 0.05, and (*3*) 0.06.

with respect to SSA increases and sharply decreases when the load exceeds 1500 kg h^{-1} m^{-3} (Fig. 2, curve *1a*). As L_{sp} growths further, β of 5–7% remains almost unchanged. Obviously, owing to the coking, the further SSA decomposition proceeds not catalytically, but under the action of a high temperature and of reducing agents present in SSA.

The pore structure of the catalyst was examined by porosimetry and scanning electron microscopy (SEM). The results obtained agree well with variations in the activity at a substantial growth of specific loads with respect to the acid. The fresh catalyst is characterized by a rather wide pore-size distribution, from 3 to 400 nm (Fig. 3, curve *1*); pores with radii of 5–10 nm dominate. During 100-h operation of the catalyst in the decomposition of alkylation SSA at L_{sp} = 900 kg h^{-1} m^{-3}, its pores increase in size practically over the whole range, the amount of thin pores decreases by 35–40%, and the total volume of pores, by 7–8% (Fig. 3, curve *2*).

As the process under study is kinetically controlled [3, 5], coke should be evenly distributed over the volume of catalyst grains [6]. In fact, the porogram of the sample coked at SSA feeding rate of 1700 kg h^{-1} m^{-3} (Fig. 3, curve *3*) indicates that coke is deposited inside pores of practically all sizes, the majority of thin pores being completely plugged. The total volume of pores decreases in this case by approximately 30%.

Electron microscopic examination confirmed that coke is distributed in the volume of the catalyst granules. For comparison we also studied the regenerated catalyst. The regeneration was carried out in an air flow at 550–600°C up to complete termination of the release of carbon oxides into the gas phase. In this case, the activity of the regenerated sample was restored to 98–100% (Fig. 2, curve *1b*).

The electron microscopic examination shows that clearly distinctive pore entrances on the surface of the starting catalyst appear to be completely blocked because of coking. After the regeneration, the pores become clearly visible again. Their amount and size increase as a result of the transformation of the support structure in the course of operation.

A similar pattern is also observed on chips of the sample granules. Pore sizes in the starting and coked catalysts are practically equal, whereas, according to the data of mercury porosimetry, they increase in the spent sample (Fig. 3, curve *2*). Obviously, the coke deposited on pore walls decreases their effective radii.

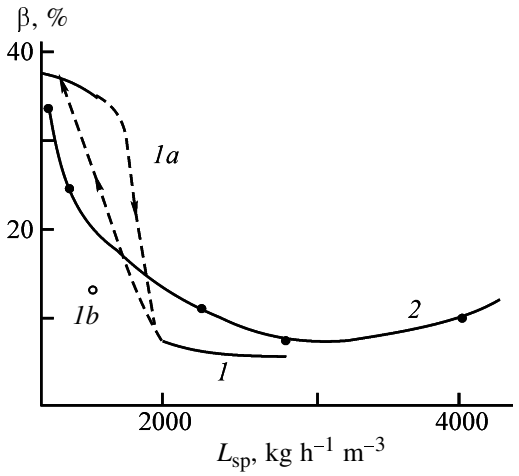

Fig. 2. Degree of decomposition β as a function of the specific load with respect to SSA L_{sp}. The catalyst operated for 100 h in the decomposition process; (*1a*) SSA form alkylation (85 wt % monohydrate, 1.7 wt % organic impurities), (*1b*) SSA form alkylation (after regeneration), and (*2*) SSA from MEK production (72 wt % monohydrate, 1.7 wt % organic impurities).

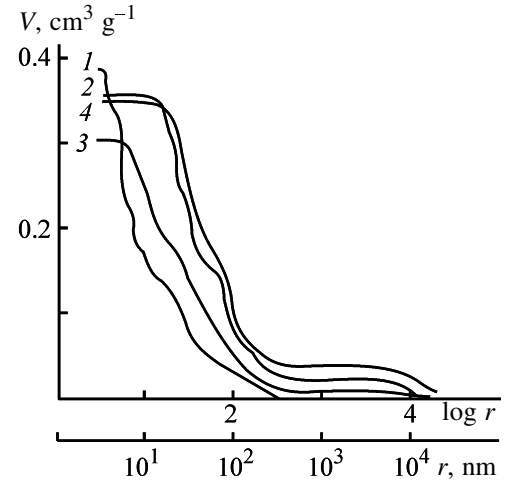

Fig. 3. Porograms of the catalyst: (*V*) total pore volume and (*r*) pore radius. Catalyst: (*1*) starting, (*2*) after operation for 100 h with SSA from alkylation, (*3*) coked at high loads with respect to SSA from alkylation, and (*4*) after operation at high loads with respect to SSA from MEK production.

After removal of coke deposits in the course of the regeneration, larger pores are seen, which became coarser in the course of the catalyst operation.

As the specific load with respect to SSA from MEK production (1.7 wt % organic substances) increasees, the degree of decomposition becomes more uniform (Fig. 2, curve *2*), which is attributable to insufficient residence time of such amount of the acid

in the bed, rather than to blocking of the catalyst active centers by coke. The study of the pore structure of the catalyst that operated at high loads with respect to SSA from MEK production has shown that the coking of the catalyst surface is insignificant, if any (Fig. 3, curve *4*). This is proved by the fact that a decrease in the specific load results in the restoration of the initial degree of SSA decomposition.

When L_{sp} exceeds 2700 kg h^{-1} m^{-3}, β starts to increase. This is apparently associated with the appearance of carbon monoxide in the reaction zone owing to incomplete oxidation of organic impurities. According to numerous papers, the amount of CO can become sufficient for the reaction $SO_3 + CO = SO_2 + CO_2$ to make an appreciable contribution to the SSA decomposition. However, these high loads with respect to SSA are not justified from the process viewpoint, because of a low degree of SSA decomposition. According to our experimental results, at the real loads of 400–900 kg h^{-1} m^{-3} both in the case of SSA from alkylation and SSA form MEK production, organic impurities are oxidized completely and the catalyst is not coked.

CONCLUSION

A quantitative relationship was found between the specific load in the thermocatalytic decomposition of spent sulfuric acid and the degree of its decomposition.

Abstract—Positional isomerization of alkenes was studied in the presence of $Pd(acac)_2$ + $20BF_3OEt_2$ catalytic system. The reactivity of alkenes decreases in the following order: 1-hexene > 1-heptene > 2-methyl-1-pentene > 4-methyl-2-pentene (*cis* + *trans*).

DOI: 10.1134/S1070427206010186

Systems containing bis(acetylacetonato)palladium $Pd(acac)_2$ and trifluoroboron etherate are efficient catalysts of dimerization of vinylaromatic hydrocarbons, e.g., selective dimerization of styrene [1, 2], telomerization of diene hydrocarbons with secondary amines [3, 4], and di- and oligomerization of ethylene and propylene [5–7]. These systems exhibit relatively high catalytic activity in positional isomerization of 1-hexene [8]. Isomerization of alkenes in the presence of Pd(II) complexes as catalysts has been extensively studied. Different isomerization mechanisms were proposed. The following processes are believed to be key steps of isomerization: (a) oxidative addition of alkene to Pd(II) to form allylpalladium(IV) hydride [9], (b) formation of carbenium ion by reaction of Pd(II) with alkene coordinated to the transition metal [10], (c) reversible addition of olefin to Pd(II) hydrides without a change in the Pd oxidation state [11]. Akenes like 1-hexene play a critical role in formation of Pd–H bonds in reactive complexes (RC) formed in the presence of $Pd(acac)_2$–BF_3OEt_2 catalytic system. Probably, the composition of these square-planar complexes is $HPd(L,L')BF_4$, where L is unsaturated hydrocarbon and L' = L or PR_3 [12].

Here we experimentally studied isomerization of alkenes in the presence of $Pd(acac)_2$–BF_3OEt_2 catalytic system, as influenced by various factors including the composition of the catalyst, preparation conditions of RC, and the solvent. With the positional isomerization of alkenes as an example, we intended to gain insight into the mechanism of transformation of unsaturated hydrocarbons including alkenes and vinylaromatic and diene hydrocarbons in the presence of bis(acetylacetonato)palladium–boron trifluoride etherate catalytic system.

EXPERIMENTAL

Isomerization of alkenes was performed under argon in a glass reactor equipped with a magnetic stirrer. A solution of appropriate alkene and $Pd(acac)_2$ was allowed to stand at 10°C for 15 min. The isomerization was initiated by addition of BF_3OEt_2. An aliquot (1 ml) of the reaction mixture was taken at regular intervals and placed into a test tube containing 3% aqueous hydrochloric acid to decompose the catalyst. The organic layer was separated and dried over calcium chloride. The isomerization products in the sample were analyzed by gas–liquid chromatography (GLC) on Tsvet-100M and Chrom-42M chromatographs equipped with a flame-ionization detector and a 100-m copper column with an internal diameter of 0.5 mm. We used vacuum oil as the stationary phase. The inlet pressure of the carrier gas was 0.6×10^5 Pa. The column temperature was 45°C.

Synthesis of $Pd(acac)_2$. To a solution of KOH (0.7310 g, 13.028×10^{-3} mol) in 15 ml of H_2O in a beaker was added acacH (1.2423 g, 12.408×10^{-3} mol). The mixture was heated at 45±5°C. A transparent solution of acacK was obtained.

To an aqueous solution (50 ml) of KCl (0.8830 g, 11.844×10^{-3} mol) in another beaker was added $PdCl_2$ (1.0000 g, 5.64×10^{-3} mol). The mixture was heated at 45±5°C with stirring until the brown precipitate completely dissolved to form a brown solution. The solution was filtered while hot.

The solutions were mixed at 45±5°C. The yellow precipitate was filtered off on a Büchner funnel, washed 5–7 times with 100-ml portions of H_2O, and dried at 50°C. $Pd(acac)_2$ was recrystallized from ace-

The solvents were treated by the standard procedures used in oranometallic chemistry [13].

The kinetic curves of 1-hexene isomerization in the presence of $Pd(acac)_2$ + $20BF_3OEt_2$ catalytic system are shown in Fig. 1. Curves *2* and *3* corresponding to fractions of *trans*-2-hexene and *cis*-1-hexene, respectively, do not pass through the origin when extrapolated. This can be due to a short induction period of the first step of 1-hexene isomerization, when 1-hexene is involved in formation of catalytically active palladium complexes. Under the experimental conditions (Fig. 1), the 1-hexene conversion into the isomerization products in 10–12 min is more than 15000 mol per mole of $Pd(acac)_2$. The major isomerization product (up to 62%) is *trans*-2-hexene.

When $Pd(acac)_2$ and BF_3OEt_2 react for 30 min in the absence of 1-hexene, i.e., when the conditions of formation of AC change, the rate of 1-hexene isomerization decreases by a factor of approximately 3. However, in this case the selectivity of isomerization into *trans*-2-hexene increases to 94.7% (Table 1).

The study of kinetic features of 1-hexene isomerization in the presence of $Pd(acac)_2$ + $20BF_3OEt_2$ system [8] showed that this process is of the first and zero order with respect to the catalysts and 1-hexene, respectively.

In the presence of PPh_3 (P/Pd = 1), the reaction is of the first and third order with respect to 1-hexene and the catalyst, respectively. Introduction of trivalent phosphorus compounds into the $Pd(acac)_2$ + $20BF_3OEt_2$ catalytic system decelerates isomerization

* $c_{1\text{-hexene}}$: (*1*) 1.89 and (*2*) 0.236 M.

of 1-hexene. The palladium catalyst is completely deactivated when the P/Pd atomic ratio increases to 2 (Fig. 2).

The structure type of trivalent phosphorous compounds has virtually no effect on the selectivity of 1-hexene isomerization (Table 2).

However, in the presence of PR_3, the ratio of *cis* and *trans* isomers of 2-hexene substantially depends on the initial concentration of 1-hexene (Table 3).

When the 1-hexene : palladium ratio changes from 1286 to 160, the ratio of *trans* and *cis* isomers of 2-hexene decreases approximately from 3 to 1.

The catalytic activity of the examined system strongly depends on the solvent. The catalytic activity increases with an increase in the polarity of the solvent in the following series: heptane + benzene (1 : 1 vol : vol) < benzene < toluene < isopropylbenzene. The catalytic activity of $Pd(acac)_2$ + PPh_3 + $20BF_3OEt_2$ system in isomerization of 1-hexene in toluene is slightly higher than that in more polar isopropylbenzene (Fig. 3). This can be due to competitive coordination of 1-hexene and the solvent to RC of palladium.

The isomerization rate decreases when the length of the hydrocarbon chain and the number of substituents at the double bond increase in the series 1-hexene, 1-heptene, 2-methyl-1-pentene, *cis* + *trans*-4-methyl-2-pentene (Fig. 4). This is typical for coordination isomerization of alkenes in the presence of transition metal complexes.

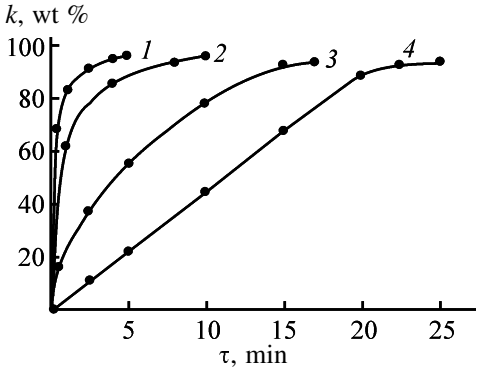

Fig. 3. Conversion of 1-hexene *k* into its isomers in the presence of $Pd(acac)_2$ + PPh_3 + $20BF_3OEt_2$ catalytic system at 283 K in (*1*) toluene, (*2*) isopropylbenzene, (*3*) benzene, and (*4*) benzene + heptane (1 : 1 vol/vol), $c_{Pd} = 1.47 \times 10^{-3}$ M, $c_{1\text{-hexene}} = 0.471$ M.

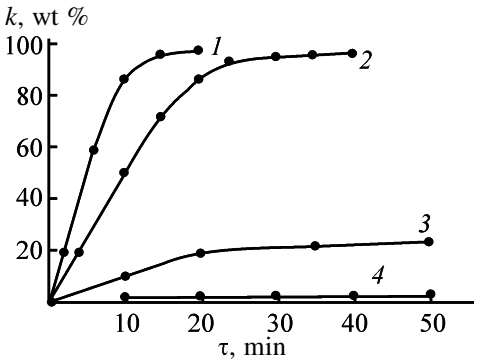

Fig. 4. Conversion k of (*1*) 1-hexene, (*2*) 1-heptene, (*3*) 2-methyl-1-pentene, and (*4*) *cis* + *trans*-4-methyl-2-pentene into their isomers in the presence of $Pd(acac)_2 + PPh_3 + 20BF_3OEt_2$ catalytic system at 283 K in benzene. $c_{Pd} = 1.47 \times 10^{-3}$ M, $c_{olefin} = 0.941$ M.

CONCLUSIONS

(1) The $Pd(acac)_2$–BF_3OEt_2 system shows high catalytic activity in positional isomerization of α-alkenes. The conversion of 1-hexene into the isomerization products under the optimal conditions (B/Pd = 20/1, $c_{Pd} = 1.47 \times 10^{-3}$ M, T = 293 K, benzene) within 10–12 min is 15000 mol g-at.$^{-1}$ of Pd. The *trans*-2-hexene content in the isomerization products is up to 62 %.

(2) The catalytic activity of the system decreases when its components are allowed to react with each other for 30 min in the absence of 1-hexene. In this case, however, the selectivity of 1-hexene isomerization into *trans*-2-hexene can be as high as 94.5%.

(3) In the presence of trivalent phosphorus compounds, the rate of α-alkene isomerization decreases, reaching zero value for 1-hexene at P/Pd = 2. The inhibiting effect can be due to blocking of the coordination vacancies of Pd in the RC. The BF_4 ligand should occupy the fourth coordination site in the AC to form Pd–F · BF_3 bond. The composition of the resulting charge-transfer complex is $HPd(L_2)FBF_3$, where L is alkene.

CATALYSIS

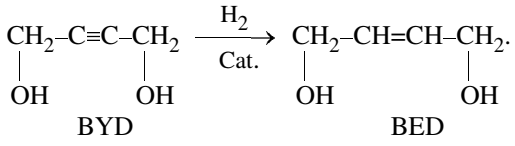
Catalytic Hydrogenation of 2-Butyne-1,4-diol to 2-Butene-1,4-diol at Atmospheric Pressure in the Liquid Phase

E. V. Pyatnitsyna, M. M. El'chaninov, and A. P. Savost'yanov

South-Russian State Technical University, Novocherkassk, Rostov oblast, Russia

Received October 10, 2005

Abstract—Selective hydrogenation of 2-butyne-1,4-diol to 2-butene-1,4-diol on suspended palladium and Raney nickel catalysts at atmospheric pressure was studied. The optimal parameters of this reaction were determined. Samples containing 90% 2-butene-1,4-diol were prepared.



DOI: 10.1134/S1070427206010198

2-Butene-1,4-diol (BED) is used to produce valuable materials such as Endosulfan (insecticide) [1], polyesters [2], alkyd resins [3], butadiene rubber [4], and plasticizers [4] for various branches of industry and medicine. However, this monomer was not produced in Russia. Selective preparation of this monomer by hydrogenation of 2-butyne-1,4-diol (BYD) is of great practical interest.

Here we studied selective hydrogenation of BYD to BED on suspended catalysts at atmospheric pressure.

EXPERIMENTAL

Hydrogenation of BED to BYD was performed in an aqueous suspensions on fine powders of palladium catalysts containing 0.8 and 2.0% Pd and on Raney nickel:

2-Butyne-1,4-diol was reduced in a 100-ml long-necked reactor fixed on a shaker. To maintain the required temperature of the reactor and buret, thermostated water was passed through their jackets. A weighed portion of BYD (1.32 g), water (20 ml), and calculated amount of finely divided catalyst were placed in the reactor. The reaction completion was judged from the volume of hydrogen absorbed, which was measured with a 300-ml gas buret. The palladium catalysts (0.8 and 2.0 wt % Pd supported by OUB carbon) was prepared by impregnation of the support with hydrochloric acid solution of palladium(II) chloride, followed by reduction to metallic Pd with formaldehyde [5]. The selective W-6 nickel catalyst was prepared by leaching a nickel–aluminum Raney alloy with a solution of sodium hydroxide (20 wt %) [6].

The hydrogenation products were analyzed on a Tsvet chromatograph using a 2000 × 3-mm column. The carrier gas was nitrogen; the column temperature was 60–200°C. The support was Chromaton Super (0.16–0.20 mm); the stationary phase was polyethylene glycol 15000.

To determine the best hydrogenation conditions, we studied the composition of the hydrogenation products as influenced by the temperature in the range from 30 to 70°C and the catalyst amount in the reaction mixture in the range from 10 to 100% relative to BYD. The results are summarized in Tables 1 and 2. Chromatographic analysis of the products showed that the target product is formed with 93–94% selectivity on both palladium catalysts, especially at 40–50°C, after absorption of hydrogen in the amount corresponding to reduction of one π bond. When the Pd/C-2 catalyst with higher metal content was used, the weight fraction of BED did not noticeably change. At 30 and 60–70°C, the selectivity decreases. This is due, in the first case, to a low reaction rate and, in the second case, to an increase in the partial pressure of water vapor and fast dehydration, isomerization, and exhaustive hydrogenation.

Hydrogenation on a Raney Ni is slower. The BED content in the reaction product is 73–76%. Under these conditions, γ-hydroxybutyraldehyde (HBA), isomerization product of BED, is formed in a large amount. This compound is dehydrated and hydro-

genated to form *n*-butanol (BTN). In addition, the hydrogenation product of BED, butane-1,4-diol (BAD), is accumulated.

We studied how the weight fraction of the catalysts in the reaction mixture affects the composition of the hydrogenation products formed at 50°C. The results are presented in Table 2. As seen from Table 2, the yield of the target product is maximal at the weight fraction of the palladium catalyst from 10 to 20%. When the catalyst content increases to 50–100%, the reaction is accelerated by a factor of 2 but the selectivity of BED formation decreases owing to side reac-

tions yielding BTN, HBA, and BAD is significant amounts. The hydrogenation is also accelerated by a factor of approximately 3 with increasing the weight fraction of the Raney nickel catalyst. In this case, the BED yield significantly decreases owing to formation of large amounts of the by-products including BAD. It should be noted that the weight fraction of HBA decreases with increasing the concentration of Raney Ni catalyst. This fact indicates that HBA is reduced to BAD in the presence of this catalyst.

We studied how the composition (wt %) of products of BYD hydrogenation at 40°C in the presence of Pd/C-0/8 depends on the reaction time (Table 3, Fig. 1). Analysis of the kinetic curves shows that the BED concentration is maximal at the time of complete consumption of BYD. Isomerization and dehydration occur simultaneously with formation of BED. The product of BED hydrogenation is formed in 30 min.

Thus, BYD is selectively hydrogenated to BED on the suspended palladium catalysts at atmospheric pressure when the process is stopped after consumption of 1 mol of hydrogen. Based on this result, we proposed a procedure for laboratory preparation of BED. For this purpose we used a solution of 2-butyne-1,4-diol [TU (Technical Specifications) 64-5-52–79; distilled water [GOST (State Standard) 6709–72]; hydrogen (technical grade, GOST 3022–80); catalyst Pd/C-0.8.

A weighed portion of catalyst (75 g) and 25 wt % aqueous solution of BYD (1.5 l) were placed in a 2-l three-necked flask equipped with a stirrer, a bubbler, and a tube connected with a Woulfe bottle for moni-

toring the evolved gas. The reaction mixture was heated to 50–60°C, the stirrer was switched on, and hydrogen bubbling was started. The composition of the hydrogenation products was determined on a Tsvet-104 chromatograph with a flame ionization detector. Th reaction was stopped when the intensity of the peak on unchanged BYD was no higher than 0.2–0.5%. Then the reaction mixture was filtered on a Büchner funnel. Water was removed from the filtrate in a water-jet pump vacuum with heating on a water bath. The residue was distilled with a dephlegmator in a vacuum of an RVN-20 pump (3 mm Hg). The BED yield was 276.2 g (~72%); bp 230–235°C at 760 mm Hg.

CONCLUSION

As shown by chromatographic analysis, 2-butyne-1,4-diol can be selectively hydrogenated to 2-butene-1,4-diol in the liquid phase on suspended finely divided palladium catalysts at atmospheric pressure in the batch mode at a fixed amount of hydrogen absorbed.

Abstract—Catalytic oxidation of acetone on samples of a copper-containing catalyst with an ac electric field applied to the catalyst bed was simulated. The distribution of temperature across the catalyst bed was studied at varied delivered specific electric power, and kinetic parameters of the catalyst samples were determined.

DOI: 10.1134/S1070427206010204

Solution of the problems of environment protection requires that gas discharges should be purified to remove volatile organic compounds (VOCs). Organization of a system for detoxication of VOC discharges and its design constitute a complicated scientific and technological problem. In this study, the major attention is given to simulation of electrocatalytic detoxication of hydrocarbon-containing gases on copper-containing catalysts and to determination of their kinetic parameters.

The catalyst was prepared from technical-grade carbon of PM-750 brand by mixing the carbon with copper hydroxo carbonate. Then a plasticizer (10% solution of polyvinyl alcohol) was added to the resulting mixture and it was formed at the optimal forming moisture content to give grains 0.5–1.0 mm in diameter, which were calcined in a flow of CO_2 at 350°C. As a model gas system we studied a mixture constituted by air and 1–2 g m^{-3} of acetone. The concentration of acetone in the gas–air mixture was determined nephelometrically on a KFK-2MP photoelectrocolorimeter at a wavelength of 320 nm [1]. The conversion of acetone on the catalyst samples synthesized was found in an isothermal plug-flow reactor. During the tests, an ac electric voltage was applied across the catalyst bed. The total specific surface area of the catalyst was measured on a Tsvet-211 sorption meter by the procedure described in [2]. The surface area of the catalysts was determined by selective low-temperature chemisorption of helium. The chemisorption measurements were performed in the pulsed mode at –136°C.

In view of the fact that application of an electric field across the catalyst bed may lead to its prolonged heating, it was suggested to use a nonstationary model describing the catalytic reactor [3]. A two-phase model was chosen. The following assumptions were made to enable solution of the system of equations: (1) the longitudinal and radial transfer was disregarded in the balance equations for the gas phase; (2) absence of temperature gradients in a grain was allowed; (3) the process was considered in the absence of heat transfer across a reactor wall; and (4) the concentration gradients in a grain were considered to be absent.

With account of these assumptions, it was suggested to solve the following system of differential equations to describe the electrocatalytic oxidation in a catalyst bed with application of an ac electric field to this bed:

$$\frac{\partial T}{\partial \tau} = \frac{\alpha S}{C_p \rho_a}(\theta - T) - U\frac{\partial T}{\partial \varepsilon}, \quad (1)$$

$$\frac{\partial \theta}{\partial \tau} = \frac{1}{C_c \rho_c}\left[-\alpha_{cm} S_m(\theta - T_{env})/V_r + P_m + \lambda\frac{\partial^2 \theta}{\partial \varepsilon^2} - \alpha S(\theta - T) + Q k_0 \exp(-E_a/RT)(1 - X_c)\right], \quad (2)$$

$$\frac{\partial X_c}{\partial \tau} = \beta(X_c - X_g) - U\frac{\partial X_g}{\partial \varepsilon}, \quad (3)$$

$$\frac{\partial X_c}{\partial \tau} = k_0 \exp(-E_a/RT)(1 - X_c) - \beta(X_c - X_g), \quad (4)$$

where T is temperature in the gas phase (K); θ, tem-

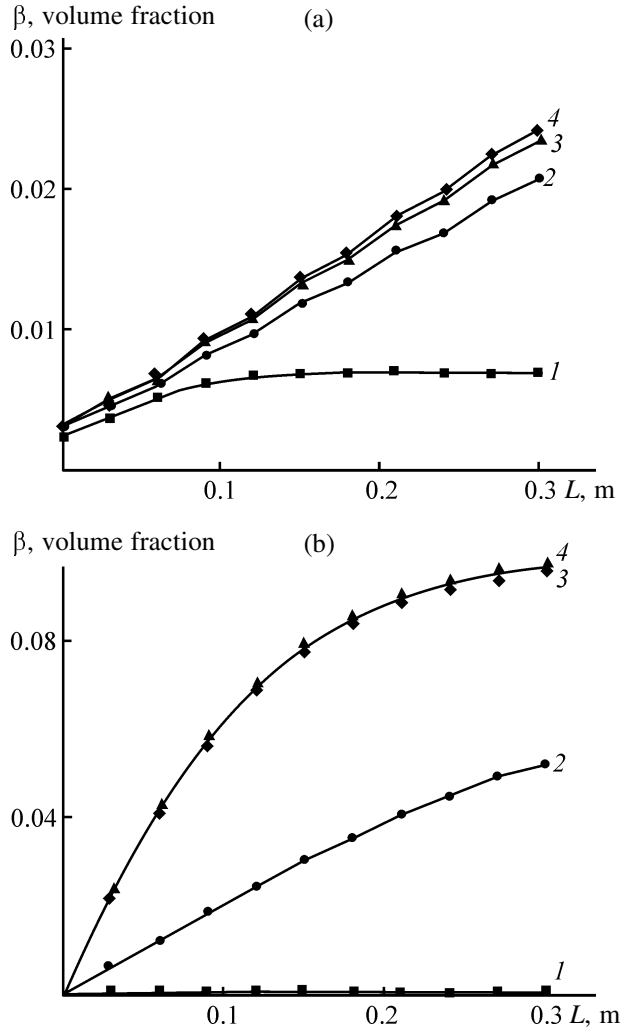

Fig. 1. Calculated distribution of the conversions β along the reactor length L for a delivered specific power of (a) 0.02 and (b) 2.00 W cm^{-3}. Time during which the gas–air mixture was passed (s): (*1*, *2*) 100, (*3*) 600, and (*4*) 1200.

perature in the catalyst grain (K); X_c, degree of purification in a catalyst grain (fraction units); X_g, degree of purification in a gas flow (fraction units); τ, running time elapsed from the time origin (s); α, coefficient of heat transfer from the outer surface of grains to the flow (W m^{-1} K^{-1}); S, volume-related specific surface area of the catalyst (m^2 m^{-3}); C_p, specific heat of air (kJ kg^{-1} K^{-1}); ρ_a, density of air (kg m^{-3}); U, true gas-flow velocity in the reactor (m s^{-1}); ε, running reactor height (m); C_c, specific heat of the catalyst (kJ kg^{-1} K^{-1}); ρ_c, apparent density of the catalyst (kg m^{-3}); λ, effective coefficient of heat conductivity via the bed "skeleton" (W m^{-1} s^{-1}); Q, amount of heat released in the course of the reaction, related to the volume of the gas flow at the initial concentration of the reagent (kJ m^{-2} K^{-1}); k_0, preexponential factor of the reaction rate constant (s^{-1}); E_a, activation energy of the reaction on the catalyst (kJ m^{-1} K^{-1}); β, coefficient of mass transfer from the flow to the surface of catalyst grains (W m^{-2} K^{-1}); P_m, power of heating of the catalyst bed by the electric current, related to the unit volume of the catalyst (W m^{-3}); α_{cm}, coefficient of heat transfer from the catalyst bed to the environment (W m^{-2} K^{-1}); S_m, surface area of heat exchange between the reactor and the environment (m^2); V_r, reactor volume (m^3); and T_{env}, environment temperature (K).

The preexponential factor k_0 and the activation energy E_a make it possible to account for the activity of the catalyst to which an electric field is applied. The system of differential equations enables analysis of the process under nonstationary conditions and evaluation of the time in which the system attains a steady state.

Equation (1) describes the heat balance in the gas phase. Equation (2) represents the heat balance in the catalyst bed, and Eqs. (3) and (4), material balance in the gas phase and in the catalyst bed, respectively. Equations (2) and (4) use as a kinetic term a first-order equation that describes the majority of processes of deep oxidation of organic compounds [3].

One (gas) phase is constituted by the flow of reagents moving across the catalyst bed, and the other (solid) is formed by the catalyst bed in which the reaction occurs. The heat transfer caused by the arising temperature gradients is distributed among the phases. A similar transfer of substance occurs only in the reagent flow. In this model, both phases are quasi-homogeneous, and, therefore, each point within the catalyst bed is represented by two sets of substance concentrations and temperatures.

To consider completely defined the problem of describing the oxidation of acetone in a catalyst bed to which an electric field is applied, it is necessary to specify the initial and boundary conditions.

Initial conditions:

$$\text{at } \tau = 0\text{: } T = T_{in},\ \theta = T_{in},\ X_c = 0,\ X_g = 0.$$

Boundary conditions:

$$\text{at } \varepsilon = 0\text{: } T = T_{inl},\ X_g = X_{inl} = 0,\ \partial\theta/\partial\varepsilon = 0,\ \partial X_c/\partial\varepsilon = 0;$$

$$\text{at } \varepsilon = h\text{: } \partial T/\partial\varepsilon = 0,\ \partial\theta/\partial\varepsilon = 0,\ \partial X_g/\partial\varepsilon = 0,\ \partial X_c/\partial\varepsilon = 0.$$

The heat- and mass-transfer coefficients α and β were found from the corresponding criterion equations

[4]. It was recommended in [5] to take the effective coefficient for the catalyst bed skeleton as 10 times the heat conductivity coefficient of air. The variation of the thermal properties of the gas phase (air, to a first approximation) with temperature was accounted for using nomographic data [6, 7]. The coefficient of heat transfer from the reactor to the environment was found using the data of [8]. The temperature dependence of the specific heat and of the heat effect of the reaction was neglected in the case under consideration.

The chosen system of equations was solved by the approximate numerical net-point method (finite-difference method). It was suggested in [5] to use an implicit scheme, with nonlinear constraints in a given temporal layer excluded (it is suggested to take nonlinear terms from the preceding temporal layer). The chosen system of differential equations (1)–(4) was solved by the explicit net-point method [9]. Heat effect of the reaction, Q_R = 1785 kJ mol^{-1} [10]; molecular weight of acetone, M = 58 g mol^{-1}. The molar volumes of the gases were used to calculate the diffusion coefficients [6].

A program in the Object Pascal language was developed in the visual-oriented programming environment Delphi version 6. The program calculates the distribution of temperature and degree of purification across the bed profile in a catalyst grain and in the flow for a given instant of time. The results of a calculation by the program for the time of passing the gas–air mixture in the range from 1 to 1200 s and delivered specific power of electric current ranging from 0.02 to 2.00 W cm^{-3} are presented in Figs. 1–3.

Figures 1a and 1b show the distributions of acetone conversion along the reactor length for different times of passing the gas–air mixture across the catalyst bed. The results of the simulation suggest that the process reaches the steady state 10–20 min after the beginning of reactor operation. This time becomes shorter as the delivered specific power increases. For example, for a delivered specific power of 2 W cm^{-3} in Fig. 1b, the distributions of acetone conversion along the reactor length for times of 600 and 1200 s virtually coincide, whereas for a delivered specific power of 0.02 W cm^{-3} in Fig. 1a, no coincidence is observed for the corresponding distributions. It can also be noted (Fig. 3) that, as the delivered specific power is raised from 0.02 to 1 W cm^{-3}, the temperature in the catalyst bed may increase from 25 to 200°C. This makes a contribution to the rise in the acetone conversion on the catalyst (Fig. 2).

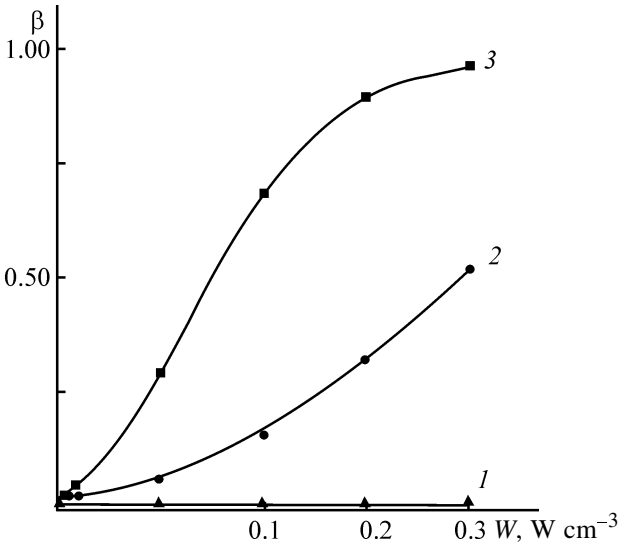

Fig. 2. Calculated conversion β of acetone vs. the delivered specific power W. Time of passing the gas–air mixture (s): (*1, 2*) 100 and (*3*) 600; the same for Fig. 3.

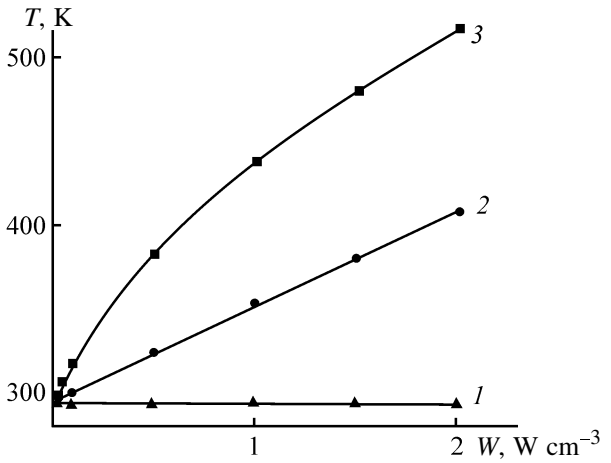

Fig. 3. Calculated dependence of the temperature T of the gas–air mixture at the exit from the catalyst bed on the delivered specific power W.

Points in Fig. 4 represent the experimental values of the acetone conversion in relation to the delivered specific power, which were obtained for a time of passing the gas–air mixture across the catalyst bed exceeding 1200 s, for catalyst samples with varied percentage content of copper oxide. These experimental values are in good agreement with the calculated dependences of the acetone conversion on a copper-containing catalyst on the delivered specific power for a time of 1200 s (solid lines).

The table lists the calculated rms deviations of the experimental values from those calculated in terms of the model. The strongest deviation is observed for catalyst samples containing copper(II) oxide at

Activation energy E_a and preexponential factor k_0 for catalyst samples, and the root-mean-square deviation S of experimental data from the calculation results

Parameter	CuO content, wt %				
	0	10	20	40	60
k_0, s^{-1}	0.3	3.0	13.0	283.0	686.0
E_a, kJ mol^{-1}	4.6	7.0	10.0	16.7	18.3
S, %	6.4	11.7	8.1	5.4	1.0

delivered specific power of electric current exceeding 2 W cm^{-3}. This is due to the fact that the air space in the catalyst bed is ionized under the experimental conditions at the given specific power of electric current. As a result, acetone can be oxidized under the given conditions not only on the catalyst surface, but also in the air space between catalyst grains, which is reflected on the degree of acetone oxidation [11].

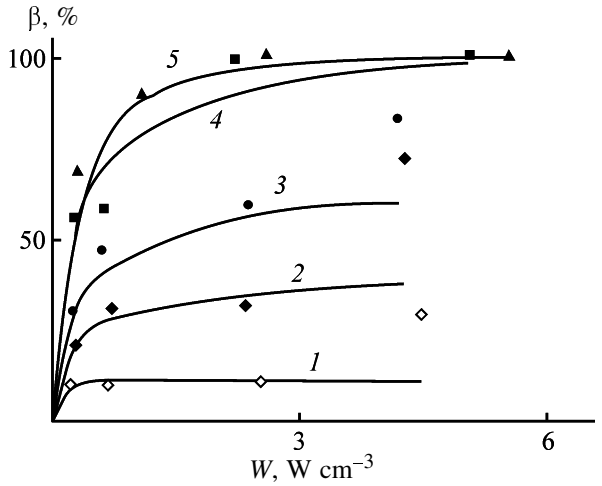

Fig. 4. Experimental (points) and calculated (lines) conversions β of acetone vs. the delivered specific power W of electric current. Content of CuO in the catalyst (wt %): (*1*) 0, (*2*) 10, (*3*) 20, (*4*) 40, and (*5*) 60; the same for Fig. 5.

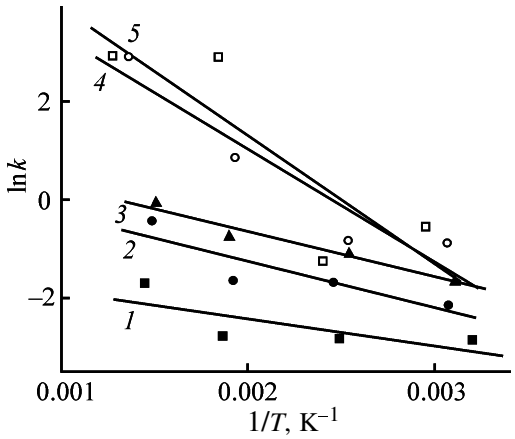

Fig. 5. Logarithm of the rate constant k vs. temperature T.

Figure 5 shows kinetic dependences calculated and plotted for catalyst samples with varied percentage content of copper oxide. The table lists the calculated kinetic parameters of the catalyst samples. The samples with a copper oxide content of less than 40% exhibit an activation energy lower than that for samples containing 40 and 60% CuO and a smaller preexponential factor. On the whole, it could be noted that the percentage of copper oxide introduced into a catalyst affects its behavior in acetone oxidation under the conditions of an applied electric field.

CONCLUSIONS

(1) The developed model of the reactor made it possible to describe how the system constituted by a catalyst bed, electric current, and gas–air mixture behaves with time.

(2) The mathematical model was used to determine the possibility of attainment of steady conditions in the oxidation of acetone, which is important for carrying out a kinetic study.

(3) The chosen mathematical model made it possible to calculate kinetic parameters of the catalyst samples synthesized.

Abstract—The solvent effect on the rate of the reaction of isoprene with maleic anhydride was studied; the total effect of the solvent polarity and cohesion energy density was revealed.

DOI: 10.1134/S1070427206010216

The Diels–Alder cycloaddition discovered in 1916 [1] is a route to valuable drugs, e.g., phencamphamine psychotropic agent, cyclothiazide diuretic, etc. [2]. The same mechanism is operative in dimerization of cyclopentadiene catalyzed by sulfuric acid with the formation of so-called Satdecanol, a raw material for production of valuable unsaturated polyesters, and in the reaction of cyclopentadiene with maleic anhydride, whose product is a raw material for production of various epoxy resins [3]. Although the rate of this reaction can vary depending on the structure of the reactants within the range covering several orders of magnitude [4], it is also affected by other factors: temperature, pressure, and solvent. Therefore, optimization of the reaction conditions, in particular, proper choice of solvent, is very important.

The kinetics of the Diels–Alder cycloaddition in various media was examined in numerous papers; many of them concern the reaction of dienes with maleic anhydride. The solvent effect on this reaction is so strong that the reaction rates in different solvents can differ by several orders of magnitude, and in some cases even different products can be obtained [5–8]. However, there is still no general concept accounting for the solvent effect on the kinetics of this reaction. Attempts to construct adequate one-parameter correlations of the rate constants of a Diels–Alder reaction with such solvent properties as cohesion energy density [9], polarity [10, 11], or Gutmann acceptor number AN [12] failed: with a relatively large set of solvents, numerous deviations from the suggested linear correlations were observed. Frish *et al.* [13] examined the possibility of correlating the kinetic data obtained for a series of reactions in different media using the concept of so-called corresponding states. According to this approach, the difference between the activation free energies of a process performed in two different media, determined from the logarithms of the corresponding reaction rates, will be proportional to the quotient from division of the difference of the critical temperatures of these solvents by the difference of their critical volumes. However, an attempt to correlate the data on the rate constants k of the reaction of maleic anhydride with isoprene in ten solvents using this concept failed also: the differences between the calculated and experimental $\log k$ values in some cases exceeded 50% [13]. The lack of a general correlation between the cycloaddition rate and any single characteristic of solvents suggests the complexity of solvation processes occurring in the system.

EXPERIMENTAL

It is generally appropriate to consider the solvent effect on physicochemical processes in terms of the linear free energy relationship taking into account various types of interaction, primarily specific and nonspecific solvation [14]:

$$\Delta G = \sum \Delta g_i. \quad (1)$$

Therefore, in this study, to correlate data on the solvent effect on the rate of addition of dienes to maleic anhydride, we used the Koppel–Palm equation [14] supplemented with additional terms taking into

account the solvent structure [15]:

$$\log k = a_0 + a_1\frac{n^2-1}{n^2+2} + a_2\frac{\varepsilon-1}{2\varepsilon+1} + a_3B + aE_T + a_5\delta^2 + a_6V_m, \quad (2)$$

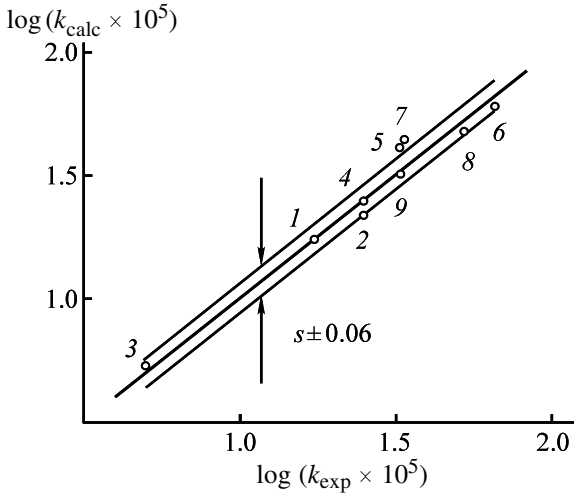
where n is the refractive index and ε, dielectric permittivity of solvents (parameters determining their polarizability and polarity and responsible for the nonspecific solvation of a substrate); B, Palm basicity [14] and E_T, Reichardt electrophilicity [6] (parameters determining the capability of a solvent for acid–base interactions, i.e., for specific solvation); δ^2, Hildebrand solubility parameter squared (parameter characterizing the cohesion energy of a solvent); and V_m, molar volume of solvents reflecting the possible effect of structural factors.

The solvent characteristics were taken from [14, 16, 17], and the calculation procedures, according to recommendations of the Group for Correlation Analysis in Chemistry at IUPAC [18].

The rates of cycloaddition of isoprene to maleic anhydride were determned in numerous studies [7, 9, 10, 13], but only in a few solvents. The most representative data set is given in [11]: The rate constants of the reaction of isoprene with maleic anhydride were determined in the range 0–100.3°C in ten solvents; for nine of them, all the characteristics required for calculation by Eq. (2) are available from the literature. The rate constants of the reaction at 30.3°C (reactant concentrations 0.5 M), taken from [11], are given in Table 1. Calculations with Eq. (2) show that these data are fitted by a six-parameter equation

$$\log(k\times10^5) = 8.82 + (3.13\pm0.78)f(n^2) + (7.89\pm1.79)f(\varepsilon) + (0.84\pm0.59)\times10^{-3}B - (0.34\pm0.08)E_T + (6.52\pm1.43)\times10^{-3}\delta^2 - (1.11\pm0.41)\times10^{-2}V_m. \quad (3)$$

Its multiple correlation coefficient, $R = 0.991$, meets the reliability criterion recommended in [18] ($R \geq 0.95$); the rms error s is ± 0.04. However, low coefficients r of pair correlation between $\log k$ and separate parameters, ranging from 0.4 to 0.7, do not allow us to assess directly the influence of these parameters on $\log k$. Therefore, in accordance with [14], the significance of particular terms of Eq. (3) was assessed by their alternate exclusion with construction of correlations with the remaining parameters and calculation of the corresponding coefficients R. If R decreases insignificantly upon exclusion of a parameter, this factor can be regarded as insignificant. Using this procedure, we found that the factors of basicity B ($R = 0.988$) and molar volume V_m ($R = 0.982$) are actually insignificant. The solvent effect on the reaction rate can be described with an acceptable accuracy by a four-parameter equation



$$\log(k\times10^5) = 4.19 + (3.72\pm1.07)f(n^2) + (3.85\pm1.12)f(\varepsilon) - (0.21\pm0.06)E_T + (6.14\pm1.38)\times10^{-3}\delta^2, \quad (4)$$

$$R = 0.981,\ s = \pm0.06.$$

Further exclusion of any of the remaining terms of Eq. (4) impairs the correlation more significantly: R decreases to approximately 0.95 or even 0.93 (with exclusion of δ^2). Nevertheless, according to the Fisher test, the three-parameter correlation taking into account the most significant factors (polarity, electrophilicity, cohesion energy density of solvents) is still adequate:

$$\log(k\times10^5) = 9.00 + (6.91\pm1.08)f(\varepsilon) - (0.37\pm0.06)E_T + (9.56\pm1.53)\times10^{-3}\delta^2, \quad (5)$$

$$R = 0.951,\ s = \pm0.10.$$

Correlation between the experimental [11] and calculated [Eq. (4)] logaritms of rate constants. Point nos. are solvent nos. in Table 1.

Thus, the solvent effect on the reaction rate is the sum of the favorable effects of the solvent self-association and nonspecific solvation of the reaction complex and negative effect of the capability of the solvent for electrophilic solvation. The latter effect is easy to understand: According to [5], the diene synthesis involving transfer of excess π electrons from a diene to a dienophile presumably occurs via charge-transfer complex. This assumption is supported by the frequently observed strong transient coloration of the reaction mixture. It is known that acid (in particular, tetrafluorophthalic) anhydrides form charge-transfer complexes with π-electron donors such as aromatic hydrocarbons [19]. Apparently, solvents capable of electrophilic solvation (having high E_T) can solvate the diene molecule. As a result, the concentration of the free diene decreases and the reaction decelerates because of competition between maleic anhydride and electrophilic solvent for the diene molecule.

Table 2. Experimental [11] rate constants k of the reaction of isoprene with maleic anhydride at 0, 60.3, and 100.3°C and the activation energies E_a

Solvent	$k \times 10^5$, l mol^{-1} s^{-1}, at indicated temperature, °C			E_a,* kcal mol^{-1}
	0	60.3	100.3	
Benzene	1.62	104	762	12.3
Anisole	2.59	166	1290	12.6
Isopropyl ether	–	43.8	411	14.2
Veratrole	–	215	–	12.7
Chlorobenzene	2.36	143	1220	12.6
m-Dichlorobenzene	–	230	–	12.5
o-Dichlorobenzene	7.62	367	2670	11.8
Benzonitrile	3.17	223	–	13.0
Nitrobenzene	4.89	292	2220	12.3
Nitromethane	3.09	210	1330	12.3

* The activation energies are given in kcal mol^{-1} in accordance with [11].

The log k values calculated by Eq. (4) and their deviations from the experimental data, $\Delta\log k = \log k_{calc} - \log k_{exp}$, are given in Table 1, and in the figure the $\log k_{calc}$ values are plotted vs. $\log k_{exp}$. As seen, almost all the $\Delta\log k$ values fall within the error corridor $s \pm 0.06$ or lie only slightly beyond it.

Dewar and Pyron [11] also determined the reaction rate constants at 60.3 (nine solvents), 0, and 100.3°C (seven solvents), and also the activation energies of the process. Their results are given in Table 2. Correlation of these data gave equations in which the coefficients at particular terms have the same sign as in Eq. (4) and only slightly differ in the absolute value.

At 0°C,

$$\log(k \times 10^5) = 6.80 + (6.48 \pm 0.81) f(\varepsilon) - (0.31 \pm 0.06) E_T + (7.11 \pm 1.57) \times 10^{-3} \delta^2, \quad (6)$$

$$R = 0.965, \; s = \pm 0.06;$$

at 60.3°C,

$$\log(k \times 10^5) = 8.53 + (6.02 \pm 0.74) f(\varepsilon) - (0.37 \pm 0.04) E_T + (7.95 \pm 1.04) \times 10^{-3} \delta^2, \quad (7)$$

$$R = 0.969, \; s = \pm 0.07;$$

and at 100.3°C,

$$\log(k \times 10^5) = 9.13 + (5.41 \pm 1.03) f(\varepsilon) - (0.29 \pm 0.06) E_T + (7.16 \pm 1.52) \times 10^{-3} \delta^2, \quad (8)$$

$$R = 0.934, \; s = \pm 0.09.$$

Since data for 0 and 100.3°C were obtained for a smaller number of solvents, the corresponding correlations are less reliable statistically. Nevertheless, we obtained excellent correlation coefficients for the six-parameter equation: 0°C, R = 0.998; 60.3°C, R = 0.988; and 100.3°C, R = 0.999. In all the three cases, three-parameter equations (6)–(8), $\log k = f(\varepsilon, E_T, \delta^2)$, are also sufficiently adequate.

In all the cases, further exclusion of any of the remaining parameters fully breaks the correlation (R

Table 3. Experimental [9] and calculated [Eq. (12)] logarithms of the rate constants of the reaction of isoprene with maleic anhydride in various solvents (relative to benzene)

Solvent	$[\log(k_{solv}/k_{C_6H_6})]_{exp}$	$[\log(k_{solv}/k_{C_6H_6})]_{calc}$	$\Delta\log(k_{solv}/k_{C_6H_6})$
Dipropyl ether	–0.7450	–0.7008	0.0442
Hexane	–0.5950	–0.7074	–0.1124
n-Butyl chloride	–0.4430	–0.3525	0.0905
Ethyl acetate	–0.3330	–0.3201	0.0129
Benzene	0.0000	0.1214	0.1214
m-Dichlorobenzene	0.1700	0.2077	0.0377
Chlorobenzene	0.1000	0.1808	0.0808
o-Dichlorobenzene	0.4800	0.2694	–0.2106
Anisole	0.0690	0.1172	0.0482
Nitrobenzene	0.4190	0.4275	0.0085
Dichloromethane	0.3160	0.1528	–0.1632
Nitromethane	0.4980	0.5400	0.0420

becomes as low as 0.5–0.6). At the same time, in accordance with the low rms deviation s, calculation by Eqs. (6)–(8) gives the $\log k$ values that only slightly differ from the experimental values. It is interesting that, with increasing temperature, the absolute term a_0 determining the reaction rate in the absence of solvation tends to increase (with a deviation at 30.3°C) and the coefficient at $f(\varepsilon)$ (i.e., the significance of the nonspecific solvation of the reaction complex) tends to decrease. The coefficients at E_T and δ^2 remain approximately constant. It should be noted here that a theoretical calculation by Eq. (8) for the same reaction in toluene gives $\log(k \times 10^5) = 2.96$, which is reasonably consistent with the experimental value $k = 600 \times 10^{-5}$ l mol^{-1} s^{-1} [$\log(k \times 10^5) \approx 2.78$] determined in [4] for the same solvent at 100°C. The deviation, $\Delta\log(k \times 10^5)$, is 0.18, i.e., it exceeds the rms error of Eq. (8), $s = \pm 0.09$, by a factor of only 2. This result confirms the validity of our calculations, the more so as the kinetic studies in [4, 11] were performed in different concentration ranges.

Correlation of the activation energies also gives consistent results. The solvent effect on E_a is adequately described by a six-parameter equation

$$E_a = -16.67 - (2.16 \pm 2.76)f(n^2) - (21.91 \pm 6.32)f(\varepsilon) - (2.15 \pm 2.08) \times 10^{-3}B + (1.05 \pm 0.29)E_T - (16.67 \pm 2.08) \times 10^{-3}\delta^2 + (0.65 \pm 0.01)V_m, \quad (9)$$

$$R = 0.974, \; s = \pm 0.27.$$

In Eq. (9), the signs at particular terms are opposite to those in the equations for $\log k$, i.e., the solvation factors favoring the reaction simultaneously decrease its activation barrier. In this case, also, the parameters B and n^2 are essentially insignificant. For adequate description of the solvent effects on E_a, it is sufficient to use a four-parameter equation

$$E_a = -1273 - (18.86 \pm 2.78)f(\varepsilon) + (0.90 \pm 0.10)E_T - (14.43 \pm 3.44) \times 10^{-3}\delta^2 + (3.93 \pm 0.93) \times 10^{-2}V_m, \quad (10)$$

$$R = 0.968, \; s = \pm 0.69.$$

However, in this case the molar volume is also significant: its exclusion actually breaks the correlation ($R = 0.910$).

Whereas in [11] the reaction was mainly studied in aromatic solvents, except aliphatic dipropyl ether and nitromethane, in [9] the aromatic and aliphatic solvents were equal in number. However, Wong and Eckert reported not the absolute rate constants but the logarithms of the rate constants of the reactions in solvents relative to benzene, for which the relative rate constant was taken as unity. These quantities, $\log(k_{solv}/k_{C_6H_6})$, are given in Table 3 and are correlated with Eq. (2). With the six-parameter equation, an excellent correlation was obtained, with the same signs at all the parameters as in Eq. (3) except the sign at the basicity parameter, which was shown to be insignificant:

$$\log(k_{solv}/k_{C_6H_6}) = 2.60 + (3.07 \pm 0.82)f(n^2) + (3.97 \pm 1.02)f(\varepsilon) - (0.69 \pm 0.28) \times 10^{-3}B - (0.13 \pm 0.04)E_T + (3.01 \pm 0.51) \times 10^{-3}\delta^2 - (8.91 \pm 1.90)V_m, \quad (11)$$

$$R = 0.989, \; s = \pm 0.06.$$

In this case, also, the parameter B can be excluded:

$$\log(k_{solv}/k_{C_6H_6}) = 2.58 + (3.72 \pm 0.96) f(n^2)$$
$$+ (3.78 \pm 1.27) f(\varepsilon) - (0.13 \pm 0.05) E_T + (2.96 \pm 0.63) \times 10^{-3} \delta^2$$
$$- (1.03 \pm 0.22) \times 10^{-3} V_m, \quad (12)$$
$$R = 0.983, \; s = \pm 0.08.$$

However, in contrast to the previous case, here the parameters of the electrophilic solvation and solvent polarity are also insignificant. Their exclusion decreases R to 0.970, whereas the exclusion of the molar volume decreases the correlation coefficient more significantly, to 0.950. This difference may be cuased by different nature of solvents included in this set. Below we give a three-parameter equation adequately describing the data in Table 3:

$$\log(k_{solv}/k_{C_6H_6}) = 1.68 + (5.77 \pm 0.89) f(n^2)$$
$$+ (1.75 \pm 0.46) \times 10^{-3} \delta^2 - (0.56 \pm 0.21) \times 10^{-2} V_m, \quad (13)$$
$$R = 0.989, \; s = \pm 0.06.$$

The $\log(k_{solv}/k_{C_6H_6})$ values calculated by this equation and their deviation from the experimental values are also given in Table 3.

CONCLUSIONS

(1) The dependence of the rate of cycloaddition of isoprene to maleic anhydride on the solvent properties can be adequately described only by multiparameter equations taking into account various solvation processes.

(2) The capability of a solvent for self-association and nonspecific solvation favors the cycloaddition, whereas the capability for electrophilic solvation exerts a negative effect.

Received October 20, 2005

Abstract—A spectrophotometric method for determination of furfural and pentoses based on their color reaction with sulfuric acid in the presence of mercury(II) was developed.

DOI: 10.1134/S1070427206010228

Furfural (furan-2-carbaldehyde) is a heterocyclic aldehyde exhibiting a series of valuable chemical properties. Furfural is readily formed from pentoses under heating in an acid medium. This reaction can also be used for spectrophotometric determination of pentoses.

Analytical determination of furfural and carbohydrates is an important problem. A number of chromatographic [1, 2], spectrophotometric (IR [3], UV [4], visible [5, 6]), and polarographic [7] methods were developed recently.

Use of UV spectroscopy for determination of furfural is based on its light absorption at 272–278 nm [8, 9]. However, as applied to aqueous process solutions, this procedure is often complicated by the presence of other substances also absorbing light in this region. The selectivity with respect to furfural can be elevated by the chemical reaction forming products with higher extinction coefficients.

It was found that the reaction of furfural and pentoses with sulfuric acid in the presence of mercury(II) acetate gives unidentified products with a very intense absorption band at 238 nm (Figs. 1a, 1b). The absorption spectrum of the product of the xylose reaction with sulfuric acid in the presence of Hg(II) completely coincides with that of the product of arabinose reaction.

EXPERIMENTAL

Chemically pure grade *L*-(+)-arabinose, glacial acetic acid, and mercury(II) acetate, analytically pure grade *D*-xylose, and pure grade concentrated sulfuric

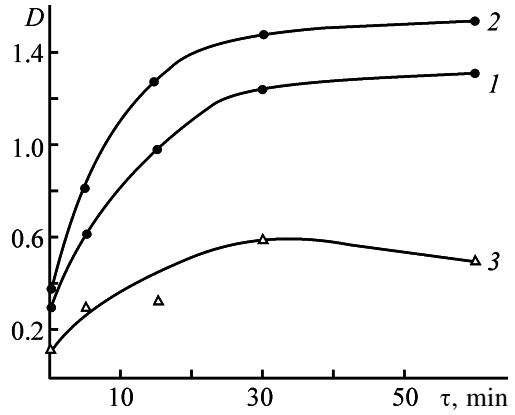

Fig. 2. Solution optical density D at 238 nm as a function of the reaction time τ. (*1*) *L*-(+)-Arabinose, (*2*) *D*-xylose, and (*3*) furfural; the same for Fig. 3.

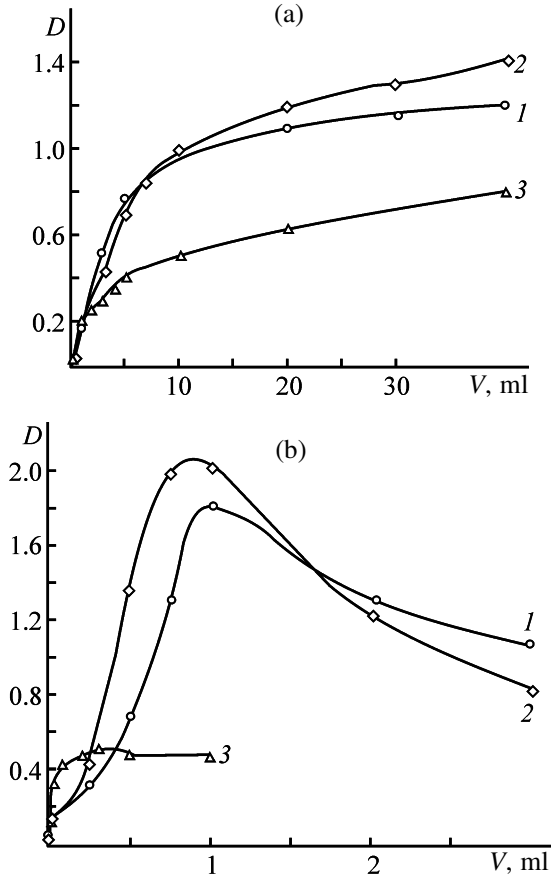

Fig. 3. Optical density D at 238 nm of the reaction product as a function of the consumption V (a) mercury(II) acetate and (b) concentrated sulfuric acid.

acid were used. Furfural was twice distilled; the 160–161°C fraction was taken.

Aqueous solution of mercury(II) acetate was prepared by dissolution of 4.00 g of the salt in a 200-ml volumetric flask with addition of 5 ml of glacial acetic acid to suppress hydrolysis.

To perform a photometric reaction, an approximately 100-mg weighed portion of furfural was dissolved in water in a 25-ml volumetric flask (solution no. 1). In the case of the reaction with pentoses, similar solution was prepared in a 100-ml volumetric flask by dissolving in water an approximately 1-g pentose sample (weighed with a 0.0001-g error). Then, aliquots of a solution no. 1 and a solution of mercury(II) acetate were introduced into a 50-ml volumetric flask, and water was added to the mark (solution no. 2). After that, 1 ml of solution no. 2 and a definite volume of concentrated sulfuric acid were mixed in a test tube. The test tube was heated for a definite time on a boiling water bath, the reaction mixture was transferred into a 100-ml volumetric flask, and water was added to the mark.

The absorption spectra were recorded on a Specord M40 spectrophotometer within the 48 000–30 000 cm^{-1} range relative to water. The optical density of solutions at 238 nm was measured on an SF-46 spectrophotometer relative to water.

The influence of the time of the photometric reaction was studied at a consumption of solutions of Hg(II) acetate of 5 ml and H_2SO_4 of 0.3 ml and heating time of 0, 5, 15, 30, and 60 min.

With increasing the reaction time, the absorption spectra substantially change. The intensity of the furfural band at 278 nm decreases, whereas the optical density at 238 nm increases. The dependences of D_{238} on reaction time are shown in Fig. 2.

As seen, 30-min heating is optimal for the photometric reaction.

The influence of the Hg(II) acetate concentration was studied with addition of 1, 2, 3, 4, 5, 10, 20, and 40 ml of the Hg(II) acetate solution and 0.3 ml of H_2SO_4; the reaction time was 30 min. The dependence of D_{238} on the Hg(II) acetate concentration is shown in Fig. 3a.

As seen, the solution optical density increases with increase in the volume of the added Hg(II) acetate solution from 1 to 5 ml and then decreases. Therefore, the optimal volume of the mercury(II) acetate solution is 5 ml.

The influence of H_2SO_4 amount on optical density of the solutions for photometry was studied with addition of 5 ml of Hg(II) acetate and heating for 30 min; 0.03, 0.1, 0.2, 0.3, 0.5, 1, 2, or 3 ml of concentrated H_2SO_4 was added (Fig. 3b). As seen, sulfuric acid

strongly affects the optical density (by a factor of 6–8 after addition of one drop of sulfuric acid). The optical density passes through a maximum at 0.3–1 ml of sulfuric acid.

Thus, addition of 0.3–1 ml of concentrated sulfuric acid into a photometric solution is optimal in the analytical method developed.

To construct the calibration plots and assess the reproducibility of the results, we performed experiments under the optimal conditions found: amount of mercury(II) acetate solution 5 ml, that of H_2SO_4 0.3 ml, and heating time 30 min. Three replicate analyses were performed. From the data obtained, we calculated the coefficients of the calibration diagrams and the pair correlation coefficients using the least-squares method [10] (Table 1).

The dependences of the optical densities on furfural or pentose concentrations are linear, which is confirmed by high values of the pair correlation coefficient R^2. The optical density of the product of the photometric reaction obeys the Bouguer–Lambert–Beer law. The calibration diagrams for xylose and arabinose are virtually the same (Table 2).

The error of the concentration determination was estimated using furfural and pentose solutions with

the known concentrations. The optical density of each solution was measured three times (Table 3).

CONCLUSION

A new highly sensitive photometric method was developed for determination of furfural and pentoses with high precision and reproducibility.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A ^{13}C and ^{1}H NMR Analysis of Perfumes

V. P. Talzi

Institute of Problems of Hydrocarbon Processing, Siberian Division, Russian Academy of Sciences, Omsk, Russia

Received September 28, 2005

Abstract—Composition of a series of formulations used in Russia for production of various perfumes, among them car air fresheners, was studied by ^{13}C and ^{1}H NMR. The main components were identified, approximate compositions of several perfumes were determined, and spectral data are given. These spectral data can be used for prompt analysis for composition of commercial odorants with the aim of monitoring their quality and hygienic characteristics.

DOI: 10.1134/S107042720601023X

In Russia, the range of perfume goods was extended in the past few years. In production of many air fresheners, deodorants, and eau de Colognes, imported mixtures of very limited set of chemicals, not much complicated in composition, are used. Data on the chemical composition of the perfumes can be useful for monitoring of their quality and analysis of their hygienic characteristics.

In some cases, a prompt analysis of aromatizers (odorants) can be performed by ^{13}C NMR on the condition that a part of experiments on the analysis of the chemicals available in Russia has been already performed and the signals in the ^{13}C NMR spectra of these chemicals were assigned to the specific components. It is just this part of experiments that we performed based on analysis of the ^{13}C NMR spectra of approximately 30 commercial concentrated fragrance compounds used for production of perfume goods, among them car air fresheners. The composition of odorants can be quantitatively estimated from their ^{1}H NMR spectra by the common procedures [1] on the condition that the compounds entering into their composition give signals not overlapping with signals of other components. These signals were found for the most of the compounds frequently entering into the composition of odorants (Table 1), which allowed determination of approximate formulation of several commercial perfumes.

Table 2 presents the approximate composition of several commercial odorants obtained with consideration of data listed in Table 1. The numbers of compounds whose composition seems to be determined most reliably are underlined.

Although the modern software for simulation of NMR spectra on the basis of a given structure is available and efficient, it gives the calculated spectra practically completely coinciding with the experimental spectra only if the corresponding spectrum from the catalog (atlas) is present in the inner database of the software. Otherwise, large differences in the chemical shifts of signals in actual and calculated spectra can take place, which is usually of minor importance for the spectrum of an individual compound but can substantially complicate the analysis of a mixture. Therefore, the data on actual NMR spectra of components of commercial odorants, summarized in this paper, is extremely useful for determination of their composition by NMR spectroscopy. The NMR spectra of the perfumes in hand usually contain signals of tens of different substances, and therefore, their qualitative and quantitative analysis based solely on NMR spectra seems to be laborious and unreliable; however, the following factors simplify the problem.

As mentioned above, the components of odorants in hand are usually fairly simple in structure and well-known organic substances from a limited set. Data on these substances are available from reference books [2].

For four samples, we succeeded in receiving the producer formulas, which allowed us, in spite of serious discrepancies between the declared and actual compositions, to identify several important and frequently occurring components of odorants and, hence, to simplify the analysis of mixtures.

Successful analysis of perfumes is favored by the fact that some samples contain only three or four

* The most typical signals are underlined; sign (+) corresponds to the signals of carbon atoms with even number of protons (including zero).

** Used for quantitative estimations of concentrations of components; the number of protons N_i entering into formula (1) is shown in parentheses.

components. In addition, the compound odor, sometimes reflected in its commercial name, can give additional information on its composition.

The components of odorants identified by ^{13}C NMR are listed below. The corresponding signals in the ^{13}C NMR spectra are presented in Table 1 without assignment, otherwise it would be too large. In identification of components the signals were assigned as usual, considering their multiplicity without proton decoupling, which gives information on the number of protons directly bonded to carbon atoms in the compound being analyzed. With the above-mentioned well-known software for simulation of NMR spectra, structural formulas of the compounds, and the list of the signals corresponding to this compound (Table 1), as a rule, assignment of signals becomes a simple procedure. In some cases, Table 1 does not contain all signals of the spectra since a part of these signals is not observed due to overlapping with the signals of other components or because of other reasons. These components are included in Table 1 only with consideration of additional data obtained from the sanitary certificates mentioned above.

In Table 1 we also give the corresponding absorption ranges not overlapping with other signals, when these signals were identified in the ^{1}H NMR spectra of odorants; from their integral intensities, the quantitative content of one or other component can be estimated. The number of protons in the molecule of the component contributing into absorption in the above ranges of the spectrum is also given. This number should be known for determination of the weight fraction of the component by the formula

$$c_i = I_i M_i / N_i, \quad (1)$$

where c_i is the weight fraction of component i; M_i is its molecular weight; I_i is the integral intensity of the

^{1}H NMR signal chosen for determination of the concentration of the ith component; and N_i is the number of protons in the component molecule, contributing to the intensity I_i.

The following data on the composition of odorants are grouped according to chemical classification of components or their destination. Typically, the majority of compounds and, in some cases, practically all compounds entering into the composition of odorants can be identified from the NMR spectra. Only in one case of 30, attempts to determine the chemical composition failed, since components of this formulation are likely not individual chemical compounds but are, for example, mixtures of terpenylcyclohexanols of the type of Sandalidol fragrance compound [2].

Solvents. The solvents, diethyl phthalate 1 and dipropylene glycol 2 [1], most frequently used in production of odorants, can be easily identified, since these chemicals and their NMR spectra are available. Many of the perfume samples contain both substances 1 and 2 or at least one of these substances. In some samples, the total concentration of solvents 1 and 2 exceeds 80%. Only three samples of odorants contain, instead of compounds 1 and 2, other solvents, 2-[2-(hydroxyethoxy)ethoxy]ethanol 3, diphenyl ether (diphenyl oxide) 4, and isopropyl ether of unidentified fatty acid, e.g., isopropyl laurate or stearate 5. In one of the samples, a part of substance 1 is substituted by dimethyl phthalate 6. In several samples, along with compounds 1 and 2, additional unidentified solvents, possibly acetates of polyols, such as ethylene glycol and glycerol, were used. Identification of the solvents is usually simplified by higher intensity of their

signals in the NMR spectra. In preparation of a series of perfume goods, the odorants in hand are dissolved in 70% aqueous ethanol.

Aromatic esters, alcohols, and aldehydes. It is well known that the widely used components of perfumes are odor fixers having a weak balsamic odor, such as, e.g., esters of salicylic and benzoic acids [2]. We found that benzyl salicylate 7 is contained in a significant concentration (more than 30%) in several samples of the odorants studied. In the ^{13}C NMR spectra of almost all the perfumes, none of the signals of compound 7 overlap with the signals of the other components. Futhermore, compound 7 is mentioned in the sanitary certificates for odorants. It was reported that salicylates in the composition of perfumes play also the role of stabilizers inhibiting polymerization and oxidation of olefin and aldehyde components [2].

Benzyl benzoate 8 was added into some compositions instead of 7. This compound corresponds to the most downfield signal in the ^{1}H NMR spectra of odorants, except the signal of aldehyde protons at approximately 8.0 ppm.

In a series of esters of aromatic carboxylic acids used in perfumery, methyl 2-aminobenzoate 9 was found in a small concentration in one of the odorants. Weak ^{13}C NMR signals assigned to 9 coincide with those in the calculated spectrum. In the corresponding ^{1}H NMR spectrum there are signals coinciding with signals of 9 given in atlas [3]. According to reference data, esters of cinnamic acid (cinnamates) are widely used in perfumes [2]. Low-intensity doublets characteristic of olefin protons (7.5 and 6.3 ppm) and the corresponding signals of carbon atoms (153 and 117 ppm) were observed in the spectra of two samples. According to published real spectra [3, 4] these ^{13}C signals correspond to cinnamates, but we failed to assign them to specific cinnamates.

The other artificial derivative of cinnamic acid with jasmine odor, 2-hexyl-3-phenylpropenal 10, not occurring in the nature, was found in a half of the samples studied, in some cases, in significant concentration (approximately 10%) and in mixtures consisting of only three or four components, so that its identity is beyond question. The concentration of aldehyde 10 is the simplest to estimate from the intensity of the signal of its aldehyde proton (δ 9.4 ppm) or triplet of allyl methylene group (δ 2.5 ppm). Hereinafter, we use for fragrance compounds the commonly accepted nonsystematic or trade names given in reference books [2].

Several samples of odorants contain 3-phenylethanol 11, benzyl acetate 12, and coumarin 13, which are well-known perfume chemicals produced on a mass scale [2]. The signals assigned to compounds 11–13, considering data given in sanitary certificates, coincide with those in the corresponding NMR spectra given in reference books [3, 4].

In the sanitary certificate, for two of four odorants the presence of lilialdehyde [3-(4-*tert*-butylphenyl)-2-methylpropanal] 14 (approximately 3%) in their composition was documented. Contrary to aldehyde 10, unambiguously identified by all signals in its spectrum, only two or three ^{13}C NMR signals, not overlapping with the signals of other components, can be assigned to 14 (Table 1).

One of the odorants named "Cherry" contains 25% benzaldehyde 15, whose odor is similar to odor of cherry pits.

Derivatives of phenols. Classic fragrance compounds vanillin and eugenol belong to derivatives of phenols. Vanillin 16 and its homolog with more intensive odor, ethyl vanillin 17 not occurring in the nature, are present in many odorants. In several samples, these components are major, which is reflected in their names, e.g., "Vanilla," so that identification of 16 and 17 presents no problems.

The presence of approximately 1% isoeugenol 18, occurring in the nature in essential oil of eugenol basil, was reliably detected in only two samples. Due to low concentration of this component, its identification required more prolonged analysis than in the case of 16 and 17, in spite of indications on the presence of isoeugenol in several odorants.

The presence of another widely known fragrance from the same series, heliotropin (piperonal) 19, occurring in small amounts (approximately 1%) in several odorants, is simpler to prove by NMR than in the case of 18, due to its highly characteristic NMR spectrum. In particular, the signals of its methylene group with chemical shifts of 102 (^{13}C NMR) and 6.0 ppm (^{1}H NMR) are very specific. In one of the sanitary certificates for an odorant, the presence of a heliotropin derivative with extremely strong flower odor, piperonylpropanal or pional 20, not occurring in the nature, was indicated. Since this odorant was much less concentrated in fragrance components than it was mentioned in the certificate, we failed to record most of the signals of compound 20 other than the signals most typical for the "heliotropin" fragment of its molecule (Table 1).

Aliphatic alcohols, aldehydes, and esters. Among ordinary aliphatic alcohols, aldehydes, and esters,

numerous compounds used as components of perfumes are well known. However, in the available sanitary certificates for odorants, only *n*-butanol and C_{12} fraction of aldehydes are indicated; however, the presence of the latter was not confirmed by the NMR spectra. When the concentration of these components in odorants is low, identification and, the more so, qualitative estimation of these components are difficult due to the closeness of the corresponding signals in the NMR spectra to the signals of compounds of other types. Considering typical spectra of individual compounds, we were able to identify more or less reliably propyl acetate 21, isoamyl acetate 22, and *n*-amyl butyrate 23 in composition of only some samples (Table 1).

Compounds with musk or ambergris odor. Other components of odorants are artificial compounds with musk or ambergris odor, which improve the scent and have also properties to fix odor [2]. Successful identification of these compounds is favored by the presence of the corresponding data in the sanitary certificates. The most frequently occurring and reliably identified compounds of this group in odorants are Galaxolide 24 and Ambralux 25. The ^{13}C NMR spectrum of 24 (Table 1) contains more than ten characteristic signals not overlapping with other signals in the range 8–150 ppm, whose assignment is unambiguous if the stimulated spectrum and spectra of several samples of odorants containing 24 in various concentrations and combinations are available. In the ^{1}H NMR spectrum of 24, there are two characteristic upfield shifted signals of aromatic protons, which allows quantitative determination of the content of this compound.

The ^{13}C NMR spectrum of 25 also contains up to 10 signals in the range 20–217 ppm; however, assignment of these signals is difficult since this substance is a mixture of compounds with various positions of the C=C double bond [2]. These signals were assigned to Ambralux since, according to the sanitary certificate and actually (according to the spectrum), one of the odorants consists by half of compound 25 with the concentrations of other components not exceeding several percents. The signals conclusively corresponding to 25 are listed in Table 1; however, we failed to assign unambiguously these signals to the specific carbon atoms in its molecules. It is difficult to estimate quantitatively the concentration of 25 based on the ^{1}H NMR spectra, since there are no characteristic signals not overlapping with signals of other components of odorants. The singlet of acetyl methyl group at approximately 2 ppm can be used for quantitative estimation of its content if this signal can be reliably assigned to 25 rather than to other acetyl derivatives giving signals in this range.

In one of the samples, instead of 25, unidentified ketone denoted as 26 was used apparently for the same purpose. In spite of the fact that compound 26 was not identified, the signals in the ^{13}C NMR spectrum of the corresponding sample can be assigned to this compound with confidence, since this compound, judging from the intensities of the corresponding signals in the spectrum of the perfume, is in significantly higher concentration than the other components.

Several odorants contain the fourth and the last component from the considered series of compounds that were present in the samples studied, musk ketone 27. This compound is indicated in the sanitary certificate for one of the odorants; the certified composition of this odorant agrees well with the spectral data. This fact, taking into account the other spectra, allowed two or three signals in the ^{13}C NMR spectra of odorants to be unambiguously assigned to 27 (Table 1). In this case, the most characteristic is the signal with a chemical shift of approximately 125 ppm, assigned to aromatic carbon atoms bonded to methyl groups, which, contrary to other carbon atoms of the benzene ring, has a satisfactory intensity (Overhauser effect) and never overlaps with other signals.

Terpenes and terpenoids. Some terpenes, mainly the corresponding alcohols, aldehydes, and ketones (terpenoids), form the most important group of fragrances.

In some samples of odorants, limonene 28 (diterpene), having lemon odor, appears practically as a solvent (concentration higher than 50%), so that its identification and estimation of its concentration from the NMR spectra present no problems (Table 1). The other, no less common, terpene with coniferous odor, forming the basis of turpentine oil, α-pinene 29, was identified from several weak characteristic signals in the ^{13}C MNR spectrum of one of the samples considering data of the sanitary certificate.

Linalool 30, linalyl acetate 31, and dihydromyrcenol 32 (Table 1) are the most abundant and reliably determined qualitatively and quantitatively terpenoids with citric odors. The other well-known fragrances belonging to this class, geraniol 33 with rose odor, citronellol 34, and citronellal 35, can be identified from their complete ^{13}C NMR spectra only in some compounds. More commonly, in the ^{13}C NMR spectra of odorants, only two or three signals belonging to compounds 33–35 can be assigned more or less reli-

ably to terpenoids against the background of signals of other components. It is diffucult to determine the characteristic signals in the ^{1}H NMR spectra of 33–35. Only in some cases these signals can be distinguished among signals of other components (Table 1).

One of the most valuable fragrances is hydroxycitronellal 36 with lime-blossom odor [2]. Taking into account data of the sanitary certificate, compound 36 was unambiguously identified by ^{13}C NMR from all signals of its spectrum (Table 1).

One of the most well-known and available cyclic terpenoids, borneol or isoborneol 37 (particular isomer was not established), having coniferous odor, was identified in two samples. The identification involved no problems, since in one of the odorants with dominant coniferous odor the concentration of 37 exceeds 50% (see the intensities of the corresponding signals in the ^{13}C NMR spectrum). The other well-known cyclic terpinoid, α-terpineol, was tentatively identified in small amount in one of the samples from several characteristic ^{13}C NMR signals (Table 1).

Specific fragrance compounds. Many of the above substances are well-known, find wide use, and are produced on the industrial scale. In two formulations for production of air fresheners, we were able to identify reliably by the ^{1}H and ^{13}C NMR the main components governing their odor, having no natural analogs but included in the reference book [2], ethyl 2,3-epoxy-3-methyl-3-phenylpropionate 39 (strawberry odor) and 2-*tert*-butylcyclohexyl acetate 40 (fruit odor). Successful identification of 39 and 40 was favored by their significant concentration and hence high intensity of the corresponding signals in the NMR spectra. The agreement of the fragments of the odorant spectra assigned to 39 and 40 and the calculated ^{13}C and ^{1}H NMR spectra is sufficient for identification with confidence, the more so as compound 39 is a component of "Strawberry" formulation and compound 40 is a component of "Golden apple" formulation.

EXPERIMENTAL

Samples of commercial odorants produced by various foreign and Russian companies were placed at our disposal by a private company producing car air fresheners.

The ^{1}H and ^{13}C NMR spectra of the samples studied were recorded on a Bruker ACP-200P spectrometer by the standard procedure.

Abstract—The influence exerted on the process of phenolphthalein coloration by the electrophysical conditions under which its pressure treatment is carried out was studied.

DOI: 10.1134/S1070427206010241

A change in the color of various substances in the course of chemical transformations is a well-known phenomenon. A particular place among compounds of this kind is occupied by chemical indicators, i.e., substances that change their color depending on the charge state of the environment. For example, colorless phenolphthalein, a known acid–base indicator, turns pink when the pH of the medium changes from neutral to alkaline. This is due to cleavage of the benzofuran ring to give a quinoid structure:

All the known processes of indicator coloration occur in the liquid phase under ordinary conditions. At the same time, it was reported in [1] that phenolphthalein turns pink when subjected to plastic deformation at a pressure of 5 GPa in a high-pressure apparatus constituted by Bridgman anvils. In this case, no absorption bands characteristic of the quinoid structure could be observed in the IR spectra of samples colored under pressure; the coloration of the sample was preserved at room temperature, but disappeared upon dissolution.

A study of the behavior of phenolphthalein subjected to plastic deformation under a high pressure was continued in [2] and the pressure dependence of the flow stress was obtained in the pressure range 0.5–5 GPa in the form of two virtually linear portions. The slope of the plot with respect to the ordinate axis decreased at a pressure of 1.2–1.5 GPa, so that a bend was formed. The presence of such a bend in the baric dependence was attributed to a polymorphic transition, even though an X-ray diffraction analysis of samples treated both below and above the bend-point pressure demonstrated that, in both cases, the substance was in an X-ray amorphous state upon a pressure treatment. At the same time, an analysis of baric dependences of the flow stress carried out in [3] for numerous organic compounds of varied structure suggested that bends in dependences of this kind reflect electronic processes that occur in various substances in the case of plastic deformation under pressure.

A vast body of experimental data obtained in studies of various aspects of the behavior of solids subjected to plastic deformation under a high pressure indicates that their electrical properties significantly change and the electric charge formed in the course of pressure treatment strongly affects the way in which various properties of the materials being treated are formed. For example, the dielectric constant of various low-molecular-weight organic compounds may increase at a pressure of up to 3–4 GPa by a factor of 2.5–3 [4]; salts and oxides of metals may dissociate under pressure treatment [5]; a high pressure stimulates injection of electrons from the metal of the anvils into pressure-treated insulators [6]; a directed

transport of carriers captured by structural defects, the so-called deformation current, is recorded in the course of plastic deformation [7]; melting parameters of polyethylene and its acoustical characteristics vary with the electrophysical conditions of pressure treatment [8, 9]; presence of charge captured by structural defects in the course of plastic deformation of polymeric samples under a high pressure has been recorded in the form of thermally stimulated currents [10].

In view of the aforesaid, it was of interest to study in more detail the behavior of phenolphthalein directly in the course of plastic deformation under a high pressure and also to analyze some properties of this material after its treatment under a high pressure, keeping in mind the fact that a thin layer of an insulator, phenolphthalein, is in close contact with the metal of which the anvils are made.

EXPERIMENTAL

Phenolphthalein of analytically pure grade was chosen for the study. The samples were treated under pressures of up to 2 GPa on anvils made of CrVMn hardened steel and a hard alloy of the VK6 brand; the diameter of the working surfaces of the anvils was 20 mm. In measurements of deformation currents under pressure, one of the anvils was made of a VK6 hard alloy, and the other, of CrVMn steel [7]. The deformation currents were measured with an M-95 needle microammeter. The coloration of phenolphthalein samples as a result of plastic deformation under pressure was recorded visually. Calorimetric studies were performed on an MAC-2M microcalorimeter at temperatures in the range 25–160°C at a sample heating rate of 8 deg min^{-1}; the mass of the samples was 20 mg. The X-ray diffraction analysis of the samples was carried out on a DRON-2 diffractometer with a monochromated copper radiation in the reflection configuration.

Already the first experiments with phenolphthalein demonstrated that the coloration process has a threshold nature: the colored form of phenolphthalein cannot be obtained at pressures of up to 1–1.1 GPa, with intense coloration of the sample appearing only upon its treatment at pressures of 1.5 GPa and more. Thus, phenolphthalein is not colored before the electronic transition, which is recorded in baric dependences of the flow stress as a bend, and intense coloration appears only at pressures exceeding the bend pressure.

When deformed under pressure, phenolphthalein is colored pink-orange uniformly over the entire working surface of the anvils. At the same time, in the case of a chemical reaction, the degree of conversion depends on the degree of deformation, and the coloration intensity of the samples markedly increases on passing from the central part of the anvils, where the deformations are at a minimum, to the peripheral zone, where they are the strongest.

The coloration of pressure-treated phenolphthalein samples is preserved at room temperature for several days, but disappears completely upon dissolution or upon heating to 70–80°C for 10–15 min. The decolorized substance retains ability to respond to changes in the charge state of the environment: addition of pressure-colored and decolorized phenolphthalein to aqueous solutions of alkalis yielded a standard color reaction.

Thus, the coloration of phenolphthalein in plastic deformation under pressure is a totally reversible process.

The materials of which the anvils were made (CrVMn steel and VK6 hard alloy) differ in the electron work function: for steel, it is lower than that for the hard alloy. This circumstance was reflected in that, at the same pressure and same rotation angles of the anvils, the coloration of samples treated on steel anvils was markedly more intense than that in the case of anvils made of the hard alloy. The result obtained indicates that injected charges can affect the process in which the coloration of an organic substance changes in plastic deformation under pressure without formation of a new product. Thus, the modification of the electrophysical conditions experienced by a sample in the course of its pressure treatment, which is associated with a change in the injecting capacity of the anvils, strongly affects the process in which the coloration varies.

All the results described above were obtained on grounded anvils. In this case, the electric charges whose formation is possible in the course of pressure treatment could leak away from the samples. The simplest way to modify the electrophysical conditions in substance treatment was to insulate the high-pressure cell from the mass of the press, i.e., to prevent leakage of electric charges.

In those cases when phenolphthalein samples were deformed under a pressure of 2 GPa on insulated anvils, the coloration of the samples was considerably less intense than that with grounded anvils.

The difference in coloration intensity in pressure treatment of samples on anvils made of different materials, as well as that on insulated and grounded anvils, point to a strong influence exerted on the

phenolphthalein coloration by the electrophysical conditions in which pressure-induced deformation is carried out.

It is well known that heating of preliminarily polarized polymers activates various kinds of molecular mobility and charge carriers are released from structural traps. In the process, an electric current, the so-called thermally stimulated depolarization current, flows through the samples.

As already mentioned, high pressure strongly intensifies the injection of electrons from the metal of the anvils into insulators subjected to pressure treatment. According to [10], part of electrons injected into a sample can be captured by structural defects and, thus, may remain in the samples after pressure is relieved. On heating such samples in the temperature range 25–130°C, an electric current flowed through the samples. This current was attributed to motion of electrons injected from the metal of the anvils and captured by structural defects of a polymeric sample.

Experiments with samples colored by deformation under a pressure of 2 GPa demonstrated that, on heating to 130°C, an electric current varying around 10^{-8} A flowed through the samples.

The following two processes can be distinguished in pressure treatment of phenolphthalein samples: (1) formation of structural defects on which charges can be localized and (2) injection of electrons from the metal of the anvils into the material of a sample. According to [11], the first of these is virtually pressure-independent in the pressure range 1–6 GPa, being determined by the extent of deformation. The second is enhanced as the pressure at which samples are treated is raised. It should also be noted that, in the course of plastic deformation, part of the structural defects leave the sample, but, at the same time, new defects are formed, i.e., the system is in a dynamic equilibrium. Thus, if the samples are first subjected to plastic deformation under pressure, which leads to coloration, and then pressure is relieved, with the number of injected electrons thereby reduced, but the deformation of the already colored samples is not terminated, i.e., the number of structural defects is maintained constant, then the following will occur. The structural defects with captured electrons will be removed from a sample and the amount of charge in the samples will be considerably smaller than that in the case when the rotation of the anvils is first stopped and then the pressure is relieved.

In the case of phenolphthalein treatment by the "deformation with pressure relieved" scheme, the material of a sample remained uncolored and the thermally stimulated currents were 10^{-11}–10^{-12} A.

As regards the stimulation of the electron injection, the action of only a high pressure of up to 6 GPa is considerably stronger than that of a pressure of 2 GPa. However, solely compression of samples under a pressure of up to 6 GPa without shear deformation caused by anvil rotation yields a very weak pinkish coloration. This may be due to plastic deformation of phenolphthalein crystals in local regions in compaction of a substance under the action of a high pressure.

The coloration of phenolphthalein may change in the presence of an electric charge not only under the action of a high pressure, but also in ordinary conditions. For example, the starting phenolphthalein was wetted with water (5–10 wt %), a pellet was compacted, and it was placed between two nickel electrodes across which a voltage of 45 V was applied. In 5–7 h, the samples started to acquire a color, to become yellow in 15–20 h. The difference in coloration between the samples colored under pressure and in an electrolytic cell is only apparent. The substance obtained after a high-pressure treatment is in the compacted state, but, on being ground in a mortar, it turns yellow-beige.

In the course of plastic deformation, structural defects with captured electrons move within a sample. According to [7], an electric current flows through the samples in pressure-induced deformation of various metals and metal–polymer composites. It was of interest in this context to study the transport of deformation currents in phenolphthalein samples in various modes of pressure treatment. Attempts to measure deformation currents at 0.3–0.5–1 GPa failed, and these currents could be only recorded at a pressure of 1.5 GPa.

At 2 GPa, a current was recorded immediately after the anvil rotation commenced. As the degree of deformation became higher, the current steadily increased to reach the limiting value of $(2–5) \times 10^{-7}$ A at anvil rotation angles of 80°–100°. As the degree of deformation increased further, the current changed only slightly. After the deformation was terminated, the current decreased to zero in several seconds. In the second and subsequent cycles of deformation, the above pattern was totally reproduced, but the deformation current was independent of the direction of anvil rotation.

The direction in which the deformation currents flowed in phenolphthalein samples coincided with that in metal samples subjected to a similar treatment. This

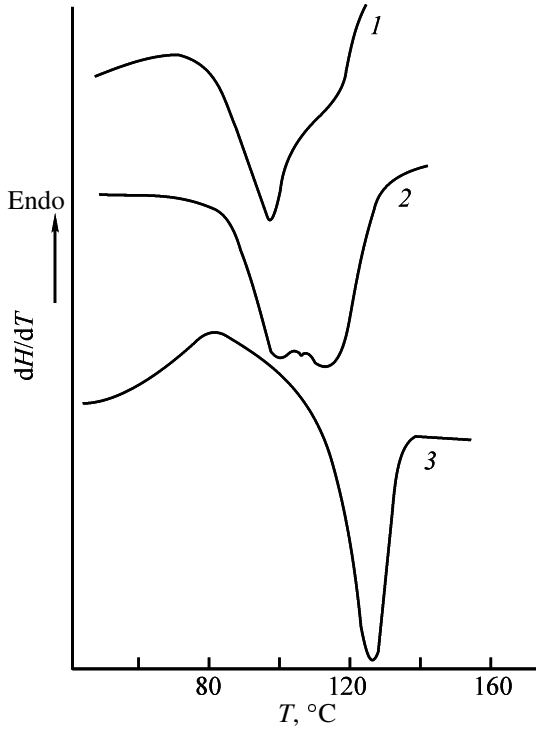

Fig. 1. Thermograms of phenolphthalein samples treated at a pressure of 2 GPa and anvil rotation angles of (*1*) 10, (*2*) 50, and (*3*) 400°C. (*T*) Temperature.

indicates that, as in the case of phenolphthalein, the current is carried by electrons that are, in all probability, injected from the anvils, rather than being intrinsic.

After deformation at 2 GPa, the pressure was reduced to 1 GPa. When relieving the pressure, a current pulse was recorded, whose direction was the opposite to that of the deformation current measured at a pressure of 2 GPa. The reverse current recorded when relieving the pressure strongly depended on the rate at which the pressure was reduced: when this rate was low, no noticeable current surges could be detected. At the same time, when the pressure was relieved rapidly, the current surge could be as large as 10–15% of the deformation current recorded directly in the course of a pressure treatment. In deformation at 1 GPa of a sample colored in treatment at 2 GPa, the maximum current strength was 2.5–3 times smaller than that at 2 GPa, the current flow was unstable, and the current decreased to zero as the extent of deformation increased.

After such a sequence of experimental procedures, the samples were either weakly colored or colorless. Repeated deformation of these samples at 2 GPa gave rise to deformation currents that virtually coincided in direction and magnitude with the current measured at the beginning of such a measurement cycle and led to appearance of a coloration.

The coloration of phenolphthalein and the appearance of deformation currents have a threshold nature. The threshold pressure coincides with the pressure at which a bend is recorded in the baric dependence of the flow pressure.

Together with the electrical measurements performed, of interest was a study by differential scanning calorimetry and X-ray diffraction analysis of specific structural features of phenolphthalein samples deformed at various pressures.

No thermal effects could be recorded in the range from room temperature to 160°C in thermograms of samples of the starting phenolphthalein; a similar situation occurred in the case of samples subjected to plastic deformation at a pressure of 1 GPa or lower.

Solely compression of samples to a pressure of 2 GPa did not lead to any changes in the thermograms. At the same time, rotation of the anvils by 10° at the same pressure led to weak coloration of the samples and to appearance of a low-intensity (enthalpy 4–5 J g^{-1}) bimodal exothermic peak (Fig. 1). As the rotation angle of the anvils was raised to 50°, the intensity of the exothermic process increased to 12–14 J g^{-1}, the ratio of peak intensities changed, but their position on the temperature scale remained constant. The thermograms of samples subjected to deformation at anvil rotation angles of 400° and more strongly differed from those described above: they contained two peaks, a broad endothermic peak at 60–70°C (enthalpy 30–40 J g^{-1}) and an exothermic peak at 127°C (enthalpy 60–70 J g^{-1}). As seen from Fig. 1, the exo- and endothermic peaks appreciably overlap; therefore, these enthalpies are very approximate. Repeated heating of the same samples was not accompanied by any thermal effects.

The coloration of a phenolphthalein sample colored in deformation under a pressure of 2 GPa became substantially less intense after four days; simultaneously, the intensity of the endothermic peak decreased to 10–12 J g^{-1}, and that of the exothermic peak, to 30 J g^{-1}. After coloration of the samples at a pressure of 2 GPa and subsequent treatment by the "deformation with pressure relieved" scheme, the intensity of the endothermic peak was 1.5 J g^{-1}, and that of the exothermic peak, 20 J g^{-1}.

Figure 2 shows an X-ray diffraction pattern of the starting phenolphthalein, which contains a set of narrow peaks of various intensities. Deformation at pressures of 0.7 and 2 GPa led to disintegration of

* Sample treated by the "deformation with pressure relieved" scheme.

the crystal structure of phenolphthalein: in both cases, amorphous halos were present in the X-ray diffraction patterns, with weakly pronounced traces of the highest-intensity lines of phenolphthalein discernible on their background.

Heating of the amorphized samples at 90–100°C for 15–20 min led to decoloration of colored samples and had virtually no effect on the crystal structure of the substance. At the same time, storage of the samples for two months at room temperature led to appearance of broad low-intensity lines shifted to smaller diffraction angles, compared with the lines of the starting phenolphthalein, in the X-ray diffraction patterns.

The X-ray diffraction technique was used to study phenolphthalein samples that were first deformed at a pressure of 2 GPa and then treated by the "deformation with pressure relieved" scheme. After a treatment of this kind, the X-ray diffraction patterns of the samples contained, on the background of an amorphous halo, well-pronounced but broadened lines of phenolphthalein shifted to smaller angles (see table, Fig. 2). This indicates that the amorphized substance can restore its crystal structure under the action of plastic deformations. This effect is presumably based on vibrational excitation of molecules in plastic deformation.

To confirm the conclusion that crystallization of amorphous low-molecular-weight substances in plastic deformation is possible, samples of a pressure-treated phenolphthalein were subjected, after their amorphous state was recorded by X-ray diffraction analysis, to treatment by the "deformation with pressure relieved" scheme, with the initial treatment carried out at 1.5–1–0.5 GPa. In all cases, the crystal structure of phenolphthalein was identified by the X-ray diffraction patterns.

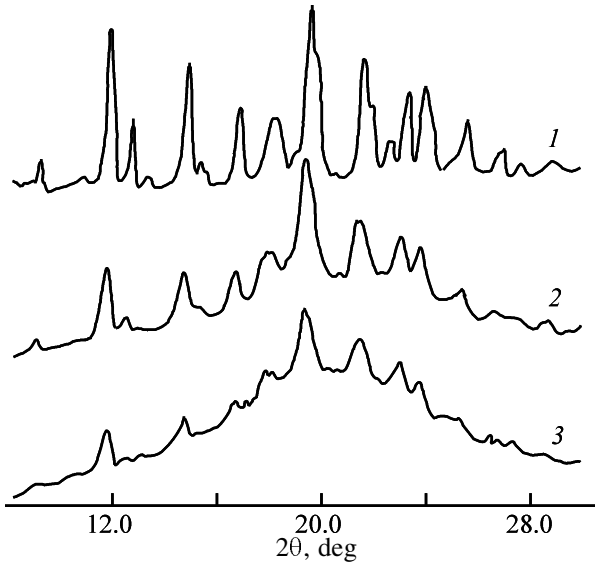

Fig. 2. X-ray diffraction patterns of (*1*) starting phenolphthalein, (*2*) that deformed at a pressure of 2 GPa and then treated by the "deformation with pressure relieved" scheme, and (*3*) amorphous phenolphthalein treated by the "deformation with pressure relieved" scheme. (2θ) Bragg angle.

The possibility that amorphous metallic alloys can crystallize in the course of plastic deformation under a high pressure was reported in [12, 13] on the basis of calorimetric and X-ray diffraction data.

CONCLUSIONS

(1) The coloration of phenolphthalein upon a high-pressure treatment does not involve formation of new products and is totally reversible.

(2) The coloration process has a threshold nature with respect to pressure, is independent of the state of the crystal structure, and correlates with changes in the electronic structure of the substance, caused by the joint action of high pressure and shear deformations.

(3) The coloration of phenolphthalein is strongly affected by charges generated in the samples in the course of their pressure treatment. These charges manifest themselves as deformation currents in deformation and as thermally stimulated currents upon completion of the pressure treatment. The most probable reason for the appearance of charged states in the samples is capture by structural defects of electrons injected into a sample from the metal of the anvil.

(4) The heat effects observed in the thermograms of samples subjected to pressure treatment indicate that relaxation processes occur in the electronic subsystem of the solid.

(5) The crystal structure of phenolphthalein, amorphized under the action of a high pressure, can be restored not only by heating of the samples, but also by their plastic deformation at low pressures.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of *p*-Cresol with Ozone in Acetic Anhydride

A. A. Sedykh and A. G. Galstyan

Received July 26, 2005

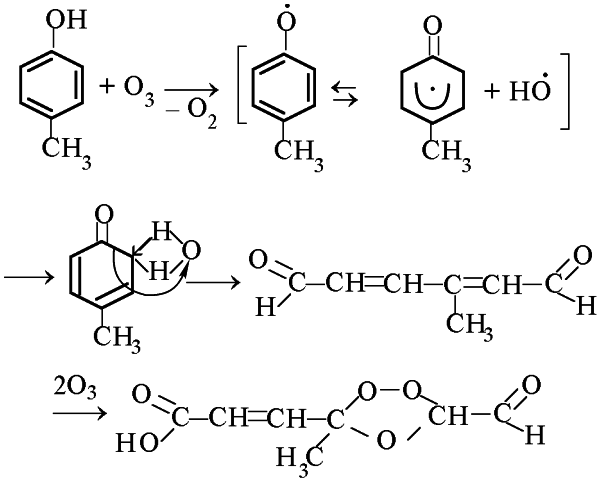
Abstract—Preparation of aromatic alcohols and aldehydes by oxidation of *p*-cresol with ozone in acetic anhydride in the presence of sulfuric acid, manganese acetate, and potassium bromide was studied. The optimal oxidation conditions were determined.

DOI: 10.1134/S1070427206010253

p-Cresol (*p*-Cr) oxidation products, *p*-hydroxybenzyl alcohol (*p*-HBA) and *p*-hydroxybenzaldehyde (*p*-HBAd), are used in production of synthetic drugs and products of fine organic synthesis [1]. These products are prepared by oxidation of *p*-cresol with sodium dichromate or chromic anhydride in concentrated sulfuric acid [2]. The disadvantages of this procedure are formation of large amounts of difficult to utilize toxic waste and relatively low selectivity. To overcome these disadvantages, environmentally clean oxidizing agent, ozone, can be used.

Ozone is used to oxidize methylbenzenes in acetic acid to the corresponding benzenecarboxylic acids [3]. The possible intermediates, aromatic alcohols and aldehydes, are readily oxidized under these conditions and cannot be isolated.

To decelerate the oxidation at the step of formation of *p*-HBA and *p*-HBAd and to develop a low-waste technology of their production, we studied the reaction of *p*-Cr with ozone in acetic anhydride in the presence of a strong mineral acid. Under these conditions, acetic anhydride is a strong acylating agent and reacts with the intermediate reaction products to form the acetate and acylal derivatives which are more resistant to oxidation [4].



It is known [5] that *p*-Cr readily reacts with ozone in the liquid phase with opening of the aromatic ring to form peroxides ($k = 2 \times 10^3$ l mol^{-1} s^{-1}, CCl_4, 293 K). In acetic acid, one *p*-Cr molecule is consumed per three ozone molecules, which suggests that this process occurs in two steps by Scheme 1 [6].

In the first step, ozone attacks the O–H bond to form the phenoxy radical. Then hydroxy radical is added to phenoxy radical with opening of the aromatic ring. The product reacts with two ozone molecules to form the aliphatic peroxide.

To stabilize the aromatic ring of *p*-cresol, its OH group was acylated. Weighed portions of *p*-Cr and acetic anhydride were loaded in a flask. A mixture of acetic anhydride and phosphoric acid taken in a 10 : 1 weight ratio was added in small portions at 5°C. The reaction mixture was poured into water after 20 min. The oil was separated, washed with a 5% solution of sodium hydroxide and water, and distilled in a vacuum. The yield of *p*-cresyl acetate (*p*-CrA) was 80%.

An ozone–air mixture with an ozone concentration of 4×10^{-4} M was bubbled through a *p*-CrA solution in acetic anhydride. The kinetic experiments showed that the reactivity of *p*-CrA with respect to ozone substantially decreases: the rate constant of this reaction at 20°C is $k = 1.3$ l mol^{-1} s^{-1}. This fact and the stoichiometric coefficient of ozone in this reaction (one ozone molecule per substrate molecule) confirm the change in the oxidation mechanism. In this case, in accordance with the classical concept on ozonolysis of

Scheme 1

alkylbenzenes [6], ozone attacks the aromatic ring to form peroxide monomers by Scheme 2:

Scheme 2

Under these conditions, virtually no aromatic alcohol and aldehyde are formed. In the presence of acylation catalyst (mineral acid such as sulfuric and phosphoric acid) in the reaction mixture, *p*-HBA and *p*-HBAd do not decompose and are converted into *p*-acetoxybenzyl acetate (*p*-ABA) and *p*-acetoxybenzylidene diacetate (*p*-ABDA) having lower reactivity with respect to ozone. However, under these conditions the total yield of the aromatic products is still as low as 10% (Fig. 1). It should be noted that the selectivity of the oxidation of the methyl group is independent of the type of the mineral acid but the reaction is accelerated in going from phosphoric to sulfuric acid (Fig. 2).

The selectivity of oxidation of the side chain increases in the presence of an oxidation catalyst, variable-valence metal salt [3]. We studied the oxidation of *p*-CrA catalyzed by manganese(II) acetate (Table 1). This reaction is fast and yields mainly *p*-ABA. The oxidation is complete in 1 h at the manganese(II) acetate concentration of 0.18 M and temperature of 5°C. The selectivity of oxidation of the methyl group is 77%; the yield of *p*-ABA and *p*-ABDA is 56 and 21%, respectively (Table 1).

After the oxidation completion, the reaction mixture was diluted with a fivefold volume of water and then was extracted with ether. The organic layer was distilled under atmospheric pressure to remove the ether and then in a vacuum (10 mm Hg) to remove the unchanged *p*-CrA. Th residue was refluxed in 5% NaOH. The resulting *p*-HBA was extracted with ether; the yield based on reacted *p*-CrA was 51%.

The methyl group is selectively oxidized in two steps with ozone in the presence of manganese(II) acetate. Under these conditions, ozone reacts mainly with Mn^{2+} {reaction (1), $k_1 = 4.7 \times 10^3$ [7]; $k_{AcOC_6H_4CH_3\text{-}p+O_3} = 1.3$ l mol^{-1} s^{-1}, our data} to form reactive Mn^{3+} species which rapidly and selectively oxidize the methyl group of *p*-CrA [reaction (2)]:

$$Mn^{2+} + O_3 + H^+ \rightarrow Mn^{3+} + HO^\bullet + O_2, \quad (1)$$

$$AcOC_6H_4CH_3\text{-}p + Mn^{3+} \rightarrow AcOC_6H_4CH_2^\bullet\text{-}p + Mn^{2+} + H^+. \quad (2)$$

For reaction (1) to occur, ozone should be continuously fed into the system. When the ozone supply is stopped, the process is decelerated up to its complete cessation. This fact additionally confirms formation of reactive catalytic species by reaction (1). Since the concentration of molecular oxygen under the experi-

mental conditions is higher by one and half orders of magnitude than that of ozone, the benzyl radical formed by reaction (2) reacts mainly with molecular oxygen by reaction (3) to form the peroxy radical which is converted into *p*-ABA by reactions (4)–(6):

$$AcOC_6H_4CH_2^{\bullet}\text{-}p + O_2 \longrightarrow AcOC_6H_4CH_2O_2^{\bullet}\text{-}p, \quad (3)$$

$$AcOC_6H_4CH_2O_2^{\bullet}\text{-}p + O_3 \longrightarrow AcOC_6H_4CH_2O^{\bullet}\text{-}p + 2O_2, \quad (4)$$

$$AcOC_6H_4CH_2O^{\bullet}\text{-}p + Mn^{2+} \rightarrow AcOC_6H_4CH_2O^{-}\text{-}p + Mn^{3+}, \quad (5)$$

$$AcOC_6H_4CH_2O^{-}\text{-}p + Ac_2O + H^{+} \rightarrow AcOC_6H_4CH_2OAc\text{-}p + AcOH. \quad (6)$$

Introduction of potassium bromide in the system increases the conversion and selectivity of catalytic oxidation of the methyl group of *p*-CrA to 84%. The major reaction product is *p*-ABDA. Its yield reaches 67% (Table 2).

After the reaction completion, the reaction mixture was poured into a glass beaker filled by two thirds with finely divided ice and then was diluted to 100 ml with cold water. The mixture was vigorously stirred until the oil solidified. The solid product was filtered off, washed with cold water, and dried. Concentrated HCl (20 ml), water (20 ml) and alcohol (4 ml) were added to crude *p*-ABDA. The mixture was refluxed with stirring for 1 h. The reaction mixture was cooled, and *p*-HBAd precipitate was filtered off. The yield based on *p*-CrA was 62%.

Potassium bromide reacts with manganese(II) acetate catalyst to form $Mn^{2+}Br^{\bullet}$ which is more reactive than Mn^{3+}:

$$Mn^{2+} + Br^{-} \rightleftarrows Mn^{2+}Br^{-}, \quad (7)$$

$$Mn^{2+}Br^{-} + O_3 \rightarrow Mn^{2+}Br^{\bullet} + HO^{\bullet} + O_2. \quad (8)$$

$Mn^{2+}Br^{\bullet}$ oxidizes the methyl group of *p*-ABA by the following scheme:

$$AcOC_6H_4CH_2OAc\text{-}p + Mn^{2+}Br^{\cdot} \rightarrow AcOC_6H_4C^{\bullet}HOAc\text{-}p + Mn^{2+} + Br^{-} + H^{+}, \quad (9)$$

$$AcOC_6H_4C^{\bullet}HOAc\text{-}p + O_2 \rightarrow AcOC_6H_4C(OO^{\bullet})HOAc\text{-}p, \quad (10)$$

$$AcOC_6H_4C(OO^{\bullet})HOAc\text{-}p + O_3 \rightarrow AcOC_6H_4C(O^{\bullet})HOAc\text{-}p + 2O_2, \quad (11)$$

Table 1. Yield of the products of oxidation of the methyl group in *p*-CrA at 5°C and various concentration of $Mn(OAc)_2$. $[p\text{-Cr}]_0 = 0.4$, $[H_2SO_4]_0 = 1.2$, $[O_3]_0 = 4 \times 10^{-4}$ M; $\tau = 1$ h

$[Mn(OAc)_2]_0$, M	Yield, %	
	p-ABA	*p*-ABDA
0.05	30.1	8.7
0.10	42.4	12.5
0.14	51.3	17.2
0.18	56.1	21.3
0.20	54.2	20.1

Table 2. Yield of the oxidation products of the methyl group in *p*-CrA at 5°C and various KBr concentrations. $[p\text{-Cr}]_0 = 0.4$, $[Mn(OAc)_2]_0 = 0.18$, $[H_2SO_4]_0 = 1.2$, $[O_3]_0 = 4 \times 10^{-4}$ M; $\tau = 50$ min

$[KBr]_0$, M	Yield, %	
	p-ABA	*p*-ABDA
0.02	40.2	39.8
0.06	24.2	51.9
0.08	19.3	60.3
0.10	17.2	67.1
0.12	17.1	66.3

$$AcOC_6H_4C(O^{\bullet})HOAc\text{-}p + Mn^{2+}Br^{-} \rightarrow AcOC_6H_4C(O^{-})HOAc\text{-}p + Mn^{2+}Br^{\bullet}, \quad (12)$$

$$AcOC_6H_4C(O^{-})HOAc\text{-}p + Ac_2O + H^{+} \rightarrow AcOC_6H_4CH(OAc)_2\text{-}p + AcOH. \quad (13)$$

The increase in the oxidative conversion of *p*-CrA in the presence of potassium bromide is due to accumulation of reactive complex $Mn^{2+}Br^{\bullet}$ in the system. Oxidation of *p*-ABA in the presence of this complex is faster than that in the presence of Mn^{3+} [9].

EXPERIMENTAL

Analytically pure grade acetic anhydride and manganese(II) acetate were used as received. Crystalline *p*-Cr was recrystallized repeatedly from water.

The experiments were performed in a glass column with a porous partition. Acetic anhydride (10 ml), *p*-Cr (0.4 M), appropriate mineral acid (1.2 M), and a weighed portion of the catalyst were placed in the

column. The column was thermostated and an ozone–air mixture (ozone concentration 4×10^{-4} M) was passed through at a flow rate of 30 l h^{-1} under the steady operation conditions of the ozonizer. The ozone concentration in the gas phase was determined spectrophotometrically by the absorption in the range 254–290 nm.

The oxidation products were identified and their concentration in the solution was determined by gas–liquid chromatography on an LKhM-80 chromatograph with a flame ionization detector using a 2 m × 4 mm column packed with Chromaton N-AW. The stationary phase was SE-30 in the 5% amount of the support weight. The analysis was performed under the following conditions: vaporizer temperature 250°C; thermostat temperature 180°C; flow rate of the carrier gas (nitrogen) 1.8, hydrogen 1.8, and air 18 l h^{-1}. *p*-Nitrochlorobenzene was used as the internal reference.

CONCLUSION

p-Cresol was oxidized with ozone in acetic anhydride in the presence of mineral acid, manganese(II) acetate, and potassium bromide as catalysts. In the presence of manganese(II) acetate, the reaction can be stopped at the step of formation of *p*-hydroxybenzyl alcohol in the form of the corresponding diacetate (yield 56%). Introduction of potassium bromide into the catalytic system allows preparation of *p*-hydroxybenzaldehyde in the form of triacetate in a 67% yield.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Low-Molecular-Weight Copolymers of *N*-Vinylpyrrolidone with 2-Hydroxyethyl Methacrylate and of Polymeric Oxacillin Esters Derived from Them

M. V. Solovskii, A. M. Korchagin, E. B. Tarabukina, E. N. Vlasova, A. A. Shpyrkov, and A. I. Amirova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received October 10, 2005

Abstract—The radical copolymerization of *N*-vinylpyrrolidone with 2-hydroxyethyl methacrylate in 2-propanol at 60°C, initiated by azobis(isobutyronitrile) and inhibited by mercaptoethanol or terminated after a short period, was studied. The low-molecular-weight copolymers obtained were used to prepare new polymeric forms of Oxacillin antibiotic. The chemical uniformity, composition, and antimicrobial activity of the new derivatives were studied, and the rate of their hydrolysis in saline (pH 7.3) and glycine buffer (pH 2.0) was determined.

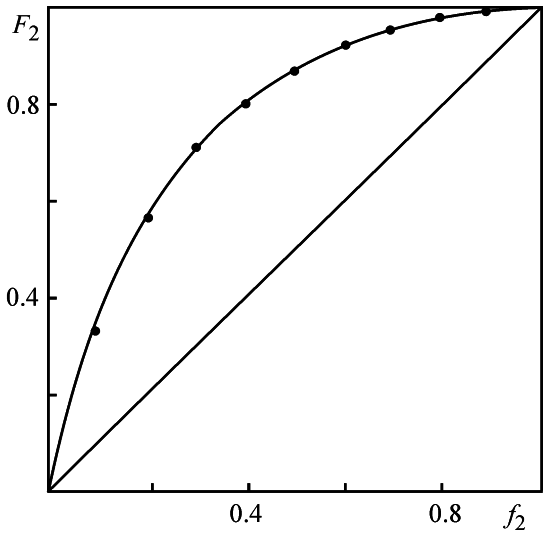
DOI: 10.1134/S1070427206010265

In the development of polymeric carriers based on *N*-vinylpyrrolidone (VP) for biologically active substances (BASs) [1], much promise is shown by copolymers of VP with 2-hydroxyethyl methacrylate (HEMA), which are hydrophilic, nontoxic, and biocompatible with a living body.

Previously [2] we studied the copolymerization of VP (M_1) with HEMA (M_2) and determined the compositions and molecular weights of the resulting copolymers. The copolymerization constants obtained, $r_1 = 0.29 \pm 0.02$ and $r_2 = 6.68 \pm 0.34$, showed that HEMA is considerably more active comonomer than VP. As a result, the calculated running composition of the copolymer is enriched in HEMA units at any composition of the starting monomer mixture (Fig. 1). This results in formation of copolymers of nonuniform composition. More compositionally uniform copolymers are formed only in copolymerization of monomer mixtures enriched in VP. The molecular weight (MW) of the resulting VP–HEMA copolymers, 50000–90000 Da, exceeded the limiting MW of synthetic non-biodegradable polymers (40000 Da) [3] passing through kidneys.

The goal of this study was to prepare low-molecular-weight (MW = 20000–30000 Da) VP–HEMA copolymers and to examine the possibility of their use as new polymeric BAS carriers.

To obtain low-molecular-weight copolymers, we performed the copolymerization of VP with HEMA in 2-propanol, initiated by azobis(isobutyronitrile) (AIBN), in the presence of a chain-terminating agent, mercaptoethanol, added in an amount of 0.1–0.2 wt % relative to the sum of the comonomers, or terminated the copolymerization after a short period. The conditions of the synthesis of low-molecular-weight VP–



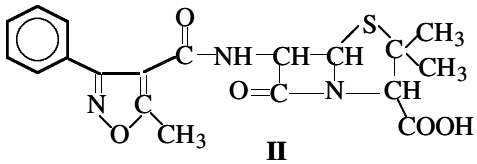


Fig. 1. Running composition of VP (M_1)–HEMA (M_2) copolymers as a function of the composition of the starting monomer mixture: (f_2) mole fraction of HEMA in the starting mixture and (F_2) mole fraction of HEMA units in the VP–HEMA copolymer.

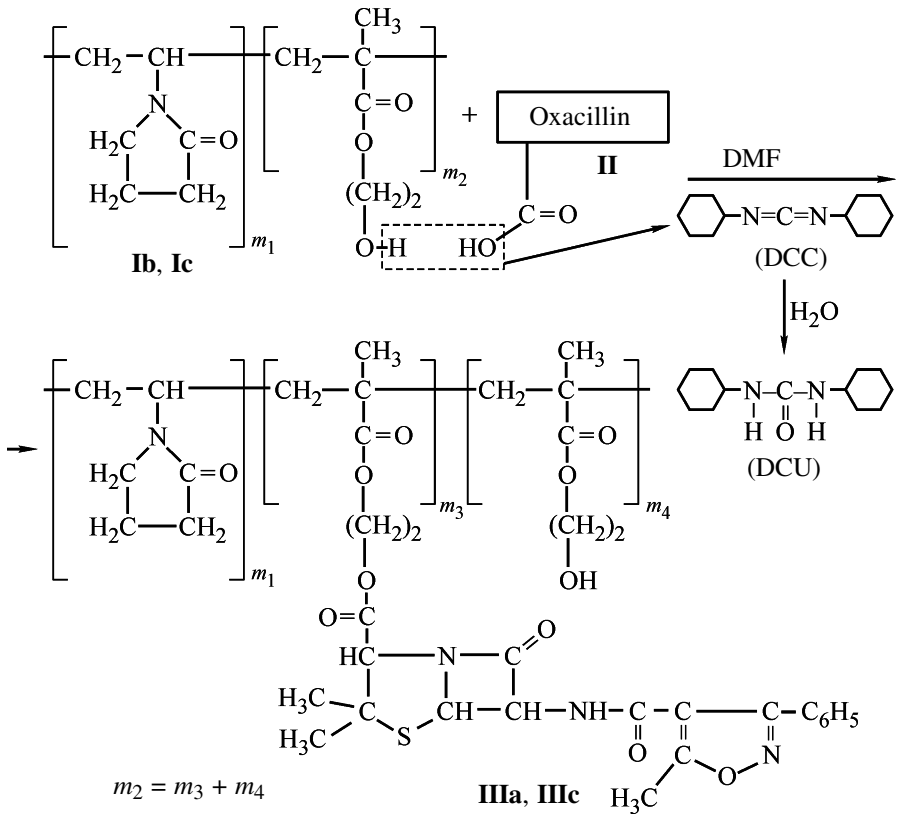
HEMA copolymers **I** and their characteristics (compositions, diffusion coefficients D, sedimentation coefficients S_0, intrinsic viscosities, molecular weights M_{SD}) are given in Table 1. It is seen that, under these conditions, low-molecular-weight (M_{SD} = 16000–31000 Da) VP–HEMA copolymers are obtained in 53–65% yield. With an increase in the mercaptoethanol content in the starting mixture, the yield and MW of the resulting copolymer decrease, which is apparently associated with an increase in the chain termination rate. Copolymers **Ia**–**Ic** are enriched in HEMA units relative to the composition of the starting monomer mixture. This effect becomes more pronounced with a decrease in the polymer yield. Copolymers **Ib** and **Ic** are readily soluble in water and contain a large amount (25.8–29.4 mol %) of hydroxyl-containing HEMA units, which allows their use for modifying Oxacillin antibiotic.



Oxacillin **II** is a semisynthetic penicillin [4] which is effective against penicillinase-forming staphylococci, acid-resistant, and nontoxic; it is widely used in clinical practice in the form of sodium salt:

II

However, the major drawback of Oxacillin is its short therapeutic effect. To maintain the therapeutic concentration of Oxacillin in blood, it should be administered every 4 h. To develop polymeric forms of Oxacillin of prolonged effect, the antibiotic was modified with copolymers **Ib** and **Ic**.

Condensation of Oxacillin with VP–HEMA copolymers **Ib** and **Ic** was performed in DMF at 0–5°C in the presence of a condensing agent, N,N'-dicyclohexylcarbodiimide (DCC). In so doing, the antibiotic was linked to the polymeric carrier by an ester bond:

The evidence of the reaction was formation of an abundant precipitate of the by-product, dicyclohexylurea (DCU).

By gel filtration (Sephadex G-50 [5]) we confirmed the chemical uniformity of condensation products **IIIa** and **IIIb** and the absence of free Oxacillin impurities.

Table 1. Copolymerization of VP with HEMA in 2-propanol at 60°C and properties of copolymers **I** ([AIBN] = 4.5 wt %, $[M_1^0] : [M_2^0]$ molar ratio 80 : 20)

Starting monomer mixture, wt %		Copolymerization time, h	Copolymer	Yield, %	N, %	m_2, mol %	$[\eta]$, dl g^{-1}, 25°C, DMF	$D \times 10^7$, cm^2 s^{-1}	$S_0 \times 10^{13}$, Sv	M_{SD}, Da

The structure of Oxacillin polyesters **IIIa** and **IIIb** was confirmed by UV and IR spectroscopy and also by quantitative iodometric analysis for penicillins [6]. As seen from Figs. 2 and 3, in the UV spectra of aqueous solutions of Oxacillin sodium salt and polymeric Oxacillin ester **IIIa** there is a shoulder at 230–250 nm, absent in the spectrum of an aqueous solution of the starting polymer **Ic**. This fact confirms the presence of Oxacillin in **IIIa** and allows estimation of the Oxacillin content in the product. Figure 4 shows the IR spectra of VP–HEMA copolymer **Ic** and polymeric Oxacillin ester **IIIa** derived from it. It is seen that a new strong band at about 750 cm^{-1}, absent in the spectrum of **Ic** and belonging to bending vibrations of the –CH= groups of the benzene ring in the Oxacillin molecule, appears in the spectrum of **IIIa**. The stretching vibration band of the ester C=O groups at about 1720 cm^{-1} in the spectrum of **IIIa** is stronger than in the spectrum of **Ic** owing to addition of Oxacillin to **Ic** through an ester bond. Finally, the methyl stretching vibration band at about 2900 cm^{-1} in the IR spectrum of **IIIa** is broadened relative to the corresponding band in the spectrum of **Ic**. This fact is also indicative of the incorporation of Oxacillin containing three CH_3 groups into the polymeric product.

The compositions of polymeric Oxacillin esters **IIIa** and **IIIb** are given in Table 2. It is seen that the Oxacillin content determined spectrophotometrically and iodometrically coincides within the analytical error. This means that Oxacillin is not inactivated in the course of the DCC-induced esterification (the β-lactam ring, actually determined in the iodometric procedure, is preserved).

The content of the incorporated Oxacillin in polyesters **IIIa** and **IIIb** is high (30–33%). The degree of conversion Q of the hydroxy groups of the polymeric carriers in their reaction with Oxacillin, calculated from these data, is 64–66%. This high value of Q indicates that the above-noted microstructural features of the starting VP–HEMA copolymers do not interfere with their reaction with Oxacillin molecules.

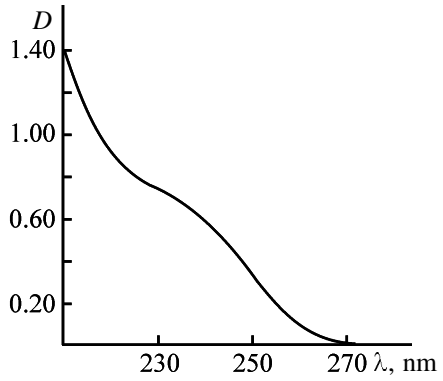

Fig. 2. UV spectrum of an aqueous solution of Oxacillin sodium salt (c = 25.7 μg ml^{-1}): (D) optical density and (λ) wavelength; the same for Fig. 3.

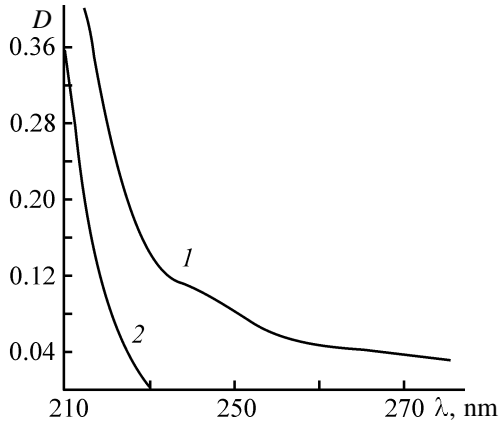

Fig. 3. UV spectra of aqueous solutions of (*1*) polymeric Oxacillin ester **IIIa** (c = 10.9 μg ml^{-1}) and (*2*) starting copolymer **Ic** (c = 19.7 μg ml^{-1}).

We found that polymeric Oxacillin ester **IIIa** exhibits high antimicrobial activity *in vitro*. When taken in concentrations of 3×10^{-3}–3×10^{-4} μg ml^{-1}, it killed standard staphylococcus strains (Table 2).[1]

[1] The authors are grateful to T.S. Potekhina for the determination of the antistaphylococcus activity of Oxacillin sodium salt and polymeric Oxacillin ester **IIIa**.

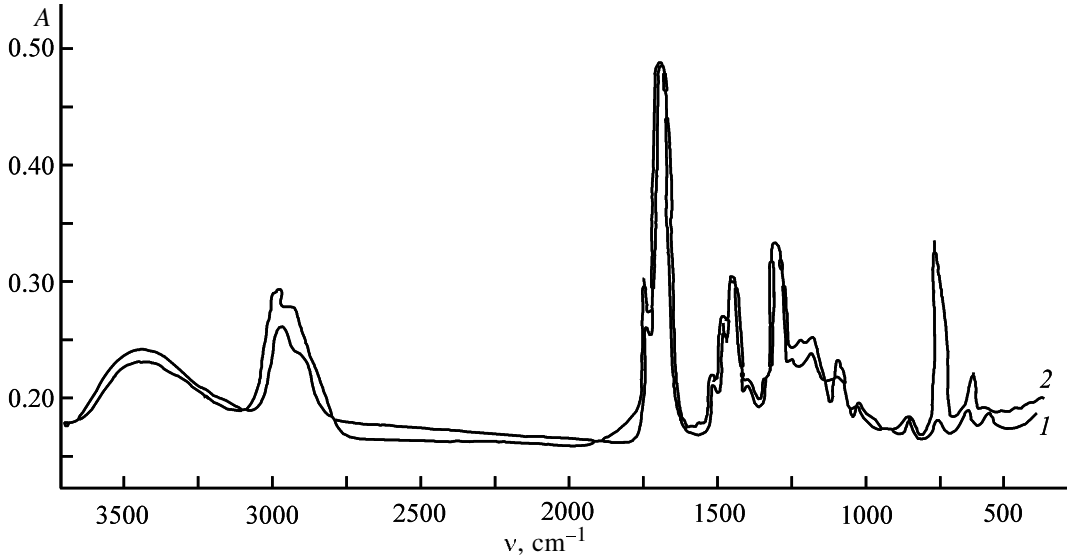

Fig. 4. IR spectra (films prepared from chloroform solution): (*A*) absorption and (ν) wavenumber. (*1*) Copolymer **Ic** and (*2*) polymeric Oxacillin ester **IIIa**.

As Oxacillin is administered parenterally and perorally, it seemed appropriate to estimate by dialysis through a semipermeable cellophane membrane the rate of cleavage of the ester bond between the antibiotic and polymeric carrier in the following model media: (a) saline, pH 7.3, 37°C; (b) glycine buffer solution, pH 2.0, 37°C. We found (Table 3) that the hydrolysis of **IIIa** in both media occurs at a noticeable rate even in the first hours of the reaction. As expected, at pH 2.0 the reaction is faster: 58% of the antibiotic is eliminated in 7 h and 84%, in 24 h. In saline, the degree of hydrolysis of **IIIa** is 44% in 7 h and 69% in 24 h.

The relatively high rate of hydrolysis of **IIIa** at both pH 2.0 and pH 7.3, in combination with the high antimicrobial activity of the preparation, indicate that the chosen approach to development of Oxacillin preparations of prolonged effect for both peroral and parenteral administration shows much promise.

EXPERIMENTAL

N-Vinylpyrrolidone was purified by threefold vacuum distillation from granulated KOH (polymerization inhibitor) in the presence of KU-2 cation-exchange resin sorbing amine impurities present in VP. The fraction boiling at 75–76°C/5–6 mm Hg was collected. Found: n_D^{20} = 1.5110, d_4^{20} = 1.0430 g cm^{-3}. Published data: n_D^{20} = 1.5130, d_4^{20} = 1.0458 g cm^{-3}. Found: molecular refraction R = 31.88 cm^3 mol^{-1}; calculated: R = 31.65 cm^3 mol^{-1}.

2-Hydroxyethyl methacrylate (Fluka) was distilled twice in a vacuum from molecular sieves in the presence of bis(naphthoquinonyl)-*p*-phenylenediamine (polymerization inhibitor). The fraction boiling at 87°C/5 mm Hg was collected. Found: n_D^{25} = 1.4500, d_4^{25} = 1.069 g cm^{-3}. Published data: n_D^{25} = 1.4505,

* (MBcC) Minimal bactericidal concentration recalculated to the Oxacillin content in the preparation.

d_4^{25} = 1.077 g cm^{-3}. Found: R = 32.68 cm^3 mol^{-1}; calculated: R = 32.62.

The initiator, azobis(isobutyronitrile) (AIBN), was recrystallized three times from chloroform–ethanol, 1 : 5. Yield of purified AIBN 76.2%, mp 103°C. Published data: mp 103°C.

Dimethylformamide was purified by the standard procedure [7]. Absolute 2-propanol, DCC (Fluka), and Oxacillin sodium salt (iodometric activity 925 μg mg^{-1}) were used without additional purification.

VP–HEMA copolymer Ib. An 80-ml glass ampule treated with live steam and dried was charged through a funnel with 0.121 g of AIBN and then with a mixture of 2 ml of VP, 0.58 ml of HEMA, 4 μl of mercaptoethanol, and 42 ml of 2-propanol. The ampule was purged with argon, sealed, and placed in a thermostat kept at 60°C. After heating for 24 h, the ampule was removed from the thermostat, cooled, and opened. The viscous transparent polymerization product was poured dropwise with stirring into a beaker containing 300 ml of diethyl ether. The precipitated copolymer was collected on a glass frit, washed with fresh portions of ether, and dried in a vacuum without heating to constant weight. Yield 1.71 g (63.2%). Found: N 8.48%.

Synthesis of Oxacillin from its sodium salt. Oxacillin sodium salt (2.5 g) was dissolved in 30 ml of water. The solution was transferred into a 250-ml separating funnel, and 50 ml of chloroform was added. To the aqueous layer, 1 N HCl was added dropwise, and the contents were shaken until the white precipitate in the aqueous layer disappeared. After the precipitation in the aqueous layer was complete, the acidification was stopped. The chloroform layer was separated, washed with three 30-ml portions of water, and dried over anhydrous sodium sulfate for 1 day at room temperature. The chloroform layer was separated, the solvent was removed on a rotary evaporator, and the residue was dried in a vacuum. Yield 1.78 g (78.4%). Iodometric activity 920 μg mg^{-1}. Found: S 7.84%; calculated: S 7.98%.

Polymeric Oxacillin ester IIIa. VP–HEMA copolymer **Ic** (0.5 g) was dissolved in 5 ml of DMF, and 0.445 g of dry Oxacillin was added. The mixture was stirred at cooling with an ice–salt mixture for 30 min, and a solution of 0.3 g of DCC in 3 ml of DMF was added. The solution was stirred for 2 h with cooling (0–5°C) and then for 5 h at room temperature. The mixture was left overnight in a refrigerator, after which the precipitate of dicyclohexylurea was filtered off, and the solution was poured into acetone to precipitate the reaction product (in so doing, unchanged Oxacillin, which is readily soluble in acetone, remained in the solution). After drying, 0.37 g (39.8%) of the water-soluble polymeric Oxacillin ester was obtained. The bound Oxacillin content was 31.7 wt % according to UV data and 30.1 wt % according to iodometric titration.

Table 3. Hydrolysis of polymeric Oxacillin ester **IIIa** at 37°C

Time from start of reaction, h	Degree of hydrolysis, %	
	pH 7.3	pH 2.0
1	12	27
2	21	36
3	29	44
4	34	47
5	37	50
6	40	54
7	44	58
24	69	84

The UV spectra of aqueous solutions of Oxacillin sodium salt, polymeric Oxacillin esters **IIIa** and **IIIb**, and copolymer **Ic** were recorded on a Specord M-40 spectrophotometer. The IR spectra of copolymer **Ic** and polymeric Oxacillin ester **IIIa** were measured on a Bruker IFS spectrometer; samples were prepared as films from chloroform solutions.

The molecular weights of copolymers **Ia**–**Ic** were determined by a sedimentation–diffusion procedure described elsewhere [2].

Hydrolysis of polymeric Oxacillin ester **IIIa** was studied in glycine buffer (pH 2.0) and saline (pH 7.3) at 37°C using the procedure described in [8].

The iodometric activity of Oxacillin and its polymeric esters was determined according to [6].

The antimicrobial activity of Oxacillin sodium salt and polymeric Oxacillin ester **IIIa** was studied by the method of tenfold serial dilutions in a liquid culture medium (meat–peptone broth, pH 7.0) [4]. The bacteria were grown for 18 h. The microbial load was 5×10^5 microbial bodies per milliliter.

CONCLUSIONS

(1) Conditions were found for preparing low-molecular-weight water-soluble *N*-vinylpyrrolidone–

2-hydroxyethyl methacrylate copolymers with a high (up to 33.4 mol %) content of 2-hydroxyethyl methacrylate units.

(2) From these copolymers, polymeric Oxacillin esters containing 30–33 wt % incorporated antibiotic and showing high antistaphylococcus activity *in vitro* were prepared.

(3) The hydrolysis of the polymeric Oxacillin ester with a molecular weight of 31000 Da at 37°C in model systems (glycine buffer, pH 2.0; saline, pH 7.3) was studied. In both systems, the hydrolysis of the polymeric ester is fairly fast: The degree of hydrolysis in 24 h is 84% in glycine buffer and 69% in saline.

ACKNOWLEDGMENTS

The study was financially supported by a Grant of the RF Ministry of Science and Education for support of leading scientific schools (no. NSh-1823.2003.3).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Cyclic Carbonates with Isocyanates under Anionic Initiation Conditions and Structure of the New Copolymers

I. L. Beilin, V. P. Arkhireev, and S. S. Galibeev

Abstract—The possibility of preparing polyamido esters from propylene carbonate and 2,4-toluene diisocyanate in the presence of *N*-methylpyrrolidone was examined. The mechanism of the reaction of the starting monomers and the structure of the resulting copolymers were determined. The properties of the copolymers were studied.

DOI: 10.1134/S1070427206010277

Along with urethane formation, much attention is given today to homo- and copolymerization of isocyanates under the conditions of anionic initiation. Of particular interest are copolymers of isocyanates with compounds of other classes (aldehydes, ketones, alkenes, etc.) [1]. Such polyamido esters (PAEs) can be used as coatings on glass, steel, and fabric supports, as films, and as fibers [2, 3]. Existing procedures for preparing polycarbonates and their copolymers are complex and time-consuming, require strict observance of the prescribed conditions and also high vacuum or elevated temperatures, and involve the use of organic solvents [4], which negatively affects the cost of the polymer and items thereof. At the same time, these materials have unique properties and in many cases are indispensable. Therefore, an urgent problem is development of procedures for preparing PAEs at atmospheric pressure and moderate temperatures. We showed in [5–7] that isocyanates in the presence of alkali metal lactamates and tertiary amines can induce ring opening in many heterocyclic compounds (lactams, lactones, oxiranes) with the formation of alternating copolymers.

In this study we examined the copolymerization of propylene carbonate (PC), 2,4-toluene diisocyanate (TDI), and *N*-methylpyrrolidone (*N*-MP). The synthesis was performed at 20°C; the monomer ratio in the starting mixture was widely varied. The catalyst (triethylamine, TEA) concentration was 0.01 mol %. The amount of the unchanged monomer was determined by extraction of the polymer in a Soxhlet apparatus for 8 h.

The reaction was monitored by ^{1}H NMR spectroscopy with a Tesla-100 spectrometer operating at 100 MHz (solvent and internal reference acetone-d_6). The middle-IR spectra of the copolymers were recorded on a Bruker FT-IR spectrophotometer; samples were prepared as KBr pellets. The elemental analysis was performed with a CNH-3 analyzer (oxidation at 1050°C). Gel-chromatographic studies were made with a Waters-150 C gel chromatograph equipped with Styrogel HR 10^3–10^6 Å columns at 25°C; eluent THF, flow rate 2 ml min^{-1}.

The reaction rate constants were determined according to [8]. To optimize a kinetic study of the ternary copolymerization, we used the simplex-lattice experimental design. As approximating polynomial we used the third-order Scheffe model.

Thermal analysis of samples was performed on an MOM Q-1500 derivatograph (Hungary) at a heating rate of 3 deg min^{-1}.

To determine the physicomechanical characteristics of the materials based on PC, TDI, and *N*-MP, we prepared films of these materials by chemical forming. As solvent for the monomers we used acetone. The breaking stress σ_b was determined with an MR-500T-2 tensile-testing machine at 20 ± 2°C. The velocity of mobile clamps was 100 mm min^{-1}.

The IR spectrum of the TDI–PC–*N*-MP terpolymer contained absorption bands absent in the spectrum of the starting monomers, cm^{-1}: 1704 and 1412 (stretching vibrations of the carbonyl group in tertiary amides formed by cleavage of the isocyanate group across

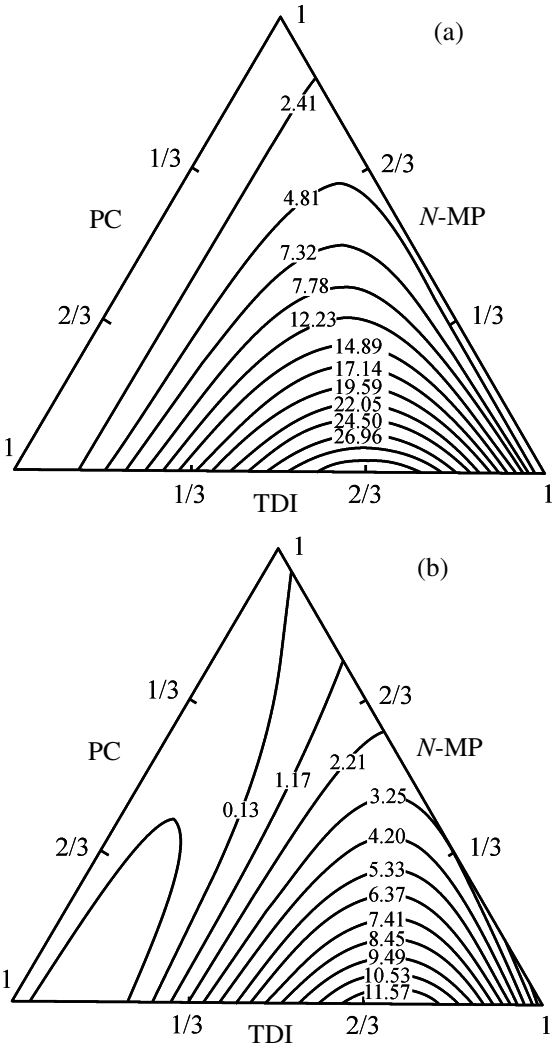

Fig. 1. Lines of (a) equal rates ($\times 10^6$ mol l^{-1} s^{-1}) and (b) equal rate constants ($\times 10^4$ l mol^{-1} s^{-1}) of copolymerization of PC, TDI, and *N*-MP (mole fraction scale).

Table 1. Copolymer yield in the reaction of TDI with PC and *N*-MP

Monomer ratio in the starting mixture, mol %			Yield, wt %
TDI	PC	*N*-MP	
60	20	20	95
40	40	20	84
40	20	40	81
20	40	40	46
20	60	20	48
20	20	60	40

the N=C bond), 1304 (C–N stretching vibrations in amides), 1216 (C–O stretching vibrations in esters), 1066 (C–O–C stretching vibrations in aliphatic esters; this band is indicative of the cleavage of PC), and also 2926 and 2860 (CH stretching vibrations in CH_2 groups). This pattern shows that the copolymerization involved both monomers.

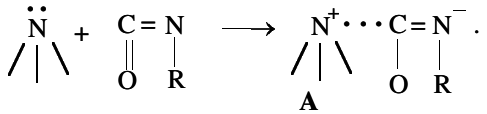
The spectrum does not contain bands at 1692 (C=O stretching vibrations in five-membered lactams), 1270, and 865 cm^{-1} (C–O vibrations in cyclic ethers). Homopolymerization of isocyanates in the presence of tertiary amines is possible, but homopolymerization of PC and *N*-MP under these conditions was not observed. However, the anion generated by cleavage of the isocyanate group is highly reactive and apparently attacks the carbonate or lactam ring, causing its cleavage. The spectrum does not contain bands characteristic of uretidinedione (1780 cm^{-1}) and triisocyanurate (1720 cm^{-1}) rings, which indicates that dimers and trimers of TDI are not formed in the course of the copolymerization [9–11].

The highest rates and rate constants at low (5–10%) conversions (Fig. 1) are observed at the monomer molar ratio in the starting mixture PC : TDI : *N*-MP = 25 : 65 : 10. This kinetic pattern suggests formation of an alternating macromolecule in the copolymerization.

The copolymer is formed in a high yield (Table 1). With an excess of TDI in the starting mixture, polyisocyanate and also (as TDI is a bifunctional agent) branched and partially cross-linked structures are apparently formed on the ends of the macromolecule. This is indirectly confirmed by the fact that the copolymer solubility in organic solvents (dimethylformamide, dimethyl sulfoxide, etc.) becomes worse with an increase in the isocyanate content. With TDI taken in deficiency, excess PC and *N*-MP do not participate in the copolymerization and are removed in the course of the product purification. With a deficiency of one of the heterocycle, after its exhaustion the reaction continues as binary (PC–TDI or *N*-MP–TDI) copolymerization. The number-average molecular weight of the copolymers, according to gel permeation chromatography, is 2900–21 400.

The relative changes in the content of functional groups, monitored by ^1H NMR spectroscopy, apparently determine the composition of the reaction product. At equal excess of both heterocycles relative to TDI in the starting mixture (molar ratio TDI : PC : *N*-MP = 10 : 45 : 45), three carbonate rings are opened per lactam ring. The analytical data (percentage of C, H, N, O) are virtually fully consistent with the assumption that the copolymer contains three PC units

Table 2. Characteristics of the thermal stability of the copolymers obtained*



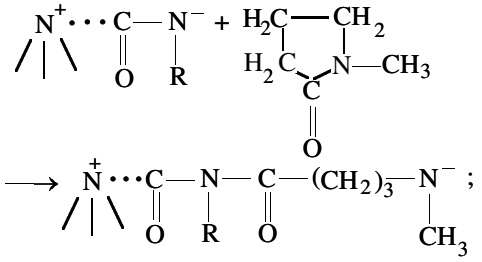
Monomer ratio in starting mixture, mol %			$T_{\Delta m,5}$	$T_{\Delta m,10}$	$T_{\Delta m,50}$	$T_{o.d}$	T_d
TDI	PC	*N*-MP	°C				
100	0	0	294	316	413	288	356
20	0	80	254	281	406	270	325
20	80	0	266	294	404	269	326
20	40	40	288	317	419	310	375
20	60	20	291	322	428	318	386
20	20	60	284	316	415	308	370

* ($T_{\Delta m,5}$, $T_{\Delta m,10}$, $T_{\Delta m,50}$) Temperatures of 5, 10, and 15% weight loss, respectively; ($T_{o.d}$) temperature of degradation onset; and (T_d) degradation temperature.

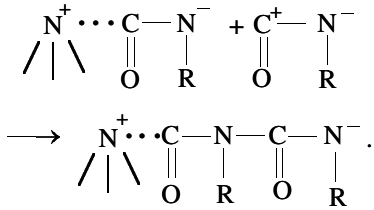
per *N*-MP unit, with the isocyanate acting as a link:

	H	C	N	O	
Found, wt %	6.0	54.4	7.5	32.1	(by difference)
Calculated, wt %	5.7	53.9	7.3	33.1	

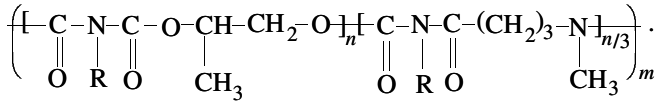
Thus, our results in combination with quantum-chemical calculations suggest that the isocyanate component in the ternary system initiates the chain propagation, and PAE is formed by the following mechanism. In the first step (initiation), nucleophilic addition of an anionic catalyst to the electrophilic carbon atom of the isocyanate group yields a charge-transfer complex. This interaction results in a shift of the electron density in the cumulated bond system and formation of anion **A** with the negative charge on N:



A



The isocyanate anion adds with the ring opening to propylene carbonate, forming an alkoxide anion:



or to the electrophilic carbon atom of lactam:

it can also add to another isocyanate molecule with the formation of a tertiary imide fragment:

The anions formed in the process can further react with isocyanate, PC, or *N*-MP to form an alternating structure which can be represented, to a first approximation, as follows:

The termination in such polymerizing systems occurs, as a rule, by exchange reactions of propagating macroanions with compounds containing a labile hydrogen atom or by chain transfer to the monomer with the formation of terminal amino groups.

The differential thermal and thermogravimetric studies of the copolymers show that their thermal stability depends essentially on the monomer ratio in the starting mixture and is, on the whole, somewhat higher than that of TDI homopolymers and of TDI–PC and TDI–*N*-MP binary copolymers (Table 2).

The feasibility of preparing ready items (including polymer films) by chemical forming is very important. Examination of the strength characteristics of these materials shows that it is possible to prepare materials with the preset properties. In particular, the highest breaking tensile stress of the films, exceeding 40 MPa, was attained at the molar ratio of the components in the starting mixture TDI : PC : *N*-MP ≈ 27 : 67 : 6 (Fig. 2).

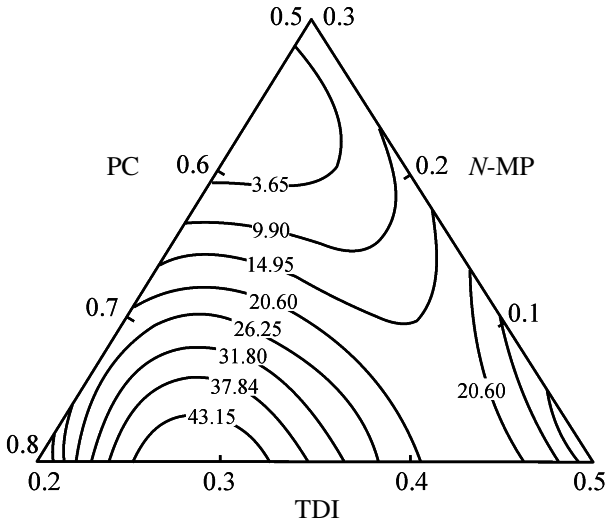


Fig. 2. Composition–property diagram for the breaking tensile stress (MPa) of PC–TDI–*N*-MP copolymers (mole fraction scale).

CONCLUSIONS

(1) Terpolymers of propylene carbonate, 2,4-toluene diisocyanate, and *N*-methylpyrrolidone were prepared in the presence of triethylamine. Although propylene carbonate and *N*-methylpyrrolidone do not homopolymerize under the action of tertiary amines, they readily copolymerize with isocyanates.

(2) The ^{1}H NMR and IR spectra, kinetic data, and elemental analysis suggest that the copolymerization mainly yields high-molecular-weight alternating block copolymers.

(3) The thermal stability (e.g., temperatures of 5, 10, and 50% weight loss; degradation onset and degradation temperatures) and physicomechanical characteristics (e.g., breaking tensile stress of films) of the copolymers can be controlled by varying the monomer ratio in the starting mixture.

Received June 20, 2005; in final form, November 2005

Abstract—Polyfunctional oligomeric antioxidants with a sterically hindered phenolic fragment were prepared. The influence of these antioxidants on oxidation and degradation of SKI-3 rubber was analyzed.

DOI: 10.1134/S1070427206010289

Unsaturated nature of rubber macromolecular units makes possible processing of rubbers into articles via vulcanization and preparation of technically valuable structural materials thereof, on the one hand, and is responsible for gradual aging of the material, above all, due to oxidation, on the other. Oxidation follows the radical-chain mechanism [1, 2]. The primary oxidation products of the polymer are polymeric peroxy radicals (PRs) and hydroperoxides (HPs).

Chemically, antioxidative stabilization of polymeric materials consists in scavenging of free radicals and hydroperoxides. The most efficient and widely applied PR scavengers are sterically hindered phenols (SHPs) and aromatic amines [3–5]. Hydroperoxides are decomposed by compounds containing sulfur(II) atoms [6]. The researchers' attention is currently focused on stabilizers whose molecules contain several centers able of decelerating oxidation of polymers. They are attractive because of possible synergism of antioxidation effects [7–9].

It should be taken into account that the use of monomeric antioxidants often causes problems due to their volatility, insufficient solubility, and washing out from polymers. At the same time, a number of studies showed that, with polymeric antioxidants eliminating such problems, the functional groups act less efficiently [9]. Oligomeric antioxidants (OAOs) would apparently be the best choice.

In this study, we developed a procedure for synthesis of OAOs whose molecules contain centers able of inhibiting oxidation via scavenging PRs and HPs and examined their stabilizing performance.

EXPERIMENTAL

As reactants served 4-dimethylaminomethyl-2,6-di-*tert*-butylphenol (Mannich base, MB), mp 93–95°C, and a sulfur-containing oligoether TPM-2 [TU (Technical Specifications) 38 103 636–87; dynamic viscosity 1.9 Pa s at 25°C] with 3.42 wt % terminal SH groups.

The antioxidants were synthesized by the following procedure. A flask equipped with a stirrer, a water-cooled reflux condenser, a thermometer, and a bubbler was charged with TPM-2 and MB (when the reaction was run in a solution, appropriate solvent was added). The amount of MB taken for the reaction was governed by the preset number of the SH groups to enter into the reaction (the calculations were carried out for 100, 75, 50, and 25% conversions of the SH groups in the oligomer). The reaction mixture was stirred at 100–140°C in a nitrogen flow. The reaction was monitored from evolution of dimethylamine absorbed by 0.1 N H_2SO_4 with indicator (Methyl Orange). The completion of the process was judged from ceased evolution of dimethylamine.

The mass fraction of the SH groups was determined by a laboratory technique according to GOST (State Standard) 12 812–80.

The resulting stabilizers were introduced into 5% solutions of SKI-3 (hereinafter, the weight percentage) in toluene and stirred at room temperature until complete homogenization, whereupon the solvent was vacuum-evaporated.

Self-oxidation of the polymer was run by the procedure from [10] under oxygen (p_{O_2} = 250 mm Hg) at 165°C (polymer weighed portion 0.1 g).

The oxidation, degradation, and mass loss temperatures of the polymer were determined by differential thermal (DTA) and thermogravimetric (TGA) analyses on an MOM (Hungary) derivatograph; the heating rate for the samples was 5 deg min^{-1}.

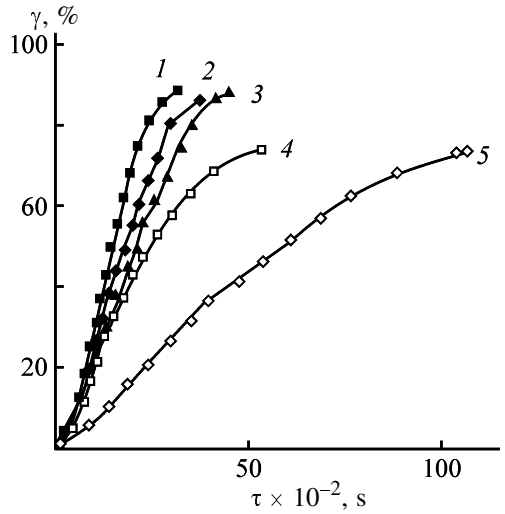

Fig. 1. Influence of temperature on the kinetics of the reaction between TPM-2 and MB in the melt. (γ) Conversion and (τ) time, the same for Fig. 2. Ratio of reacting centers 1 : 1; the same for Fig. 2. Temperature, °C: (*1*) 140, (*2*) 130, (*3*) 120, (*4*) 110, and (*5*) 100.

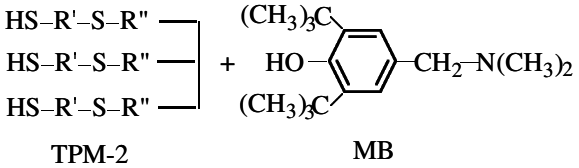
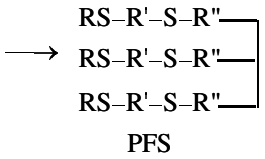


The IR spectra were recorded at 4000–400 cm^{-1} on a 16 PC-FT-IR Perkin–Elmer instrument. To study accumulation of the carbonyl groups from 10% solution of SKI-3 in toluene, containing the stabilizer, we prepared 1.0–1.2-mm-thick films on polyethylene terephthalate support. The films were subjected to thermooxidative aging in air under static conditions at 100°C.



As the base in synthesis of polyfunctional antioxidants served a sulfur-containing polyether with SH terminal groups, TPM-2. This choice was determined by the presence in TPM-2 of sulfide and thiol groups, able of inhibiting oxidation of polymers by decomposing HPs. Also, reactive terminal thiol groups can be used for introduction into the oligomer molecule of a second center of antioxidative stabilization, a PR scavenger (in our case, SHP fragment).

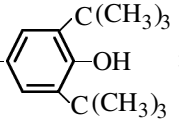


Table 1. Temperature dependence of the rate constant k and preexponential factor A in the reaction between TPM-2 and MB

T, °C	$k \times 10^4$	$A \times 10^4$
	mol l^{-1} s^{-1}	
100	2.3562	2.416
110	4.9218	5.044
120	8.3252	8.526
140	13.9103	14.229

Polyfunctional stabilizers (PFSs) were synthesized by the reaction of TPM-2 and MB:

where R = H, 

;

R' = $CH_2CH_2OCH_2OCH_2CH_2$; and R" = $[CH_2CH\cdot(CH_3)O]_n$.

We chose MB as oxybenzylating agent because of a fairly high reactivity of this class of compounds in substitution of dimethylamino group [11].

To reveal the best conditions for synthesis, we examined how the rate of the reaction between TPM-2 and MB is influenced by the reaction conditions: temperature, presence of the solvent, and solvent polarity. We found that, in melt, this reaction goes at appreciable rate at temperatures above 80°C. Our experimental data showed that the process is substantially accelerated by rising temperature to 120–140°C (Fig. 1).

Based on the kinetic data, we determined the reaction rate constants at different temperatures (Table 1), as well as the preexponential factors and the activation energy of the process, which was estimated at 77.8 kJ mol^{-1}. We found that the reaction between TPM-2 and MB is a first-order reaction with respect to each of the reactants [12].

The activity of 2,6-dialkyl-substituted oxybenzylated agents in reactions with nucleophiles is determined [13] by the possibility of formation at elevated temperature of 2,6-dialkyl-4-hydroxybenzyl carbocation. Under assumption that the reaction goes through deamination, we can suggest that the rate of the process will be affected not only by the temperature but also by the solvent polarity. Our experimental data showed that, in nonpolar solvents (ethylbenzene, decane) at 130°C, the conversion of the reactants attains a maximum within 3–4 h (Fig. 2).

When the process is run in polar solvents (2-buta-

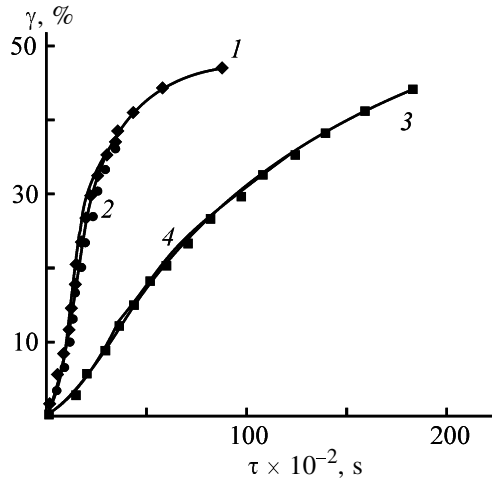

Fig. 2. Kinetics of the reaction between TPM-2 and MB at 130°C as influenced by the solvent polarity. (*1*) DMF, (*2*) 2-butanol, (*3*) decane, and (*4*) ethylbenzene.

nol, DMF), the reaction time is reduced to 1.5 h. The fact that the reaction rate is influenced by the solvent polarity confirms that the reaction goes via a polar transition state.

To elucidate how the number of the SHP fragments introduced into the molecules of PFSs affects their stabilizing performance, we varied the MB proportion in such a way that 25, 50, 75, and 100% of the SH groups of TPM-2 participated in the reaction. The process was run in melt at 120–130°C and was terminated after dimethylamine ceased to evolve. When the process was complete, the chromatogram of the reaction mixture (Silufol-254 plate, eluent benzene : acetone = 5 : 1) did not exhibit a spot characteristic of MB (R_f = 0.1). We determined the content of the SH groups in the resulting PFSs (Table 2). It is seen that the theoretically calculated and experimental data are close, which suggests complete conversion of MB.

The DTA data for PFSs suggest their fairly high stability: The mass loss onset temperature is close to 250°C.

The antioxidative performance of PFSs was studied for SKI-3 rubber samples. To this end, we utilized the manometric method of measuring the induction periods of oxidation of polymers [2], as well as IR spectroscopy, DTA, and TGA.

The manometric method is based on studying the kinetics of thermal oxidation [10]. It is underlain by oxygen absorption by the polymer when heated in air or under oxygen. The induction period is the period before the onset of oxygen absorption by the polymer. Our experimental data showed that, when the concentration of the initial TPM-2 introduced was 1–5 wt parts per 100 wt parts of SKI-3, the induction period before the onset of SKI-3 oxidation increased to a certain extent (Table 3). This suggests that TPM-2 exhibits a weak antioxidative power. Introduction into the TPM-2 molecule of an SHP fragment substantially increases the induction period of the

	°C		onset	5%	10%	50%
TPM-2	225	335	250	309	325	363
TPM-2–SHP_{50}	256	345	250	312	336	378
TPM-2–SHP_{100}	262	350	250	323	345	388

* T_{ox} is the rubber oxidation temperature; T_d, rubber degradation temperature; and $T_{m.l.}$, rubber mass loss temperature.

rubber oxidation. In this connection, two essential points should be mentioned. First, the induction period of SKI-3 oxidation linearly increases with increasing concentration of the antioxidant within 1–3 wt parts per 100 wt parts of the rubber and attains saturation with further increase in the PFS concentration. Second, replacement of all the SH groups in TPM-2 by SHP–S fragments is accompanied by a certain decrease in the induction period of oxidation. This may be due to the synergism of the antioxidative effects in the presence of thiol groups. The antioxidative power of the stabilizer seems to be at a maximum at the 1 : (1–0.5) ratio of the SHP–S to –SH groups in the stabilizer molecule.

The fact that the antioxidative power is improved upon introducing an SHP fragment into the TPM-2 molecule is also demonstrated by the IR spectroscopic monitoring of the SKI-3 oxidation [14]. The IR spectra suggest that thermal oxidation of SKI-3 is accompanied by a decrease in the intensity of absorption near 1666 ($\nu_{C=C}$) and 890 cm^{-1} ($\nu_{H-C=C}$) and appearance of bands at 1720 ($\nu_{C=O}$) and 3475 cm^{-1} (ν_{OH}).

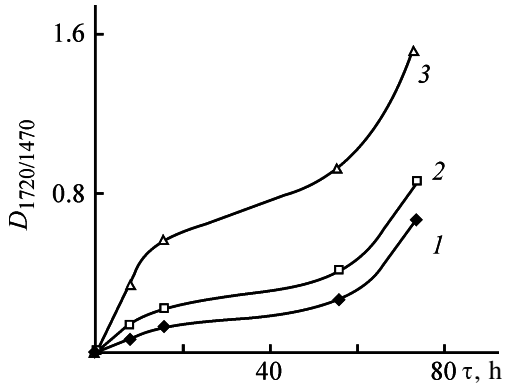

Fig. 3. Ratio of the optical densities D of the absorption bands of the C=O (1720 cm^{-1}) and CH_2 (1470 cm^{-1}) groups as influenced by the oxidation time τ of the SKI-3 films (100°C, air). (*1*) TPM-2–SHP_{100}, (*2*) TPM-2–SHP_{50}, and (*3*) TPM-2 (content of PFS 3 wt parts per 100 wt parts of SKI-3).

With increasing content of the SHP fragments in the PFS oligomer, the time before appearance of the bands at 3475 (ν_{OH}) and 1720 cm^{-1} ($\nu_{C=O}$) tends to increase, and the growth of their intensity is decelerated. As the band characterizing SKI-3 oxidation we chose the absorption band at 1720 cm^{-1}. The band at 1470 cm^{-1} (δ_{CH_3} and δ_{CH_2}) served as internal reference. The extent of the rubber oxidation at the preset thermal oxidation time was estimated from the ratio of the optical densities at 1720 and 1470 cm^{-1}. The experimental results are illustrated by Fig. 3.

The thermal stability of the PFS-containing polymer was estimated by TGA [15]. The rubber stability was estimated from the oxidation and degradation temperatures at which the polymer loses 5, 10, and 50% of the initial mass, as estimated at a constant heating rate.

Our experimental data suggest (Table 4) that, with increasing amount of the SHP fragments introduced into TPM-2, the SKI-3 oxidation temperature increases relative to the rubber free from SHP-S fragments. Introduction of PFS into SKI-3 does not markedly affect the mass loss onset temperature of the rubber, but the mass loss is decelerated.

CONCLUSIONS

(1) Antioxidants for carbon-chain polymers with different ratios of the polymer oxidation inhibition centers, sulfide sulfur and sterically hindered phenolic fragments, were synthesized by the reaction of terminal HS groups of the oligomeric thioether TPM-2 with *N,N*-dimethyl-3,5-di-*tert*-butyl-4-hydroxybenzylamine.

(2) Polyfunctional additions exhibit high antioxidative and themostabilizing power in SKI-3 rubber stabilization. The induction period of thermal oxidation of SKI-3 and the rate of accumulation of the carbonyl groups in the rubber vary with the ratio of the

different inhibition centers, sulfide sulfur : sterically hindered phenolic fragment.

Abstract—The kinetics of sedimentation of kaolin suspension in the presence of copolymers of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone was studied as influenced by the concentrations, molecular weight, and chemical composition of the copolymer and by the concentration of salts added (NaCl, $CaCl_2$).

DOI: 10.1134/S1070427206010290

Water-soluble polyelectrolytes are widely used to control the stability of dispersion systems [1]. In treatment of natural and waste waters and in concentration and drying of suspensions, the stability of dispersion systems should be decreased and, vice versa, in the case of drilling muds, mortars, and drugs it should be increased. Owing to high flocculation [2], adhesion [3], thickening [4], and complexation properties, copolymers of sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMPS) with *N*-vinylpyrrolidone (VP) show promise for controlling the stability of mineral suspensions. The flocculation properties of Na-AMPS–VP copolymers at their low concentrations ($<2.5 \times 10^{-3}$ wt %) were studied previously using kaolin suspensions, but the data on the stabilization power of these copolymers, which is observed at high concentrations, are lacking. In this study we examined the effect of Na-AMPS–VP copolymers on the stability of kaolin suspensions as influenced by the concentrations, molecular weight (M), and chemical composition of the copolymer and by the concentration of salts added (NaCl, $CaCl_2$).

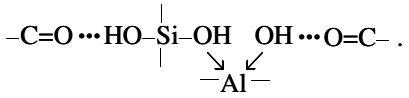
EXPERIMENTAL

In the experiments we used copolymers of Na-AMPS and VP prepared by radical copolymerization in aqueous solutions by the procedure given in [3]. The resulting polymers were precipitated from aqueous solutions with excess acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum at 50°C. The content of ionic Na-AMPS units in the copolymer of Na-AMPS and VP was determined from the content of sulfur [6]. Since in accordance with the Mark–Houwink equation $M \sim [\eta]$, the molecular weights of the copolymers were calculated from the intrinsic viscosities $[\eta]$ of their solutions, which were measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 capillary viscometer (d_c = 0.43 mm). The properties of copolymers are listed in the table.

The experiments were performed at 20°C with KE-1 brand kaolin (Eleninskoe field), because this dispersion system with the uniform particle size distribution (average particle size 0.2×10^{-6} m) is widely used to evaluate the flocculation properties of water-soluble polymers.

The sedimentation was performed in a 50-ml volumetric cylinder with a ground-glass stopper. The degree of clarification (%) of the kaolin suspension

was determined by the shift of the boundary between the clarified and unclarified fractions of the suspension after mixing by tenfold overturning of the cylinder. The tests were carried out at a concentration of the dispersed phase c_d 5 wt %, which provided distinct boundary between the clarified and unclarified fractions of the suspension in the cylinder in the absence of the copolymer and thus allowed us to compare the rates of sedimentation in the presence of copolymer and without it.



First we studied the effect of the concentration of the dispersed phase c_d (3–10 wt %) on the kaolin sedimentation in the absence of the copolymer. The kinetics of clarification of the kaolin suspension at various c_d is shown in Fig. 1. The sedimentation rate was determined from the slopes of the kinetic curves. As seen from Fig. 1, the rate of kaolin sedimentation decreases with increasing c_d, which is probably due to the effect of hindered sedimentation of the dispersed particles.

The effect of the Na-AMPS–VP flocculant concentration (c_p) on the kaolin suspension sedimentation was studied in the $(0.2–5.0) \times 10^{-3}$ wt % range; here and hereinafter, c_d 5 wt %. The flocculating power D was evaluated as

$$D = (v - v_0)/v_0,$$

where v and v_0 are the sedimentation rates of the kaolin suspension in the presence of the copolymer and without it, respectively.

The dependence of D on c_p is shown in Fig. 2. As seen, the $D = f(c_p)$ dependence passes through a maximum. With increasing c_p in the $(0.2–2.5) \times 10^{-3}$ wt % range, D increases (ascending branch) owing to a decrease in the suspension stability caused by adsorption of the copolymer on the kaolin particles. It is known [7] that the kaolin ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$ with impurities of Fe_2O_3, MnO, Na_2O, K_2O, and TiO_2) particles form hexagons whose basal surfaces are charged negatively at various pH, whereas lateral faces can be either neutral or positively and negatively charged depending on the solution pH. In this study, the experiments were performed at pH 6.8, and adsorption of Na-AMPS–VP copolymer occurred predominantly on the lateral faces of the kaolin particles owing to formation of the hydrogen bonds between the hydroxy groups on the kaolin surface and functional groups of the copolymer:

Properties of Na-AMPS–VP copolymers

Sample no.	Content of ionic units in copolymer, mol %		[η], $cm^3\ g^{-1}$
	Na-AMPS	VP	
1	3.5	96.5	132
2	36.6	63.4	136
3	37.3	62.7	185
4	38.6	61.4	95
5	40.5	59.5	170
6	47.6	52.4	185

In the course of copolymer adsorption, the kaolin particles got bound with macromolecular bridges to form coarse floccules, lost their aggregative stability, and precipitated. As seen from Fig. 2, with further increasing c_p (>2.5×10^{-3} wt %), D decreases (descending branch). This is obviously due to the structuring of the system and attainment of its aggregation and sedimentation stability. Since the flocculation properties at small concentrations of Na-AMPS–VP copoly-

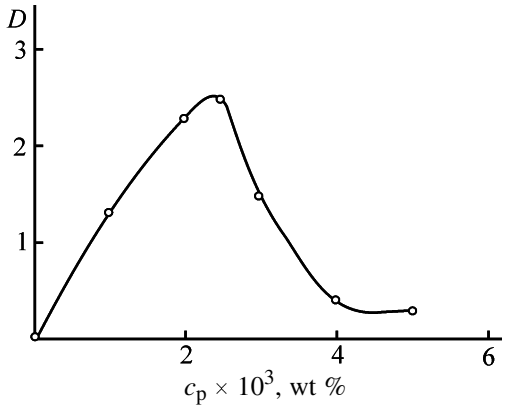

Fig. 2. Flocculation power D as a function of the concentration c_p (wt %) of Na-AMPS copolymer with VP (sample no. 1).

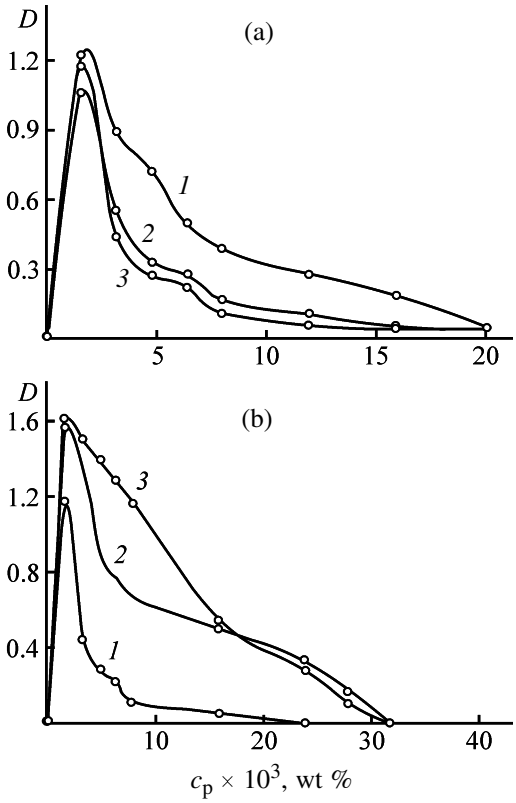

Fig. 3. Flocculation power D as a function of the concentration c_p of Na-AMPS copolymers with various (a) molecular weights M and (b) chemical compositions. Sample nos. (a): (*1*) 3, (*2*) 2, and (*3*) 4; (b): (*1*) 3, (*2*) 5, and (*3*) 6.

mers were studied previously [1], further experiments were performed only at high c_p at which the kaolin suspension is stabilized.

The influence of the chemical composition of the copolymer on the sedimentation of a kaolin suspension was studied using the copolymer samples with similar [η], whereas the content of Na-AMPS units was varied from 37.3 to 47.6 wt % (see table, sample nos. 3, 5, 6). The results of these experiments are shown in Fig. 3a. As seen, at c_p = const the flocculation effect D decreases with decreasing content of the ionic units in the copolymer (Fig. 3a, passing from curve *3* to curve *1*). This effect is observed in a wide concentration range. We assumed that this effect is probably due to a decrease in the effective size $(r^2)^{1/2}$ of macromolecular aggregates owing to weakening of electrostatic repulsion between the similarly charged units along the copolymer chain. This, in turn, decreases the probability of formation of macromolecular bridges between the kaolin particles and thus increases the sedimentation stability of the suspension.

The influence of [η] of Na-AMPS–VP copolymer on D is illustrated in Fig. 3b. The experiments were carried out using the samples of similar compositions, whereas [η] was varied from 95 to 185 $cm^3\ g^{-1}$ (see table, sample nos. 2–4). As seen, at constant c_p, D decreases with increasing [η] in a wide range of c_p (Fig. 3b, passing from curve *3* to curve *1*). Similar effect of the molecular weight of Na-AMPS copolymers with carboxymethyl cellulose at c_p 2.5 wt % on the stabilization of bentonite drilling muds (c 3 wt %) was found previously in [8]. In accordance with [2], at small c_p D increases with increasing M, and, as seen from Fig. 3b, at high c_p D decreases with increasing M. This extremal dependence of D on M well agrees with experimental data on the flocculation of a calcium phosphate suspension in the presence of polyacrylamide [9] and of gold and silver iodide sols in the presence of polyethylene oxide and polyvinyl alcohol [10]. The experimental dependence of the flocculation parameter D on the molecular weight of copolymer M shown in Fig. 3b is predominantly due to the fact that at high c_p the coverage of the kaolin particle surface with copolymer macromolecules increases, and with increasing M the probability of multipoint adsorption of the copolymer on the kaolin particles also increases. The resulting surface layers of the copolymer hinder aggregation of the kaolin particles and thus increase the stability of the kaolin suspension. As seen from Figs. 3a and 3b, the kaolin suspension is stabilized in the c_p range $(2.4–3.2) \times 10^{-2}$ wt %.

In this study we also examined the effect of the ionic strength of the solutions μ (provided by addition of $CaCl_2$ and NaCl) on the sedimentation stability of a kaolin suspension in the presence of Na-AMPS–VP copolymer (sample nos. 3, 5, 6, see table). Our preliminary experiments showed that, in the absence of the copolymer, v_0 slightly decreases with increasing μ, and in further experiments with addition of the copolymer the D values were calculated from v and v_0 determined at similar μ (for both $CaCl_2$ and NaCl). The dependences $D = f(c_p)$ determined in the presence of $CaCl_2$ and NaCl and without them are shown in Fig. 4. As seen from the comparison of experimental data at c_p = const, with increasing μ D increases in a wide range of copolymer concentrations for all the samples studied (Fig. 4, passing from curves *1–3* to curves *4–6* and *7–9*, respectively). It was found [11] that with increasing μ the electrostatic repulsion between the shielded sulfonate anions (Na^+ and Ca^{2+} counterions) along the Na-AMPS–VP copolymer chain decreases. Similarly, the increase in μ decreases the repulsion between the Na-AMPS–VP polyanions and the kaolin surface (ζ potential 4.2 mV); this

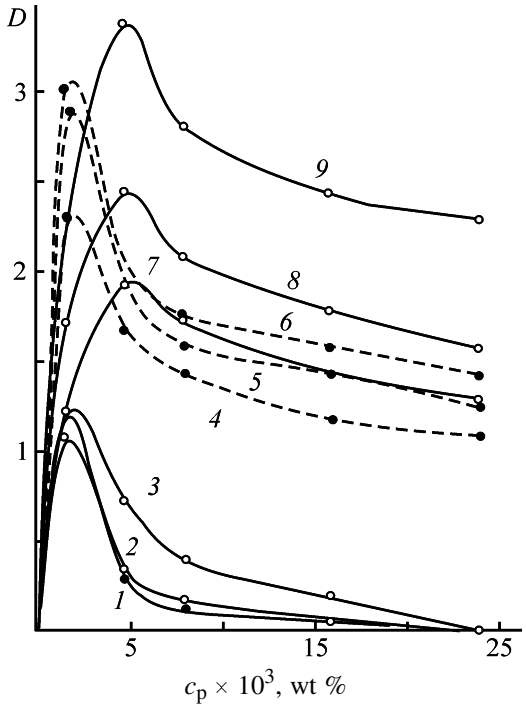

Fig. 4. Flocculation parameter D as influenced by the concentration of Na-AMPS–VP copolymer c_p (*1–3*) in the absence of additives and in the presence of (*4–6*) NaCl (0.5 M) and (*7–9*) $CaCl_2$ (0.5 M). Sample nos.: (*1, 4, 7*) 3, (*2, 5, 8*) 5, and (*3, 6, 9*) 6.

effect prevails over the decrease in D with decreasing $(r^2)^{1/2}$.

As seen from Fig. 4, at μ = const smaller D are observed with $CaCl_2$ as compared to NaCl. This is probably due to stronger binding of Ca^{2+} counterions, as compared to Na^+ cations, with polysulfonate anions [11]. As a result, on substitution of NaCl by $CaCl_2$, $(r^2)^{1/2}$ and the flocculation power of the copolymer both decrease.

CONCLUSIONS

(1) The flocculation effect of copolymers of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone on a kaolin suspension at a copolymer concentration of $(2–32) \times 10^{-3}$ wt % decreases with increasing concentration and intrinsic viscosity of the copolymer and with decreasing content of 2-acrylamido-2-methylpropanesulfonate units in the copolymer. The kaolin suspension (5 wt %) is completely stabilized at a copolymer concentration of $(2.4–3.2) \times 10^{-2}$ wt %.

(2) The flocculation parameter decreases with a decrease in the ionic strength of the solution (provided by NaCl and $CaCl_2$) and on substitution of NaCl by $CaCl_2$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Criteria for Assessing the Leveling Effect of Agents Used for Batch Dyeing of Synthetic Fibrous Materials

N. P. Prorokova and S. Yu. Vavilova

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received May 25, 2005

Abstract—Various methods for assessing the performance of levelers in batch dyeing of synthetic fibrous materials were analyzed. Criteria most suitable for technological and scientific applications were chosen.

DOI: 10.1134/S1070427206010307

One of the major indicators of the quality of dyed fibrous materials is uniformity of coloration. The achievement of uniform coloration is hindered by both inhomogeneous properties of the fibrous substrate and the difference in the sorption powers of individual components of mixed dyes. In batch dyeing, nonuniform coloration is also due to fast sorption when the dyeing solution contacts the outer layers of the fibrous material. The solution circulating from the periphery to the center of the material package gets exhausted, and the inner layers get less intensely colored, which requires redistribution of the dye throughout the bulk of the material. This can be avoided by creating dyeing conditions that afford slow sorption and as uniform initial distribution of the dye as possible.

The dye sorption intensity can be varied by varying the temperature rising rate: Slow rising of temperature in the dyeing bath affords uniform distribution of the dye throughout the fibrous substrate. Another important means to achieve more uniform coloration of fibrous materials consists in the use of special surfactant-based agents, levelers. Their action mechanism depends on the type of the surfactants they incorporate (advanced levelers are, for the most part, mixed formulations), the type of the fibrous material, and the dye class [1, 2]. In batch dyeing of synthetic fibrous materials, more uniform coloration is achieved by decelerating the dye sorption due to solubilizing effect of surfactants and further redistribution of the surface-sorbed dye inside the polymer. The former mechanism is universal; it operates in leveling of the coloration of all kinds of fibrous materials with virtually all dyes. The latter mechanism applies only to dyeing of synthetic fibers having a small number of reactive centers and not forming strong bonds with dyes [2]. Designers of textile auxiliary agents often do not take into consideration this mechanism, which deteriorates the performance of levelers they develop for synthetic fibers.

In this study, we analyzed the suitability of various methods for assessing the performance of levelers for batch dyeing of synthetic fibrous materials and chose the criteria most suitable for technological and scientific applications.[1]

EXPERIMENTAL

Uniform application of dyes onto fibrous materials in the first stage of dyeing can be considered as one of the most important prerequisites to uniform coloration. This is most relevant to cases when ionic dyes are used for dyeing of polymers having a large number of reactive centers, for which further redistribution of the dye strongly sorbed by the reactive centers of the fibrous material is a very complex task. The uniformity of distribution of the dye over the fibrous material in the beginning of the dyeing was assessed using the dyeing nonuniformity coefficients K and the leveling power of the agent R. Below, we describe the procedure for estimating the parameters K and R for the case of dyeing of polyamide materials with acid metal complex based dyestuff Dasher Blue Z, using Ivalon K and Lyogen RAM as levelers [3].

This procedure involved dyeing of two samples of a polyamide fibrous material, which were successively charged into the same dyeing bath with a 3-min interval. Total dyeing time 10 min, dyeing bath temperature $98 \pm 2°C$. Dyeing bath composition, %: leveler 1, acetic acid 2, and dye x.

[1] The analysis was carried out for agents developed or studied with participation of the authors.

The dyeing nonuniformity coefficient K was calculated by the formula

$$K = I_1/I_2,$$

where I_1 and I_2 are the coloration intensities of the first and second samples, respectively.

The coloration intensity was determined as the Kubelka–Munk function, based on the reflection coefficients of the colored sample, measured on a Specol-11 instrument. The leveling power R, %, was calculated by the formula

$$R = 100 - \frac{(K_i - 1) \times 100}{K_b},$$

where K_i and K_b are the nonuniformity coefficients for the analyzed and blank samples, respectively.

Table 1 compares the leveling power indicators of Ivalon K and Lyogen RAM. To illustrate how introduction of the leveler into the dyeing system affects the dye sorption and, correspondingly, the K and R parameters, the data in Table 1 are correlated with the uptake curves for the dyestuff Dasher Blue Z [1]. We determined experimentally the uptake curves (the content of the dye on the fibrous material vs. the dyeing time). The amount of the dye in the polymer was determined as the difference between the contents of the dye in the initial dyeing solution and in the residual bath. The dye concentration in solution was determined spectrophotometrically on a Specol-11 instrument in the region where the optical density of the colored solutions linearly varies with the concentration of the dissolved dye. The resulting curves clearly illustrate the run of the sorption process on a fibrous material, but recording them is a time- and labor-consuming procedure. This makes these curves unsuitable for express determination of the leveling power of textile auxiliaries.

Figure 1 shows that introduction of the leveler in the first dyeing stage (0–30°C) decreases the dye sorption by the fibrous material, thereby decreasing the coefficient K (Table 1). It is seen from Fig. 1 that the dye sorption is higher in the case of Lyogen RAM than in the case of Ivalon K, which is consistent with a lower leveling power R of Lyogen RAM (Table 1). Thus, the parameters K and R fairly completely and adequately describe the influence of the agents on the uniformity of dyeing of fibrous materials and can be recommended for estimation of the leveling power and optimal concentration of agents.

The above-described procedure of assessing the uniformity of distribution of the dye in the first dyeing stage can be used for characterizing the processes of dyeing of synthetic fibers at temperatures $T \leq 100$°C. However, this procedure is unsuitable for dyeing under pressure (for example, batch dyeing of polyester fibrous materials is carried out at 130–135°C). We assessed the uniformity of the initial application of the dye onto the polyester material by a more labor-consuming procedure, determination of the moments of the kinetic sorption curves M [4]. They were calculated using our experimental curves of the dye sorption by the first layer of the polyester membrane by the formula [5]

$$M = c_\infty^{-1} \int_0^\infty \tau \frac{\partial c}{\partial \tau} d\tau,$$

where c_∞ is the equilibrium concentration of the dyestuffs in the polymer, g of dye per kg of polymer, and τ, time.

The equilibrium concentration of the dye in the polymer was determined by the multilayer membrane method [5]. To this end, a purified 40×500 mm polyester film was reeled onto a metallic rod 5 mm in diameter. The faces and free end of the roll were

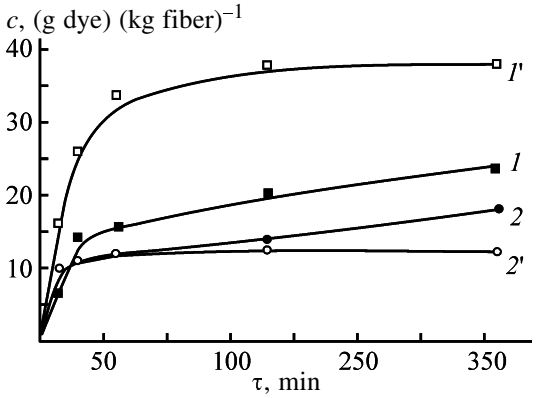

Fig. 2. Kinetic curves of sorption of disperse dyestuffs by the first layer of the polyester membrane when dyed at 135°C. Dyestuff: (*1, 1'*) Disperse Blue 2 PE and (*2, 2'*) Disperse Ruby PE. (*1, 2*) Commercially used technology and (*1', 2'*) 1.5 g l^{-1} of Ivlan-2.

thoroughly sealed. The reeled films were dyed under pressure at 135°C at the bath ratio of 1 : 150 for 360 min. When the treatment was complete, the film was cut across the layers, treated with acetone for 15 min and then with distilled water, and dried. The dye content in each film layer was determined spectrophotometrically.

Figure 2 shows as an example the kinetic curves of sorption by polyester threads of two disperse dyestuffs produced by the Pigment Production Association [4]. We used Disperse Blue 2 PE, an anthraquinone dye with a low leveling power (curves *1, 1'*), and Disperse Ruby PE, an azo dye with a high leveling power (curves *2, 2'*). Polyester threads were dyed at 135°C by the Rapid Color isothermal procedure [6] in the presence of an agent that showed efficient performance in production (a mixture of 1 g l^{-1} of Egonal W4027 leveler with 1 g l^{-1} of carrier, Remol NT) (curves *1, 2*) in the presence of Ivlan-2[2] (intensifying leveler for dyeing Dacron) (curves *1', 2'*).

Using the curves taken at the Ivlan-2 concentrations of 0–3 g l^{-1}, we calculated the sorption moments *M* (see Fig. 3). Since the sorption moment is an integrated characteristic of the process, we cannot state unambiguously that a decrease in *M* favors uniform dyeing, as this can be due not only to deceleration of sorption but also to a decrease in the dye uptake by the fibrous material. A certain decrease in the dyeability of fibrous materials in the presence of levelers is an ordinary drawback of such technologies and can be due to formation of labile complexes between the dye and the surfactant, which degrade incompletely with rising temperature. Formation of such compounds is a prerequisite to deceleration of sorption in the first dyeing stage, but at the same time it decreases the dye uptake by the fibrous material [7].

Thus, in analyzing the data we obtained, it is reasonable to take as the optimal sorption moments the corresponding characteristics of a composition that efficiently performed in production processes. The diagram in Fig. 3 allows the sorption moments of the dyes for different concentrations of the leveler developed to be compared with such characteristics and, thus, the optimal concentrations of the preparation to be estimated. It should be noted that the optimal concentrations depend on dye used: For dyestuff Disperse Dasher Blue 2 PE, the optimal sorption moments are achieved with the solution containing 1.0–2.0 g l^{-1}, and for Disperse Ruby dyestuff, 0.5–2.0 g l^{-1}, of Ivlan-2.

When the uptake of the dye by the fibrous material is decreased, its content in the residual bath increases. We estimated the degree of the dye utilization in the system using the distribution coefficient Γ determined by the Henry–Nernst equation [8]. It characterizes the ratio of the dye concentration in the film dyed for 360 min to that in the residual bath:

$$\Gamma = c_f/c_s,$$

where c_f is the dye concentration in the film, g of dye per kg of film, and c_s, dye concentration in the residual bath, g of dye per kg of solution.

Figure 4 presents the coefficients of distribution of dyestuffs Disperse Blue 2 PE and Disperse Ruby PE between the polyester fibrous material and the dyeing bath at different contents of Ivlan-2 in the bath. It is seen that introduction of any of the levelers decreases to a certain extent the degree of utilization of the dye, but it is possible to choose such concentrations of the preparations at which a decrease in the dyeability will be so insignificant that it will leave virtually unaffected the resulting color characteristics. For example, the uptake by the fibrous material of dyestuff Disperse Blue 2 PE is virtually unaffected by 0.5–1.5 g l^{-1} of Ivlan-2 and that of Disperse Pink PE, by 0.5–2.5 g l^{-1} [4].

It should be noted that leveling of the color in batch dyeing of polyester materials by disperse dyestuffs has specific features. The agent should not only decelerate the dye sorption by the polymer, which underlies the action of levelers for most of dyes and fibrous materials, but also afford major redistribution of the dye sorbed by the polymer [2].

[2] Developed with participation of the authors.

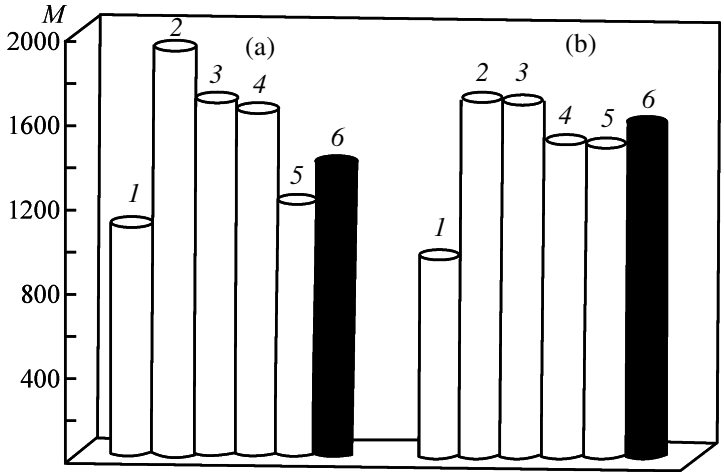

Fig. 3. Moments M of kinetic curves of sorption of dyes for polyester materials in relation to levelers. Dyestuff: (a) Disperse Blue 2 PE and (b) Disperse Ruby PE; the same for Fig. 4. (*1*) Without and (*2–6*) with leveler; (*2–5*) Ivlan-2, g l^{-1}: (*2*) 0.5, (*3*) 1.0, (*4*) 1.5, and (*5*) 2.0; (*6*) Egonal W4027, 1 g l^{-1} + Remol NT, 1 g l^{-1}.

The ability of the agent to afford redistribution of the dye sorbed on the fiber surface into the polymer bulk is estimated quantitatively by the migration method [5, 9]. This method consists in determining the amount of the dye migrating from the colored to uncolored sample in a reel made of two samples of the fabric, twisted together, simulating a nonuniformly colored polyester material. The experiment was carried out in the presence of Ivlan-2 under conditions similar to those in dyeing. The migration effect m was calculated by the formula

$$m = \frac{c_b/c_a}{c_b^0/c_a^0},$$

where c_a^0 and c_a are the contents of the dye in the samples of the preliminarily dyed material in the blank experiment and in the experiment with the leveler added, respectively, and c_b^0 and c_b, contents of the dye in a sample of undyed material in the blank experiment and in the experiment with the leveler added, respectively.

When polyester is dyed by batch high-temperature procedures, sections of the packages with a low density of reel of the fibrous material sorb a larger amount of the dye than sections with a high density. This is especially characteristic of dyeing by isothermal procedures with poorly leveling dyes having a high affinity for the fiber. Special preparations can cause the polyester structure to loosen, which will be responsible for redistribution of the dye in the bulk of the fibrous material owing to migration. However, redistribution of the dye should be uniform, as too high migration intensity deteriorates again the quality of dyeing of the polyester. The dye migration intensity depends on the type of the fibrous material, the leveler and dye used, the leveler concentration, and the temperature of the process. Therefore, theoretical substantiation of the optimal intensity of migration is a very difficult task. In this connection, we can suggest to take a textile auxiliary formulation successfully used in production processes, as a system with optimal characteristics. For example, in dyeing of polyester by Rapid Color high-temperature isothermal procedure, a good performance is demonstrated by a formulation including 1 g l^{-1} of leveler, Egonal W4027, and 1 g l^{-1} of the carrier, Remol NT.

Figure 5 shows how the migration effect m of a disperse dyestuff with a low leveling power, Disperse Blue 2 PE, is affected by the Ivlan-2 concentration at temperatures within 90–135°C. For comparison, we presented the migration effects for the optimal system

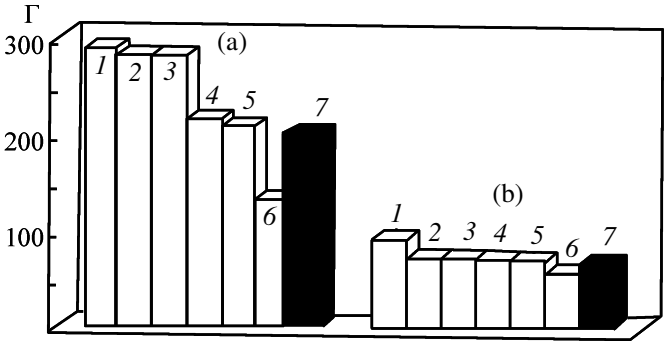

Fig. 4. Dye distribution coefficients Γ in relation to the textile auxiliary agent. (*1*) Without and (*2–7*) with leveler; (*2–6*) Ivlan-2, g l^{-1}: (*2*) 0.5, (*3*) 1.0, (*4*) 1.5, (*5*) 2.0, (*6*) 3.0; (*7*) Egonal W4027, 1 g l^{-1} + Remol NT, 1 g l^{-1}.

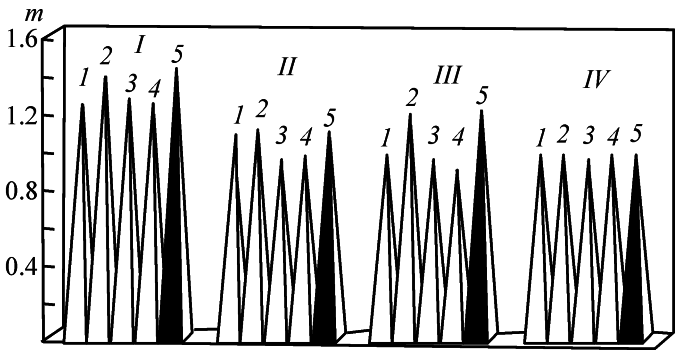

Fig. 5. Migration effect m of the dyestuff Disperse Blue 2 PE in a polyester thread as influenced by the Ivlan-2 concentration. (*1–4*) Ivlan-2, g l^{-1}: (*1*) 0.5, (*2*) 1.0, (*3*) 1.5, and (*4*) 2.0 and (*5*) Egonal W4027, 1 g l^{-1} + Remol NT, 1 g l^{-1}. Temperature, °C: (*I*) 90, (*II*) 115, (*III*) 130, and (*IV*) 135.

(commercially used process). Figure 5 shows that the dye migrates most intensively at 90°C, evidently, due to a purely superficial application of the dye onto the polyester, which is responsible for its easy redistribution. At temperatures above the glass transition point of the polyester (115–135°C), dyes penetrate inside the fibrous material, and the migration intensity decreases. The closest to the optimum are migration effects observed at 135°C and Ivlan-2 concentration of 1.0–1.5 g l^{-1}.

The diffusion coefficients D of the disperse dyestuffs were calculated using the curves of distribution of the dyestuffs over the layers of a multilayer film polyester membrane when dyed for 360 min [5]:

$$X_{c=c_0/2}/(D^{1/2})\tau = 0.964,$$

where $X_{c=c_0/2}$ is the distance to which the dye has penetrated when 50% of the equilibrium sorption is achieved; c, concentration of the dye at the given penetration depth, and τ, dyeing time.

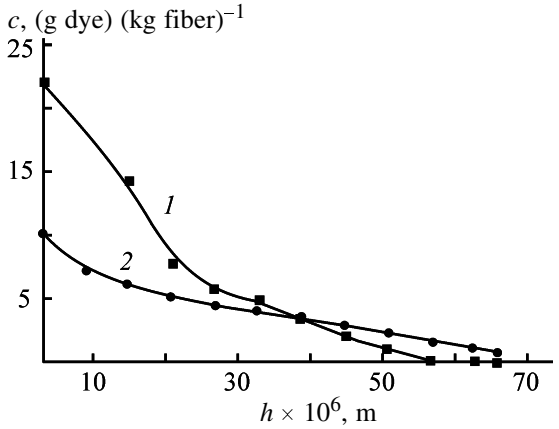

Fig. 6. Curves of redistribution of the dyes over the polyester membrane layers in the presence of 1.5 g l^{-1} of Ivlan-2 at the dyeing temperature of 135°C and dyeing time of 360 min. (*c*) Concentration of the dye on the fiber and *h*, thickness of the polyester membrane layer.

Figure 6 presents as an example the typical curves of distribution of the dyes over the layers of the multilayer polyester membrane in the presence of Ivlan-2. Table 2 lists the calculated diffusion coefficients.

As known, high diffusion coefficients are indicative of possible formation of a nonuniform color on a fibrous material, while a significant decrease in them can cause the dye uptake by the fiber to decrease. The closest to the optimum are the coefficients of diffusion of the dye from a system containing Ivlan-2 in amounts of 1.5 (for Disperse Blue 2 PE) and 0.5–1.0 g l^{-1} (for Disperse Ruby PE).

Analysis of the migration and sorption characteristics of the dye–leveler system for polyester materials shows that, compared to sorption moments and diffusion coefficients, the migration effects determine a narrower range of the leveler concentration, 1–1.5 g l^{-1}, corresponding to highly uniform coloration

Table 2. Coefficients of diffusion of dyes into the polyester film in relation to the levelers

Leveler, g l^{-1}	Diffusion coefficient $D \times 10^{13}$, m s^{-1}, of	
	Disperse Blue 2 PE	Disperse Ruby PE
None	5.7 ± 0.1	11.0 ± 0.2
Ivlan-2:		
0.5	3.5 ± 0.1	7.8 ± 0.1
1.0	8.4 ± 0.1	7.7 ± 0.1
1.5	6.9 ± 0.1	2.1 ± 0.1
2.0	10.9 ± 0.2	3.9 ± 0.1
3.0	3.9 ± 0.1	5.7 ± 0.1
Egonal W 4027, 1 + Remol NT, 1	7.8 ± 0.1	7.4 ± 0.1

of the polyester. This holds for dyes with both high and low leveling powers.

CONCLUSIONS

(1) In batch dyeing of synthetic fibrous materials at temperatures $T \leq 100°C$ in the presence of levelers, such characteristics as the dyeing nonuniformity coefficients K and the leveling power of the agent R fairly completely and adequately describe the influence of the agents on the uniformity of dyeing of fibrous materials. This makes them suitable for assessing the leveling powers of agents and determining their optimal concentration.

(2) In batch dyeing of polyester fibrous materials at 130–135°C, the leveling power of the agents can be completely assessed using the sorption (sorption moment M) and migration (migration effect m and diffusion coefficient D) characteristics. We found that, compared to sorption moments and diffusion coefficients, the migration effects determine a narrower range of the leveler concentration, 1–1.5 g l^{-1}, corresponding to highly uniform coloration of the polyester. Thus, it is more reasonable to use the migration effects for express assessment of the properties of the leveler and determination of its optimal concentration.

(3) In batch dyeing of any synthetic fiber, the degree of utilization of the dye can be assessed using the distribution coefficient Γ.

Received January 26, 2005; in final form, November 15, 2005

Abstract—The method of polymerization in the plasma of a dc glow discharge was used to obtain thin-film polysiloxane coatings on metallic substrates. The chemical composition, structure, and deposition rate of the coatings were studied in relation to process parameters.

DOI: 10.1134/S1070427206010319

This study is concerned with deposition of thin organosilicon coatings on metallic substrates by polymerization in the plasma of a glow discharge in a vacuum. Coatings of this kind can be used as antifriction, dielectric, protective, and hydrophobic films. Use of plasma polymerization minimizes the expenditure of materials and makes it possible to obtain thin coatings with a thickness of fractions of a micrometer [1–4]. To solve the problem, a deposition installation and a procedure for measuring the thickness of the coatings obtained were developed. The composition and structure of the coatings were determined by reflection IR spectroscopy.

EXPERIMENTAL

The installation developed in the study is shown schematically in Fig. 1.

The installation includes as a basic unit the working chamber fabricated in the form of a 500 × 300 mm 12Cr18Ni10Ti stainless steel cylinder. The cowling of the chamber has three windows for visual inspection of the process and a hatch with an inner diameter of 250 mm. The lids of the working chamber have apertures for voltage supply to the working electrodes. The 10-mm-thick electrodes are fabricated from D16T aluminum alloy. Systems of parallel electrodes of diameters D 90 and 45 mm are used. An annular hollow, made within the upper electrode, is closed with a tightly fit Teflon cover. The hollow is connected with the lower surface of the electrode by a number of fine (D = 0.8 mm) apertures. The Teflon cover has a pipe for delivery of the monomer vapor into the hollow. This design provides uniform distribution of the monomer vapor over the entire interelectrode space.

The pressure in the working chamber was monitored with a VT-3 thermocouple vacuum gage. The discharge was electrically fed from a UIP-1 versatile power source with a ballast resistor of 6.9 kΩ. The vessel with the starting monomer was connected with the working chamber via a leak. The vessel was heated with an electric heater. The chamber had a special inlet for a wire probe for measuring by the Klagge method the discharge parameters and the thickness of a film being deposited [5].

The 132-24 oligodiethylsiloxane liquid was used as the monomer. Its functional composition was the following: $(C_2H_5)_3SiO_{0.5}$, $(C_2H_5)SiO$, and $C_2H_5SiO_{1.5}$

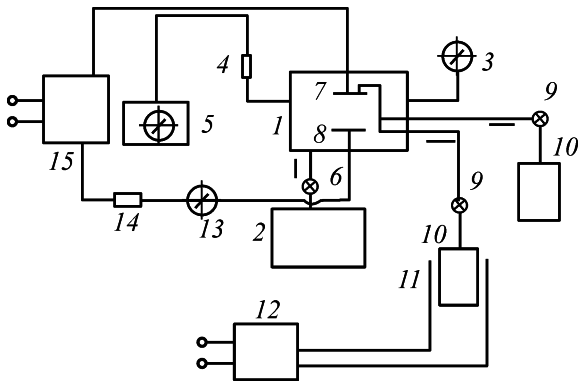

Fig. 1. Schematic of the installation: (*1*) working chamber, (*2*) vacuum pump, (*3*) mechanical vacuum gage, (*4*) thermocouple tube, (*5*) thermocouple vacuum gage, (*6*) evacuation valve, (*7*) upper electrode, (*8*) lower electrode, (*9*) leak, (*10*) vessel with the monomer, (*11*) electric heater, (*12*) laboratory autotransformer, (*13*) milliammeter, (*14*) ballast resistor, and (*15*) power source.

units [6, 7]. This siloxane has a comparatively high partial pressure P of the monomer at room temperature ($P \approx 50$ Pa [6]), which facilitates its feeding into the reactor.

The experiments were carried out as follows. A sample (12Cr18Ni10Ti steel foil strip of thickness 40 μm) was placed on the lower electrode. The small thickness of the sample made it possible to exclude any disturbance of the discharge. The monomer was fed into the interelectrode discharge zone after preliminary evacuation of the reactor. The interelectrode spacing L was varied within the range 10–30 mm, and the ignition voltage in the siloxane vapor was U_i = 450–600 V.

The occurrence of a discharge was visually inspected via windows in the walls of the working chamber.

The coating thickness was determined by weighing. The spectra were measured on a Shimadzu spectrometer. After a spectrum was obtained (100 times with the subsequent averaging), the spectrum of the starting sample was subtracted from that of the coating, the resulting curve was smoothed with a Fourier filter to the fifth frequency, and the spectrum was identified using the database of the Novosibirsk Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences.

The geometric parameters of the discharge system strongly affect the course of plasmochemical processes that occur in this system. At the critical interelectrode spacing, which depends on the composition of the gas medium, the discharge becomes unstable, and a still smaller spacing, disappears at all [8, 9].

The dependence of the current–voltage (I–U) characteristic of the discharge on the interelectrode spacing was studied in the range L = 10–30 mm. The measurements were made at P = 50 Pa and D = 90 mm. At the interelectrode spacing L = 10 mm, the discharge becomes unstable and spark microdischarge breakdowns of the interelectrode space are observed. At the interelectrode spacing L = 5 mm, there is no discharge in the interelectrode space. The $I(U)$ dependences are linear.

The main results of the experiments are the following: the total thickness of the near-cathode region of the discharge and of the anode space is 5–10 mm for the given gas medium and experimental conditions; as the interelectrode spacing increases, the I–U characteristic of the discharge changes only slightly, i.e., the main voltage drop occurs in the near-cathode region. The voltage drop in the positive column (whose length increases with the interelectrode spacing) is about 20–30 V cm^{-1}.

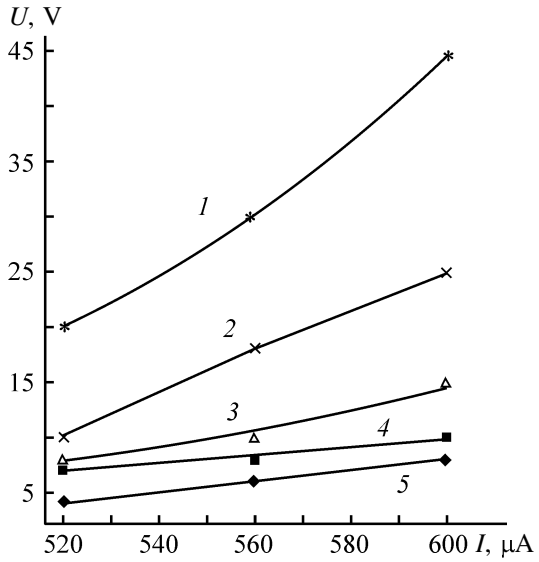

Fig. 2. I–U characteristics of the discharge at different pressures. (U) Voltage and (I) current. P (Pa): (*1*) 100, (*2*) 60, (*3*) 40, (*4*) 25, and (*5*) 15.

The dependence of the I–U characteristic on the pressure P in the chamber was studied at L = 20 mm and D = 90 mm. The results obtained are shown in Fig. 2. It can be seen that the dependence of the I–U characteristic on the pressure P in the working chamber is considerably stronger than that on the interelectrode spacing L. When the pressure is varied within the range 10–40 Pa, the I–U characteristic changes only slightly. If, however, the pressure is raised to 50–100 Pa, the I–U characteristic changes dramatically because of a decrease in the discharge resistance, i.e., an increase in its conductance.

Hence follows that the effect of the electron impact on the dissociation rate and on other plasmochemical processes in the discharge zone changes fundamentally [8, 9].

The rate of coating deposition is determined in plasmochemical processes by the parameters of the working process and by the rate of monomer supply. The following basic processes may occur in this case [10, 11]: (1) homogeneous polymerization in the gas phase, (2) heterogeneous polymerization on the sample surface, and (3) plasmochemical etching of the sample surface.

Depending on a discharge mode, either deposition of a polymer film onto the sample surface or etching of this surface occurred. Three different types of plasma polymerization, depending on the process

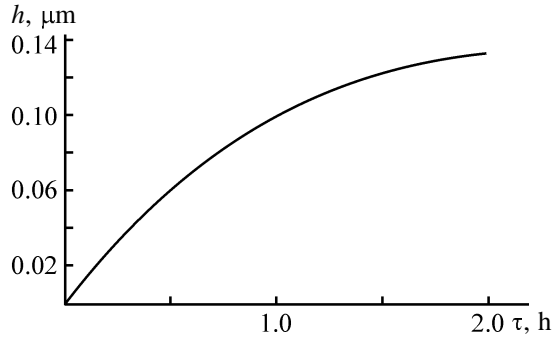

Fig. 3. Polymer film thickness h vs. the deposition time τ.

mode, were revealed in the study. These mode are conditionally termed "mild," "medium," and "severe." The mild process mode has the following parameters: P = 40–50 Pa, I = 8–12 mA, D = 90 mm, j = 0.12–0.19 mA cm^{-2}, L = 20–30 mm, and U = 520–540 V. In each experiment, three samples were placed on the lower electrode, with the arithmetic mean over the three samples taken as the gain in mass. The dependence of the coating thickness on the deposition time is shown in Fig. 3. The film deposition rate is about 0.1 μm h^{-1} in this mode.

It follows from the spectral data obtained that the coating is composed of organosilicon structures containing the starting polysiloxane base and aromatic and unsaturated hydrocarbon units. The low growth rate of the coating (about 0.1 μm h^{-1}) indicates that the polymerization occurs heterogeneously, rather than in the gas phase [1].

The medium process mode has the following parameters: P = 60 Pa, I = 20 mA, D = 90 mm, j = 0.3 mA cm^{-2}, U = 580–600 V, and L = 20–30 mm. When the experiments were performed in this mode, the sample mass decreased, i.e., the sample etching rate exceeded the rate of polymer deposition.

The film deposition rate can be raised by passing to a mode in which the monomer polymerization occurs not only on the electrode surface, but also in the gas phase, with its subsequent deposition onto the surface. For this purpose, it is necessary to make higher the current density and concentration of monomer species in the working zone. Further experiments were performed with electrodes of a smaller (D = 45 mm) diameter. With these electrodes, the third, severe mode could be implemented. This mode has the following parameters: P = 50 Pa, I = 20 mA, j = 1.26 mA cm^{-2}, U = 540 V, L = 20 mm. In this mode, a considerable electrode heating (to above 100°C) was observed.

The results of the experiments consist in the following: (1) the coating deposited in this mode is thicker than that obtained in the mild mode; (2) according to IR data, the specific content of organic units in the coating is considerably lower than that in the preceding experiments. As the deposition mode becomes more severe, the organic component is more intensively removed from the coating.

The coating deposition rate in this mode was about 0.25 μm h^{-1}, i.e., polymerization occurred not only on the sample surface, but also in the gas phase [1, 11]. In this case, the deposition rate of the polymerized product from the gas phase onto the sample surface exceeded that of plasmochemical etching of the surface. As the working pressure was raised to $P \approx$ 120 Pa, and the current, to 40 mA (i.e., to a current density j = 2.5 mA cm^{-2}), no significant increase in the growth rate was observed.

According to the IR data, the resulting coating is mostly composed of SiO_2 (absorption bands of organic compounds are virtually absent). The coating exhibits a high hydrophobicity and it is not wetted by water, methylene chloride, and toluene.

CONCLUSIONS

(1) An installation for deposition of polysiloxane coatings by polymerization in the plasma of a dc glow discharge was developed.

(2) It was shown that raising the working pressure and current density leads to a change of the deposition mechanism from heterogeneous to homogeneous-heterogeneous. The coatings obtained exhibit hydrophobic properties.

Received August 24, 2005

Abstract—The thermal stabilities of limestone with varied content of iron are compared. The nature of the differences observed is discussed.

DOI: 10.1134/S1070427206010320

The properties and thermal stability of limestone with a high content of iron (0.81 wt %) were considered in [1–3] in comparison with analytically pure grade $CaCO_3 \cdot 0.17H_2O$. Here we compare the thermal stabilities of limestone with a low content of iron and of the same analytically pure grade reagent.

Limestone from the Torgashino deposit in Krasnoyarsk krai was used. After its dispersion, the 0.08-mm fraction was separated by sieving and kept over P_2O_5 for five days. Then the preparation was degassed at 200°C for 6 h. This limestone was taken to be the starting material. The quantitative analysis of the samples was performed in conformity with GOST (State Standard) 4530–76 and 5382–91; a DRON-3 diffractometer served for X-ray diffraction analysis. Mass-spectrometric measurements were made with an MI-1305 ionization spectrometer.

Thermal studies were performed in air with a Q-1500D derivatograph. Mössbauer spectra were measured on an electrodynamic spectrometer based on an AI-5006-3M-V100 analyzer operating in the constant-acceleration mode. The spectra obtained were processed on an ES1022 computer. The ^{57}Co isotope in a chromium matrix, with an activity of 0.5 GBq, served as the source of γ-radiation. Kinetic curves of limestone decomposition were obtained by the volumetric method at 825 ± 0.5°C, with 0.100-g weighed portions used. The procedures used were described in more detail in [1–4].

The chemical composition of limestone is the following (wt %): main substance $CaCO_3$ 93.50, Fe 0.40, (K + Na) 0.11, Si 1.91, Al 0.20, Mg 0.60, and other impurities 3.28. The X-ray phase analysis (Fig. 1) suggested that the starting limestone contains $CaCO_3$ in the calcite modification, goethite FeOOH, and wustite FeO. The content of other crystalline phases is less than 3.16%.

Additional evidence concerning iron minerals was

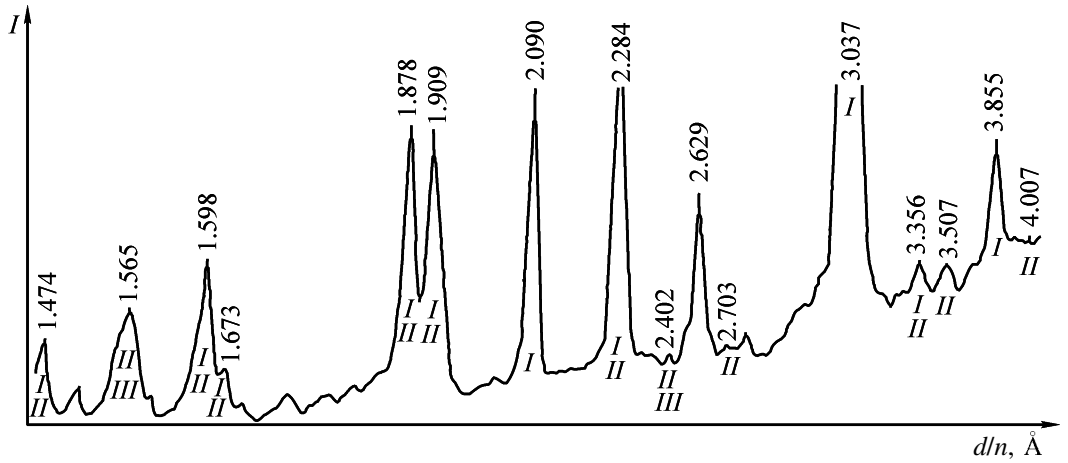

Fig. 1. X-ray diffraction pattern of the starting limestone. (*I*) Absorption intensity and (*d*/*n*) interplanar spacing. (*I*) $CaCO_3$, (*II*) goethite FeOOH, and (*III*) wustite FeO.

obtained by Mössbauer spectrometry on heating the limestone at 825°C (Fig. 2). The shape of the spectrum and its parameters (quadrupole splitting ΔE_Q and isomer chemical shift δE) indicate the following [5]: the doublet of peaks at the center belongs to siderite $FeCO_3$, and broad weak peaks on the periphery of the spectrum, to magnetite Fe_3O_4 and hematite α-Fe_2O_3. It follows from the derivatogram (Fig. 3) that a noticeable change in the mass of the weighed portion of limestone starts in air at 220°C. The decomposition of the preparation is the most pronounced at 860±1°C; the mass of the weighed portion stabilizes at around 879°C. According to the mass-spectrometric data (Fig. 4), the decomposition rate of limestone in a vacuum with a residual pressure of 10^{-6} torr is the highest at 610±1°C. The strong discrepancy between the temperatures of the highest decomposition rate in air and in a vacuum is typical of calcite [6].

The three experimentally obtained peaks of the dehydration rate of limestone (Fig. 4) point to the existence of at least three centers of water localization in limestone. The total content of water in limestone as a whole and at these centers can be judged from the areas delimited by curve *1* (H_2O^+) from above, temperature axis from below, and either the boundaries of the curve or temperature sections of this curve from the right and left (Fig. 4). These areas were calibrated against the mass of water with the use of gravimetric data (Fig. 3, TG curve). The portion of the TG curve below 400°C corresponds to a decrease in the mass of the weighed portion of limestone solely through release of H_2O. However, according to curve *1* in Fig. 4, water is released from limestone beginning at 50°C. Gravimetry fails to detect this water because of the low sensitivity of this technique as compared to mass spectrometry. Therefore, the calibration can be based on the assumption that only 1 mg of H_2O is removed from the starting limestone samples up to 400°C (Fig. 3). This corresponds in Fig. 4 to the area under curve *1*, delimited from the right by the section at T = 400°C. The portion of curve *1* in the range from 50 to 540°C corresponds to dehydration and decomposition of hydrogoethite [7–10]. The X-ray diffraction data (Fig. 1) and the calculations based on the results of chemical analysis and mass-spectrometric data (Fig. 4) confirm this conclusion and yield the formula $FeOOH \cdot 0.7H_2O$. The third peak in Fig. 4 (610°C) corresponds to H_2O from dehydration of calcite [1–4, 6]. The calculation yields the formula $CaCO_3 \cdot 0.02H_2O$. Water is completely removed from the starting limestone only in a vacuum (residual pressure 10^{-6} Torr) at 800°C, when calcite itself completely decomposes also. On the whole, the starting limestone sample contain, according to gravimetric and mass-spectrometric data, 1.20 wt % H_2O.

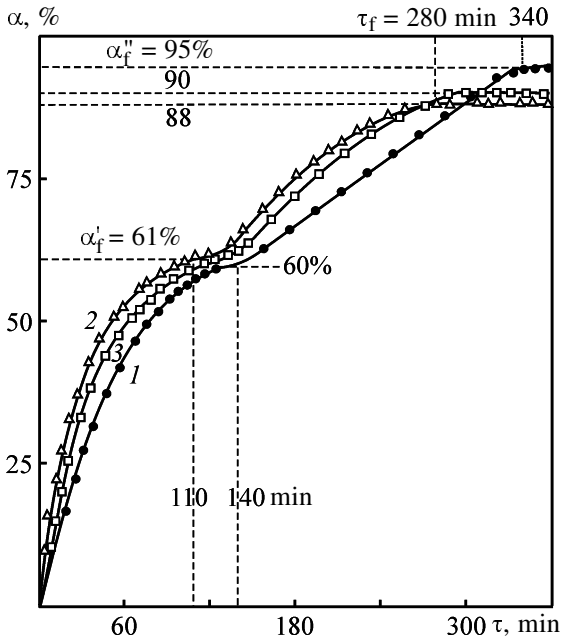

Fig. 5. Kinetic curves for decomposition of (*1*) $CaCO_3 \cdot 0.17H_2O$ reagent and (*2, 3*) limestones at 825 ± 0.5°C. (α) Degree of decomposition of the samples, (τ) time, (α'_f, α''_f) degrees of decomposition to the first and second equilibria, and (τ_f) time in which the second equilibrium is attained. Sample: (*1*) $CaCO_3 \cdot 0.17H_2O$ reagent, (*2*) limestone from the Solomenskoe deposit, and (*3*) that from the Torgashino deposit. (τ) Decomposition time.

grade (curve *1*) and for limestone from the Solomenskoe and Torgashino deposits (curves *2, 3*). All these curves were obtained [2, 4] using the same procedure. It was found that, as regards the shape of the kinetic curve, the Torgashino limestone (curve *3*) is close to that from the Solomenskoe deposit (curve *2*). This similarity is manifested in the decomposition rate, in the time in which the first equilibrium state is attained, and, what is the most important, in the kinetic type of decomposition after that, rather than the diffusion type as in the case of the reagent [2]. The fact that the second equilibrium is reached later for the Torgashino limestone can be attributed to the lower (by a factor of 2) content of iron, which favors slower establishment of the second equilibrium.

Comparison of the chemical and mineralogical compositions of the $CaCO_3 \cdot 0.17H_2O$ reagent and the Solomenskoe [1, 2] and Torgashino varieties of limestone with the shape of the kinetic curves of their decomposition (Fig. 5) suggests that the key factor leading to a decrease in their thermal stability is the presence of iron impurities in the form of various compounds. Previously, this has been established in a study of the decomposition of the $CaCO_3 \cdot 0.17H_2O$ reagent with addition of various iron oxides [11]. The amount of iron in the Solomenskoe limestone is twice that in the Torgashino mineral, and this is, undoubtedly, the basic reason for the difference between curves *2* and *3* in Fig. 5.

CONCLUSIONS

(1) The limestone from the Torgashino deposit contains 1.20 wt % H_2O, which is not removed by drying of dispersed limestone at 200°C for 6 h.

(2) The composition of limestone is the following (wt %): $CaCO_3 \cdot 0.02H_2O$ 94.00, $FeOOH \cdot 0.7H_2O$ 3.52, FeO 0.25, other impurities 2.23.

(3) The Torgashino limestone is close in the kinetics of thermal decomposition at 825°C to that from the Solomenskoe deposit, which is due to the twice lower content of iron in the former.

(4) The lower thermal stability of the Torgashino limestone, compared with the $CaCO_3 \cdot 0.17H_2O$ reagent, is due both to the lower content of water ($CaCO_3 \cdot 0.02H_2O$) and to the considerable content of iron.

Abstract—Nickel–zinc ferrite was prepared by coprecipitation from liquid waste formed in chemical and electrochemical processing of metals.

DOI: 10.1134/S1070427206010332

In industry, spent etching solutions for chemical and electrochemical processing of steel articles are converted into a solid phase that is mainly composed of heavy metal hydroxides. In various countries, this solid waste is stored on specially allocated territories and, being exposed there to the atmosphere, contaminates the environment through washing-out of heavy metals. At the same time, spent solutions containing expensive components can serve as valuable secondary raw materials and their use to synthesize ferrites would be a good way to utilize these solutions.

In this context, development of methods for synthesis of valuable products from the liquid waste formed in nickel and zinc plating and from spent solutions produced in electrochemical processing of metals, which would simultaneously eliminate their environment hazard, is, undoubtedly, a matter of current interest. Here we report a method that can be used to obtain highly dispersed powders of nickel–zinc ferrites from these solutions.

Magnetically soft nickel–zinc ferrites having low coercive force and high resistance are extensively used in transformer cores in a wide variety of radioelectronic devices. A promising method for synthesis of nickel–zinc ferrites is coprecipitation, which provides high chemical homogeneity of a magnetic material without repeated grinding and annealing at very high temperatures inherent in the ceramic technology. At the same time, the coprecipitation yields powdered materials whose particle size and stoichiometry can be preset and controlled. Here we report the results obtained in synthesis by coprecipitation of a powdered nickel–zinc ferrite of the composition $Ni_{0.35}Zn_{0.65}\cdot Fe_{1.984}O_{4\pm\gamma}$ from liquid waste formed in nickel and zinc plating, and also from a liquid solution of iron(II) sulfate, produced in chemical processing of steel in its metallurgical manufacture.

EXPERIMENTAL

The waste formed in electrochemical and chemical processing of metals, used in this study, had the following composition (g l^{-1}): (1) $ZnCl_2$ 50–80, $ZnSO_4$ 50–80, NH_4Cl 180–200, additives 35–45, Fe ≤ 0.03; (2) $NiSO_4$ 250–300, NaCl 7–15, Formalin 1.2, 1,4-butynediol 0.15–0.3, Fe ≤ 0.06; and (3) $FeSO_4$ 70–110, H_2SO_4 180.

Samples of a precursor of the ferrite $Ni_{0.35}Zn_{0.65}\cdot Fe_{1.984}O_{4\pm\gamma}$ were obtained by coprecipitation from a mixture of the required amounts of iron sulfate solutions and of the liquid waste from baths for nickel and zinc plating. Preliminarily, complexometry (Na_2EDTA) was used to determine the content of iron (Methylthymol Blue as indicator), nickel (murexide), and zinc (Eriochrome Black). A sodium carbonate solution served as a precipitating agent. A solution containing cations of nickel, zinc, and iron was slowly added to a solution of sodium carbonate, in which the pH was maintained at 9–10 during the precipitation. After the precipitation, the suspension was agitated for 5 h, washed with water to a negative reaction for sulfate and chloride anions, and filtered. Then the precursor was dried in air at 80°C and subjected to thermal treatment in the temperature range 400–950°C. The phase formation was monitored by X-ray phase analysis (CuK_α radiation). Thermogravimetric studies were performed on an MOM Q-1000 derivatograph (Hungary) in the temperature range 20–1000°C.

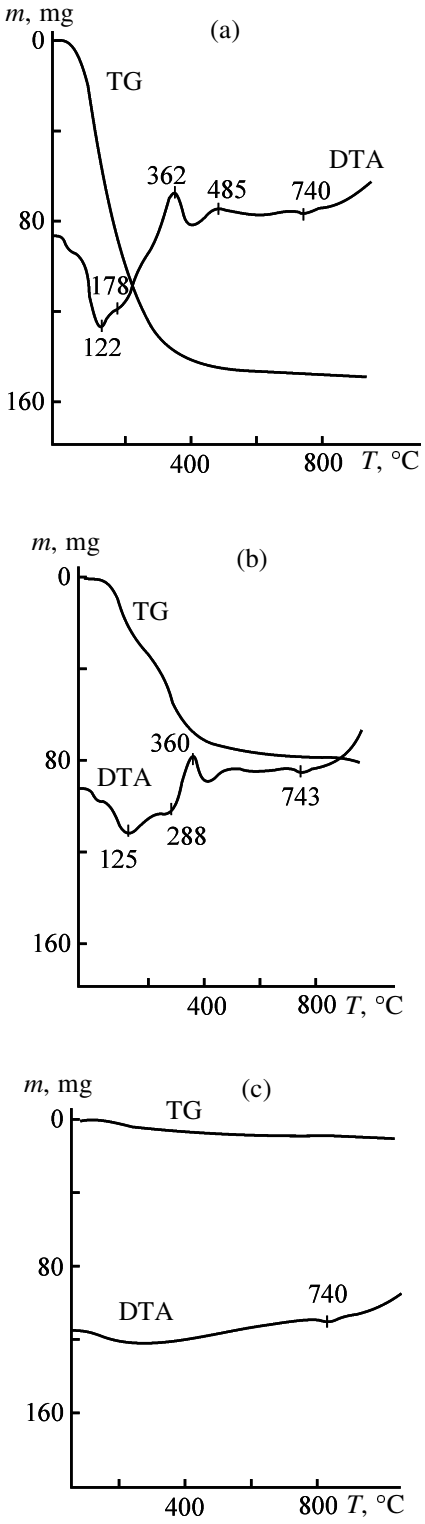

Fig. 1. DTA and TG curves of the precursor of the Ni–Zn ferrite, recorded in air for different samples. (*m*) Weight loss and (*T*) temperature. Sample: (a) dried at 80°C, (b) dried at 180°C, and (c) subjected to preliminary thermal treatment in air at 600°C.

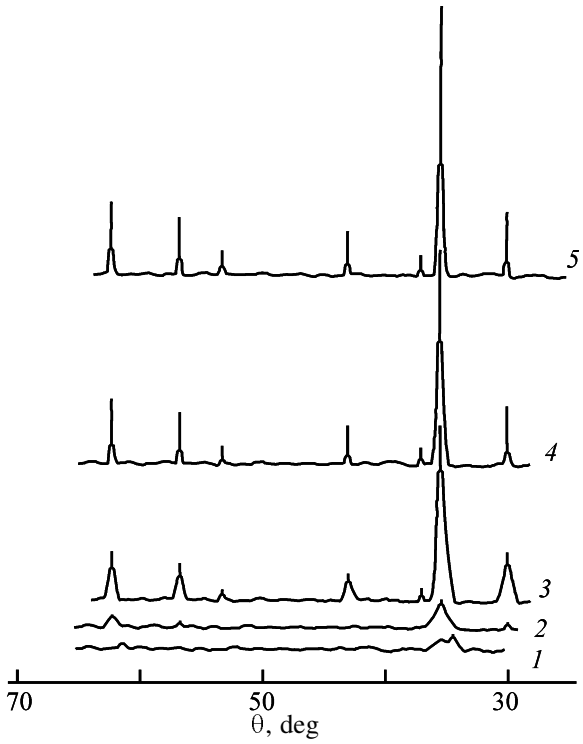

Fig. 2. Powder X-ray diffraction patterns of precursor calcined at different temperatures. (2θ) Bragg angle. *T*, °C: (*1*) 80, (*2*) 400, (*3*) 750, (*4*) 850, and (*5*) 950.

The initial permeability was measured by the induction method with samples fabricated in the form of rings with an outer diameter of 12 mm. The rings were pressed from powders to which polyvinyl alcohol was added and then were sintered at 1100–1250°C. The Curie point was determined from the temperature dependence of the specific saturation magnetization.

The size of powder particles was determined with a SediGraph 5100V2.00 particle size analyzer. The microstructure of the powders and articles fabricated from the nickel–zinc ferrite was determined by scanning electron microscopy on a JEOL 840 instrument with a REVEX (EDS) energy-dispersive analyzer.

The precursor synthesized by precipitation with an aqueous solution of Na_2CO_3 from a mixture of iron(II) solutions and solutions from baths for nickel and zinc plating is composed of a mixture of hydroxides, hydroxo carbonates, and carbonates of iron, nickel, and zinc. Figure 1a shows a derivatogram of a sample dried at 80°C, whence follows that adsorbed water is lost and the starting precursor decomposes with the weight loss in the temperature range 80–400°C. It should be noted that, according to the results of X-ray phase analysis (Fig. 2, curve *1*), the X-ray diffraction pattern of the starting precursor contains

several broadened reflections with maxima at 2.55 and 1.50 Å. This coincides with the X-ray diffraction pattern of the "bilinear" ferrihydrite phase [1], which shows only two broad diffraction bands. A similar X-ray diffraction pattern was observed in [2] for the precursor of the Ni–Zn–Cr ferrite, obtained by coprecipitation from wastes of steel works. This leads to a conclusion that cations of nickel and zinc are captured by the precipitating phase with a structure of ferrihydrite. After this phase decomposes at 360–365°C and the removal of water and carbon dioxide is complete, an exothermic effect appears in the DTA curve (Figs. 1a, 1b). This effect is, in all probability, due to formation of the spinel structure of a poorly crystallized Ni–Zn ferrite. The assignment of the exothermic effect at $T \approx 360$°C to the formation of the spinel phase is supported by the fact that this effect is not observed in the DTA curve of the sample already calcined at 600°C (Fig. 1c) and by the presence of several broad reflections associated with the poorly crystallized spinel phase in the X-ray diffraction pattern of the sample calcined at 400°C for 2 h (Fig. 2, curve *2*). It should be noted that the X-ray diffraction pattern of this sample contains no reflections related to iron oxide. All the DTA curves show a minor, with no weight loss, endothermic effect at $T \approx 740$°C, which cannot be assigned to any process as yet.

We found that the lattice constant of the forming spinel phase varies only slightly with the calcination temperature. This indicates that the composition of the phase with a spinel structure is invariable in the course of its synthesis at so low temperatures, in contrast to the ceramic technique of synthesis of Ni–Zn ferrites, in which the synthesis temperature is considerably higher [3]. In the latter case, the composition of Ni–Zn ferrites is enriched in zinc in early stages of formation.

An increase in the temperature of thermal treatment to 950°C makes higher the intensity of reflections in the X-ray diffraction pattern and leads to their narrowing, which indicates that spinel crystals become larger.

The powders synthesized at 400, 750, 850, and 950°C were used to press toroids (with a 10% solution of polyvinyl alcohol), which were then sintered at 1100, 1200, and 1250°C (3 h). The initial permeability μ was measured for these toroids. The highest initial permeability that could be obtained in sintering at 1250°C was 700 units. Figure 3 shows how the synthesis temperature of the Ni–Zn ferrite and the sintering temperature of the powders affect the permeability of the articles formed. It can be seen that

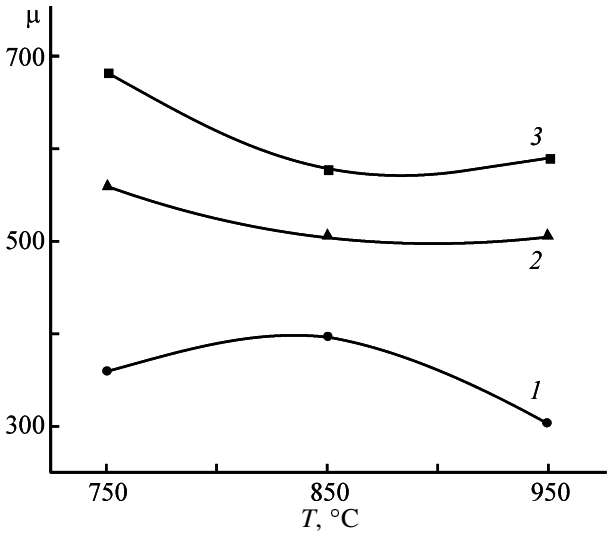

Fig. 3. Initial permeability μ of toroids fabricated from Ni–Zn ferrite vs. temperature T of their synthesis. Sintering temperature (°C): (*1*) 1100, (*2*) 1200, and (*3*) 1250.

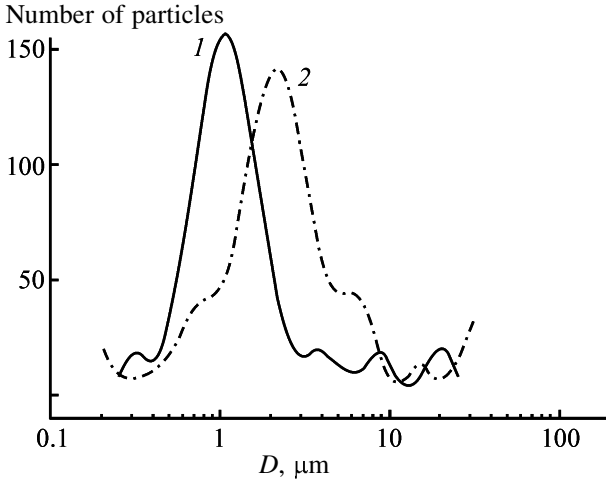

Fig. 4. Particle size (D) distribution of Ni–Zn ferrite powders synthesized at (*1*) 750 and (*2*) 850°C in 2 h.

the sintering temperature strongly affects μ, whereas the synthesis temperature affects μ to a considerably lesser extent in the range 750–950°C. This is presumably due to the fact that the particle size of powders of Ni–Zn ferrites synthesized at 750, 850, and 950°C changes only slightly. The particle size distribution curves show that the average particle size in this temperature range of synthesis is 1.0–2.2 μm (Fig. 4). The slight decrease in the initial permeability, observed as the synthesis temperature is raised, can apparently be attributed to a decrease in the activity of Ni–Zn ferrite powders synthesized at a higher temperature.

The microstructural features of the sintered toroids were studied by scanning electron microscopy of

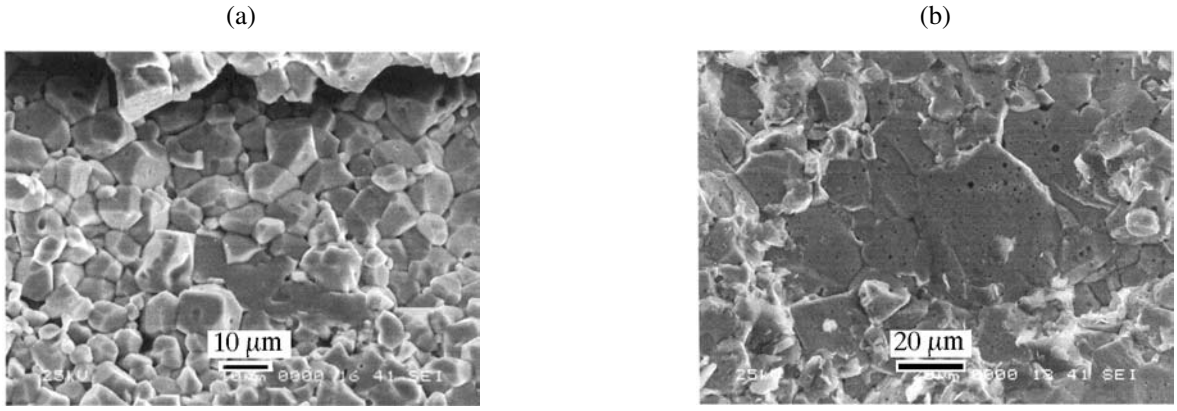

Fig. 5. Microstructure of a cleavage of Ni–Zn ferrite samples sintered at 1250°C. Synthesis duration 2 h. Synthesis temperature, °C: (a) 750 and (b) 950.

cleaved samples. A good uniformity of the grain size was only observed for samples synthesized at 750°C (Fig. 5a). It was found that raising the ferrite synthesis temperature leads to predominant growth of separate grains in sintering and is accompanied by a decrease in the initial permeability for such samples. In all probability, the extent to which the activity of ferrite particles synthesized at temperatures exceeding 750°C decreases varies with the particle size. It is this circumstance that initiates the predominant growth of separate grains in sintering of such powders at 1250°C. The samples synthesized at 950°C and sintered at 1250°C exhibit, in addition, an intragrain porosity (Fig. 5b), which also makes lower the initial permeability.

A typical temperature dependence of the specific saturation magnetization for the $Ni_{0.35}Zn_{0.65}Fe_{1.984} \cdot O_{4\pm\gamma}$ composition is shown in Fig. 6. The shape of the curve points to a rather good homogeneity of the chemical composition of the powder, and the specific saturation magnetization (σ_s = 35 G cm^3 g^{-1}) and the Curie point (θ = 227°C) correspond to the preset composition of the precursor of the Ni–Zn ferrite.

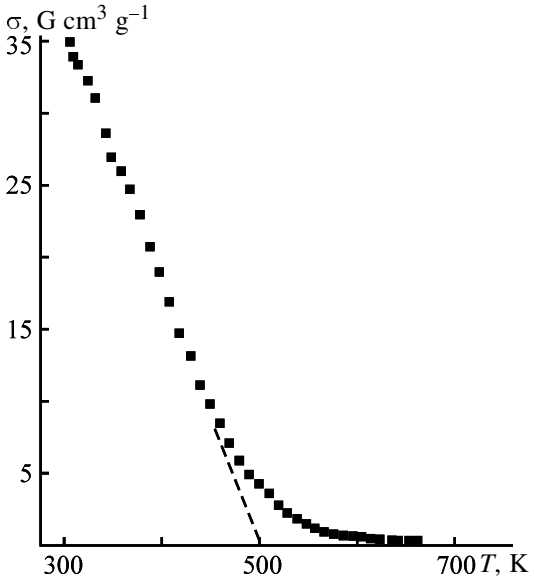

Fig. 6. Specific saturation magnetization σ vs. temperature *T* for the Ni–Zn ferrite. Synthesis temperature 750°C, sintering temperature 1250°C.

CONCLUSIONS

(1) Coprecipitation with an aqueous solution of sodium carbonate from a liquid waste produced in chemical and electrochemical processing of metals yielded a precursor from which a Ni–Zn ferrite of the spinel type is formed even upon heating to 400°C.

(2) Thermal treatment of such a powder at 750°C and sintering at 1250°C make it possible to obtain, without doping, articles with an initial permeability of more than 600 units.

Abstract—The possibility of obtaining residual graphite nitrate by water treatment of graphite nitrate and its subsequent drying was studied. The expansion coefficients were determined in the temperature range 500–900°C with a step of 100°C for the samples obtained.

DOI: 10.1134/S1070427206010344

Graphite nitrate produced by treatment of graphite with fuming nitric acid is of particular interest for synthesis of flexible graphite and use in the conventional application areas of expandable graphite intercalation compounds [1]. This product is characterized by nearly zero content of sulfur [2], readily undergoes subsequent modification [3], and is effectively expanded when heated to an even relatively low temperature. The manufacture technology of this product is simple and efficient and it employs only a single cheap reagent, fuming nitric acid. However, graphite nitrate is one of the most unstable graphite intercalation compounds and is inconvenient for practical use because of the release of nitric acid introduced into the interlayer space and sorbed on the surface. Graphite nitrate isolated from the reaction mass starts to decompose immediately after being brought in contact with air [4]. The decomposition is accompanied by egress of a part of nitric acid molecules from the interlayer space and, possibly, by ingress of water molecules sorbed from air into the interlayer space [5, 6]. As a result, the so-called residual graphite nitrate is formed [6].

The above-described processes of formation of residual compounds in air are very slow and take several weeks. Attempts to accelerate the process by heating to 50–100°C lead to removal of sorbed nitric acid, but the product itself virtually completely disintegrates and loses its ability to be expanded [5, 6].

It could be assumed *a priori* that residual compounds produced by water treatment of a freshly prepared graphite nitrate must retain a high capacity for expansion and other properties useful for consumers. This study is concerned with the possibility of obtaining practically valuable residual compounds based on graphite nitrate by its water treatment. Natural scaly graphite of the GT-1 brand from the Zaval'evskoe deposit (Ukraine) with an ash content of 5.58 wt % was subjected to oxidation. The bulk of the graphite is represented by two fractions with a particle size of 0.630–0.315 (74.3 wt %) and 0.315–0.200 mm (22.1 wt %). Fuming (98%) nitric acid was used (d = 1.51 g cm^{-3}). The residual graphite nitrate was synthesized at room temperature by the following procedure. A necessary amount of nitric acid was added to 25 g of the starting graphite, and then the reaction mixture was agitated for 10 min under the conditions that provide efficient removal of the forming nitrogen oxides from the reaction mass.

When the reaction was complete, 200 cm^3 of water was poured into the reactor. The reaction mass was agitated for 1 min and then quantitatively transferred to a Büchner funnel and washed with 2 dm^3 of water. The product, washed and squeezed on a filter, was quantitatively transferred to Petri dishes and dried in air to constant weight (about 3 days at 20–30°C). The data on the yield of the product were used to calculate the content m_0 of the intercalant in the product on the assumption that phase oxidation reactions do not occur at room temperature, i.e., the whole amount of carbon from the graphite matrix passes into the final product.

The product obtained, residual graphite nitrate, is a dry loose graphite-like powder with a pH value of

its water extract falling within the range 2.4–3.3, which makes it convenient for practical use. The product is effectively expanded on heating to give expanded graphite with a bulk density as low as 4 kg m^{-3}.

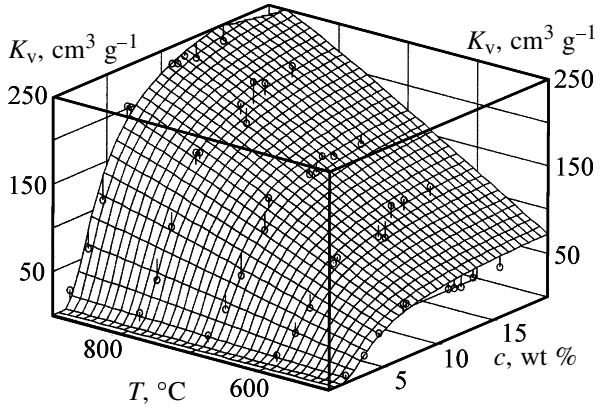

Fig. 1. Expansion coefficient K_v of samples of residual graphite nitrate vs. the intercalant content c and expansion temperature T.

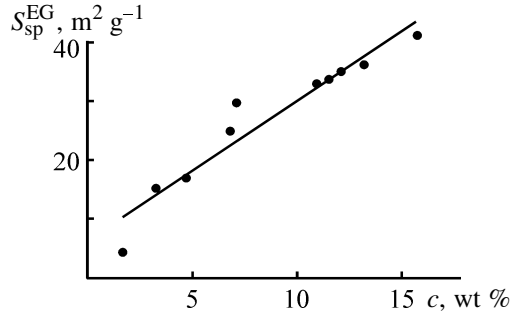

Fig. 2. Specific surface area S_{sp}^{EG} of expanded graphites obtained from samples of residual graphite nitrate at 700°C vs. the content c of the intercalant in these samples.

The expansion coefficient of the products obtained was determined as follows. A weighed portion of the product (m = 0.2–0.3 g) was introduced into a stainless steel cell preliminarily placed in a muffle furnace heated to 500–900°C and was kept there to complete expansion. The cell with the expanded graphite was withdrawn from the furnace, its contents were transferred with caution into a glass volumetric cylinder, and the volume V (cm^3) occupied by the expanded graphite was measured. The expansion coefficient was determined using the formula $K_v = V/m$ as an arithmetic mean of the results of three replicate measurements. The BET specific surface area of samples of expanded graphite, S_{sp}, was found from low-temperature adsorption of argon in conformity with GOST (State Standard) 13144–79. The pH values of water extracts from the samples of residual graphite nitrate were determined in accordance with GOST 17818.6–90.

The table shows how nitric acid in the stage of graphite oxidation affects the intercalant content and the expansion coefficient of the final product at different temperatures.

Figure 1 shows that the expansion coefficient of residual graphite nitrate increases with the content of intercalant in the graphite and with the expansion temperature. In the temperature range studied (500–900°C), the temperature dependences of the expansion coefficient are nearly linear for all values of c and tend to flatten out only at 800–900°C. The dependence of the expansion coefficient on the intercalant content is similar in the entire temperature range studied.

Figure 2 shows that the specific surface area of expanded graphite grows linearly with the intercalant

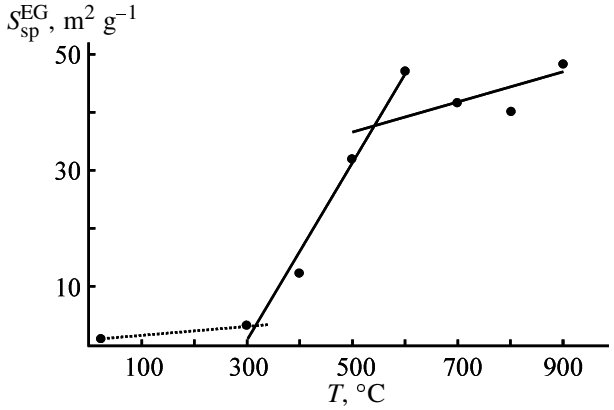

Fig. 3. Specific surface area S_{sp}^{EG} of expanded graphites obtained from a sample of residual graphite nitrate synthesized at an expenditure of fuming nitric acid of 90 g/100 g graphite (c = 15.71 wt %) vs. the expansion temperature T.

content in the starting samples of residual graphite nitrate and reaches a value of about 40 m^2 g^{-1}, which is characteristic of expanded graphite obtained from graphite intercalation compounds in their interaction with acids.

It is appropriate to discuss the plot of the specific surface area of expanded graphite vs. the temperature at which it is obtained (Fig. 3). Three linear portions can be distinguished in this plot. These portions correspond to three temperature ranges: 0–300, 300–550, and 550–900°C. In the first of these, raising the temperature at which the expansion is performed causes only a slight increase in the specific surface area S_{sp}^{EG}. Raising the expansion temperature from 300 to 550°C leads to a steep rise in S_{sp}^{EG} (about 10 m^2 g^{-1}) per 100°C, and in the third temperature range, values of S_{sp}^{EG} grow by only ~2 m^2 g^{-1} per 100°C. Such a run of this dependence can be attributed to the fact that both the starting residual graphite nitrate and expanded graphite prepared from it have virtually zero porosity in the classical understanding of this term. Then the pronounced increase in the specific surface area can occur only via formation of a new open surface.

In the first temperature range, there is no effective expansion of the graphite matrix. Only a pre-expansion occurs to give lens-like particles whose surface area only slightly exceeds that for flat particles of the starting residual graphite nitrate. In this case, the lenses are not ruptured and, as a result, no new surface is formed.

In the second temperature range, the volume of close lenses further increases and they break up to form a new open surface. The fraction of broken-up lenses increases with temperature and, at the end of the second range, virtually all the lenses are broken.

Raising the expansion temperature from 550 to 900°C causes, in all probability, a deeper breakup of the lenses and thereby leads to an additional separation of carbon layers, and just this fact is responsible for the additional gain in the new open surface area.

CONCLUSIONS

(1) Water treatment of graphite nitrate with the subsequent air drying of the resulting product yields residual graphite nitrates that can effectively expand on heating to form expanded graphite. The products obtained are convenient in handling and can find practical use in fire prevention and metallurgy.

(2) The temperature dependences of the expansion coefficient are nearly linear and, depending on the content of intercalate, have the form of ascending curves that level off at approximately 10 wt % intercalate. The maximum expansion coefficient is 230 cm^3 g^{-1}.

(3) The expanded graphite formed when products of this kind are heated compares well in its parameters, bulk density and specific surface area, with that produced from graphite hydrosulfate and can be successfully used as a petroleum sorbent and catalyst support, as well as in manufacture of flexible graphite and articles made of this material.

Abstract—The distribution of C_{60} and C_{70} fullerenes in the extraction system (C_{60} + C_{70})–α-pinene– ethanol–H_2O was studied at constant C_{60} to C_{70} ratio and variable total fullerene concentration at 25°C. The relationship between the C_{60} and C_{70} content in ethanol (I) and α-pinene (II) phases is nonlinear over the entire fullerene concentration range.

DOI: 10.1134/S1070427206010356

The development of new high-performance techniques for recovery of fullerenes from their mixtures to obtain relatively cheap commercially available individual fullerenes of high purity is an urgent problem. In this respect, the solvent extraction shows certain advantages as compared to commonly used preparative chromatography.

The first data on distribution of light fullerenes C_{60} and C_{70} in three extraction systems based on *o*-xylene as extractant were reported in [1, 2]. Proceeding with development of extraction system for separation of fullerene mixtures, we looked for a nonaromatic solvent that would readily dissolve fullerenes and form with nonaromatic polar components a multicomponent system with a large area of phase separation. Furthermore, solvated fullerenes (liquid or solid) which can be formed in such an extraction system must be sufficiently readily converted to nonsolvated pure fullerenes.

EXPERIMENTAL

It was found previously that commercial turpentine and turperntine oils containing α-pinene (2,6,6-trimethylbicyclo[3.1.1]hept-2-ene) fairly readily dissolve fullerenes. The treatment of fullerene-containing soot with these solvents allows preparation of organic solutions containing 1.5–2.5 g l^{-1} of C_{60}–C_{70} mixture, which is comparable with the solubility of fullerenes in toluene but is somewhat lower than their solubility in *o*-xylene [3–7].

On mixing α-pinene or its organic solutions with several polar solvents (H_2O, C_2–C_4 *n*-alkanols, diols), two-phase systems are formed without addition of specific phase-separating reagents as it is required in the systems studied in [1, 2]. This feature simplifies the preparation of extraction systems suitable for separation of fullerene mixtures. Since α-pinene is immiscible with water and fullerenes are insoluble in the aqueous phase, the binary pinene–water system is useless for separating fullerene mixtures. At the same time, the two-phase system formed by α-pinene with *n*-alkanol (e.g., ethanol) or *n*-alkanol–water mixture is characterized by more even distribution of all the components (among them fullerenes) and, therefore, can be used for extractive separation of fullerenes. In the case of α-pinene (or α-pinene-based solvent)–ethanol–water system, the lower phase is enriched in α-pinene (hereinafter this phase is referred to as the α-pinene phase) and the upper phase is enriched in ethanol (hereinafter referred to as the ethanol phase). In the course of phase equilibration, the α-pinene phase considerably contracts whereas the ethanol phase volume increases. In our experiments, the final (equilibrium) volume ratio of the ethanol and α-pinene phases was approximately 1 : 2.

It should be noted that commercial nonaromatic solvents (turpentine, turpentine oils, α-pinene) suitable for extractive treatment of fullerenes are much cheaper than chemically pure or analytically pure grade aromatic solvents (e.g., *o*-xylene).

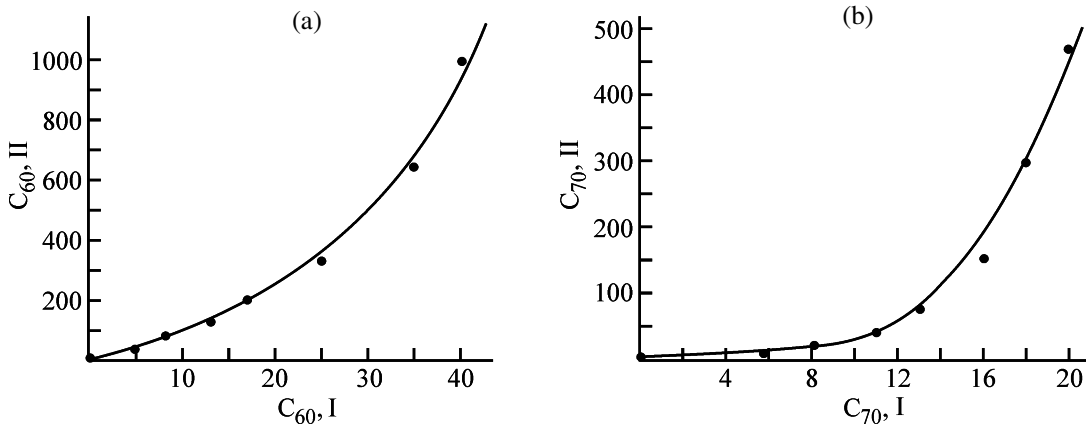

Fig. 1. Distribution of (a) C_{60} and (b) C_{70} between (I) ethanol and (II) α-pinene phases in the system (C_{60} + C_{70} fullerenes)–α-pinene–ethanol–H_2O at 25°C. For comments, see text.

In our experiments we studied the distribution of C_{60} and C_{70} fullerenes in the five-component two-phase system (C_{60} + C_{70} fullerenes)–α-pinene–ethanol–H_2O at 25°C. The extraction equilibria in this system were studied by the technique reported in [1, 2]. The C_{60} + C_{70} mixture was introduced into the extraction system in the form of a solid solution $(C_{60})_{0.68}(C_{70})_{0.32}$ which dissociates into individual fullerenes in the solvating solvents [8]. The equilibrium distribution of fullerenes was attained within 4–6 h. This time was by an order of magnitude shorter than that in the similar systems studied in [1, 2].

The main component contents in the coexisting phases as determined chromatographically was as follows (wt %). α-Pinene phase: α-pinene, 90; ethanol, 5; and water, 5; ethanol phase: α-pinene, 12; ethanol, 62; and water, 26.

Figures 1a and 1b show the distribution of C_{60} and C_{70} between the αpinene and ethanol phases at constant C_{60} content (68 wt %) in the C_{60}–C_{70} mixture and variable total fullerene concentration. The corresponding distribution curves are nonlinear over the entire fullerene concentration range. The similar nonlinear distribution of fullerenes was observed in other extraction systems [1, 2]. In our systems, the maximal C_{60} + C_{70} fullerene concentrations in the α-pinene and ethanol phases were 1400 and ~60 mg l^{-1}, respectively. These values are higher than those in the dimethylformamide-containing system [2] but lower than in the *n*-butylamine- and monoethanolamine-containing systems [1, 2]. Our results show also that in all the systems the α-pinene phase is enriched in C_{60} and C_{70} fullerenes, except for the region of very low C_{70} concentration in the ethanol phase (Fig. 1b).

The C_{60} distribution factor (the fullerene concentration ratio in the α-pinene and ethanol phases) gradually increases from 6.7 to 25 with an increase in the C_{60} + C_{70} concentration in the α-pinene phase from ~40 to 1400 mg l^{-1} (Fig. 1a). The C_{70} distribution factor gradually increases from 0.8 to 2.0 in going from dilute to concentrated solutions of fullerene in the α-pinene phase (Fig. 1b).

The C_{60} distribution factors in our systems are lower than those in the system (C_{60} + C_{70})–*o*-xylene–dimethylformamide and are commensurable with those in the system (C_{60} + C_{70})–toluene–dimethylformamide [2]. The C_{70} distribution factors in our and the above-noted systems [2] are commensurable.

The C_{60}/C_{70} separation factors K_s (the ratio of C_{60} and C_{70} distribution factors) gradually increase from ~8.4 to ~12.5 in going from dilute to concentrated fullerene solutions. It should be noted that in preliminarily studied systems of similar type [1, 2] K_s either remains constant or gradually decreases with increasing the total fullerene content.

Figure 2 shows that C_{60} preferentially accumulates in the α-pinene phase (its relative content ranges from 68 to 87 wt %). At the same time, the ethanol phase is enriched in C_{70} fullerene (its relative content ranges from 35 to 64 wt %). These results show that the aromatic α-pinene phase of lower polarity is enriched in less polarizable (spheroidal) C_{60} fulerene, whereas more polarizable ellipsoidal C_{70} fullerene is accumulated in the more polar phase (amine, monoethanolamine, DMF, ethanol). The similar relationships were preliminarily reported in [1, 2].

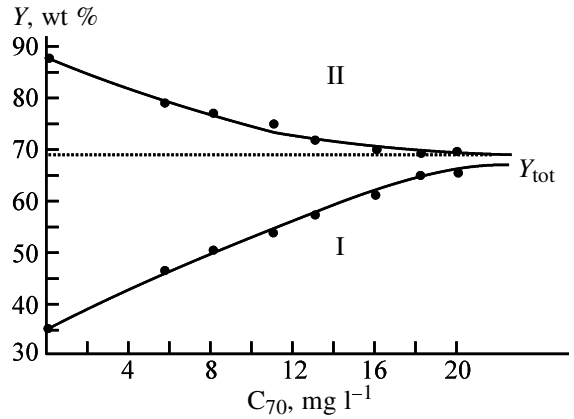

Fig. 2. C_{60} content Y in the $C_{60} + C_{70}$ mixture in (I) ethanol and (II) α-pinene phases vs. the C_{70} content in the ethanol phase in the system ($C_{60} + C_{70}$ fullerenes)–α-pinene–ethanol–H_2O at 25°C. Dotted line: starting $C_{60} + C_{70}$ mixture containing 67.9% C_{60}. Y values corresponding to the zero C_{70} content in the ethanol phase were obtained by extrapolation.

CONCLUSIONS

(1) The distribution of C_{60} and C_{70} in the system ($C_{60} + C_{70}$)–α-pinene–ethanol–H_2O can be used for separation of C_{60} from C_{70}.

(2) The C_{60} distribution factors (fullerene concentration ratio in α-pinene and ethanol phases) gradually increases from 6.7 to 25 with an increase in the $C_{60} + C_{70}$ concentration in the α-pinene phase from ~40 to 1400 mg l^{-1}.

(3) The C_{70} distribution factor gradually increases from 0.8 to 2.0 in going from dilute to concentrated solution of fullerenes in the α-pinene phase.

(4) The C_{60}/C_{70} separation factor K_s (ratio of distribution factors of C_{60} and C_{70}) gradually increases from ~8.4 to ~12.5 in going from dilute to concentrated solutions of fullerenes.

Received May 18, 2005

Abstract—The effect of spray drying of aerosil dispersions in a superheated steam on the formation of microspherical grains and their pore structure was studied.

DOI: 10.1134/S1070427206010368

Modern procedures of liquid chromatography require supports with microspherical grains less than 100 μm in size [1–4]. The preferable technique for synthesis of silica microspheres is spray drying, which combines several important procedures: filtration, drying, and granulation [4–9]. It was noted in [9–11] that drying of suspensions in a superheated steam is advantageous: because of the smaller humidity gradient between the heat carrier and the material being dried, the process occurs in a milder mode, and the fact that the specific heat of steam is 20–30% higher than that of air results in a higher efficiency and rate of drying and lower specific consumption of heat. In [4, 12] we suggested that, in spray drying of silica dispersions with a superheated steam, microspherical particles will be subjected to an additional (even though short-term) hydrothermal (or heat-and-steam) treatment. In the present study we experimentally checked this hypothesis.

It is known that high-purity pyrogenic oxides, and primarily aerosil, are promising for preparation of supports used in catalysis and chromatography. Oxides of this kind can be easily formed as grains and articles of various shapes and dimensions to give uniformly mesoporous structures [4, 13]. Therefore, we examined the influence exerted by the conditions of spray drying of aerosil dispersions in water and ammonia solutions on the properties of the microspherical product, with a superheated steam used as heat carrier.

EXPERIMENTAL

The dispersions studied were prepared from A-175 and A-380 aerosils mixed with distilled water or 2 and 5% ammonia solutions at an aerosil content of 15 wt %, which approximately corresponds to the critical concentration of structurization for these systems [8, 14]. Dispersions with such a content of the solid phase have the best structural-mechanical and rheological parameters for their granulation [8]. The spray drying in a superheated steam with a temperature of 300–600°C was performed on a pilot installation described in [15]. The specific surface area S was measured on a GKh-1 gas meter, using the thermal desorption of argon; and the total pore volume V_Σ, pore size distribution, and the most probable pore diameter d were determined on a PA-3M mercury porosimeter. The granulometric analysis of microspherical aerosilogels was carried out with an Optima microscope (Germany), with the number of grains measured equal to 100–150. The data obtained in these measurements were used to plot the particle-size distribution histograms and to calculate the average grain size D_{av}.

The table lists the structural parameters of the aerosils obtained. It can be seen that even a short-time con-

* Dispersion medium, water; heat carrier, air.

tact of aerosilogel grains with steam (residence time of a particle in the drying chamber equal to 15–40 s [9]) leads to rather significant changes in the porosity parameters. This can be attributed to the following: (i) very high temperature of steam; (ii) catalytic effect of ammonia on the mass transfer of silica, which underlies changes in porosity [16]; and (iii) high degree of dispersion spraying and, accordingly, the instantaneous warming-up of its drops over the entire cross section. It can be noted for comparison that the ordinary hydrothermal treatment of silicas at temperatures of 100–300°C, as a rule, requires 3–5 h for an effect of this kind to be achieved [2, 4, 16], and, because of the poor heat conductivity of silica, operation of large semicommercial autoclaves frequently requires a treatment duration of up to 24 h [17] for a product with uniform properties to be obtained.

The patterns of variation of the pore structure, observed as the temperature of the heat carrier (steam) increases, are conventional: the specific surface area decreases and pores grow in volume and size (see table and Fig. 1). At a high ammonia concentration (5%), a minor relative rise in S and the corresponding decrease in V_Σ and d are observed, apparently because of the partial peptization of silica (see table, sample nos. 5 and 14).

It should be noted that use of a steam superheated to 300–600°C, instead of air, provides milder conditions for removal of the liquid from dispersion drops

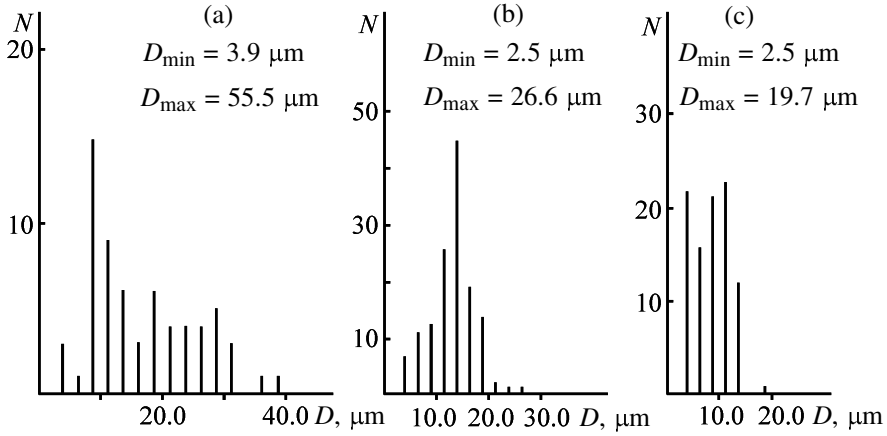

Fig. 2. Histograms of the distribution of the number N of aerosilogel grains with respect to their size D. Sample no.: (a) 1, (b) 5, and (c) 11.

and, consequently, allows the build-up of large stresses in the structure of the forming dry aerosilogel to be avoided. At the same time, the high temperature of the heat carrier and the accordingly high temperature of the intermicellar liquid in the gel result in that the surface tension of this liquid decreases and a very large (>3 $cm^3 g^{-1}$) pore volume in microspherical grains is formed.

According to the table and Fig. 2, the spray drying in a superheated steam leads to formation of finer, and more uniform in size, microspheres, compared with drying with hot air (compare the scatter of grain sizes from D_{min} to D_{max} for both cases). This points to technological advantages of the drying process under consideration.

It should also be added that the heat carrier steam is formed from aerosil dispersions in the course of drying and can be repeatedly used upon condensation to prepare new portions of aerosil dispersions, i.e., the process can be organized as a closed cycle.

CONCLUSION

Use of superheated steam in spray drying of aerosil dispersions makes it possible to obtain a microspherical aerosilogel with a uniform granulometric composition (grain size 10–12 μm). As a result of a hydrothermal treatment, the parameters of the porous structures of the samples vary widely: pore volume, up to 3.4 $cm^3 g^{-1}$, and pore size, up to 160 nm.

Professor M.I. Usanovich (1894–1981), a known Russian physical chemist and historian of chemistry, wrote these essays as far back as 1941–1945. However, numerous difficulties encountered when promoting the manuscript, and accusations of underestimation of the role of Russian scientists in the development of the world's chemical science, which were typical of that time, forced the author to give up his attempts to publish the book. Only nowadays, more than 20 years after the scientist's death, his widow, prof. T.N. Sumarokova and a group of Usanovich's disciples could publish this interesting book with the support by the management of Kazakh National University.

The many years' scientific activities of Usanovich were devoted to experimental and theoretical studies of nonaqueous solutions, their physicochemical analysis, and development of the generalized theory of acids and bases. He also wrote a number of papers on the history of chemistry. His investigations in the field of theory of acids and bases made him worldwide known; biographic evidence about the scientist is included in the collection of works *Biografii velikikh khimikov* (Biographies of Outstanding Chemists), Berlin, 1977; Moscow, 1981.

The scientific activities of Usanovich commenced in the autumn of 1918, after he graduated from the natural department of the physicomathematical faculty of the Kiev University, at the biogeochemical laboratory of Academician V.I. Vernadsky (1863–1945), which was among the institutions affiliated with the newly organized Ukrainian Academy of Sciences. Usanovich was a professor at the Tomsk State University in 1930–1934 and headed the chair of physical chemistry at the Central-Asian State University (Tashkent) in 1935–1944 and the chair of physical chemistry at the Kazakh State University in 1944–1981. In 1962, he became academician of the Academy of Sciences of Kazakh SSR. The most important Usanovich's scientific works were included in the collection of works *Issledovaniya v oblasti teorii rastvorov i teorii kislot i osnovanii. Izbrannye trudy* (Investigations in the Theory of Solutions and Theory of Acids and Bases, Selected Works), Alma-Ata: Nauka Kaz. SSR, 1970.

The collection of essays under discussion covers the main events in the history of chemistry from ancient times till the 1940s. People whose biographies are presented in the book are of different ethnic origins and nationalities, but all of them are united by the outstanding contribution to some field of chemistry at a certain period of history. The short author's preface to the collection of essays reads: "The science is international in its origin, because it is a fruit of activities of representatives of all cultured nations and its mission is to serve to the entire humankind." The book comprises 24 brief chapters arranged in historical order.

Chapter I (pp. 15–17) is devoted to the development of chemistry in the Ancient world. The concepts of Aristotle (384–322 B.C.) and Avicenna (980–1037) are presented. Evidence about alchemists of the later time, XIII century, is presented for Albert Magnus, Count Bollstadt (1193–1280), and Roger Bacon (1214–1294). Chapter II (pp. 28–40) discusses works of the most outstanding chemists of the XV and XVI centuries: Paracelsus (1493–1541), Agricola (1494–1555), and van Helmont (1577–1644). Chapter III (pp. 41–44) is concerned with the appearance of the concept of chemical elements. The central position in this chapter is devoted to the life and works of Robert Boyle (1627–1691). Chapter IV (pp. 45–55) presents evidence about the theory of phlogiston and works by H. Stahl (1659–1734), K.W. Scheele (1742–1786), J. Priestley (1733–1804), and H. Cavendish (1731–1810). In chapter V (pp. 56–65), the author analyzes the positive aspects and disadvantages of the theory of phlogiston. The whole chapter VI (pp. 66–76) is devoted to the life and activities of a Russian physical chemist, M.V. Lomonosov (1711–1765). A prominent role in the correct assessment of the scientific achievements of Lomonosov was played by B.N. Menshutkin (1874–1938), who found at the beginning of the

XX century manuscripts of Lomonosov's works, mostly written in Latin, translated these works, and made them accessible to the scientific community. Already in 1904, Menshutkin published a large article "Lomonosov as Physical Chemist" in *Izvestiya Sankt-Peterburgskogo politekhnicheskogo instituta* (Transactions of St. Petersburg Polytechnic Institute), in *Zhurnal russkogo fiziko-khimicheskogo obshchestva* (Journal of the Russian Physicochemical Society), and as a separate edition. The author of these publications was the first to make a full review of all done by Lomonosov in the field of chemistry and physics. In 1911, in connection with the celebration of the 200th anniversary of Lomonosov's birthday, Menshutkin wrote his biography. The many years' studies of the Lomonosov's life and scientific activities culminated in the monograph *Trudy M.V. Lomonosova po fizike i khimii* (M.V. Lomonosov's Works in Physics and Chemistry, 1935).

Chapter VII (pp. 77–84) considers works by C.L. Berthollet (1748–1822) and J.L. Proust (1754–1826), the prolonged polemics between these two about the constancy of composition of substances, and studies by J.B. Richter (1762–1807). Chapter VIII (pp. 85–90) is devoted to the contribution by John Dalton (1766–1844) to the creation of the atomistic theory. Chapter IX (pp. 91–96) describes works by J.L. Gay-Lussac (1778–1850) and A. Avogadro (1776–1856), associated with the further development of the atomic-molecular theory.

Chapter X (pp. 97–104) is devoted to great electrochemists of their time, H. Davy (1778–1829) and M. Faraday (1791–1867). Chapter XI (pp. 105–110) considers works by Swedish scientist J.J. Berzelius (1779–1848), one of the most versatile and successful chemists of the first half of the XIX century. Chapter XII (pp. 111–123) contains evidence about the basic research in the field of organic chemistry. It discusses works by J. Liebig (1803–1873), F. Wöhler (1800–1882), N.N. Zinin (1812–1880), and A.A. Voskresenskii (1809–1880). Chapters XIII (pp. 124–132), XIV (pp. 133–140), and XV (pp. 141–151) continue consideration of the fundamental aspects of organic chemistry, with special attention given to the First International Congress of Chemists in Karlsruhe (Germany) in September 1860, and discuss works by F.A. Kekule (1829–1896), A.M. Butlerov (1828–1886), and C. Schorlemmer (1834–1892).

Chapter XVI (pp. 152–160) is devoted to the origination of the theory of catalysis, to works by L.J. Thenard (1777–1857) and I.V. Dobereiner (1780–1849). Chapter XVII (pp. 161–173) considers thermochemical studies by G.H. Hess (1802–1850), N.N. Beketov (1827–1911), and M. Berthelot (1827–1907). Chapter XVIII (pp. 174–205) is devoted to the life and activities of D.I. Mendeleev, discovery of the Periodic law, and studies of other scientists in the field of systematization of chemical elements. Chapter XIX pays primary attention to the discovery of the phenomenon of radioactivity and works by M. Sklodowska-Curie (1867–1934), P. Curie (1859–1906), and E. Rutherford (1871–1937). Chapter XX (pp. 227–248) considers works by J. van't Hoff (1852–1911) in the field of stereochemistry, studies of the osmotic pressure and chemical affinity by the same scientist, and works by Russian scientists D.P. Konovalov (1856–1929) and N.S. Kurnakov (1860–1941).

Chapter XXI (pp. 249–275) is devoted to the appearance of modern physical chemistry, which is conventionally associated with the beginning of publication of the first specialized journal in this field, *Zeitschrift für physikalische Chemie*, and discussed works by W. Ostwald (1853–1932), S. Arrhenius (1859–1927), N.A. Menshutkin (1842–1907), and I.A. Kablukov (1857–1942). Chapter XXII (pp. 276–282) familiarizes the reader with the life and activities of the founders of modern coordination chemistry, A. Werner (1866–1919) and L.A. Chugaev (1870–1922). Chapter XXIII (pp. 283–297) contains evidence about works of outstanding representatives of the national organic chemistry, academicians A.E. Favorskii (1860–1945), S.V. Lebedev (1874–1934), and N.D. Zelinskii (1861–1953). The primary attention in Chapter XXIV (pp. 298–316) is given to geochemical studies by Academician V.I. Vernadsky (1863–1945) and his disciple and closest associate Academician A.E. Fersman (1883–1945). Of high cognitive value are commentaries by Usanovich to each of the essays.

The book is captivating, interestingly readable, and well published, although the quality of the photographs is, unfortunately, not always satisfactory. The author managed to trace, using essays devoted to the life and activities of separate scientists or groups of scientists, the development of chemistry from ancient times till the middle of the XX century. Among the scientists to whom no essay is devoted for some reason, but who deserve being included, mention should be primarily made of Academician V.N. Ipat'ev (1867–1952), one of the most outstanding chemists of the first half of the XX century.

The book by Usanovich is of indubitable interest for anybody concerned with the history of chemistry and contains an exceedingly valuable evidence for teachers of chemical disciplines at secondary and higher-school institutions, for masters and postgraduate students specialized in chemistry and chemical technology. The book is prefaced by the text "The Word about the Author," written by Prof. Sumarokova.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Possibility of Quantum Chemical Evaluation of the Probability of Various Chemical Transformations in Syntheses of Phosphorus-, Titanium-, Silicon-, and Vanadium-containing Structures on the Silica Surface

Abstract—Application of minimum quantum-chemical models for predicting chemical transformations in syntheses of phosphorus-, titanium-, silicon-, and vanadium-containing structures on the silica gel surface by molecular layering is considered. Possible pathways for transformation of the groups synthesized under the action of water vapor and hydrogen chloride are analyzed in terms of the models constructed.

DOI: 10.1134/S1070427206020017

Synthesis of low-dimension systems with prescribed composition and properties on the surface of solid substances can be used in diverse areas of science and technology. The method of molecular layering [1–5] can be used for this purpose. This method consists in alternate cyclic treatment of the surface of a solid matrix carrying chemically active functional groups with low-molecular-weight reagents. As these reagents are commonly used vapors of volatile chlorides: $TiCl_4$ [4], various chlorosilanes [6], $VOCl_3$ [7], $POCl_3$ [8], PCl_3 [9], CrO_2Cl_2 [10], etc. Silica, which has hydroxy groups on its surface, has been the most extensively studied as a substrate for molecular layering. The concentration and mutual positions of these groups depend on the pretreatment temperature and affect the structure and composition of interaction products. As the pretreatment temperature is raised, the content of silanols on the silica surface decreases and the average distance between them increases, which leads, at temperatures above 600°C, to formation of a hydroxy cover mainly composed of isolated OH groups.

In this case, the interaction of a molecular chloride with surface silanols can be represented in the most general case as

$$\equiv\text{Si–OH} + \text{XCl}_n \rightleftarrows \equiv\text{SiO–XCl}_{n-1} + \text{HCl}, \quad (1)$$

where, e.g., X = PO (n = 3), Ti (n = 4), Si (n = 4), and VO (n = 3).

A scheme of this kind is operative in treatment with chlorides of the surface of silica preliminarily calcined at sufficiently high temperatures (600–700°C). On treatment of the products formed by reaction (1) with water vapor

$$\equiv\text{SiO–XCl}_{n-1} + (n-1)\text{H}_2\text{O} \rightleftarrows \equiv\text{SiO–X(OH)}_{n-1} + (n-1)\text{HCl} \quad (2)$$

it is possible to produce a layer of new functional structural units incorporating active hydroxy groups on the surface and to perform by cyclic repetition of processes by schemes (1) and (2) chemical assembly of low-dimension systems of prescribed composition, which are chemically bound to the matrix surface [1–5, 7–11]. With various modifiers XCl_n (X = Ti, VO, CrO_2, PO, Si) used at various stages of molecular layering, it is possible to synthesize multicomponent systems with prescribed alternation of structural units [3]. To ensure in this case the maximum extent of utilization of OH groups in the reactions, the synthesis is performed under an excess of molecular reagents [1–4, 11].

It should be noted that chemical assembly of element-containing nanosystems by the schemes suggested presumes that, under the synthesis conditions, new groups $(\equiv\text{SiO–})_m\text{X(OH)}_{n-m}$ formed in each cycle (1), (2) are stable against H_2O vapor and the gaseous product of reaction (2), hydrogen chloride. How-

ever, experimental data have been reported indicating that element-containing structures may disintegrate under the action of water vapor or hydrogen chloride [7, 12, 13, 15, 16].

For example, a study of the stability of $(\equiv Si–O–)_nECl_{m-n}$ groups (E = VO, Ti, CrO_2, PO) against the action of HCl [7, 12] demonstrated that surface groups may disintegrate under certain conditions under the action of hydrochloric acid to evolve the corresponding chlorides into the gas phase, with the stability against HCl decreasing in the order Ti–V–Cr.

The authors of [14] concluded, based on IR spectroscopic data, that $(\equiv SiO–)TiCl_3$ groups synthesized on the surface of aerosil samples completely disintegrate in the course of vapor-phase hydrolysis.

Of the same opinion are the authors of [14], who observed the formation of bulk titanium oxide in chemisorption of titanium tetrachloride on the silica gel surface, as indicated by X-ray diffraction and NMR spectroscopic data.

In [15], a conclusion was made, on the basis of IR spectral data obtained by *in situ* monitoring and the results of chemical analysis of KSS-4 silica gel samples treated with $TiCl_4$ at 200°C, that titanium-oxochloride groups bound to the surface by a single Si–O–Ti bond may disintegrate. The same authors [16] noted a lesser susceptibility of the Si–O–V bond to disintegration in the stage of vapor-phase hydrolysis compared with titanium-containing groups.

According to the results of various studies, the possible main reason for disintegration in a stage of vapor-phase hydrolysis is water vapor [13, 14] or hydrogen chloride [15], whose corrosive activity is known to increase dramatically in the presence of water.

Therefore, it was of interest to assess the contribution of both water and HCl released in vapor-phase hydrolysis to disintegration of surface structure. In this case, the following reactions are possible:

$$\equiv SiO–XCl_{n-1} + H_2O \rightleftarrows \equiv Si–OH + XCl_{n-1}(OH), \quad (3)$$

$$\equiv SiO–X(OH)_{n-1} + H_2O \rightleftarrows \equiv Si–OH + X(OH)_n, \quad (4)$$

$$\equiv SiO–X(OH)_{n-1} + HCl \rightleftarrows \equiv Si–OH + X(OH)_{n-1}Cl. \quad (5)$$

A combination of experimental studies with model approaches and, in particular, quantum-chemical methods is promising for deeper understanding of the mechanisms of surface chemical processes, interpretation of experimental data, and prognostication of surface nanostructures.

Owing to a large share of covalence of chemical bonds and local nature of interatomic interactions, silica is a convenient object for constructing cluster models [17]. The success in application of cluster models of the silica surface in such processes as sorption of water molecules [18, 19] and dehydroxylation [20], and some studies devoted to the modeling of chemical reaction on the surface of solids [21, 22] give us reason to believe that application of the given approach to molecular layering processes is appropriate.

The main active sites of the silica surface, silanol groups, are modeled with clusters of different sizes, which contain hydrogen atoms as pseudoatoms that saturate ruptured bonds: from the simplest H_3SiOH [18] to structures incorporating several tens of silicon atoms [21–25]. An increase in the cluster size leads, on the one hand, to improvement of the quality of quantum-chemical models and, on the other, to a dramatic increase in the required computer resources. In addition, construction of large clusters requires that structural motifs of some crystalline modification of silica (as a rule, β-cristobalite) should be used [21, 22, 24, 25], which may not quite well correspond to the real surface of the amorphous support.

In addition to choosing the cluster model of active sites for making prognoses, it is also necessary to specify a basis of atomic orbitals and a level of the calculation theory. There is no alternative to nonempirical methods in analysis of chemical structures that include transition elements, beginning from period III of the Periodic Table. In doing so, various authors use Gaussian bases from 3-21G [20, 22] to 6-31G** [21, 24, 26] to construct models.

However, even the widest bases and largest clusters are insufficient for obtaining calculated parameters with accuracy comparable with that of experimental data. Therefore, the quantum-chemical models constructed commonly yield information for comparison of relative changes in characteristics of objects of about the same nature. Because quantitative data on bond lengths and valence angles for element-containing structures obtained in chemical modification of the silica surface cannot be found in the literature, no structural or charge characteristics of the cluster models developed are presented here. Because of this circumstance, the quality of the models and their prognosticating capacity were assessed by comparative analysis of the energy characteristics of structures in-

Table 1. Calculated changes in the total energy, ΔE, in the reactions of formation and vapor-phase hydrolysis of element-containing groups on the silica surface

Scheme	Reaction	ΔE, kJ mol^{-1}, for indicated modifier X			
		PO, $n=3$	Ti, $n=4$	Si, $n=4$	VO, $n=3$
1	$\equiv Si–OH + XCl_n \rightleftarrows \equiv SiO–XCl_{n-1} + HCl$	–167	–137	–137	–130
2	$\equiv SiO–XCl_{n-1} + (n-1)H_2O \rightleftarrows \equiv SiO–X(OH)_{n-1} + (n-1)HCl$	–238	–102	–225	–82
3	$[1/(n-1)]\equiv SiO–XCl_{n-1} + H_2O \rightleftarrows [1/(n-1)]\equiv SiO–X(OH)_{n-1} + HCl$	–118	–34	–75	–41

corporating various modifying elements (P, Ti, Si, V), together with experimental data when possible.

Thus, the development of model approaches, combined with experimental studies, is undoubtedly not only of theoretical, but also of practical interest for solution of problems of applied chemistry, associated with creation of heterogeneous catalysts, sorbents, and fillers for composites with prescribed properties and service characteristics.

The aim of this study was to construct, on the basis of the minimum cluster H_3SiOH and minor basis 3-21G, simplest models of element-containing groups formed on the surface of silica in its successive treatment with a vapor of the chloride of a modifier-element and that of water and to assess their applicability to prognostication of chemical transformations in synthesis by molecular layering.

As objects of study were considered quantum-chemical cluster models of products formed in interaction of volatile chlorides $POCl_3$, $TiCl_4$, $SiCl_4$, and $VOCl_3$ with isolated silanol groups of the silica surface and their possible secondary chemical transformations in reactions with H_2O vapor and HCl. Silanol groups were modeled with the minimum cluster H_3SiOH having the form of an isolated silanol group, which characterizes the surface of silica calcined at a sufficiently high temperature [27]. The models of the interaction products were also in the form of isolated element-containing groups that are bound to the matrix surface by a single Si–O–E bond and do not interact with one another.

Nonempirical quantum-chemical calculations of models of the starting substances and products of chemical reactions on the surface were performed using the restricted Hartree–Fock method and PC GAMESS 6.4 software [28, 29]. The standard set of Gaussian atomic functions 3-21G was used, with the exception of the basis set 3-21G* for the phosphorus atom. All the characteristics are given for models whose structure was determined by minimizing the total potential energy, with a threshold value of the maximum gradient, equal to 10^{-5} Hartree A^{-1}.

The total energy of interaction between nuclei and electrons in the models, obtained by quantum-chemical calculations, served to evaluate the stability of the structures under consideration and the comparative probability of occurrence of surface chemical reactions by schemes (1)–(5). As a measure of the probability of occurrence of chemical reactions served the change in the total energy, ΔE, in accordance with the stoichiometric scheme of a reaction, e.g., for vanadium-containing structures

$$\equiv Si–OH + VOCl_3 \rightleftarrows \equiv SiO–VOCl_2 + HCl, \quad (6)$$

$$\Delta E = E(HCl) + E(H_3SiOVOCl_2) - E(H_3SiOH) - E(VOCl_3), \quad (7)$$

where E is the total energy of interaction between the nuclei and electrons of the structures specified.

This approach, to a certain extent similar to thermodynamic estimations, makes it possible to prognosticate the shift of chemical equilibria by comparing the values of ΔE for chemical reactions. A negative value of ΔE will indicate a preferable shift of the equilibrium toward final products, and a positive value, toward starting substances.

The calculated changes in energy, ΔE, in transformations by schemes (1) and (2) are listed in Table 1. For the reactions of interaction between a molecular chloride and the OH group (1), this quantity can be regarded as the chemical affinity of the corresponding chloride to an isolated silanol group.

It follows from an analysis of the data obtained that, in terms of the quantum-chemical model used,

the affinity is 130–167 kJ mol^{-1} for all the chlorides under consideration. This points to a considerable energy gain as a result of the reaction by scheme (1). The noticeable number of surface silanols not involved in the interaction may be mostly due to steric hindrances [11, 30]. As already mentioned, the calculation level used does not pretend to be chemically accurate, and, therefore, the absolute changes in energy are less reliable than its relative changes in the series of modifies under consideration.

For example, $POCl_3$ exhibits, according to published data, a lower activity than $VOCl_3$ and $TiCl_4$ in the reaction with OH groups on a completely hydroxylated surface of silica, i.e., with adjacent (not isolated) OH groups [7, 8].

At the same time, the presence of an insignificant amount of vanadium-containing functional groups on the surface leads to a dramatic increase in the reactivity of $POCl_3$ both in interaction with free OH groups and in substitution of vanadium atoms by phosphorus in $(Si–O)_nVOCl_{3-n}$ [3].

As follows from the data in Table 1, the energy of formation of the Si–O–E bond, $\Delta E_{Si–O–E}$, in interaction of silanols and chlorides is the highest for phosphorus-oxochloride groups and decreases in the order P–Ti, Si–V. This suggests that the Si–O–P bond is stronger than other bonds, at least with respect to hydrogen chloride. By contrast, the probability of disintegration of vanadium-and-chlorine-containing structures under the action of HCl is the highest among the modifiers considered, in agreement with the results obtained in a study of processes on the silica surface hydroxylated to the maximum possible extent [7, 12].

The calculated data obtained may be of interest for prognostication of chemical transformations in synthesis of multicomponent systems in the course of interaction between silanol groups on the silica surface and a mixture of volatile chlorides. A number of experimental results obtained in studies of chemical interactions in the system constituted by $POCl_3$, $TiCl_4$, $VOCl_3$, and silica gel [30, 31] demonstrated that phosphorus oxochloride displaces titanium-and-chlorine-containing groups from the silica surface, and titanium tetrachloride, in turn, displaces vanadium-and-chlorine-containing groups. This pattern agrees with the calculation results obtained and confirms the prognosticating value of the quantum-chemical models suggested.

As mentioned above, the molecular layering of an oxide monolayer of prescribed thickness involves multiple repetition of reactions (1) and (2). In the process, new reactive OH groups are formed in stage (2). These groups are bound to new atoms X in the functional groups synthesized by scheme (1), rather than to silicon atoms of the starting substrate.

The corresponding energy changes in the formation of an OH group are also negative for all the modifiers (Table 1), which corresponds to energetically favorable processes. Two or three chlorine atoms are present in the element-oxychloride, depending on the nature of a modifying element. Calculation of the change in energy upon substitution of all the chlorine atoms by OH groups gives values that exceed, in the case of phosphorus and silicon (–238 and –225 kJ mol^{-1}, respectively) the changes in energy in reactions (1) (–167 and –137 kJ mol^{-1}). However, for the structures containing titanium and vanadium, these energies are, by contrast, lower than those in reaction (1). It should be noted that the stoichiometries of reactions (1) and (2) are different. For this reason, to ensure a correct comparison of the interactions by schemes (1) and (2), Table 1 lists changes in energy in reaction (2) recalculated per H_2O molecule [Table 1, reaction (3)].

It can be seen in Table 1 that the absolute gain in energy, ΔE, in the formation of the E–OH bond is lower than that in the case of the Si–O–E bond by a factor of 2–4, with the exception of phosphorus-containing groups. Such a result suggests, even with the limited accuracy of quantum-chemical models taken into account, that the extent of the hydrolytic substitution of chlorine atoms by a hydroxo group is lower than that in the case of interaction between chlorides and surface silanols.

It should be noted again that vapor-phase hydrolysis of phosphorus-oxochloride groups must occur with the least pronounced hindrance and the energy of formation of P–OH groups (–118 kJ mol^{-1}) is only slightly lower than that for the Si–O–P bond (–167 kJ mol^{-1}). This process is the least favorable for titanium-containing groups [–34 kJ mol^{-1}, compared with –137 kJ mol^{-1} for reaction (1)], in agreement with published data on incomplete substitution of chlorine atoms by hydroxo groups in vapor-phase hydrolysis of structures of this kind [11]. According to Table 1, silicon- and vanadium-containing groups occupy an intermediate position, i.e., are hydrated more easily than titanium-containing groups, and more difficultly than those containing phosphorus and chlorine.

As already noted, there is a discussion in the literature, concerned with the possibility of rupture of

Table 2. Calculated changes in the total energy, ΔE, in reactions of destruction of element-containing groups on the silica surface

Scheme	Reaction	ΔE, kJ mol^{-1}, for indicated modifier X			
		PO, $n=3$	Ti, $n=4$	Si, $n=4$	VO, $n=3$
3	$\equiv SiO–XCl_{n-1} + H_2O \rightarrow \equiv Si–OH + XCl_{n-1}(OH)$	+38	+36	+49	+39
4	$\equiv SiO–X(OH)_{n-1} + H_2O \rightarrow \equiv Si–OH + X(OH)_n$	+31	+45	+43	+49
5	$\equiv SiO–X(OH)_{n-1} + HCl \rightarrow \equiv Si–OH + X(OH)_{n-1}Cl$	+146	+30	+109	+62

the Si–O–E bond in element-containing surface groups in the course of vapor-phase hydrolysis by reactions (3)–(5), which constitute a set of competitive processes with respect to formation of OH groups bound to the atom of the modifying element [reaction (2)].

Disintegration of element-oxochloride structures in a process of this kind may give as final products silanol groups and hydrated oxides of the corresponding elements. The latter may widely vary in size, from nanoclusters to macroscopic phases. In addition, it is known from the results obtained in studies of transformations of such objects in aqueous solutions that widely diverse variants of compounds differing in both composition and structure are possible, which leads in the given case to severe difficulties in quantum-chemical modeling [32]. Therefore, the present study is only concerned with the initial stages of disintegration, which consist in rupture of Si–O–E bonds in groups formed on the surface in interaction between element chlorides and isolated hydroxy groups of silica.

The possible pathways of the reactions with H_2O vapor (in stage 2) or with HCl (gaseous product of the vapor-phase hydrolysis of chlorine-containing surface structures) can be represented by schemes (3)–(5).

It can be assumed that, from the standpoint of analysis of the energy of such transformations, there undoubtedly exists an uncertainty, because polycondensation, being a spontaneous process, leads to a decrease in the total energy of the system and makes higher the probability of rupture of Si–O–E bonds. At the same time, comparison of the first elementary stages of disintegration for various modifiers can serve as a basis for prognostication of the further behavior of the system.

The calculated changes in the energy of the Si–O–E bond rupture under the action of water vapor (Schemes 3, 4) and hydrogen chloride (Table 2, Scheme 5) are positive in contrast to those in the interaction between chlorides and silanols (Scheme 1) and hydrolytic substitution of chlorine atoms (Scheme 2), i.e., differ not only in magnitude, but also in sign. This suggests that at least the first stages of the disintegration processes are energetically hindered.

Naturally, further polycondensation may lead to another energy pattern of disintegration. In this case, the values listed in Table 2 can be regarded as calculated estimates of the height of energy barriers for destruction reactions, which enables prognostication of the predominant pathways of disintegration of Si–O–E bonds.

From this standpoint, the data in Table 2 demonstrate that the modifiers under consideration behave in strongly different ways. For example, the lowest barrier height is observed for titanium-containing groups in the case of interaction between hydrogen chloride and hydroxylated structures:

$$\equiv SiO–Ti(OH)_3 + HCl \rightarrow \equiv Si–OH + Ti(OH)_3Cl, \quad (8)$$
$$\Delta E \approx +30 \text{ kJ mol}^{-1},$$

whereas for the rest of modifiers, this pathway (Scheme 5) is the least probable (energy barrier 62–146 kJ mol^{-1}). Another competing pathway of the possible destruction of titanium-containing groups is interaction of chlorine-containing structures with water:

$$\equiv SiO–TiCl_3 + H_2O \rightarrow \equiv Si–OH + TiCl_3(OH), \quad (9)$$
$$\Delta E \approx +36 \text{ kJ mol}^{-1},$$

for which the barrier height somewhat exceeds that for reaction (8).

The preferable destruction mechanisms for phosphorus-containing groups are those of interaction with water molecules:

$$\equiv SiO–POCl_2 + H_2O \rightarrow \equiv Si–OH + POCl_2(OH), \quad (10)$$
$$\Delta E \approx +38 \text{ kJ mol}^{-1};$$

$$\equiv SiO–PO(OH)_2 + H_2O \rightarrow \equiv Si–OH + PO(OH)_3, \quad (11)$$
$$\Delta E \approx +31 \text{ kJ mol}^{-1},$$

which is in a quite good agreement with the known concepts of high hygroscopicity of oxygen compounds of phosphorus(V).

Silicon-containing structures are the least susceptible to disintegration, with pathways in which the bonds with the surface of both chlorine-containing and hydroxylated groups are ruptured under the action of water are virtually equally probable:

$$\equiv SiO–SiCl_3 + H_2O \rightarrow \equiv Si–OH + SiCl_3(OH), \quad (12)$$
$$\Delta E \approx +49 \text{ kJ mol}^{-1};$$

$$\equiv SiO–Si(OH)_3 + HCl \rightarrow \equiv Si–OH + Si(OH)_3Cl, \quad (13)$$
$$\Delta E \approx +43 \text{ kJ mol}^{-1}.$$

Finally, the lowest barrier for disintegration of groups containing vanadium corresponds to the reaction of chlorine-containing structures with a molecule of water:

$$\equiv SiO–VOCl_2 + H_2O \rightarrow \equiv Si–OH + VOCl_2(OH), \quad (14)$$
$$\Delta E \approx +39 \text{ kJ mol}^{-1}.$$

It can be noted in summarizing the above reasoning that, in terms of the quantum-chemical models under consideration, the highest stability against disintegration under the action of water vapor or hydrogen chloride would be expected for silicon-containing structures, and the lowest, for those containing titanium. Groups containing phosphorus and vanadium have approximately the same stabilities and occupy an intermediate position among the modifiers. According to the calculated data, a noticeable destruction under the action of hydrogen chloride may only occur for titanium-containing groups.

Thus, according to the results of modeling, destruction of element-containing groups in the stage of vapor-phase hydrolysis is only possible under strongly nonequilibrium conditions of an excess of water vapor or hydrogen chloride or at elevated temperatures sufficient for energy barriers to be overcome. Therefore, of exceedingly high importance is the choice of a synthesis mode, especially in the stage of vapor-phase hydrolysis. A particular significance is assumed by the problem of identification of synthesis products, whose solution can be promoted to a fairly great extent by quantum-chemical modeling.

CONCLUSIONS

(1) Analysis of the results obtained suggests that quantum-chemical modeling of the synthesis of element-containing structures on the silica surface enables high-quality prognostication of the preferable pathways of chemical transformations even with the minimal cluster models and low level of the calculation theory.

(2) The minimum nature of these models makes the approach under consideration accessible to a large number of researchers, because it does not require considerable computing resources. An ordinary personal computer can be used to obtain in several hours or even minutes a prognosis of the development of chemical transformations on the silica surface, which involve new reagents.

(3) The calculations performed for products of synthesis by the method of molecular layering on the silica surface carrying isolated hydroxy groups, i.e., element-containing structures with $POCl_3$, $TiCl_4$, $SiCl_4$, and $VOCl_3$, suggest that the most probable is the pathway that involves chemisorption of molecular chlorides on the silica surface and subsequent hydrolysis. However, disintegration of the structures synthesized is possible under certain conditions (large excess of water or hydrogen chloride in the system). It would be expected that the stability against disintegration under the action of water vapor or hydrogen chloride is the highest for silicon-containing structures and the lowest for titanium-containing groups.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydroxylation of the Surface of Calcium Sulfates in Aqueous Media and Processes of Their Solidification

Yu. P. Gladkikh and V. I. Zavrazhina

Received January 26, 2005

Abstract—Mechanisms of hydroxylation of the surface of calcium sulfates and their formulations in aqueous media and processes of their solidification are considered.

DOI: 10.1134/S1070427206020029

Various calcium sulfates, such as calcium sulfate hemihydrate $CaSO_4 \cdot 0.5H_2O$, calcium sulfate dihydrate $CaSO_4 \cdot 2H_2O$, anhydrite $CaSO_4$, estrich gypsum $CaSO_4 \cdot CaO$, and formulations with a number of inorganic and organic compounds, are gypsum binders, which are widely used in building.

The chemistry of calcium sulfate hemihydrate is the best studied. It is known [1] that the structure of the gypsum stone is formed in aqueous media through dissolution of the binder to give calcium and sulfate ions and then calcium sulfate dihydrate, which is less water soluble than calcium sulfate hemihydrate.

$$Ca^{2+} + SO_4^{2-} + 2H_2O \rightarrow CaSO_4 \cdot 2H_2O. \quad (1)$$

According to other data [2], the solidification of gypsum binders occurs by the topochemical mechanism, i.e., water is added directly to solid particles. The solidification reaction in a solidifying mixture of calcium hemihydrate sulfate with water is described by the following scheme:

$$CaSO_4 \cdot 0.5H_2O + 1.5H_2O \rightarrow CaSO_4 \cdot 2H_2O. \quad (2)$$

Thus, there are different explanations of the solidification of gypsum binders in terms of the solution and topochemical mechanisms. However, there are examples [3–5] of solidification of calcium sulfate dihydrate and its formulations with various substances, which cannot be understood in terms of reactions (1) and (2). This indicates that these binders harden by a different mechanism. No other concepts of the solidification of calcium sulfate dihydrate have been formulated. Furthermore, it is impossible to explain satisfactorily the role of some additives of organic compounds in the solidification of gypsum binders and the mechanism of their action on the basis of the available concepts of the processes of solidification of gypsum binders.

Thus, despite the large body of theoretical and experimental data on the solidification of gypsum binders, the existing mechanisms require rethinking.

In this paper, we discuss the hydroxylation of the surface of mixtures of calcium sulfates with water and the condensation mechanism of their solidification. The known procedures for production of gypsum materials, including their preparation from calcium sulfate dihydrate and mixtures of gypsum binders with inorganic and organic additions are considered in terms of this mechanism.

It is known [6, 7] that finely dispersed particles of inorganic solid substances, including gypsum binders, obtained by a mechanical milling and thermal treatment have free unsaturated valence bonds on the surface and possess a free surface energy. When water molecules are adsorbed on surface defects of calcium sulfates these defects are hydrated to calcium sulfate dihydrate and are hydroxylated similarly to defects on the surface of mechanically activated silicon dioxide [7].

When other particles of this kind, with surface defects, are placed in a humid atmosphere or in water, there occurs dissociative adsorption of water molecules on electron-acceptor and electron-donor centers on the surface, formed upon cleavage of crystals. For example, a separate fragment of the surface of calcium

sulfates, gypsum binders $CaSO_4 \cdot nH_2O$ (n = 0–2), formed upon their mechanical dispersion can be represented as $^{\cdot}Ca–(O–SO_2–O–Ca \cdot nH_2O)_x–OSO_2O^{\cdot}$.

Depending on their intensity, duration, thermal treatment, and other factors, physical actions can also cleave a crystal at oxygen–sulfur valence bonds.

The scheme of hydroxylation of a separate unit (fragment) of the surface of calcium sulfate dihydrate is presented below:

$$^{\cdot}Ca–(O–SO_2–O–Ca \cdot 2H_2O)_x–OSO_2O^{\cdot} + HOH \rightarrow HOCa–(OSO_2OCa)_x–OSO_2OH \cdot 2H_2O. \quad (3)$$

In this case, rupture of valence bonds between oxygen atoms and sulfur atom on the hydroxylated surface of calcium sulfates may result in formation of di- and trihydrosulfate groups.

In the presence of a sufficient amount of water in systems constituted by calcium sulfate and water, hydrated ions $Ca^{2+} \cdot nH_2O$, $CaOH^+ \cdot (n - 1)H_2O$, $HSO_4^- \cdot (m - 1)H_2O$, and $SO_4^{2-} \cdot mH_2O$) are also formed.

Calculations performed using the second dissociation constants of calcium hydroxide (4.9×10^{-2}) and sulfuric acid (1.2×10^{-2}) [8] confirm the predominance of hydroxocalcium and hydrosulfate ions in the aqueous phase. For example, the amount of hydroxocalcium ions is five times that of calcium ions, and the amount of hydrosulphate ions is nine times that of sulfate ions.

Thus, depending on the amount of water in a mixture of gypsum binders with water, different systems are formed, which contain different amounts of calcium, sulfate, hydroxylated hydroxocalcium ions and hydrosulfate ions, product of their interaction $HO–CaO–SO_3–OH$, and hydroxylated solid particles, which can react with one another and possess properties of solid polyampholytes [9]. Hydroxylated sulfate groups of solid gypsum particles are of acid nature, and calcium atoms, of basic nature, i.e., hydroxylated solid gypsum particles exhibit amphoteric properties. They can further react both with acids and with bases to form more soluble acid and basic calcium sulfates. Apparently, this interaction is of acid–base, condensation nature, with water molecules released in the condensation reaction. The presence of acid and basic centers on the surface of solid catalysts, including sulfates, has been reported previously [9].

Some of the schemes of condensation processes involving separate fragments of hydroxylated gypsum are presented below:

$$2HO–Ca–(OSO_3Ca \cdot 2H_2O)_x–OSO_2OH \rightarrow HO–Ca–(OSO_3Ca \cdot 2H_2O)_{2x+1}–OSO_2OH + HOH, \quad (4)$$

$$HO–Ca–(OSO_3Ca \cdot 2H_2O)_x–OSO_2OH + Ca(OH)_2 \rightarrow HO–Ca–(OSO_3Ca \cdot 2H_2O)_x–OSO_2O–Ca–OH + HOH, \quad (5)$$

$$HO–Ca–(OSO_3Ca \cdot 2H_2O)_x–OSO_2OH + HO–SO_2–OH \rightarrow HO–SO_2–O–Ca–(OSO_2Ca \cdot 2H_2O)_x–OSO_2OH + HOH. \quad (6)$$

Thus, the acid-base condensation of hydroxylated binders with other hydroxylated particles results in an increase in the molecular weight. The growth of the forming particles leads to the formation of colloids and crystallization in the course of hardening of gypsum binders.

It has been established [3] that mechanochemical activation of a mixture of quicklime with gypsum dihydrate at room temperature yields products of lime addition to gypsum: basic salts, hydroxocalcium sulfates. When brought in contact with mechanically activated and hydroxylated gypsum particles, the forming basic salts can be involved in polycondensation with these particles and with each other, which predetermines their binding power.

We used lump quicklime and a lime dust from the Belgorod Combine of building materials and gypsum stone from the Artemovsk deposit as components of raw mixtures being subjected to mechanical activation. Weighed amounts of quicklime (or lime dust) and of gypsum stone were subjected to a joint milling at room temperature in a VM-4 vibration mill for 1–3 min. This resulted in activation of the mixture to give products of lime addition to gypsum, which was confirmed by X-ray phase analysis and IR spectroscopy [3]. The addition is only possible with the formation of basic salts by the simplified scheme

$$CaSO_4 \cdot 2H_2O + CaO \rightarrow Ca(OH)_2SO_4 \cdot H_2O$$

or in modification of the surface of gypsum or lime. These methods demonstrated that milling of a mixture of gypsum with lime does not result, either, in the formation of calcium sulfate hemihydrate and slaked lime. Quicklime is also absent in the resulting mechanically activated mixture.

Compositions of mixtures and data obtained in sample testing

Composition no.	Content of components, wt %			Water absorption capacity, %	Ultimate strength, MPa	
	quicklime	lime dust	calcium sulfate dihydrate		compression	bending
1	1	–	99	13.0	22	5.4
2	5	–	95	12.0	21	5.4
3	10	–	90	12.2	21	5.5
4	20	–	80	12.6	20	5.4
5	30	–	70	18.6	18.6	5.3
6	–	1	99	10.0	19	–
7	–	2.5	97.5	10.0	18.5	–
8	–	5.0	95	12.0	17	–

To determine the binding power of the mechanically activated mixture, a milled mixture was moistened (w/s = 0.1) and cylindrical samples 20 mm in diameter and height and 50 × 50 × 10 mm plates were compacted under a specific compaction pressure of 20 MPa. The samples were solidified under ordinary atmospheric conditions at room temperature. Their hardness was determined at the age of seven days in conformity with GOST (State Standard) 8462–85.

The water-absorption capacity of the samples was determined from a relative increase in a sample mass after keeping the samples in water at a room temperature for 48 h (see table).

It is seen from the table that the stones obtained from the formulations investigated have a sufficiently high hardness. The low water-absorption capacity of the solid structures formed confirms the (poly)condensation mechanism of solidification of the formulations. If solely more soluble basic salts were formed in solidification, the water-absorption capacity of the gypsum stone would be much higher. The same would take place in the presence of free lime in the structure of the stone.

Condensation processes in solidification of formulations with quicklime for separate units (fragments) of hydroxylated gypsum can be written as follows:

$$\mathrm{HO–Ca–(OSO_3Ca\cdot 2H_2O)_x–OSO_3H + CaO}$$
$$\rightarrow \mathrm{HO–Ca–(OSO_3Ca\cdot 2H_2O)_x–OSO_2–O–Ca–OH.} \quad (7)$$

Water-resistant structures are also formed in contact solidification of calcium sulfate dihydrates in a formulation with an acid oxide, chromic anhydride [4], soda, and cobalt sulfate [5].

$$\mathrm{HO–Ca–(OSO_3Ca\cdot 2H_2O)_x–OSO_3H + CrO_3}$$
$$\rightarrow \mathrm{HO–CrO_2–O–Ca–(OSO_3Ca\cdot 2H_2O)_x–OSO_3H,} \quad (8)$$

$$\mathrm{HO–Ca–(OSO_3Ca\cdot 2H_2O)_x–OSO_3H + Na_2CO_3 + CoSO_4}$$
$$\rightarrow \mathrm{NaO–Co–O–Ca–(O–SO_2–O–Ca\cdot 2H_2O)_x–O–Ca–O–SO_2–O–Na + HOH.} \quad (9)$$

The condensation mechanism of solidification of hydroxylated particles formed by calcium sulfates in aqueous media is confirmed by a large body of experimental data. For example, it is known [9] that the solidification of gypsum binders is terminated upon introduction of methanol into a solidifying system constituted by calcium sulfate hemihydrate and water, which is can be attributed to occurrence of a condensation reaction between hydroxylated particles of calcium sulfates, formed in their mixtures, with water and the alcohol. This results in that surface hydroxyl groups capable of being involved in the condensation reaction disappear and protective (inert) OR groups are formed. The surface of particles is deactivated, with the result that condensation processes in hardening of separate units (fragments) of the binder surface are terminated (crystal water in gypsum is disregarded):

$$\mathrm{HO–Ca–(O–SO_2–O–Ca)_x–O–SO_2–OH + 2ROH}$$
$$\rightarrow \mathrm{R–O–Ca–(O–SO_2–O–Ca)_x–O–SO_2–O–R + HOH.} \quad (10)$$

A similar termination of solidification in the presence of methanol has been observed for other mineral

binders with a polycondensation mechanism of hardening, e.g., for calcium silicates [10].

Another evidence in favor of the occurrence of condensation processes in solidification of gypsum binders is the strong influence of multifunctional additives on the solidification of gypsum binders [11–16]. These are additives of succinic and other polyatomic acids, oxyacids, superplasticizers, ethylene diamine, maleic and phthalic anhydrides, and other substances capable of polycondensation. When a gypsum binders is added to a solidifying system they enter into a chemical interaction of condensation nature with hydroxylated particles of the binder and thus appear in the composition of a gypsum stone, a heteropolymer that contains not only calcium and sulfate ions, but also fragments of the above-mentioned multifunctional additives. In general form, the scheme of these reactions involving a separate unit (fragment) of the surface of a gypsum crystal is as follows:

$$\mathrm{Ca{-}(OSO_2OCa)_{\mathit{x}}{-}OSO_2OH + 2HO{-}R{-}OH}$$
$$\rightarrow \mathrm{HO{-}R{-}O{-}Ca{-}(OSO_2OCa)_{\mathit{x}}{-}OSO_2OR{-}OH + 2HOH}. \quad (11)$$

The above-stated condensation mechanism of solidification of calcium sulfate dihydrate and its formulations is also valid for other calcium sulfates and their formulations with water, because the processes of their solidification first include formation of hydrated and hydroxylated calcium dihydrate, and then, further acid–base condensation of hydroxylated particles.

Thus, the consideration of the solidification processes of gypsum binders in terms of the physical chemistry of solid surfaces, examination of the known experimental data on the solidification of gypsum binders in aqueous media, and establishment of the analogy between solidification processes of gypsum binders and binders with a polycondensation mechanism of solidification indicate that the solidification processes of all calcium sulfates are also of polycondensation nature. This fundamentally changes the chemical nature and chemical processes occurring in solidification of all calcium sulfates.

CONCLUSION

An unconventional condensation mechanism of solidification of gypsum binders and their formulations was suggested and explained for the example of mixtures of calcium sulfate dihydrate with certain inorganic and organic substances.

Abstract—The effect of phase formation at the interface between macroscopic agglomerates constituting a porous aliminosilicate ceramic on its properties was studied by physicochemical methods, with an alumino-phosphorous binder used as a modifying agent.

DOI: 10.1134/S1070427206020030

The transformation of acid phosphates of multiply charged ions has been rather well studied in view of their importance for production of construction materials [1–4]. The mode in which viscous phosphate solutions are used as binders or gluing substances in composites and the effect of their application are determined by the nature of the skeleton-forming material.

It has been shown previously [5] that the performance characteristics of sintered macroporous silicate articles can be improved by making interparticle contacts stronger by means of an aluminophosphate binder (APB). This is due to the fact that aluminophosphates have a crystal-chemical affinity to silicate materials containing quartz and its allotropic modifications as skeleton-forming elements. However, an extremal dependence of the strength on the amount of binder introduced would be expected because formation of new phases not bound to the skeleton must have a wedging effect on the structure. Therefore, the aim of this study was physicochemical examination of certain specific features of phase formation at the interface between macroscopic (0.1–1.0 mm) agglomerates.

EXPERIMENTAL

We used as objects of study cylinders with an outer diameter of 60 mm, height of 54 mm, and wall thickness of 3 mm. The cylinders were made of macroporous (pore size >1 μm) ceramics commonly used in filters. The main phases of the starting ceramics are quartz and mullite. We used APB for modification. The flow sheet of production of filter elements, their main characteristics, and a detailed procedure for synthesis of APB have been described previously [5]. We prepared impregnating solutions on the basis of the APB synthesized by diluting a concentrate with water or phosphoric acid solutions. As in the previous study, we used samples treated with formulations with mass ratios APB : H_2O = 1 : 2 (no. 1), APB : 50% solution of H_3PO_4 = 1 : 2 (no. 2), and a 50% solution of H_3PO_4 (no. 3). After the impregnation, the samples were heat treated in air at 20–800°C, with subsequent measurement of their mechanical properties and physicochemical parameters. To study the influence exerted by the amount of APB and free phosphoric acid on the properties of the ceramic, we repeatedly impregnated the cylinders with formulation nos. 2 and 3. To fix the modifier, we dried them at 100°C and then heated at 500°C.

We prepared samples for physicochemical studies by careful (without disintegration of skeleton-forming particles) grinding in an agate mortar to a particle size of 20–40 μm. An X-ray analysis was carried out on a DRON-2 installation with Cu_{K_α} radiation. A differential thermal analysis (DTA) was performed on an MOM derivatograph (Hungary) with heating in air from 20 to 1000°C at a rate of 10 deg min^{-1}. We used corundum with a particle size of 0.5–1.0 mm as a filler inert in this temperature range [4] to prevent foaming of the phosphate binder in the course of heating. The APB : corundum mass ratio was 1 : 4. The IR spectra were recorded on a Midas IR Fourier

spectrometer in the range 400–4000 cm^{-1}. We prepared samples by compaction of pellets with KBr (sample mass 4 mg).

We determined the content of water-soluble substances in the modified cylinders by analysis of water extracts. For this purpose, we boiled the cylinders in distilled water for 0.5 h at a water volume to cylinder mass ratio of 2 : 1. The degree of transfer of the hydrolysis products to the water phase was tentatively estimated by titration of the extracts with a 0.1 N KOH solution, using as indicators methyl orange and phenolphthalein, whose equivalence points correspond to the first and second dissociation constants of phosphoric acid, respectively. The difference in titrant expenditure makes it possible to judge the ratio between purely acidic and substituted components of phosphates passing into the water phase.

No exothermic effects are seen in the DTA curves for the filter samples impregnated with the three formulations, although they occur at about 500°C when pure aluminum dihydrophosphate is heated [6]. This points to the absence of crystallization processes in the composites under study. On heating the modified ceramic after a single impregnation, the main process for all the samples is the removal of chemically bound water, accompanied by an endothermic effect (Fig. 1). In this case, the mass loss is mostly complete at 500°C and constitutes about half of the absorbed amount of APB. For example, the water loss was 1.6% for sample no. 1 (APB/H_2O) with the minimal initial content of the aluminophosphate phase on the ceramic support (3.3%, after keeping at 20°C). For sample no. 2 (APB/H_3PO_4), the content of APB is the highest (15.5%), and the mass loss on heating was 6.7%. For formulation no. 3, the increase in mass after impregnation and mass loss was 9.5 and 4.8%, respectively. According to the X-ray analysis, no new crystalline phases were found in the samples, either, on heating at 500°C within the sensitivity limits of the method.

With another filler, corundum, heat treatment of APB is accompanied by formation of trimetaphosphate, which gives rise to a bend at 500°C in the curve of mass loss [6]. In this case, the final product on heating to 1000°C is aluminum orthophosphate in the form of tridymite [6, 7], the only phase detected by X-ray analysis, with a content of about 12%. This phase may be produced not only via natural transformation of aluminum trimetaphosphate at a sufficiently high temperature (800–1000°C) but also via corrosive pitting of the matrix under the action of products formed in dehydration of free phosphoric acids contained in APB.

We could raise the content of aluminophosphate phase on the ceramic by almost a factor of 2 by repeated impregnation of the matrix, with intermediate heating of the samples at a temperature exceeding that of reversible rehydration, specifically, at 500°C. As a result of four impregnations, the content of deposited aluminophosphate was brought to virtually the maximum possible value of 13.8%. As can seen in Fig. 2, each subsequent impregnation results

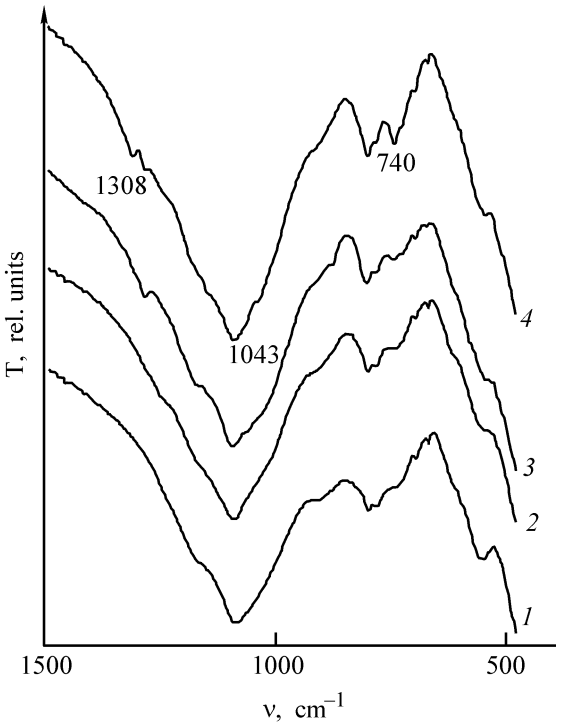

Fig. 3. IR spectra of (*1*) unmodified and (*2*–*4*) modified ceramic heat treated at (*2*, *4*) 800 and (*3*) 500°C. (T) Transmission and (ν) wave number. Number of impregnations: (*2*) 1 and (*3*, *4*) 4.

in a progressively decreasing mass gain. Only in the case of the maximum APB content, weak peaks of aluminum trimetaphosphate are observed in X-ray patterns as a separate phase on the background of the crystalline phases of the starting ceramic on heating at 500°C, and peaks of aluminum orthophosphate with the crystal lattice of tridymite appear at 800°C [6, 7]. Presumably, the appearance of this orthophosphate is associated with secondary reactions of the excess acid with the aluminosilicate matrix.

Because of the mutual overlapping of the absorption frequencies of SiO_4^{4-} and PO_4^{3-} tetrahedra, the vibrational spectroscopy is comparatively poorly informative for identification of new phases in the system under study. Nevertheless, clearly pronounced bands appear at 1308, 1043 (inflection), and 740 cm^{-1} in the spectrum of the sample repeatedly impregnated after a heat treatment at 500°C on the background of the absorption spectrum of silicates (Fig. 3). These bands correspond to the most intensive bands of pure aluminum tri- and tetrapoliphosphates [6] and are absent in the spectrum of a sample impregnated once. The fact that the general character of the IR spectrum is preserved when the heat treatment temperature is raised to 800°C is consistent with the DTA data presented above. The appearance of the band at 740 cm^{-1} may also indicate that APB reacts with the aluminosilicate matrix to give surface silicophosphates [8]. The above-mentioned sequence of transformations of the reactants, revealed by the X-ray and DTA data, together with the IR spectra, is in full agreement with the generally known scheme of transformations of acid aluminophosphates via dihydrotripolyphosphates to give aluminum trimetaphosphate [7, 9].

The formation of a new phase in the intergranular space leads to (i) a natural decrease in porosity and (ii) a less obvious decrease in the strength via loosening of interparticle contacts because of the formation of the crystalline phase. It can be seen in Fig. 4 that, within certain limits of modifier contents, the permeability of the cylinders tested remains almost unchanged at a substantial increase in strength. As expected previously [5], a mechanically strong porous structure can be constructed by creating interparticle contact interactions without any signs of crystallographic phase formation. A similar extremum in the plot of the strength against the binder content was observed for the aluminochromophosphate binder [4]. This, however, occurred for a different reason: the authors of [4] attributed this effect to the formation of a film that prevented gradual removal of the gas phase during the heat treatment, with the result that a porous structure responsible for a decrease in the strength parameters was formed.

A titrimetric analysis of water extracts of modified ceramic cylinders supplements the information obtained and allows a more complete understanding of the occurring chemical reactions. The amount of

Analysis of water extracts of modified ceramics samples

	2	500	14.6	2.08 (20.4)	5.33 (26.1)
	5	500	22.7	2.83 (27.7)	6.44 (31.6)

washed-out phosphorus-containing compounds is directly related to the content of free phosphoric acid in the impregnating solutions (see table).

With a mixture of APB and H_3PO_4 used as a modifying composition at a moderate heat treatment temperature, a certain amount of metaphosphoric acids is always present on the surface of the ceramic. These acids provide the acidity of the surface in operation of the composites in a gas atmosphere, but they are washed-out in an aqueous medium without any substantial decrease in the strength and filtering characteristics of the products. As the content of free phosphoric acid in the modifying solutions decreases, the amount of metaphosphates capable of being hydrolyzed may be decreased, as demonstrated by the negative results of analytical determination of free acids in the samples treated with the modifying solution containing no phosphoric acid, i.e., formulation no. 1.

The results of the analysis of aqueous extracts show a distinct tendency toward a rise in the degree of extraction of phosphorus-containing compounds, observed as the heat treatment temperature increases. This to a certain extent correlates with the fact that peaks do not overlap with the reflections of the matrix appear in the X-ray diffraction patterns. These peaks are close in the interplanar distances to the highest-intensity lines of aluminum orthophosphate in the form of tridymite. With account of the IR spectroscopic data, we believe that, at elevated temperatures, a fraction of tri- and tetrametaphospates in samples enriched in phosphates disintegrates to give orthophosphate and metaphosphoric acids, in agreement with the scheme of transformation suggested in [9].

CONCLUSIONS

(1) Synthesis of mechanically strong silicate composites that preserve their porosity in treatment with aluminophosphate binders should not be accompanied by crystallization processes.

(2) New crystalline phases not only disintegrate the interparticle contacts, but also fill the free volume of a composite, which results both in a loss of mechanical strength and in a decrease in the gas and hydraulic permeability.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Vapor Pressure and Activity of Components of Melts Formed by Manganese Chloride and Chlorides of Alkaline-Earth Metals

V. E. Kritskii, B. P. Burylev, and E. B. Kritskaya

Inter-Oil Produkt OOO, Krasnodar, Russia

Received April 6, 2005

Abstract—The boiling points of melts were measured at different pressures over the melts for certain concentrations of components of the liquid phase in binary systems constituted by manganese chloride and chlorides of alkaline-earth metals. The temperature dependences of the saturated vapor pressure, normal boiling points, and enthalpies of evaporation were calculated. The concentration dependences of the thermodynamic activities of the components of four binary systems were analyzed.

DOI: 10.1134/S1070427206020042

The lack of rich manganese deposits in Russia gives rise to an acute problem of processing of lean manganese ores from West Siberia, Krasnodar krai, etc. Certain deposits are characterized by an increased content of phosphor, and, therefore, to obtain a high-quality metal, it is necessary to perform dephosphorization.

In the case of the economic feasibility of processing by method of the chloride metallurgy [1, 2], a study of systems based on manganese chlorides is a matter of current interest. Compounds of alkaline-earth metals are used in dephosphorization, with preference given to compounds of barium and strontium, including their chlorides [3–6]. In the technological scheme used, the systems $MnCl_2$–MCl_2 (M = Mg, Ca, Sr, Ba) are of practical importance. The binary systems have been studied [7], whereas more complex systems are not understood. Therefore, binary and multicomponent systems are of interest for analysis of real industrial melts. Analysis of the physicochemical properties of systems of this kind is difficult; even more complicated, because of the uncertainty in determining the interparticle interactions, is interpretation of the results obtained. Studies of binary melts in terms of various models and evaluation of parameters of the interparticle interaction will make it possible to reveal strongly interacting systems and assess the possibility of their generalization to multicomponent melts, with weak interactions neglected if necessary.

The aim of this study was to calculate the dependence of the vapor pressure on temperature and composition of binary systems from the results of experimental measurements of the boiling point and to evaluate the interaction parameters for the whole variety of melts in order to obtain expressions that can be used to calculate the thermodynamic activities of the components of melts of manganese chloride and chlorides of alkaline-earth metals.

The experimental procedure is based on measuring the boiling points of chloride systems at different pressures. An experimental setup was assembled for the study from a platinum resistance furnace with transducers measuring with high accuracy the pressure and temperature. The main part of the setup was the furnace in the form of a quartz tube 24 mm in diameter, on which the heater made of a platinum wire 0.5 mm in diameter was wound. The length of the isothermal zone was 100 mm. The furnace worked for a long time in the temperature range from the melting point of the salts to 1450 K. The resistance furnace was placed in another quartz tube 60 mm in diameter with a branch for evacuation of the system. Current was supplied to the heater via the lower part of the tube. The rarefaction was created in the experimental setup with a roughing pump.

The system included a 5-l buffer vessel to eliminate pressure fluctuations occurring because of the irregular operation of the vacuum pump. A leak was installed before the buffer vessel to control the pressure in the vacuum system. This was done at a permanently working vacuum pump by making higher the rate of air delivery to the leak. The rarefaction created in the experimental system was in the range

from 100 to 100 000 Pa. The rarefaction produced was measured with a U-shaped sealed mercury vacuum gage connected to the setup directly after the buffer vessel. The accuracy of pressure measurements was ±70 Pa. The resistance furnace was heated with an autotransformer with a reduction gear driven by a low-speed electric motor. The existence of several stages in the gearbox enabled gradual heating of the furnace at a certain prescribed rate. The setup was reliable and, owing to its small volume, rapidly cooled on switching off the current, which enabled fast and multiple experiments.

A substance under study was placed in a quartz test tube 8–10 mm in diameter, which was mounted in the furnace in the middle of the isothermal zone. A thermocouple was introduced from below into a recess at the bottom of the test tube. To prevent the thermocouple from the attack of the medium, its most part was coated with corundum splints. Temperature was measured with a standard platinum–platinum rhodium thermocouple whose cold junctions were thermostated at 273 K. The accuracy of indications of the thermocouple was verified against reference points. The thermal electromotive force of the thermocouple was measured using a complex of measuring, amplifying, and recording devices: electronic dc amplifier I-37 and electronic self-recorder N-37 recording the signal on a 100-mm-wide tape. As starting preparations taken to produce the mixtures served salts of special-purity, chemically pure, and analytically pure grades, which were dehydrated by passing dried gaseous hydrogen chloride through the salts gradually heated to the melting point and kept at this temperature for 2 h. Gaseous hydrogen chloride was obtained by reacting concentrated sulfuric acid with crystalline potassium chloride. The dehydration process was monitored thermographically on a derivatograph and spectroscopically on UR 20 spectrophotometer.

The procedure used to measure the saturated vapor pressure was the following: mixtures were prepared from dehydrated reagents by weighing the components on an analytical balance. Then the weighed portion in a quartz test tube was placed in the resistance furnace and heated to melting. The platinum–platinum rhodium thermocouple was brought to the melt from below. Then the vacuum pump created in the whole system a rarefaction measured with the sealed mercury vacuum gage. After that the sample was gradually heated using the autotransformer with the multistage gearbox. At that instant of time when the external pressure coincided with the saturated vapor pressure over the mixture, a clearly pronounced temperature stop was observed on the tape of the N-37 self-recorder. Just this temperature is the boiling point of the sample. The boiling point was recorded as a well visible stop for 15–20 s. Then the pressure in the system was elevated by 3000–10000 Pa, depending on a system under study, and a detailed measurement was made from the beginning. For each composition, 5–8 measurements were made. The loss of mass of the highly volatile component was 0.01–0.03 g for difficultly volatile systems and 0.08–0.12 g for highly volatile systems, i.e., less than 1% and up to 4% relative to the mass of the weighed portion, respectively. The I-37 amplifier makes it possible to work with a platinum–platinum rhodium thermocouple with a sensitivity of 1 mV per the entire scale of the instrument below 1373 K, and 2.5 mV per scale above 1373 K; the measurement accuracies are ±2 and ±5 K for the lower and upper temperature ranges, respectively.

The experimentally determined boiling points of melts of the systems $MnCl_2$–MCl_2 (M = Mg, Ca, Sr, Ba), listed for constant compositions (x_{MCl_2} is the mole fraction of an alkaline-earth metal) in Table 1, were processed using the least-squares method by the equation

$$\log P = (B \pm \Delta B) - (A \pm \Delta A)/T. \qquad (1)$$

Here, P is the saturated vapor pressure (Pa); T, absolute temperature (K); A and B, constants found by the least-squares procedure; and ΔA and ΔB, confidence intervals for a confidence probability $p = 0.95$.

The values of these quantities are listed for four systems in Table 2, together with the enthalpies of

evaporation ΔH^{ev} and standard boiling points T^{sb} (for P = 101 325 Pa), given by the equations

$$\Delta H^{ev} = 19.14A, \quad (2)$$

$$T^{sb} = A/(B - 5.006). \quad (3)$$

The vapor pressure isotherms plotted using the data from Table 2 characterize the systems studied as systems with a monotonic increase in deviations, in which the share of the chemical interaction grows in going from $MgCl_2$ as additive component to $CaCl_2$, then to $SrCl_2$, and finally to $BaCl_2$. This behavior can be quantitatively described by the mutual exchange energy Q for a binary system composed of components 1 and 2.

The total vapor pressure in the absence of polymerization and complexation is given by

$$P = P_1^0 x_1 f_1 + P_2^0 x_2 f_2, \quad (4)$$

where f_1 and f_2 are the activity coefficients of components 1 and 2, and P_0^1 and P_0^2 are the vapor pressures of pure components; here and hereinafter index 1 refers to $MnCl_2$, and index 2, to $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$ as components being added.

In accordance with the results of [8], the degree of dimerization of manganese chloride is low; the same refers to chlorides of alkaline-earth metals [9]. In the case of applicability of the equations for regular solutions:

$$RT\ln f_1 = Q(1 - x_1)^2, \quad (5)$$

$$RT\ln f_2 = Q(1 - x_2)^2, \quad (6)$$

we obtain for the equimolar composition $x_1 = x_2 = 0.5$:

$$Q = 4RT\ln\frac{2P}{P_1^0 + P_2^0}. \quad (7)$$

The vapor pressures of the pure components are as follows (Pa): $P^0_{MnCl_2}$ = 14 270 [10], $P^0_{MgCl_2}$ = 2570 [9], $P^0_{CaCl_2}$ = 8.1, $P^0_{SrCl_2}$ = 2.5, $P^0_{BaCl_2}$ = 1.6 [9]. From Eq. (7) we obtain for the systems composed of $MnCl_2$ with $MgCl_2$, $CaCl_2$, $SrCl_2$, or $BaCl_2$, Q = +10 790, –7500, –4800, and –19 500 J mol^{-1} for 1300 K.

Because the vapor pressures of calcium, strontium, and barium chlorides are negligible as compared with that of manganese chloride, the activities α of $MnCl_2$ in alloys with Ca, Sr, and Ba chlorides are given by the expression

$$\alpha_{MnCl_2} = P/P^0_{MnCl_2}. \quad (8)$$

We obtain from the data in Table 2

$$\log P - \log P^0_{MnCl_2} = -\frac{\delta A}{T} + \delta B. \quad (9)$$

For an arbitrary composition, we have

$$Q = \frac{19.14T(-\delta A/T + \delta B) - RT\ln x_{MnCl_2}}{(1 - x_{MnCl_2})^2}, \quad (10)$$

and for the equimolar composition at 1300 K

$$Q = 99\,530(-\delta A/1300 + \delta B) + 29\,960. \quad (11)$$

Calculations by the last equations show that the concentration dependences of the activity (and vapor pressure) for the systems $MnCl_2$–MCl_2 are more complex than those described by expressions (5) and (6). Therefore, it is necessary to use for quantitative description equations that take into account the nonadditivity of the energy of a binary solution [11]:

$$RT\ln f_1 = (Q_1 - Q_2)(1 - x_1)^2 + 2Q_2(1 - x_1)^3, \quad (12)$$

$$RT\ln f_2 = (Q_1 + 2Q_2)(1 - x_2)^2 - 2Q_2(1 - x_2)^3, \quad (13)$$

in which constants Q are found from experimental data.

Analysis of the dependences obtained makes it possible to determine how the activities of the components vary with their concentration. To compare the experimental and calculated data, we use the data from Table 1 and the results of calculation by Eq. (4) for 1300 K. We obtain, from Eqs. (5) and (6) for the system $MnCl_2$–$MgCl_2$:

$$\ln f_i = 0.432(1 - x_i)^2. \quad (14)$$

The calculated and experimental values are compared below (1, $MnCl_2$; 2, $MgCl_2$):

x_1	f_1	P_{exp}	P_1	P_2	P_{calc}
0.2	1.890	5917	5393	2136	7529
0.4	1.431	8448	8164	1807	9971
0.5	1.282	10 793	9144	1645	10 789
0.6	1.172	11 218	10 036	1468	11 504
0.8	1.040	13 280	11 876	970	12 846

The strongest difference is observed for two compositions with high content of magnesium chloride. An asymmetry of thermodynamic properties is noticeable for the system $MnCl_2$–$CaCl_2$. Therefore, we have from Eqs. (12) and (13) that $Q_1 = -8150$ and $Q_2 = 7600$ J mol^{-1} and obtain for the activity coefficients

$$\log f_1 = -0.633(1 - x_1)^2 + 0.611(1 - x_1)^3, \quad (15)$$

$$\log f_2 = -0.283(1 - x_2)^2 - 0.611(1 - x_2)^3, \quad (16)$$

where, again, 1 stands for $MnCl_2$, and 2, for $CaCl_2$.

The results of the calculations are presented below:

x_2	α_1	α_2	P_1	P_2	P_{calc}	P_{exp}
0.2	0.763	0.019	10888	0.15	10888	–
0.4	0.520	0.378	7417	3.0	7420	7418
0.5	0.414	0.494	5908	4.0	5948	–
0.6	0.321	0.608	4575	5.0	4580	4651
0.8	0.162	0.818	2307	6.6	2314	2307

A good agreement between the experimental and calculated data is observed.

For the $MnCl_2$–$SrCl_2$ system, the best way to find the activity coefficients was by Eqs. (5) and (6) for $Q = -10000$ J mol^{-1}, whence we have

$$\log f_i = -0.402(1 - x_i)^2. \quad (17)$$

For various compositions, we obtain

x_2	α_2	f_1	P_1	P_{exp}
0.2	0.193	0.964	10998	10231
0.4	0.345	0.862	7381	8156
0.5	0.396	0.793	5659	6378
0.6	0.430	0.717	4089	4080
0.8	0.442	0.553	1578	1488

The partial pressures of strontium chloride somewhat exceed 1 Pa, and, therefore, $P_{calc} \approx P_1$. The agreement between the calculated and experimental data is good, except for the equimolar composition.

For the $MnCl_2$–$BaCl_2$ system, we can take as a first approximation Eqs. (5) and (6) for $Q = -20000$ J mol^{-1}. The best agreement between the experimental and calculated values is achieved with expressions (12) and (13) with $Q_1 = -29730$ J mol^{-1} and $Q_2 = 19280$ J mol^{-1}, whence we have

$$\log f_1 = -1.970(1 - x_1)^2 + 1.550(1 - x_1)^3, \quad (18)$$

$$\log f_2 = 0.355(1 - x_2)^2 - 1.550(1 - x_2)^3, \quad (19)$$

and obtained for various compositions

x_2	α_1	α_2	P_1	P_{exp}
0.2	0.686	0.054	9795	8244
0.4	0.365	0.248	5205	5205
0.5	0.251	0.393	3585	4542
0.6	0.169	0.316	2410	2539
0.8	0.068	0.133	973	974

The strongest difference between the experimental and calculated data is observed for the compositions with x_2 0.2 and 0.5. At other concentrations, the agreement is satisfactory.

Analysis of the results obtained suggests that minor positive deviations from the Raoult law are observed only in the $MnCl_2$–$MgCl_2$ system, whereas small negative deviations from the laws for ideal solutions are characteristic of the systems $MnCl_2$–$CaCl_2$, $MnCl_2$–$SrCl_2$, and $MnCl_2$–$BaCl_2$. The activities of the components steadily decrease at the same concentrations in going from $MnCl_2$–$CaCl_2$ to $MnCl_2$–$SrCl_2$, and further to $MnCl_2$–$BaCl_2$.

The saturated vapor pressures can be prognosticated for the systems studied, using the expression

$$P = \Sigma P_i^0 x_i f_i. \quad (20)$$

The only quantities to be known are the activity coefficients of multicomponent melts. The procedure for determining these coefficients was described in [12].

CONCLUSIONS

(1) The boiling points of chloride melts of manganese and alkaline-earth metals (Mg, Ca, Sr, and Ba) were determined at various pressures in the systems for a wide range of fixed parameters. Metrological characteristics of the experimental setup and the method used were presented.

(2) The pressure dependences of the boiling points were presented for four binary systems $MnCl_2$–$MgCl_2$, $MnCl_2$–$CaCl_2$, $MnCl_2$–$SrCl_2$, and $MnCl_2$–$BaCl_2$ for constant concentrations of the melts. These parameters were used to obtain temperature dependences of the saturated vapor pressure for the given systems. The dependences were approximated with two-parameter expressions, whose constants were found using methods of mathematical statistics.

(3) The experimental data obtained were used to calculate the thermodynamic activities of the components, which were described by equations that take

into account the nonadditivity of the energy of a binary solution. It was shown that the $MnCl_2$–$MgCl_2$ system shows minor positive deviations from ideality, whereas the systems $MnCl_2$–$CaCl_2$, $MnCl_2$–$SrCl_2$, and $MnCl_2$–$BaCl_2$ exhibit moderate negative deviations from ideality, which become more pronounced on passing from the systems with calcium chloride to those with strontium chloride and barium chloride.

(4) It was shown that a model description of the thermodynamic properties of the multicomponent system $MnCl_2$–$MgCl_2$–$CaCl_2$–$SrCl_2$–$BaCl_2$ is possible.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Properties of the Extraction System Constituted by Phosphoric Acid Produced from Khibiny Apatite and Tri-*n*-Butyl Phosphate

Abstract—Data on the equilibrium distribution of phosphoric acid among the aqueous and organic phases in extraction of phosphoric acid with tri-*n*-butyl phosphate are presented for the system constituted by phosphoric acid produced from the Khibiny concentrate and by the extracting agent from the industrial system for purification of extraction phosphoric acid at 25–50°C.

DOI: 10.1134/S1070427206020054

Liquid extraction with organic solvents is a promising method for purification of substances and, in particular, that to remove impurities from the extraction phosphoric acid (EPhA). Liquid extraction is used on the industrial scale to purify the apatite EPhA with tri-*n*-butyl phosphate (TBP) as extracting agent [1].

The properties of the following systems have been described in the literature: H_3PO_4–H_2O–TBP at 25°C [2] and 293–343 K [3], and H_3PO_4–H_2SO_4–H_2O–TBP at 293–353 K [4]; the systems were composed of reagent phosphoric acid of pure grade and TBP of technical grade.

The present study is concerned with the distribution of phosphoric acid among the organic and aqueous phases of composition close to that in industrial manufacture of purified phosphoric acid. The experiments were performed at 25–50°C and 255–764 g l^{-1} phosphoric acid in the aqueous phase (in terms of P_2O_5). The choice of the given range of temperatures and concentrations was governed by the real conditions of industrial purification of EPhA. The solutions were prepared by saturating an extracting agent from the industrial system with extraction phosphoric acid. In the concentration of impurities in the aqueous and organic phases, this system corresponds to that in the stage of EPhA extraction in manufacture of purified phosphoric acid.

An evaporated desulfated EPhA produced from the Khibiny apatite concentrate was used in the experiments. The acid had a density of 1.537 g cm^{-3} and the following composition (wt %): P_2O_5 47.5, SO_4^{2-} 0.33, F^- 0.262, and Fe_2O_3 0.21. The extracting agent from the technological system was used for extraction. The temperature in the experiments was maintained constant by thermostating to within ±0.5°C. The content of phosphoric acid in the organic phase was determined by potentiometry [5]. The results of the experiments are presented in Table 1 and Fig. 1.

A mathematical processing of the experimental data demonstrated that the equilibrium contents of P_2O_5 in the organic and aqueous phases are related by an extraction equation similar to the Hand equation [6]:

$$c_{P_2O_5\,org.ph} = a c^{b}_{P_2O_5\,aq.ph}, \quad (1)$$

where $c_{P_2O_5\,org.ph}$ is the content of P_2O_5 in the organic phase (g l^{-1}); $c_{P_2O_5\,aq.ph}$, that in the aqueous phase (g l^{-1}); and a and b, coefficients of the equation.

It should be noted that the re-extraction of phosphoric acid from the extracting agent with water was calculated using the data reported in [3], where equations describing the process were also presented. However, two equations for two different temperature ranges were reported. Therefore, a similar pro-

cessing of published data [3] was done for the system H_3PO_4–H_2O–TBP. The data used are presented in Fig. 1 (curves *1–3*).

Table 2 lists coefficients a and b and the reliability of approximation, R^2, for each curve. The data of Table 2 were used to plot coefficients a and b against temperature (Fig. 2) for the system H_3PO_4–H_2O–TBP (system I, curve *1*) and for that constituted by apatite EPhA and an extracting agent from the industrial system (system II, curve *2*). The temperature dependences of the coefficients for these systems are similar. The temperature dependence of coefficient a can be described by the equation

$$a = ne^{pT}, \quad (2)$$

and that of coefficient b, by

$$b = kT + m, \quad (3)$$

where T is temperature (°C); n and p, coefficients of Eq. (2); and k and m, those of Eq. (3).

Table 3 lists the coefficients of Eqs. (2) and (3) and the reliability of approximation, R^2, for the system H_3PO_4–H_2O–TBP (I) and for that constituted by apatite EPhA and an extracting agent from the industrial system II.

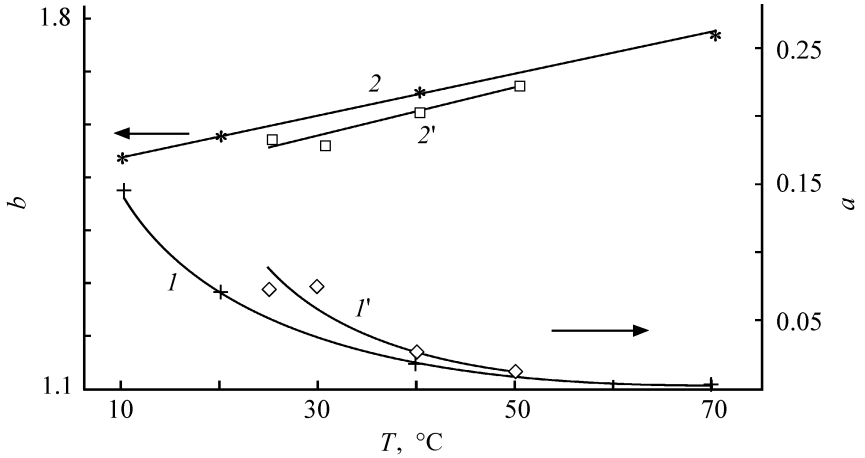

Fig. 2. Coefficients a and b of Eq. (1) vs. temperature T for (*1*, *2*) technical-grade TBP and (*1'*, *2'*) extracting agent from the technological system.

Table 4. Average technological performance parameters of an installation for EPhA purification with TBP in April 2005

T,°C	Parameters of the organic phase				Parameters of the aqueous phase				V_{aq} : V_{org}		Number of stages
	at the column inlet		at the column outlet		at the column inlet		at the column outlet				
	ρ, g cm^{-3}	P_2O_5, g l^{-1}	ρ, g cm^{-3}	P_2O_5, g l^{-1}	ρ, g cm^{-3}	P_2O_5, g l^{-1}	ρ, g cm^{-3}	P_2O_5, g l^{-1}	experiment	calculation	
Stage of extraction											
48	1.002	22.1	1.091	152.0	1.606	834.3	1.294	337.6	0.24	0.263	2.8
Stage of extract washing											
57	1.091	152.0	1.081	130.0	1.000	0.0	1.411	596.4	0.03	0.026	1.0
Stage of re-extraction											
56	1.081	130.0	1.002	22.1	1.000	0.0	1.306	506.7	0.23	0.23	4.4

Consequently, Eq. (1) can be rewritten as

$$c_{P_2O_5\,org.ph} = (ne^{pT})c_{P_2O_5\,aq.ph}^{kT+m}, \quad (4)$$

where T is temperature (°C); n, p, k, and m, coefficients of the equation, which are affected by the degree of contamination of the system by impurities.

Thus, similar equations of the isotherms of extraction and re-extraction of phosphoric acid with tributyl phosphate were obtained for the temperature interval 10–70°C and content of P_2O_5 in the aqueous phase in the range 79 – 930 g l^{-1}:

extraction equation

$$c_{P_2O_5\,org.ph} = (0.6634e^{0.0807T})c_{P_2O_5\,aq.ph}^{0.0118T+0.8836}, \quad (5)$$

and re-extraction equation

$$c_{P_2O_5\,org.ph} = (0.2776e^{0.0685T})c_{P_2O_5\,aq.ph}^{0.0102T+1.0266}. \quad (6)$$

Table 1 lists the contents of P_2O_5 in the organic phases, calculated by Eq. (5) and also presents discrepancies between the experimental and calculated values

$$\Delta = \frac{c_{P_2O_5\,org.ph.exp} - c_{P_2O_5\,org.ph.calc}}{c_{P_2O_5\,org.ph.exp}} \times 100\%.$$

It was found that the discrepancies do not exceed 12.1%.

Using the results obtained to plot the isotherms of extraction and re-extraction makes it possible to determine by the graphical method [7] certain technological parameters of the process of EPhA purification with tributyl phosphate. Figure 3 shows the isotherms of extraction (*1*) and re-extraction (*2*), as well as the working lines (*3–5*) for the industrial process of purification of the apatite EPhA with tributyl phosphate on three pulse columns. The calculations were based on the average monthly performance parameters of the installation in April 2005 (Table 4). During this period of time, the installation worked by the scheme with intermediate washing of the extract with water. The working lines constructed were

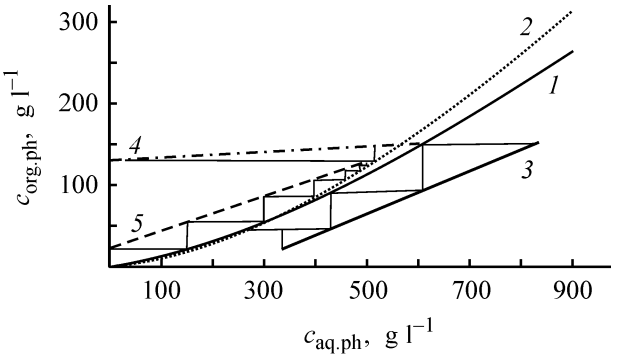

Fig. 3. Isotherms of (*1*) extraction and (*2*) re-extraction and (*3–5*) working lines of the process of extraction purification of EPhA. ($c_{aq.ph}$) Content of P_2O_5 in the aqueous phase and ($c_{org.ph}$) that in the organic phase. Working line of a process: (*3*) extraction, (*4*) washing of the extracting agent, and (*5*) re-extraction.

used to graphically calculate the number of theoretical stages of extraction and re-extraction and to find the theoretical ratio between the volumes of the aqueous and organic phases, $V_{aq} : V_{org}$, equal to the slope of the working line; Table 4 compares the calculated value of this ratio with that observed in practice. It was found that the number of theoretical stages of extraction is 2.8, and that of re-extraction, 5.3.

It should be noted that the extraction isotherm is characterized by lower values of the distribution coefficient of phosphoric acid over the entire range of equilibrium concentrations of the acid. This is due to the fact that the EPhA solution contains various salt impurities, which bind part of H_3PO_4 molecules and make lower the content of free phosphoric acid in solutions [8].

CONCLUSION

It was shown that the dependence of the content of P_2O_5 in the organic phase on that in the aqueous phase can be represented by Eq. (4) whose coefficients are affected by the degree of contamination of the system by impurities.

Abstract—The liquid (I)–liquid (II) extraction equilibria in the five-component system fullerene C_{60}–fullerene C_{70}–1,2,4-$C_6H_3Cl_3$–C_2H_5OH–H_2O were studied at 25°C. Isothermal diagrams of distribution of the fullerene components among stratifying liquid phases at a constant content of H_2O were obtained.

DOI: 10.1134/S1070427206020066

This communication continues a series of articles [1–3] devoted to extraction equilibria in systems containing light fullerenes, C_{60} and C_{70}. These papers considered successively the extraction equilibria in the systems constituted by C_{60}, C_{70}, *ortho*-xylene (α-pinene), isobutylamine (dimethylformamide, monoethanolamine, ethanol), and H_2O at 25°C. As a macrocomponent of the extraction system, a solvent, served *ortho*-xylene [1, 2], which has a high ability to dissolve fullerenes and is the most frequently used both to extract fullerenes from fullerene black and to separate C_{60} and C_{70} by means of chromatography [4–6]. In [3], *ortho*-xylene was replaced with a somewhat "weaker" nonaromatic solvent α-pinene, in which the solubility of both the fullerenes, C_{60} and C_{70}, at room temperature is somewhat lower than that in *ortho*-xylene [7]. In [3], as well as in previously studied systems with *ortho*-xylene [1, 2], we could separate C_{60} and C_{70} by means of extraction; however, the efficiency of separation somewhat decreased upon replacement of *ortho*-xylene.

A naturally following next stage of selection of the most effective system of solvents for extraction separation of light fullerenes was our attempt to use other, now "stronger" solvents in which the solubility of fullerenes exceeds that in *ortho*-xylene. The choice was forced to be made among a rather narrow variety of exclusively aromatic solvents: various isomers of trimethylbenzenes, di- and trichlorobenzenes, chloronaphthalene, etc. [8–11]. For convenience in carrying out the experiments (and, further, possibly also in developing the technology), we restricted, from the very beginning, the choice to solvents that are in the liquid state at 25°C. Another fundamentally important issue [naturally, with the exception of harnessing the two-phase equilibrium liquid (I)–liquid (II)] is that it has been impossible to achieve a high solubility in both the liquid phases simultaneously. The exception is provided by the systems constituted by C_{60}, C_{70}, *ortho*-xylene, isobutylamine, and H_2O and by C_{60}, C_{70}, *ortho*-xylene, and monoethanolamine [1]. Unfortunately, the first system was the only one in which C_{60} and C_{70} could not separated at all, and in the second, highly stable and difficultly decomposed compounds of fullerenes with monoethanolamine were formed. In other systems [1–3], one of the phases was always strongly depleted of fullerenes, so that their running concentrations rarely exceeded 100 mg l^{-1}, which is very technologically inconvenient.

We chose as object of study the five-component system C_{60}–C_{70}–1,2,4-$C_6H_3Cl_3$–C_2H_5OH–H_2O at 25°C. The main aromatic solvent 1,2,4-$C_6H_3Cl_3$ has the following properties: this is the only trichlorobenzene that is in the liquid state at room temperature (mp ~17°C). Its isomers, 1,2,3- and 1,3,5-$C_6H_3Cl_3$, melt at 53.5 and 65.5°C, respectively [12]. In practice, we used industrial 1,2,4-$C_6H_3Cl_3$ twice distilled at 212–215°C, which contains, according to the results of a chromatographic analysis, the main product in an amount of 91 wt % and a mixture of 1,2,3- and 1,3,5-$C_6H_3Cl_3$

(9 wt %) (this mixture is not crystallized at 10 ± 1°C during at least 7 days).

1,2,4-$C_6H_3Cl_3$ excellently dissolves C_{60}, C_{70}, and mixtures of these. We could prepare solutions of (C_{60} + C_{70}) with a total concentration of fullerenes, c_{full}, ranging from 20 to 40 g l^{-1}.

Visible and near-UV spectra of fullerenes in 1,2,4-$C_6H_3Cl_3$ are quite ordinary and show absorption peaks at wavelengths of 335 ± 2 and 472 ± 3 nm, which enables spectrophotometric determination of fullerenes in solutions by the conventional technique [13], with an appropriate correction for shifts of the absorption peaks.

1,2,4-$C_6H_3Cl_3$ well dissolves C_2H_5OH and vice versa; their mixtures rapidly stratify upon addition of H_2O to the system (~2 wt %); both the stratifying phases contain high concentrations of 1,2,4-$C_6H_3Cl_3$ and well dissolve fullerenes.

EXPERIMENTAL

An experimental study of the system C_{60}–C_{70}–1,2,4-$C_6H_3Cl_3$–C_2H_5OH–H_2O at 25°C revealed a certain specificity related to the exceedingly high solubility of C_{60} and C_{70} in 1,2,4-$C_6H_3Cl_3$.

To introduce a mixture of fullerenes into the stratifying system, we prepared a diffusion-stable solution of $(C_{60})_{0.83}(C_{70})_{0.17}$. This solid solution was completely dissolved in an excess amount of 1,2,4-$C_6H_3Cl_3$ to give the base liquid solution-1 with concentrations (g l^{-1}): $C_{60}^{base\text{-}1}$ 19.8 and $C_{70}^{base\text{-}1}$ 4.0; with the total concentration of fullerenes, $c_{full}^{base\text{-}1}$ = 23.8 g l^{-1}.

On mixing the base solution with an aliquot amount of C_2H_5OH (abs.) and adding H_2O ($c_W \approx 2.9$ wt %) to cause stratification, solid mixed fullerene solvates instantaneously started to precipitate from both of the stratifying phases. On separating the liquid phases and filtering them off, we obtained a homogeneous predominantly "chlorobenzene" phase, base solution-2, containing (g l^{-1}): $C_{60}^{base\text{-}2}$ 5.6 and $C_{70}^{base\text{-}2}$ 2.3; with the total concentration of fullerenes $c_{full}^{base\text{-}2}$ = 7.9 g l^{-1}.

Base solution-3, whose only distinction was the total absence of fullerenes in the phase, was prepared similarly to solution-2. The last base solution-4 had the form of a predominantly "ethanol" phase in equilibrium with base solution-3. This phase did not contain fullerenes, either.

It should be noted that the following pattern was observed when preparing base solutions-2, -3, and -4: upon mixing, the volume of the trichlorobenzene phase decreased dramatically as compared with the aliquot volume; by contrast, the volume of the ethanol phase increased. Under the experimental conditions, the equilibrium ratio of these volumes was approximately 1.0 : 2.5.

In the first set of experiments, we fixed the composition of the fullerene mixture to be distributed, $(C_{60})_{0.72}(C_{70})_{0.28}$, and the content of H_2O ($c_W \approx$ 2.9 wt %). Further, base solution-3 was mixed with base solution-2 in volume ratios ranging from 100 : 1 to zero, and an aliquot volume of base solution-4 was added to the resulting mixture.

In the second set of experiments, we also fixed the composition of the $(C_{60})_{0.83}(C_{70})_{0.17}$ fullerene mixture to be distributed and the total concentration of fullerenes in a stratifying system. In this case, the content of H_2O in the system, c_W, was varied. First, base solution-1 and 1,2,4-$C_6H_3Cl_3$ were mixed in an approximately 1 : 4 ratio (to preclude precipitation of solid fullerene solvates), then aliquots of C_2H_5OH (abs.) were added to the solutions obtained, and, finally, different amounts of H_2O ($c_W \approx$ 2.3–3.9 wt %) were introduced. In this case, the volumes of the trichlorobenzene phases were again markedly lower than those of the ethanol phases.

The extraction equilibrium was attained in both sets of experiments in 36 h at thermostating to within ±0.03°. After that, the coexisting phases were sampled for analysis.

The phases were analyzed for the content of the fullerene components, C_{60} and C_{70}, as follows: the trichlorobenzene phase, by ordinary spectrophotometry with respect to 1,2,4-$C_6H_3Cl_3$ (at dilutions of 1 : 30 to 1 : 2000 and cuvette width l = 1 cm); aliquots of the ethanol phase were first evaporated to dryness at a temperature of 110°C and a residual pressure of 0.01 mm Hg and then "dry samples" were dissolved in aliquots of *ortho*-xylene and also analyzed by spectrophotometry [13].

The concentrations of the main components of the solvents (1,2,4-C_6H_3Cl, C_2H_5OH, and H_2O) were determined by chromatography [1, 2]. It should be noted that, as regards the macrocomponents, the phase compositions depend on the content of H_2O, c_W. For example, the trichlorobenzene phase virtually did not contain any water in all samples ($c_{H_2O}^{C_6H_3Cl_3} < 1$ wt %), and the content of H_2O in the ethanol phase, $c_{H_2O}^{C_2H_5OH}$, steadily increased from 3.2 to 4.5 wt % as c_W changed from 2.6 to 3.9 wt %. At the same time, the concentrations $c_{C_6H_3Cl_3}^{C_2H_5OH}$ and $c_{C_2H_5OH}^{C_6H_3Cl_3}$ steadily decreased from 21 to 11 and from 11 to 7 wt %, respectively.

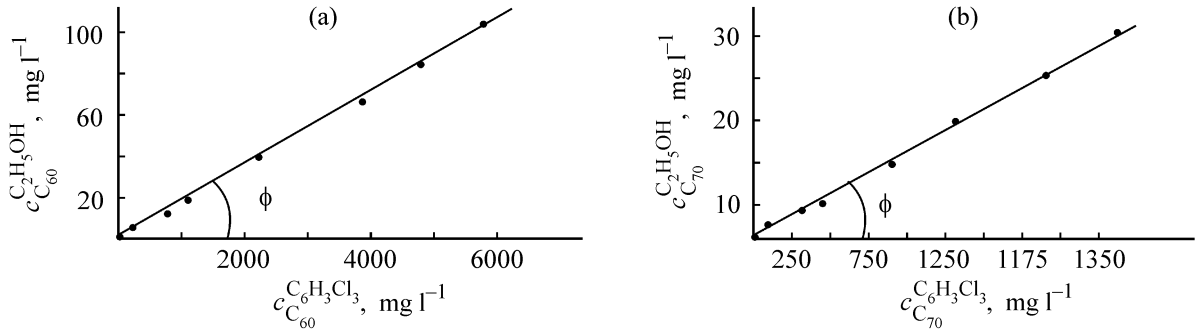

Fig. 1. Diagrams of distribution of fullerenes (a) C_{60} and (b) C_{70} among the ethanol and trichlorobenzene phases in the system C_{60}–C_{70}–1,2,4-trichlorobenzene–C_2H_5OH–H_2O at 25°C. (*c*) Fullerene concentration; (a) $\cot\phi = K_{distr}(C_{60}) = 55.5$ and (b) $\cot\phi = K_{distr}(C_{70}) = 78.7$. For explanation, see text.

Figures 1a and 1b show the distribution diagrams of the fullerene components C_{60} and C_{70} among the trichlorobenzene and ethanol phases for the five-component system C_{60}–C_{70}–1,2,4-$C_6H_3Cl_3$–C_2H_5OH–H_2O at 25°C. The diagrams are plotted for fixed composition of the mixture of fullerenes C_{60} and C_{70} in the system (72 wt % C_{60}) and content of H_2O ($c_W \approx$ 2.9 wt %). As can be seen in Fig. 1, the trichlorobenzene phase is always richer in both the fullerenes than the ethanol phase. The distribution diagrams for C_{60} and C_{70} were virtually rectilinear in the entire concentration range studied, similarly to systems with *ortho*-xylene and isobutylamine [1]. At $c_W \approx 2.9$ wt %, rather high maximum total concentrations of fullerenes in the coexisting phases could be achieved: $c^{C_2H_5OH}_{full} \approx 140$ and $c^{C_6H_3Cl_3}_{full} \approx 7800$ mg l^{-1}.

Figure 2 shows how the relative mass content of C_{60} (in the $C_{60} + C_{70}$ mixture) in the coexisting phases depends on the concentration of C_{60} in the trichlorobenzene phase, also at a fixed c_W (the dashed line represents the composition of a fullerene mixture being distributed: 72 wt % C_{60}). It can be well seen that the ethanol phase is always richer in C_{60} than the trichlorobenzene phase, and the compositions of the phase become closer as the solution concentrations are lowered, beginning at $c^{C_6H_3Cl_3}_{C_{60}} < 700$ mg l^{-1}.

Figure 3 shows the dependence of the concentration of fullerenes C_{60} and C_{70} in the ethanol and trichlorobenzene phases in the system C_{60}–C_{70}–1,2,4-trichlorobenzene–C_2H_5OH–H_2O at 25°C on the content of H_2O in the heterogeneous system, c_W (composition of a fullerene mixture being distributed, Y^{sum} = 83 wt % C_{60}). Figure 4 shows how the relative mass content of C_{60} (in the $C_{60} + C_{70}$ mixture) in the coexisting phases on c_W (the dashed line corresponds to Y^{sum} = 83 wt % C_{60}).

As can be seen in Figs. 3 and 4, the distribution coefficients K_{distr} (ratio between the concentrations in

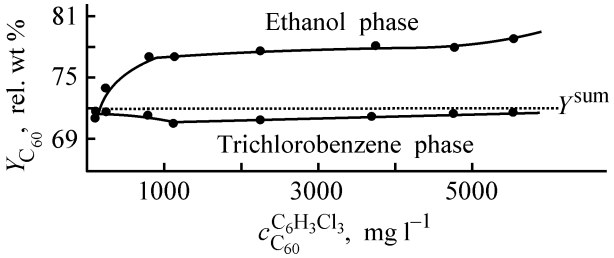

Fig. 2. Relative mass content of C_{60}, $Y_{C_{60}} = [c_{C_{60}}/(c_{C_{60}} + c_{C_{70}})] \times 100$, in the mixture $C_{60} + C_{70}$ in the coexisting phases vs. the concentration of C_{60}, $c^{C_6H_3Cl_3}_{C_{60}}$, in the trichlorobenzene phase in the system C_{60}–C_{70}–1,2,4-trichlorobenzene–C_2H_5OH–H_2O at 25°C. The *dashed line* corresponds to a brutto composition of the fullerene mixture being distributed equal to 72 wt % C_{60}.

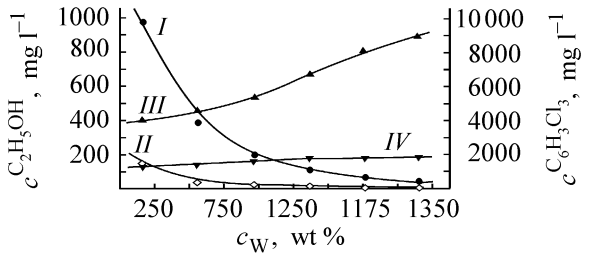

Fig. 3. Concentrations of fullerenes C_{60} and C_{70} in the ethanol and trichlorobenzene phases in the system C_{60}–C_{70}–1,2,4-trichlorobenzene–C_2H_5OH–H_2O at 25°C vs. the content of H_2O in the heterogeneous system, c_W. (*I*) $c^{C_2H_5OH}_{C_{60}}$, (*II*) $c^{C_2H_5OH}_{C_{70}}$, (*III*) $c^{C_6H_3Cl_3}_{C_{60}}$, and (*IV*) $c^{C_6H_3Cl_3}_{C_{70}}$.

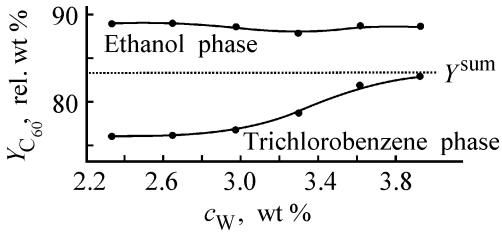

Fig. 4. Relative mass content of C_{60}, $Y_{C_{60}}$, in the $C_{60} + C_{70}$ mixture in coexisting phases vs. c_W. The *dashed line* corresponds to a composition of the fullerene mixture being distributed equal to 83 wt % C_{60}.

the trichlorobenzene and ethanol phases) strongly depend on the content of H_2O in the system, c_W. The coefficients K_{distr} increased with c_W for both the fullerene components. For example, $K_{distr}(C_{60}) \approx 4.2$ and $K_{distr}(C_{70}) \approx 9.3$ rel. units at $c_W \approx 2.3$ wt %; $K_{distr}(C_{60}) \approx 61$ and $K_{distr}(C_{70}) \approx 120$ rel. units at $c_W \approx 3.3$ wt %; and, finally, $K_{distr}(C_{60}) \approx 228$ and $K_{distr}(C_{70}) \approx 360$ rel. units at $c_W \approx 3.9$ wt % (all the figures are given for aliquot ratios of 1,2,4-$C_6H_3Cl_3$ and C_2H_5OH). Simultaneously with an increase in c_W, the content of fullerenes in the ethanol phase critically decreased. For example, the total concentration of C_{60} and C_{70} was as high as 1120 mg l^{-1} at $c_W \approx 2.3$ wt % and decreased to 124 mg l^{-1} at $c_W \approx 3.2$ wt %, whereas at $c_W \approx 3.9$ wt %, $c_{full}^{C_2H_5OH}$ was only 44 mg l^{-1}. In this case, the concentrations of fullerenes in the trichlorobenzene phase, $c_{full}^{C_6H_3Cl_3}$, changed in opposite directions and comparatively slowly and steadily increased from 5350 to 10700 mg l^{-1}. The enrichment coefficients K_{enr} [equal to the ratio of $K_{distr}(C_{70})$ to $K_{distr}(C_{60})$] also varied monotonically, decreasing from 2.2 at $c_W \approx 2.3$ wt % to 1.6 at $c_W \approx 3.9$ wt %.

If the extraction pattern in the system C_{60}–C_{70}–1,2,4-$C_6H_3Cl_3$–C_2H_5OH–H_2O is characterized as a whole, it should be noted that this system somewhat less effectively separates the fullerene components C_{60} and C_{70} as compared with systems with *ortho*-xylene and dimethylformamide, α-pinene, and ethanol [1–3], and more effectively than the system with *ortho*-xylene and isobutylamine [1], although separation is observed in the last system. The only, but very important advantage of the system studied is that the concentrations of fullerenes in both phases are high, compared with those in other systems and reach values of more than 1.1 g l^{-1} for the ethanol phase and more than 7.8 g l^{-1} for the trichlorobenzene phase at the minimum content of H_2O. This fact is exceedingly important for development of an efficient technology for extraction separation of light fullerenes.

CONCLUSIONS

(1) The liquid (I)–liquid (II) extraction equilibria in the five component system constituted by fullerenes C_{60} and C_{70}, 1,2,4-$C_6H_3Cl_3$, C_2H_5OH, and H_2O at 25°C were obtained. As a result, isothermal diagrams of distribution of the fullerene components among the stratifying liquid phases were obtained at a constant content of H_2O. These diagrams were found to be nearly rectilinear for both the fullerene components.

(2) It was shown that the distribution coefficients strongly depend on the content of H_2O in the system, c_W. The coefficients K_{distr} increase with c_W for both the fullerene components.

(3) As c_W increased, the content of fullerenes in the ethanol phase critically decreased, with the concentrations of fullerenes in the trichlorobenzene phase changing in opposite directions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of the Critical Parameters of Substances by Certain Empirical Relations

Yu. V. Shabalina and I. B. Sladkov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received November 22, 2005

Abstract—A large body of statistical data was used to determine the numerical values of constants for five empirical relations between the physicochemical properties of substances for different classes of compounds. The accuracy of calculation of the critical parameters was determined using these relations.

DOI: 10.1134/S1070427206020078

Methods of the theory of thermodynamic similarity are widely used to prognosticate the physicochemical properties of substances [1, 2]. Calculation of physicochemical properties by these methods requires data on the critical parameters of substances. Because experimental data on critical parameters are rather scarce, of practical importance is their determination by calculation.

It was shown in [3, 4] that expressions composed from certain physicochemical parameters retain an approximately same value for different substances, i.e., they can be regarded as constants. Below we present these relations, empirically obtained by us
Quayle equation (I)

$$V_{cr} T_{cr}^{0.3} / \Pi^2 = C_1, \quad (1)$$

Quayle equation (II)

$$\Delta H_b / \Pi P_{cr} = C_2, \quad (2)$$

Egert equation

$$\Delta H_b / (T_{cr} - T_b) = C_3, \quad (3)$$

modified Trouton equation

$$\Delta H_b / RT_{cr} = C_4, \quad (4)$$

and Boutaric equation

$$P_{cr} V_{cr} / T_{cr} = C_5. \quad (5)$$

Here, Π is the parachor ($J^{1/4}$ $cm^{5/2}$ mol^{-1}); T_b, boiling point (K); ΔH_b, enthalpy of evaporation at the boiling point (kJ mol^{-1}); T_{cr}, critical temperature (K); V_{cr}, critical volume (cm^3 mol^{-1}); P_{cr}, critical pressure (MPa); and R, universal gas constant (8.314 J mol^{-1} K^{-1}).

Equations (1)–(5) can be used to calculate the critical parameters if the numerical values of the constants are known. In the first stage of the study, we determined values of constants C_1–C_5 (Table 1). These values were calculated from an array of experimental data obtained in [5–7] for 70 substances.

All the substances we consider can be divided into the following classes of compounds: nonpolar and weakly polar compounds: $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, BBr_3, $SnBr_4$, PBr_3, MoF_6, UF_6, PCl_3O, SCl_2O, ClO_3F, WCl_4O, $SiHBr_3$, $CBrF_3$, CBr_2F_2, $SiBrCl_3$, $SiBr_2Cl_2$, BI_3, and SnI_4; moderately and strongly polar: $SbCl_3$, SbI_3, $BiCl_3$, $SeCl_2$, $TeCl_4$, $SeOF_2$, $SeCl_2O$, CO_2, ClO_2, N_2O, OsO_4, RuO_4, SO_2, Re_2O_7, Tc_2O_7, CSO, HCl, HI, NHF_2, NH_3, N_2H_4, and H_2O; low-boiling: CO, CH_4, CF_4, NF_3, B_2H_6, SiH_4, GeH_4, and PF_3; and organometallic: $Ge(CH_3)_4$, $Ge(CH_3)_3Cl$, $Ge(CH_3)_2Cl_2$, $Ge(CH_3)Cl_3$, $Ge(C_2H_5)_4$, $Ge(C_2H_5)_3Cl$, $Ge(C_2H_5)_2Cl_2$, $Ge(C_2H_5)Cl_3$, $Si(CH_3)_4$, $Si(CH_3)_3Cl$, $Si(CH_3)_2Cl_2$, $Si(CH_3)Cl_3$, $Si(C_2H_5)_4$, $Si(C_2H_5)_3Cl$, $Si(C_2H_5)_2Cl_2$, $Si(C_2H_5)Cl_3$, $Pb(CH_3)_4$, $Pb(C_2H_5)_4$, $Sn(CH_3)_4$, and $Sn(C_2H_5)_4$.

It can be seen from Table 1 that constants C_1, C_2, and C_5 do have virtually identical values for all the classes of substances considered, whereas C_2 and C_5 strongly vary between different classes of compounds. Thus, with Eqs. (1)–(5) used for applied calculations, the necessary numerical values of the constants can

Table 1. Constants C_1–C_5 for various classes of compounds

Constant	Average value of a constant for indicated substances			
	nonpolar and weakly polar	moderately and strongly polar	low-boiling	organometallic
C_1	368	374	348	375
C_2	1.73	1.66	1.56	1.14
C_3	0.15	0.15	0.13	0.11
C_4	6.72	7.03	5.94	4.05
C_5	2.34	2.33	2.41	2.31

Table 2. Accuracy of calculation of the critical parameters by Eqs. (6)–(12)

Parameter	Equation	Average error, %, for indicated substances			
		nonpolar and weakly polar	moderately and strongly polar	low-boiling	organometallic
V_{cr}	(6)	1.4	3.5	5.5	3.6
	(11)	1.4	4.7	1.0	3.2
P_{cr}	(7)	4.6	8.5	7.1	–
	(10)	1.4	4.7	1.0	3.2
T_{cr}	(8)	1.8	4.1	3.6	–
	(9)	2.5	7.7	5.9	–
	(12)	1.4	4.7	1.0	3.2

be chosen from Table 1, with the choice governed by the class of compounds to which a substance under study belongs.

Also, we analyzed the possibility of applying the empirical relations (1)–(5) to calculation of the critical parameters. For this purpose, we rearranged the equations under study in such a way that they were explicitly written in the parameter being determined. It follows from Eq. (1) that

$$V_{cr} = C_1 \Pi^{1.2} / T_{cr}^{0.3}. \quad (6)$$

In principle, relation (1) can be also used to calculate the critical temperature

$$T_{cr} = (C_1 \Pi^{1.2} / V_{cr})^{10/3}.$$

However, a high accuracy of calculation of T_{cr} can hardly be expected, because the input parameters are raised to the power 10/3 and a minor inaccuracy in their determination will lead to a gross error in the calculated value of T_{cr}.

Relation (2) can be used to derive a formula for calculating the critical temperature

$$P_{cr} = \Delta H_b / C_{cr} \Pi. \quad (7)$$

Relation (3) can be used to derive a formule for calculating the critical temperature.

$$T_{cr} = \Delta H_b / C_3 + T_b. \quad (8)$$

The critical temperature can also be calculated using Eq. (4):

$$T_{cr} = \Delta H_b / (C_4 R). \quad (9)$$

Relation (5) can be used to derive formulas for calculating all the critical parameters (P_{cr}, V_{cr}, T_{cr}):

$$P_{cr} = C_5 T_{cr} / V_{cr}, \quad (10)$$

$$V_{cr} = C_5 T_{cr} / P_{cr}, \quad (11)$$

$$T_{cr} = P_{cr} V_{cr} / C_5. \quad (12)$$

The results we obtained in calculating the critical parameters by Eqs. (6)–(12) are listed in Table 2. It can be seen that all the equations provide a high accuracy of prognostication of the critical parameters for nonpolar and weakly polar compounds. Some equations give a satisfactory accuracy for organometal compounds. For substances with a noticeable polarity, only the critical temperature can be predicted with a sufficient accuracy by Eqs. (6) and (8). The rest of the equations provide only a satisfactory accuracy of prognostication. For low-boiling substances, the whole set of critical parameters can be determined with a high accuracy by Eqs. (10)–(12).

For organometal compounds, the inaccuracy of formulas (7)–(9) is rather high (>10%). This can be attributed to the fact that published data for one of the input parameters, ΔH_b, are rather contradictory for organometal compounds and reliable values of this quantity are unknown. For this reason, errors for Eqs. (7)–(9) are not given in Table 2.

In Eqs. (6) and (10)–(12), the critical parameters are calculated one in terms of the others. For poorly studied substances, it is important to have as input parameters the readily accessible properties of a compound, e.g., parameters of the boiling point, T_b and ΔH_b, and the parachor Π. The last parameter is easily calculated using the stoichiometric formula of the compound [5].

Let us rearrange Eqs. (6) and (10)–(12) in order to pass to more accessible input data. We obtain from Eqs. (6) and (8)

$$V_{cr} = C_1 \Pi^{1.2}/(\Delta H_b/C_3 + T_b)^{0.3}. \quad (13)$$

It follows from Eqs. (10), (8), and (13) that

$$P_{cr} = C_5(\Delta H_b/C_3 + T_b)^{1.3}/(C_1 \Pi^{1.2}). \quad (14)$$

We performed a calculation by these formulas for nonpolar and weakly polar substances (Table 3).

It can be seen from the data in Table 3 that the average error of calculation of the critical volume by Eq. (13) is 1.7%, and that for the critical pressure by formula (14), 3.4%. For the case when the initial formulas are used (with the critical parameters as input data), the average error is 1.4% (Table 2). Hence it can be seen that passing to more accessible input data makes somewhat larger the error in calculation of the critical parameters. Table 4 presents recommendations for choice of equations providing the highest accuracy for various classes of compounds.

Comparison of the accuracies of the equations we considered with those for calculation of the critical parameters [5] shows that the accuracy for nonpolar and weakly polar substances is as good as that of the best methods used to prognosticate the critical parameters. For other classes of compounds, the equations considered provide a poorer accuracy than the best of the published methods.

Table 3. Results of calculation of the error in the critical parameters by Eqs. (13) and (14)

Substance	Error, %	
	V_{cr} (13)	P_{cr} (14)
$SiCl_4$	–0.5	0.9
$GeCl_4$	1.0	3.6
$SnCl_4$	–0.6	7.2
$TiCl_4$	–0.7	–2.0
BBr_3	1.3	–3.2

Table 4. Expected error of calculation of the critical parameters by the optimal equations

Parameter	Expected error, %, for indicated substances*		
	nonpolar and weakly polar	moderately and strongly polar	organometallic
T_{cr}	1.4 (12)	4.1 (8)	3.2 (12)
V_{cr}	1.4 (6)	3.5 (6)	3.2 (11)
P_{cr}	1.4 (10)	4.7 (10)	3.2 (10)

* Equation numbers are given in parentheses; at equal accuracies, preference was given to an equation using more accessible input data.

CONCLUSIONS

(1) The accuracy of five empirical relations was analyzed for a data array for 70 substances belonging to different classes of compounds.

(2) It was shown that the empirical relations can be used to calculate the critical parameters if the choice of the numerical values of the constants is governed by the class of compounds to which a substance under study belongs.

(3) It was shown that, for nonpolar and weakly polar substances, the precision of the equations stud-

ied compares well with that of the best methods used to prognosticate the critical parameters.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Critical Parameters of Methylbromo- and Ethylbromosilanes

N. S. Shoshkova and I. B. Sladkov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received November 22, 2005

Abstract—Critical parameters of nine methylbromo- and ethylbromosilanes were determined.

DOI: 10.1134/S107042720602008X

Tetramethylsilane (TMS) and tetraethylsilane (TES) are widely used in various chemical and metallurgical technologies [1, 2]. In recent years, halogen derivatives of these compounds have also come to demand. These derivatives are numerous, and most of them have been poorly studied. Since experimental determination of physicochemical properties of chemical compounds is frequently difficult, it is important to develop calculation methods for their estimation.

Methods of the thermodynamic similarity theory [3] are widely used to predict physicochemical properties of substances. However, the critical parameters of substances, which are the input data for calculations, are often unknown, which prevents use of such methods. The experimental critical parameters of methylchloro- and ethylchlorosilanes are well known, whereas similar data for bromine derivatives are lacking.

This gap can be filled today by calculating the critical parameters of methylbromo- (MBS) and ethylbromosilanes (EBS) by the equations given in [4–6]. Some of these equations are based on the theory of thermodynamic similarity and, along with physicochemical constants of a substance, contain the main criterion of thermodynamic similarity. Calculation of one of them, ψ, requires data on the boiling point T_b and molar volume V_b at the boiling point of the liquid [4]:

$$\psi = 0.1\ln T_b - 0.122\ln V_b + 0.006.$$

Another criterion, f, is calculated through the parachor Π and T_b [5]:

$$f = \ln T_b - \ln \Pi - 4.$$

In this case, the calculation is based on a single experimental characteristic, boiling point, since, to calculate parachor, we must know only the stoichiometric formula of the compound [4].

We calculated the critical parameters of MBS and EBS by the following equations:

critical temperature

$$T_{cr} = \frac{T_b}{-0.15f + 0.68}, \quad (1)$$

$$T_{cr} = 1.5T_b, \quad (2)$$

$$T_{cr} = \frac{T_b}{0.667 - 0.055f^{0.5}}; \quad (3)$$

critical volume

$$V_{cr} = V_b(2.69 + 0.05f), \quad (4)$$

$$V_{cr} = V_b(2.69 + 1.067\psi), \quad (5)$$

$$V_{cr} = 240.1\frac{\Pi^{1.2}}{T_b^{0.25}}; \quad (6)$$

critical pressure

$$P_{cr} = 0.87T_{cr}/V_b, \quad (7)$$

$$P_{cr} = 1.039T_{cr}/b, \quad (8)$$

where $b = V_b(0.2f + 1.12)$,

$$P_{cr} = \frac{1.185T_{cr}}{V_b(2 - T_b/T_{cr})}. \quad (9)$$

In Eqs. (8) and (9), T_{cr} was calculated by formula (2).

The first step of the study consisted in confirming the validity of these formulas for calculation of the critical parameters of MBS and EBS. For this purpose, we determined the accuracy of Eqs. (1)–(9) using the related substances with known critical parameters. These substances and the input data for calculation are listed in Table 1, and the results of calculation by Eqs. (1)–(9), in Table 2.

It can be seen that the equations used enable fairly reliable prediction of the critical parameters of the substances concerned. We used Eqs. (1)–(9) to calculate the unknown critical parameters of nine MBS and EBS. The input data for the calculations were taken from [4–6] (Table 3). The results are listed in Table 4.

As can be seen, the calculation of critical parameters by various methods gives well coinciding results. Therefore, the averaged values can be recommended (Table 4) (expected error ±2%). Figures 1–3 illustrate the principles of comparative calculation of physicochemical properties. The starting data for the plots were taken from [4, 7, 8]. The well-defined

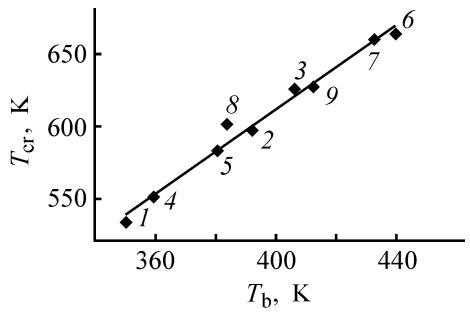

Fig. 1. Critical temperature T_{cr} vs. boiling point T_b for alkylchloro- and alkylbromosilanes. Room-mean-square error s = 0.9%, correlation coefficient r = 0.9916. *Point numbers* are substance numbers in Table 3; the same for Figs. 2 and 3.

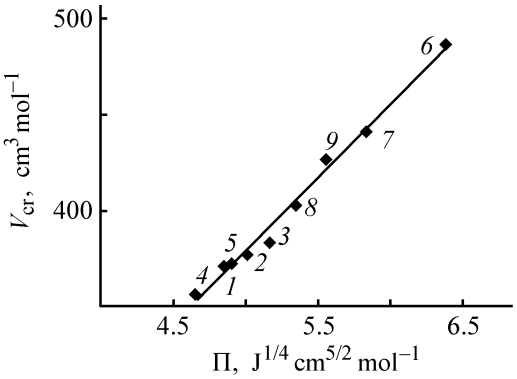

Fig. 2. Critical volume V_{cr} vs. parachor Π for alkylchloro- and alkylbromosilanes. s = 0.9%, r = 0.9962.

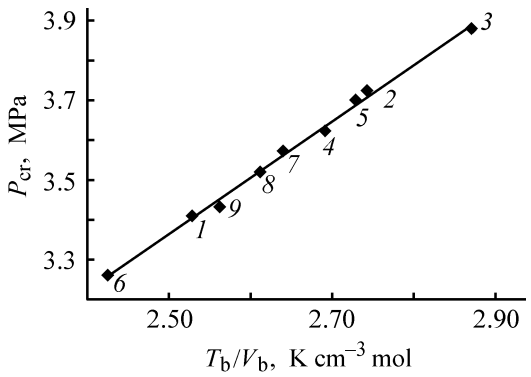

Fig. 3. Critical pressure P_{cr} vs. the ratio T_b/V_b at the boiling point of alkylchloro- and alkylbromosilanes. s = 0.1%, r = 0.9996.

linear dependences in these plots additionally confirm the reliability of the results obtained.

CONCLUSIONS

(1) Critical parameters of nine methylbromo- and ethylbromosilanes were calculated by methods whose reliability was checked on well-studied substances with a similar structure.

(2) The reliability of the results obtained was confirmed by the method of the comparative calculation.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calorimetric Study of the Solvation of Benzene and Its Chloro-, Nitro-, and Aminoderivatives by *n*-Hexane, 1-Butanol, and Mixed Solvent *n*-Hexane–1-Butanol

Received June 3, 2005

Abstract—The heats of dissolution of benzene, chlorobenzene, *ortho*-dichlorobenzene, nitrobenzene, and aniline in *n*-hexane and 1-butanol and those of benzene, chlorobenzene, nitrobenzene, and aniline in a mixture of *n*-hexane and 1-butanol were measured by calorimetry at 25°C. The enthalpies of solvation of the compounds were calculated. The correlation between the enthalpies of solvation of the compounds and their molar refraction was studied. The enthalpies of solvation of the compounds and their functional groups by the mixture of *n*-hexane and 1-butanol were considered.

DOI: 10.1134/S1070427206020091

Studies of the solvation of aromatic compounds by individual and mixed solvents are of both theoretical and practical importance. The interest in analysis of energy parameters of solvation of benzene and its derivatives is due to the following. On the one hand, many of these substances are characterized by a nonspecific type of solvation, and on the other, solutions of benzene and its derivatives frequently have fundamentally different properties. For example, the excess volume of an equimolar mixture of benzene and *n*-hexane has a positive value (0.401 $cm^3\ mol^{-1}$) [1], and that of a mixture of chlorobenzene and *n*-hexane is negative (–0.448 $cm^3\ mol^{-1}$) [3]. The excess volume of an equimolar mixture of benzene and 1-butanol is as small as 0.17 $cm^3\ mol^{-1}$ [3]. Thus, the mixture of benzene and *n*-hexane is more nonideal in its volume properties than that of benzene and 1-butanol. It is also of interest that the second derivative of the internal energy with respect to volume at a constant temperature is negative for benzene [2], i.e., benzene can be classed with Van der Waals fluids. At the same time, this derivative is positive for chlorobenzene, nitrobenzene, and aniline [2]. This means that these substances do not belong to Van der Waals fluids. The wide use of aromatic substances in manufacture of plastics, medicines, and dyes also stimulates studies of solvation of these compounds. A particular interest has been expressed recently in analysis of solutions of benzene chloroderivatives. This is due to the fact that these compounds (e.g., *ortho*-dichlorobenzene) are good solvents for fullerenes [4]. Binary mixtures of alcohols with nonpolar solvents, including alkanes, show interesting specific features in the case of minor alcohol additives. In particular, the partial molar specific heats of alcohols in systems of this kind exhibit a clearly pronounced maximum at alcohol content of up to several hundredths of a mole fraction [5].

In the present study, the solvation of benzene, chlorobenzene, *ortho*-dichlorobenzene, and aniline by *n*-hexane and 1-butanol, as well as that of benzene, chlorobenzene, nitrobenzene, and aniline by mixtures of *n*-hexane and 1-butanol, was studied by the thermochemical method. As a result of chloro- and nitrosubstitution in the aromatic ring, the polarizability and dipole moment of the molecules increase. The protons of the amino group favor formation of H-bonds between molecules of aniline and alcohol. A study of the influence exerted by the chemical nature and polarity of molecules on their solvation may be of use for detailing of spectral effects in those cases when aromatic compounds serve as solvatochromic indicators of the solvating capacity of individual [6] and mixed [7] solvents.

EXPERIMENTAL

The integral heats of dissolution were measured in a calorimeter of the ampule type with variable temperature, with an isothermal sheath and a 60-cm^3 reaction vessel. The calorimeter design was described in the monograph [8]. The thermometric and heat sensitivities of the installation were, respectively, 5×10^{-6} deg and 5×10^{-3} J mm^{-1} of the scale of the recording device.

The compounds used in the study were purified using the methods described in [9]. The content of water in 1-butanol was monitored by titration with the Fischer reagent [10]. It did not exceed 0.1 wt %. Aniline was purified by triple vacuum distillation (according to GLC data, the content of water <0.5 wt %). Benzene, nitrobenzene, chlorobenzene, and *ortho*-chlorobenzene of chemically pure grade "for chromatography" were used without additional purification.

Arithmetic mean values of the heat effects of dissolution, $\Delta_s H^m$ (Table 1) were taken as standard enthalpies of dissolution, $\Delta_s H^0$, of the compounds used in the study. This was done because the difference between these two parameters is within the experimental error, estimated to be 2–3%.

The standard enthalpies of dissolution of aniline and benzene in 1-butanol are in a good agreement with published data, 2.95 [11] and 2.51 kJ mol^{-1} [12], respectively. Also, the enthalpies of solution of benzene, nitrobenzene, and aniline in hexane, obtained in the present study, were compared with the enthalpies of dissolution of these substances in heptane [13] and a directly proportional dependence was obtained ($R^2 = 0.9999$). This fact also confirms the reliability of the experimental data obtained.

Relation (1) was used to calculate the enthalpies of solvation of aromatic compounds by *n*-hexane and 1-butanol.

$$\Delta_{solv} H^0 = \Delta_s H^0 - \Delta_{ev} H^0, \quad (1)$$

where $\Delta_{solv} H^0$ is the standard enthalpy of solvation, and $\Delta_{ev} H^0$, enthalpy of evaporation.

Data on the heats of evaporation of the compounds, necessary for the calculation, were taken from [14] (see Table 2).

Enthalpies of solvation are calculated using different approaches. The semiempirical approach was used in [12] to describe enthalpies of solvation of

hydrocarbons in a number of nonpolar and polar aprotic nonaqueous solvents:

$$\Delta_{solv}H^0 = V_A[p_s - 2(p_A p_s)^{1/2}] - RT. \quad (2)$$

Here p_s and p_A are the densities of the cohesion energy of the solvent (S) and solute (A) [$p = (\Delta_{ev}H^0 - RT)/V_m$], where V_m is the molar volume (Table 2); R, universal gas constant; and T, absolute temperature.

Relation (2) was used to calculate the enthalpies of solvation of CCl_4 by *n*-alkanes and 1-alkanols [15]. The results of calculation were compared with the experimental data. The calculation error increased from *n*-hexane (1%) to *n*-hexadecane (5%). However, the error decreased dramatically from methanol (43%) to 1-decanol (1%). Interestingly, the calculated enthalpies of CCl_4 solvation are less negative than the experimental values in the case of alcohols (with the exception of *tert*-butyl alcohol and decanol), whereas for such solvents as *n*-alkanes, the opposite behavior was observed.

The experimental heats of solvation of aromatic compounds by *n*-hexane or 1-butanol are compared with those calculated by Eq. (2) in Fig. 1.

As would be expected, the calculated and experimental values of $\Delta_{solv}H^0$ for nonpolar or weakly polar compounds (C_6H_6, CCl_4, C_6H_5Cl, $C_6H_4Cl_2$) in solutions in *n*-hexane are in a good agreement. Similar conclusions follow from comparison of the experimental and calculated data for butanol solutions. For nitrobenzene in 1-butanol and aniline in *n*-hexane, Eq. (2) gives unsatisfactory results.

Wide acceptance for analysis of enthalpies of solvation has been gained by correlation approaches. It was shown in [16] that a linear dependence of the enthalpies of solvation of compounds in CCl_4 on the values of their molar refraction (R_m) is observed. This dependence is calculated by the relation

$$R_m = V_m(n^2 - 1)/(n^2 + 2), \quad (3)$$

where n is the refractive index (Table 2).

It was of interest to check whether or not this relation is valid for the systems studied. It was found that there is a tendency for the solvation of the compounds by *n*-hexane and 1-butanol to become more pronounced as R_m grows. However, $\Delta_{solv}H^0$ can be described by the linear dependence (4) with an accuracy close to that in the experiments only for C_6H_6, CCl_4, C_6H_5Cl, and $C_6H_4Cl_2$, with the dependence (4) being common to *n*-hexane and 1-butanol

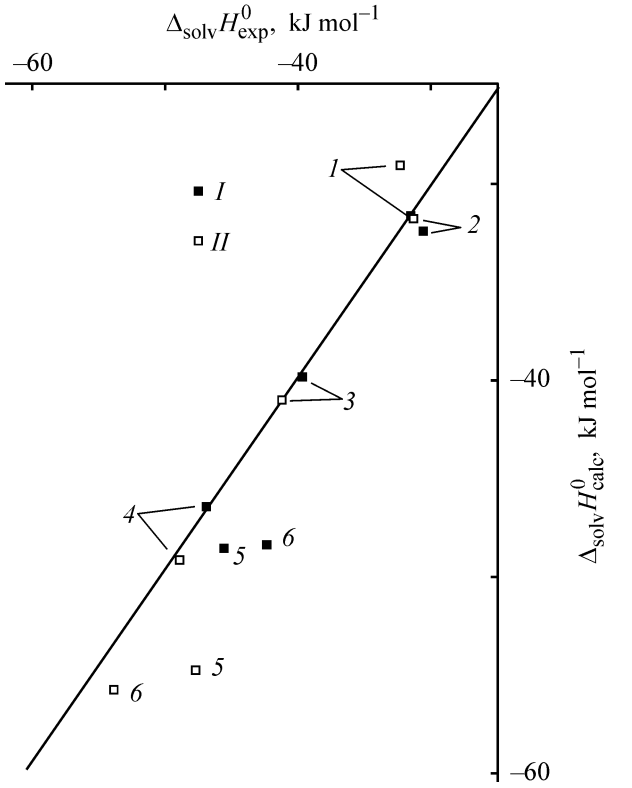

Fig. 1. Experimental enthalpies of solvation by (*I*) *n*-hexane or (*II*) 1-butanol ($\Delta_{solv}H^0_{exp}$) and those calculated by Eq. (2) ($\Delta_{solv}H^0_{calc}$). Substance being solvated: (*1*) CCl_4, (*2*) benzene, (*3*) chlorobenzene, (*4*) *ortho*-dichlorobenzene, (*5*) nitrobenzene, and (*6*) aniline.

$$\Delta_{solv}H^0 = (12.2 \pm 5.7) - (1.64 \pm 0.20)R_m, R\ 0.9991. \quad (4)$$

* n, refractive index; μ, dipole moment; V_m, molar volume; and $\Delta_{ev}H^0$, enthalpy of evaporation.

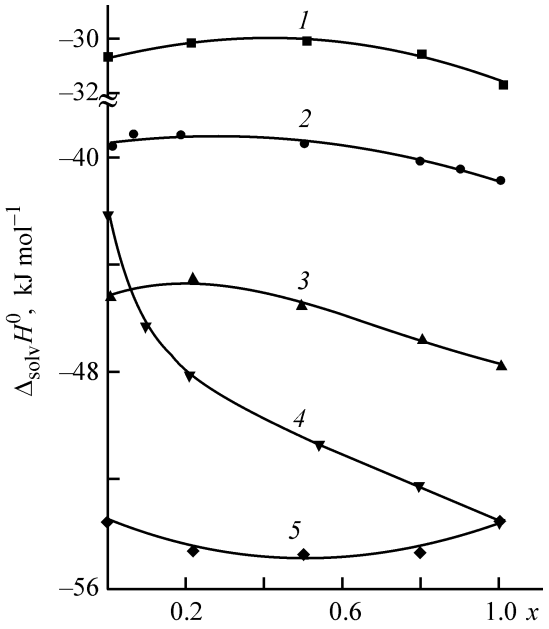

Fig. 2. Enthalpies of solvation ($\Delta_{solv}H^0$) of (*1*) benzene, (*2*) chlorobenzene, (*3*) nitrobenzene, and (*4*) aniline by a mixed solvent composed of *n*-hexane and 1-butanol, and also (*5*) that of aniline by a mixed solvent composed of dihexyl ether and 1-butanol. (*x*) Mole fraction of 1-butanol; the same for Fig. 3.

The only exception from this dependence is the strongly negative enthalpy of solvation of aniline in 1-butanol, which is due to the formation of an intermolecular H-bond. The enthalpies of solvation of $C_6H_5NO_2$ and $C_6H_5NH_2$ in *n*-hexane and $C_6H_5NO_2$ in 1-butanol are also more negative, by approximately 4 kJ mol^{-1}, than those predicted by Eq. (4). Presumably, the small difference between the $\Delta_{solv}H^0$ of the compounds in 1-butanol and *n*-hexane (< 2 kJ mol^{-1}) is due to mutual compensation of the contributions from the intermolecular interaction and void formation in the solvent. The specific relative enthalpies of void formation in *n*-hexane and 1-butanol, calculated in this study by the method described in [17] as the slope rate (k_S) of the linear dependences $\Delta_s H^0 = k_S V_m$ for *n*-alkanes with the use of data from [12, 17–19], were 1.1 and 25.8 J cm^{-3}, respectively. At V_m = 100 cm^3 mol^{-1}, this leads for a difference between the relative enthalpies of void formation by approximately 2.5 kJ mol^{-1}, and between the enthalpies of interaction, by 4 kJ mol^{-1}.

The best results were obtained when the experimental enthalpies of solvation of the substances (Table 2), except aniline, were described separately by linear two-parameter equations for the solvents *n*-hexane (5) and 1-butanol (6), in which μ is the dipole moment (Table 2):

$$\Delta_{solv}H^0 = -(1.19 \pm 0.01)R_m - (1.65 \pm 0.12)\mu, \quad (5)$$

$$R\ 0.9999.$$

$$\Delta_{solv}H^0 = -(1.22 \pm 0.01)R_m - (1.95 \pm 0.16)\mu, \quad (6)$$

$$R\ 0.9999.$$

The negative signs of the coefficients in Eqs. (5), (6) mean that the solvation becomes more exothermic as either R_m or μ increases. The coefficients R_m in Eqs. (5), (6) have the same value, and, therefore, the contribution from R_m will be eliminated for the enthalpy of transfer of the substances studied from *n*-hexane to 1-butanol.

The fact that Eqs. (5), (6) well describe the experimental values of $\Delta_{solv}H^0$ suggests the following. The solvation of aromatic compounds in both polar and nonpolar solvents is determined not only by the dispersion interaction, but also by interactions dependent on the dipole moment. This result contradicts the conclusion made in [16, 17] that neither the dipole moment of the molecule as a whole, nor the moments of the bonds (and, consequently, the orientation and induction interactions affect to any significant extent the enthalpy of nonspecific solvation.

Figure 2 shows how the enthalpies of solvation of benzene, chlorobenzene, nitrobenzene, and aniline by a mixture of *n*-hexane and 1-butanol depend on the composition of this mixture. The same figure presents for comparison the data of [20] for a mixture of dihexyl ether, 1-butanol, and aniline. It can be seen that adding to *n*-hexane a component with a higher solvating capacity, 1-butanol, first ($x < 0.2$) make somewhat lower the exothermicity of solvation of benzene, chlorobenzene, and nitrobenzene, and only then, as the pure alcohol is approached, the solvation becomes more exothermic.

The specific interactions of aniline with 1-butanol dissolved in *n*-hexane lead to a dramatic increase in the exothermicity of aniline solvation at small *x*. Aniline interacts with dihexyl ether as an H-donor, and with 1-butanol both as an H-donor and an H-acceptor. However, the specific interaction of aniline with the alcohol requires that the H-bonds in the solvent should be ruptured. As a result, the enthalpy of aniline solvation by the alcohol becomes equal to the enthalpy of aniline solvation by the ether. It should be noted that aniline is solvated the most exothermically by the equimolar mixture of dihexyl ether and 1-butanol. The ability of the NH_2 group of aniline to

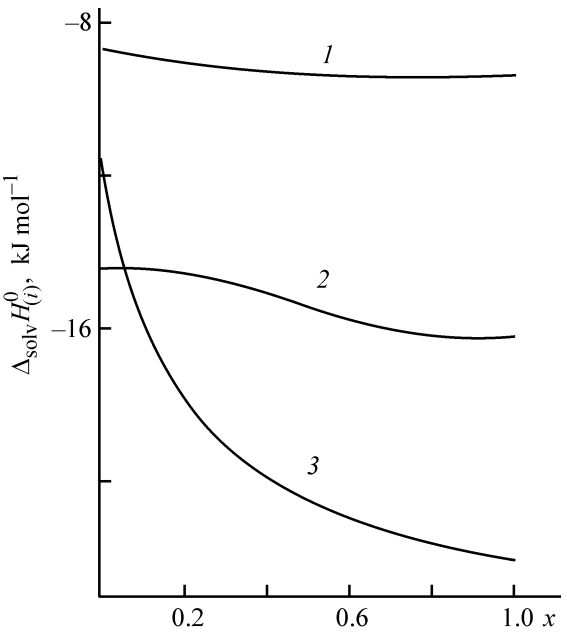

Fig. 3. Contribution of *i*th group to the enthalpies of solvation ($\Delta_{solv}H^0$) of the compounds by a mixed solvent composed of *n*-hexane and 1-butanol. *i*: (*1*) Cl, (*2*) NO_2, and (*3*) NH_2.

be an H-donor and H-acceptor is manifested in this case to the greatest extent.

Figure 3 shows the enthalpies of solvation of the substituents, calculated as the difference of the enthalpies of solvation of the corresponding compounds and benzene. The solvation of the substituents in *n*-hexane is nonspecific. It becomes 3 kJ mol^{-1} more exothermic in going from Cl to NH_2, and the exothermicity increases by additional 3 kJ mol^{-1} in going from NH_2 to NO_2. Already at 5 molecules of the alcohol per 95 molecules of the alkane, the NH_2 and NO_2 groups are solvated similarly. At $x > 0.05$, the solvation of these groups becomes increasingly exothermic in the order Cl, NO_2, and NH_2. In the pure alcohol, the solvation of the NH_2 groups is already 6 kJ mol^{-1} more exothermic than that of NO_2. Thus, the solvation of these groups can be differentiated by varying the composition of the alkane–alcohol mixture.

CONCLUSIONS

(1) The enthalpies of dissolution of benzene, chlorobenzene, *ortho*-dichlorobenzene, nitrobenzene, and aniline in *n*-hexane and 1-butanol, and that of benzene, chlorobenzene, nitrobenzene, and aniline in a mixed solvent composed of *n*-hexane and 1-butanol, were determined experimentally.

(2) Specific features of the solvation of the substances studied by *n*-hexane and 1-butanol were discussed. The correlation of the enthalpies of solvation of the compounds with their molar refraction becomes better if the dipole moments of the molecules are taken into account.

(3) It was found that the composition of the mixture of *n*-hexane and 1-butanol comparatively weakly affects the enthalpies of solvation of benzene, chlorobenzene, and nitrobenzene, whereas the solvation of aniline becomes considerably more exothermic as the content of the alcohol in the mixture increases.

(4) It was shown that the results obtained can be used to supplement the available reference database on heats of solution of aromatic substances in individual and mixed solvents and may be of use in studies of reactions that occur in solutions containing benzene derivatives.

Abstract—The structural and sorption characteristics of microporous sorbents from industrial lignin with respect to some toxic substances, Pb^{2+}, Cd^{2+}, Cu^{2+}, and NH_4^+ ions, and also the possibility of accumulation of methane on these carbons were studied. Simple procedures for modification of the carbon surface to improve the sorption power of the carbons were suggested.

DOI: 10.1134/S1070427206020108

Carbon adsorbents from plant raw materials find diverse applications. Lignin, large-tonnage waste from chemical reprocessing of wood, is of doubtless interest as a raw material for carbon production. Procedures for preparation of activated carbons (ACs) from hydrolyzed lignin [1–3], cotton lignin [4], and cellolignin formed as waste in synthesis of furfural by acid-free method of wood hydrolysis [4] have been published. Due to highly developed volume of micropores, the resulting activated carbons have the best adsorption characteristics in comparison with the well-known industrial carbons of AG-3, AR, and UAF brands.

Traditionally, adsorbents from industrial lignin (IL) are produced by its steam and gas activation after precarbonization (pyrolysis).

New methods have been developed for pyrolysis of wastes formed in chemical and mechanical treatment of wood (industrial lignins, wastewater sludges, bark, sawdust, liquors), such as combined process of pyrolysis–steam-and-gas activation, oxidative pyrolysis of high-ash wastes, e.g., wastewater, thermochemical activation at 800–840°C with chemicals used in wood delignification (Na_2SO_4, Na_2CO_3, NaOH) [5–7], and a new method for production of ferromagnetic adsorbents [5, 8, 9].

The aim of this study was to examine some structural sorption and physicochemical characteristics of AC produced by thermochemical activation of IL after its precarbonization[1] [5–9] to find additional possibilities for its use in adsorption technology.

EXPERIMENTAL

The adsorbents synthesized by the procedure described in [8] have a mixed pore structure with predominance of micropores. The volume of micropores with radii r = 10–25 Å in these carbons reaches 1.2 $cm^3\ g^{-1}$, and the volume of mesopores varies in the range 0–0.5 $cm^3\ g^{-1}$.

The carbon sample (approximately 2 kg) was nonuniform in the particle size. The powder fraction (approximately 30%) was sifted off. The sample with particle size from 0.25 to 1.0 mm^2 was used. The pH of the aqueous carbon extract from IL was about 2.5 (Table 1). Therefore, the initial sample was subjected for subsequent testing to additional treatment, washing with hot distilled water until pH of the aqueous extract reached approximately 7 (Table 1) and special oxidation with 25% nitric acid in the liquid phase on a boiling water bath or calcination in an argon flow for 1 h at 700°C [10, 11] (activated sample), with the aim to impart properties of an effective cation or anion exchanger to carbon [10–12] for its

use in adsorption technology and for environment protection.

The parameters of the carbons studied (Table 1) were evaluated by standard procedures [GOST (State Standard) 6217–74, GOST 4453–74]. We determined the total volume of sorption pores with respect to benzene W_s, moisture content, ash residue, pH of aqueous extract, bulk density Δ, anion-exchange capacity (from sorption of Cl^- ions from 0.01 M aqueous HCl), and cation-exchange capacity (SEC) (from sorption of Na^+ ions from 0.1 N NaOH). A qualitative analysis of pores was based on the adsorption of markers [12]: Methylene Blue (MB, molecular weight 319) and oxyhemoglobin (OH, molecular weight 68 000). Low-temperature (77 K) adsorption of N_2 was used for characterizing the pore structure [13]. BET isotherms of N_2 adsorption and curves of pore radius distribution (Fig. 1) were obtained on a Quantachrome NOVA 2200E high-rate gas sorption analyzer. The specific surface areas S_{sp} of the samples (Table 1) were evaluated by the BET method.

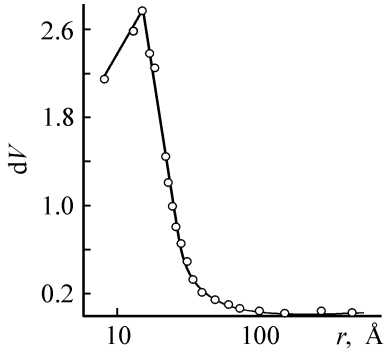

Fig. 1. Curve of differential distribution of pores dV with respect to radius r in the initial carbon prepared from industrial lignin and washed with water.

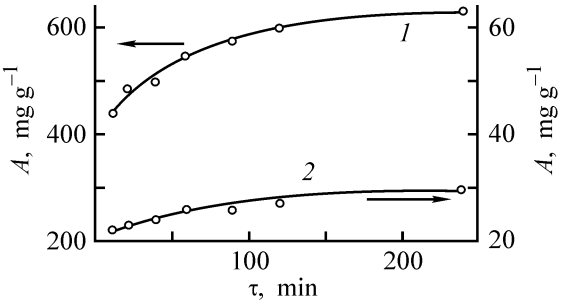

Fig. 2. Kinetics of sorption A of (*1*) Methylene Blue and (*2*) oxyhemoglobin on carbon prepared from industrial lignin and washed with water. Weighed portion of carbon 0.1 g; solution volume 50 ml, T = 20°C. (τ) Process duration.

We found that, similarly to all carbon adsorbents based on lignosulfonates, the carbon studied has a high specific surface area, 1450–2100 $m^2\ g^{-1}$, large volume of sorption area of W_s = 1–1.4 $cm^3\ g^{-1}$, and high clarification power with respect to MB (540–670 $mg\ g^{-1}$).

Table 1 shows that the carbons prepared from IL are highly competitive in structural sorption characteristics and kinetics of absorption of markers (Fig. 2): MB molecules with lower molecular weight are sorbed more readily than OH molecules with higher molecular weight) with well-known granulated sorbents, e.g., carbons from the KAU natural raw materials and can be used for absorption of "small-" and "medium-size" molecules [10].

The presence of a microporous structure in the samples studied is confirmed not only by the behavior in sorption of markers of various molecular weights but also by the low-temperature adsorption of N_2. The sample, indeed, was uniformly microporous with the pore size r = 20 Å, which is a valuable characteristic for practical use.

The experiments showed that the carbon is readily oxidized: upon boiling in nitric acid on a water bath for 1 h, a fairly high ion-exchange capacity (SEC = 3.2 mg-equiv g^{-1}) with predominant content of strongly acidic and phenolic surface groups is reached, whereas, e.g., KAU carbons from pits are oxidized under similar conditions to similar values of SEC only in 15–20 h [10, 11]. It is likely that mineral impurities (ash residue approximately 10%) exert a catalytic effect on the carbon oxidation; similar phenomena have been observed previously [14].

It should be noted that a distinctive feature of activated carbons prepared by thermochemical activation is their capacity for ion exchange. The ion-exchange capacity is acquired without additional oxidative treatment and reaches 1.6 mg-equiv g^{-1} (Table 1). This is apparently caused by the fact that sodium sulfate oxidize the kraft lignin matrix on heating to a temperature above 800°C, with reduction to sulfide and other reduced sulfur compounds [6]. In the process, the content of oxygen-containing acidic groups, responsible for the cation-exchange capacity of the resulting carbon material, increases.

In studying ion exchangers, the amount and quality of individual types of functional groups capable of ion exchange are most frequently estimated from the titration curves [15]. The titration curves of the samples of activated and oxidized carbons from industrial lignin in 0.2 N NaCl with HCl and NaOH are shown in Fig. 3. The integral and differential pH dependences of the Na^+ sorption on the oxidized sample A, evaluated from these titration curves, are shown in Fig. 4. It is seen from Figs. 3 and 4 that the anion exchange on the activated carbon starts, as usually [14, 15], at pH 8.5, and the exchange proceeds on the oxidized sample even at pH 2–2.5; with increasing pH, weaker acidic groups are involved into the exchange. From the most pronounced inflections in the dependence of dA/d pH on pH, we determined the pK values for ionization of three types of functional groups present in the sample studied: 4.7, 9.7, and 10.7, which corresponds to carboxy groups dissociating in the pH range 1–8 and phenolic groups dissociating at pH 8–10 [15].

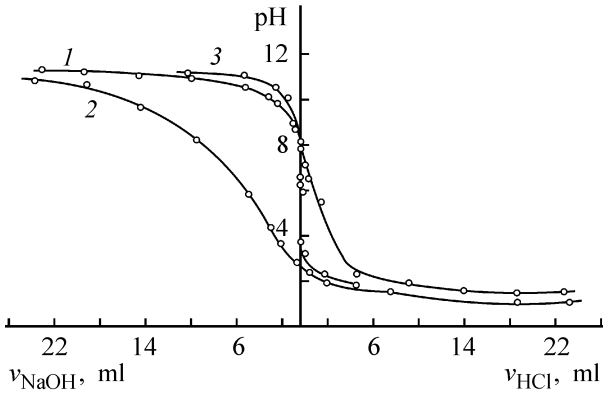

Fig. 3. Curves of pH-potentiometric titration of (*1*) activated and (*2*) oxidized carbon from lignin. (*v*) Amount of HCl and NaOH solutions. (*3*) Blank experiment (without carbon).

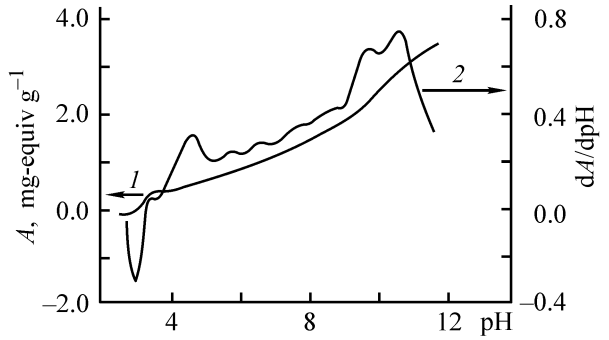

Fig. 4. (*1*) Integral and (*2*) differential pH dependences of the sorption of sodium ions, A, on oxidized sample of carbon from industrial lignin.

The chemical methods used to determine the amount of acidic groups in oxidized carbons from lignin (titration with alkalis with various strengths [16]) confirmed the results of potentiometric titration. It was found that the surface of the carbons studied, with a total exchange capacity of 3.2 mg-equiv g^{-1}, contains strongly acidic carboxy groups in an amount of 1.8 mg-equiv g^{-1} with pK ~ 4 and phenolic groups in an amount of 1.4 mg-equiv g^{-1} (pK ~ 9). Thus, the sample obtained by additional oxidation is a polyfunctional cation exchanger with a widely varying of acidic characteristics of groups responsible for the ion exchange (pK ~ 2–10).

The ion exchange power of the carbons studied is confirmed by the sorption isotherms of toxic metal ions Cu^{2+}, Cd^{2+}, and Pb^{2+} from aqueous solutions of their salts on the initial sample (SEC = 1.6 mg-equiv g^{-1}) in the H form at 20°C (Fig. 5a). The sorption experiments were performed under static conditions. The ratio of the solid and liquid phases was 1 : 250. The initial and equilibrium concentra-

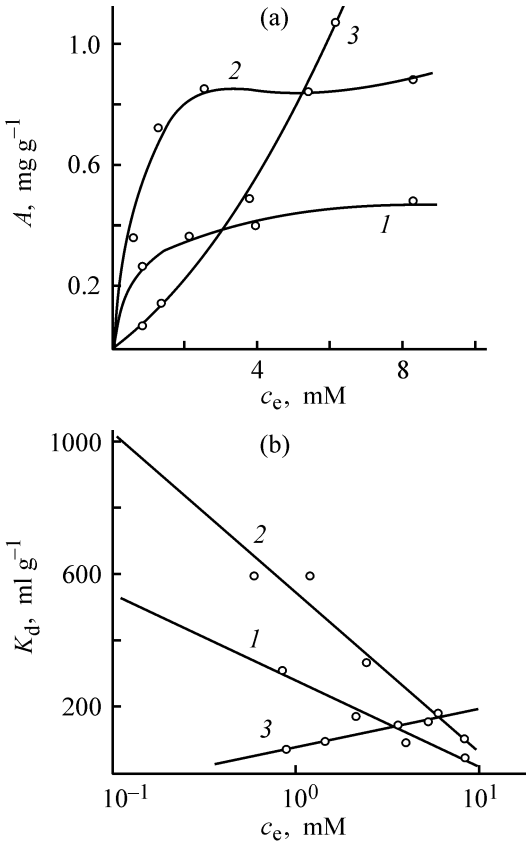

Fig. 5. (a) Sorption isotherms A and (b) dependences of distribution coefficients K_d of (*1*) Cu^{2+}, (*2*) Cd^{2+}, and (*3*) Pb^{2+} ions on the equilibrium concentration c_e for the initial carbon (SEC = 1.6 mg-equiv g^{-1}). Weighed portion of carbon 0.1 g; solution volume 25 ml.

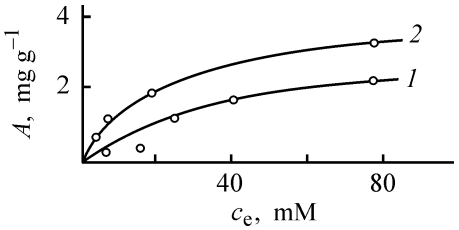

Fig. 6. Sorption isotherm A of ammonium ions on (*1*) H and (*2*) Cu forms of oxidized carbon prepared from lignin. (c_e) Equilibrium concentration of sorbed ion.

tions of metal ions were determined on a KAS-120.1 device [12]. It is seen from Fig. 5a that the sorbability of the ions decreases in the order $Cd^{2+} > Cu^{2+} > Pb^{2+}$. Copper and cadmium ions were best sorbed when the equilibrium concentration c_e was approximately 3 mmol g^{-1}, and the isotherm of lead(II) sorption under the selected conditions did not level off. At $c_e > 6$ mmol g^{-1}, the sorbability order became $Pb^{2+} > Cd^{2+} > Cu^{2+}$.

From the sorption isotherms of the metal ions we evaluated the distribution coefficients K_d (ml g^{-1}) with respect to each ion, brought to the standard conditions: the equilibrium concentration of ions in the solution was 1 mM as in [17]. The concentration dependences of the distribution coefficients of the ions in a wide range of their equilibrium concentrations in solution (from 10^{-1} to 10^{1} mM) are shown in Fig. 5b. The resulting order of sorption selectivity with IL carbons is typical of the majority of oxidized carbons of various origins [15, 17].

Among detrimental products of metabolism are nitrogen-containing substances, which, at increased concentrations, exert toxic effect on a living body: ammonia, uric acid, urea, and creatinine [17]. Removal of these substances from a body is an important and urgent problem [18]. In this context, it was of interest to study how the carbons produced from the cheap raw materials extract some substances mentioned above. The isotherms of sorption of ammonium ions from solutions of ammonium chloride on the H and Cu forms of oxidized carbon produced from lignin (static exchange capacity 3.2 mg-equiv g^{-1}) are shown in Fig. 6. As expected, carbon in the Cu form, in which the content of the modifying ion was 1.2 mg-equiv g^{-1}, absorbed ammonium ions a factor of 2 better than did the carbon in the H form. It is likely that the increase in the sorption capacity with respect to NH_4^+ ions can be favored by possible formation of fairly stable ammonia complexes with copper ions [15] at the surface of Cu form of the oxidized carbon.

Carbon adsorbents attract attention as possible molecular-sieve materials, which can serve as accumulating systems for increasing the capacity of gas cylinders filled with methane to be used as motor fuel. Previously [19, 20] it was shown that addition of carbon sorbents to gas cylinders to be filled with methane allows its accumulation in the same amount at 25–35 atm as in the absence of a sorbent at 150–200 atm.

Absorption of methane on carbon materials was studied on a specially designed volumetric installation. A carbon sample was preliminarily vacuum treated, first at room temperature for 0.5 h and then, at 250°C for 1 h, after which the cooled sample was vacuum treated at room temperature for 0.5 h. The sufface of the carbon prepared by this procedure was saturated with methane (methane accumulation), using multicycle treatment of the sample with methane at room temperature under a gas pressure of 25 atm for 0.5 h and subsequent desorption of CH_4 for a short time (1–2 min) at atmospheric pressure. Five cycles of

Table 2. Adsoption of methane during several cycles of operation on the initial carbon, oxidized sample, and some of its ionic forms

Cycle	Adsorption on samples modified with indicated ions, ml g^{-1}						
	initial carbon	H^+	Li^+	Na^+	K	Rb^+	Cs^+
1	115	10	16	16	7	10	0
2	42	20	0	0	2	0	0
3	0	10	6	17	12	–	4
4	–	0	10	0	8	–	–
5	–	10	10	0	0	–	–
Total	157	50	42	33	29	10	4

adsorption–desorption of methane were performed (Table 2).

For the study we used the initial finely porous washed sample prepared from industrial lignin, the same carbon oxidized with nitric acid (H form), and also K, Na, Li, Rb, and Cs forms of carbon specially modified with ions of the same nature but different sizes. Alkali metal ions were sorbed on carbon material at pH 10–10.5 [14].

The values of methane absorption after each adsorption–desorption cycle on various carbons are listed in Table 2. It follows from Table 2 that CH_4 was best accumulated on the initial carbon and on carbon in the H form; with increasing radius of substituting ion (from Li^+ to Cs^+), the adsorption abruptly decreased. This coincides with theoretical calculations and assumptions [19, 20] that the features of the pore structure and predominant content of micropores play an important role in the process. For example, according to published data [20], to attain the highest affinity for methane, the diameter of micropores of activated carbons should correspond to the sum of the critical diameters of three methane molecules, i.e., approximately 11.2 Å. It is precisely this diameter of slitlike pores at which the closest volume filling of these pores with methane is observed.

It is likely that, in the experiments on directed modification of the carbon surface with cations of various sizes, the diameter of slitlike pores decreases with increasing radius of substituting ions; in this case, the amount of sorbed methane decreases. These studies indicate that the tested samples of carbon sorbents from wastes of forest industry plants show much promise for accumulation of methane.

CONCLUSIONS

(1) The main structural parameters of carbon sorbents based on industrial lignin were determined, and their specific surface area and total volume of sorption pores were found to be $S_{sp} \sim 2000$ m^2 g^{-1} and $W_s \sim 1.4$ cm^3 g^{-1}, respectively. Micropores predominate in these sorbents, and their radius is $r \sim 20$ Å.

(2) The chemical nature of the carbon surface was modified by liquid-phase oxidation (impartment of cation-exchange properties) and high-temperature activation in argon flow (anion-exchange properties).

(3) The ion-exchange power of oxidized carbons from industrial lignin was determined, and isotherms of adsorption of Pb^{2+}, Cu^{2+}, Cd^{2+}, and NH_4^+ ions were obtained.

(4) Owing to their microporous structure, carbon sorbents from wood treatment wastes can efficiently accumulate methane.

SORPTION AND ION-EXCHANGE PROCESSES

Bentonite-based Phosphoric Acid Organomineral Cationite

A. M. Akimbaeva and E. E. Ergozhin

Received March 31, 2005

Abstract—The conditions under which bentonite-based phosphoric acid organomineral cationite is obtained were assessed and its acid-base and physicochemical properties were studied.

DOI: 10.1134/S107042720602011X

Until recently, synthetic organic polymers with ionogenic functional groups containing inorganic substances (silica, aluminum oxide, zeolites) have constituted two main classes of ion-exchangers. The wide use of organopolymer sorbents is due to the versatility oftheir action, ease of regeneration, and possibility of widely varying the nature and content of functional groups. The advantages of inorganic ionites include the nonswellability in solvents, mechanical strength, thermal stability, radiation hardness, and, in some cases, unique catalytic properties. Combination of the valuable properties of both classes of sorbents enables development of few-stage methods for synthesis of new effective ion-exchangers with a set of valuable properties. In this context, a necessity arises for creating a new type of materials combining the advantages of these ion exchangers. The materials are obtained by modifying the surface of inorganic substances with organic compounds containing functionally active groups [1]. Of particular importance among these materials are phosphorus-containing organomineral ion-exchangers with a silica matrix, which are used in sorption, concentration, and various types of chromatography [1, 2]. A promising solution in this area is to use natural raw materials and various kinds of industrial waste [3–5].

The aim of the present study was to synthesize a phosphoric acid organomineral cationite based on natural bentonite.

EXPERIMENTAL

Bentonite (Bt), whose main rock-forming mineral is montmorillonite, served as a mineral support. The acid activation of the natural sorbent was done in 20% H_2SO_4 on a boiling water bath in the course of 6 h [6].

After distillation, glycidyl methacrylate (GMA) had the following parameters: $d_4^{20} = 1.0333$, $n_D^{20} = 1.4480$. Slime orthophosphoric acid ($\rho = 1.588$ g cm^{-3}) was taken from the waste of Zhambyl phosphorus plant (Kzakhstan).

The mineral was modified with phosphoric acid in dioxane, with the subsequent polymerization of GMA at 100°C [7]. Then cationite samples were converted from Na^+ to the H-form and back, each time with washing to a neutral reaction of the washing water. The static exchange capacity SEC (mg-equiv g^{-1}) of the final products was determined with a 0.1 N KOH solution [8].

The samples were subjected to potentiometric titration by the method of separate weighed portions. The ionic strength was maintained by adding a certain amount of the electrolyte (KCl). After equilibrium between the cation exchanger and the solution was established, the pH value was measured with an EV-74 ion meter equipped with glass and silver chloride. The results of these measurements were used to plot the curve of potentiometric titration as a graph of pH versus the amount of the titrant.

To determine the chemical and thermal stability of the cationite in the H-form, three weighed portions of the ionite (each 1.0 g in terms of dry substance) were placed in 250-ml round-bottom flasks. The first of these was poured over with a 5 N H_2SO_4 solution (100 ml); the second, with a 5 N NaOH solution (100 ml); and the third, with distilled water (100 ml); after which all the samples were kept at room tem-

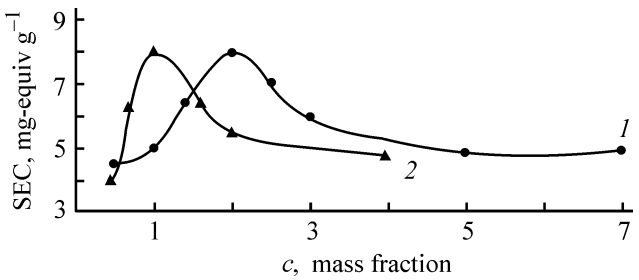

Fig. 1. SEC of the cationite vs. the content c of the modifying agents (modification at 100°C for 3 h). (*1*) H_3PO_4 (Bt : GMA = 1 : 1) and (*2*) GMA (Bt : H_3PO_4 = 1 : 2).

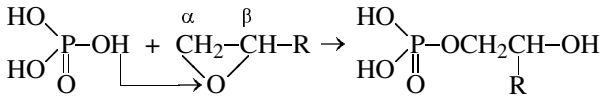
perature for 0.5 h (chemical stability) and on a boiling water bath for 24 h (thermal stability). The mixture was cooled to room temperature, the filtrate was separated from the ionite, and the latter was converted to the H-form and its SEC was determined. The chemical and thermal stability V (%) was calculated by the formula

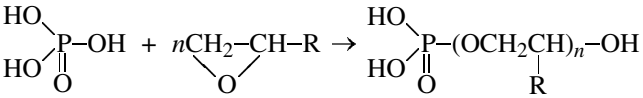
$$Y = E_1/E_0,$$

where E_0 and E_1 are the SEC (mg-equiv g^{-1}) before and after the treatment of the ionite, respectively.



IR spectra of the samples were measured on a UR-20 spectrophotometer in KBr pellets or in thin layer in the spectral range 400–4000 cm^{-1}.

It has been found [9] that the reaction of concentrated H_3PO_4 with kaolin occurs at room temperature via binding of acid molecules by clay particles, whereas at elevated temperature, the structure of the mineral undergoes a deep disintegration [9]. It was shown that the interaction products are partly soluble in water. The best acceptable way to obtain mineral-based sorbents is to use cross-linking agents that can firmly fix functional groups to the support surface.



Modification of the bentonite surface with an epoxy compound in the presence of H_3PO_4 promotes involvement of a large number of active centers into condensation and favors uniform cross-linking of polymer chains.

In setting-up the problem, the authors proceeded from the results of previous studies [3–5], in which the possibility of obtaining organomineral products was demonstrated. GMA, which combines an easily polymerizing double bond and a reactive oxirane ring, served as an epoxy compound. Use of monomers of this kind makes it possible to synthesize ionites with a high mechanical strength and a wide variety of functional groups via polymer-analogous transformation of their α-oxide and anhydride groups [10].

It is known that GMA derivatives readily enter into the phosphorylation reaction under rather mild conditions. Adsorption of H_3PO_4 on the clay surface and further polymer-analogous transformation of acid groups under the conditions suggested leads to polymerization of GMA and additional cross-linking of monomer links both via OH groups in the β-position of the epoxy monomer and via surface OH groups of aluminosilicate. In the interaction of glycidyl ethers with H_3PO_4, there occurs [12] a nucleophilic attack of the oxirane ring to give an intermediate associate, which then isomerizes into a phosphoric acid ester. Then the oxide ring is cleaved, the P–O–H bond is transformed into the P–O–C bond, and a hydroxy group appears at the β-carbon atom:

The compounds formed in this case have hydroxy groups in the β-position. These groups can add next molecules of the monomer with an oxide group:

When studying the conditions under which ionites are obtained, it is necessary to take into account factors that affect the exchange properties and physicochemical parameters of the products formed. As the optimality criterion of these parameters serves the value of SEC, which depends on the ratio of the starting components, temperature, and process duration.

A key factor in the synthesis of ionites is the ratio of the starting reagents. The effect of the content of GMA and H_3PO_4 on the ion-exchange properties of the sample studied is illustrated in Fig. 1. It was found that the SEC of the cationites increases from 4.50 to 7.96 mg-equiv g^{-1} (mass ratio Bt : GMA = 1 : 1) as the content of H_3PO_4 in the initial mixture is raised from 0.50 to 2.00 mass parts. A further increase in the amount of H_3PO_4 leads to a decrease in SEC because it impairs the conditions under which the process products are formed.

The ion-exchange and physicochemical properties of the process products are strongly influenced by the amount of an epoxy compound. Its low or high content adversely affects the properties of the sorbent. The content of GMA in the range from 0.5 to 1.0 mass parts leads to an increase in the SEC of cationites from 4.00 to 7.96 mg-equiv g^{-1}. A further

increase in the amount of the epoxy monomer does not make the SEC higher. The study performed revealed the optimal mass ratio Bt : H_3PO_4 : GMA = 1 : 2 : 1.

A necessary condition for ionites with a high exchange capacity and acceptable physicochemical parameters to be obtained is that the optimal process duration and temperature, which strongly affect the basic characteristics of the ionite formed, should be chosen. The influence exerted by the duration of chemical conversion on the exchange properties of the products was studied at 100°C in the range 1–7 h. It was established that the SEC increases from 3.49 to 7.96 mg-equiv g^{-1} in the course of 3 h. A decrease or an increase in this time with respect to that for the material under study makes the SEC lower, which is presumably due, respectively, to degradation of strength properties or densification of the cationite structure. An effective way to improve the exchange properties of the products formed in the process is to raise the temperature of sample modification. It was found that no significant changes in the basic parameters of the products obtained occur above 100°C. Lowering the temperature relative to that specified above leads to a pronounced loss of the SEC of the cationite, to 3.86 mg-equiv g^{-1}. This is due to the low the degree of chemical transformation of active groups in the formation of macromolecules on the bentonite surface. It was found in the study performed that the optimal curing duration and temperature are 3 h and 120°C.

Under industrial conditions, sorbents may come in contact with various aggressive media and aqueous solutions at high temperatures. This may result in chemical destruction of samples, which leads to a decrease in their capacity. The recent achievements in the analysis of the mechanisms and kinetics of destruction of ionites under heating make it possible, in some cases, to choose an appropriate type of an ion exchanger and to prognosticate its service life. The table lists the results obtained in studying the chemical and thermal stability of the organomineral cationite synthesized, which has an exchange capacity for a 0.1 N HCl solution equal to 7.96 mg-equiv g^{-1} and a swelling ability of 3.02 ml g^{-1}. It can be seen that the sorbent samples are rather inert toward the action of 5 N H_2SO_4 and 5 N NaOH. It was found that the SEC of the cationite somewhat increases upon treatment with aggressive solutions (8.02, 8.04 mg-equiv g^{-1}). This is probably due to a facilitated accessibility of active groups upon washing-out of low-molecular-weight impurities, which favors a more complete ion exchange. Treatment with solutions of acids and alkalis at a high temperature also causes a stronger swelling of a cross-linked organic phase of the sorbent, which opens up access to the functional groups that were not involved in the ion exchange before that. Upon a thermal treatment in water for 24 h, the loss of capacity is 3.23%.

Chemical and thermal stability of the phosphoric acid cationite

SEC, mg-equiv g^{-1}, after treatment at 96–98°C		
Stability, %		
5 N H_2SO_4, (0.5 h)	5 M NaOH, (0.5 h)	H_2O (24 h)
8.04 / 101.01	8.02 / 100.81	7.70 / 96.77

An important factor that characterizes the functional groups of the ionites and determines the degree of dissociation is the pH of the medium. The acid–base properties of the cationite were studied by means of potentiometric titration. The run of the curve (Fig. 2) shows two inflections indicating the presence of several types of ionogenic groups. The apparent constants of acid dissociation of the active groups (pK), calculated by the Henderson–Hasselbach equation, are 5.9 and 11.8. These pK values are in a good agreement with published data and correspond to two stages of dissociation of phosphoric acid groups [13].

The IR spectrum of the acid-activated form of natural bentonite (Fig. 3, curve *1*) contains absorption bands associated with stretching and deformation vibrations of the Si–O bond at 472, 520, and 1040 cm^{-1}, and those related to stretching vibrations of Si–O–Al at 790 cm^{-1}. The shoulder at 930 cm^{-1}, which belongs to vibrations of the H–O–Al bond, is characteristic of all layered dioctahedral aluminosilicates.

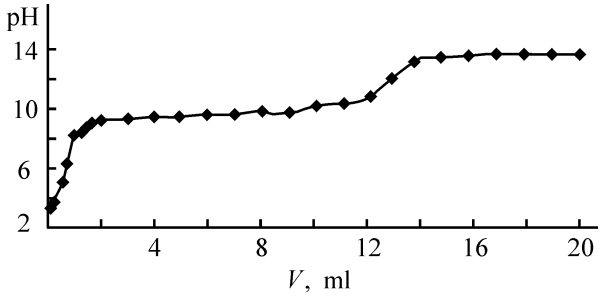


Fig. 2. Potentiometric titration curve for organomineral phosphoric acid cationite. (*V*) Volume of a 0.1 N solution of KOH.

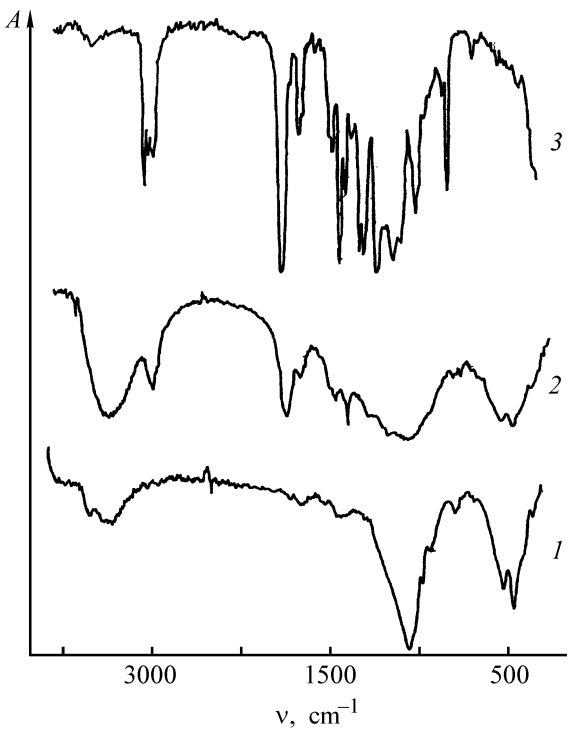

Fig. 3. IR spectrum of bentonite and organomineral phosphoric acid cationite on its base. (*1*) Bentonite, (*2*) cationite, and (*3*) GMA. (*A*) Absorption and (ν) wave number.

In the spectrum of modified bentonite (Fig. 3, curve *2*), the intensity of characteristic absorption bands decreases, compared with that before modification. Absorption bands related to deformation and asymmetric stretching vibrations of the C–H bond appear at 1380, 1440, and 2930 cm^{-1}, respectively. The absorption bands at 1160 and 1270 cm^{-1} are characteristic of stretching vibrations of P=O. Absorption bands associated with antisymmetric stretching vibrations of carbonyl groups appear in the spectrum of the cationite at 1725 cm^{-1}, and the absorption band related to C=C bonds, observed in the spectrum of the starting monomer at 1640 cm^{-1}, disappears. The Characteristic absorption bands associated with deformation and stretching vibrations of the epoxy ring of the starting GMA at 840, 984, and 1272 cm^{-1} (Fig. 3, curve *3*) are not present in the spectrum of modified bentonite, either.

CONCLUSION

Bentonite was modified with H_3PO_4 and then subjected to polymerization with glycidyl methacrylate at 100°C to give a new organomineral phosphoric acid cationite. The optimal conditions of its synthesis in relation to the content of the starting components, temperature, and process duration were found. It was shown that the sorbent obtained is chemically and thermally stable medium-acidity cationite with dissociation constants of 5.9 and 11.8.

SORPTION AND ION-EXCHANGE PROCESSES

Comparison of the Complexation Abilities of Bifunctional Polysiloxane Xerogels and Chemically Modified Silica Gels

Abstract—Complexation of copper(II) on the surface of chemically modified silica gels and polysiloxane xerogels both containing the same functional groups, 3-aminopropyl and 3-mercaptopropyl, was studied. The composition of the complexes formed on the surface of these two classes of sorbents was determined by ESR and electronic spectroscopies.

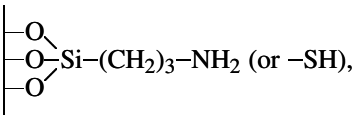
DOI: 10.1134/S1070427206020121

Chemically modified silica gels (CMSG) and polysiloxane xerogels (PSXG) with a monofunctional surface layer belong to classes of substances that have been rather well studied. However, creating a polyfunctional surface layer on these gels opens up wide prospects for synthesis of new complex-forming sorbents and catalysts because this provides an opportunity to vary not only the nature, but also the molar ratio of functional groups in such a layer. An important role can be played in this case by the type of distribution and by the position of chemical bonds of varied nature, which are covalently bound to the SiO_2 surface and form this multifunctional layer. For example, it has been shown previously in studies of complexation of copper(II) on the surface of a silica gel containing simultaneously 3-aminopropyl and 3-mercaptopropyl groups [1, 2] that several ligand centers containing sulfur or nitrogen atoms are simultaneously involved in complexation at the maximum filling of such a surface. However, no formation of heteroligand complexes of copper with a [N, S] environment was observed on the surface of CMSG of this kind. This is probably due to different spatial positions of grafted ligands in the surface layer [2]. According to [3, 4], 3-aminopropyl groups are arranged horizontally with respect to the silica gel surface, and 3-mercaptopropyl groups and products of their oxidation in interaction with Cu(II), dimercaptopropyl groups, are perpendicular or inclined to the SiO_2 surface.

The aim of this study was to compare (i) processes of complexation of copper(II) on the surface of CMSG and PSXG containing simultaneously the same, 3-aminopropyl and 3-mercaptopropyl, functional groups and (ii) some performance parameters of the sorbents belonging to these two classes.

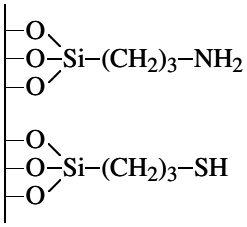
EXPERIMENTAL

PSXGs with a bifunctional surface layer were produced by the reaction of hydrolytic polycondensation [5]



$$\mathrm{Si(OC_2H_5)_4 + (CH_3O)_3Si(CH_2)_3SH + (C_2H_5O)_3Si(CH_2)_3NH_2} \xrightarrow[-\mathrm{ROH}]{+\mathrm{H_2O}} \mathrm{SiO_2/SiO_{3/2}(CH_2)_3SH/SiO_{3/2}(CH_2)_3NH_2}.$$

The following alkoxysilanes manufactured by Aldrich were used as starting substances: $Si(OC_2H_5)_4$ (TEOS, 98%), $(C_2H_5O)_3Si(CH_2)_3NH_2$ (APTES, 99%) and $(CH_3O)_3Si(CH_2)_3SH$ (MPTMS, 95%). To obtain PSXG samples, first 0.096 mol of TEOS was added to 20 cm^3 of methanol under constant agitation, and then MPTMS and APTES taken in molar ratios of 4 : 0, 3 : 1, 1 : 1, and 1 : 3, but in a total amount not exceeding 0.048 mol. Further, 0.264 mol of water was introduced and agitation was terminated [the sample containing only thiol groups was obtained using an aqueous NH_4F solution with F^-/Si = 1/100 (mol)].



After several minutes, transparent solutions turned into gels, which started to opalesce in the course of time. After 24 h, they were crushed and dried in a vacuum at 90°C for 6 h. Then they were washed with 1 dm^3 of water and again dried under the same conditions.

As the starting substance for synthesis of CMSGs was used Silika 60 silica gel manufactured by Merck, with a specific surface area of 260 $m^2 g^{-1}$ and average pore diameter of 12 nm [3].

Silica gels with a monofunctional layer

and those with various molar ratios of grafted 3-aminopropyl and 3-mercaptopropyl groups in this layer

were synthesized by the same technique: 20 g of a silica gel preliminarily dried at 400°C was placed in a reactor equipped with a stirrer and a reflux with a calcium chloride tube. A 80-cm^3 portion of toluene was added and (under agitation) a modifying agent, APTES or MPTMS, or a mixture of these in varied molar ratio and total amount of 0.05 mol, was introduced. The resulting mixture was brought to boiling under agitation and then synthesis was performed in boiling toluene in the course of 6 h. After that the silica gel was washed in a Soxhlet apparatus, first with toluene and then with acetone for 48 h. The washed product was dried in a vacuum at a residual pressure of 2×10^3 Pa and temperature of 95–100°C.

A silica gel with disulfide (–S–S–) groups was obtained by oxidation of the SH groups of a CMSG-1 sorbent with iodine [3].

The content of amino groups in the thus obtained PSXG and CMSG was determined by back acid–base titration, and that of thiol groups, by back complexometric titration of an excess amount of a standard silver nitrate solution with unithiol in 0.1 M HNO_3. As a metallochromic indicator served di(*para*-sulfophenyl)thiocarbazone [6]. In this way, the concentrations of thiol groups can be determined both on the surface of sorbents with a monofunctional coating and on heteroligand sorbents simultaneously containing SH and NH_2 groups, because Ag^+ ions do not interact with 3-aminopropyl groups in 0.1 M HNO_3.

The structural-adsorption parameters of the samples obtained were determined from isotherms of low-temperature adsorption of nitrogen. The specific surface area was calculated by BET, and the pore size distribution in PSXG, from the pore sizes, using the approach described in [7–9]. All the PSXG and CMSG used had the same granulometric composition, 0.06 – 0.16 mm.

The complexation was studied using aqueous solutions of copper sulfate, prepared from $CuSO_4 \cdot 5H_2O$ (chemically pure). The precise concentrations of the solutions were determined by means of complexometry [10]. The working solutions were prepared by diluting the standard solution with twice-distilled water. The equilibrium concentration of Cu(II) was determined by photometry [11]. The content of copper adsorbed on CMSG or PSXG was found as the difference of its amount in the initial and equilibrium solutions.

The sorption was studied in the static mode (sorbent mass 0.25 g, volume of working solutions 25 cm^3). The suspensions obtained were kept for 24 h with agitation at regular intervals of time. The pH values of the solutions were measured with Ionometr I-130.2m1 pH-meter.

Electronic diffuse-reflectance spectra (EDRS) of the samples were recorded on a Specord M40 spectrophotometer, and ESR spectra, on a 3-cm RE-1306 radiospectrometer at 293 K. The resonance frequency was measured with a Ch3-54 frequency meter with a YaZCh-87 frequency converter. Diphenyl picryl hydrazyl (DPPH, g = 2.0036) and ions of bivalent manganese in a MgO matrix (g = 2.0015) served as calibration samples. The samples were placed in the resonator in ampules 3 mm in diameter. The parameters of the anisotropic spectra were calculated from the positions of lines in the parallel orientation of the g-factor ($g_{\|}$) with an accuracy of 0.005 or evaluated from the positions of lines in the perpendicular orientation of the g-factor ($g_{\perp}$) [12].

As can be seen in Table 1, the functionalized xerogels obtained have close surface areas (214–234 $m^2 g^{-1}$) and total concentrations of functional groups (3.2–4.2 mmol g^{-1}). It is noteworthy that the xerogel containing only 3-mercaptopropyl groups

(PSXG-1) differs from the other xerogels synthesized in lower values of V_s and d_{eff}. In addition, it has, in contrast to bifunctional xerogels, only a single system of mesopores that have size at the boundary between the micro- and mesoscopic ranges. The appearance of these mesopores is, in all probability, due to presence of SH groups, which create a weakly acid medium in synthesis. Attempts to synthesize PSXG-1 with $(n\text{-Bu})_2Sn(O_2CCH_3)_2$ [13–15] as catalyst yielded a xerogel with a specific surface area of less than 1 $m^2\ g^{-1}$; in addition, the time of gelation substantially increased [5]. At the same time, use of alkalis or acids as catalysts in synthesis of PSXG-1 is undesirable because of the possible formation of salts or rapid oxidation of the thiol sulfur. These disadvantages are eliminated if the fluoride ion is used as catalyst [16]. In this case, gelation occurs in the course of several minutes, and the xerogel itself has a developed specific surface area (Table 1). The xerogels with a bifunctional surface layer were synthesized without a catalyst. In this case, the role of a catalyst was played by the amino group, which created an alkaline medium upon introduction of water.

As mentioned above, the starting silica gel used to synthesize CMSG had a specific surface area of 260 $m^2\ g^{-1}$ and average mesopore diameter of 12 nm. In addition, this mesoporous sorbent contained a very small amount of micropores with d = 0.8–1.2 nm (V_{mic} < 0.005 $cm^3\ g^{-1}$), which are inaccessible to large molecules of the modifying agents, including APTES and MPTMS [3]. After modification, the diameter of mesopores somewhat decreases. For example, the curves of pore volume distribution over the effective pore diameters calculated from data on desorption of *n*-hexane vapor with the Thomson–Kelvin equation show peaks at d = 6.0 nm for 3-mercaptopropyl silica gel (CMSG-1) and d = 8.4 nm for 3-aminopropyl silica gel (CMSG-5). The decrease in d for CMSG-1, compared with CMSG-5, is rather due, in the opinion of the authors of [3], to the different orientations of molecules of modifying agents with respect to the SiO_2 surface, which is horizontal in APSG and horizontal or inclined in MPSG. Thus, the structural-adsorption parameters of the CMSG and PSXG samples synthesized are close (Table 1), which is important in comparing their sorption properties.

The concentration of grafted functional groups in CMSG containing 3-aminopropyl and 3-mercaptopropyl groups is about 0.004 mmol m^{-2}, whereas for PSXG with the same functional groups, this concentration is approximately 0.016 mmol m^{-2}, which is an unquestionable advantage of PSXG.

Table 1. Content of functional groups and structural-adsorption parameters of the xerogels and chemically modified silica gels synthesized

Sample	c_{NH_2}	c_{SH}	Structural-adsorption parameters*		
	mmol g^{-1}		S_{sp}, $m^2\ g^{-1}$	V_s, $cm^3\ g^{-1}$	d_{eff}, nm
PSXG-1	–	3.2	216	0.152	3.5
PSXG-2	1.0	3.2	214	0.358	4.0 and 9.8
PSXG-3	2.0	2.1	217	0.302	6.1 and 22.0
PSXG-4	2.4	0.9	234	0.675	3.2 and 16.2
CMSG-1	–	0.93	–	–	–
CMSG-2	0.66	0.33	–	–	–
CMSG-3	0.44	0.33	260	–	12
CMSG-4	0.18	0.81	–	–	–
CMSG-5	0.88	–	–	–	–

* Structural-adsorption parameters for PSXG are given for samples stored for a year.

In sorption of Cu(II) on 3-mercaptopropyl silica gel, copper(II) is reduced to copper(I) and dimercaptodipropyl groups having arch structure, $[\equiv Si(CH_2)_3–S–S–(CH_2)_3Si\equiv]$, are formed. The thus produced Cu(I) ions are bound by the remaining 3-mercaptopropyl groups [17] covalently fixed on the silica gel surface, to form colorless complexes exhibiting low-temperature luminescence [18]. The colorless complexes are also formed via interaction of Cu(I) with dipropyl disulfide groups. Thus, EDRS can furnish information about the composition of the coordination sphere of only Cu(II) complexes. Figure 1 shows EDRS of PSXG-2, PSXG-3, and PSXG-4 samples with different contents of copper sorbed on their

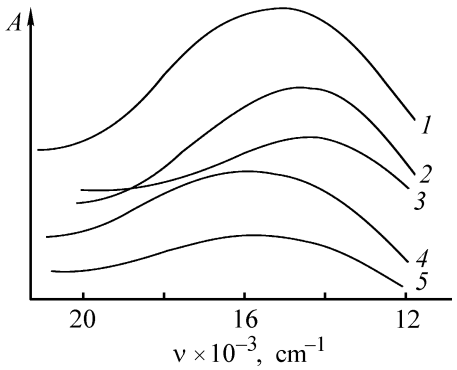


Fig. 1. Electronic reflectance spectra of samples with Cu(II) adsorbed on the PSXG surface. (*A*) Absorption and (ν) wave number. PSXG (mg g^{-1} sorbent): (*1*) PSXG-4, 29; (*2*) PSXG-2, 31; (*3*) PSXG-3, 36; (*4*) PSXG-4, 10; and (*5*) PSXG-2, 10.

surface. All of them contain a broad band at 14600–16000 cm^{-1}. This band is associated with *d–d* transitions in nitrogen- and oxygen-containing tetragonal complexes of copper(II). In the case of PSXG-2 and PSXG-4, the peak position of this band is shifted to lower frequencies as the filling of their surface by copper(II) ions increases (Fig. 1, curves *5* and *2*, *4* and *1*), However, no shift of this kind is observed for PSXG-3 (Fig. 1, curve *3*).

As is known [19], amine complexes of copper(II) with the nearest environment of the central atom of the [3NO] type exhibit electronic absorption at 16000 cm^{-1}, and complexes of composition [2N2O], absorption at 14500 cm^{-1}. Sulfur-containing complexes of copper(II) exhibit absorption at >25000 cm^{-1} [20]. Therefore, it may be assumed that complexes with coordination sites of Cu[2N2O] and Cu[3NO] types are formed, with predominance of the former, in sorption of copper(II) ions by PSXG containing, together with 3-mercaptopropyl groups, also 3-aminopropyl groups at $c_M < c_L$. As the filling of the PSXG surface by the metal increases, the fraction of complexes containing only two amino groups in the coordination sphere of copper grows. In addition, the composition of the already formed complexes may become simpler in the process: [3NO] $\rightarrow$ [2N2O]. A similar conclusion about the composition of the Cu(II) complexes has been made in a study by EDRS of copper(II) sorption on the surface of heteroligand N,S-CMSGs [1]. However, the observed shift of the band peak in the EDRS of PSXG samples can be explained in another way: complexes with a coordination site of the Cu[2N2O] type are formed already in the initial stages of sorption of copper(II) ions. As the filling of the surface by the metal increases, a tetrahedral distortion of the forming complexes starts to manifest itself, which makes lower the frequency of the *d–d* transitions [21].

Now, the ESR spectra of the Cu(II) complexes formed on the surface of PSXG samples (Fig. 2a, 2b) are considered. All these spectra shown an asymmetry of signals and anisotropy and hyperfine structure of the $g_{\|}$ signal [22]. The shapes of the signals and the calculated parameters of the spectra, presented in Table 2, are characteristic of tetragonal complexes of copper(II). It can be seen from Table 2 that for Cu(II) complexes on the surface of PSXG-2–PSXG-4, the parallel component of the *g*-factor fall within the range 2.242–2.272, and the hyperfine interaction constant takes values of (169–178) $\times 10^{-4}$ cm^{-1}. The shape and parameters of the spectra are characteristic of the coordination environment of Cu(II) of composition [2N2O] [23], which remains unchanged as the content

of 3-aminopropyl groups on the PSXG surface is varied. Consequently, even if Cu[3NO] complexes are formed in the initial stage of copper sorption, their fraction must be insignificant. A similar conclusion concerning the composition of copper(II) complexes on the surface of CMSG can be made on the basis of the parameters of their ESR spectra (Table 1). In this case, however, the concentration of the complexes of composition Cu[3NO] must be even lower because of the difference between the content of functional groups on the surface of CMSG and that on PSXG.

At approximately equal amounts of aminopropyl and mercaptopropyl groups on the surface of silicas, the values of $g_\perp$ for the ESR spectra of copper complexes on the surface of CMSG are somewhat lower than those for copper complexes on PSXG (Table 2). The values of $g_\parallel$ are virtually the same for both types of sorbents. The range of variation of the hyperfine interaction constant for copper complexes on the surface of PSXG is narrower [$(169–178) \times 10^{-4}$ cm^{-1}] than that for complexes on CMSG [$(150–182) \times 10^{-4}$ cm^{-1}].

However, the parameters of the ESR spectra of the copper complexes on CMSG and PSXG do not fall outside the range of values typical of the [2N2O] environment of copper.

It is necessary to consider separately PSXG-1, which contains only 3C-SiC groups. Despite the possibility of Cu(II) reduction to Cu(I) in interaction with SH groups, high-intensity ESR spectra of Cu(II) complexes are observed at c_M, c_L even for PSXG-1 samples (Fig. 2b). The g-factors and values of $A_\parallel$, calculated from these spectra, are characteristic of octahedral oxygen complexes Cu[4O2O], adducts of copper bichelates with a strong axial coordination in the positions 5 and 6 [24], and(or) octahedral complexes of the type of those existing in $CuSO_4 \cdot 5H_2O$ [25, 26]. Complexes of this kind can be formed via coordination of copper(II) with the oxygen atoms of the polysiloxane matrix and water. It is not completely improbable, either, that there is a contribution from physically sorbed copper sulfate. Similar results were obtained in a study of ESR spectra of copper sorbed on the surface of a silica gel modified with 3-mercaptopropyl groups (Table 2).

Thus, a similarity can be noted in the structure of copper(II) complexes formed on the surface of heteroligand (amino thiol) sorbents, irrespective of the method used in their synthesis: sol-gel method in the case of PSXG and chemical modification of the surface for CMSG.

Table 2. Parameters of the ESR spectra of the complexes of Cu(II) ions, formed on the surface of heteroligand sorbents

Sample	Amount of Cu(II) sorbed on the surface, mmol g^{-1} sorbent	$g_\parallel$	$g_\perp$	$A_\parallel$, cm^{-1}
PSXG-1	0.157–0.756	2.362	2.080	139
PSXG-2	0.157–0.661	2.257	2.050	170
PSXG-3	0.157–0.976	2.265	2.058	175
PSXG-4	0.157–0.835	2.255	2.050	178
CMSG-1	0.031–0.183	2.345	2.082	140
CMSG-2	0.060–0.190	2.266	2.048	173
CMSG-3	0.060–0.170	2.265	2.048	177
CMSG-4	0.030–0.090	2.262	2.048	177
CMSG-5	0.062–0.190	2.263	2.048	177

The effect of pH on the sorption of copper(II) by the sorbents under consideration at $c_L^0 \gg c_{Cu}^0$ is illustrated by Fig. 3a. It can be seen (curve *1*) that quantitative sorption of Cu(II) on PSXG-1 is observed

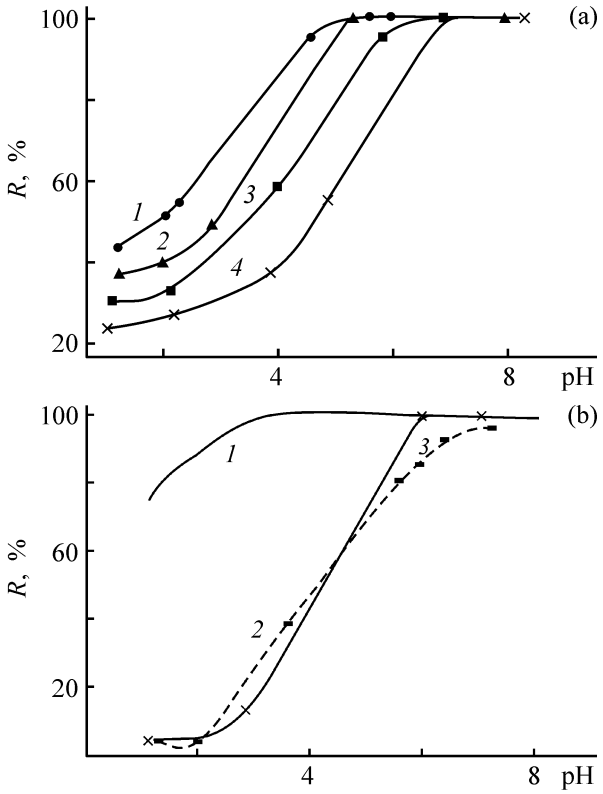

Fig. 3. Recovery of Cu(II), R, vs. the pH of the medium on (a) PSXG and (b) CMSG. (a) V = 25 cm^3, m_{PSXG} = 0.1 g, $c_{Cu(II)}$ = 238 μg/25 cm^3, τ = 24 h. (*1*) PSXG-1, (*2*) PSXG-2, (*3*) PSXG-3, and (*4*) PSXG-4. (b) V = 25 cm^3, m_{CMSG} = 0.2 g, $c_{Cu(II)}$ = 118 μg/25 cm^3, τ = 30 min. (*1*) CMSG-1, (*2*) silica gel with S–S groups, and (*3*) CMSG-5.

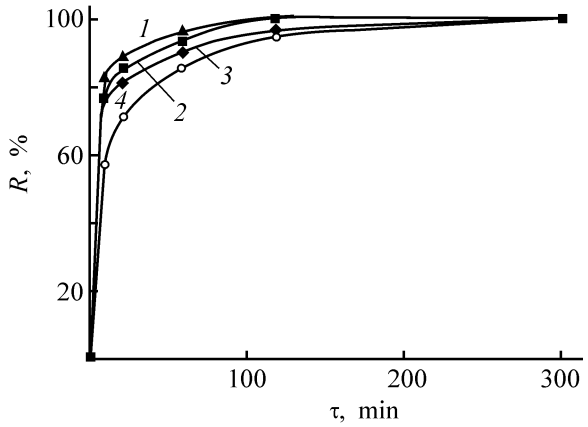

Fig. 4. Kinetic curves of Cu(II) sorption on PSXG. V = 25 cm^3, m_{PSXG} = 0.1 g, $c_{Cu(II)}$ = 238 μg, pH 6. (R) Recovery and (τ) time. (*1*) PSXG-1, (*2*) PSXG-2, (*3*) PSXG-3, and (*4*) PSXG-4.

at pH 5.6. In this case, Cu(II) is reduced to Cu(I) and sorbed either on the remaining (unoxidized) HS groups, or on newly formed S–S groups. As the concentration of NH_2 groups in heteroligand PSXG increases, the pH of 50% sorption of the metal is shifted to a more alkaline region (Fig. 3a, curves *2–4*). This shift indicates that the complexation of copper ions on the surface of the bifunctional xerogels under consideration occurs, as in the case of heteroligand CMSG [3], at several sorption centers to give complexes with different stabilities. The stability of copper complexes with these ligands decreases in the order SH > S–S ≈ NH_2. This is in a good agreement with the type of the dependence $R = f(\text{pH})$ observed for CMSG with the corresponding monofunctional layers (Fig. 3b). If the coordination of copper occurred only at thiol groups (because $c_L^0 \gg c_{Cu}^0$), the above-mentioned shift of the $pH_{50\%}$ would not be observed. The shift of the $pH_{50\%}$ of sorption into the more alkaline region, which occurs as the molar fraction of 3-aminopropyl groups in PSXG becomes larger, indicates that copper complexes are formed on their surface not only with a –SH environment, but also with that of the –S–S– and NH_2 types.

An important criterion for assessing the performance of sorbents is the rate at which the sorption equilibrium is attained. As can be seen in Fig. 4, quantitative recovery of copper(II) is achieved in 5 h, irrespective of the composition of the surface layer of PSXG. In the case of silica gels chemically modified with these groups, the sorption equilibrium is attained in 10 min [1]. Thus, PSXG are strongly inferior to CMSG in their kinetic characteristics. This is, in all probability, due both to difference in the geometric structure of pores in PSXG and CMSG and to a higher concentration of functional groups on the PSXG surface. In the last case, it is assumed that, after first portions of the metal are adsorbed on the PSXG surface, the already formed complexes give rise to additional hindrance to sorption of subsequent portions of the metal.

CONCLUSIONS

(1) Copper(II) is sorbed on the surface of heteroligand chemically modified silica gels and polysiloxane xerogels containing 3-aminopropyl and 3-mercaptopropyl groups via formation of complexes of the same composition, with copper ions surrounded by atoms of sulfur or nitrogen, but there are no copper complexes with heteroligand [S,N] environment.

(2) The specificity of complexation is, in all probability, due to different spatial arrangements of functional groups with respect to the surface of chemically modified silica gels and polysiloxane xerogels: horizontal in the case of 3-aminopropyl groups and vertical (or inclined) for 3-mercaptopropyl groups.

(3) Polysiloxane xerogels severalfold exceed chemically modified silica gels in sorption capacity, but are markedly inferior to the latter in the rate at which the sorption equilibrium is attained.

SORPTION AND ION-EXCHANGE PROCESSES

A Study of the Influence of Modifying Iron and Aluminum Chloride Additives on the Water-Absorbing Capacity and Thermal Stability of Peat

L. B. Naumova, L. A. Egorova, and A. A. Slivinskaya

Received December 16, 2005

Abstract—The influence exerted by modifying additives of inorganic nature on the hydrophilicity of peats from the Orlovskoe deposit in Tomsk oblast and on their thermal stability was studied. The acid–base, equilibrium, and kinetic properties of the starting peat samples and those modified with solutions of iron(III) and aluminum chlorides were examined. Their physicochemical parameters were determined: total exchange capacity, acidity by acid and basic groups, relative humidity, distribution coefficients, effective diffusion coefficients, and activation energy. The effect of modifying cations on the thermal decomposition of peat was analyzed.

DOI: 10.1134/S1070427206020133

The wide diversity of the physicochemical properties of peat, one of the most valuable kinds of natural raw materials, has stimulated a wide interest in the problem of its effective use [1–3]. Application of various procedures for processing and modification of peat makes it possible to obtain new polyfunctional materials on its basis. For example, on imparting to peat necessary chemical and physicochemical properties, it is successfully used as a fertilizer in agriculture, in manufacture of building materials, etc. [1, 2]. The high hydrophilicity of some kinds of peat enables their use as sorbents in purification of wastewater to remove various ions, whereas other kinds of peat can serve, owing to their low hydrophilicity, to absorb nonpolar hydrocarbons, such as phenols and petroleum products [4–7]. The last feature is a matter of current interest, because it can be used to solve a wide variety of practical ecological problems and, in particular, to cleanup water and soil after oil spills. The hydrophilicity of peat can be lowered by various treatments [8]. A promising way to obtain peat-containing formulations with prescribed parameters is to introduce modifying additives [9].

The present communication reports the results obtained in a study of the influence exerted by the nature of chemical additives on the water-absorption capacity of peat and on the structural organization of a modified sample in thermal treatment. As objects of study served peats of upland, intermediate, and lowland types from the Orlovskoe deposit. Solutions of aluminum(III) and iron(III) chlorides of various concentrations were used as modifying agents.

It was presumed that introduction of polyvalent metal ions into a water-saturated peat should shift the existing equilibrium and, accordingly, will give rise to ion-exchange processes resulting from the interaction with the functional groups of the organic and inorganic components of peat. Replacement of singly charged ions with those of trivalent nature will alter the structure of the disperse system of peat via cross-linking of associates by the cations introduced and, as a result, will change the water-absorption capacity of peat.

The fact that iron(III) and aluminum ions were chosen as modifying agents is no accident. This is due to the difference in their electronic structure (Al is a *p*-element, and Fe, *d*-element), ionic radius Al^{3+} 0.057 nm, Fe^{3+} 0.067 nm), and capacity for complexation with carboxy groups ($\log K^{Al}_{1,2,3} = 16.3$, $\log K^{Fe}_{1,2,3} = 20.2$).

Thus, it is possible to vary the nature of moisture transfer and thermal destruction processes and the surface activity of the materials obtained by taking into

account the chemical activity of the components introduced and by choosing the modification conditions.

In the study, the acid–base properties of peat were analyzed by means of potentiometric titration. The titration curves were used to calculate the total exchange capacities (TEC) for acid and basic groups and to evaluate the effective ionization constants. The cationic forms were prepared by treating the starting peat samples with aqueous solutions of metal chlorides under static conditions, with vigorous shaking during seven days at a constant ionic strength. To prevent hydrolysis, the peat samples were treated with salts of iron(III) and aluminum at pH 1.8. The concentration range of the metal chloride solutions used in the study was chosen to be 0.100 – 0.025 M (equivalence factor $f = 1/3$). The solution volume was 200 ml, and the weighed portion of peat, 0.5000 g.

The content of metal ions in the equilibrium solution was monitored by complexometry. The difference of the initial and equilibrium concentrations was used to determine the content of a metal in the peat phase. In studying the equilibrium, the distribution coefficients D were calculated. The kinetics of absorption of Fe^{3+} and Al^{3+} ions was studied by the method of limited volume at different temperatures (298, 323, 348 K), concentrations of starting solutions, and peat particle dispersities (r 0.025 and 0.050 cm). The study was carried out in a thermostated vessel, with the solutions agitated with a set of rabbles. After certain intervals of time, t, the solution was separated from the sorbent and analyzed for the content of iron(III) and aluminum ions. Kinetic dependences of the degree of completeness of the process, F, on time t were plotted. The results obtained were processed using the approximate Boyd equation for spherical particles [10].

Because an important role in the manifestation of associate interactions in peat (formation of supramolecular structures [8]) belongs to water, the swelling kinetics of peat samples in their modification with ion(III) and aluminum ions was studied. For this purpose, the relative humidity W (%) of modified peat samples was determined after sorption of ions in each particular case (at a certain time t) by centrifugation [11]. Further, peat samples were dried in drying oven at a temperature of 105°C and the $W(\%) = f(t)$ dependences were plotted.

To evaluate the thermal stability, a thermal analysis of the starting and modified samples was carried out on a Q-1500 derivatograph at a heating rate of 9.5 deg min^{-1} in platinum crucibles.

Table 1. Degrees R of decomposition, TEC, and pK of ionization for the starting peats

Peat	R, %	TEC_{H^+}, mmol g^{-1}	pK_a	TEC_{OH^-}, mmol g^{-1}	pK_b
Upland	5–10	3.67	8.75	2.17	11.80
Intermediate	15–20	3.96	9.60	1.93	10.70
Lowland	25–30	6.33	9.20	1.17	11.05

A study of the acid–base properties of peat samples demonstrated that these samples are high-capacity ampholytes with weakly acid and weakly basic groups (Table 1). The resulting values of TEC for acid and basic groups approach the TEC of synthetic ion exchangers and even somewhat exceed these values.

The TEC for acid groups grows in going from upland to lowland peat, because the latter is more decomposed and, as a result, the amount of humic substances containing COO^- groups in the lowland peat is higher.

The TEC values obtained were used to evaluate the amount of a modifying agent, which should not exceed the total capacity for acid and basic groups. It was as follows: 5.84 mmol g^{-1} for upland peat, 5.89 for intermediate peat, and 7.50 for lowland peat.

The equilibrium parameters of modification of peat samples with solutions of salts of iron(III) and aluminum chlorides are listed in Table 2.

The results obtained indicate (Table 2) that the moisture capacity of peat samples strongly decreases upon sorption of metal ions, compared with the starting samples. The minimum absorption of water is observed at c = 0.049 M for all kinds of peat. Together with a decrease in moisture capacity, these samples show at c = 0.049 M an increase in selectivity (the distribution coefficients D increase). In addition, peat samples change their structure upon centrifugation at a given concentration in solution: on drying they become denser and harder as compared with the starting samples. The experimental data obtained can probably be understood as follows. Absorption of iron(III) ions (c = 0.049 M), probably, creates more favorable conditions for their coordination with the functional groups of peat (mainly with carboxy groups), which causes an increase in the degree of cross-linking of polymer formations and a rise in the structuring of the peat system. The last factor leads to an increase in the viscosity and strength pa-

rameters of peat and, as a result, to a decrease in its swelling ability, which is not inconsistent with published data. According to [8], structures of first kind are formed in such cases in the peat phase. At other concentrations, conditions are created for formation of structures of second kind [8]. In the opinion of the authors of the present study, the decrease in the swelling ability of peat samples modified with iron(III) ions is also promoted by the fact that polynuclear dimers of iron are formed in solution at low pH values. Being quadruply charged, these dimers bind, with a high probability, polar active groups on the surface of peat and thereby hinder further penetration of moisture into peat (Table 2).

Aluminum ions, which have a larger hydration shell as compared with iron ions, presumably penetrate in pores in peat, throwing off their hydration shell, and only after that coordinate COO^- groups around them, which leads to a decrease in the swelling ability of peat samples (Table 2) and a possible formation of structures of first kind at $c(AlCl_3)$ = 0.049 M. As stated in [8], further introduction of metal cations leads to such a pronounced development of interassociate bonds that peat particles are transformed to give new associates, which are more compact than the original ones. Such a disordering of the system leads to a decrease in the viscosity and strength of the material and to an increase in its moisture capacity. The so-called new structures, structures of second kind, are formed [8].

The occurrence of structuring in peat, with water molecules involved, is beyond doubt, because it has been confirmed by electron microscopy, electron paramagnetic resonance, and nuclear magnetic resonance [13, 14].

Thus, modification of peat with solutions of iron(III) and aluminum chlorides causes internal transformations in the peat phase and affects the water-absorption capacity of peat. In this case, the supramolecular phases are formed in the same way despite the difference in chemical nature between the modifying ions studied. It should be noted that all kinds of peat studied here exhibit a sufficiently high selectivity with respect to iron(III) and aluminum ions (Table 2).

The kinetics of absorption of iron and aluminum ions was studied using the method of limited volume [10, 11]. An advantage of this method consists in the simplicity of the kinetic experiment, which is performed by sampling at certain intervals of time. This method allows rapid termination of the contact between the phases at any instant of time and reveals the limiting stage of the exchange.

The kinetic problems were solved by plotting the dependence of the degree of completeness of the process, $F = Q_t/Q_\infty$, as a function of the sorption time (Q_t, Q_∞ are the amounts of ions absorbed by peat during a time t elapsed from the beginning of the process and in the equilibrium state, respectively).

As demonstrated by the results of kinetic studies, the exchange rate depends on the concentration of the starting solutions, temperature and peat particle size. This points to a mixed-diffusion mechanism of sorption. It was found, on plotting the kinetic curves in the $-\ln(1 - F) = f(t)$ coordinates, that, in early stages of absorption, the process is limited by outer-sphere diffusion for both iron(III) and aluminum ions. The rate constants R, effective outer-sphere diffusion coefficients D_{eff}, and activation energies E_a of the process were calculated for this region of the ki-

Table 3. Effective diffusion coefficients D_{eff} of Fe^{3+} and Al^{3+} ions activation energies E_a at $c(MCl_3)$ = 0.049 M

	298	323	348	
		Fe^{3+} ions		
Upland	$(7.2 \pm 0.2) \times 10^{-6}$	$(1.8 \pm 0.1) \times 10^{-5}$	$(2.9 \pm 0.1) \times 10^{-5}$	5.4 ± 0.2
Intermediate	$(6.7 \pm 0.2) \times 10^{-6}$	$(1.4 \pm 0.1) \times 10^{-5}$	$(2.5 \pm 0.1) \times 10^{-5}$	7.9 ± 0.2
Lowland	$(6.3 \pm 0.2) \times 10^{-6}$	$(1.1 \pm 0.1) \times 10^{-5}$	$(2.0 \pm 0.1) \times 10^{-5}$	8.1 ± 0.3
		Al^{3+} ions		
Upland	$(2.0 \pm 0.1) \times 10^{-6}$	$(3.2 \pm 0.1) \times 10^{-6}$	$(1.9 \pm 0.1) \times 10^{-5}$	7.8 ± 0.3
Intermediate	$(1.9 \pm 0.1) \times 10^{-6}$	$(3.0 \pm 0.1) \times 10^{-6}$	$(1.0 \pm 0.1) \times 10^{-5}$	8.6 ± 0.3
Lowland	$(0.8 \pm 0.1) \times 10^{-6}$	$(2.7 \pm 0.2) \times 10^{-6}$	$(0.9 \pm 0.1) \times 10^{-5}$	16.5 ± 0.6

netic dependence (Table 3). As already mentioned, a strong decrease in the swelling ability of peat samples was observed after contact (for 7 days) with salt solutions with a concentration of 0.049 M. Therefore, it was appropriate to calculate the activation energy under the same conditions. E_a was found from the Arrhenius equation. The experimental results are listed in Table 3.

As can be seen from the data in Table 3, the diffusion coefficients of iron(III) and aluminum ions are close to the diffusion coefficients of these ions in solution, and the small values of E_a point to the predominance of the outer-sphere diffusion in the mixed diffusion process. For iron(III) and aluminum ions, these values are close, which confirms the previously made suggestion about the similarity of ion-exchange processes and coordination interactions with the carboxy groups of peat.

An analysis of the kinetic curves of swelling in modification of peats with iron(III) and aluminum ions demonstrated their complex nature, which indicated that internal transformations occur in the peat phase at its various fillings with metal ions. However, despite the complexity of the structuring process, the $W(\%) = f(t)$ curves show a steep decline in swelling ability, irrespective of the concentration of the solutions under study, upon contact for 5 min. This suggests that, already during the first minutes of sorption, supramolecular structures are formed in peat and this process involves the ions being absorbed and water molecules. As a result, the samples acquire an enhanced hardness. A further increase in the time of sorption does not lead to any significant changes in swelling ability and strength parameters.

Thus, the results of the kinetic study suggest that, to obtain hydrophobic peat samples by their modification with solutions of iron(III) and aluminum chlorides, it suffices to perform the process of ion sorption for no more than 5 min.

To study the effect of additives on thermal destruction processes, derivatograms of the starting and modified samples of up- and lowland peat were measured. The results of the thermographic measurements confirmed the suggestion that transformation processes associated with coordination of metal ions with active groups occur in the peat systems. The formation of strong bonds between metal cations and active centers of peats was manifested in that the shape of TG and DTA curves changed upon modification of the starting samples.

Two processes accompanied by loss of mass are revealed for all the samples in the temperature range 20–650°C: the first, low-temperature process involves thermal desorption and removal of water; the second process corresponds to destruction and thermochemical decomposition of the organic component of peat to give gaseous products. The changes in the mass of peat samples are listed in Table 4. Thermogravi-

Table 4. Changes in the mass of initial and modified peat

Peat	Sample	Process 1		Process 2	
		ΔT, °C	Δm, %	ΔT, °C	Δm, %
Upland	Initial	96–232	59.7	303–494	38.6
	Modified:				
	Al^{3+}	89–177	27.7	212–538	44.1
	Fe^{3+}	76–105	14.5	163–527	54.7
Lowland	Initial	84–296	56.3	367–580	37.5
	Modified:				
	Al^{3+}	73–328	63.2	410–580	23.7
	Fe^{3+}	90–343	52.1	428–580	34.8

metric calculations demonstrated that 100 g of lowland peat contains 0.07 mol of aluminum and 0.05 mol of iron.

The observed asymmetry and broadening of DTA peaks indicate that there occur complex processes of destruction of multiphase peat systems.

A comparative analysis of the TG curves of modified and starting peats demonstrated that mineral additives of iron(III) and aluminum chlorides change the temperature range and nature of thermal destruction by modifying the structure of peat. The effect of modifying additives is manifested to a greater extent in the low-temperature region, where thermal desorption of weakly bound water and disintegration of crystal hydrates are observed. The data obtained are consistent with the results of kinetic studies of the swelling ability.

Modification of upland peat with iron(III) and aluminum(III) ions leads to changes in the destruction processes. Apparently, sorbed iron(III) ions form with the active groups of upland peat bonds whose strength approaches that of chemical bonds, which is manifested in clearly pronounced peaks in the DTA and DTG curves at 219°C. The high-temperature disintegration of the sample is identical to the destruction of lowland peat.

Thus, the use of derivatographic data in studies of the equilibrium state and kinetics of absorption of iron(III) and aluminum ions confirmed the suggestion that solid formulations are formed during the first minutes of ion absorption. This makes it possible to rather rapidly obtain hydrophobic peat samples and then use these samples for sorption of nonpolar hydrocarbons. A promising way to obtain a sample of this kind is to use lowland peat modified with solutions of aluminum and iron(III) chlorides.

CONCLUSIONS

(1) The distribution coefficients of Fe^{3+} and Al^{3+} cations in the system constituted by peat and a metal chloride solution, effective diffusion coefficients, activation energy, and relative humidity were used to establish that the hydrophobicity of modified peat samples depends on the concentration of the chloride solutions.

(2) The results of thermographic studies of peat samples modified with solutions of iron(III) and aluminum chlorides suggest that supramolecular structures are formed, constituted not only by various functional groups of peat and metal cations, but also by water molecules. The weakening of the hydrophilic properties of modified peats and the enhancement of their strength can be attributed to the appearance of structures of this kind.

(3) It was shown that the structuring and moisture transfer in peat can be controlled by introduction of modifying additives.

Abstract—Thermodynamics and mechanism of processes that occur in solid-phase reduction of oxygen compounds of lead are considered.

DOI: 10.1134/S1070427206020145

At present, there is no alternative to use of lead batteries in various vehicles, whose number steadily grows. Utilization of worked-out batteries becomes increasingly economically and ecologically important everywhere. The general situation with collection and processing of lead batteries in Russia and abroad has been the subject of several studies [1–6]. Modern schemes of utilization of battery scrap involve, in most cases, its preliminary cropping (after discharging the electrolyte), with separation into the metallic, oxide-sulfate, and organic fractions. Into the oxide-sulfate fraction passes the active paste of both negative and positive plates of a battery. According to the available results of chemical and X-ray diffraction analyses, the main components of this fraction are PbO_2 (plattnerite, tetragonal modification) and $PbSO_4$ (anglesite), which are present in comparable amounts (Fig. 1) [7, 8]. Also possible is presence of exceedingly small amounts of lead(II) oxide and metallic lead.

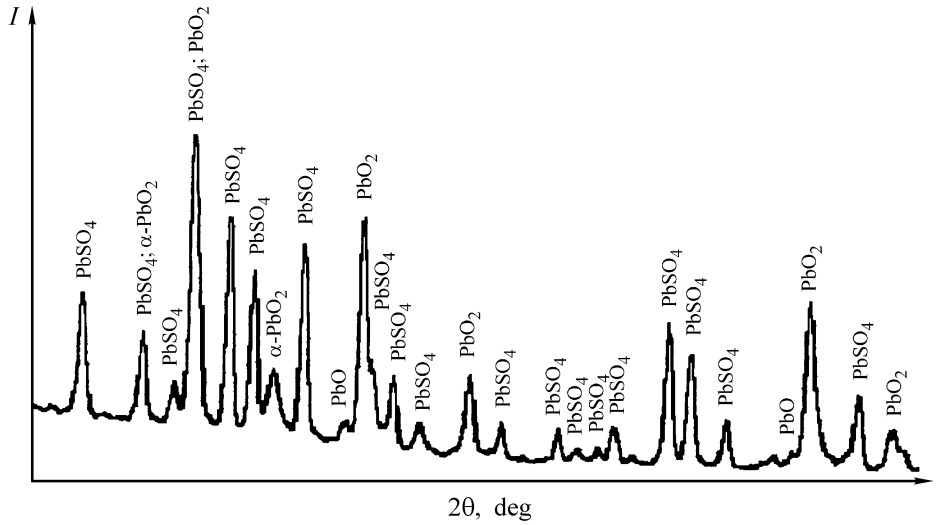

Fig. 1. X-ray diffraction pattern of the starting oxide-sulfate fraction (active paste from the positive and negative plates of lead batteries). (I) Intensity and (2θ) Bragg angle; the same for Figs. 2, 3, and 5.

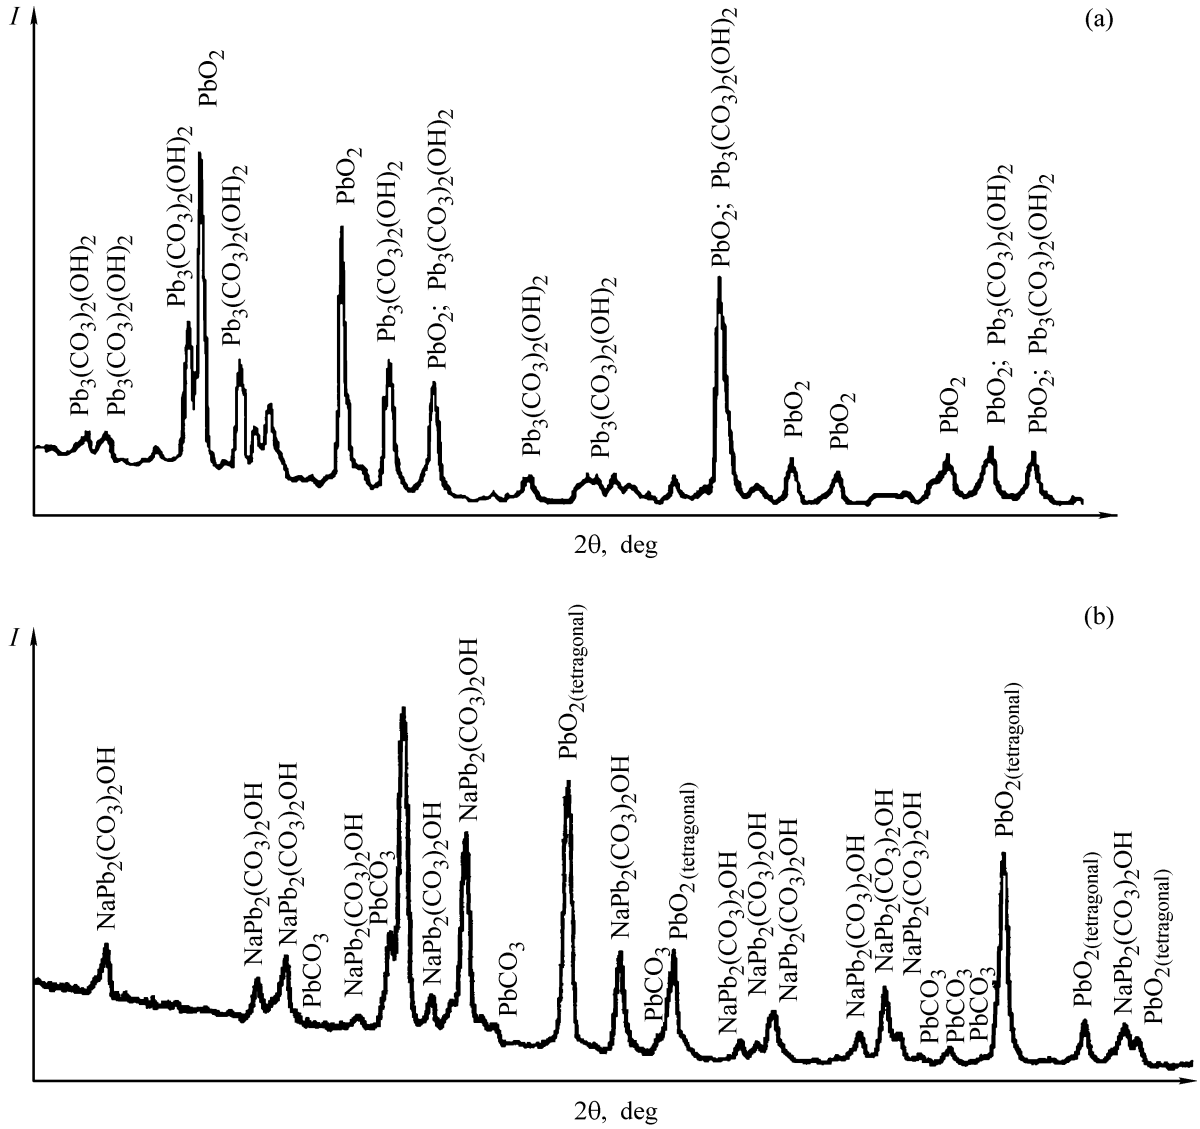

Fig. 2. X-ray diffraction patterns of the oxide-carbonate cake formed in desulfation with sodium carbonate. Formation of (a) hydrocerussite $Pb_3(CO_3)_2(OH)_2$ and (b) $NaPb_2(CO_3)_2OH$.

The presence of lead sulfate substantially complicates the reduction process and leads to appearance of SO_2 in the gas phase and to formation of mattes and slags, whose rational utilization is difficult. To convert $PbSO_4$ into other compounds, it is appropriate to perform a hydrometallurgical procedure (desulfation), which consists in treatment of a crushed oxide-sulfate paste with aqueous solutions of sodium or potassium carbonates o give an oxide-carbonate cake [9, 10]. Aqueous solutions of sodium carbonate are mostly used for this purpose. In desulfation, an excess amount of soda is taken, up to 20% relative to that calculated in accordance of the stoichiometry of the reaction

$$PbSO_4 + Na_2CO_3 = PbCO_3 + Na_2SO_4.$$

Solid to liquid phase ratio s : l = 1 : 4, process temperature 50°C, and duration 1 h under continuous agitation.

Depending on particular process conditions, either hydrocerussite $Pb_3(CO_3)_2(OH)_2$ (Fig. 2a) or the so-called double salt $NaPb_2(CO_3)_2OH$ (Fig. 2b) is formed in desulfation with soda. Both these compounds have rather low solubility products (SP). According to the available rough estimates [9], SP at 25°C is 3.5×10^{-46} for hydrocerussite and 1×10^{-31} for the double salt. It should be noted for comparison that the SP at 25°C for $PbSO_4$ and $PbCO_3$ are 1.6×10^{-8} and 7.4×10^{-14}, respectively. The boundaries of the stability regions of $PbCO_3$, $Pb_3(CO_3)_2(OH)_2$,

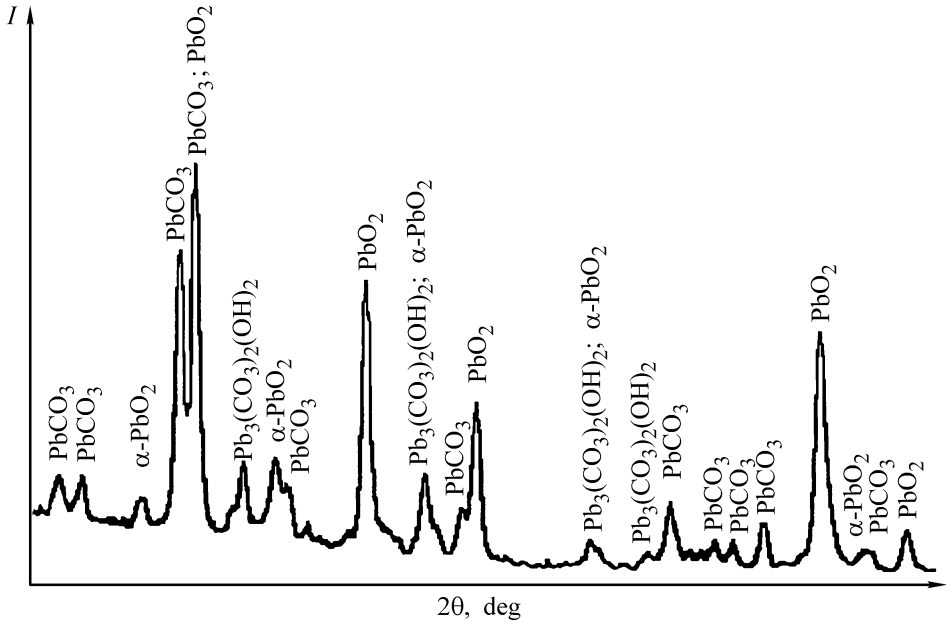

Fig. 3. X-ray diffraction pattern of the oxide-carbonate cake formed in desulfation with potassium carbonate.

$NaPb_2(CO_3)_2OH$ are determined at a given temperature by concentrations of the ions Na^+, $1/2\,CO_3^{2-}$, HCO_3^-, $1/2\,SO_4^{2-}$. The corresponding calculations can be found in [9]. The formation of the double salt from basic lead carbonate (hydrocerussite) can be represented by the reaction

$$2\,[2\,PbCO_3 \cdot Pb(OH)_2] + CO_3^{2-} + HCO_3^- + 3\,Na^+ = 3\,[NaPb_2(CO_3)_2OH] + H_2O.$$

The formation of the same salt from lead carbonate (cerussite) is described by the reaction

$$2PbCO_3 + Na^+ + CO_3^{2-} + H_2O = NaPb_2(CO_3)_2OH + HCO_3^-.$$

Both these reactions can be named "secondary" with respect to the reaction in which hydrocerussite is formed; their occurrence requires that the corresponding compounds should be accumulated. It should be noted that, at a sufficient amount in a sample, the compounds $Pb_3(CO_3)_2(OH)_2$ and $NaPb_2(CO_3)_2OH$ are sufficiently reliably identified by X-ray diffraction analysis.

If potassium carbonate is used for desulfation, no compound similar to the double salt is formed. As can be seen from the X-ray diffraction pattern in Fig. 3, the desulfation products include, together with PbO_2, cerussite and hydrocerussite [7].

Thus, the oxide-carbonate cake formed in desulfation can include, depending on the process conditions, plattnerite PbO_2, cerussite $PbCO_3$, hydrocerussite $Pb_3(CO_3)_2(OH)_2$, and the double salt $NaPb_2(CO_3)_2OH$. Also possible is presence of minor amounts of PbO and $PbSO_4$.

On being heated, the cake decomposes. As is known, lead forms with oxygen a number of oxides: PbO_2, Pb_3O_4, PbO, Pb_2O_3, $Pb_{12}O_{17}$, and $Pb_{12}O_{19}$ [11]. The first three of these exist in two crystalline modifications. It is noted in the monograph by Mostovich and Anisimov [12] that decomposition of PbO_2 to give Pb_3O_4 begins at 280°C and is complete at 400°C. The compound Pb_3O_4 (red lead) also decomposes on further heating, with PbO formed and oxygen evolved. It is emphasized in [12] that all lead oxides that are richer in oxygen than PbO (yellow lead) completely decompose into PbO and O_2 at temperatures exceeding 600°C and the only stable oxide at higher temperatures is PbO.

According to the thermodynamic dependences presented in the reference book by Kulikov [13], the temperature of transition from PbO_2 to Pb_3O_4 is 242°C, and the decomposition temperature of Pb_3O_4, 527°C. According to [14], PbO_2 decomposes in several stages, with the temperatures of formation and decomposition of intermediates affected to a certain extent by the synthesis conditions and structural modification of lead dioxide itself. $Pb_{12}O_{19}$, $Pb_{12}O_{17}$, and Pb_3O_4 are identified as intermediate phases. The following sequence of processes can be adopted in view of the aforesaid: $PbO_2 \rightarrow Pb_{12}O_{19} \rightarrow Pb_{12}O_{17} \rightarrow Pb_3O_4 \rightarrow PbO$.

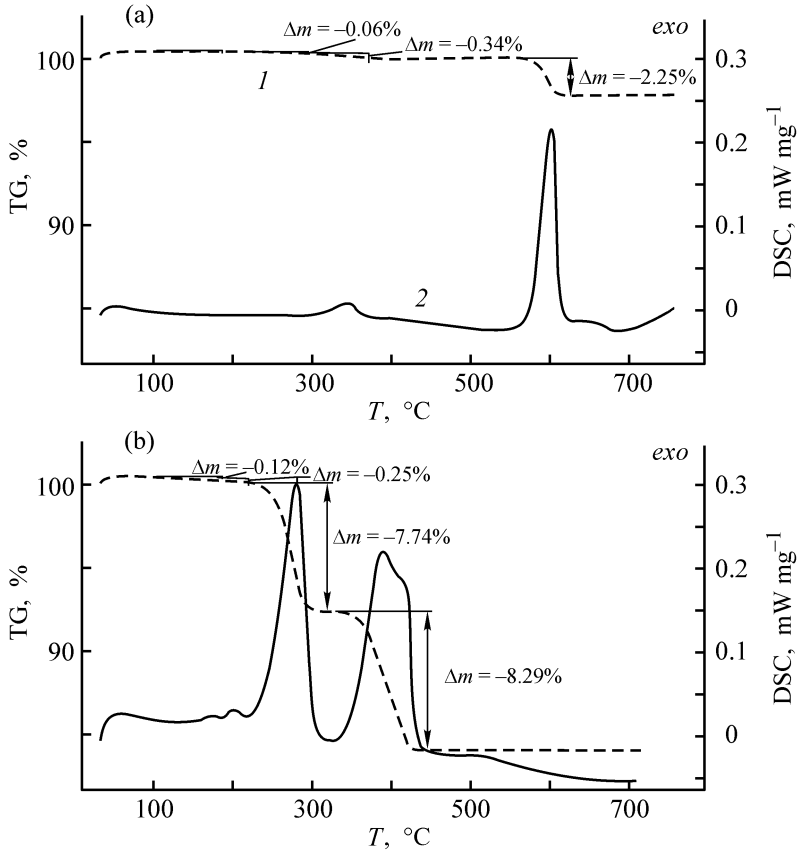

Fig. 4. Curves of (*1*) mass change and (*2*) heat effects, obtained in a comprehensive thermal analysis of (a) Pb_3O_4 and (b) $PbCO_3$.

A comprehensive thermal analysis of the decomposition of Pb_3O_4 demonstrated that its conversion into PbO also occurs in stages. Samples of mass 50 mg, weighed with an accuracy of 0.05 mg, were placed in a corundum crucible of mass 192.5 mg with a corundum cover (cover mass 57.5 mg), heated at a constant rate of 10 deg min^{-1} in the temperature range 20–800°C, and then cooled at the same rate. The experiments were performed on a NETZSCH STA 449 installation for synchronous thermal analysis (Germany).

The analysis included simultaneous determination of the mass of a sample (TG curve) and heat effects accompanying its thermal transformations (DSC curve).

Three steps of mass loss (%) can be distinguished in the TG curve for Pb_3O_4 (Fig. 4a): 0.06 at 237–290°C, 0.34 at 290–368°C, and 2.25 at 553–638°C. The total mass loss was 2.65%, which somewhat exceeds its theoretical value for the process $Pb_3O_4 \rightarrow 3PbO + 1/2O_2$ (2.33%). The DSC curve shows two endothermic effects corresponding to the second and third steps of mass loss. The first step (0.06%) is so small that it virtually cannot be seen in the DSC curve. The endothermic effect peaked at 608°C can be regarded as a characteristic of the transformation of Pb_3O_4 into PbO. At temperatures above 638°C, no changes in mass or in heat effects were observed, which suggests that conversion of Pb_3O_4 to PbO comes to completion at this temperature.

The melting point of PbO is 883°C, and the boiling point, 1470°C. The vapor phase in equilibrium with lead(II) oxide was studied in detail by Kazenas *et al.* [15, 16]. According to their data, the vapor phase is composed at 737–880°C of polymer molecules Pb_nO_n, with n in the range from unity to six. The main component of the sublimation and dissociation products constituting the vapor phase over solid PbO is Pb_4O_4 (61.9% at 747°C). The total vapor pressure over PbO is 5.4×10^{-6} atm at 740°C. The reference book by Gerasimov *et al.* [17] gives a somewhat higher value for the total vapor pressure over solid PbO: 2.35×10^{-5} atm at 750°C.

The available published evidence concerning the decomposition of $PbCO_3$ on heating at a varied content of CO_2 in the gas phase was analyzed in the review [9]. It was established in [18] that cerussite decomposes to PbO at low CO_2 pressures (<1 atm) with only a single intermediate formed:

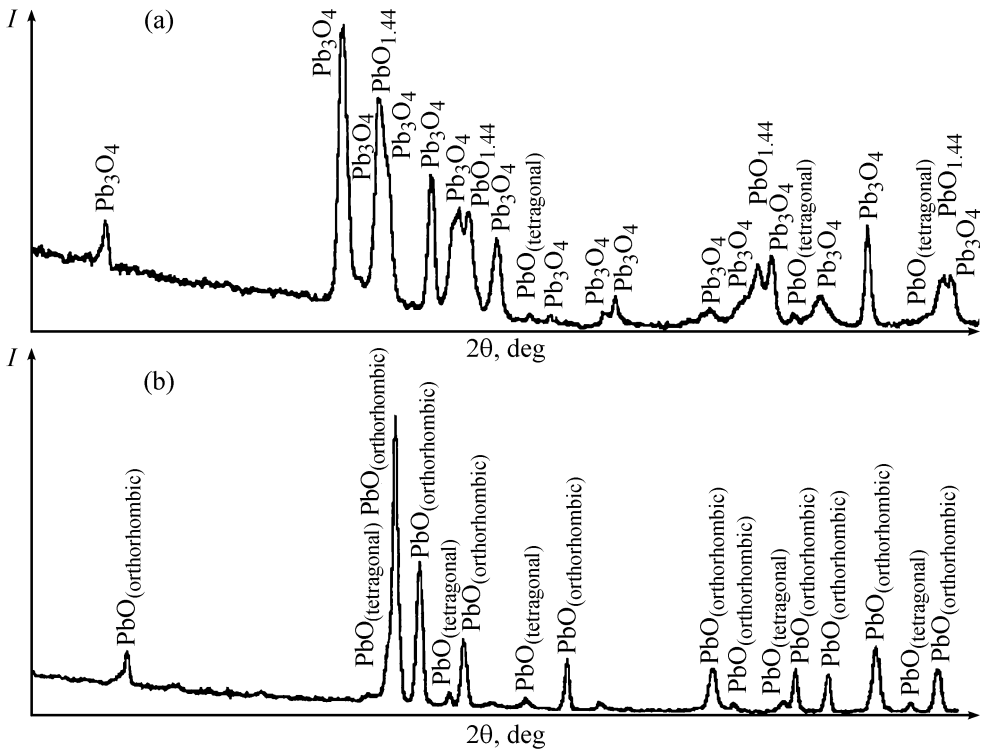

Fig. 5. X-ray diffraction patterns obtained after annealing of the oxide-carbonate cake at (a) 400 and (b) 600°C.

$$PbCO_3 \xrightarrow{200^\circ C} PbCO_3 \cdot 2PbO \xrightarrow{310^\circ C} PbO.$$

At moderate CO_2 pressures (~1 atm), two intermediates are formed [18]:

$$PbCO_3 \xrightarrow{300^\circ C} PbCO_3 \cdot PbO \xrightarrow{310^\circ C} PbCO_3 \cdot 2PbO \xrightarrow{420^\circ C} PbO.$$

The data of [18] confirm the results of an earlier study [19], in which it was noted that the number and composition of intermediates depend on the partial pressure of CO_2 in the gas phase. According to [19], the decomposition of $PbCO_3$ is complete at 430°C.

Four principal steps of mass loss (%) can be distinguished in the TG curve for $PbCO_3$ (Fig. 4b): 0.12 at 150–185°C, 0.25 at 185–220°C, 7.74 at 220–324°C, and 8.29 at 324–455°C. The total mass loss is 16.40%, which virtually coincides with the theoretical mass loss by the solid phase for the reaction $PbCO_3 \rightarrow PbO + CO_2$ (16.47%). The DSC curve shows four endothermic effects corresponding to all the steps of mass loss. The last effect has a double peak, at 392 and 418°C. All these facts point to the complex nature of cerussite decomposition in an experiment carried out in air. The temperatures of the endothermic effects are close to those reported in [18, 19].

Yamaguchi and co-authors studied by various methods the decomposition of hydrocerussite $2PbCO_3 \cdot Pb(OH)_2$ on heating [20]. The DTA curves obtained in air ($P_{CO_2} \ll 1$ atm) show two endothermic peaks, at about 250 and 340°C. The thermogravimetric curves demonstrate mass loss in two temperature ranges: 200–270 and 330–400°C. The results obtained in air suggest the following scheme of hydrocerussite decomposition on heating:

$$2PbCO_3 \cdot Pb(OH)_2 \xrightarrow{200^\circ C} PbCO_3 \cdot PbO \xrightarrow{300^\circ C} PbO.$$

In the first stage, CO_2 and H_2O are released into the gas phase, and in the second stage, only CO_2. Thus, hydrocerussite is stable in air up to a temperature of approximately 280°C, even though it starts to decompose at 200°C. The compound $PbCO_3 \cdot PbO$ is stable in the temperature range 200–400°C, PbO starts to accumulate beginning at 350°C. The existence regions under the experimental conditions of [20] cannot be clearly defined.

Separate heating of PbO and $PbSO_4$ is not accompanied by appearance of any features in the TG and DSC curves. The aforesaid suggests that the only component remaining on heating the oxide-carbonate cake (after desulfation of the active paste) to above 600–620°C is lead(II) oxide PbO. This conclusion is confirmed by X-ray diffraction analysis. Annealing of the oxide-carbonate cake at 400°C for 2 h leads to formation of the oxides Pb_3O_4 (tetragonal lattice) and $PbO_{1.44}$ (*F*-cubic lattice), whose contents are presumably comparable (Fig. 5a). PbO (red, tetra-

Table 1. Thermodynamic characteristics of reactions (1)–(3)

gonal modification, lead ocher) is present in a minor amount. The phase composition of the annealed paste was independent of what compounds were contained in the oxide-carbonate cake: cerussite, hydrocerussite, or the double salt).

Annealing of the cake at 600°C results in that the yellow, orthorhombic modification of PbO (massicot) becomes the main phase. The tetragonal modification of PbO is present in a minor amount (Fig. 5b).

The reduction of PbO with solid carbon may occur by the reactions

$$PbO + C = Pb + CO, \quad (1)$$

$$PbO + CO = Pb + CO_2. \quad (2)$$

An important role in the reduction process is played by the reaction

$$C + CO_2 = 2CO. \quad (3)$$

Table 1 lists the changes in the standard Gibbs energy (ΔG_T^0) and enthalpies of formation (ΔH_T^0), calculated for reactions (1)–(3) in the temperature range 300–1000 K. The calculation was done using data from the reference manual [21]. The experimental ΔG_T^0, obtained for reaction (2) by Tsvetkov *et al.* [22], were close to the calculated values (kJ): –81.0 (973 K) and –82.4 (1023 K).

As is known, according to the most widely accepted concepts of reduction of metal oxides by solid carbon, of fundamental importance in the process is the gas phase, and carbon monoxide CO, rather than solid carbon, is the actual reducing agent [23–25]. However, thermodynamic calculations show that regeneration of CO by reaction (3) cannot proceed to any significant extent at temperatures below 1000 K.

Previously, reduction of individual lead(II) and (IV) oxides by solid carbon has been considered [26]. According to the data obtained, intense reduction of PbO_2 onsets at temperatures of 380–390°C, proceeds with strong heat release, and comes to completion at 400–410°C. The reduction of PbO by carbon begins at higher temperatures, with the onset temperature of the process and its rate being dependent on the amount of the reducing agent introduced. Intense reduction of PbO by solid carbon is in the range 600–700°C [26].

According to Tseft's data [27], reduction of PbO_2 by carbon occurs in several stages: $PbO_2 \rightarrow Pb_2O_3 \rightarrow Pb_3O_4 \rightarrow PbO \rightarrow Pb_2O \rightarrow Pb$.

Reduction of PbO_2 begins at a temperature of 190–210°C, proceeds at a high rate at 360–390°C, then slows down, and then again becomes fast at temperatures exceeding 500°C. The rate of the process was judged by the author of [27] from the volume of gases evolved in unit time.

In [28], the mechanism and kinetics of PbO reduction by carbon were studied in the temperature range 550–700°C. The authors noted that the reduction process is rather slow at 550°C, with only 5% of the initial mass of PbO reacted in 2 h. At the same time, the reaction is virtually complete at 700°C in 20 min. Based on various experimental observations and taking into account that the gas phase is approximately 90% composed of CO_2, the authors of [28] made a number of conclusions concerning the mech-

anism and kinetics of the solid-phase reduction process. Reaction (2) occurs at 600–700°C at a high rate and cannot be the limiting stage of the overall reduction process. As can be seen in Table 2, the thermodynamic characteristics of this reaction are rather favorable for its occurrence. At the same time, the extent of reaction (3) at temperatures below 800°C is not sufficient and, accordingly, cannot provide reaction (2) with the necessary amount of carbon monoxide. During the entire reduction process, its rate is determined by reaction (1). Of key importance is the chemical interaction of solid carbon with lead(II) oxide.

Shafrinskii [29] studied the reduction of cerussite $PbCO_3$ by solid carbon at temperatures of 600–700°C. The author noted that, simultaneously with reduction of $PbCO_3$, there occurs its thermal dissociation to give lead(II) carbonate and oxide as intermediate compounds. Under real industrial conditions, the process of reduction of cerussite must not differ significantly from that of PbO. Complete reduction of lead-containing compounds is favored by their close contact with carbon particles.

Ashin *et al.* [30] studied the kinetics of PbO reduction by graphite at 540–660°C in the atmosphere of argon. Under the experimental conditions, the process rate is strongly affected by temperature: the process is complete in 20 min at 660°C and in no less than 180 min at 580°C. Virtually only a single reaction product, carbon dioxide, was present in effluent gases. The intensity of the reduction process is strongly affected by the degree of grinding of the starting materials. A decrease in the particle size of lead(II) oxide from 1–2 to 0.25–0.50 mm makes the reduction rate approximately three time faster, and passing to a 0.07-mm fraction causes a dramatic acceleration of the process. Grinding of the reducing agent (graphite) intensifies the process to a considerably greater extent than does the corresponding grinding of the oxide. Making larger the relative content of carbon in the PbO + C mixture also rather strongly affects the reduction rate.

The authors of [30] confirmed the concept according to which CO is the primary reaction product under conditions of a comparatively low-temperature reduction of oxides (below 800°C), but it is not regenerated in the course of the process and reaction (3) does not advance. Thus, carbon monoxide cannot act as the main reducing agent and its involvement cannot account for the mechanism of interaction between PbO and carbon at 720–740°C. However, the authors of [30] do not rule out the possibility of sublimation of PbO and interaction of its vapor with carbon. Presence of graphite, which interacts with the PbO vapor, in the stock intensifies the process of sublimation of lead oxide. The whole body of the above evidence concerning the role of carbon in low-temperature solid-phase reduction of metal oxides is in agreement with the approaches used by Elyutin *et al.* [25, 31].

Table 2. Thermodynamic characteristics of reaction (4)

T, K	ΔH_T^0	ΔG_T^0
	kJ	
300	–290.4	–350.2
400	–290.8	–370.6
500	–293.5	–391.0
600	–296.8	–411.5
700	–300.6	–431.9
800	–304.9	–452.4
900	–309.1	–472.5
1000	–313.5	–492.9

Ashin *et al.* [32] also studied the reduction of PbO_2 by graphite at temperatures in the range 320–370°C. At 360–370°C, a steep increase in the process rate was observed, which was due to the occurrence of the reaction

$$3PbO_2 + C = Pb_3O_4 + CO_2. \quad (4)$$

The thermodynamic characteristics of this process are listed in Table 2.

Kinetic curves indicate that the process rate increases with temperature [32]. The thermodynamic characteristics are favorable for occurrence of reaction (4) in the entire range of temperatures considered. The gaseous products formed in reduction of PbO_2 contained, together with CO_2, 5–7 wt % free oxygen.

As noted by Tsvetkov [33], there is no sufficient reason to apply the adsorption-catalytic model to reduction of lead oxides. Autocatalytic phenomena are not characteristic of reactions yielding liquid products.

Electrothermal methods for production of metals and alloys, whose theoretical foundations were considered by Kozhevnikov *et al.* [34], should not be extended to lead oxides because of their comparatively low melting point and high volatility.

In laboratory and enlarged-laboratory conditions, reduction of the oxide-carbonate cake by carbon or carbon-containing materials is nearly complete (yield

of lead ≥95%) at 720–740°C [35, 36]. The occurrence of the process is favored by a higher degree of grinding of both the starting material and the reducing agent. The reduction process is sufficiently ecologically safe, does not require intricate apparatus, and can be performed under low-scale industrial conditions.

CONCLUSION

It is advisable, in processing of lead batteries by their cropping into fractions in order to recover lead from the active paste of positive and negative plates (oxide-sulfate fraction), to perform two successive technological procedures: (i) to convert lead sulfate (anglesite) into carbonate compounds to obtain an oxidecarbonate cake and (ii) to reduce it after drying and grinding with carbon-containing materials at 720–740°C. Both the procedures are sufficiently ecologically safe, do not require intricate apparatus, and can be performed under low-scale industrial conditions. It is advisable to heat the cake at 600°C prior to reduction in order to convert all lead-containing compounds to lead(II) oxide.

Abstract—The dependence of the kinetic characteristics of electrochromic indicator devices based on films of amorphous tungsten oxide α-WO_3 on the speed of reversible coloration of their working electrode with a film of this kind was studied.

DOI: 10.1134/S1070427206020157

Films of amorphous tungsten oxide α-WO_3 are used in electrochromic devices [1–3]. Their coloration and decoloration in the near-IR and visible spectral ranges occur via double ion–electron injection and extraction [1, 4]. The α-WO_3 electrode is colored on passing the cathode current via capture of electrons injected into the film by free *d*-orbitals of W^{6+} centers, which are thereby reduced to W^{5+} centers and become color centers in α-WO_3. The charge of these electrons in the film bulk is neutralized by mobile singly charged cations H^+, Li^+, or Na^+, which come into the film from the electrolyte and are arranged near oxygen atoms that form bridge and terminal bonds of the types W–O–W and W=O [5, 6]. Extraction of injected carriers from the colored film on reversing the current flow direction in the α-WO_3 electrode leads to its decoloration.

A simple and economical way to obtain α-WO_3 films with well reproducible electrochromic characteristics is cathodic electrodeposition, which is commonly performed from an electrolyte containing soluble peroxotungstates [1, 7–12]. The deposits obtained are commonly X-ray-amorphous [7, 9, 12]; the mechanism of cathodic deposition of α-WO_3 was considered in [7]. In the galvanostatic deposition mode, a linear dependence of the film thickness on the deposition time is observed, but the film retains a smooth uniform surface only to thicknesses not exceeding 1 μm [7, 12]. It has been shown that, because of the high porosity and large content of water molecules, the specific density of the deposit on the cathode is less than half density of crystalline WO_3. Therefore, these films have in the decolorized state a very low optical refractive index, n = 1.6–1.7 (at n = 2.5 for crystalline WO_3).

The coloration of the film begins with the appearance in their optical spectrum of a high-intensity absorption band peaked at $h\omega \leq 1$ eV, but, as current flows at a cathodic shift of the potential of the α-WO_3 electrode, injected electrons start to fill also higher-energy free *d* orbitals of W^{6+} centers with double bonds of the W=O type [12, 13]. α-WO_3 has a nanocluster structure [14, 15] and a decrease in the cluster size enhances the influence exerted by terminal oxygen atoms (terminal double bonds W=O) on the energy position of free *d* orbitals of W^{6+} centers and on the potential of their reduction to W^{5+}, which gives rise to an additional absorption band peaked at $h\omega \approx$ 2 eV [12, 13]. Because of the wide energy scatter of free *d* orbitals of W^+ centers in films of this kind, their successive filling by injected electrons, at a cathodic potential of the α-WO_3 electrode, is accompanied by an increase in the Fermi energy and a reversible shift of the fundamental absorption edge of this amorphous semiconductor to higher photon energies [12, 13]. As a result, films of this kind show a correlation between the concentration of injected carriers, degree of coloration, position of the fundamental absorption edge, Fermi energy, and potential of the α-WO_3 electrode, whose values are also retained on disconnecting the electrode from the power source [12, 13].

This communication reports the results obtained in a study of joint diffusion transport of injected electrodes and protons in a cathodically deposited α-WO_3 at various potentials. The experimental data obtained confirm the nanocluster structure of cathodically deposited α-WO_3 films.

EXPERIMENTAL

α-WO_3 films were produced by cathodic electrodeposition from an aqueous solution of Na_2WO_4 (0.2 M) with addition of 30% hydrogen peroxide (0.13 M) and H_2SO_4 (to pH 1). The deposition was performed in a transparent electrochemical cell with a platinum counter electrode at a constant cathode current density of about 1 mA cm^{-2} and temperature of 23–25°C. The α-WO_3 films were deposited onto a transparent current-conducting SnO_2 film of thickness 0.23 μm on a glass substrate or on a polished surface of sheet tungsten. The design of the electrochemical cell enabled interferometric monitoring of the course of deposition by recording interference patterns simultaneously for two He–Ne laser beams with different angles of incidence on the electrode surface. Computer processing of these diffraction patterns by the procedure described in [12, 16] enabled separate determination of the running values of the thickness and optical refractive index of a growing α-WO_3 layer.

The optical and electrochemical parameters of the electrode fabricated were measured in the transparent electrochemical cell filled with a 1 N solution of H_2SO_4, equipped with a platinum counter electrode and silver chloride reference electrode, relative to which all the potentials E are given. The coloration and decoloration of the α-WO_3 electrodes was achieved by steplike variation of the control potential with an EP-21 potentiostat. The time dependences of the electrode current and intensity of monochromatic light reflected by the α-WO_3 electrode or passed through this electrode were recorded with an automated measuring setup similar to that described previously [17].

In the colored α-WO_3 film, the charge of injected electrons (with a concentration on the order of 10^{21} cm^3) is neutralized by the charge of mobile protons. Because of the large content of water molecules in the structure of a cathodically deposited film, transport of protons in this film occurs via the hydrogen bonds of H_2O molecules (in the form of OH_3^+) [18]. The most probable at so high concentrations of differently charged carriers is the diffusion mechanism of their joint transport in the bulk of α-WO_3. Under nonstationary conditions, the difference between the mobilities of electrons and protons should give rise, by analogy with concentrated solutions of liquid electrolytes, to a diffusion potential, which equalizes the motion velocities of these particles. In this case, the effective coefficient of joint diffusion in the film bulk, D_{eff}, is mainly determined by the motion velocity of the less mobile particle, for which the proton is commonly taken.

Because of the high porosity and large content of water molecules, electrodeposited α-WO_3 films have no potential barrier for protons at the interface with the electrolyte. This makes it possible to assume that a carrier concentration N_0 that is the equilibrium concentration for a given E is rapidly attained at the film surface and to regard the coloration as a diffusion process of joint transport of protons and electrons into a film of finite thickness d from a permanent source with concentration N_0 on the surface. In this case, the common solution to the diffusion equation for the flux (of protons) across the WO_3–electrolyte interface has the form [19]

$$i(t) = (2eN_0D_{eff}d^{-1})\Sigma\exp\{-[(2n + 1)^2\pi^2D_{eff}t(2d)^{-2}]\}, \quad (1)$$

where D_{eff} is the effective coefficient of joint diffusion of protons and electrons; e, elementary charge; and t, time of coloration.

A solution of the same kind is obtained for decoloration. The series (1) rapidly converges and does so the better, the larger t. At $t \geq t_D = 0.25d^2/D$ (t_D is the characteristic time of diffusion) it is possible to retain only the first term of sum, with an error not exceeding 1%. Then, except in the initial stage of coloration or decoloration, the following expression can be written at $t > t_D$

$$\ln|i(t)| = \ln(2eN_0D_{eff}d^{-1}) - \pi^2D_{eff}t(2d)^{-2}, \quad (2)$$

i.e., the dependence $i(t)$ plotted in the coordinates $\ln i(t)$–t is a straight line with a slope $-\pi^2D_{eff}(2d)^{-2}$. Hence, it is possible to find, at a known film thickness d, D_{eff} and N_0, because this straight line intersects the ordinate axis at $\ln(2eN_0D_{eff}d^{-1})$.

Figure 1 shows the experimental time dependences of the current density $|i(t)|$ and normalized intensity of monochromatic light (625 nm) that passed through the electrode. These dependences were obtained in a cycle of coloration–decoloration of an electrode with an α-WO_3 film on glass with a current conducting layer of SnO_2. To minimize the influence exerted on the electrode current by the sheet resistance of the current-conducting substrate, the working area of the α-WO_3 electrode was considerably smaller than that of the SnO_2 layer. The remaining part of the SnO_2 surface was insulated from the electrolyte with a layer of chemically resistant lacquer. The time of the coloration process of the given electrode at λ = 625 nm after a steplike change of its potential E from 0.4 to –0.4 V was about 0.3 s at a transmission contrast of about 80%. At such a rate of electrode coloration, its efficiency was $\Delta D/Q$ = 57 cm^2 C^{-1},

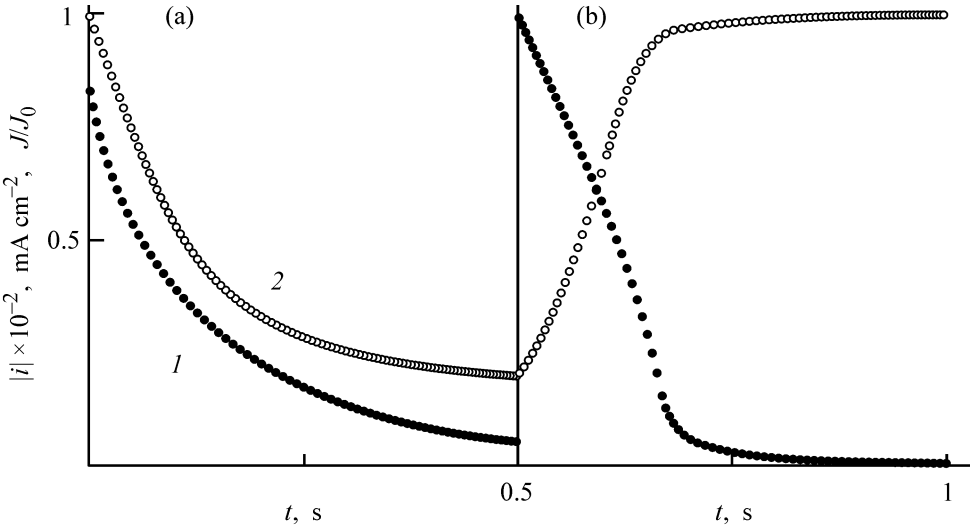

Fig. 1. (*1*) Current i and (*2*) normalized intensity of transmitted light, J/J_0, at λ = 625 nm vs. time t for an electrode with a 343-nm α-WO_3 film (on glass with a SnO_2 layer) in a cycle of coloration–decoloration of this electrode via a steplike change in its potential from 0.4 to –0.4 V. (a) Coloration at E = –0.4 V and (b) decoloration at E = 0.4 V.

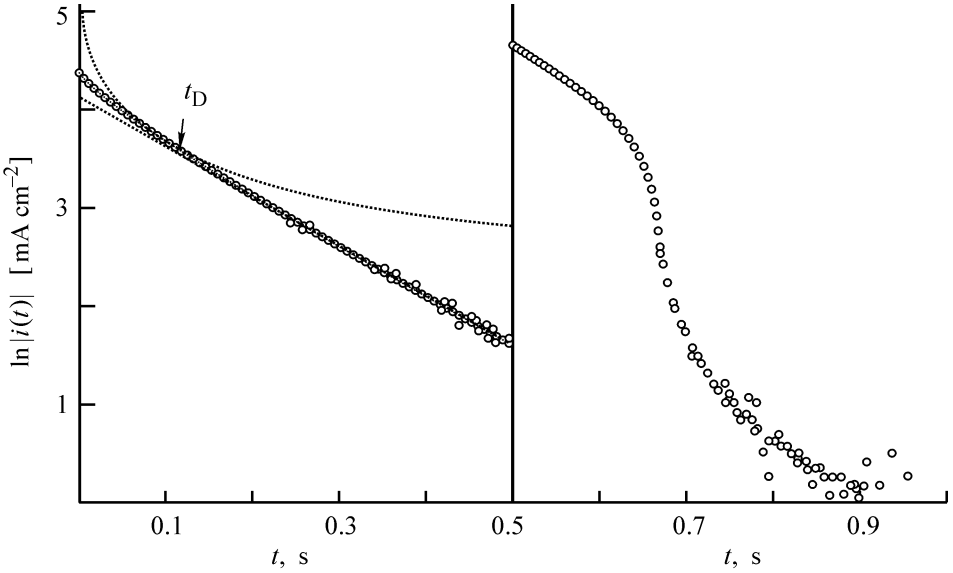

Fig. 2. $\ln|i(t)|$–t dependence for an α-WO_3 electrode with kinetic characteristics shown in Fig. 1. (*i*) Current density. *Dotted line*: expected run of this dependence at the calculated values of D_{eff} and N_0 for the case when $d \to \infty$.

where $D = \log(I_0/I)$ is optical density and Q is the quantity of charge injected into the electrochromic film (at E = –0.4, $Q \approx 12.4$ mC cm^{-2}). These parameters were retained during more than 10 coloration-decoloration cycles. At cathodic potentials exceeding –0.4 V, a part of the electrode current was expended for the reaction of hydrogen evolution, which gradually led to irreversible structural changes in the electrochromic layer and in that of SnO_2.

In Fig. 2, the time dependence of the current $i(t)$ (Fig. 1) is plotted in the $\ln|i(t)|$–t coordinates. At $t >$ 0.12 s, a straight line can be drawn through its experimental points in Fig. 2, which confirms the diffusion mechanism of a concerted motion of protons and electrons from the surface of the α-WO_3 layer toward the interface between this layer and that of SnO_2. The parameters of the electrochromic material, found in accordance with Eq. (2), have the following values: $D_{eff} = 2.38 \times 10^{-9}$ cm^2 s^{-1}, $N_0 = 2.73 \times 10^{21}$ cm^{-3}, t_D = 0.125 s. Because t_D is the time in which protons injected into the film reach the SnO_2 layer, their joint transport with electrons in the film can be regarded as diffusion into a semifinite body from a permanent source with a constant concentration N_0 on its surface.

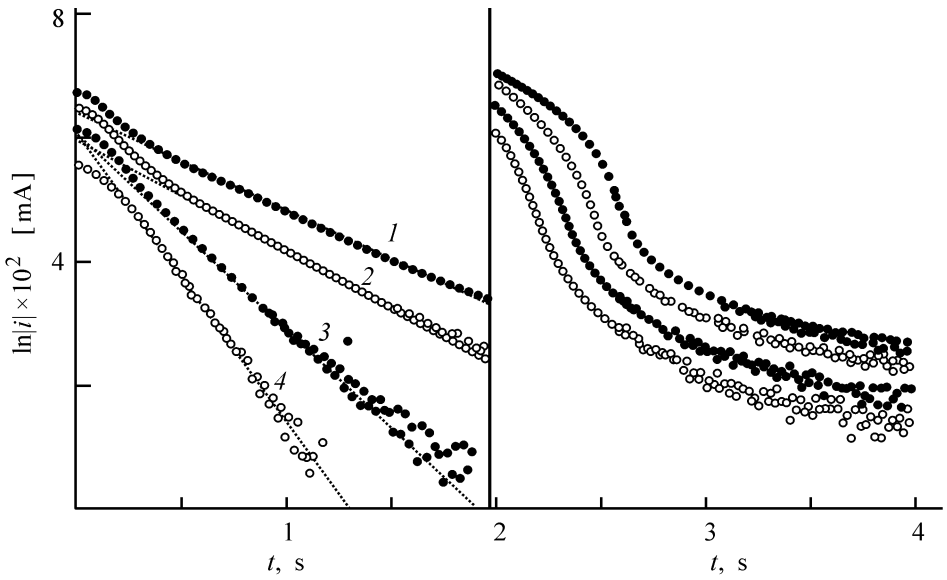

Fig. 3. $\ln|i(t)|$–t dependence for a 0.64-μm α-WO_3 film in its coloration at different control potentials and subsequent decoloration at E = 0.4 V. (*i*) Current. Coloration potential E (V): (*1*) –0.4, (*2*) –0.2, (*3*) –0.1, and (*4*) 0; decoloration at 0.4 V.

In this case, the dependence $i(t) = N_0[D_{\text{eff}}/(\pi t)]^{1/2}$ corresponds to solution to Fick diffusion equations. This dependence is shown in Fig. 2 with account of the value found for N_0. However, the arrangement of experimental points of $i(t)$ in Fig.2 at $t < t_D$ disagrees with this theoretical dependence because the equilibrium carrier concentration N_0 is attained on the film surface only a certain time after the steplike change of the control potential E from 0.4 to –0.4 V, rather than instantaneously.

The decoloration of the film at $E > 0.3$ V occurs faster than the coloration (Fig. 1) because the equilibrium concentration of W^{5+} centers already cannot be attained on its surface. In this case, even a complete disappearance of the color cannot compensate the potential difference applied to the WO_3–electrolyte interface. The uncompensated part of this potential difference creates an electric field, which penetrates into the bulk of the semiconducting α-WO_3 and accelerates transfer of protons into the electrolyte [4]. In this case, the slope rate of the dependence $\ln|i(t)|$–t in the initial and final stages of decoloration is close to that in coloration. In the initial stage of decoloration, this is due to the fact that the penetration depth of the electric field into the film at its surface is as yet small as compared with d. In the final stage of decoloration, the velocity at which carriers are transported to the surface again becomes virtually equal to that of the diffusion transport because of the low electric field strength in the bulk of α-WO_3.

The dependence of D_{eff} on E was determined by changing stepwise the control potential to its various values in coloration and decoloration. In doing so, the use of electrodes in which the α-WO_3 film was deposited on the polished surface of sheet tungsten made it possible to minimize the series resistance for the electrode current. The experimental $i(t)$ dependences obtained on such an electrode with a layer of cathodically deposited α-WO_3 for several coloration potentials are plotted in the $\ln|i(t)|$ coordinates in Fig. 3. At t exceeding 0.4 s, straight lines can be drawn through the experimental points of these dependences. The difference between those values of D_{eff} to which the slopes of straight lines in Fig. 3 correspond and the position of circles in Fig. 4 is due to the dependence of the diffusion coefficient on the coloration potential, whose value in α-WO_3 also sets

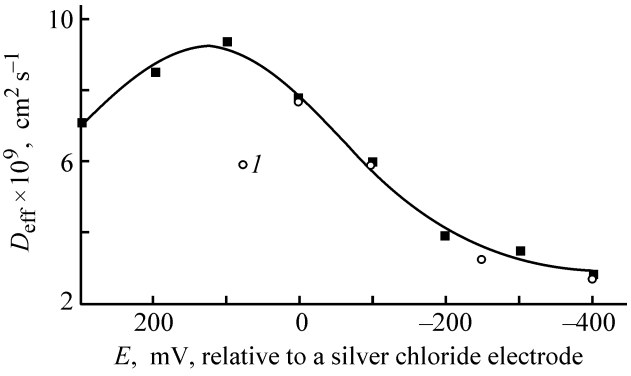

Fig. 4. Coefficient of joint (ambipolar) diffusion of protons and electrons in the bulk of a α-WO_3 film, D_{eff}, vs. the potential E. (*1*) $D_{\text{eff}}(E)$ values found from the slopes of the straight lines in Fig. 3.

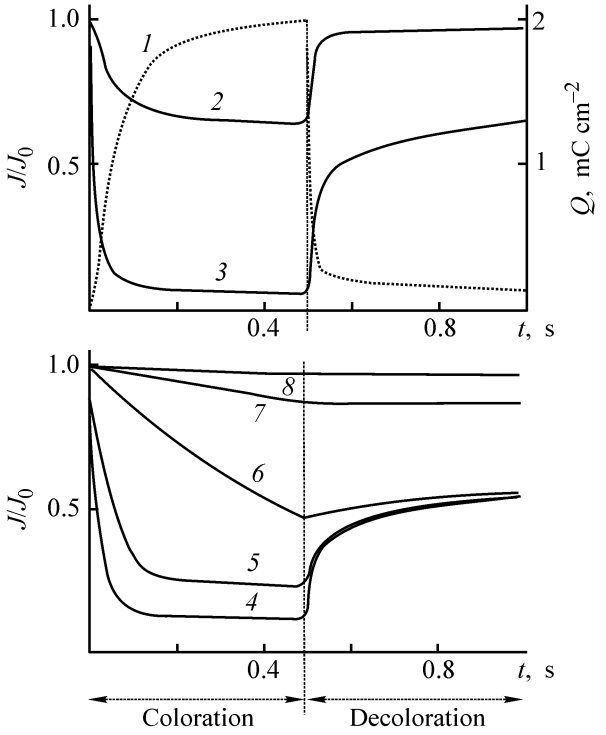

Fig. 5. (*1*) Injected electron charge Q and (*2–8*) normalized intensity of reflected light, J/J_0, at λ of (*2*) 0.6 and (*3–8*) 1.0 μm for an α-WO_3 film on tungsten. Coloration potential E (V): (*1–3*) –0.5, (*4*) –0.3, (*5*) –0.2, (*6*) –0.1, (*7*) –0.05, and (*8*) 0; decoloration at (*1–8*) 0.5 V.

the final concentration of injected carriers, N_0, in the film. At the same time, (1) and (2) are derived from the Fick equation $\partial N/\partial t = D(\partial^2 N/\partial x^2)$ on the assumption that D_{eff} is independent of the concentration of the diffusing substance. If D depends on N, a more general equation $\partial N/\partial t = \partial/\partial x[D(N)(\partial n/\partial x)]$, should be used; however, it is rather difficult to directly solve it in the general form. Therefore, the rest of the points in Fig. 4 correspond to those values of D_{eff} which were obtained from the time dependence of the anode current of this electrode, with the control potential raised stepwise by a small amount (0.1 V). It is assumed that, within each interval of this kind on the potential scale at E between 0.3 and –0.4 V, the variation of D_{eff} with E is small and can be neglected. It was established that, within each of these intervals, the experimental points of the $\ln|i(t)|$ dependences obtained fall on straight lines having the same slope as those for coloration and do not deviate in the course of time from the straight lines because of the dependence of D_{eff} on E.

The dependence of D_{eff} on E, shown in Fig. 4, has a maximum at E of about 0.1 V. A similar D_{eff}–E dependence has been obtained previously in impedance measurements for α-WO_3 films deposited in a vacuum (in their coloration in propylene carbonate containing 1 M $LiClO_4$) [5]. In this study, the decrease in D_{eff}, observed as the concentration of cations increased, was attributed to closure of paths for their motion in the film along bonds of the type W^{6+}=O and O–W^{6+}–O upon reduction of W^{6+} centers to W^{5+}, and the initial rise in D_{eff}, to transition from Li^+ transport within separate clusters to their faster motion over the surface of these clusters, on which the terminal W^{6+}=O bonds are localized. According to [20], a continuous increase in D_{eff} at all values of the control potential is characteristic of WO_3 films produced by the sol-gel method and annealed at 240°C, in the course of their coloration with Li^+. The authors of [20] regard the rise in D_{eff} of this oxide as a result of an increase in its electronic conductivity. Possibly, the rise in D_{eff} in the initial stage of coloration of a cathodically deposited α-WO_3 film in a 1 N H_2SO_4 solution (Fig. 4) is also due to an increase in its electronic conductivity. At the same time, the increase in the (W^{6+}=O)/(O–W^{6+}–O) ratio in the initial stage of film coloration, observed in [5] in Raman scattering measurements, can be attributed to capture of electrons mostly by W^{6+} centers. These centers have no bonds of the W^{6+}=O type, which have a lower energy position of the free *d*-orbital than in centers with W^{6+}=O bonds [12, 13].

Figure 5 shows kinetic dependences obtained on one of the electrodes studied, which had an α-WO_3 film deposited from an electrolyte with acidity raised to pH 2. At $E \geq -0.1$ V, the coloration of the α-WO_3 layer of this electrode is strongly decelerated. This range of coloration potentials E (0.3 to –0.1 V) corresponds to formation of W^{5+} centers within the largest clusters and to appearance of an absorption band peaked at $\lambda \approx 1000$ nm. The extraction of injected electrons captured by these centers is also markedly decelerated in decoloration of the film at E = 0.5 V. Their charge constitutes about 5% of the maximum value of Q in the film at E = –0.5 V, whereas the separation accelerated by the electric field and the removal of most of carriers occur in this case in $t \approx 0.1$ s. It is unlikely that such a pronounced, by several orders of magnitude, change in the carrier mobility in the film between E = –0.1 and –0.2 V could be associated with a change of the pathways of proton transport by the mechanism suggested in [5]. Such a "steplike" change in mobility can be attributed to filling by injected electrons of energy levels that lie on different sides of the "mobility threshold" for electrons in this amorphous semiconductor. The considerable distance between separate large clusters in

the oxide prevents electrons captured by these clusters from being involved in transport phenomena. At $E > 0.1$ V, the probability of an electron hop between clusters of this kind is low, because they are separated by pores filled with water molecules and by smaller nanoclusters with W^{6+} centers having a higher (by 0.3–0.4 eV) energy of the free *d*-orbital. In addition, it is necessary, for the film coloration to begin, that the injected electrons should preliminarily pass across a layer of completely decolorized WO_3 with a low electronic conductivity [20]. Therefore, the initial portion of the *i–t* dependences in Figs. 2 and 3 disagrees with the general solution to the diffusion equations, which is particularly noticeable in the case of coloration at $E = 0$ V (from the position of the experimental points corresponding to the initial stage below the straight line drawn).The steplike increase in the motion velocity of injected carriers in the film, observed at the cathodic potential, presumably corresponds to that energy position of the Fermi level, at which electron transfer occurs across its entire thickness via a macroscopic chain of clusters, between which electrons can move by hopping.

CONCLUSIONS

1) The reversible coloration of cathodically deposited electrochromic α-WO_3 films via joint transport of electrons and protons (in the form of H_3O^+) injected into the film occurs by the diffusion mechanism.

(2) In the course of coloration of the film and cathodic shift of its potential, the effective diffusion coefficient of these mobile carriers first increases to approximately 10^{-8} $cm^2\ s^{-1}$ and then gradually decreases. The occurrence of a maximum in the dependence of this coefficient on the potential of the α-WO_3 electrode at $E \approx 0.1$ V is due to a decrease in the mobility of electrons in the film to values lower than the mobility of protons, observed as the potential of the film is shifted into the anodic region.

(3) Raising the acidity of the initial electrolyte favors deposition of films with an abrupt "mobility threshold" (on the energy scale) for electrons. Its existence is due to the presence of pores and to specific features of the cluster structure of these films, characterized by predominance of small nanoclusters in which most of tungsten atoms have double bonds of the W=O type with terminal oxygen atoms.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Layers Formed in Polyphosphate Electrolytes on Rectifying Metals

Abstract—Results obtained in studying the elemental and phase composition of anodic layers formed on titanium, aluminum, niobium, and zirconium under the action of electric discharges in aqueous electrolytes with hexametaphosphate complexes of Ni(II), Mg(II), and Mn(II) are presented.

DOI: 10.1134/S1070427206020169

It has been shown previously [1–4] that layers containing metal phosphates, along with aluminum oxides, can be formed on the surface of aluminum and its alloys by the method of plasma electrolytic oxidation (PEO)[1] in aqueous electrolytes containing polyphosphate complexes of the metals. Such layers exhibit properties typical of metal phosphates. For example, films containing zinc phosphates can act as biocides [5, 6]. Aluminum–nickel PEO structures on aluminum exhibit a catalytic activity in oxidation of CO to CO_2 [7]. In the general case, composites that are constituted by a metal and a thin layer and contain high-temperature phosphates of doubly, triply, and multiply charged metals have found a wide diversity of applications [8–13].

The composition and thickness of the anodic PEO structures on aluminum depend on the molar ratio n = polyphosphate/M^+ in the electrolyte (Fig. 1), or, in other words, on the state of a solution [1–3]. The coatings formed in true solutions ($n > n_0$) are composed of aluminum oxide and contain insignificant amounts of elements from the electrolyte. The coatings formed in a colloid electrolyte or in an electrolyte that approaches this state ($n < n_0$) are mainly composed of the electrolyte components. According to X-ray phase and thermogravimetric analyses, the elemental composition and mass of the PEO coatings formed in polyphosphate electrolytes with different values of n remain unchanged upon annealing in air at temperatures of up to 1000°C [14–16]. IR spectroscopy has revealed di-, ortho-, and metaphosphate groups in the composition of the layers [15, 16]. Annealing leads to an increase in the content of the crystalline phases in the layers. In this case, complex titanium phosphates, such as $NaTi_2(PO_4)_3$ and $Mn(II)Mn(III)Ti(PO_4)_3$, can crystallize in layers on titanium, in contrast to analogous structures on aluminum [14].

In this communication, we present the results obtained in a study of how the nature of a rectifying metal and an alloy and high-temperature annealing in air affect the composition of PEO layers formed in polyphosphate electrolytes.

EXPERIMENTAL

The coatings were formed on aluminum (99.9%) and its alloys AMTsM, AD1, AD33, D16, AMg6, and V95, a well as on technical grade VT1-00 titanium, niobium of NbTsu brand, and zirconium. We prepared electrolytes using commercial reagents: sodium hexamethaphosphate $Na_6P_6O_{18}$ (30 g l^{-1}), sodium tripolyphosphate $Na_5P_3O_{10}$ (36.1 g l^{-1}), $Mg(CH_3COO)_2 \cdot 4H_2O$, $Ni(CH_3COO)_2 \cdot 4H_2O$, and $Mn(CH_3COO)_2 \cdot 4H_2O$, and distilled water. The molar ratio $n = P_6O_{18}^{6-}/M$ was calculated for the starting reagents. The preparation of the electrolyte and electrodes, the electrochemical cell, and the thyristor power source have been described previously [1–3].

Anodic layers were formed galvanostatically in the course of 10 min (if not specified otherwise) at

[1] Plasma electrolytic oxidation is a method in which anodic layers are formed under the action of electric discharges near the electrode.

Table 1. Elemental composition of coatings formed on various aluminum alloys*

Alloy (main alloying additives, %)	U, V	Content, wt %

* GMF and TPF are electrolytes containing 30 g l^{-1} $Na_6P_6O_{18}$ and 36.1 g l^{-1} $Na_5P_3O_{10}$, respectively, and Ac = CH_3COO^-.

the effective current density i = 5 A dm^{-2}. Samples of dimensions $10 \times 40 \times 1$ and $40 \times 40 \times 1$ mm were treated. In all cases, a spark discharge appeared on the anode surface during the first minute of the process. The temperature of the electrolyte during the anodizing did not exceed 30°C. The coated samples were washed with distilled water and dried in air. The samples were heated in a muffle furnace at a prescribed temperature for 2 h in air.

The elemental composition of the surface layer of the coatings was determined on a JXA-5A electronic X-ray fluorescence microprobe analyzer (Japan) and on an EMAL-2 laser mass-spectrometer (Russia). The micrographs of the surface were obtained on a LEO-400 electron microscope (France). The phase composition was determined using X-ray diffraction patterns obtained on a DRON-2 diffractometer with Cu_{K_α} radiation (Russia) or on a D8 ADVANCE X-ray diffractometer (Germany) in the Bragg–Bretano configuration with Cu_{K_α} radiation. In the last case, the EVA search software with a PDF-2 database was used in the X-ray phase analysis.

The coating thickness was determined with a VT-201 eddy current thickness meter (Russia).

The data in Table 1 show that the alloying additives in the aluminum alloys affect only slightly the content of the main elements in the coatings, but alter the final potential of coating formation, U. The potential U is at a maximum for coatings formed on pure aluminum. Probably, the coatings are the densest in this case and have the best dielectric characteristics. According to the results of an elemental analysis, the alloying additives are present in the composition of the coating in trace amounts.

The data in Tables 1–3 and Figs. 1, 2 show that the molar ratio n = polyphosphate/M^+ in the elec-

trolytes affects the elemental composition and thickness of the coatings formed on titanium, niobium, zirconium, and aluminum in similar ways. The main changes in the elemental composition ($\Delta c/\Delta n$) and thickness ($\Delta h/\Delta n$) of the coatings formed on all of the metals studied are observed when the electrolyte approaches the colloid state ($n < 3–6$ transition or metastable region), i.e., the electrolyte components are incorporated in noticeable amounts and the coating thickness grows when the solubility of metal polyphosphate complexes decreases and the solutions are metastable, or hydrated metal polyphosphates are precipitated. Under these conditions, the gain in mass and the coating composition are mostly determined by the products formed in thermolysis of the precipitate and by the high-temperature interactions between the compounds and oxides in the vicinity of electric discharge channels.

At the same time, the nature of a rectifying metal markedly affects the phosphorus content of the layers and their thickness at $n > 2$, i.e., in the case when the films are formed in true solutions and the role of the colloidal precipitate in film formation is insignificant. In the case under study, the metals are arranged in the following order with respect to the phosphorus content in the coatings (wt %) and their thickness: Ti > Nb > Al (Fig. 2). Furthermore, the phosphorus content in the coatings formed on titanium and niobium changes in the transition and colloid regions ($n < 3$) to a lesser extent than that in coatings on aluminum. Presumably, titanium (and to a lesser extent niobium) and their oxides are more susceptible than aluminum and its oxide to formation of phosphate compounds sparingly soluble in water in interaction with the polyphosphate electrolyte in the course of PEO. Apparently, the high content of phosphorus in the coatings formed on titanium is due not only to thermolysis of the precipitate and high-temperature interactions with polyphosphates at places of TiO_2 break-downs, but also to egress of titanium cations into solution to form titanium polyphosphate complexes, which undergo thermolysis at the anode under discharge conditions. Comparison of the data of [18, 19] shows that, in oxidation of titanium and aluminum under the action of electric spark and micro-arc discharges, the titanium concentration in the electrolyte markedly (severalfold) exceeds that of aluminum. A high content of phosphorus (approximately 5–10 wt %) is characteristic of PEO coatings formed on titanium in electrolytes containing water-soluble phosphorus compounds [20, 21]. For PEO structures formed on aluminum and its alloys under the similar conditions, the phosphorus content does not exceed 3–4 wt % [22].

According to the data of laser mass-spectrometry (Table 2), carbon is present in considerable amounts in coatings formed on titanium, and the amount of carbon depends on the nature of a metal cation in the electrolyte. The mechanism of carbon incorporation into the coatings remains unclear.

The composition of the PEO coatings galvanostatically formed at a current density of 5 A dm^{-2} in 6 min on VT1-00 titanium in an aqueous electrolyte containing 30 g l^{-1} $Na_6P_6O_{18}$ and $Mn(CH_3COO)_2$ was studied in [14]. It was found that the original layers are X-ray-amorphous and crystalline phases are formed at annealing temperatures above 650°C. The whole set of results obtained in [14] (thermogravimetric data; constant content of titanium, phosphorus, and manganese in annealing at temperatures of up to 800°C; phase composition and its behavior in the course of annealing) led to a conclusion that coatings formed on titanium in a polyphosphate electrolyte contain sodium and manganese titanophosphates at any n in the polyphosphate electrolyte. For example, the following phases crystallize upon annealing of samples with coatings formed in a polyphosphate electrolyte without Mn(II) acetate (analysis of X-ray diffraction patterns, DRON-2.0): TiO_2 anatase, $NaTi_2(PO_4)_3$, $Na_{0.23}TiO_2$ (bronze-like), and, possibly (weak reflections), titanium diphosphate TiP_2O_7. In coatings formed in an electrolyte containing Mn(II) complexes ($n \le 5$), phosphatotitanates $Mn(II)Mn(III)Ti(PO_4)_3$ and manganese diphosphate $Mn_2P_2O_7$ crystallize in addition to the substances mentioned above. The coatings formed in electrolytes at $n < 1$, i.e., in the solutions with a precipitate, possibly contain Mn_2TiO_4 along with the above phases. As n in the forming electrolyte decreases, which corresponds to a rise in the manganese(II) concentration in the coatings, the crystallinity of the anodic layers and the number of the phases recorded increase.

Similar results were obtained in a study (with a D8 instrument) of the influence exerted by annealing on the phase composition of the coatings formed on titanium in an electrolyte containing 30 g l^{-1} $Na_6P_6O_{18}$ and $Ni(CH_3COO)_2$ (Table 4). The original coatings are either X-ray-amorphous ($n > 5$) or contain the amorphous phase ($n < 2$). TiP_2O_7, $NaTi_2(PO_4)_3$, and TiO_2 (anatase) crystallize above 500°C in films formed in a purely polyphosphate electrolyte (without nickel acetate), in agreement with the results of [14]. Intro-

duction of nickel acetate, results in that sodium titanophosphate $Na_4(TiO)(PO_4)_2$, nickel titanophosphate $Ni_{0.5}(TiO)(PO_4)$, and nickel diphosphate $Ni_2P_2O_7$ additionally crystallize in the layers. As *n* in the forming electrolyte decreases, the number of the phases recorded grows.

In layers formed on niobium, in contrast to those on titanium, annealing leads to crystallization of a considerably lesser amount of phosphates. These are $NbOPO_4$ and, at $n \le 1$, nickel diphosphate (Table 5). It is noteworthy that annealing of a powdered coating, formed on an aluminum alloy in an electrolyte with Ni(II) polyphosphate complexes at low values of *n* and then detached from the aluminum support, results in the crystallization of Al_2O_3, $NiAl_2O_4$, and $Ni_2P_2O_7$. Consequently, layers with the widest diversity of phosphates are formed on titanium. This is in an agreement with the above-mentioned result that the phosphorus content of PEO layers on titanium exceeds that on other supports.

The study showed that annealing of the samples with coating formed in an electrolyte with polyphosphate complexes of magnesium on niobium and zirconium (Table 3) leads to the following sequence of phase transformations: on niobium

$$\text{Amorphous phase} \xrightarrow{1000^\circ C} Nb_2O_5 + \alpha\text{-}Mg_2P_2O_7$$

and on zirconium:

$$ZrO_2(c) + ZrO_2(m) \xrightarrow{1000^\circ C} ZrO_2(c) + ZrO_2(m) + NaMgPO_4,$$

where c stands for the cubic or tetragonal modification of zirconium oxide, and m, for its monoclinic modification.

The micrographs in Fig. 3 show the surface organization of PEO structures formed on the titanium alloy in an electrolyte containing 30 g l^{-1} $Na_6P_6O_{18}$ and $Ni(CH_3COOO)_2$ at different values of *n*.

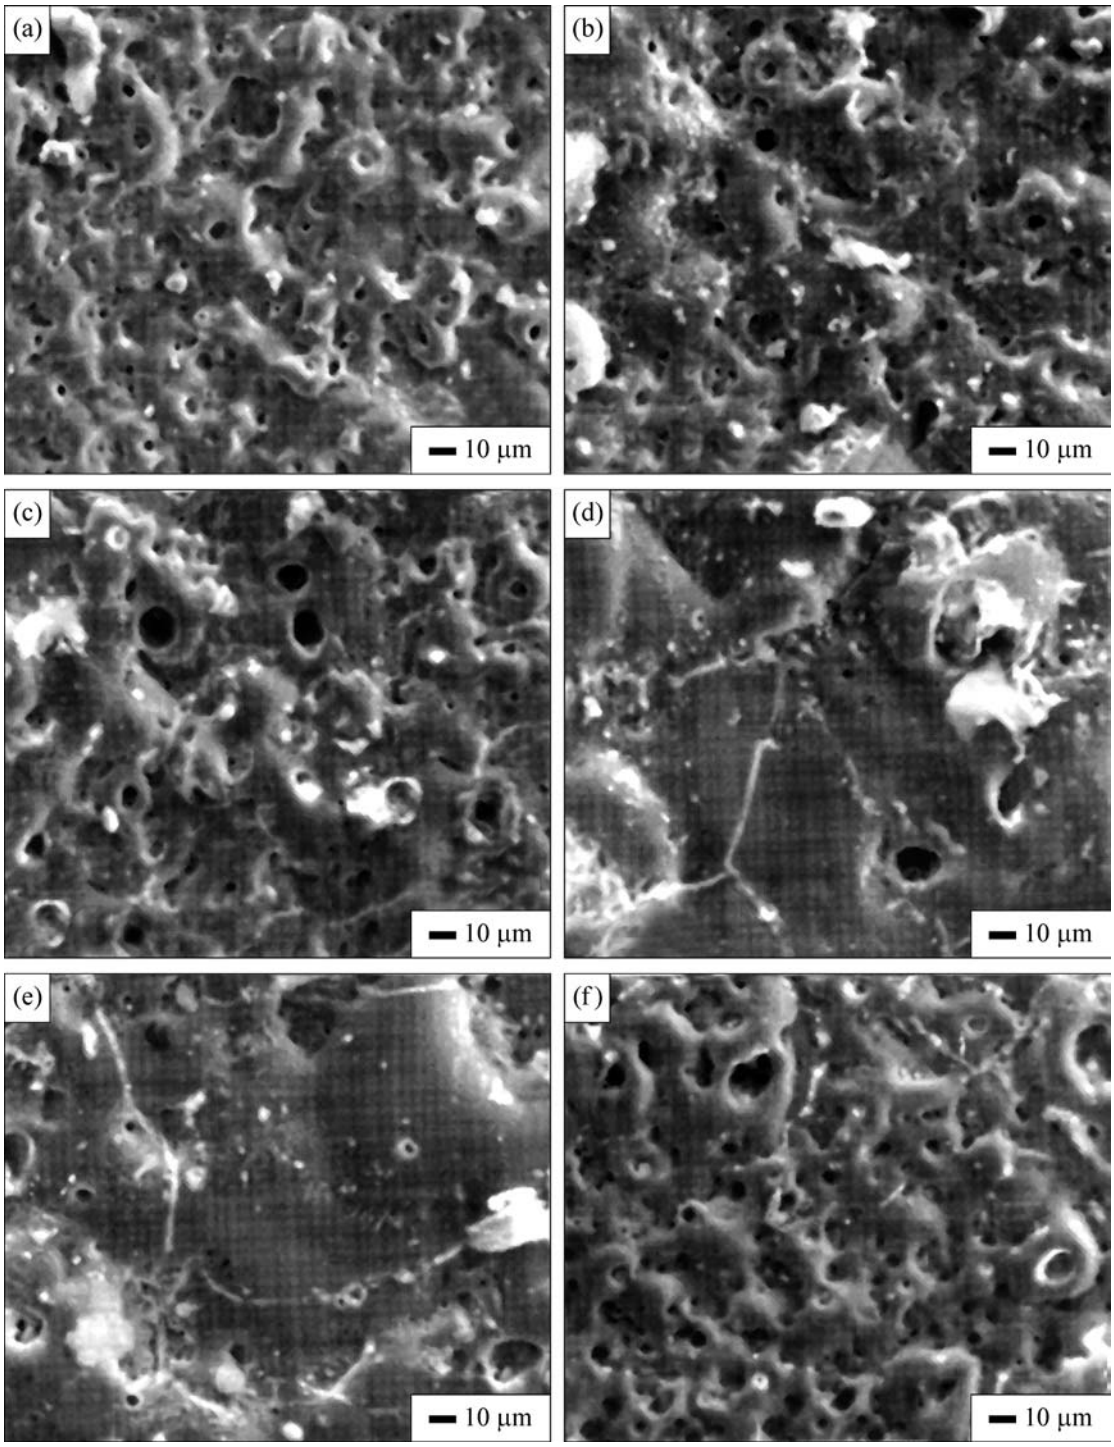

Fig. 3. Surface of PEO structures formed on titanium in an electrolyte containing 30 g l^{-1} $Na_6P_6O_{18}$ + $Ni(CH_3COO)_2$. (a) without $Ni(Ac)_2$; *n*: (b) 7.5; (c) 2, (d) 1.5, (e) 1, and (f) 0.5.

The most uniform and dense, as if partly melted, were coatings obtained at *n* equal to 1 and 1.5, i.e., in the region of transition to a solution with a precipitate. At *n* greater than 1.5 or equal to 0.5, the surfaces have a developed profile and a considerable porosity. It is believed that the pores seen in the micrographs (Fig. 3) are traces of the break-down channels, and the regions surrounding them, subjected to a virtually pulsed heating (the cross-sections of electric discharges vary within 0.01–1.35 mm^2 and

the lifetime of a discharge is ~0.25–3.5 ms [23]) and cooling (the electrolyte has nearly room temperature), contain the highest concentrations of the electrolyte components.

The anodic PEO structures are formed by two basic concurrent processes: (a) electrochemical oxidation on the surface free of discharges and (b) high-temperature synthesis in the breakdown channels. The conditions created in the discharge regions and adjacent zones (high temperature, pressure differences, and electrolyte evaporation) initiate high-temperature reactions involving the electrolyte components, the electrode, and the anode film. These reactions are characteristic of plasmochemistry, hydrothermal synthesis, interactions in melts, solid-phase synthesis, and thermal transformation of precipitates formed from an electrolyte. In these cases, reaction products that are insoluble in the electrolyte remain in the coatings.

The previously obtained results [1–4, 14–16] and our data show that the thermolysis of a precipitate formed in an electrolyte containing metal polyphosphate complexes at $n < 3–6$ makes the main contribution to the formation of PEO layers on rectifying metals and alloys. According to [13, 24–29], annealing at approximately 300°C of the precipitates filtered-off from the solutions containing metal polyphosphate complexes, i.e., hydrated polyphosphates of M(II), M(III), and M(IV), leads to dehydration, rupture of polyphosphate chains or cycles, and formation of a mixture of amorphous or crystalline phosphates of varied structure and degree of condensation. Further heating and prolonged keeping at temperatures of 300 to 900°C (depending on the polyphosphate structure and type of a cation) leads to formation of a high-temperature phosphate characteristic of the given cation in amorphous or crystalline state. For example, for Cu(II), Ni(II), Co(II), Mn(II), and Ba(II), this is a cyclic tetrametaphosphate $M^{II}_2P_4O_{12}$ [26]; for Y(III), Eu(III), and La(III), these are polyphosphates $Ln(PO_3)_3$ [27, 28];, and for Ga and Al, phosphates $M^{III}PO_4$ [29]. A fast cooling of the melt may lead to formation of metaphosphate glasses $M^{II}O \cdot P_2O_5$ or $M^{III}_2O_3 \cdot 3P_2O_5$ [8].

As for the mechanism of thermolysis of polyphosphate complexes in near-breakdown regions on a rectifying anode, it is in part similar to, and partly different from that established in [13, 24–29] in a study of annealing of precipitates formed in the similar solutions. The difference consists in that thermolysis of polyphosphates in anodizing under the action of electrical discharges occurs in specific conditions (parallel deposition and thermolysis in the vapor phase, pulsed changes in pressure and temperature, action of an electric field and illumination). The thermolysis and its products are affected by the nature of the anode metal. Polyphosphates or hightemperature M(II) and M(III) phosphates containing the $AlPO_4$ impurity phase are major thermolysis products formed on aluminum and its alloys (these compounds are also formed in annealing of the precipitates), whereas phosphatotitanates are mostly formed on titanium. In the latter case, polyphosphates or products of their thermolysis intensely interact with titanium or its oxide. Consequently, the thermal transformation mechanism is affected by presence in the reaction regions of rectifying metal, its oxide, and a large number of of other elements: carbon, sodium, alloying additives to rectifying metals and alloys (manganese, iron, magnesium, silicon, etc.). Moreover, it should be kept in mind that the thermolysis of a precipitate from the electrolyte is not the only anode process. In the near-breakdown region there may occur reactions characteristic of plasmochemistry, interactions in melts, solid-phase interactions, and photolysis and electrolysis of water. These processes can also affect the thermolysis mechanism and contribute to the coating formation.

Intense incorporation of the electrolyte components into PEO-coatings in the regions of instability, where the electrolytes containing metal polyphosphates and salts are in the metastable state, suggests that a similar phenomenon can take place in a variety of electrolytes capable of forming precipitates under certain conditions.

CONCLUSIONS

(1) For anodic layers formed on titanium, niobium, and zirconium electrodes in polyphosphate aqueous electrolytes under the action of electrical discharges, the relationship between the concentration of electrolyte components and the elemental composition and thickness of the layers is the same as that for layers formed on aluminum.

(2) For layers formed under similar conditions in electrolytes containing metal polyphosphate complexes, the rectifying metals can be arranged in the following order with respect to the phosphorus content in the layers (wt %) and their thickness: Ti > Nb > Al.

(3) In the course of annealing of the coatings formed on titanium, both metal phosphates incorporated into a polyphosphate complex and metal polyphosphates crystallize.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Chemisorption of Adamantane and Its Derivatives on the Surface of Anodically Polarized Aluminum and Titanium Alloys in Anodizing Electrolytes

E. A. Fedorova and E. K. Lysova

State Technical University, Nizhni Novgorod, Russia

Received July 7, 2005

Abstract—The mechanism of action of adamantane compounds added as modifying agents to anodizing electrolytes was studied. The additives improve the electrically insulating properties of the surface of aluminum and titanium alloys during anodic treatment.

DOI: 10.1134/S1070427206020170

The theoretical and practical interest in surfactants whose molecules contain adamantane structures increases owing to their high lipophilicity [1], thermal stability [2], chemical and electrochemical stability in anodic-treatment processes [3–6], and other distinctive properties [7]. To expand the application areas of adamantane derivatives, it is of importance to reveal the mechanism of their surface activity.

Previously, we have studied the surface activity and adsorption of adamantane and of a number of its derivatives on the untreated and anodically polarized iron, aluminum, and titanium alloys in highly concentrated electropolishing electrolytes, in which ions have virtually no hydration shells [3, 4].

The introduction of adamantane and its derivative, remantadinum, into low-concentrated anodizing solutions based on sulfuric and oxalic acids (up to 0.6 M) appeared to be effective in formation of anodic oxide films (AOF) on aluminum alloys [8].

According to [9], chemisorption from aqueous solutions onto metal oxides cannot take place, because, having a higher affinity for the surface, water molecules hinder adsorption of other compounds. Therefore, the present study is devoted to analysis of surface phenomena at the alloy–solution and AOF–solution interfaces in low-concentrated aqueous solutions for anodizing of aluminum and titanium alloys.

EXPERIMENTAL

Samples of aluminum (AMts, AMg, and D16) and titanium (VT10, VT6, and VT16) alloys were subjected to anodic oxidation in an electrolyzer with a cooling unit and lead cathodes.

Standard anodizing solutions (0.55 M $H_2C_2O_4$ and 0.15 M H_3BO_3 + 0.075 M $Na_2B_4O_7$) were modified by addition in an amount of 1.0–3.0 g l^{-1} of the following organic compounds: adamantane (Ad) $C_{10}H_{16}$, remantadinum (Rem) $C_{10}H_{15}$–NH_2–$C_2H_4 \cdot HCl$ (1-α-aminoethyladamantane hydrochloride), and fluoroderivatives of adamantane, hexafluoropropyl adamantanol $C_{10}H_{15}$–C_3HF_6 (Ad–R_1F_6) and perfluoro-1-propenyl adamantanol $C_{10}H_{15}$–CF=$CFCF_3$ (Ad–R_2F_5).

We used for anodic polarization of electrodes a PI-50-1 potentiostat, LKD-4 *X*–*Y* recorder, three-electrode cell, and saturated silver-chloride reference electrode.

We studied surface phenomena at the alloy–solution, solution–air, and AOF–solution interfaces, using methods for measurement of contact angles with a Wilhelmi plate [4, 10], boundary tension of solutions after Rebinder [4], and surface hardness after Rebinder [3, 9].

We determined the contact angles from the length l of the chords of a drop profile and drop height h, both measured with a reading microscope by the procedure described in [4], with the drop assumed to be spherical:

$$\theta = 2\arctan(2h/l), \quad (1)$$

$$\cos\theta = \frac{(l/2)^2 - h}{(l/2)^2 + h}. \quad (2)$$

To establish the presence of adamantane and its derivatives in anodic oxide films formed on the surface of alloys in electrolytes with these compounds added, we used the highly sensitive method of mass-spectrometry, combined with chromatography [11].

The breakdown voltage U_{br} (kV) and the electrical resistance R_{ins} (Ω) of the anodic oxide films, which characterize the dielectric properties of the these coatings, were measured with a UPU-1 voltmeter and an E6-17 megohmmeter, respectively. The porosity of the anodic oxide films formed on aluminum and titanium alloys during anodizing was determined in conformity with GOST (State Standard) 9.302–88 [12].

In aqueous solutions of sulfuric and oxalic acids or their mixtures to be used for anodizing of aluminum alloys and in a boric–borate solution for anodizing of titanium alloys, adamantane and its derivatives improved the electrically insulating properties of the anodic oxide films formed. The maximum resistance and breakdown voltage of anodic oxide films were obtained on aluminum alloys in the presence of an adamantane additive in the oxalic acid solution (Table 1). It was found that R_{ins} and U_{br} of films on anodized titanium alloys VT10 and VT16 increase when Rem, Ad–R_1F_6, and Ad–R_2F_5 are added to the boric-borate electrolyte (Table 1).

On the whole, the resistivity and breakdown voltage of oxide films on alloys of various brands increased by a factor of 1.3–2.3, with the process duration becoming shorter, in the presence of Ad, Rem, Ad–R_1F_6, and Ad–R_2F_5 in anodizing solutions (Table 1). In this case, the porosity of AOF on alloys of various brands decreased by a factor of 1.3–1.5.

The kinetic aspects of spreading of a drop of an oxalic acid solution with and without a remantadinum additive, obtained on an untreated surface of the AMg alloy (Table 2 and Fig. 1), allowed us to estimate changes in drop parameters (chord Δl, height Δh, and

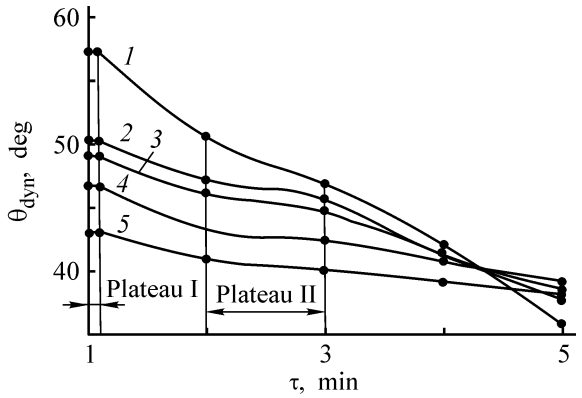

Fig. 1. Kinetic curves for spreading of a drop of an oxalic acid solution on the surface of the AMg alloy. (θ_{dyn}) dynamic contact angle of a solution drop and (τ) spreading time. 0.55 M solution of $H_2C_2O_4$ with a Rem additive (g l^{-1}): (*1*) 0, (*2*) 1.0, (*3*) 2.0, (*4*) 3.0, and (*5*) 4.0.

the rate of its spreading V_{sp}), depending on the Rem concentration and process duration. The presence of Rem in the background solution virtually eliminated spreading of drops in the first 5 min and made it possible to reduce V_{sp} by more than a factor of 2 (Table 2).

In the presence of Rem in the oxalic acid solution, the θ–τ curves have two well-pronounced plateaus characterized by quasi-equilibrium contact angles θ_0 and θ, respectively (Fig. 1). Transition from the quasi-equilibrium state of the surface (plateau I), which reflects the efficiency of competitive adsorption of solution components, to the second portion (plateau II), which characterizes the drop spreading in the viscous diffusion mode, can be evaluated by the driving force of spreading or by the Gibbs energy of spreading, ΔG_{sp} (mJ m^{-2}):

$$\Delta G^0_{sp} = \sigma_{s-g}(\cos\theta_0 - \cos\theta). \quad (3)$$

Here σ_{s-g} is the surface tension at the solution–air interface.

Comparison of the Gibbs energies of spreading of the background solution and that with a Rem additive (Table 2) confirms the hindering effect of the organic additive on the anodic dissolution of the alloy.

We can make the following conclusions on the basis of the experimental and calculated data of Table 2: (i) the decrease in the spreading rate with increasing concentration of remantadinum indicates that the surface chemical reaction and etching processes are hindered by the additive in use; (ii) the $\theta_{din} = F(\tau)$ curves level-off to form a plateau in the presence of Rem in the solution (Fig. 1), which suggests that there is a limiting saturation of the surface layer with remantadinum agglomerates.

The adsorption of Rem on the alloys was determined according to [3] from the surface tension isotherm by graphical differentiation of the dependence $\sigma\cos\theta = f(\ln c)$, using Eq. (4).

$$\Gamma = \frac{d(\cos\theta)\sigma}{dc}\frac{c}{RT}. \quad (4)$$

Here θ is the contact angle of an electrolyte drop and c is the surfactant concentration in solution.

The maximum surface concentration Γ_{max} of Rem in the oxalic acid solution on the AMg alloy was 9.0×10^{-7} mol cm^{-2}. As a rule, the concentrations of $(1–5) \times 10^{-10}$ mol cm^{-2} correspond to a monolayer of an adsorbate on a geometrically smooth surface in the absence of complex intermolecular interactions [10].

Γ_{max} was found in a similar way to be 1.2×10^{-9} mol cm^{-2} for remantadinum in a boric-borate solution on the VT16 alloy.

The resulting overestimated Γ_{max} values, especially on the surface of an aluminum alloy, seem to indicate the following: bulky skeleton agglomerates of surface compounds are formed; there occurs capillary absorption of a solution enriched with an organic substance by the alloy surface and the anodic oxide layer formed; there exists a polymolecular electrolyte layer retaining the saturated solution of an organic substance; and the aging and the subsequent decomposition of supersaturated solutions of organic compound, formed near the electrode surface, are accelerated. Mass-spectrometric data support such a mechanism of action of adamantane additives.

The anodic oxide films formed on the surface of alloys during oxidizing were subjected to cathodic reduction in a 20% H_2SO_4 solution, the solution was neutralized, and then organic components were extracted with methylene chloride. The extracted solution was analyzed in a mass-spectrometer, in which the substance under study was transferred into the gaseous state by electron impact, with the molecules ionized, the resulting ions separated, and their masses and relative amounts recorded in accordance with their mass-to-charge ratio mz^{-1} [11].

Adamantane hydrocarbons markedly differ from other polycyclic hydrocarbons in the nature of their disintegration. They rather readily form a highly stable adamantyl cation $C_{10}H^+_{15}$ characterized by the ratio $mz^{-1} = 135$, as recorded in a mass spectrogram.

In all probability, molecules of adamantane and its derivatives are sorbed on the surface of alloys because of the presence of active species of the adamantyl cation $C_{10}H_{15}^{+}$. Furthermore, remantadinum and electronegative fluoropropyl derivatives of adamantane can be also adsorbed on those parts of the surface which have an excess positive charge owing to the presence of unpaired electrons of nitrogen or fluorine atoms.

An addition of Rem to a boric-borate solution decreased the surface hardness H on the VT16 titanium anode in a wide range of potentials, the effect being the most pronounced at $E > 2.0$ V in the region of oxide formation (Fig. 2). Alternating maxima and minima in the H–E dependence, observed in the additive-free solution, can be accounted for by the presence of several electrocapillary curves [3, 9, 13, 14]. The observed decrease in H values near the peaks of the electrocapillary curves in the presence of remantadinum in the anodizing electrolyte is due to adsorption of Rem molecules on the surface of the anode under study.

Therefore, only organic compounds that form stronger chemical bonds with the surface than the hydrogen bond can be selectively adsorbed on the surface of alloys in the anodically polarized state, with water replaced from the surface.

According to Nechaev's chemisorption theory [15, 16], the adsorption of organic substances on the surface of metals and their oxides from aqueous solutions is determined by the fact that molecules of organic substances have potentials E_i close to the resonance ionization potentials E_r of a metal or an oxide, which actually are sorption characteristics of a solid (a difference of no more than 0.1–0.15 eV between the E_i and E_r values is possible).

The resonance ionization potential of titanium oxide TiO_2 is 9.7 eV [15]; among modifying additions, remantadinum and perfluoro-1-propenyladamantanol have ionization potentials the closest to this value (Table 3). These additives provided the most pronounced improvement of the electrically insulating characteristics of AOF formed on titanium alloys (Table 1).

Thus, we can consider confirmed that the effect of modifying organic additives in anodizing electrolytes on the results of the anodization is due to their adsorption on the surface of both untreated and anodically polarized alloys. However, this fails to reflect the true mechanism of the effect of organic additives, especially if it is considered in the dynamics of a nonequilibrium process of anodic dissolution of alloys in the passive and trans-passive regions.

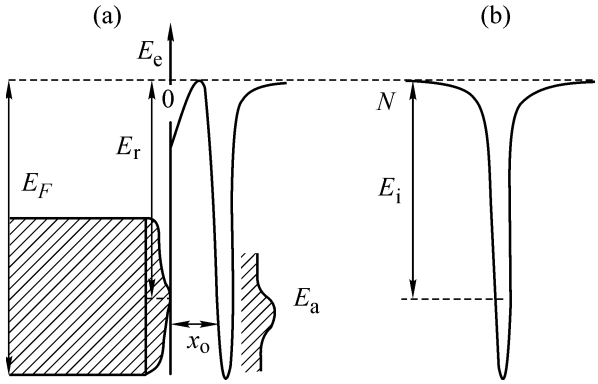

Fig. 3. Schematic of the electron distribution in a system constituted by a metal, oxide film, and adsorbed molecule of an organic substance. (E_e) electron energy, (x_o) distance from the center of an electron orbit to the adsorbent surface, (N) distance to an isolated adsorbent molecule. (a) Adsorbed organic molecule with a shifted electron level $\Delta E = E_a + E_i$, where E_a is the potential of an adsorbed molecule; E_F, position of the Fermi level in the metal; and E_r, resonance ionization potential of the oxide; (b) an isolated molecule with an ionization potential E_i.

Electrons in a molecule of an organic compound in the solution bulk occupy strictly fixed levels with energies determined by the ionization potential E_i (Fig. 3). When an organic molecule approaches

Table 3. Ionization potentials E_i of selected organic compounds [17]

Compound	E_i, eV
$C_{10}H_{16}$	9.25 ± 0.03
$C_{10}H_{15}$–OH	9.23 ± 0.03
$C_{10}H_{15}$–CF=$CFCF_3$	9.55 ± 0.03
$C_{10}H_{15}$–NH_2–C_2H_4 · HCl	9.60 ± 0.03

the surface of the anode, its electron levels are split owing to the interaction of electrons of the adsorbate with those of the adsorbent, with the levels shifted by ΔE [15, 16]. As a result, a set of levels with different energies appears instead of a strictly fixed electron level. The difference between the energies of the system with molecules situated far from an adsorbent surface and directly on the surface determines the adsorption energy E_{ads}.

It has been shown [4] that multiply charged ions of metals entering into the composition of the alloys under study are formed in stages via intermediate formation of monovalent ions (subions): Al^+, Ti^+, V^+, Mo^+, etc., which are further anodically oxidized to the ions Al^{3+}, Ti^{4+}, V^{5+}, and Mo^{6+}.

When the electron wave functions of the adsorbate and adsorbent molecules overlap, there occurs an exchange interaction to form a common electron system. The chemical bond formed in this way is similar in nature to a covalent bond, and the energy gain is determined by the change in the energy of electrons upon the formation of this bond. Both π and σ electrons of the adsorbate can be involved in bond formation.

Thus, we can assume that it is the stage-by-stage anodic dissolution of metals contained in alloys in the series $Ti^+ \rightarrow Ti^{3+} \rightarrow Ti^{4+}$, $Al^+ \rightarrow Al^{3+}$, and others that ensures the strength of the surfactant–AOF chemical bond with an energy exceeding that of the hydrogen bond.

CONCLUSIONS

(1) Additives of remantadinum, adamantane, and its fluoroderivatives in oxalate, sulfuric-oxalate, and boric–borate anodizing electrolytes improve the electrically insulating properties of anodic oxide films on aluminum and titanium alloys: the resistivity and the breakdown voltage of films increases by factors of 1.5–2.3 and 1.3–1.5, respectively; and the porosity decreases by a factor of 1.3–1.5.

(2) The additives have a surface-active effect at the solution–air and solution–alloy interfaces and, being adsorbed on the untreated and anodically polarized surfaces of the alloys, can enter in the composition of the forming oxide layer.

(3) The maximum adsorption of remantadinum on AMg and VT16 alloys was calculated. The high value of Γ_{max} indicates that the adsorption is accompanied by the formation of complex agglomerate structures constituted by remantadinum molecules and metal ions contained in alloys. It is probable that a strong chemisorption of adamantane compounds on the anodically polarized surface of the alloys becomes possible because of the stage-by-stage ionization of various metals contained in the alloys.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Concentration of Solutions being Titrated on the Shape of Conductometric Titration Curves

A. I. Demidov and M. S. Kokhatskaya

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received December 29, 2005

Abstract—The influence exerted by the concentration of solution being titrated on the shape of the theoretical curves of conductometric titration was studied. The concentrations at which the equivalence points are clearly observed in the conductometric titration curves were determined.

DOI: 10.1134/S1070427206020182

Conductometric titration is a technique in which the equivalence point is found by measuring the electrical conductivity of a solution being analyzed. The conductivity changes as a result of chemical reactions between the titrant and the substance being determined that occur in the course of titration [1]. Commonly, theoretical curves of conductometric titration are plotted using the electrical conductivities of infinitely diluted solutions [2]. Because the total electrical conductivity of a solution depends on its concentration, the increase in the initial concentration of a solution being titrated affects the shape of a conductometric titration curve. This can impair the accuracy of analysis and make narrower the areas of its applicability [3].

In the study, the influence exerted by the concentration of the solutions being analyzed on the shape of the theoretical curves of conductometric titration was demonstrated for the example of titration of solutions containing sodium hydroxide, sodium carbonate, mixtures of sodium hydroxide and sodium carbonate, and those of sodium carbonate and sodium hydrocarbonate with sulfuric acid. The concentrations at which the equivalence points are clearly manifested in the conductometric titration curves were determined.

The solutions mentioned above were analyzed in processing of worked-out nickel–iron (NI) batteries, in which aqueous sodium hydroxide solutions are the most frequently used as electrolyte. The drawback of alkaline electrolytes is their susceptibility to carbonization, which mainly occurs via absorption of atmospheric carbon(IV) dioxide. In storage of worked-out NI batteries in air, the electrolyte remaining in pores of the active paste undergoes further carbonization. As a result, sodium hydroxide is converted into sodium carbonate, and the carbonate, into hydrocarbonate [4].

The theoretical dependences of the electrical resistivity of the solutions on the number of titrant equivalents were constructed using data from the reference book [5]. In doing so, the dilution of the solution being analyzed during titration was disregarded. The calculation was performed for solutions with an initial concentration of a substance (or substances) to be determined equal to 0.01–0.1 N. The concentration of the titrant was 0.1 N in all cases.

In titrating a sodium hydroxide solution with a standard solution of sulfuric acid, the total electrical conductivity of the solution, χ_Σ, varies as follows:

before the equivalence point, at $0 < y < 1$,

$$\chi_\Sigma = \chi_{NaOH}(1 - y) + \chi_{Na_2SO_4}y,$$

at the equivalence point, at $y = 1$,

$$\chi_\Sigma = \chi_{Na_2SO_4},$$

after the equivalence point, at $1 < y < 2$,

$$\chi_\Sigma = \chi_{Na_2SO_4} + \chi_{H_2SO_4}(y - 1),$$

where χ_{NaOH} is the electrical conductivity of the initial solution of sodium hydroxide; $\chi_{Na_2SO_4}$, electrical

conductivity of the sodium sulfate solution; and y, number of titrant equivalents.

In titrating a sodium carbonate solution with sulfuric acid, the total electrical conductivity of the solution, χ_Σ, varies in the following manner:

before the first equivalence point, at $0 < y < 1$,

$$\chi_\Sigma = \chi_{Na_2CO_3}(1 - y) + \chi_{NaHCO_3}y + \chi_{Na_2SO_4}y,$$

at the first equivalence point, at $y = 1$,

$$\chi_\Sigma = \chi_{NaHCO_3} + \chi_{Na_2SO_4},$$

before the second equivalence point, at $1 < y < 2$,

$$\chi_\Sigma = \chi_{NaHCO_3}(2 - y) + \chi_{Na_2SO_4}y,$$

at the second equivalence point, at $y = 2$,

$$\chi_\Sigma = 2\chi_{Na_2SO_4},$$

after the second equivalence point, at $2 < y < 3$,

$$\chi_\Sigma = 2\chi_{Na_2SO_4} + \chi_{H_2SO_4}(y - 2),$$

where $\chi_{Na_2CO_3}$ and χ_{NaHCO_3} are the electrical conductivities of the initial solution of sodium carbonate and of the solution of sodium hydrocarbonate, respectively.

Before the titration, the total electrical conductivity of a solution containing sodium hydroxide and carbonate is the sum of the electrical conductivities of the solutions of the initial substances $\chi_\Sigma = \chi_{NaOH} + \chi_{Na_2CO_3}$. During titration, the electrical conductivity of the solution varies as follows: before the first equivalence point, at $0 < y < 1$,

$$\chi_\Sigma = 0.5(\chi_{NaOH} + \chi_{Na_2CO_2})(1 - y) + \chi_{NaHCO_3}(y/2) + \chi_{Na_2SO_4}y,$$

at the first equivalence point, at $y = 1$,

$$\chi_\Sigma = 0.5\chi_{NaHCO_3} + \chi_{Na_2SO_4},$$

before the second equivalence point, at $1 < y < 1.5$,

$$\chi_\Sigma = \chi_{NaHCO_3}(1.5 - y) + \chi_{Na_2SO_4}y,$$

at the second equivalence point, at $y = 1.5$,

$$\chi_\Sigma = 1.5\chi_{Na_2SO_4},$$

after the second equivalence point, at $1.5 < y < 2$,

$$\chi_\Sigma = 1.5\chi_{Na_2SO_4} + \chi_{H_2SO_4}(y - 1.5).$$

During the titration of a solution containing sodium carbonate and hydrocarbonate with sulfuric acid, there first occurs the reaction in which sodium hydrocarbonate $NaHCO_3$ and sodium sulfate Na_2SO_4 are formed:

$$Na_2CO_3 + 1/2\,H_2SO_4 \longrightarrow 1/2\,Na_2SO_4 + NaHCO_3.$$

Further, sodium carbonate originally contained in the solution and sodium carbonate produced in titration are neutralized to give sodium sulfate Na_2SO_4:

$$NaHCO_3 + 1/2\,H_2SO_4 \longrightarrow 1/2\,Na_2SO_4 + H_2O + CO_2.$$

Thus, the electrical conductivity of the solution varies during titration as follows:

before the first equivalence point, at $0 < y < 1$,

$$\chi_\Sigma = \chi_{Na_2CO_3}(1 - y) + \chi_{NaHCO_3}(1 + y) + \chi_{Na_2SO_4}y,$$

at the first equivalence point, at $y = 1$,

$$\chi_\Sigma = 2\chi_{NaHCO_3} + \chi_{Na_2SO_4},$$

before the second equivalence point, at $1 < y < 3$,

$$\chi_\Sigma = \chi_{NaHCO_3}(3 - y) + \chi_{Na_2SO_4}y,$$

at the second equivalence point, at $y = 3$,

$$\chi_\Sigma = 3\chi_{Na_2SO_4},$$

after the second equivalence point, at $3 < y < 5$,

$$\chi_\Sigma = 3\chi_{Na_2SO_4} + \chi_{H_2SO_4}(y - 3).$$

The resulting values of the total electrical conductivity were used to construct the theoretical dependences of the electrical resistivity of the solutions on the number of titrant equivalents (Figs. 1a–1d). It can be seen that the curves obtained in titration of dilute solutions show clearly pronounced inflections corresponding to the equivalence points. It was established that the concentrations of a substance (or a mixture of substances) to be determined, at which the equivalence points are clearly observed in the curves of conductometric titration, should not exceed 0.05 N.

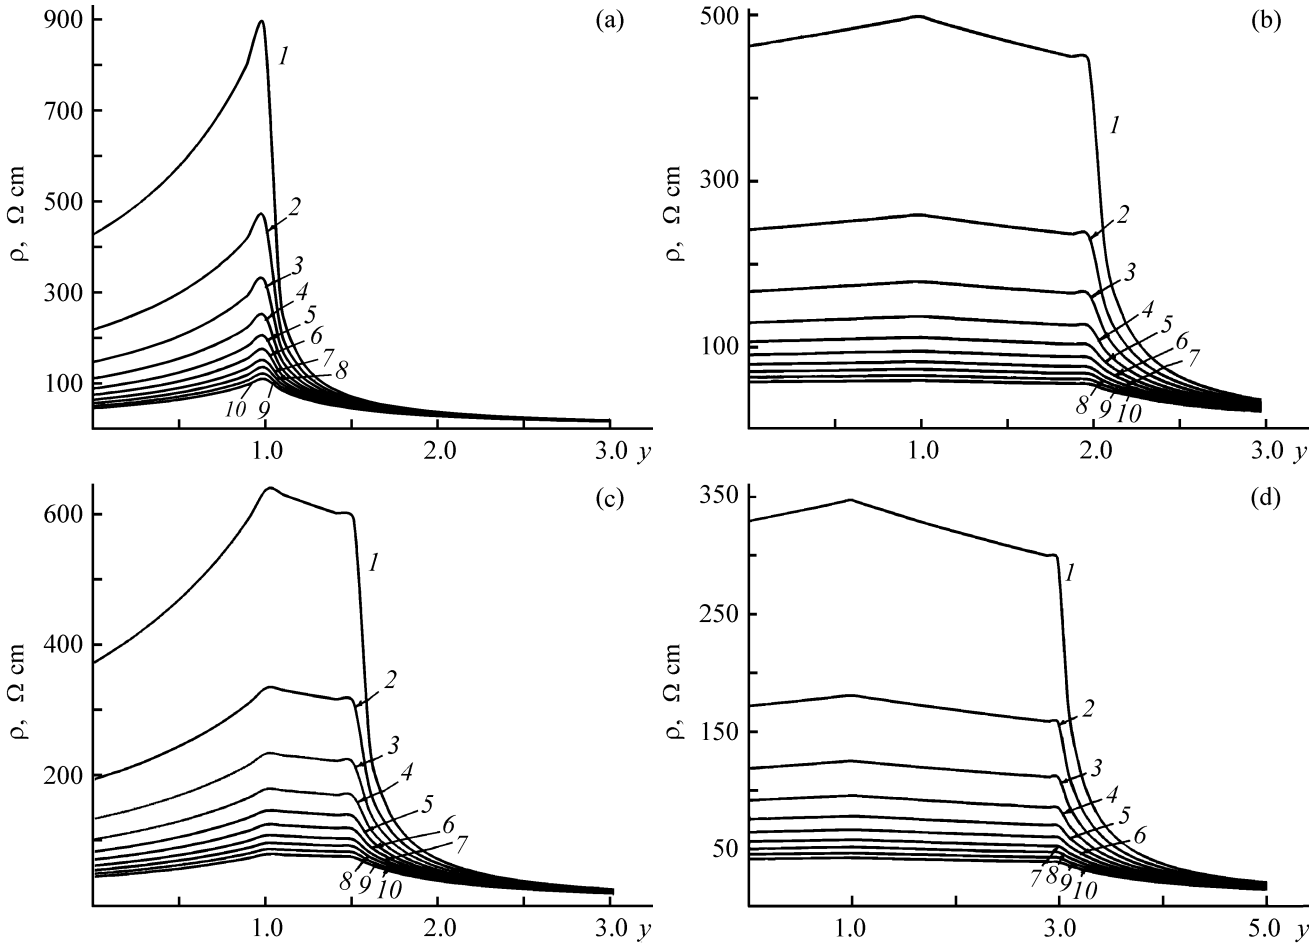

Fig. 1. Theoretical dependence of the electrical resistivity ρ of the solution on the number of titrant equivalents, *y*, in titration of solutions of (a) sodium hydroxide, (b) sodium carbonate, (c) sodium hydroxide and sodium carbonate, and (d) sodium carbonate and sodium hydrocarbonate with 0.1 N H_2SO_4 at 25°C. Concentration (g-equiv l^{-1}): (*1*) 0.01, (*2*) 0.02, (*3*) 0.03, (*4*) 0.04, (*5*) 0.05, (*6*) 0.06, (*7*) 0.07, (*8*) 0.08, (*9*) 0.09, and (*10*) 0.1.

CONCLUSIONS

(1) Theoretical curves of conductometric titration of solutions containing sodium hydroxide, sodium carbonate, mixture of sodium hydroxide and sodium carbonate, and that of sodium carbonate and sodium hydrocarbonate with sulfuric acid were presented and the influence exerted by the concentration of the solutions being analyzed on the shape of the theoretical curves of conductometric titration was demonstrated.

(2) It was found that the concentration of a substance (or a mixture of substances) to be determined, at which the equivalence points are clearly pronounced in the conductometric titration curves, should not exceed 0.05 N.

(3) It was recommended to use conductometric titration to analyze dilute solutions.

Abstract—A method for quantitative conductometric titration of chitosan in aqueous hydrochloric and acetic acids was developed. The stoichiometry of complexation of chitosan with Co(II) was studied.

DOI: 10.1134/S1070427206020194

Chitosan, high-molecular-weight polyelectrolyte {poly[β(1-4)-amino-2-deoxy-*D*-glucose]}, is prepared by deacetylation of natural polysaccharide chitin with aqueous alkali. As a rule, the degree of deacetylation ranges from 78 to 92%. Chitosan prepared by this method contains both *D*-glucosamine and *D*-glucosacetamide units. Chitosan and materials on its basis are widely used in various areas: in medicine (dressing), in pharmacology (carriers for drugs of prolonged effect), in aqriculture (encapsulating agents for seed granulation), and in industry (sorbents, selective membranes, flocculants) [1]. The use of chitosan for binding of heavy metals is one of promising areas of its application. Chitosan is coordinated with metals by complicated mechanisms which are poorly understood at present [1]. It is believed that these mechanisms are based on complexation of chitosan macromolecules with metal cations. The binding of metals with chitosan in heterogeneous systems is accompanied by sorption and precipitation, which complicates the elucidation of chitosan-metal interactions. The mechanism of coordination of chitosan with metals in homogeneous solutions is also poorly understood. Only chelation has been discussed, although other kinds of complexation are also possible.

In this study, we developed a technique for quantitative determination of both the chitosan content in solutions and its complexation with cobalt(II).

The main technique used in our experiments was conductometric titration, which allows monitoring of acid-base and coordination interactions in the solutions. This technique is suitable for quantitative determination of the chitosan content in solutions and for study of its complexation with metals. The main aspects of application of conductometric titration to solution of these problems were reported in [2]. The results of conductometric titration are compared with those obtained by pH-metric titration.

EXPERIMENTAL

Solutions of chitosan of a required concentration in 0.1 M aqueous hydrochloric and 0.1 M aqueous acetic acids were used. The molecular weight of chitosan was determined viscometrically in the mixed solvent (0.3 M aqueous CH_3COOH + 0.33 M aqueous NaCl). The viscosity was measured with an Ubbelohde viscosimeter at 21 ± 0.1°C. The chitosan molecular weight was calculated by the equation $[\eta] = KM^{\alpha}$ {$K = 3.41 \times 10^{-3}$ and $\alpha = 1.02$ [3]}.

Solutions of cobalt salts (~1 M) were prepared from their weighed portions in water. The Co(II) concentration was refined by complexometric titration.

The complexation of cobalt with chitosan was studied conductometrically with an Impul's KL-2 conductometer at room temperature. The electrical conductivity of solutions was measured in a conductometric cell with a broadened part [2] at various ratios of cobalt(II) and chitosan. To attain the equilibrium, the solutions were kept for 24 h.

As a rule, solutions of chitosan are prepared in aqueous hydrochloric or aqueous acetic acid. The degree of deacetylation of chitosan was determined by addition of hydrochloric acid, followed by potentiometric back-titration of its excess. The content of monomeric units in chitosan macromolecules was de-

termined by displacement of the amino groups of chitosan with aqueous alkali. This determination can be carried out in both aqueous hydrochloric and aqueous acetic acid media.

Figure 1, curve *1*, shows the conductometric titration curve of a solution of chitosan in aqueous hydrochloric acid. In the initial portion of the titration curve, the electrical conductivity decreases due to neutralization of the excess hydrochloric acid with aqueous sodium hydroxide, and then it increases due to displacement of HCl bound to the primary amino groups of chitosan hydrochloride. The addition of excess aqueous alkali strongly increases the electrical conductivity. The resulting titration curve has two breaks corresponding to the final titration points (FTPs) of free and bound HCl, respectively. The correct positions of these points can be determined by linear extrapolation of the adjacent portions of the titration curve. The chitosan concentration in the solution was determined from the difference between aqueous alkali volumes corresponding to the second and first FTPs, respectively. For comparison, the identical solution of chitosan was titrated with aqueous NaOH potentiometrically. This titration curve also shows two breaks. The chitosan content in the solution was determined by back-titration of a solution corresponding to the first break. We found that the solution of chitosan becomes turbid at pH 9, and chitosan precipitates at higher pH. The chitosan concentration in aqueous HCl, determined by the direct conductometric titration, was 0.0287 ± 0.0006 M ($P = 0.95$, $n = 5$). The degree of deacetylation of chitosan (for monomeric unit with Mr = 161), recalculated to air-dry chitin, was 92.1%. From the pH corresponding to half-displacement with aqueous NaOH of HCl bound with the amino groups of chitosan, we determined the base ionization constant pK_b of the amino groups. This value was found to be 7.7 at 20°C, which is close to published data.

Figure 1, curve *2*, shows conductometric titration curves for solutions of chitosan in aqueous acetic acid. This curve also has two breaks. It is known [2] that the order of titration with strong aqueous alkali of a weak acid in a mixture containing this weak acid and its salt of weak base is governed by the ratio between pK_a of the weak acid and pK_b of the weak base. In our system, this ratio is such that, first, excess acetic acid and then the acetic acid bound to the amino groups of chitosan are titrated with aqueous sodium hydroxide. In the course of titration of the excess acetic acid, the electrical conductivity increases due to the formation of a strong electrolyte (sodium acetate). In the second stage of titration, acetic acid is displaced from chitosan acetate by sodium hydroxide to form

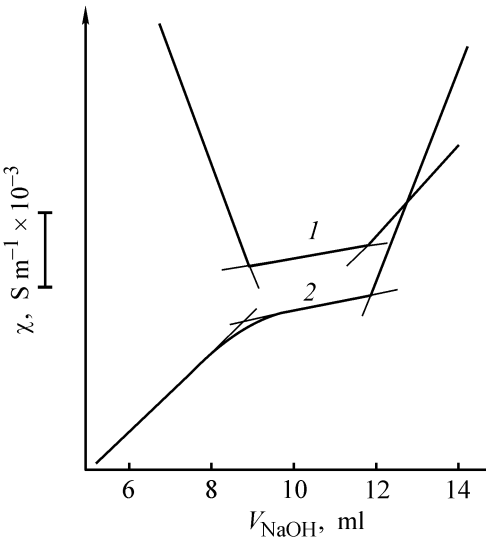

Fig. 1. Conductometric titration curves of solutions of chitosan in (*1*) aqueous hydrochloric and (*2*) aqueous acetic acids with aqueous sodium hydroxide in the coordinates of electrical conductivity χ vs. volume of 0.1 M aqueous NaOH.

sodium acetate. This process also increases the electrical conductivity since the mobility of the chitosan polycation is lower than that of the sodium cation. In this stage of titration, the slope of the plot of the electrical conductivity vs. the volume of aqueous NaOH is smaller than that in titration of excess acetic acid. As a result, the titration curve shows a break corresponding to the completion of neutralization of free acetic acid. Upon further addition of aqueous sodium hydroxide, a second break appears in the titration curve, which corresponds to neutralization of acetic acid bound to the amino groups; it is followed by a steeper increase in the conductivity. Although this break is rounded, its position can be determined sufficiently reliably by extrapolation of the adjacent portions of the titration curve. The chitosan concentration determined from the difference between the volumes of aqueous alkali corresponding to the second and first breaks, was 0.0284 ± 0.0011 M ($P = 0.95$, $n = 5$). We found that, in pH-metric titration of chitosan solutions, the titration curve shows a single break corresponding to titration of a sum of the excess acetic acid and that bound to the amino groups of chitosan. Therefore, determination of chitosan concentration is impossible in this case.

The stoichiometry of coordination of cobalt(II) with chitosan was studied by conductometric titration with aqueous sodium hydroxide of a solution of a cobalt salt in acetic acid in the presence of excess chitosan.

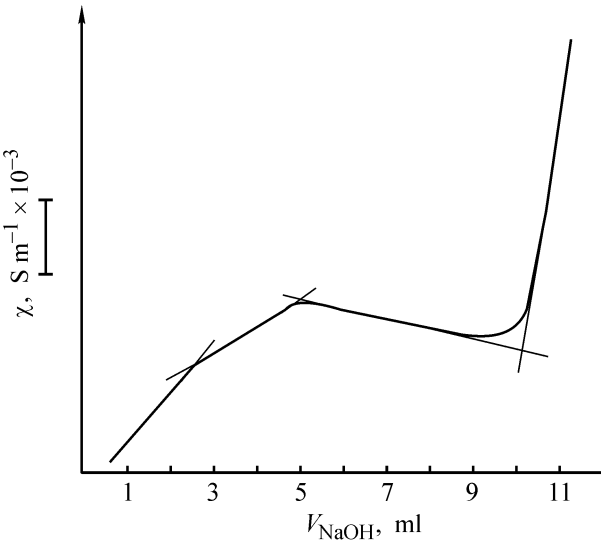

Fig. 2. Conductometric titration curves of solutions containing a chitosan–Co(II) mixture at their molar ratio of 2 : 1 in the coordinates of electrical conductivity χ vs. volume of 0.1 M aqueous NaOH.

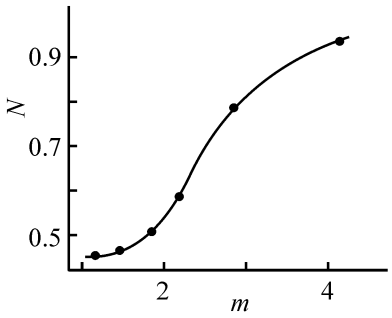

Fig. 3. Number *N* of chitosan moles bound with 1 mol of Co(II) in the chitosan–Co(II) complex vs. chitosan : Co(II) molar ratio *m* in the acetic acid solution.

The titration curve (Fig. 2) consists of four portions. Comparison of the slopes of separate portions of this titration curve with those of the titration curve of chitosan solution containing no Co(II) (Fig. 1, curve *2*) allows elucidation of the main processes occurring in different stages of titration of the Co(II)–chitosan mixture with aqueous NaOH. The first portion of the titration curve reflects the neutralization of the excess acetic acid; the second portion corresponds to titration of the excess chitosan, which is followed by formation of chitosan suspension; and the third portion reflects the superposition of several reactions followed by precipitation of a poorly soluble cobalt hydroxide. This means that, in the final stage of titration, weak chitosan–Co(II) complexes are destroyed and free chitosan is released.

The stoichiometry of coordination of chitosan with cobalt(II) was determined by conductometric back-titration. The excess chitosan was determined from the second portion of the titration curve. The chitosan amount bound to Co(II) was determined as the difference between the total content of chitosan in the system under consideration and its excess. The chitosan concentration in the initial solutions was approximately 0.1 M. In our experiments, all the solutions contained equal amounts of chitosan. The molar ratio of chitosan and Co(II) ranged from 1.33 to 5. Figure 3 shows the number *N* of chitosan molecules bound to Co(II) in the chitosan–Co(II) complexes as a function of the chitosan : Co(II) molar ratio *m* in the solution. It can be seen that, at a more than fourfold excess of chitosan, chitosan–Co(II) complexes containing approximately one Co(II) per chitosan monomeric unit are formed. The deviations from this stoichiometry at smaller excess of chitosan are apparently caused by decomposition of weak chitosan–Co(II) complexes.

CONCLUSIONS

(1) The chitosan concentration and the degree of deacetylation of chitosan can be quantitatively determined with a sufficiently high accuracy by conductometric titration.

(2) The number of chitosan molecules bound to the Co(II) ion is a function of the chitosan to Co(II) molar ratio. At a fourfold excess of chitosan, the chitosan– Co(II) complexes containing approximately one Co(II) ion per chitosan monomeric unit are formed.

Abstract—The influence of sodium salt of humic acids on the reduction of Chrome Green Anthraquinone dye with thiourea dioxide under aerobic and anaerobic conditions was studied.

DOI: 10.1134/S1070427206020200

Sulfur-containing reductants, sodium ditionite $Na_2S_2O_4$ (DTN), sodium hydroxymethanesulfinate $HOCH_2SO_2Na$ (HMS), and thiourea dioxide $(NH_2)_2CSO_2$ (TUDO), are widely used as reductants of vat dyes [1]. The reduction of vat dyes with HMS can be substantially accelereated with catalysts, among which the most commonly used are cobalt dioximates and anthraquinone derivatives [2]. We have shown [3] that the reaction of HMS with a water-soluble model of a vet dye in an alkaline medium is accelerated by humic acids (HAs), a special group of natural organic compounds formed from plant residues; they are the main part of organic matter in the biosphere [4]. In the environment, HAs may act as reductants (they can reduce Fe^{3+}, Sn^{4+}, V^{5+}, Cr^{6+} ions [5]) and as oxidants (due to their quinoid groups capable of reversible reduction) [4]. Quinoid groups may impart to HAs the catalytic properties in various redox reactions.

In this study, we examined the influence of HAs on the reaction of TUDO with superoxide and water-soluble dye Chrome Green Anthraquinone CGA (CI Acid Green 27) as oxidants. Special attention was paid to the effect of oxygen on the dye reduction in the presence of HAs, which was not considered in [3].

EXPERIMENTAL

We used TUDO and HA sodium salt from Aldrich and potassium peroxide from Merck. Technical grade CGA was purified according to [6].

The rate of CGA reduction by excess TUDO was determined by measuring the optical density at the absorption peak of oxidized dye (λ_{max} = 612 nm, ε = 10 870 l mol^{-1} cm^{-1}). Preliminarily, it was verifird that this band is well-resolved from the band of the reduced dye. The CGA concentration was found in the range of validity of the Bouger–Lambert–Beer law.

The rate of DTN formation by TUDO decomposition under aerobic conditions was estimated spectrophotometrically by measuring the optical density at λ_{max} = 315 nm, (ε = 8043 l mol^{-1} cm^{-1} [7]). A Specord M-40 spectrophotometer was used in all kinetic experiments. To eliminate the oxygen effect, the solutions were preliminarily bubbled with Ar for 30 min.

The kinetic curves of CGA reduction by TUDO at various NaOH concentrations in the presence of atmospheric oxygen are shown in Fig. 1. The influence of small HA additions on this process is also illustrated (preliminarily, we found that, under anaerobic conditions and at c_{NaOH} = 0.01–0.5 M, the rate of CGA reduction is independent of HA). It follows from Fig. 1 that at the smallest alkali concentration HA virtually does not affect CGA reduction kinetics, but this influence increases with the alkali concentration.

Most of the kinetic curves in Fig. 1 are linear (this means the zero order with respect to CGA); deviation from linearity is observed only at the final stage of the reaction. When HMS is used as reductant, the kinetic curves are nonlinear and can be well described by first-order equations [3]. The first order with respect to CGA in the reaction of CGA with HMS shows that the initial HMS molecule is involved in the reaction. The zero order with respect to CGA in the reaction of CGA with TUDO shows that

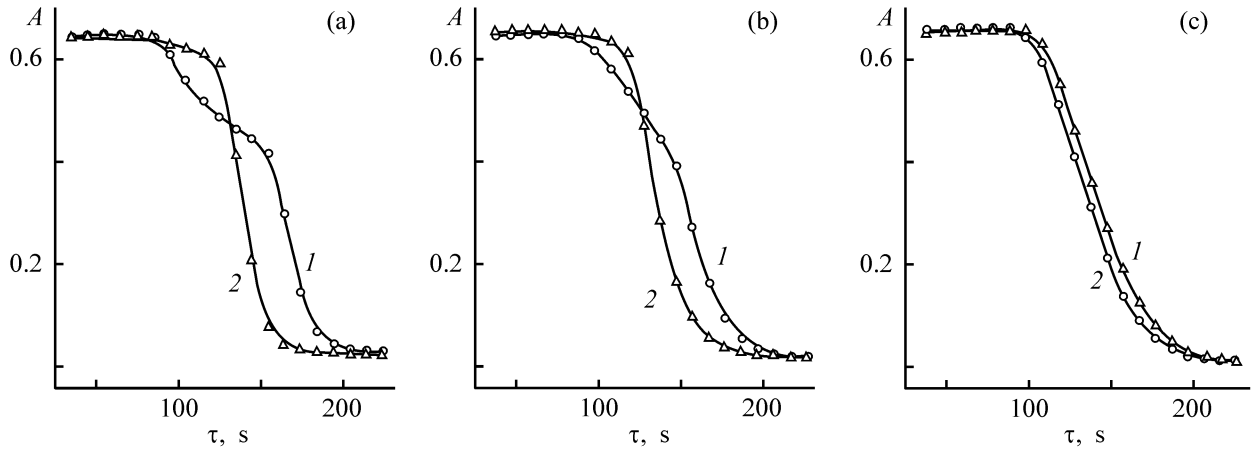

Fig. 1. Influence of solution alkalinity and presence of HA additive on kinetics of CGA reduction by thiourea dioxide at 20°C. $c_{CGA} = 5.98 \times 10^{-5}$ M, $c_{TUDO} = 4.62 \times 10^{-2}$ M, and $c_{HA} = 0.1$ g l^{-1}. (*A*) Optical density of the CGA solution and (τ) time; the same for Figs. 2, 3. c_{NaOH} (M): (a) 0.1, (b) 0.05, and (c) 0.0125. (*1*) Without HAs and (*2*) in the presence of HAs.

the product of its decomposition, rather than TUDO, reacts with oxidant. This product is SO_2^{2-} ion [8] generated by the reaction

$$(NH)_2CSO_2^{2-} + H_2O \rightarrow (NH)_2CO + SO_2^{2-}. \quad (1)$$

In a strongly alkaline solution, TUDO is deprotonated [9], and, therefore, it is represented in reaction (1) as dianion. Reaction (1) determines the overall rate of the CGA reduction.

It is known that the SO_2^{2-} ion rapidly reacts with oxygen to form another strong reductant, radical anion $SO_2^{\cdot-}$ [8]:

$$SO_2^{2-} + O_2 \rightarrow SO_2^{\cdot-} + O_2^{\cdot-}. \quad (2)$$

The reaction of oxygen with SO_2^{2-} ion precedes its reaction with CGA. This gives rise to induction periods in the reduction of CGA, irrespective of pH (Fig. 1). Similar induction periods (conventionally termed first induction periods) have also been observed in reactions of TUDO with other dyes [2]. It was found that the duration of the first induction period depends only on the oxygen concentration, which amounts to 2.4×10^{-4} M in an air-saturated aqueous solution [8], irrespective of the concentrations of active oxygen species (superoxide and peroxide) [10].

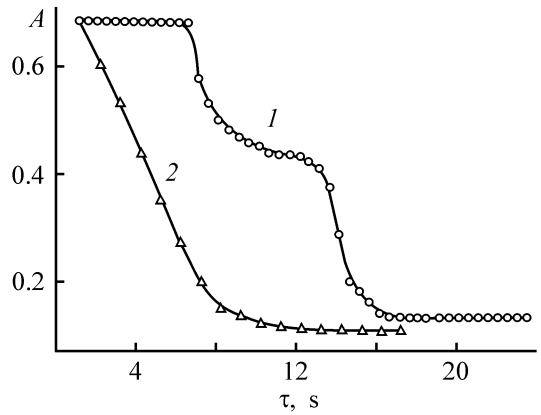

Fig. 2. Influence of atmospheric oxygen on the kinetics of CGA reduction by thiourea dioxide at 20°C. $c_{CGA} = 5.98 \times 10^{-5}$ M, $c_{TUDO} = 1 \times 10^{-3}$ M, $c_{NaOH} = 0.1$ M. (*1*) Without and (*2*) with preliminary bubbling with Ar.

It follows from Fig. 1 that the alkali concentration does not noticeably affect the first induction period. This is natural, since the rate of TUDO decomposition in strongly alkaline solutions [reaction (1)] is independent of pH.

Thus, the mechanisms of HMS and TUDO reactions with CGA substantially differ. The influence of HAs on the CGA reduction by the above sulfur-containing compounds is also manifested differently. The HA additives substantially increase the rate of reduction by HMS [3], whereas in the case of TUDO, their effect is insignificant. The induction period becomes longer when CGA is reduced by TUDO in a strongly alkaline solution in the presence of HA additives and atmospheric oxygen (under anaerobic conditions, the induction period is absent in the presence of HAs). At the same time, the shape of the kinetic curve changes: the curve portion corresponding to a slow decrease in the CGA concentration (conventionally termed second induction period) disappears. It should be noted that both induction periods are absent under anaerobic conditions (Fig. 2). Hence, we may assume that the second induction period is caused by the presence in the reaction mixture of an oxygen reduction product, superoxide [reaction (2)].

To verify this assumption, we examined the effect of potassium superoxide and combination of potassium superoxide with HAs on the shape the kinetic curve of CGA reduction by TUDO in a solution containing 0.5 M NaOH (Fig. 3). The strongly alkaline medium was chosen because disproportionation of the superoxide [reaction (3)] is substantially slower in this case, compared with weakly alkaline or neutral solutions [11]:

$$HO_2^{\cdot} \rightarrow O_2 + H_2O_2. \quad (3)$$

In accordance with Fig. 3, the second induction period in the reduction of CGA, which becomes substantially longer on adding KO_2 (curve *2*), completely disappears in the presence of HAs, whereas the duration of the first induction period increases (curve *3*). This correlation shows that HAs act as superoxide dismutase, i.e., they accelerate the disproportionation of the superoxide.

To confirm this conclusion, we studied the effect of HAs on dithionite formation in alkaline TUDO solutions under aerobic conditions. It was shown in [8] that the $S_2O_4^{2-}$ ion is formed in TUDO alkaline solutions via dimerization of the $SO_2^{\cdot-}$ radical ion generated by reaction (2):

$$2SO_2^{\cdot-} \rightarrow S_2O_4^{2-}. \quad (4)$$

The induction period caused by the reaction of both SO_2^{2-} and $SO_2^{\cdot-}$ with atmospheric oxygen [8] precedes the formation of the $S_2O_4^{2-}$ ion; neither the superoxide nor the peroxide affect the induction period [8, 12].

We found that HA additives make longer the induction period of accumulation of the $S_2O_4^{2-}$ ion in the solution (Fig. 4), i.e., this effect is similar to the effect of CGA reduction under conditions of increasing oxygen concentration [reaction (3)]. It is interesting that an increase in the induction period in the $S_2O_4^{2-}$-vs.-time curves in anaerobic decomposition of TUDO has been observed earlier upon addition of superoxide dismutase [12]. Thus, the data obtained confirmed the accelerating effect of HAs on the disproportionation of the superoxide.

In this context, it should be noted that the catalytic activity of the superoxide dismutase enzyme sharply decreases in alkaline solutions [13]. In this study, we showed that, in contrast to enzymes, the catalytic effect of HAs is fairly high even in 0.5 M NaOH.

Reactions involving the superoxide play an important part in the vital activity of animals and plants [13]. On the one hand, its role as precursor of high reactive hydroxyl radical and singlet oxygen is negative;

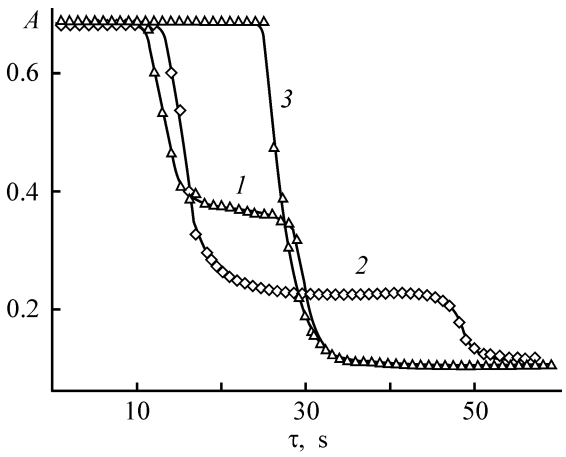

Fig. 3. Reduction of CGA by thiourea dioxide in strongly alkaline solution at 20°C: (*1*) without additives, (*2*) in the presence of KO_2, and (*3*) in the presence of KO_2 and HA. $c_{CGA} = 5.98 \times 10^{-5}$ M, $c_{TUDO} = 1.0 \times 10^{-3}$ M, $c_{NaOH} = 0.5$ M, $c_{KO_2} = 1.0 \times 10^{-4}$ M, and $c_{HA} = 0.1$ g l^{-1}.

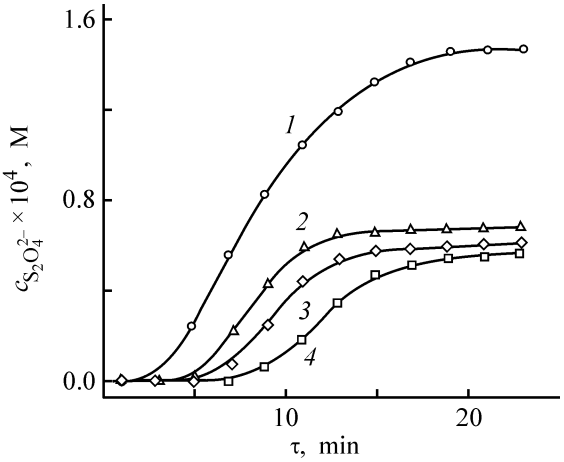

Fig. 4. Influence of HA concentration on the kinetics of $S_2O_4^{2-}$ accumulation in alkaline solution during TUDO decomposition under aerobic conditions at 20°C. $c_{TUDO} = 1.0 \times 10^{-3}$ M, $c_{NaOH} = 0.5$ M, $c_{KO_2} = 1.0 \times 10^{-4}$ M. ($c_{S_2O_4^{2-}}$) Dithionite concentration in the solution and (τ) time. HA concentration (g l^{-1}): (*1*) 0, (*2*) 0.03, (*3*) 0.05, and (*4*) 0.1.

on the other hand, it is involved in processes that prevent tumor development. The mechanisms of superoxide transformations are being actively studied today. Because the biological and medical aspects of chemistry of humic compounds also attract growing attention [14], the catalytic effect of HAs in superoxide disproportionation, found above, is important for determining the biological role of these compounds. This effect may be of interest for industrial processes involving sulfur-containing reductants. For instance, it is known that the reaction of vat dyes with sulfur-con-

taining reductants, especially with TUDO, is accompanied by "overreduction" of dyes [15], which leads to their unproductive consumption. It was found that the fraction of overreduced dye substantially increases with the concentration of active oxygen species [16]. In addition, the rate of decomposition of reductants substantially increases under aerobic conditions. The results of this study show that HA additives can substantially decrease the loss of dyes and reductants.

CONCLUSIONS

(1) The effect of natural humic acids on reduction of water-soluble Chrome Green Anthraquinone dye (CI Acid Green 27) with thiourea dioxide is governed by the presence of atmospheric oxygen in the solution.

(2) Humic acids are efficient catalysts of superoxide disproportionation.

(3) In the technology of dyeing and printing of fibrous materials with vat dyes, addition of humic acids may decrease the consumption of dyes and reductants.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Application of New Types of Fibrous Sorbents for Sampling of Dissolved Species of Heavy Metals in Natural Waters

Yu. E. Dolgova and V. A. Kudryavtseva

St. Petersburg Scientific Research Center for Ecological Safety, Russian Academy of Sciences, St. Petersburg, Russia

Received December 2, 2005

Abstract—The article discusses the importance and specific features of the preparatory stages in ecoanalytical monitoring of natural water, aimed to determine the content of heavy metals. A procedure was developed for sampling of dissolved species of heavy metals with sorbents. The influence of humic substances on the sorption of heavy metals was elucidated. The results obtained with the technique suggested are reported.

Analytical monitoring of pollution of natural water is an urgent problem faced by modern hydroecology and environmental analytics. In particular, of special importance is monitoring of the content of heavy metals (HMs) [1] ranking among the most hazardous biologically components of natural water.

The general scheme of ecoanalytical monitoring of any natural object includes the following successive stages: sampling, preservation and transportation of samples, sample preparation, instrumental analysis, and processing and interpretation of the results [2].

Sampling is very important in environmental monitoring; it primarily determines the accuracy of the subsequent analysis. Above all, it is necessary to ensure conditions under which the sample is representative. Of much importance are the specific features of the object and the goal of investigation. There is a need in several replicate measurements, which increases the minimal volume of the sample. Even in the sampling stage, it is necessary to take special measures to avoid contamination. Such measures are typically described in detail either in appropriate techniques or in special manuals of analysis. Careless handling and inappropriate storage may be responsible for changes in the composition of the samples via photolytic or thermal decomposition, chemical reactions, or microbiological transformations.

In many cases, practicians have to preserve the samples, so as to carry out the analysis at a later time [1], rather than under field conditions; this can increase the inaccuracy of the subsequent analysis.

Sample preparation is the first stage of the analytical procedure proper. It is aimed to convert the component being analyzed to a form suitable for analysis by the chosen method, to remove or mask interfering substances, and, in some cases, to precisely adjust the concentration to make the expected content of the component being analyzed close to the middle of the operating range of the analytical method used [3].

Analysis of dissolved species of metals typically requires taking no less than a 1-l isokinetic water sample (or several liters of separate samples taken across the entire river section). The water samples taken should be conserved at the sampling site, and analysis should be carried out within a brief period (not later than in 5–7 days). The use of various conserving agents after sampling of natural water has been reported. To preserve dissolved species of heavy metals, the samples are acidified with nitric acid to pH < 2 or cooled to 3–4°C and stored at this temperature [4], which is technically troublesome. However, sample preservation does not afford a constant composition of a water sample for an infinite period [5]. Bringing samples to stationary analytical laboratories frequently takes a relatively long time, up to several weeks. This inevitably entails loss of dissolved species of heavy metals, e.g., via biochemical processes and sorption on the dishware, which distorts analytical data.

Analytical practice widely uses sorption preconcentration, in particular, in preparation of natural water samples for analysis. The sorption preconcentration has advantages of simplicity and easy performance, high efficiency, rapidity, and possibility of combina-

Table 1. Sorption capacity C of the sorbents

Sorbent	C, mg g^{-1}					
	Cu(II)	Ni(II)	Co(II)	Mn(II)	Pb(II)	Zn(II)
Poliorgs-33n	245	40	40	80	330	100
Poliorgs-34	130	40	40	80	330	66
Poliorgs-35	140	42	80	60	270	74

tion with various analytical methods [6]. For preconcentration of trace elements, certain promise is offered by "filled" fibrous complexing sorbents, i.e., thin polyacrylonitrile fibers retaining a finely ground complexing filling sorbent inside. Such sorbents are distinguished by good kinetic and filtration properties, combined with a high sorption capacity. Complexing sorbents with amidoxime and hydrazidine groups can sorb many transition metals from aqueous solutions [7]. Fibrous sorbents are especially promising for in situ preconcentration of trace elements from natural water.

In this study, we developed a technique for sampling of dissolved species of heavy metals, using fibrous sorbents. A small weighed portion (<0.1 g) of a sorbent allows preconcentration of dissolved species of metals from a large water volume and their further retention without quantitative changes for a long time. The technique we suggest avoids transportation of large water volumes. Without transportation and preservation of liquid samples, the inaccuracy of analysis significantly decreases. Preconcentration of dissolved species of metals by fibrous sorbents even in the sampling stage decreases their detection limits. At the same time, this allows use of less sensitive measuring instrumentation in the subsequent analysis.

EXPERIMENTAL

The initial solutions of metals (0.1 g l^{-1}) were prepared by dissolution of weighed portions of appropriate metals (available from Merck and Aldrich, analytical grade) in a solution of ultrapure nitric acid, pH 2.0 ± 0.1, in twice-distilled water. The working solutions were prepared by dilution of the initial solutions. In implementation of the "introduced–found" procedure, portions of the metal solutions were introduced into model samples close in composition to natural water. The model solutions were prepared using a humic extract isolated from peat. The natural water samples taken were prefiltered across a membrane filter with a pore diameter of 0.45 μm. The concentrations of the metals in solution were determined just before the sorption experiment.

We used a number of sorbents differing in the nature of the reactive groups. Experiments with polyurethane foam showed that it is unsuitable for group sorption of a number of metals (Cd, Pb, Cu, Zn, Fe, Mn) under the conditions suggested in [8, 9]. The content of the metals was determined by atomic absorption on an AAS-30 instrument.[1]

In further experiments we used "filled" sorbents Poliorgs-33n, Poliorgs-34, and Poliorgs-35 exhibiting high sorption capacities (Table 1). Owing to the stability in aqueous media and easy regeneration, these sorbents are suitable for repeated sorption–desorption cycles [7].

Sorption was run under static conditions, by stirring of the model solutions with the sorbent in a shaker (mass ratio of the solid to liquid phase 1 : 2000). The phase contact time in studying the sorption kinetics was varied from 10 min to 3 h. The pH of the solutions studied was kept within 5–6 pH units, since, according to [7, 10], the metals are most completely recovered by the sorbent at these solution acidities. Quantitative desorption was carried out with a 1 M nitric acid solution. The amount of nondesorbed metals was determined by wet ashing of the sorbent.

The content of the metals in the solutions after sorption and in the eluates, as well as in natural water, was determined by the anode stripping voltammetry on an SVA-1BM instrument (Burevestnik Research and Production Enterprise), using a three-electrode cell with carbon-devitrified glass indicator electrode and a platinum auxiliary electrode. As reference elec-

[1] This part of the study was carried out at the Institute of Water and Environmental Problems, Siberian Division, Russian Academy of Sciences.

trode served saturated silver chloride electrode with a salt bridge filled with 0.1 M KNO_3. The accumulation potential was –1.350 V. The accumulation time was varied from 30 to 120 s, depending on the concentration of the components being analyzed in solution. Electric accumulation of the metals was carried out on a rotating indicator mercury-carbon-devitrified-glass disk electrode with a Pentaplast coating, which was followed by the relaxation period. The metal oxidation was performed in the potentiodynamic mode of polarization of the electrode. The linear sweeping of the potential at a rate of 100 mV s^{-1} was carried out until the regeneration potential of the indicator electrode surface of +0.600 V was reached. The concentration of the heavy metals was estimated from the height of the anode current peaks, using the standard addition method.

Our experiments showed that the most suitable sorbent for group concentration of metals is Poliorgs-33n, prepared by treatment of freshly formed polyacrylonitrile fiber with a mixture of hydroxylamine and hydrazine hydrate. Comparison of the patterns of interphase distributions of the metals showed that sorption from the solutions containing a single kind of metal and mixture of metals on Poliorgs-33n sorbent proceeds similarly (Fig. 1). Figure 2 shows that the maximal sorption of all the metals is achieved within 30–40 min, the degree of sorption being 95 ± 5%. Our experiments show that the degree of sorption of the metals remains unchanged at their initial concentrations in the range 5–50 μg l^{-1} (Fig. 3).

One of important and complex stages in studies of natural objects is to ensure the maximal correspondence between the model and real natural samples. Of no less importance is to convert a sample to a form suitable for analysis and to bring it into strict correspondence with the reference samples used, in both the form and chemical composition. In surface waters, characteristic macrocomponents are humic substances (HSs), high-molecular-weight polydisperse compounds containing reactive functional groups of varied nature (phenolic, carboxy, imino, thioether, etc.). All these groups can bind the metal ions into strong compounds like chelates or retain them via coordination bonding [11]. This required a study of the sorption performance of Poliorgs-33n with respect to heavy metals in the presence of HSs, which can interfere with the metal sorption. Our studies of model solutions containing various (specific to different types of natural water) amounts of HSs (0–300 mg l^{-1}) showed that the degree of sorption of heavy metals

is independent of the HS concentration (Fig. 4). Comparison of the degrees of sorption of HMs in the presence (Fig. 4) and absence (Fig. 3) of HSs shows that the HMs are completely bound by the sorbent in solutions containing HSs as well. Our results confirm that the technique we suggested for sampling of dissolved species of heavy metals is applicable to various kinds of water, differing in the content of HSs.

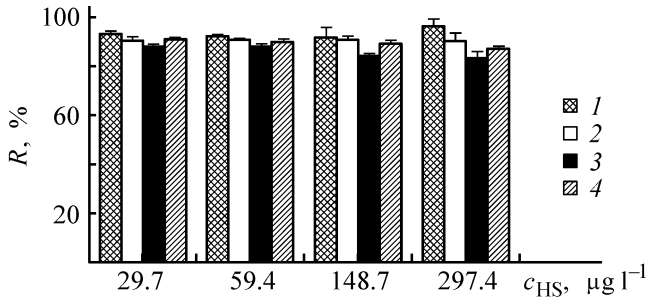

Fig. 4. Degree of sorption R of metals, vs. the concentration of humic substances c_{HS}, in solution.

The technique we developed was tested on real samples of natural water (surface and ground). We took samples from a big river (Neva) and a small river (Oredezh), differing in the aeration and hydrodynamic conditions and in the chemical composition of water. Comparison of the contents of HMs in the samples taken by the "classical" procedure (conservation with acid) and using the sorbent (Table 2) convincingly demonstrated that the technique we suggested does not distort the results of determination of the total content of dissolved species of metals in such complex multicomponent systems as various kinds of

natural water. It is essential that the metals sorbed can be stored on the sorbent for a long time. A 2-month monitoring of the content of HMs on the sorbent showed that, within this period, the concentration remained unchanged. This characteristic of the sorbent seems to be of interest not only for hydrochemistry and environmental analytics, but also for ecological criminology.

CONCLUSIONS

(1) The suitability of fibrous sorbents for sampling and reliable storage before analysis of dissolved species of heavy metals was demonstrated experimentally.

(2) The degrees of sorption of the metals from solutions containing a single kind of metal and a mixture of metals are identical, and the maximal degree of sorption of the metals ($95 \pm 5\%$) is achieved within 40 min.

(3) The maximal degree of sorption of heavy metals is independent of the concentration of humic substances and the concentration of heavy metals in natural water.

ACKNOWLEDGMENTS

The authors are grateful to staff members of the Laboratory of Organic Reagents, Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, for providing the sorbents.

Abstract—Surfactant properties of hydroxyethylated fats were studied.

DOI: 10.1134/S1070427206020224

There are obvious advantages of polymeric microspheres as bioligand carriers over particles of the biological origin (bacteria, erythrocytes, etc.). The primary advantage is in the possibility of obtaining monodisperse polymer suspensions with a fixed particle size of polymeric microspheres having surface sites capable of covalent binding to functional groups of the bioligand.

Monodisperse polymeric suspensions are prepared by various methods of heterophase polymerization in the presence of initiators and surfactants. In this case, the stability of the particles with respect to coalescence in the course of polymerization is provided by the structural-mechanical and electrostatic factors.

The polymerization is commonly initiated with potassium persulfate. The presence of ionic fragments of the initiator at the ends of polymeric chains promotes their orientation at the interface with the formation of an electric double layer. To form the structural-mechanical factor of stabilization of the particles in the interfacial layer, surfactants insoluble in water and incompatible with the resulting polymer are used. These are carboxyl-containing [1] and organosilicon [1, 2] surfactants, oligoglycol maleates, etc. [3]. It may be suggested that modified fats of taiga mink (TM), fox (TF), and sea mammals are classified with this type of fats. The last type has already found wide use in various areas of research and in chemical, pharmaceutical, and cosmetic industries. At the same time, the fat of Baikal seal (BS), which is a by-product, obtained in seal-fishing is virtually not used anywhere.

In this study, we examined properties of surfactants synthesized on the basis of hydroxyethylated fats of TM, TF, and BS. The resulting products were used in heterophase polymerization of styrene to prepare monodisperse polymer suspensions.

EXPERIMENTAL

The composition of fats was determined using a Hewlett–Packard 5890-2 gas chromatograph with an HP-5971 mass-spectrometric quadrupole detector. It was demonstrated that BS fat differs from TM and TF fats in a higher content of unsaturated acids C_{20}–C_{22} (Table 1).

Table 1. Composition of BS, TM, and TF fats

Parameter	TM	TF	BS
Acid number	1.3	2.0	0.6
Iodine number	78	70	145
Composition of fatty acids, wt %:			
C_{12}–C_{14}	4.1	4.4	7.1
C_{16}–C_{18}	94.4	95.6	69.7
C_{20}–C_{22}	0.5		23.2
Content of acids, wt %:			
saturated	31.2	34.1	15.5
monounsaturated	59.4	53.9	54.5
polyunsaturated	7.0	9.4	30.0
Degree of hydroxyethylation of modified fats	6(TM-6) 12(TM-12)	6(TF-6) 12(TF-12)	13(PEG-600) 45(PEG-2000) 12(MPEG-550) 42(MPEG-1900)

Table 2. Colloidal-chemical properties of TM- and TF-based surfactants at water/hydrocarbon interface

Surfactant	G, mN m^2 mol^{-1}	σ_{min}, mN m^{-1}	$\Gamma_{max} \times 10^6$, mol m^{-2}	S_{min}, Å	CMC, mM
TM-6	22.7	5.0	2.7	60	1.5
TM-12	32.5	2.0	4.8	36	1.1
TF-6	30.0	2.0	3.6	46	1.0
TF-12	50.0	2.0	4.8	36	0.7

Table 3. Critical micelle concentration of surfactants based on mono- and diesters of BS fatty acids

Ester	CCM $\times 10^4$, M
MPEG-550	0.5–0.8
PEG-600	5.6–6.8
MPEG-1900	7.1–8.3
PEG-2000	7.9–10.2

Di- and monoesters of BS fatty acids and poly(ethylene glycol) (PEG) were synthesized by condensation of the corresponding acyl chlorides with PEG-600 (number of hydroxyethylene groups n = 13) and PEG-2000 (n = 45), and also with poly(ethylene glycol) methyl ethers MPEG-550 (n = 12) and MPEG-1900 (n = 42) in the presence of triethylamine in 1,2-dichloroethane at 30°C for 1 h in an inert atmosphere [4, 5]. The structure of the products was confirmed by IR and ^{1}H NMR spectra.

In the experiments, we used modified TM and TS fats with a degree of hydroxyethylation of 6 (TM-6 and TF-6) and 12% (TM-12 and TF-12)[1].

To optimize the conditions of heterophase polymerization of styrene, we studied the solubility of these products and their colloidal-chemical properties at the hydrocarbon/water interface. The results are summarized in Table 2.

We selected *o*-xylene as a hydrocarbon phase, because its properties are close to those of styrene, i.e., the monomer frequently used in such a research. The solubility of hydroxyethylated fats in *o*-xylene appeared to be sufficiently high (34%). Their solubility in water is considerably lower (mostly 3–5%). The interfacial tension at the *o*-xylene solution of surfactant/water was determined by stalagmometry at a drop formation time of 45–50 and 2 s [6]. The dynamic interfacial tensions were determined to be higher than the corresponding static values (Fig. 1). The surfactants studied demonstrated a high surface activity (G) at the interface, decreasing the interfacial tension σ_{min} to 2–5 mN m^{-1}. The surface activity G was found to be 30–50 mN m^2 mol^{-1} on the average (Table 2).

The limiting adsorptions Γ_{max} and the areas occupied by the molecules in the saturated adsorption layer, estimated by the Gibbs equation, suggest a dense vertical orientation of the surfactant molecules at the water/hydrocarbon interface. The observed small S_{min} (35–60 Å^2) is caused by the orientation of the hydrocarbon chain of the surfactant toward the bulk of the hydrocarbon, and of the hydrophilic polyoxyethylene moiety, toward the aqueous phase.

The surface tension of the aqueous surfactant solutions was measured using the Wilhelmy method [6]. The surfactants based on BS fatty acids and PEG of various molecular weights reduced the surface tension at the water/air interface to 30–42 mN m^{-1}. From the surface tension data, we determined the critical micelle concentrations (CMC). The results show that CMC increases with the number of polyethylene oxide units in the surfactant molecules (Table 3).

The heterophase polymerization of styrene was carried out in dilatometers and in a 1-l reactor at a 1 : 9 styrene to water volume ratio and 80°C to complete conversion of the monomer [7]. As an initiator, we used potassium persulfate (1 wt % based on styrene).

The stability of the styrene emulsions stabilized with the surfactants investigated was characterized by a settling time upon centrifugation at 1500 rpm. It was demonstrated that the stability of styrene emulsions stabilized with TM and TF fats increases with

the degree of hydroxyethylation of the surfactants. With esters of the fatty acids and PEG as stabilizers, the highest stability was observed for the polystyrene suspensions prepared in the presence of monoesters of the fatty acids with MPEG-550 and MPEG-1900.

The dispersity of drops in the styrene emulsions formed by mixing the hydrocarbon and aqueous phases at a stirring rate of 200 rpm was determined to be high by laser spectroscopy (average size of the monomer drops was about 3 μm).

The dispersity of styrene emulsions considerably increased when the phase distribution of the surfactant was nonequilibrium. In this case, the surfactant was added to water, in which it is less soluble than in the organic phase. We observed an intensive mass transfer of the surfactant from the aqueous phase to styrene. As a result of a local decrease in the interfacial tension $\sigma_{1,2}$, a microemulsion with a drop size of 0.2 μm was formed. It should be pointed out that, in preparing emulsion by mixing the surfactant solution in styrene with water, the microemulsion of the monomer is not formed, since the solubility of the surfactant in styrene is much higher than that in water.

The surfactants investigated demonstrated a tendency to form a stable interfacial layer on the drop surface. We measured the limiting shear stress P of the interfacial adsorption layers of hydroxyethylated TM and TF fats, which control the emulsion stability. As can be seen from the log P-vs.-log τ dependences (Fig. 2), P is nearly doubled during the formation of the interfacial layers. Because the polymerization starts and proceeds in the adsorption layers around the particles, the polymer is involved in the formation of the interfacial layer and influences its strength. Figure 2 (curves *1*, *2*) shows data on the strength of the interfacial layers at the surfactant solution/polystyrene interface in the system styrene–water. In the presence of polystyrene, P increases by about an order of magnitude. Therefore, the stability of the styrene emulsions in the presence of the surfactants investigated is primarily caused by the structural-mechanical barrier formed in adsorption of surfactant molecules that can form an ordered layer at the interface. Despite that the surface activity of the surfactant is not high, polystyrene formed in the surface layer promoted formation of a 3*D* structure, i.e., of a gel, in the interfacial layer, thus stabilizing the emulsion particles in the course of polymerization.

Our results allowed optimization of the synthesis of monodisperse polystyrene suspensions, as required for their use as carriers for bioligands.

The conversion-vs.-time curves (Fig. 3) show that the polymerization of styrene proceeds without induction period at a constant rate up to high conversions.

The reaction system was stable throughout the synthesis, which confirms that a strong adsorption layer of the surfactant is formed on the surface of polymer–monomer particles, starting from very low monomer conversion. This is also evidenced by a narrow size distribution of particles of the polystyrene suspension in the course of polymerization. This distribution was studied by electron microscopy and photon correlation spectroscopy. The mean size of particles obtained in the presence of modified TM and TF fats was 0.3 and 0.5 μm, respectively, and that in

Table 4. Characteristics of polystyrene suspensions obtained in the presence of surfactants based on hydroxyethylated BS fatty acids

Surfactants based on mono- and diesters of BS fatty acids with MPEG and PEG	Particle size, μm	Polydispersity factor
PEG-600	0.298	1.00
PEG-2000	0.380	1.02

PEG-2000/BS fat acid diester	0.380	1.02
MPEG-550/BS fat acid monoester	0.477	1.02
MPEG-1990/BS fat acid monoester	0.258	1.37

the presence of surfactants based on BS fat, 0.26–0.48 μm. The polydispersity factor was mostly no more than 1.2, except for the ester of MPEG-1900 and BS fatty acids (Tables 4, 5). The mean molecular weights of the polymers M_n corresponded to the common values observed in polymerization of styrene for particles of this size, being about $(7–8) \times 10^5$.

CONCLUSIONS

(1) Surfactant properties of hydroxyethylated fats containing a mixture of unsaturated fatty acids with a degree of hydroxyethylation of 6 and 12, and also of esters of these acids with poly(ethylene glycols) (MW 600 and 2000) and poly(ethylene glycol) methyl ethers (MW 550 and 1900) with the number of oxyethylene groups from 12 to 45, were studied. The surfactants investigated demonstrate a high surface activity at the hydrocarbon/water interface, which reduces the interfacial tension to 2–5 mN m^{-1}.

(2) Monodisperse polystyrene suspensions (particle size 0.25–0.50 μm) were obtained by heterophase polymerization of styrene in the presence of the surfactants investigated. These suspensions show promise as carriers for bioligands in immunochemical research.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Sterically Hindered Nitrogen-containing Compounds in Radical Polymerization of Styrene

Abstract—The influence exerted on the radical polymerization of styrene by organic compounds containing a *tert*-butyl group and a nitrogen atom in various oxidation states (*tert*-butylamine, 2-methyl-2-nitrosopropane, 2-methyl-2-nitropropane) was examined.

DOI: 10.1134/S1070427206020235

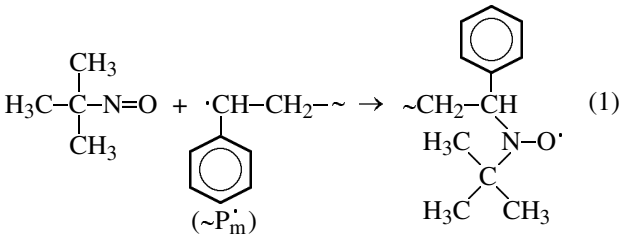
Controlling the chain propagation step under the conditions of radical initiation and, in particular, performing the polymerization without autoacceleration is a topical problem of the modern synthetic chemistry of macromolecules [1]. By introducing appropriate additives, it is possible to control the chain propagation, perform the process without gelation, and obtain (co)polymers of a definite composition with a relatively narrow molecular-weight distribution, as well as to design specific macromolecules. In polymerization of vinyl monomers, such additives are actively used as nitroxyl radicals and their precursors [1–4], organometallic compounds [5], and some other reactive additives.

In this study, we made a comparative analysis of the performance of sterically hindered nitrogen compounds (2-methyl-2-nitrosopropane, MNP; 2-methyl-2-nitropropane, $ButNO_2$; *tert*-butylamine, TBA) in synthesis of polystyrene (polyST). The choice of these compounds is governed by the fact that, on the one hand, they have the same hydrocarbon skeleton (*tert*-butyl group) and, on the other hand, they contain nitrogen atoms in different oxidation states (amino, nitroso, nitro groups). All these compounds can be expected to form nitroxyl adducts (species controlling the polymerization) directly in the reaction system (*in situ*).

As initiator we chose benzoyl peroxide (BP) traditionally used in commercial syntheses of macromolecules [6].

EXPERIMENTAL

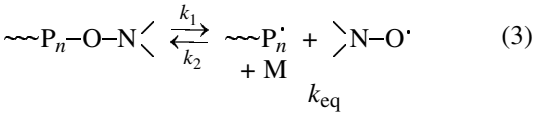
MNP and $ButNO_2$ were prepared by the procedures described in [7, 8]; commercially available TBA was dried over sodium and distilled; BP and solvents were purified by the standard procedures [9, 10]. Styrene (ST) was purified to remove hydroquinone by washing with several portions of 5% alkali (until the monomer became colorless) and then with water to remove residual alkali (until the wash water became neutral), after which it was dried over $CaCl_2$. The dried monomer was distilled under reduced pressure. The physicochemical constants of the compounds used agreed with the reference data.



Samples were prepared as follows: The monomer was placed in glass ampules, degassed by threefold freeze–pump–thaw treatment (freezing in liquid N_2), and subjected to polymerization at a residual pressure of 1.3 Pa. The polymerization kinetics was monitored gravimetrically, dilatometrically [11], and thermographically [12].

The molecular weight M of the polymer was determined viscometrically [13] and by gel permeation chromatography with a set of five styrogen columns with pore diameters of 10^5, 3×10^4, 10^4, 10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector. The eluent was tetrahydrofuran. The device was calibrated with close-cut polystyrene references [14].

To estimate the kinetic parameters of the polymerization of styrene in the presence of nitrogen-containing organic compounds at low conversions, we analyzed the initial portions of the kinetic curves obtained dilatometrically at 60°C. We found that addition of TBA in various concentrations and $ButNO_2$ exerted no significant influence on the initial polymerization rate. The rate of synthesis of the macromolecules somewhat decreased but remained comparable with the rate



of polymerization initiated by BP without nitrogen-containing additives (Table 1).

At the same time, addition of MNP to the reaction system at the same temperature gives rise to a long induction period (more than 6 h), which may be due to the reaction of the propagating styrene macroradicals ($\sim P_m^{\bullet}$) with the nitroso compound (MNP):

It should be noted that a similar induction period is observed in the polymerization of ST in the presence of 2,2,6,6-tetramethylpiperidine-1-oxyl, the most known and best studied agent for pseudo-living polymerization [15].

As the temperature strongly affects the formation of macromolecules in the presence of nitroxyl radicals [1, 2], it seemed interesting to examine the effect of nitrogen-containing additives on the polymerization of styrene at a higher temperature (100°C), at which the contribution of the reversible inhibition becomes decisive:

We found that at 100°C the kinetics of bulk polymerization of styrene is strongly affected not only by MNP, but also by TBA and $ButNO_2$. Figure 1 shows differential kinetic curves of the ST polymerization in the presence of MNP and $ButNO_2$ at 100°C. It is seen that addition of these nitrogen-containing compounds appreciably reduces the gel effect. It is known [6] that the gel effect is extremely undesirable in the commercial synthesis of polymers, as it favors uncontrollable heat release and spontaneous growth of the molecular weight, which negatively affects the physicomechanical properties of macromolecules.

Table 1. Initial rate v_0 of ST polymerization in the presence of TBA (initiator BP, 1 mol %; reaction temperature 60°C)

Run no.	Addition, mol %	$v_0 \times 10^4$, mol l^{-1} s^{-1}
1	–	1.3
2	TBA:	1.1
3	2	0.9
4	4	0.7
5	8	0.6
6	$ButNO_2$, 3	1.1

It should be noted that the concentration of the additive required to eliminate the autoacceleration up to high conversions is considerably lower with MNP than with $ButNO_2$.

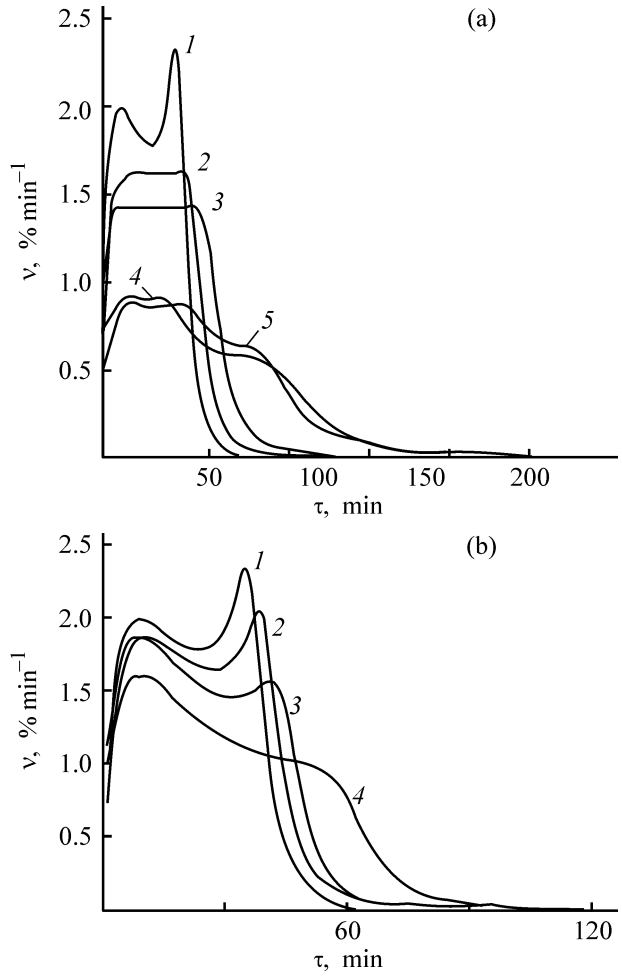


Fig. 1. Differential kinetic curves of the polymerization of ST in the presence of (a) MNP and (b) $ButNO_2$ at 100°C. Initiator BP, 1.0 mol %; the same for Fig. 2. (v) Polymerization rate and (τ) polymerization time. (a) MNP concentration, mol %: (*1*) 0, (*2*) 0.2, (*3*) 0.3, (*4*) 0.5, and (*5*) 0.8. (b) $ButNO_2$ concentration, mol %: (*1*) 0, (*2*) 1, (*3*) 4, and (*4*) 8.

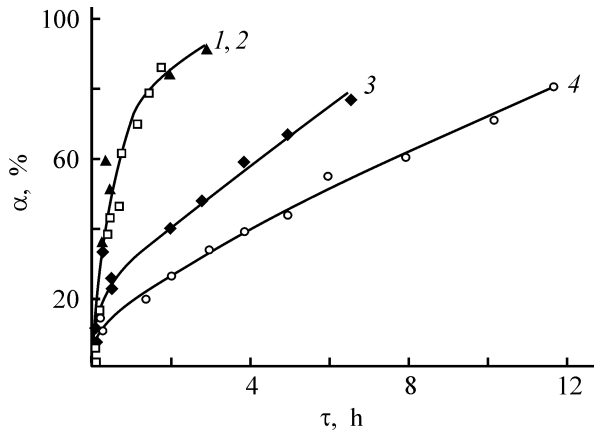

Fig. 2. Integral kinetic curves of the polymerization of ST in the presence of TBA (gravimetric monitoring) at 100°C: (α) conversion and (τ) polymerization time. TBA concentration, mol %: (*1*) 0, (*2*) 1.0, (*3*) 4.0, and (*4*) 8.0.

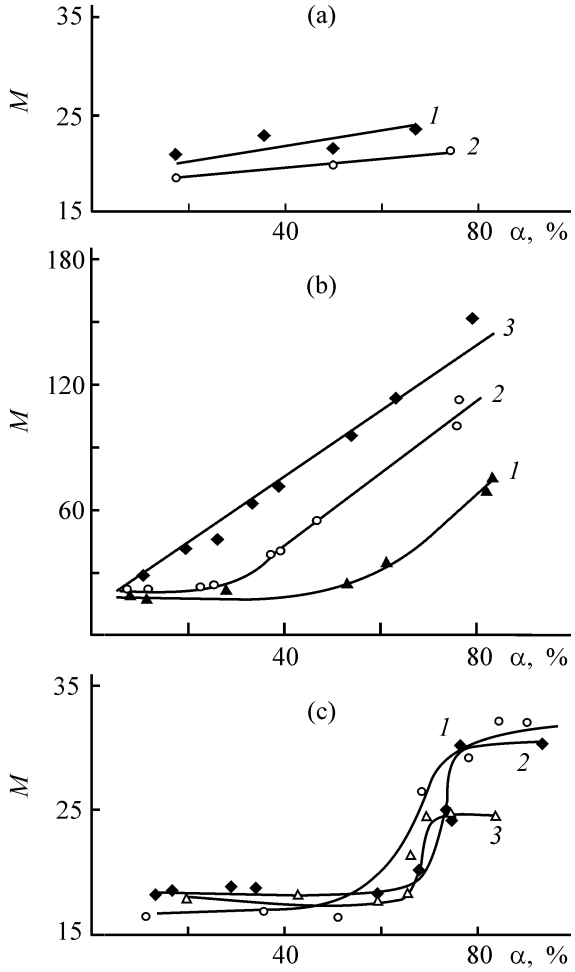

Fig. 3. Molecular weight *M* of polyST vs. conversion α. Initiator BP, 1.0 mol %; polymerization temperature 100°C; the same for Fig. 4. (a) 0.8 mol % MNP; *M*: (*1*) viscosity-average and (*2*) number-average; (b) viscosity-average *M*; TBA concentration, mol %: (*1*) 2.0, (*2*) 4.0, and (*3*) 8.0; (c) viscosity-average *M*; $ButNO_2$ concentration, mol %: (*1*) 0, (*2*) 4.0, and (*3*) 8.0.

As follows from the integral kinetic curves shown in Fig. 2, addition of TBA to the system also leads to a considerable decrease in the overall polymerization rate. The initial rate of the polyST formation in the presence of 1.0–4.0 mol % TBA remains fairly high (~30% conversion in 1 h), but the further reaction is slow. At a higher TBA concentration (8.0 mol %), its inhibiting effect becomes more significant and is manifested already at low conversions.

The molecular-weight characteristics of polyST prepared in the presence of MNP, TBA, and $ButNO_2$ also indirectly suggest that the nitrogen-containing compounds are directly involved in the chain propagation; however, as expected, their effect varies, depending on the compound structure.

We found that the molecular weights of the samples prepared with MNP as a controlling additive linearly increased with the monomer conversion (Fig. 3a), which is one of the evidences of the controlled radical polymerization [1].

The molecular-weight characteristics of polyST synthesized in the presence of TBA showed interesting features. As can be seen from Fig. 3b, on introduction of 8.0 mol % amine, the viscosity-average molecular-weight *M* linearly increases with the conversion, indirectly suggesting the controlled polymerization mechanism. However, with a decrease in the concentration of the additive (to 2–4 mol %), the contribution of the uncontrolled process increases, and, in this case, the curve of *M* vs. conversion consists of two branches with an inflection point characteristic of polymerization with the gel effect. In the initial parts of the curve, *M* of polyST remains approximately constant, but at high conversions it sharply grows. At the amine concentration equal to the initiator concentration (1.0 mol %), TBA exerts no appreciable influence on the molecular-weight characteristics of the polymer, and the dependence of *M* on the conversion is S-shaped, which is typical of the common (uncontrolled) radical polymerization with the gel effect.

In contrast to MNP and TBA, addition of $ButNO_2$ does not noticeably affect the molecular-weight characteristics of the polymer. In particular, the dependences of *M* of polyST samples prepared in the presence of various concentrations of the nitro compound are similar to the case of the common radical initiation (Fig. 3c). At the same time, the polydispersity coefficients of the polymers prepared with the system [$ButNO_2$ + BP] are lower, compared to the samples prepared without additives (Table 2). The above features of the polymerization in the presence of $ButNO_2$

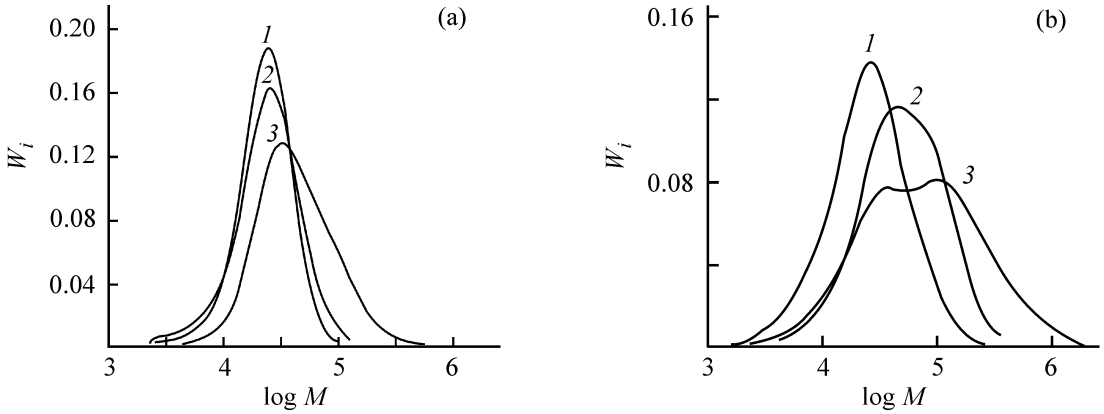

Fig. 4. MWD curves of polyST samples synthesized in the presence of TBA to various conversions. (W_i) weight proportion of the fraction and (log M) logarithm of molecular weight. (a) TBA concentration 1.0 mol %; conversion, %: (*1*) 17, (*2*) 43, and (*3*) 85.7; (b) TBA concentration 4.0 mol %; conversion, %: (*1*) 25, (*2*) 48, and (*3*) 67.

are typical of the processes performed in the presence of weak inhibitors [2, 6].

Taken in combination with published data on the reactivity of nitro compounds [16, 17], our results suggest the following scheme of propagation of the polymeric chain in the presence of $ButNO_2$: The propagating macroradical reacts with the nitro compound to form a nitroxyl spin adduct:

$$\sim\sim P_n^{\cdot} + ButNO_2 \rightarrow But{-}N\begin{matrix}O^{\cdot}\\ \diagdown\\ O{-}P_n\sim\sim\end{matrix} \quad (4)$$

The low-reactive oxygen-centered nitrogen-containing radical formed by this reaction can terminate the second radical chain to form an ether and MNP:

$$But{-}N\begin{matrix}O^{\cdot}\\ \diagdown\\ O{-}P_n\sim\sim\end{matrix} + \sim\sim P_n^{\cdot} \rightarrow But{-}N{=}O + \sim\sim P_nOP_n\sim\sim \quad (5)$$

As shown above, MNP also actively affects the kinetics of radical polymerization of ST.

In synthesis of polyST in the presence of MNP, the polydispersity coefficients of the samples do not noticeably vary with the conversion and amount to 1.3–1.4 (Table 2). These values are appreciably lower than those for the polymer prepared under the comparable conditions of radical initiation but without additives [6].

The effect of TBA on the molecular-weight characteristics of the polymer is determined by the concentration of the additive. When the amine is added in low concentrations (1.0 mol %), the polydispersity coefficients of the polyST synthesized are relatively low, and the molecular-weight distribution (MWD) is unimodal (Fig. 4a). With an increase in the amine concentration, the MWD curves get considerably broadened and become bimodal (Fig. 4b). The polydispersity coefficients of the samples prepared in the presence of 2–8 mol % TBA at high conversions exceed those of the samples prepared without the additives. This may be caused by the occurrence of certain side processes, in particular, of chain transfer to the amine and of other reactions characteristic of such systems. Also, accumulation of 2-methyl-2-nitroprop-

ane formed by oxidation of the amine with benzoyl peroxide [18],

$$RNH_2 \xrightarrow{(O)} [RNHOH] \xrightarrow{(O)} [RN(H)O\cdot] \xrightarrow{(O)} RNO_2,$$

and its involvements in the polymerization cannot be ruled out.

With an increase in the amine concentration, the contribution of side processes involving these compounds increases, which results in bimodal MWD and increased polydispersity of the samples.

CONCLUSIONS

(1) 2-Methyl-2-nitrosopropane, *tert*-butylamine, and 2-methyl-2-nitropropane are directly involved in the propagation step in the styrene polymerization initiated by benzoyl peroxide.

(2) Addition of these compounds affects the overall polymerization kinetics by decreasing the reaction rate in the autoacceleration step and controlling the molecular-weight characteristics of polystyrene. 2-Methyl-2-nitrosopropane controls the chain propagation under the conditions of bulk polymerization of styrene more efficiently than do 2-methyl-2-nitro-propane and *tert*-butylamine.

Abstract—The radiation-initiated copolymerization of *N*-vinylpyrrolidone with acrylic acid at low temperatures in glass-forming ethanol or dimethylformamide solutions was studied. The mechanism of the copolymer formation was elucidated, and conditions were determined for preparing alternating and random block copolymers.

DOI: 10.1134/S1070427206020248

Copolymers of *N*-vinylpyrrolidone (VP) with unsaturated carboxylic acids are used in medicine and biology [1, 2]. In liquid-phase copolymerization, the copolymer composition is determined by the mutual reactivity of the comonomers. As the active monomer is consumed, the resulting copolymer, as a rule, gets enriched with the less reactive monomer, so that the composition of the polymer chains becomes nonuniform. Radiation-chemical initiation makes it possible to accumulate active reaction centers and perform the process in the solid or viscous supercooled state at considerably lower temperatures than with substance initiation. These specific reaction conditions, manifested in a considerable increase in the contact time of the reactants, allow preparation of copolymers whose composition is independent of the conversion and is determined by the composition of the starting mixture [3].

In this study, we examined radiation-initiated copolymerization of VP with acrylic acid (AA) in ethanol or dimethylformamide (DMF) solutions forming a glass at low temperatures.

EXPERIMENTAL

N-Vinylpyrrolidone and acrylic acid were purified by double distillation in a vacuum; ethanol and DMF were not specially purified. The reaction mixtures were placed in glass calorimetric cells, freed from atmospheric oxygen in a vacuum unit, and sealed in a vacuum. Samples were gamma-irradiated from a ^{60}Co source (Gammatok-100 installation) at 77 K. The polymerization was monitored calorimetrically [4]. The irradiated samples were placed in a calorimetric unit precooled to 77 K, and the calorimeter was slowly (at a rate of ~0.35 deg min^{-1}) warmed up. The polymer yield was determined gravimetrically after the removal of the unchanged monomers in a vacuum. The composition of the products was determined by elemental analysis from the nitrogen content in the copolymer.

Figure 1 shows the calorimetric curves of heating of the unirradiated and gamma-irradiated samples of

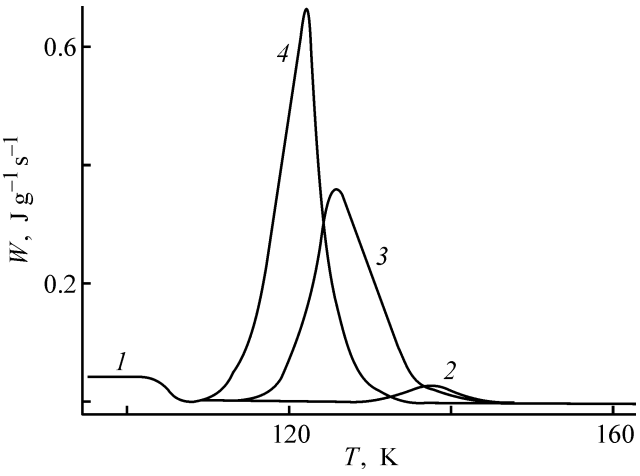

Fig. 1. Calorimetric curves of heating: (*1*) unirradiated solutions of VP, AA, and VP + AA in ethanol; gamma-irradiated solutions of (*2*) VP, (*3*) AA, and (*4*) VP + AA in ethanol. Total concentration of VP, AA, and VP + AA in solution 10 wt %; relative concentration of VP in comonomer mixture 50 mol %; irradiation dose 20 kGy. (*W*) Heat release and (*T*) temperature.

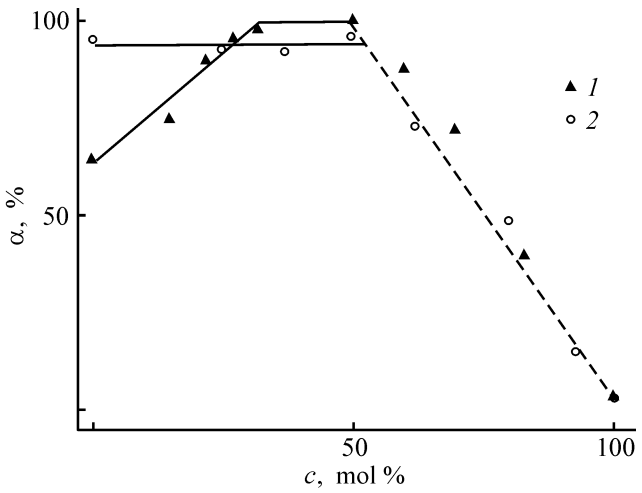

Fig. 2. Copolymer yield α in solutions of VP + AA in (*1*) ethanol and (*2*) DMF as a function of the relative concentration *c* of VP in the comonomer mixture. Total concentration of monomers in solution, wt %: (*1*) 10 and (*2*) 20. Irradiation dose, kGy: (*1*) 20 and (*2*) 2.

VP, AA, and their mixture in ethanol. On cooling to 77 K, these solutions fully transform into a glassy state, and their calorimetric heating curves in the temperature interval 100–105 K exhibit a step corresponding to the transition from a solid glassy state to a supercooled liquid. Then, on warming to 200 K, the calorimeter records no changes associated with the presence or formation of a crystalline phase: The calorimetric heating curves for solutions of VP, AA, and their mixture in ethanol virtually coincide (Fig. 1, curve *1*). Warming of the preliminarily gamma-irradiated (77 K) VP + AA sample is accompanied by heat release after the glass → liquid transition, associated with the formation of VP–AA copolymers (Fig. 1, curve *4*). Hence, in the temperature interval 100–160 K, when the system is in the state of a viscous supercooled liquid, VP efficiently copolymerizes with AA.

It should be noted that the homopolymerization of AA on heating of the preliminarily gamma-irradiated glassy solution of AA in ethanol also occurs after the glass → liquid transition of the system (Fig. 1, curve *3*). The polymer yield steadily increases with the AA content in the solution and reaches 80% at a monomer concentration of about 16 wt % [5].

By contrast, the homopolymerization of VP under these conditions is inefficient. The calorimetric heating curves of the preliminarily gamma-irradiated glassy solutions of VP in ethanol show only slight heat release associated with the VP polymerization (Fig. 1, curve *2*). The polymer yield at an irradiation dose of 20 kGy is as low as ~3%. It has been shown previously [6] that the low chemical activity of VP in the homopolymerization is not associated with the initiation step. The radicals generated by gamma-irradiation, which are stable at 77 K, rapidly take up monomer molecules in the glass → liquid region (R_0 + M → R_p^{VP}) to form active polymerization centers ($R_p^{VP} \approx 0.5R_0$). However, the arising active centers inefficiently take up the like monomer molecules in the course of further heating: The calorimeter records only a slight heat release corresponding to approximately 3% yield of the polymer (Fig. 1, curve *2*).

In copolymerization of VP with AA, addition of low-active VP to the solution should seemingly decrease the polymerization rate and copolymer yield. However, both these quantities actually increase.

Figure 2 shows the dependence of the copolymer yield on the initial comonomer ratio at the total comonomer concentration in ethanol of 10 wt % and irradiation dose of 20 kGy (curve *1*). The yield of the AA homopolymer under these conditions is 65%. On adding VP to a solution of AA in ethanol, the copolymer yield increases with the VP concentration, reaching 100% at 30 mol % content of VP.

The increased reactivity in the VP–AA system and the accordingly higher copolymer yield are attributed to the formation of a 1 : 1 intermolecular complex of AA with VP [7]. Formation of this complex, as noted in [7], makes lower the barriers of intermolecular interactions and accelerates the propagation of the polymer chains.

The ~100% yield of the copolymer is attained at the initial relative VP concentration ranging from 30 to 50 mol %. At a higher VP content, the product yield decreases, reaching 3% with pure VP (Fig. 2, curve *1*).

Then we studied the polymerization of VP and AA and their copolymerization in DMF solutions with a higher glass transition point (T_g ~135 K). The polymerization and copolymerization on warming of preliminarily irradiated solutions of these monomers occur in DMF, as in ethanol, at temperatures above T_g and are not accompanied by product precipitation.

Figure 2 (curve *2*) shows the dependence of the copolymer yield on the relative concentration of VP in a mixture with AA at a total comonomer concentration in DMF solution of 20 wt %, after preliminary irradiation to a dose of 2 kGy. Under these conditions, as in ethanol, the homopolymerization of AA is very efficient (homopolymer yield 90–97%), whereas that of VP is strongly suppressed (3%). However, addition

of VP to a solution of AA in DMF does not decrease the copolymerization rate. The copolymer yield remains constant at a relative VP concentration of up to 50 mol % (Fig. 2, curve *2*). Hence, with an increase in the relative concentration of VP in its mixture with AA to 50 mol %, the propagation of polymer chains is not suppressed.

An increase in the polymerization temperature in the DMF solutions relative to ethanol solutions (by ~30 K) does not appreciably affect the capacity of VP for polymerization. As in the ethanol solution, the monomer conversion does not exceed 3%. As already noted, this is caused by the low activity of the radicals with the terminal VP fragment, R_p^{VP}. Experimental results show that, when involved in copolymerization in both DMF and ethanol solutions, the acrylate radicals R_p^A generated from AA by gamma-irradiation at 77 K readily take up not only the like (AA) monomer molecules (the reaction is fast and the product yield is high), but also less active VP molecules ($R_p^A + VP \rightarrow R_p^{VP}$). As already noted, the resulting R_p^{VP}, does not add VP molecules but actively adds AA molecules. Hence, VP can add to the propagating macroradical mostly as single units, and the polymeric molecule should not contain VP blocks. The polymer chains will propagate until complete exhaustion of AA, after which the propagation should stop.

Formation of random copolymers of the composition corresponding to that of the starting mixture was observed in copolymerization of AA with acrylamide (AM) in glass-forming ethanol solutions [3]. In the viscous supercooled liquid, the time of the mutual contact of the reacting species is considerably longer than that in the gas and liquid phases, and the frequencies of addition of a monomer to the active center of a propagating polymer chain are close to those of translation motion. Under these conditions, the composition of the forming copolymers is determined by the initial concentrations of the comonomers, rather than by their mutual reactivity. It should be noted that the polymerization of AA and AM in glass-forming ethanol solutions is very efficient. In copolymerization of AA with VP, the capacity of one of the comonomers, VP, for polymerization in the supercooled liquid is very low. Then, at the same diffusion mobilities of the comonomers, the polymer chain propagation will stop at the VP concentration exceeding 50 mol %. The excess VP will remain nonpolymerized, and the copolymer yield will decrease with an increase in its concentration. This pattern is actually observed in copolymerization of VP with AA in ethanol and DMF (Fig. 2, curves *1*, *2*).

Content of VP units in copolymers prepared by copolymerization of 20 wt % solutions of VP + AA in DMF at various initial comonomer ratios

VP concentration in starting mixture, mol %	Yield, %	Content of VP units in copolymer, mol %
25.0	93.4	23.8
37.0	94.0	30.6
50.0	96.2	50.4
62.8	73.0	53.4
79.8	39.6	55.5

It follows from the suggested mechanism of copolymerization of VP with AA that at a VP concentration lower than 50 mol % the copolymer composition will correspond to that of the starting comonomer mixture, and the copolymer will consist of –VP–$(AA)_n$– blocks. With an increase in the VP content in the starting mixture, *n* will decrease, and at a VP concentration of 50 mol % *n* will become equal to unity, i.e., a 1 : 1 random copolymer will form. A further increase in the concentration (>50 mol %) will also result in formation of the alternating copolymer, but its yield and molecular weight will be lower, because the chain length will be determined by the relative concentration of low-active VP in the comonomer mixture.

The copolymer yield Γ in the copolymerization of VP with AA at the relative concentration of VP exceeding 50 mol % in ethanol and DMF solutions can be estimated from the initial comonomer concentrations by the expression

$$\Gamma = (N_1M_1 + N_1M_2)/(N_1M_1 + N_2M_2), \qquad (1)$$

where N_1 and N_2, M_1 and M_2 are the amounts (moles) and molecular weights of AA and VP, respectively.

The experimental data on the decrease in the copolymer yields are well described by Eq. (1) [Fig. 2: points, experimental data; dashed line, calculation by formula (1)].

The suggested mechanism of formation of the copolymers is confirmed by the data on the copolymer composition (see table). Indeed, at VP concentrations less than 50 mol %, the copolymer compositions are close to those of the starting mixtures. At VP concentrations exceeding 50 mol %, when the copolymer yield decreases virtually linearly with an increase in the VP content in the starting mixture, the copolymer composition does not noticeably change and is close to 1 : 1.

Thus, our results show that the copolymerization of VP with AA in ethanol and DMF solutions forming a glass at low temperatures allows preparation of alternating and random copolymers of composition determined by the initial comonomer ratio. The mechanism of formation of such copolymers is elucidated, and conditions for their preparation are determined.

CONCLUSIONS

(1) The radiation-initiated copolymerization of *N*-vinylpyrrolidone with acrylic acid in glass-forming ethanol and dimethylformamide solutions was performed. The process occurs after the transition of the systems to the viscous supercooled liquid in the temperature range 100–140 K.

(2) It was found that at the relative concentration of *N*-vinylpyrrolidone less than 50 mol %, the composition of the resulting copolymer corresponds to that of the starting comonomer mixture. At the *N*-vinylpyrrolidone concentration exceeding 50 mol %, an alternating copolymer of *N*-vinylpyrrolidone with acrylic acid is formed.

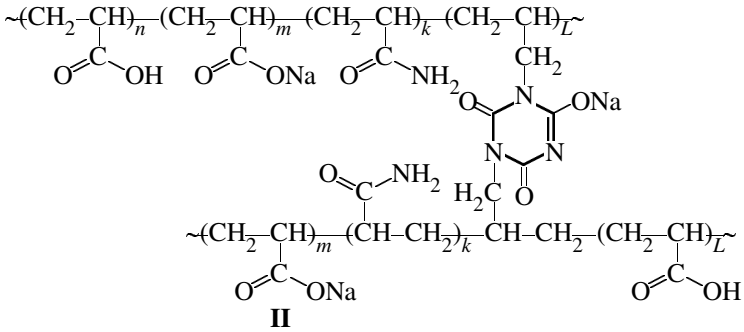
Abstract—Water absorption by copolymers of acrylic acid, sodium acrylate, and sodium 1,3-diallyl isocyanurate and of acrylic acid, sodium acrylate, acrylamide, and sodium 1,3-diallyl isocyanurate was studied in relation to their composition and the concentration of cross-linking agent.



DOI: 10.1134/S107042720602025X

Water absorption by copolymers of acrylic acid and its derivatives has been extensively studied. Acrylate systems absorbing no less than 500 g of water per gram of copolymer were examined in [1–4]. Cross-linked copolymers of various structures exhibiting high absorption capacity (no less than 850 g of water per gram) have been prepared previously [5, 6] from acrylic acid (AA), sodium acrylate (Na-AA), and sodium 1,3-diallyl isocyanurate (Na-DAIC). Similar absorption properties are typical of cross-linked copolymers prepared from AA, Na-AA, Na-DAIC, and acrylamide (AM) [7]. However, data on the rate of water absorption by copolymers based on AA and its reactive hydrophilic derivatives are virtually lacking.

In this study, we measured the rate of water absorption by cross-linked copolymers of AA, Na-AA, and Na-DAIC (**I**) and of AA, Na-AA, Na-DAIC, and AM (**II**), as influenced by the copolymer composition. The structure of the copolymers studied can be represented as:

I

II

Owing to the presence of polar functional and ionic groups, copolymers **I** and **II** are strongly hydrated and swell in water. The maximal (stationary) swelling rate is attained when the cross-linked copolymer fragment is opened to the greatest extent in water and does not hinder free diffusion of water in the intermolecular space of the cross-linked copolymer network. The time required for the maximal opening of the copolymer networks, after which the copolymer swells at a constant rate, can be termed induction period (τ_{in}). It was found that τ_{in} directly depends on both the functional composition of the copolymer and the concentration of the ionic groups.

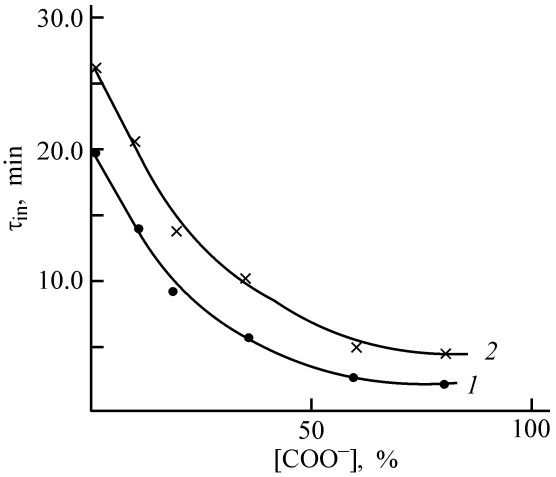


Fig. 1. Induction time of water absorption, τ_{in}, vs. the concentration of COO^- groups [COO^-] in copolymers **I** at concentrations of Na-DAIC equal to (*1*) 1.25×10^{-2} and (*2*) 2.5×10^{-2} M.

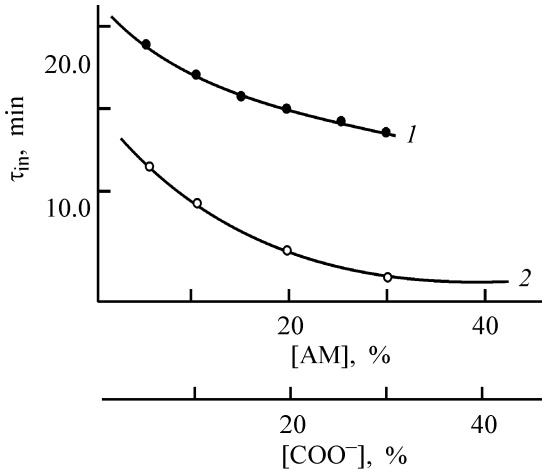

Fig. 2. Induction time of water absorption, τ_{in}, of copolymers **I** and **II** vs. the concentration of (*1*) AM units [AM] in the copolymer chain and (*2*) COO^- groups [COO^-] in the copolymer containing 30% AM units relative to [AA].

The dependence of τ_{in} on the concentration of COO^- groups in copolymer **I** is shown in Fig. 1. It can be seen that, as the concentration of COO^- groups in the copolymer increases, the time in which the stationary rate of water absorption is attained exponentially decreases and then becomes nearly constant at approximately 50% content of the COO^- groups. As can be seen from Fig. 1, τ_{in} depends on the concentration of Na-DAIC; with increasing content of Na-DAIC, the copolymer becomes more compact due to the increased density of cross-linking, which hinders the diffusion of water.

Rate of water absorption as influenced by the composition of the cross-linked copolymers

[COO^-]/[COOH]	V_w, $cm^3\ s^{-1}$, at indicated [Na-DAIC], M	
	1.25×10^{-2}	2.5×10^{-2}
0	3×10^{-3}	1.8×10^{-2}
0.1	6.8×10^{-3}	4.33×10^{-3}
0.2	9.3×10^{-3}	6.8×10^{-3}
0.3	1.75×10^{-2}	1.23×10^{-2}
0.6	5.5×10^{-2}	3.13×10^{-2}
0*	7.6×10^{-3}	5.8×10^{-3}
0.05*	8.1×10^{-3}	6.9×10^{-3}
0.1*	1.2×10^{-3}	8.5×10^{-3}
0.2*	2.1×10^{-2}	1.4×10^{-2}
0.3*	3.2×10^{-2}	2.3×10^{-2}
0.4*	4.5×10^{-2}	3.1×10^{-2}

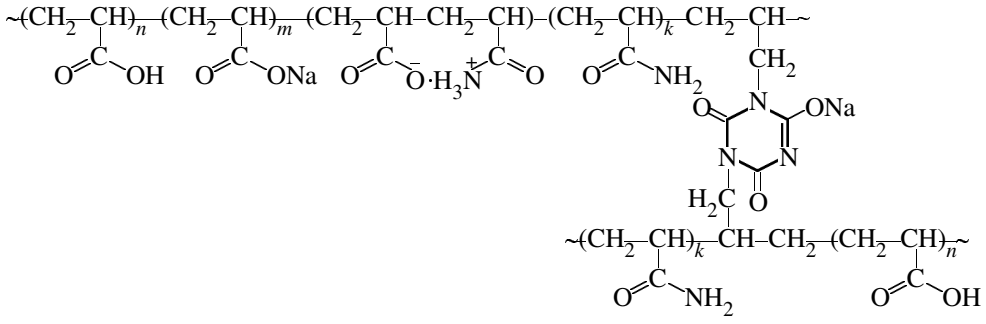
* Content of AM units in the copolymer 30% relative to [AA].

The data on the stationary rate of water absorption V_w by cross-linked copolymers **I**, as influenced by the [COO^-]/[COOH] molar ratio and the concentration of the cross-linking agent [Na-DAIC], are listed in the table.

It can be seen that, as the concentration of COO^- groups in the copolymer increases by a factor of 6, the rate of water absorption grows by a factor of more than 8 $(5.5 \times 10^{-2})/(6.8 \times 10^{-3})$. As the density of intermolecular cross-links increases, the rate of water absorption decreases. For example, as the concentration of Na-DAIC in the comonomer mixture increases by a factor of 2, the rate of water absorption decreases (on the average) by a factor of 1.5.

Thus, to attain the maximal water absorption by the cross-linked copolymer, it is necessary to provide the optimal ratio of the ionic and hydrophilic groups and their uniform distribution in the copolymer chain and the optimal density of cross-links between the copolymer macromolecules.

Copolymer **II** exhibiting higher water absorption than copolymer **I** seems to be more promising for technical applications. In particular, 1 g of copolymer **II** absorbs up to 1200 g of water.



It was found that τ_{in} of copolymer **II** is determined not only by the COO^-/COOH molar ratio, but also exponentially depends on the content of AM units in the copolymer network (Fig. 2).

As can be seen from Fig. 3, τ_{in} decreases as the content of AM units in the copolymer increases. This is

probably due to intermolecular salt formation by interaction of the –COOH and NH_2 groups in the copolymer.

The IR spectra of the copolymers are characterized by absorption in the following ranges ν, cm^{-1}: 763 (*sym*-triazine ring); 1420, 1590–1630 (COO^-); 1490–1530, 1840–1950 ($-C(O)NH_3^+$); 1670–1695 ($-C(O)NH_2$); 1710–1730 (COOH), and 2890–2980 (–CH). The absorption bands at 1490–1530 and 1840–1950 cm^{-1} suggest the presence of the ion pair ($-C(O)N^+H_3^-OOC$).

Based on the above data, the structure of copolymer **II** can be represented as:

The water absorption by copolymer **II** in the linear portion of the kinetic plots is determined by both the COO^-/COOH molar ratio and the content of AM units in the copolymer network. The linear portions of the dependence of the water absorption of copolymer **II** on the concentration of AM units in the copolymer is shown in Fig. 3. Copolymers **II** were prepared at a varied concentration of AM component and [AA] = 1.5, [Na-AA] = 0.45, and [Na-DAIC] = 1.25×10^{-2} M. As can be seen from Fig. 3, copolymer **II** containing 30% AM relative to [AA] exhibit high water absorption capacity.

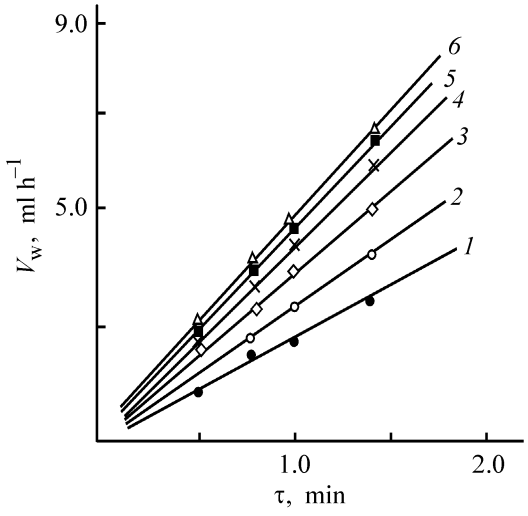


Fig. 3. Water absorption capacity V_w of copolymer **II** vs. time at a varied content of AM units in the copolymer. [AM] relative to [AA], %: (*1*) 5, (*2*) 10, (*3*) 15, (*4*) 20, (*5*) 25, and (*6*) 30.

As the content of the cross-linking agent increases, the density of intermolecular bonds between the macromolecular chains grows thereby decreasing water the absorption capacity of the copolymers.

EXPERIMENTAL

The IR spectra of copolymers were recorded on a UR-20 spectrophotometer. The distilled fraction of acrylic acid (mp 141°C, n_D^{20} 1.4224) was used. Sodium 1,3-diallyl isocyanurate was prepared in accordance with [7]. Acrylamide (mp 85°C) was recrystallized from methanol. Ammonium persulfate was recrystallized from ethanol. Copolymers **I** and **II** were prepared by the procedure described in [6].

To determine the water absorption capacity of copolymers **I** and **II**, a copolymer sample (0.25 g) was placed in a volumetric cylinder (0.5 mm in diameter and 30 cm high); the cylinder was filled with water to the mark and brought to the required temperature. The upwards motion of the boundary of the swollen gel in the course of time was recorded.

CONCLUSIONS

(1) Copolymers of acrylic acid, sodium acrylate, and sodium 1,3-diallyl isocyanurate and of acrylic acid, sodium acrylate, acrylamide, and sodium 1,3-diallyl isocyanurate exhibit a high water absorption capacity.

(2) Water absorption by copolymers increases with the COO^-/COOH molar ratio and the content of acrylamide units in the copolymer.

(3) As the content of the cross-linking agent (sodium 1,3-diallyl isocyanurate) increases, the water absorption capacity of the copolymer decreases.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Flocculation Activity of Anionic Copolymers of Acrylamide with Respect to Titanium Dioxide Suspension as Influenced by Their Molecular Properties

V. E. Proskurina and V. A. Myagchenkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 21, 2005

Abstract—The kinetics of sedimentation of titanium dioxide suspension in the presence of ionic (anionic) acrylamide copolymers in the mode of free (unrestricted) sedimentation was studied. The effect of concentration and molecular properties of the copolymers on their flocculation activity was evaluated by sedimentation analysis.

DOI: 10.1134/S1070427206020261

An efficient way to improve and intensify various industrial processes and, in particular, those of separation of solid and liquid phases in the course of flocculation, flotation, and filtration in stages of selective concentration or recovery of one of components of the dispersed phased (DP), is to add small amounts of water-soluble synthetic and natural macromolecular flocculants [1]. Among these widely applicable water-soluble polymeric additives, ionic (anionic and cationic) polyacrylamide flocculants (PAAFs) show much promise, because they are relatively available and highly efficient agents controlling the sedimentation stability of various disperse systems (DSs) [2]. The PAAF efficiency is determined by the chemical nature of the alternating units, chemical structure and composition of the copolymer macromolecules, molecular properties and concentration of the flocculant, and a wide set of chemical, physicochemical, and physical properties of the particles of the dispersed phase and the dispersion medium [1, 2].

Among various active factors strongly affecting the sedimentation stability of disperse systems, two parameters of given (co)polymer-flocculant, namely molecular weight and molecular weight polydispersity [3], are the most important. Since the overall effect is determined by a wide set of interrelated active parameters of the system, adequate evaluation of the contribution of each parameter on the flocculation process is possible only for model systems. Ocher, kaolin, and copper oxide are the common standard model DSs for comparative studies of the flocculation properties of water-soluble (co)polymers [1, 2, 4]. The titanium dioxide suspension is used as model DS with high density of DP particles and high charge density on their surface [5, 6]. In comparison with ocher, kaolin, and copper dioxide, titanium dioxide is characterized by more stable average size, size polydispersity, and physicochemical properties at the phase boundary of the TiO_2 particles and a significantly smaller content of impurities and water-soluble inclusions, which allows more reliable evaluation of the effect of the given factors on the flocculation parameters of the system. Therefore, systematic studies of the effect of specific active parameters on the flocculation kinetics of the titanium dioxide suspension are of particular theoretical and practical importance.

In this study, we examined the effect of the molecular weight and molecular weight polydispersity of the ionic (anionic) acrylamide copolymer on the kinetics of TiO_2 suspension flocculation in the mode of free (unrestricted) sedimentation, which is the most convenient for quantitative sedimentation analysis. The effect of molecular properties on the flocculation characteristics of the model and real disperse systems has been examined previously [2, 7, 8]. It should be noted that use of acrylamide copolymer flocculants involves additional severe complications related to the variability of the copolymer composition (β) and compositional heterogeneity. To overcome these problems, samples of copolymers with different molecular weights were prepared by an unconventional technique, ultrasonic degradation across the carbon–carbon skeleton bonds of macromolecules [2, 9].

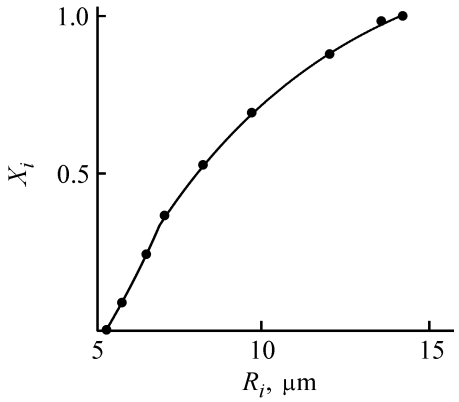

Fig. 1. Integral curve of the particle size distribution of the titanium dioxide dispersed phase (c_d = 0.4%) (X_i) Integral weight fraction of the *i*th fraction and (R_i) particle radius in the *i*th DP fraction.

EXPERIMENTAL

In our study, we used a titanium dioxide suspension [rutile modification, TU (Technical Specifications) 24.1-05762329-001–2003] with the average particle radius $\bar{R} = 8.7 \times 10^{-6}$ m and $\rho = 3.9 \times 10^3$ kg m^{-3}. To obtain more detailed data on the particle size of the system studied, we constructed the integral curve of the DP particle size distribution (Fig. 1), using the results of a sedimentometric analysis in the mode of free (unrestricted) sedimentation. It can be seen that this DS is characterized by a relatively narrow range of particle sizes ($R_{min} = 5.3 \times 10^{-6}$ m and $R_{max} = 14.3 \times 10^{-6}$ m). The flocculation kinetics of the TiO_2 suspension in the presence of acrylamide copolymers in the mode of free sedimentation was determined from accumulation of the precipitate on the pan of a VT-500 torsion balance in a 400-ml cylinder. The optimal working concentration of the dispersed phase (in all the tests, c_d = 0.4%) was determined from the preliminarily analysis of the sedimentation rate of the TiO_2 suspension as influenced by c_d [2]. The required amounts of aqueous solutions of copolymers (the concentration c was varied from 0.01 to 0.1%) were added to the supernatant and, to provide the direct contact between the DP particles and polymer additives, the resulting system was agitated with a perforated (12 holes) disk stirrer, which was slowly shifted within the cylinder 10 times in the vertical direction. Samples of the anionic acrylamide copolymers with various molecular weights M were prepared from a commercial sample of a high-molecular-weight random copolymer of acrylamide and sodium acrylate (DP9-8177 brand, $M = 3.75 \times 10^6$, bulk content of ionic units β 3.7 mol %). Samples with a smaller molecular weight were prepared by ultrasonic degradation in the mild mode in accordance with the procedure described in [9, 10]. The degradation was performed in a 0.1% aqueous solution of the copolymer, using UZDN-2T ultrasonic disperser (22 kHz working frequency) at varied exposure time and ultrasonic treatment power. As can be seen from Table 1, the ultrasonic degradation made it possible to vary the molecular weight of the copolymers in a rather wide range from 7.4×10^4 to 3.75×10^6. It is very important that the parameter β and the composition heterogeneity (CH) remained constant for all the nine copolymer samples studied, similarly to [9, 10]. The molecular weights of the resulting copolymers were calculated from the Staudinger–Mark equation $[\eta] = KM^a$, where $[\eta]$ is the intrinsic viscosity, and K and a are the constants (a = 0.785 and $K = 6.8 \times 10^{-3}$ [11]).

Table 1. Characteristics of samples A1-A9 of the anionic acrylamide copolymers (β = 3.7 mol %) prepared by ultrasonic degradation

Sample no.	Ultrasonic treatment power, W cm^{-2}	Exposure time, min	$[\eta]$, m^3 kg^{-1}	$M \times 10^{-6}$
A1	–	–	0.984	3.75
A2	1.02	6	0.765	2.72
A3	4.4	3	0.628	2.12
A4	4.4	4	0.500	1.59

A6	8.0	5	0.213	0.53
A7	11.8	4.3	0.155	0.36
A8	15.2	5	0.106	0.22
A9	18.9	4	0.043	0.070

The kinetic data illustrating the effect of the concentration and molecular weight of the polymer (samples A1 and A4) on the sedimentation stability of the titanium dioxide suspension are shown in Figs. 2a and 2b. It can be seen that even insignificant amounts of flocculants (about 5×10^{-6}%), when added to the system, strongly accelerate the sedimentation of the titanium dioxide particles, and as the concentration of the copolymer grows this effect steadily increases. Taking into account the same (negative) sign of charge on the DP particles and copolymer macromolecules, the data given in Fig. 2 suggest the predominantly bridging (rather than that of neutralization type) mechanism of flocculation in the systems studied. Using the kinetic curves, we calculated the flocculation activity λ, i.e., the relative change in the sedimentation rate per unit concentration of the polymeric additive by the following equation [2]:

$$\lambda = (\bar{v}/\bar{v}_0 - 1)/c,$$

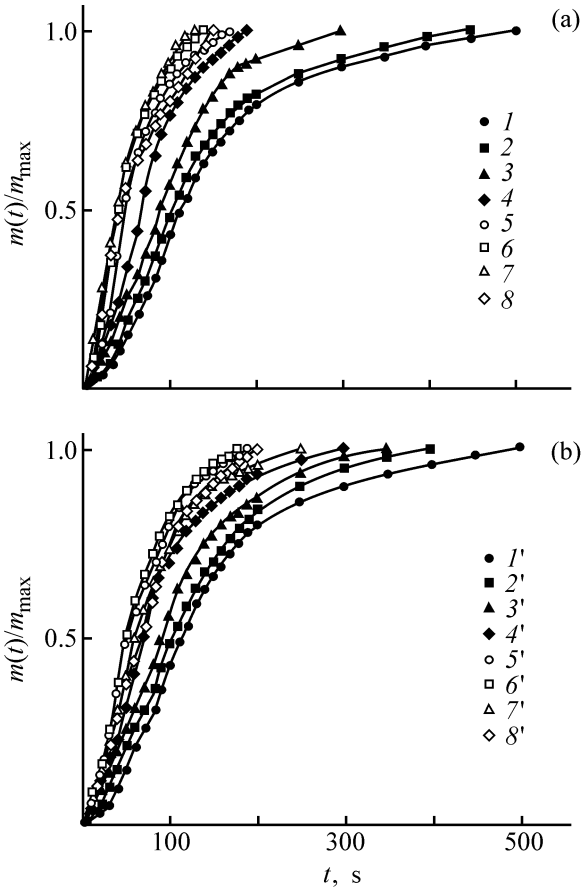

Fig. 2. Kinetic curves of sedimentation of the titanium dioxide suspension in the absence and in the presence of acrylamide copolymer samples (a) A1 ($M = 3.75 \times 10^6$) and (b) A4 (M 1.59×10^6). $c \times 10^4$, wt %: (*1*, *1'*) 0, (*2*, *2'*) 0.05, (*3*, *3'*) 0.15, (*4*, *4'*) 0.35, (*5*, *5'*) 0.74, (*6*, *6'*) 1.53, (*7*, *7'*) 3.05, and (*8*, *8'*) 6.31.

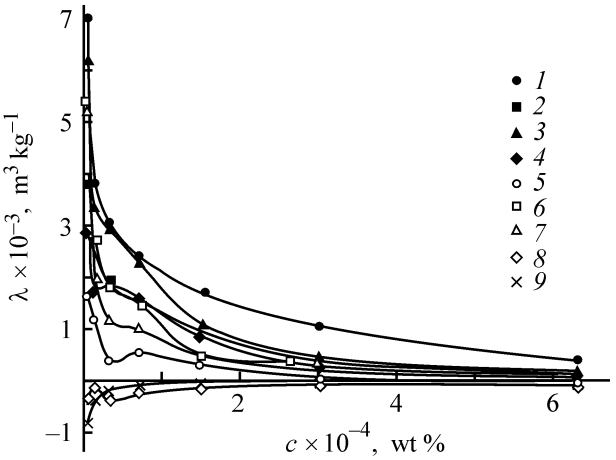

Fig. 3. Flocculation activity λ vs. the concentration c of the anionic acrylamide copolymers A1–A9. $M \times 10^{-6}$: (*1*) 3.75, (*2*) 2.72, (*3*) 2.10, (*4*) 1.59, (*5*) 0.89, (*6*) 0.53, (*7*) 0.36, (*8*) 0.22, and (*9*) 0.07.

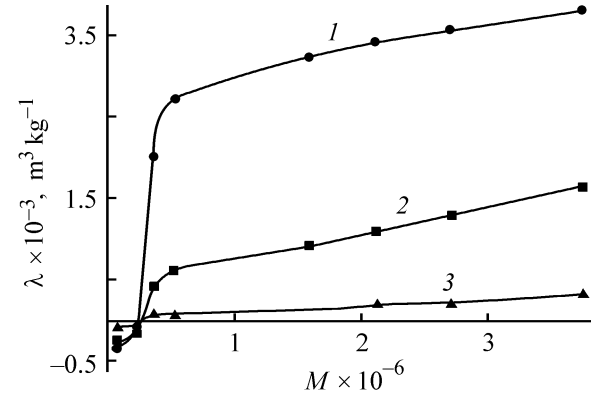

Fig. 4. Flocculation activity λ vs. the molecular weight M of the anionic acrylamide copolymers. $c \times 10^4$, wt %: (*1*) 0.15, (*2*) 1.53, and (*3*) 6.31; the same for Fig. 5.

where $\bar{v}$ and $\bar{v}_0$ are the average rates of sedimentation [at $m(t)/m_{max} = 0.4$] of the titanium dioxide suspension in the presence of flocculant and without it, and c is the concentration of the polymeric additive.

As can be seen from comparative analysis of curves (*2*–*8*) and (*2'*–*8'*) (Figs. 2a and 2b), the flocculation activity increases with the molecular weight of the flocculant.

To obtain more detailed data on the relationship of λ and M, let us consider the experimental dependences of the flocculation activities on the flocculant concentration for all the samples of acrylamide copolymers with various molecular weights shown in Fig. 3. It can be seen that, as the molecular weight decreases and the copolymer concentration increases, the flocculation activity is strongly depressed (curves *1*–*7*). This trend may be due to a decrease in the efficiency of thePAAF macromolecules in floccule formation with increasing concentration of the flocculant [1, 2]. It should be noted that the flocculation activity becomes negative for polymer additives of relatively low molecular weight (curves *8*, *9*), which means that the low-molecular-weight samples (A8 and A9) provide kinetic stabilization of the DP particles.

The quantitative data on the flocculation of the titanium dioxide suspension in the presence of the anionic acrylamide copolymers with various molecular weights are summarized in Fig. 4. In analysis of this data, significant differences in the $\lambda = f(M)$ dependences for curves *1*–*3* (Fig. 4) with relatively low and high ($M > 5 \times 10^5$) molecular weights should be taken into account. In the concentration range studied, the flocculation activity sharply increases for the copolymers with low and intermediate molecular weights,

		6.31	12.5			6.31	10.9	A1–A5	1.45	6.31	23.2

whereas for copolymers with high molecular weight, λ tends to a constant value out. The decrease in the flocculation activity, observed as the copolymer concentration insreases (passing from curve *1* to curves *2* and *3*)and *M* decreases, is probably due not only to an increase in the stabilization of the DP particles (shown above), but also to a specificity of the processes of adsorption and formation of the structural elements (floccules) from TiO_2 particles and copolymer macromolecules [1, 2]. This is additionally confirmed by selected data, for a series of copolymers, on the effective average size $\bar{R}_{eff}$ of the structural elements formed from DP particles and copolymer macromolecules in the course of flocculation (Table 2). The asymmetry of the floccules was disregarded in calculating the $\bar{R}_{eff}$ values from the data of sedimentometric analysis of the TiO_2 suspensions in the presence of flocculants. As can be seen from Table 2, the DP floccules become significantly coarser in the presence of macromolecular samples A1–A4, whereas for low-molecularweight copolymers A5–A7, $\bar{R}_{eff}$ are typical of floccules of medium size, formed in the absence of the flocculant. Similar results were obtained after preliminarily evaluation of $\bar{R}_{ef}$ of the floccules by microscopy (MBI-3 optical microscope).

The complex nonlinear shape of the $\lambda = f(M)$ dependences found in the experiments indicates that the flocculation activity of the anionic acrylamide copolymers depends not only on the molecular weight of the polymer but also on the polydispersity of the copolymer molecular weight. This conclusion, important in both theoretical and practical aspects, was confirmed by the results of experiments with model ocher system [2, 12]. It was of particular interest to verify this conclusion using another model system (TiO_2) with higher charge density and more stable characteristics of the phase boundary surface.

The copolymers with fixed average molecular weight $\bar{M} = 1.59 \times 10^6$ and various composition polydispersities were prepared using artificial blends of copolymers A1–A9. In the simplest (binary) compositions of copolymers with $M_a > \bar{M}$ and $M_b < \bar{M}$, the weight fractions of the polymer components w_a (for sample with $M = M_a$) and $w_b = 1 - w_a$ (for sample with $M = M_b$) were calculated using the following expression:

$$w_a M_a + (1 - w_a) M_b = \bar{M}.$$

As a quantitative criterion of the molecular weight polydispersity, we used an analog of the Schulz parameter F' [3]:

$$F' = \frac{M_w}{M_n} - 1 = \sum_{i=1}^{k}(w_i M_i) \sum_{i=1}^{k}(w_i / M_i) - 1,$$

where w_i and M_i are the weight fraction and molecular weight of the *i*th sample; *k*, number of fractions in question; and $\bar{M}_w$ and $\bar{M}_n$, weight-average and number-average molecular weights of the copolymer blends, respectively.

In contrast to the "common" calculation of the Schulz parameter *F* using very narrow fractions with $\bar{M}_w = \bar{M}_n$, F' parameter was evaluated using unfractionated copolymer samples for which $\bar{M}_w$ was certainly unequal to $\bar{M}_n$ (obviously, $\bar{M}_w > \bar{M}_n$). The ultrasonic degradation of the copolymer samples is described by dependences of a random degradation without depolymerization [13]. In accordance with the Eniklopov theory for these processes, the copolymer samples are characterized by the molecular weight polydispersity, which virtually coincides with the classical Flory distribution [14] for which $\bar{M}_w/\bar{M}_n = 2$. Since the same relationship of $\bar{M}_w$ and $\bar{M}_n$ is observed for the reference copolymer A4 ($M = 1.59 \times 10^6$), all the calculated data for the analogue of the Schulz parameter F' (including F' for A4) were increased by unity in com-

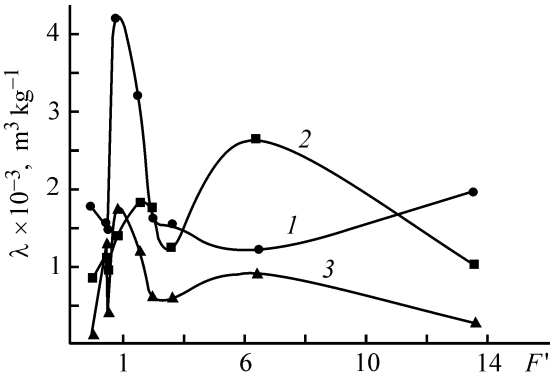

Fig. 5. Flocculation activity λ vs. the F' parameter in the presence of mixed samples of the anionic acrylamide copolymers ($M = 1.59 \times 10^6$).

parison to the calculated F values for the case of uniform copolymer fractions. Apparently, the greater the F and F' parameters, the higher the polydispersity of the polymeric system in question.

Figure 5 illustrates the complex nonmonotonic behavior of the $\lambda = f(F')$ dependences for all the three fixed concentrations of the copolymer blends. Table 2 suggests a certain correlation between $\bar{R}_{\text{eff}}$ and F' for copolymer compositions with $\bar{M} = 1.59 \times 10^6$ and thus indirectly confirms the complex relationships between λ and F'. A strong effect of the flocculant concentration on these dependences is understandable, if we take into account the dynamics and random nature of the processes of segmental adsorption of macromolecules with their subsequent anchor fixation at two particles of the dispersed phase that have approached each other to the critical distance of 0.01–0.1 μm [1, 2, 15, 16]. Rather complex dependences are also typical of the second stage of flocculation, i.e., formation of floccules [1, 16]. On the whole, we can conclude that the control over the molecular weight polydispersity of polymeric flocculants can intensify (or even optimize) the flocculation processes for both model and real disperse systems.

CONCLUSIONS

(1) Nine samples of the anionic copolymer with a wide range of molecular weights and identical composition and compositional heterogeneity were prepared from a random high-molecular-weight copolymer of acrylamide and sodium acrylate with a low degree of hydrolysis (β = 3.7mol %) by ultrasonic degradation of 0.1% aqueous solutions of the copolymer under mild conditions.

(2) The flocculation kinetics was studied at varied molecular weight and concentration of copolymers for the example of negatively charged particles of a disperse system (0.4% suspension of titanium dioxide) in the mode of free (unrestricted) sedimentation. The flocculation activity of the ionic acrylamide copolymers depends not only on the molecular weight of copolymers, but also on the molecular weight polydispersity.

Abstract—Conditions for the preparation of modified Caprolons were determined and optimized. A number of laboratory and industrial samples was prepared. Their main mechanical, physicochemical, and electrical properties were determined.

DOI: 10.1134/S1070427206020273

Caprolon is a block polyamide. It is used as a structural and antifrictional material. Owing to its unique properties, Caprolon is widely used in shipbuilding, agriculture, power engineering, and chemical, petroleum, pulp and paper, and food industries. Since Caprolon is a strong and lightweight (lighter by a factor of 6–7 than bronze and steel) polymer having low constant of friction, it can be used without lubricants in friction units. It is resistant to hydrocarbons, oils, alcohols, alkalis, and weak acids. In addition, this polymer is nontoxic. In particular, in shipbuilding it is used to produce slide bearings, guides, bushes of friction units, pulleys, blocks and bearing rollers of hoisting devices, body plans, brackets, wheel naves, and other parts for which high impact strength and thermal resistance are required.

The Caprolon properties can be changed by its modification with fillers that are uniformly distributed in the polymeric matrix. Introduction of solid, in particular, powdered fillers allows variation of Caprolon properties in the widest range. These modifiers, when introduced in small amounts (up to several percent), can be nucleating agents and can affect the degree of crystallinity of the polymer. The most efficient is introduction of small amounts of fine (particle size smaller than 10 μm) and ultrafine (particle size smaller than 1 μm) fillers, in particular, of carbon materials. Finely divided graphite is the most widely used as a modifier to improve the hardness, compressive, bending, and electric strength, and other properties of Caprolons [1, 2]. Introduction of graphite changes the strength and electrical properties of Caprolon. In particular, the dielectric constant and dielectric loss tangent increase and the moisture absorption decreases.

It is known [3] that fullerenes and fulleroids (in particular, fullerene-containing soot) strongly affect polymerization of various organic compounds and dramatically change the polymer properties. We suggested that introduction of fullerenes should significantly improve the strength and elasticity of the polymer. The tribological properties of pure fullerenes with respect to metals were studied in [4]. Fullerene-containing soot partly retains these properties. All these factors, along with the reduction of the production cost of fullerene soot and fullerenes, allow us to expect that the consumer properties of Caprolons can be substantially improved by modification with fullerenes without any significant rise in the price of the product.

We tested four types of fullerene materials: (1) C_{60}–C_{70} mixture (weight fraction of C_{60}, C_{70} and higher fullerenes 68, 30, and 2%, respectively); the procedure for determining the fullerene concentration in different phases is described in detail in [5–8]; (2) pure (99.9 wt%) C_{60}; (3) fullerene soot; and (4) washed fullerene soot (fullerene black).

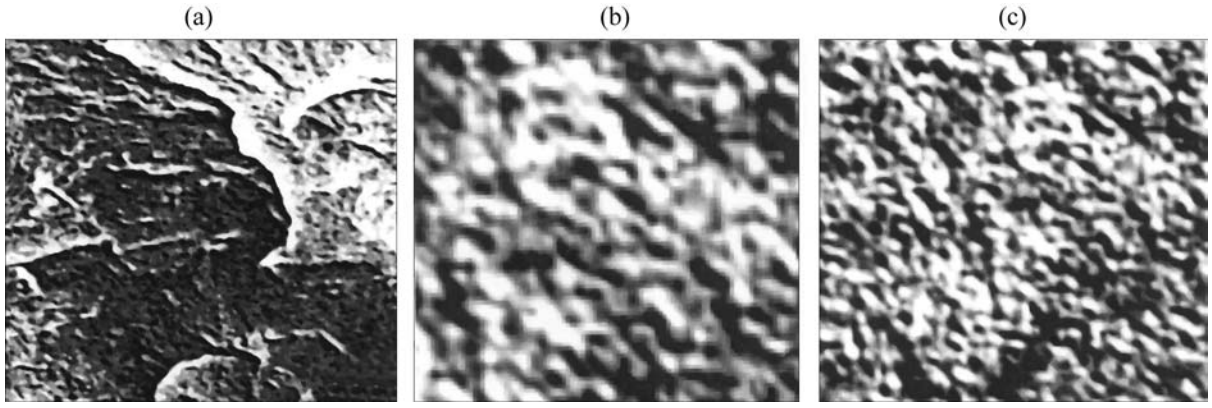

Fig. 1. Electron micrographs of polished sections of (a) unmodified Caprolons, (b) Caprolons modified 0.0017 wt % C_{60} of 99.9 wt % purity, and (c) Caprolons modified with 0.11 wt % fulleren soot. Magnification ×40000.

Fullerene soot (initial product) is a fine carbon powder obtained by arc combustion of graphite electrodes in an inert atmosphere (average particle size 0.5–2.0 μm). Fullerene soot is the main raw material for production of fullerenes. The total fullerene content in the soot is 12.7 wt %. A C_{60}–C_{70} mixture containing up to 2 wt % higher fullerenes (C_{76}, C_{78}, C_{84}, C_{90}) is obtained by extraction of fullerene soot. The washed fullerene soot is the residue formed after extraction of fullerenes. The residual fullerene content in it is not higher than 0.05%. All fullerene products used in this study were prepared at SUDPLAST-SERVIS Private Company (St. Petersburg) by the previously described procedure [9].

Caprolons produced by the modified industrial process, with all of the above substances used as modifiers, are denoted as CMF.

The main starting materials for production of CMF were the same as in the conventional technique for manufacture of Caprolon: caprolactam, metallic sodium (catalyst), 2,4-toluene diisocyanate (TDI) (activator), and argon (inert gas). In the course of CMF synthesis, caprolactam samples were dried in an oven in a vacuum or in air for 2 days. Then calculated amounts of an appropriate fulleroid material were introduced the dry samples. The mixture was stirred until it became visually homogeneous. The mixture was heated to ~100°C and melted in an oven with intermittent stirring. The melt was divided in two equal portions. To one of these portions metallic sodium was added. It completely dissolved in the melt. To the other portion, TDI was added. Both portions were heated in an oven at 130 ± 5°C and mixed in a preheated metallic mold (reactor) with vigorous stirring. The mixture was allowed to stand at the temperature naturally attained in the exothermic polymerization (the maximal temperature rise due to heat release was 10–20°C higher than the oven temperature). The oven was switched off and the mixture was furnace-cooled.

We prepared compact CMF samples containing 0.05 to 1.0 wt % fullerene soot or fullerene black and 0.01 to 0.02 wt % of C_{60} + C_{70} or pure C_{60}. The weight of these samples was 220, 2000–2100, 7900–8100, and 15500–16500 g. The visually homogeneous samples modified with fullerene soot and fullerene are black and gray-green, respectively. The initial unmodified Caprolon is white. The samples were analyzed with a JEM-100S (JEOL) electron microscope at a $(10–100) \times 10^3$ magnification. Typical electron micrographs of chips of CMFs and initial Caprolon are shown in Fig. 1. As can be seen from Fig. 1, modification with both fullerenes and fullerene soot decreases the size of crystal grains and makes the intercrystal spacings narrower and smeared. The structural changes in CMF modified with fullerene soot are more pronounced than those observed upon introduction of fullerenes proper. This is due to the fact that the content of the modifier in the form of a soot is naturally always 1–3 orders of magnitude than that of fullerenes. In particular, the content of the soot and the fullerenes in the samples shown in Fig. 1 is 0.11 and 0.0017 wt %, respectively.

The properties of CMF samples were measured in accordance with GOSTs (State Standards) for study of polyamides, since unmodified Caprolons a polyamide. The average results of 3–10 parallel measurements are summarized in Tables 1 and 2.

As can be seen from Table 1, introduction of even small amounts of fullerene modifiers substantially increases the strength and elasticity of almost all the samples. Modification with metallic additives has a similar effect. However, the fullerene content in the sample is lower by approximately 1–3 orders of magnitude and has virtually no effect on the sample

Table 1. Some mechanical and physicochemical properties of CMF

Property	Unmodified Caprolon	CMF modified with fullerene soot	CMF modified with fullerenes
Moisture absorption (boiling for 24 h), wt %	1.5–2.0	<2.0	<2.0
Brinell hardness* MPa [GOST (State Standard) 4670]	130	135–160	125–150
Ultimate compressive strength, MPa	80–90	120–125	100–110
Charpy impact resilience*, kJ mol^{-1} (GOST 4647)	40	>70	60–70
Yield point under compression*, MPa (GOST 4651)	100–110	110–130	70–90
Density*, g cm^{-3}	1.15–1.16	1.18–1.23	1.16–1.20
Attrition resistance*, mm^3 (GOST 23509–79)	35	<25	<20
Slip coefficient over steel without lubricant*, rel. units (GOST 27492–87)	0.20–0.30	<0.15	<0.10

Table 2. Electrical properties of CMF

Property	Unmodified Caprolon	CMF modified with fullerene soot	CMF modified with fullerenes
ε, rel. units (ν = 1 kHz)	3.0–3.2	3–10	8–20
$\tan\delta \times 10^4$:			
ν = 1 kHz	0.030	0.3–1.2	0.1–0.2
ν = 10 kHz	–	0.03–0.1	0.1
Resistivity, Ω cm	10^{14}	10^{10}–10^{13}	10^8–10^{10}
Electrical strength, kW mm^{-1}	30–35	60–100	>100

density. The determination error of the mechanical properties of CMF, listed in Table 1, ranges from ±5 to ±10 rel %. This accuracy is sufficient to conclude that the mechanical properties of Caprolon strongly change after modification. The slip coefficient over steel and abradability decrease by 40%; the softening and melting points and temperature of thermal degradation in air increase (Fig. 2); thermal conductivity decreases; and the density and moisture absorption do not noticeably change.

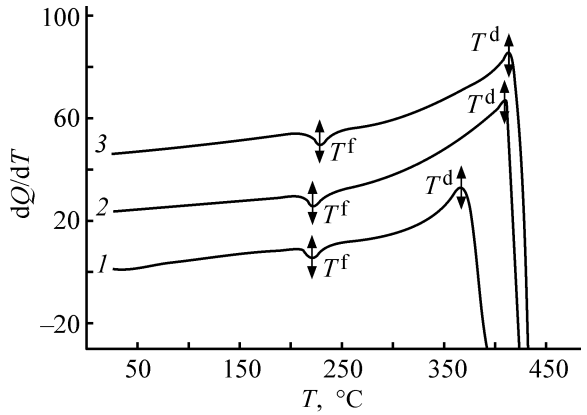

Fig. 2. Thermal analysis curves of (*1*) unmodified Caprolons and Caprolons modified with (*2*) 0.0017 and (*3*) 0.11 wt % C_{60} of 99.9 wt % purity. (T) Temperature, (T^f) melting point, and (T^d) onset temperature of thermolysis on heating in air at a rate of 3 deg min^{-1}.

The electrical properties of CFM, listed in Table 2, show that modification substantially improves the antistatic properties. The decrease in the resistivity of some samples by several orders of magnitude favors accelerated leakage of static electricity. The dielectric constant and hence the breakdown voltage substantially increase.

Thus, use of CMF articles under conditions of contamination with combustible and explosive gases (e.g., in the case of methane outburst in coalbeds) is much safer as compared to that of unmodified Caprolon articles.

CONCLUSIONS

(1) The compatibility of polyamides with fullerene materials was demonstrated for the example of Caprolon.

(2) Modification of Caprolon with small amounts of fullerenes increases the hardness, impact resilience, attrition resistance, and softening and melting points and decreases the moisture absorption and moisture capacity of the samples.

(3) Introduction of fullerenes allows variation of the electrophysical properties (volume and surface conductivity, dielectric constant, and dielectric loss tangents) of the polymers in a wide range.

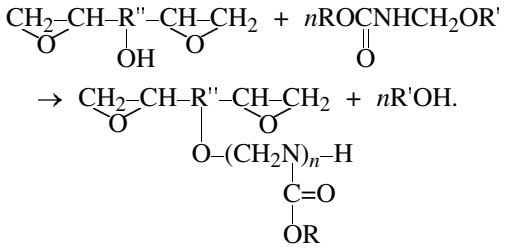
MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Urethane-containing Epoxy Oligomers

V. V. Mikheev and R. R. Ivanova

Kazan State Technological University, Kazan, Tatarstan, Russia



Received November 25, 2005

Abstract—A procedure for preparing urethane-containing epoxy oligomers from reactive monourtheanes was developed.

DOI: 10.1134/S1070427206020285

To improve properties of epoxy polymers and to extend the field of their application, initial epoxy oligomers (EOs) are modified with various functional groups including urethane groups. Urethane groups are usually introduced into EOs using diisocyanates. Urethane-containing EOs are used in practice [1, 2]. However, diisocyanates are expensive and toxic compounds. Therefore, development of a procedure for preparing urethane-containing polymers without using diisocyanates is of interest [3–6].

Here we studied the possibility of preparing urethane-containing epoxy oligomers (UEOs) without using isocyanides by the reaction of EO hydroxy groups with reactive monourethanes (RUs) $ROCONHCH_2OR'$ (R–C_4H_9, C_5H_{11}; R'–*iso*-C_3H_7, C_4H_9):

Reactive monourethanes were prepared in two steps. The first step is reaction of butyl or amyl alcohol with urea to form monourethanes:

$$ROH + H_2NCONH_2 \rightarrow ROCONH_2 + NH_3.$$

To raise the reactivity of monourethanes, *N*-methylol (R' = H) or *N*-alkoxymethylene (R' = *iso*-C_3H_7, C_4H_9) groups were introduced into their structure. *N*-methylolurethanes were prepared by reaction of urethanes with formaldehyde (in the form of paraformaldehyde or Formalin) in an alkaline solution:

$$ROCONH_2 + CH_2O \rightarrow ROCONHCH_2OH.$$

Synthesis of *N*-alkoxymethylurethanes was performed in alcoholic solution at pH 2–3:

$$ROCONH_2 + CH_2O + R'OH \rightarrow ROCONHCH_2OR' + H_2O.$$

The IR spectra of RUs contain the bands of urethane groups at 1260, 1710, and 3320 cm^{-1}. The properties of RUs are listed in Table 1. Reactive mono-

Table 1. Properties of RUs $ROCONHCH_2OR'$

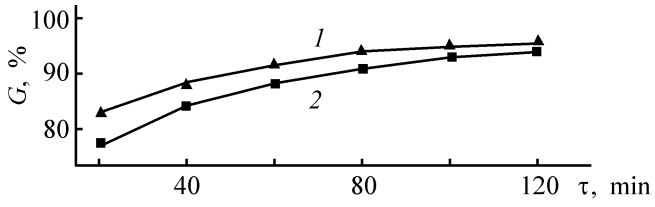
urethanes colorless and odorless liquids stable in prolonged storage.

We used commercial E-40, E-41, and E-44 oligomers as EOs (Table 2).

Condensation of *N*-methylol and *N*-alkoxymethylene groups with alcohols is catalyzed by acids [7, 8]. Phthalic anhydride is used, in an amount of 1% of the total weight of the reaction mixture, as an acid catalyst for UEO synthesis. The reaction course was monitored by the liberation of the by-product. The oligomerization of RU-1 and RU-2 was faster. In this case, the liberation of water (by-product) in a vacuum started at 90°C and the reaction was complete upon slow warming to 125°C.

When RU-3 and RU-4 were used, isopropanol and isobutanol were liberated only at 130–145°C. The difference in reactivity between RUs is consistent with the known data on the reactivity of other compounds containing *N*-methylol and *N*-alkoxymethylene groups [7]. An attempt to accelerate UEO synthesis by heating above 150°C failed, since the reaction mixture became viscous or even gelatinous under these conditions, owing to the reaction of the epoxy groups with the N–H bonds of urethanes [8].

It is known that compounds containing *N*-methylol and *N*-alkoxymethylene groups not only react with alcohols, but are also capable of self-condensation [7, 9]. This is the case for reactive monouretanes too. Urethane oligomers were synthesized by heating RU-1 and RU-4 in a vacuum at 130–145°C in the presence of catalytic amounts of phthalic anhydride. These compounds are viscous liquids with a molecular weight of 600–800. The reaction can be described by the scheme



$$n\mathrm{HNCH_2OR'} \rightarrow \mathrm{H(NCH_2)}_n\mathrm{OR'} + (n-1)\mathrm{R'OH}.$$
$$\mathrm{C{=}O} \qquad\qquad \mathrm{C{=}O}$$
$$\mathrm{OR} \qquad\qquad \mathrm{OR}$$

The structure of these oligomers was confirmed by elemental analysis and IR spectroscopy.

Hence, RU can also condense with the OH groups of EO at their molar ratio higher than 1 : 1. Although a molecule of E-40 oligomer contains only one hydroxy group, its UEOs were prepared at the E-40 RU molar ratio from 1 : 0.5 to 1 : 3.

The UEOs derived from E-40 are highly viscous substances; the oligomers derived from E-41 and E-44 are solid. The content of epoxy groups and nitrogen in the oligomers and their molecular weights M_n are listed in Table 3.

The suggested structure of UEOs is confirmed by IR spectroscopy and by the fact that these substances

Content of the gel fraction G in curing of a mixture of UEO-2 with (*1*) diethylenetriamine and (*2*) hexamethylenediamine at 120°C vs. time τ.

are cured to form cross-linked polymers. In going from E-40 to UEO, the band of epoxy group is preserved (900 cm^{-1}), the band of the hydroxy group (3450 cm^{-1}) disappears, and the bands of the urethane group at 1260 and 3330 cm^{-1} appear.

UEOs are readily cured in the presence of aliphatic polyamines. Accumulation of the gel fraction in the course of curing of UEO-2 in the presence of stoichiometric amounts of hexamethylenediamine and diethylenetriamine, which are widely used, [10] as curing agents for EO, is shown in the figure. The high content of the gel fraction (more than 90%) in the curing products suggests that RUs are chemically bound to EO molecules and do not polymerize to form homopolymers.

EXPERIMENTAL

Butyl and amyl urethanes were prepared by refluxing the corresponding alcohols with urea in the presence of catalytic amounts of zinc [9, 11]. RU-1 was prepared as follows. Butyl urethane (58.5 g, 0.5 mol), paraformaldehyde (16.5 g, 0.55 mol), and 0.4 g of 50% aqueous solution of NaOH were placed in a three-necked flask equipped with a stirrer, thermometer, and reflux condenser. The mixture was heated at 55–60°C for 2 h. The resulting liquid was cooled, neutralized, dissolved in chloroform, and washed with water. The organic layer was separated and the solvent was removed in a vacuum. RU-2 was prepared similarly. The synthesis of RU-3 and RU-4 differed in that isopropanol or isobutanol was used as solvent (pH 2–3).

Synthesis of UEO with RU-1 and RU-2 was performed by the following procedure described with an example of RU-1. EO (62 g, 0.1 mol), RU-1 (14.7 g, 0.1 mol), and phthalic anhydride (0.8 g) were placed in a three-necked flask equipped with a stirrer, thermometer, and descending condenser with a condensate receiver. The mixture was slowly heated with stirring at a residual pressure of 0.5 kPa. The onset of water liberation was observed at 90°C. The water condensate was collected in the receiver. Water liberation was complete at 125°C. The reaction mixture was heated at this temperature for 0.5 h and then cooled.

Synthesis of UEO from RU-3 and RU-4 was performed similarly with the exception that the reaction mixture was heated at 130–145°C for 1.5 h.

The content of nitrogen, hydroxy groups, and epoxy groups in the oligomers was determined by the Kjeldahl procedure [12], acetylation procedure [12], and reaction with a solution of hydrochloric acid in acetone [13], respectively. The molecular weight of the oligomers, M_n, was calculated from the content of the epoxy groups. To determine the content of the gel fraction in the course of curing of UEO mixtures, weighed portions of the samples of the reaction mixture were extracted with acetone in a Soxhlet apparatus for 6 h [14].

CONCLUSION

Urethane-containing epoxy oligomers were prepared by reaction of the epoxy oligomers with monourethanes containing *N*-methylol or *N*-alkoxymethylene groups.

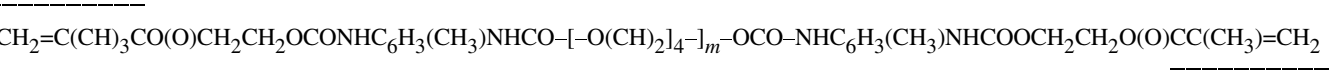
Abstract—The kinetics of consumption of double bonds, photoinitiators, and dyes in photocuring of formulations based on oligourethane methacrylate and trimethylolpropane triacrylate was studied. The kinetic parameters and quantum efficiencies of the processes were determined. The contributions from shielding and inhibition to the total polymerization deceleration by the dyes were estimated. The curing of dyed formulation and dye consumption were analyzed in relation to the structural features of the photoinitiators and dyes.

DOI: 10.1134/S1070427206020297



UV-curable dyed oligomer-monomer formulations (so-called UV paints) are widely used in various industries, especially in polygraphy [1–3]. Printing on textile materials with UV paints has a number of environmental and technical benefits, which makes this procedure fairly promising [4, 5]. However, there are no data on how the photocuring of formulations is influenced by textile dyes and on the stability of these dyes during polymerization.

In this study, we elucidated the kinetic relationships in photocuring of dyed formulations and determined the parameters characterizing both the polymerization proper and the consumption of photoinitiators and dyes during polymerization. The primary attention was given to a more detailed analysis of the previously [6] revealed specific features of the process, consisting in that the performance of photoinitiators is affected by the dyes and the consumption of dyes during photocuring of formulations is influenced by the nature of a photoinitiator.

As photopolymerizing binder served a formulation based on oligourethane methacrylate (OUMA) and trimethylolpropane triacrylate (TMPA). The choice of these components was governed by the need to ensure a fairly high adhesion of the resulting polymer to hydrophilic polymer fibers (cotton and viscose), combined with high strength and elasticity. In selection of photoinitiators among aromatic ketones and quinones, as well as among derivatives of thioxanthone and phosphine oxide, we took into account the known data for other photopolymerizing systems [7]. Disperse dyes from various classes with various structures, which are used in textile industry, served as dyes.

EXPERIMENTAL

Oligourethane methacrylate with the formula

$$CH_2=C(CH)_3CO(O)CH_2CH_2OCONHC_6H_3(CH_3)NHCO–[–O(CH)_2]_4–]_m–OCO–NHC_6H_3(CH_3)NHCOOCH_2CH_2O(O)CC(CH_3)=CH_2$$

and a number-average molecular weight M_n = 1400 was prepared from oligotetrahydrofuran with terminal toluene isocyanate groups at the Institute of Chemical Physics, Russian Academy of Sciences. A prototype-commercial sample of TMPA available from Yarsintez Research Institute, Open Joint-Stock Company, as well as commercial samples of 2,6-di-*tert*-butylanthraquinone (Research Institute for Organic Semiproducts and Dyes, Russia), 2-isobutylanthraquinone (Lovson Chemicals, the United Kingdom), and phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide (Irgacure 819, Ciba, Switzerland) were used without further purification. Photoinitiators, 1-chloro-4-propoxythioxanthone, benzophenone, and benzil, were purified by recrystallization from ethanol. Commercial samples of the dyes were purified, when necessary, by

Benzil	1.0	0.68	0.68	1.4	12

recrystallization from acetone or chromatographically. Chemically pure acetone was used without further purification.

Films, 50 μm thick, were cast from acetone solutions on supports made of polyethylene films hydrophilized by a special procedure. The components of the photopolymerizing formulations, OUMA, TMPA, photoinitiators, and dyes, were dosed, i.e., the required amounts of their solutions in acetone with the known concentrations were taken. The resulting films were exposed in air at room temperature ($20 \pm 2°C$) with the light (λ = 365 nm) cut from the total spectrum of a DRSh-1000 Hg lamp with UFS-6 and BS-6 light filters. The degree of cross-linking of the polymerizing formulation was estimated from the decrease in the optical density of the C=C stretching vibration band at 816 cm^{-1}. The extent of photocuring was also judged from the disappearance of the film stickiness [6, 8]. The consumption of the photoinitiators and dyes was monitored by the decrease in the optical density in the UV and visible ranges.

The choice of the film thicknesses, the OUMA/TMPA ratio (75/25 by weight), and the concentrations of the photoinitiators and dyes was governed both by practical (need for a sufficient intensity of color, high curing rate, and good physicomechanical properties) and experimental (need for optimizing the conditions of recording of the reactant concentrations) considerations.

The intensity of incident light for the samples was determined using polyvinyl chloride and polyethylene films containing benzophenone or 2,6-di-*tert*-butylanthraquinone as chemical actinometers. The intensity was calculated from the quantum efficiencies of consumption of benzophenone in polyvinyl chloride and polyethylene, equal to 0.16 [9] and 0.20 [10, 11], respectively.

The initial rates of polymerization (consumption of double bonds) (v_p), conversion of the photoinitiator (v_i), and conversion of dye (v_d), were calculated by differentiation of the experimental kinetic curves.

The absorption spectra in the UV and visible ranges were recorded on a Specord UV-Vis spectrophotometer, and the IR spectra, on a Specord IR-75 spectrophotometer.

When samples containing different photoinitiators are UV-irradiated in the absence of dyes, the double bonds are rapidly consumed (Fig. 1) and a stickiness disappears owing to cross-linking of the formulation (Table 1). The photoinitiators strongly differ in the performance characteristics: phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide and anthraquione and thioxanthone derivatives exhibit the highest (Fig. 1, curves *1*–*4*), and aromatic ketone and diketone (Fig. 1, curves *5*, *6*), the lowest activity. Indeed, Fig. 1 characterizes specifically the activity of the photoinitia-

Photoinitiator concentration, %	$v_p \times 10^3$, s^{-1}	Φ_p	$v_i \times 10^3$, s^{-1}	Φ_i	τ_p, min
1	5.9	22	3.5	0.49	10
2	19	35	3.6	0.49	4.5
3	17	23	4.0	0.60	3.5
4	33	35	6.0	0.60	3.0

tors, i.e., their ability to generate free radicals under the given conditions, since the optical densities at the irradiation wavelength of all the samples studied are small and comparable, namely, close to 0.1.

The kinetics of consumption of the double bonds in the cross-linking initiated by 2-isobutylanthraquinone, 1-chloro-4-propoxythioxanthone, benzophenone, or benzil (Fig. 1, curves *3–6*) are satisfactorily fitted by the first-order equation of the type

$$(A_t - A_\infty) = (A_0 - A_\infty)\exp(k_p t). \quad (1)$$

Here, t is the irradiation time; k_p, polymerization constant; A_t, optical density at a given instant of time t; and A_0 and A_∞, optical densities at $t = 0$ and $t \to \infty$, respectively.

The parameter A_∞ was introduced to take into account the kinetic inhibition of the process because of the diffusion limitations at high conversions, when the sample becomes hard.

In the presence of more active photoinitiators, phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide and 2,6-di-*tert*-butylanthraquinone (Fig. 1, curves *1*, *2*), the kinetics of the process is described by the sum of two exponents:

$$(A_t - A_\infty) = (A_0 - A_\infty) \times [a\exp(-k_{p1}t) + (1 - a)\exp(-k_{p2}t)]. \quad (2)$$

Here, a and $(1 - a)$ are the relative contributions from the faster (with k_{p1}) and slower (with k_{p2}) processes, respectively.

We show below that more complex description of the polymerization kinetics in these two systems is due to the need to take into account the consumption of the photoinitiators. It should be noted that, although the k_p constants, relative initial rates v_p, and quantum efficiencies Φ_p of the polymerization differ sharply (by more than two orders of magnitude, Table 1), the times of irradiation until curing is completed, τ_p, differ less strongly (by only a factor of 4).

The consumption rate of double bonds is proportional to the photoinitiator concentration within the experimental error (Table 2), since, as noted above, the optical density at the irradiation wavelength is small. Consequently, the quantum efficiency of the process is constant, 29 ± 7 on the average. This is consistent with the fact that the quantum efficiency of the photoinitiator conversion (0.55 ± 0.06 on the average) is independent of its concentration (Table 2). The time of irradiation until the curing of the formulation is completed naturally, decreases as the photoinitiator concentration increases (Table 2). Considering the shape of the concentration dependence, as well as the crystallization of the photoinitiator in the formulation being cured at relatively high concentrations (≥4 wt %) and the economical aspects, we conclude that the optimal concentration is ca. 3 wt %.

Upon introduction of disperse dyes, the initial polymerization rate v_p, as a rule, significantly decreases and the time of irradiation until curing of the formulation τ_p, typically noticeably increases (Fig. 2, Table 3). The process kinetics is fairly adequately described by Eq. (1) corresponding to a second-order reaction (Fig. 2, curves *1–4*). Only in a single case, namely, in the presence of Yellow K dye, a biexponential dependence of type (2) was observed. The limiting extent of polymerization, defined as A_∞/A_0, changes insignificantly upon introduction of the dye. This is due to the fairly low shielding coefficients at the irradiation wavelength. At the same time, the A_∞/A_0 ratio in curing of dyed formulations, like in the case of undyed formulations, is noticeably larger in a number of cases

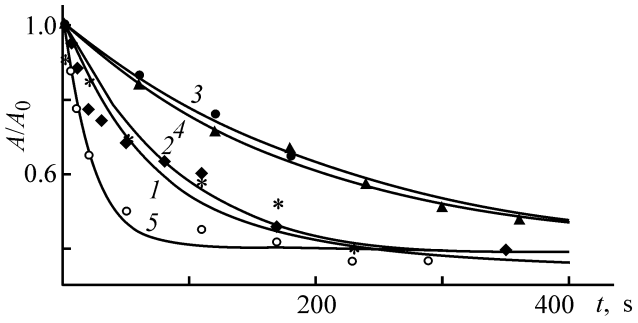

Fig. 2. (*1–4*) Photopolymerization of the formulations containing 3 wt % 2,6-di-*tert*-butylanthraquinone as photoinitiator with different dyes: (*1*) Disperse Blue K, (*2*) Disperse Orange Zh, (*3*) Disperse Red-Brown, and (*4*) Disperse Yellow K and (*5*) consumption of double bonds in the absence of dyes. For dye concentrations, see Table 3.

in the presence of phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide than in the presence of 2,6-di-*tert*-butylanthraquinone (Fig. 3). This suggests a general character of the dependence of the limiting extent of polymerization on the structure of the photoinitiator, due to its action mechanism. Photoinitiators decomposing into small radicals under irradiation can migrate by diffusion to significant distances [e.g., phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide]; they cause more profound transformations of the polyfunctional monomer than photoinitiators acting via detachment of the H atom from the environment (e.g., 2,6-di-*tert*-butylanthraquinone) and forming significantly larger radicals.

Detailed analysis of the data in Table 3 reveals three most important features of the photocuring of dyed formulations.

(1) The initial polymerization rates v_p tend to decrease in the presence of a number of dyestuffs more sharply (by two orders of magnitude at a maximum) than increases the irradiation time until curing τ_p (typically severalfold).

(2) The influence of a dye on the polymerization initiated by phenylbis(2,4,6-trimethylbenzoyl)phos-

phine oxide is stronger, compared to initiation by 2,6-di-*tert*-butylanthraquinone.

(3) The activity of the photoinitiators in the presence of dyes may vary so widely that this can change the ratio of their activities: Phenyl-bis(2,4,6-trimethylbenzoyl)phosphine oxide, more active in the absence of dyes, becomes less active than 2,6-di-*tert*-butylanthraquinone in the presence of dyes.

General considerations suggest that one of the main mechanisms by which dyes affect the polymerization is shielding. Table 3 lists the shielding coefficients γ calculated as [12]

$$\gamma = [(A_1 + A_2)/A_1][(1 - 10^{-A_1})/(1 - 10^{-(A_1+A_2)})], \quad (3)$$

where A_1 and A_2 are the optical densities of the undyed samples and samples in the presence of dyes, respectively.

Using these γ parameters, we can calculate the corrected quantum efficiencies of polymerization $\Phi_{pc} = \gamma\Phi_p$. The Φ_{pc} parameters typically slightly exceed the Φ_p parameters (Table 3), since the calculations actually take into account only the amount of light absorbed by the photoinitiator proper, and the dye is regarded as an internal filter only. However, the Φ_{pc} parameters for most of the dyed systems are also substantially lower than the Φ_p parameters for undyed systems. This suggests that, along with shielding (UV absorbers), most of the dyes studied are involved in chemical reactions. It is well known [13] that many disperse dyes and, in particular, azo dyes can react with free radicals, which is one of the main factors making them highly efficient photostabilizers with respect to polydienes. It should be noted that the influence of the dyes on polymerization under the actual conditions fairly well correlates qualitatively with their photoprotection action in polydienes. For example, the photoresistance of polydienes in the presence of azo compounds increases in the following order: 3-methyl-5-*tert*-butyl-6-hydroxyazobenzene (analog of dyestuff Yellow 6 Z) < 4-dimethylamino-4-nitroazobenzene (Disperse Orange Zh) < 4-hydroxy-3-methyl-4-benzeneazo(azobenzene) (Yellow Fast 4K) [13]. The same trend is characteristic of the inhibiting action of these dyes during polymerization (Table 3).

The consumption of the photoinitiators in the presence of dyes (Table 4) is described by dependences of types (1) and (2), characteristic of undyed formulations as well. The inhibition effects for this process are an order of magnitude weaker, compared to polymerization, and do not exceed 7–8 (Table 4). Another feature of this process consists in that the dyes exert comparable influence on the performance of photoinitiators of varied nature (Table 4).

A decrease in the consumption rate of the photoinitiators in the presence of the dyes is only partially due to the shielding effect (Table 4). The action of the dyes, evidently, includes, along with shielding, quenching of excited states of the photoinitiators by the energy transfer mechanism. This, naturally, decelerates the formation of free radicals, thereby decelerating the initiation.

The dye consumption during photocuring of the formulations is also described by equations of types (1) and (2), except for the systems containing Yellow Z or Yellow Fast 4K dyes and 2,6-di-*tert*-butylanthraquinone as photoinitiator.

In the two last-named cases, we observed autocatalytic (S-shaped) curves. The essential features of this process are as follows.

(1) The dye consumption rate and its limiting conversion substantially depend on the dye structure (Fig. 4, Table 5). The least stable are dyes containing amino group (Yellow 4 Z, Yellow 2 K, Orange Zh, Pink 2 S, Blue K, and Blue PE).

(2) The rate and limiting degree of the dye conversion substantially depend on the nature of the photoinitiator as well (Fig. 5, Table 5). For five of the twelve systems studied, dyes are consumed faster in the presence of phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide compared to 2,6-di-*tert*-butylanthraquinone. For four systems (Yellow Z, Yellow Fast 4K, Orange Zh, and Red-Brown dyes), the dye consumption is virtually independent of the nature of the photoinitiator. Only one dye, Pink 2 S, is consumed faster in the presence of 2,6-di-*tert*-butylanthraquinone. Yellow 6 Z and Yellow K dyes are the most stable and are not noticeably consumed in the presence of any of the photoinitiators studied.

There is a qualitative correlation between the conversion rate of the dyes and their influence on the consumption of double bonds. For example, Yellow 4 Z, Yellow 6 Z, Yellow 6 Z PE, and Yellow K dyes are insignificantly consumed themselves in the case of initiation with 2,6-di-*tert*-butylanthraquinone and cause a decrease in the quantum efficiency of conversion of double bonds to only a small extent (Tables 3, 5), unlike Yellow Fast 4 K which is converted fairly rapidly and strongly inhibits the polymerization.

Thus, the influence of disperse dyes on photocuring of oligomer-monomer formulations is due to several simultaneous processes: (1) absorption of photochemically active light (shielding); (2) interaction with the photoinitiator responsible for deceleration of its consumption and, thereby, of initiation; and (3) inhibition of polymerization due to interaction with free radicals, which is also responsible for consumption of the dyes.

Table 5. Dye consumption rates during photocuring of formulations, initiated by 2,6-di-*tert*-butylanthraquinone or phenylbis(2,4,6-trimethylbenzoyl)phosphine oxide (in parentheses) at the photoinitiator concentration of 3 wt %

CONCLUSIONS

(1) Kinetic features and kinetic parameters of consumption of double bonds, photoinitiators, and dyes were determined for formulations based on oligourethane methacrylates and trimethylolpropane triacrylate.

(2) The activity of the photoinitiators changes in the presence of dyes.

(3) Consumption of the dyes in photocuring of the formulations depends on the nature of the photoinitiators.

(4) The optimal compositions of the dyed formulations having a fairly high photosensitivity and preserving the color during photocuring were determined.

Abstract—Influence of peat humus acid microadditions on the structure of starch gels for sizing cotton yarn is studied by rheology.

DOI: 10.1134/S1070427206020303

Sizing is an inherent part of weaving works, consisting in coating of the warp yarn with a polymeric adhesive, such as starch, in order to assist efficient weaving. At the same time, there is strong reason to reduce the starch consumption for sizing. First of all, starch is a valuable raw material for food industry, and the demand for starch steadily grows. Furthermore, both the warp sizing and the fabric desizing processes generate a lot of wastewater containing starch, making wastewater treatment more difficult and expensive (biochemical oxygen demand increases by 0.63 mg O_2 per 1 mg starch).

Previously, we have demonstrated that the starch concentration in the sizing mixture for cotton yarn can be considerably reduced by using humus acid (HA) microadditives [1–3]. Humus acids are natural macromolecular compounds formed by microbial fermentation of plant residues or through purely chemical processes (redox reactions, hydrolysis, and condensation) [4]. The structure of humus acids contains very diverse fragments and functional groups, which causes a broad spectrum of their properties, including the tendency to be involved in intermolecular interactions, catalytic activity in redox reactions, and surfactant properties [5, 6].

Humus acids specifically interact with starch-containing sizing mixtures. As the increasing HA concentration in starch sizing gels increases from 0 to 0.08–0.12%, the relative viscosity of the gels decreases by a factor of tens and hundreds (depending on the starch concentration), reaching values which are only 2–4 times higher than the viscosity of a straight solvent, water. Further increase in the HA concentration abrupt leads to an rise in the viscosity to the point of formation of a glassy mass [2]. The lower the viscosity of the starch–humus hydrogel, the higher its sizing efficiency. For example, hydrogels with the lowest viscosity provide an increase in the tensile stress of 25-tex cotton yarn by 51–57% with a simultaneous decrease in the elasticity loss by 12–20% [3].

It is well known that, if the ordinary starch size acquires such a low viscosity in the course of pulping (suggesting starch dextrinization), it is unsuitable for sizing because it forms a brittle, readily peeling film on the fiber surface [7]. Nevertheless, the films formed from low-viscosity starch-humus gels are well comparable in strength with the starch films [8].

Previously we have demonstrated [9] that one of the reasons for the decrease in the relative viscosity of the starch hydrogel modified with HA microadditives is deeper oxidation of starch by *N*-chlorobenzenesulfonamide, which is a component of the sizing mixture (oxidized group content increases by 50–55%), and the related enhancement of the hydrolysis of the polysaccharide across α-glucoside bonds under the action of NaOH (degree of polymerization of the unit branch of amylopectin decreases from 13.2–15.6 to 11.4–13.6).

At the same time, introduction of 0.1% HA into the starch gels reduces their viscosity severalfold even in the absence of the indicated reagent in the mixture. Therefore, the reasons for the abnormally low viscosity of the gelatinized starch-humus systems consist not only in the chemical modification of the polysaccharide. Evidently, some other mechanism exists, which is responsible for the observed decrease in the relative viscosity of the starch mixture with a simultaneous increase in the sizing efficiency. The high content of HA functional groups that are susceptible to intermolecular interactions suggests that humus acids are in-

volved in the formation of a supramolecular structure in the starch gels.

In this study, we examined the influence of humus acids on the structure of sizing starch gels.

EXPERIMENTAL

The starch-based sizing mixture was prepared using the procedure described in [2, 3].

The structure of starch and starch-humus gels was studied rheologically on a Rheotest-2 rotary viscometer with a cylinder-cylinder working unit over the rate range 0.5–437 s^{-1}.

The activation energy of viscous flow of the starch gels, ΔG_{visc}, was estimated from the temperature dependence of the viscosity, using the Frenkel–Eyring equation:

$$\eta = A\exp(\Delta E_{visc}/RT)$$

or

$$\log\eta = \log A + \Delta E_{visc}/RT,$$

where η is the dynamic viscosity of the starch gel; *A*, preexponential factor; *R*, gas constant; and *T*, temperature.

The relative viscosity was measured at 80°C with a VPZh-2 Ostwald viscometer (capillary diameter 1.2 mm).

The degree of polymerization was estimated from data on selective oxidation of starch with sodium periodate [9].

The IR spectra of starch films were recorded at 20°C on an IKS-29 double-beam spectrophotometer.

Figures 1a and 1b show the flow curves for the starch (curves *1*–*5*) and starch-humus gelatinized systems (curves *1*'–*5*') with a polysaccharide concentration of 4 and 5%, respectively, over the temperature range 30–70°C. The results show that, in all the cases, the dependences of the viscosity on the shear stress are incomplete (there is no portion corresponding to the maximal Newtonian viscosity), which is caused by the high molecular weight and flexibility of the polysaccharide macromolecules. At the same time, the curves for the starch gels (curves *1*–*5*) also contain no portions of the minimal Newtonian viscosity, either, while this portion is clearly seen in the curves of the starch-humus gels. This fact suggests a larger length of macromolecules of the gel-forming polymer in the HA-free systems, since a higher shear stress is required to attain the limiting state corresponding to $\eta = \eta_{nm}$. As the temperature rises, all the flow curves become flatter, reflecting the degradation of the structure of gelatinized starch. At the same time, the structurization remains clearly pronounced in the starch gels even at 70°C, whereas it is practically lacking in the starch-humus gels. Therefore, the latter can be regarded as solutions, rather than polysaccharide gels.

To elucidate whether the previously reported [9] decrease in the degree of polymerization of amylopectin is the only factor responsible for the observed degradation of the structure in the starch-humus sizing gels, we performed the following experiment. A HA-free gelatinized starch was subjected to long-term cooking with monitoring of its relative viscosity and the degree of polymerization of amylopectin. For the rheological study we selected a paster (referred to as dextrin paster) with the same degree of polymerization of amylopectin as in the starch-humus gel. Data on the relative viscosity and degree of polymerization of three gelatinized systems with the same

polysaccharide content (ordinary starch, that after dextrinization, and starch-humus gels) are listed in the table.

It is worth noting that the dextrinized gel is characterized not only by the same degree of polymerization of the amylopectin unit branch as the starch-humus gel, but also by the same relative viscosity. By contrast, the behavior of the dextrinized gel under the shear stress strongly differs from that of the starch-humus gel, being closer to the behavior of the ordinary starch gels: at all temperatures, a distinctly pronounced portion corresponding to structured gels is found in the flow curves, and the stage of full breaking of the structure is not attained over the acceptable range of the shear stress (Fig. 1b, curves *1*''–*5*''). Therefore, despite the equally low relative viscosity and similar degree of polymerization of amylopectin, the dextrinized starch gel, like the ordinary starch gel, has a higher degree of structurization as compared to the starch-humus gels. Note that the fact of high degree of structurization in starch gels is well documented [10]. It was demonstrated that the structure of a starch gel consists of supramolecular species, such as globules, colloid particles, and conglomerates, in which the polysaccharide macromolecules are involved in intra- and intermolecular hydrogen bonding. In flowing of the gel out of the capillary of the viscometer, the indicated structural units move in the solvent medium without their breaking, while at high shear rates reached in the experiment even separate globules are broken.

The lack of a stable structure in the starch-humus gels suggests that humus acids (as is known, they are hydrophilic and tend to be involved in an intermolecular interaction) the colloid particles and rupturing of starch by penetrating into these particles interchain hydrogen bonds. Most likely, a fluctuating 3*D* network is formed in this case and this work readily degrades under the shear stress.

The transition of the polymer molecules from one equilibrium state to another by overcoming the intermolecular interaction forces can be characterized by the activation energy of viscous flow ΔE_{visc} [11].

The activation energies estimated for the three systems under consideration at a shear rate ($f = 0.274$ s^{-1}) close to that occirring in the practice of sizing are presented in Fig. 2. It can be seen that the activation energy of viscous flow decreases by 17–20% on passing from ordinary starch to starch-humus gels, thus supporting the suggestion about their fluctuating structure. At the same time, the effect of dextrinization is considerably weaker. For example, the dextrinization resulted in only 7% decrease in ΔG_{visc} in a 5% starch mixture.

Relative viscosity and mean degree of polymerization of amylopectin unit chain in starch gels (composition of starch gel, %: starch 5, NaOH 0.1, and *N*-chlorobenzenesulfonamide 0.05)

System, %	Cooking time, h	η_{rel} at 80°C	DP
Gel:			
ordinary starch	1	37.75	14.4 ± 1.2
dextrinized	7	1.75	12.7 ± 1.0
starch-humus*	1	1.75	12.5 ± 1.1

* HA content 0.1%.

When analyzing the reasons for the decrease in the degree of structurization in starch gels, one more factor should be taken into consideration, namely, the increase in the content of oxidized groups in starch [9]. As is known, oxidized starches are characterized by increased solubility, and their gels, by decreased viscosity, which is caused to a large extent by the dissociation of the carboxy groups formed in the course of oxidation. It is the occurrence of charged groups that is generally accepted as the factor responsible for the nearly tenfold increase in the electrical conductivity of starch after oxidative treatment [10].

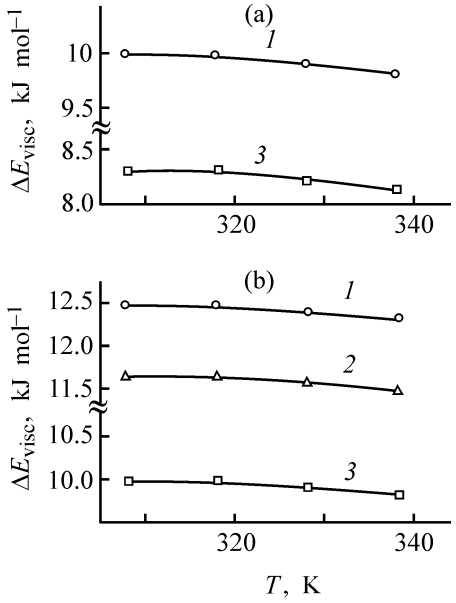

Fig. 2. Activation energy ΔG_{visc} of viscous flow of gelatinized starch mixtures. Component concentration (%): starch (a) 4 and (b) 5, NaOH 0.1, *N*-chlorobenzenesulfonamide 0.05, and HA 0.1. (*T*) Temperature. Systems: (*1*) starch, (*2*) dextrinixed starch, and (*3*) starch-humus gels.

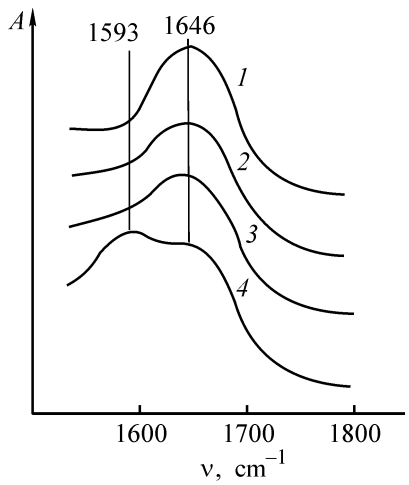

Fig. 3. Infrared spectra of films cast from (*1*) final starch size and (*2–4*) samples of starch-humus sizing mixtures, taken during their cooking. (*A*) Transmission and (ν) wavenumber. Cooking stage at which the samples were taken: (*2*) starch gelling (~67°C), (*3*) viscosity drop stage (~75°C), and (*4*) full fluidification of the sizing mixture (~90°C).

It is notable that, in the presence of HA in the starch gel, such charged groups were found even in the film, as demonstrated by the IR spectra of the films prepared from ordinary starch and starch-humus sizing mixtures (the latter were sampled at different stages of the cooking) (Fig. 3). The band at 1646 cm^{-1} is assigned to the H-bonded carboxy groups of starch, and the band at 1593 cm^{-1}, to the deprotonated carboxy groups [12]. It can be seen that all the carboxy groups are H-bonded in the film formed by the starch size, while ionized groups dominate in the starch-humus film.

CONCLUSIONS

Addition of microamounts of peat humus acids as a second hydrophilic polymer provides extensive structural modification of starch sizing mixtures in the gelation stage, initiating virtually complete degradation of separate colloidal particles of the starch gel. The resulting sizing mixtures better spread over the surface of cotton yarn, ensuring formation of a continuous thin, but sufficiently strong film, thus improving the basic parameters of sizing.

Abstract—A new procedure for preparing aqueous colloidal dispersion of C_{60} in water was developed.

DOI: 10.1134/S1070427206020315

Fullerene C_{60} is insoluble in water, which complicates its practical use. However, colloidal aqueous dispersions of fullerenes can be prepared. A large portion of fullerenes in their solution is in the form of clusters [1]. Dispersions of C_{60} are prepared by addition of water to an organic solution of the fullerene, with the subsequent treatment resulting in precipitation of colloidal particles [2–5]. In the process, the organic solvent is not removed from the solution.

The aim of this study was to prepare colloidal dispersions of fullerene C_{60} in water free of admixtures of other solvents.

A water–acetone mixture (1 : 3) containing 5–20 mM of sodium dodecyl sulfate as a stabilizer was prepared. To this mixture, a solution of fullerene C_{60} in chlorobenzene (2.2 mg ml^{-1}) was added dropwise with vigorous stirring on a magnetic stirrer. The resulting yellow homogeneous solution was distilled under atmospheric pressure with vigorous stirring. The first evaporated fraction was acetone. The second fraction was chlorobenzene–water azeotrope. In the course of evaporation of the azeotrope, the fullerene became dispersed in water. Finally, water [refractive index n = 1.3330 (20°C)] was distilled off. Dispersions containing 0.05 to 0.50 g l^{-1} of C_{60} were prepared. Their color varied from yellowish to brown as the fullerene concentration increased. The chlorobenzene band with λ_{max} = 264 nm [6] is absent in the electronic absorption spectrum of the aqueous dispersion of C_{60}. Hence, chlorobenzene was completely removed from the dispersion. It should be noted that the dispersions are highly stable: no coagulation is observed in the course of at least a month. The average particle size of aqueous dispersions of C_{60} was calculated from the turbidity spectrum by the equation [7]

$$r_{av} = \lambda_{av}\alpha/2\pi\mu_0,$$

where λ_{av} is the geometric mean wavelength of the spectral range examined; μ_0, refractive index of the dispersion medium; and α, coefficient dependent on the parameter n ($n = \Delta\log D/\Delta\log\lambda$).

The average size of the colloidal particles is 40 nm.

A yellow homogeneous solution (the initial C_{60} solution in chlorobenzene is violet) is also formed when a C_{60} solution in chlorobenzene is added dropwise with vigorous stirring to a water–acetone mixture (1 : 3) without a stabilizer. The $D(\lambda)$ spectrum dramatically changes under these conditions, i.e., the solvatochromic effect is observed. The $D(\lambda)$ spectrum of a C_{60} solution in chlorobenzene contains bands in the ranges λ = 380–410 and 510–570 nm. In going to a chlorobenzene–water–acetone system, the optical density significantly increases in the whole wavelength range (Fig. 2).

The solvatochromic effect is due to aggregation of fullerenes upon a change in the solvent composition

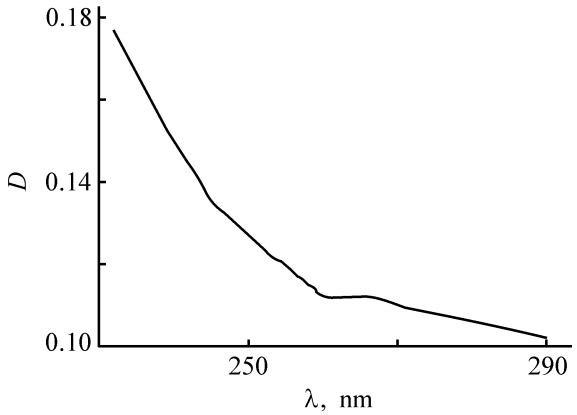

Fig. 1. Absorption spectrum of colloidal dispersion of fullerene C_{60} in water. (D) Optical density and (λ) wavelength. Fullerene concentration 3.5×10^{-3} g l^{-1}.

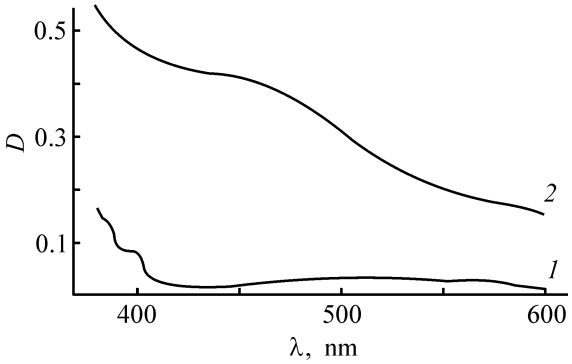

Fig. 2. Absorption spectrum of C_{60} solution in (*1*) chlorobenzene and (*2*) chlorobenzene-water-acetone mixture. (*D*) Optical density and (λ) wavelength. Fullerene concentration 1.6×10^{-5} M.

[1]. The increase in the optical density of the system in the presence of C_{60} is caused not only by light absorption but also by strong light scattering on colloidal fullerene particles. The fact that the optical density of spectrum *2* is significantly higher than that of spectrum *1* (Fig. 2) is due to this effect. When the nonstabilized solution is distilled, no colloidal dispersion is formed and the fullerene coagulates. The stabilization effect can be explained as follows: sodium dodecyl sulfate molecules are sorbed through their hydrocarbon fragments on the surface of C_{60} clusters and their partially dissociated sulfate groups form a charged layer on the surface, thus preventing coagulation. The structure of a colloidal fullerene particle stabilized with sodium dodecyl sulfate can be described by the formula

$$\{n[C_{60}]mC_{12}H_{25}SO_4^-(m - x)Na^+\}xNa^+.$$

Thus, we prepared colloidal solutions of fullerene C_{60} in water free of admixtures of organic solvents.

EXPERIMNETAL

The absorption spectrum of the colloidal dispersion of fullerene C_{60} was recorded in 1-cm quartz cells on an SF-26 spectrophotometer. The reference cell was filled with water. The refractive index was measured on a URL refractometer (model 1). All measurements were performed at $20 \pm 2°C$.

Fullerene C_{60} (99.5 %) was purchased from Merck; sodium dodecyl sulfate was of chemically pure grade. Chlorobenzene was dried over P_2O_5 and distilled; acetone was dried over $CaCl_2$ and subjected to fractional distillation.

CONCLUSIONS

(1) The particle size was determined from the turbidity spectrum.

(2) A solvatochromic effect was observed on adding a C_{60} solution in chlorobenzene to a water–acetone mixture.

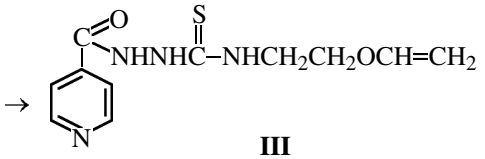
Abstract—The reaction of isonicotinic acid hydrazide with vinyloxyethyl isothiocyanate was studied. The reaction product exhibits antifungal activity toward Candida albicans strain.

DOI: 10.1134/S1070427206020327



Isonicotinic acid hydrazide **I**, which exhibits strong antitubercular effect and is an antagonist of nicotinamide, the factor of redox processes in a cell, is undoubtedly of interest in a search for new physiologically active substances [1].

Many hydrazine derivatives exhibit a broad spectrum of biological activity, depending on the structure, position, and reactivity of substituents. Therefore, it is of particular interest to prepare hydrazine derivatives from vinyloxyethyl isothiocyanate, because introduction of a sulfur atom into organic molecules decreases their toxicity and gives rise to new types of biological activity [2].

With the aim to search for new bioactive substances and reveal structure–bioactivity relationships, we performed the reaction of isonicotinic acid hydrazide **I** with vinyloxyethyl isothiocyanate **II**. The reaction was performed at equimolar ratio of the reactants in alcohol at 0±5°C with the subsequent heating to 35–40°C:

I **II**

III

Compound **III** obtained from this reaction is a white crystalline substance soluble in organic solvents. Its structure and composition were confirmed by elemental analysis and IR spectroscopy. The IR spectrum of **III** exhibits characteristic absorption bands of N–H, NHCS, CH_2=CH, and C=S stretching vibrations at 3460–3440, 1510–1500, 1645–1640, and 1220–1200 cm^{-1}, respectively. The bending mode of the NH–CO– group is manifested at 1650–1645 cm^{-1}.

Compound **III** was tested for the bactericidal activity against a series of strains, and its antifungal activity against *Candida albicans* strain was revealed.

EXPERIMENTAL

The IR spectrum was recorded on an AVATAR-320 device (KBr pellets).

Isonicotinic acid vinyloxyethylthiosemicarbazide III. A solution of 2.56 g of vinyloxyethyl isothiocyanate **II** in 5 ml of ethanol was slowly added to a solution of 2.74 g of isonicotinic acid hydrazide **I** in 15 ml of ethanol. After the whole amount of **II** was added, the mixture was stirred while heating to 45–55°C over a period of 2–3 h. The solvent was distilled off, and 4.85 g (91%) of isonicotinic acid vinyloxyethylthiosemicarbazide **III** was obtained; mp 193–195°C.

Found, %: C 49.62, H 5.26, N 21.05.
$C_{11}H_{14}N_4O_2S$.
Calculated, %: C 49.56, H 5.22, N 21.0.

The antimicrobial activity of **III** was studied by the procedure described in [3]. The sensitivity of microorganisms to the compound was evaluated by

the method of successive dilutions in a liquid cultural medium. The following strains were used: *S.aureus* 505, *P.vulgaris* 1, *P.aeruginosa* ATC 464, *E.coli* M-17, *B.subtilis* ACCC 6633, *S.agalactiae*, and *C.albicans*. The concentrations of **III** in these tests were 8.0, 4.0, 2.0, 1.0, 0.5, 0.25, and 0.125 mg ml^{-1}. In parallel, we checked the cultural medium and compound **III** for sterility. For the cultivation of *S.aureus* 505, *P.vulgaris* 1, *P.aeruginosa* ATC 464, and *E.coli* M-17, we used the peptone meat agar; for that of *S.agalactiae*, 1% glucose broth; for that of *C.albicans*, Saburo liquid medium; for that of staphylococci, yolk–salt agar; for that of E.coli, the Endo medium; and for that of streptococci, the blood–sugar agar.

The minimal bactericidal concentration was determined by reinoculation to dense cultural media from a liquid cultural medium in which the visible growth was absent. The minimal bacteriostatic concentration was estimated turbidimetrically (SF-26 spectrophotometer) by comparing the intensities of the microorganism growth on liquid cultural media. The cultural medium with the same concentration of **III** as in the given test was used as reference.

We revealed the antifungal activity of **III** against Candida albicans; however, compound **III** showed no antibacterial activity against *S.aureus* 505, *P.vulgaris* 1, *P.aeruginosa* ATC 464, *E.coli* M-17, *B.subtilis* ACCC 6633, and *S.agalactiae* strains. The minimal bactericidal and bacteriostatic concentrations of **III** with respect to *Candida albicans* are 0.25 and 0.125 mg ml^{-1}, respectively.

CONCLUSION

Isonicotinic acid vinyloxyethylthiosemicarbazide was prepared; it exhibits antifungal activity against *Candida albicans* clinical strain.

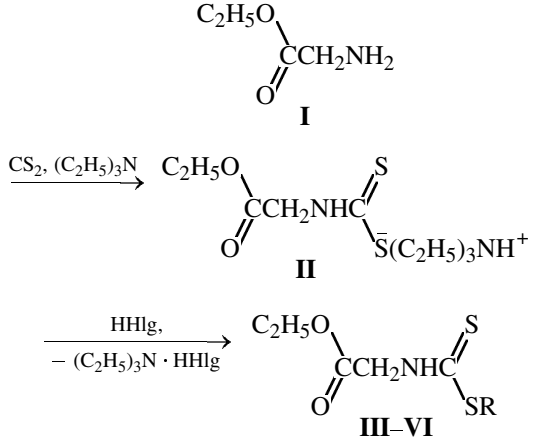
Synthesis and Biological Activity of Ethyl [*N*-(Alkylthio)thiocarbonyl]aminoacetates

M. K. Ibraev, Zh. M. Kozhina, A. M. Gazaliev, and S. D. Fazylov

Institute of Organic Synthesis and Coal Chemistry of the Republic of Kazakhstan, Limited Liability Company, Karaganda, Kazakhstan



Received June 7, 2005

Abstract—Ethyl [*N*-(alkylthio)thiocarbonyl]aminoacetates were prepared and tested for the fungicidal activity.

DOI: 10.1134/S1070427206020339

Dithiocarbamic acid derivatives exhibit pesticidal [1], fungicidal [2, 3], nematocidal, and herbicidal [4] activity.

With the aim to further study dithiocarbamic acid derivatives, we prepared ethyl [*N*-(alkylthio)thiocarbonyl]aminoacetates **III**–**VI** from ethyl aminoacetate **I** and studied their biological properties:

where R = CH_3 (**III**), C_2H_5 (**IV**), C_3H_7 (**V**), or CH_2=$CHCH_2$ (**VI**); Hlg = I or Br.

The reaction was performed in absolute benzene at 0±5°C with the subsequent heating to 45–50°C. The yields of **III**–**VI** were 75–85%. The yield and the reaction time depend on the size and electron-donor power of the alkyl group in alkyl halide RHlg. The activity of RHlg toward **I** decreases in the following order: CH_3I > C_2H_5Br > C_3H_7Br > CH_2=$CHCH_2Br$. Compounds **III**–**V** are crystalline, and compound **VI** is a viscous oil; compounds **III**–**VI** are soluble in polar organic solvents, but insoluble in water.

The composition and structure of the compounds were confirmed by elemental analysis and IR spectroscopy. The IR spectra contain characteristic bands of stretching vibrations of the N–H, NH–CS, and C=S groups at 3320–3316, 1417–1124, and 1257–1220 cm^{-1}, respectively; also, a strong band of the ester C=O group is observed at 1730–1710 cm^{-1}.

EXPERIMENTAL

Ethyl [*N*-(methylthio)thiocarbonyl]aminoacetate III. A solution of 0.76 g of CS_2 in 10 ml of benzene was slowly added to a solution of 1.47 g of ester **I** and 1.45 g of triethylamine in 30 ml of benzene at 0±5°C. Then a solution of 1.38 g of CH_3I in 10 ml of benzene was slowly added at the same temperature. The mixture was stirred with gentle heating (35–40°C) for 2–3 h. The solvent was distilled off, and 1.54 g (84%) of **III** was obtained; mp 71–72°C.

Found, %: C 36.92, H 5.69, N 7.3.

$C_6H_{11}NO_2S_2$.

Calculated, %: C 36.90, H 5.70, N 7.26.

Esters **IV**–**VI** were prepared similarly.

Ethyl [*N*-(ethylthio)thiocarbonyl]aminoacetate IV. Yield 83%, mp 74–75°C.

Found, %: C 40.61, H 6.18, N 6.34.

$C_7H_{13}NO_2S_2$.

Calculated, %: C 40.63, H 6.10, N 6.30.

Ethyl [*N*-(propylthio)thiocarbonyl]aminoacetate V. Yield 81%, mp 38–40°C.

Found, %: C 43.40, H 6.82, N 6.34.

$C_8H_{15}NO_2S_2$.

Calculated, %: C 43.41, H 6.80, N 6.30.

Ethyl [*N*-(allylthio)thiocarbonyl]aminoacetate VI. Yield 75%.

Found, %: C 43.80, H 5.93, N 6.45.

$C_8H_{13}NO_2S_2$.

Calculated, %: C 43.74, H 5.58, N 6.42.

The fungicidal activity of esters **III**–**VI** was studied as described above. Compounds **III**–**VI** were sterilized by filtration on a Nolgene System apparatus and aseptically introduced into agarized Czapek cultural medium in various concentrations. Phytopathogenic fungi *Fusarium oxysporum* and *Botrytis cinerea* were used as test cultures. The fungicidal activity was evaluated by the intensity of development of the microorganisms on the cultural medium in comparison with the control experiments without addition of **III**–**VI**.

We found that ethyl [*N*-(ethylthio)thiocarbonyl]-aminoacetate **IV** tested in vitro exhibits pronounced fungicidal activity against *Botrytis cinerea* (62–66% growth suppression). Compounds **III**–**VI** also showed pronounced fungicidal activity against *Fusarium oxysporum* (58–65% growth suppression).

CONCLUSIONS

(1) Ethyl [*N*-(alkylthio)thiocarbonyl]aminoacetates were prepared by alkylation of the dithiocarbamic acid derived from glycine.

(2) These compounds showed pronounced fungicidal activity against phytopathogenic fungi *Botrytis cinerea* and *Fusarium oxysporum*.

Abstract—Epithio-substituted primary-tertiary dialkyl peroxides were prepared by treatement of *tert*-alkyl oxiranylmethyl peroxides with potassium thiocyanate and were tested as polymerization initiators in synthesis of light-resistant polystyrene.

DOI: 10.1134/S1070427206020340

It is known that thermal polystyrene is insufficiently light-resistant. Polymerization in the presence of initiators containing a norbornane core [1] yields polystyrene samples whose light resistance exceeds that of the thermal polymer by only 10–15%.

With the aim to prepare polystyrene with enhanced light resistance (containing chemically bound sulfur), we performed polymerization of styrene in the bulk, using an epithio-substituted peroxide, 3-*tert*-butylperoxy-1,2-epithiopropane (**I**), as initiator. Compound **I** was prepared by treatment of 3-*tert*-butylperoxy-1,2-epoxypropane **II** (for the preparation procedure and properties of **II**, see [2–4]) with a suspension of potassium thiocyanate in absolute alcohol:

II

I

Analysis of the epithio-containing polymers obtained shows that the epithio peroxide not only initiates polymerization of styrene by ensuring presence of reactive groups in terminal units but also is grafted to polymeric chains, abstracting a hydrogen atom from them. Incorporation of S(II) in an amount of 0.2–0.5% into the polymer substantially enhances its light resistance (see table).

For light resistance tests, polymer samples were dissolved in benzene and cast to obtain 200–400-μm-thick films, which were irradiated for 17 h in air with the UV light from four LE-60 lamps (60 W each) arranged at a distance of 20 cm from the films and of 4 cm from each other. After the irradiation was complete, the films were dissolved in toluene to obtain 1% solutions (which were then diluted), and the intrinsic viscosity of the polymer samples at 298 K was measured and compared to that of the unirradiated samples. The molecular weight was determined by the Mark–Houwink formula [6].

The 0.29% content of sulfur corresponds to the 0.53% content of epithio groups, or, on the average, to 24.7 epithio groups per polymer macromolecule.

Data on the preparation of light-resistant polystyrene by polymerization of styrene initiated by epithio peroxide **I** are listed in the table.

Depending on the concentration of **I**, the polymerization is accelerated by a factor of 3–10, compared to the thermal polymerization. The light resistance of polystyrene prepared with this initiator depends on the initiator concentration and polymerization time and exceeds the light resistance of thermal polystyrene by 30–40% on the average.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a BS-497 spectrometer (operating frequency 100 MHz) in CCl_4,

Rate of styrene conversion and the light resistance of polystyrene obtained under various conditions in the presence of epithio peroxide **I**[*]

with TMS as internal reference; the chemical shifts (ppm) are given in the δ scale.

3-*tert*-Butylperoxy-1,2-epithiopropane I. A reaction flask equipped with a stirrer, liquid seal, and thermometer was charged with a solution of 7.3 g of epoxy peroxide **II** in 25 ml of anhydrous ethanol and with 5.0 g of potassium thiocyanate. The suspension was stirred at 303 K for 40 h; the reaction progress was monitored by TLC on Silufol UV-254 plates (eluent acetone–*p*-xylene, 3 : 20 by volume; development with iodine vapor). After the reaction was complete, the mixture was diluted with 50 ml of water, and epithio peroxide **I** was extracted with diethyl ether (5 × 25 ml). The ether solution was dried over anhydrous magnesium sulfate; the solvent was distilled off at 308–313 K first at ambient pressure and then at a pressure gradually reduced to 10 mm Hg. The residue was chromatographed on a column (100 × 1 cm) with silica gel (eluent benzene). After removing the solvent and keeping for 2–3 h in a vacuum (1–2 mm Hg) at 308–313 K, 4.0 g (49%) of **I** was obtained; d_4^{20} = 1.3590 g cm^{-3}, n_D^{20} = 1.4760, MR_D = 44.25 (calculated MR_D = 44.43).

Found, %: C 53.16, H 8.93, S 19.38; $[O]_{act}$ 9.5; M 158.14.

Calculated, %: C 53.82, H 8.70, S 19.76; $[O]_{act}$ 9.9; M 162.25.

^{1}H NMR spectrum, δ, ppm (J, Hz): 1.22 s (9H, $3CH_3$), 2.18 d.d (1H, H^X, $^3J_{AX}$ 2, $^2J_{DX}$ 5), 2.48 d.d (1H, H^D, $^3J_{AD}$ 6), 3.04 m (1H, H^A), 3.51 d.d (1H, H^C, $^3J_{AC}$ 8, $^2J_{BC}$ 12.5), 4.17 d.d (1H, H^C, $^3J_{AC}$ 4).

Epithio-containing polystyrene. Epithio peroxide **I** (0.81 g) was dissolved in 50 ml of styrene (initiator concentration 1.7 wt %). The solution was charged into ampules under N_2, and the ampules were cooled with dry ice and sealed. The polymerization was performed in the course of 15 h at 373–374 K. Then the ampules were opened, the polymer was dissolved in 100 ml of anhydrous toluene, and the product was precipitated by adding the solution to 100 ml of methanol. The reprecipitation was repeated to remove low-molecular-weight fractions. The product was dried to constant weight in air at 333–343 K. Yield 45.1 g (quantitative), molecular weight 272 200 (determined viscometrically from the intrinsic viscosity in toluene at 298 K [5]).

Found, %: S 0.29.
Calculated, %: S 0.34.

At 373–374 and 413–414 K, in the presence of 3.65–14.6 g of **I**, the yield of the epithio-containing polystyrene was 15–100% (the reaction time was varied).

CONCLUSIONS

(1) Treatment of 3-*tert*-butylperoxy-1,2-epoxypropane with potassium thiocyanate under mild conditions gives an epithio peroxide in ~50% yield. This peroxide can be used as initiator of bulk polymerization of styrene, accelerating it by a factor of 3–10, compared to the thermal polymerization.

(2) Polystyrene prepared in the presence of 3-*tert*-butylperoxy-1,2-epithiopropane surpasses thermal polystyrene in light resistance by 30–40%.

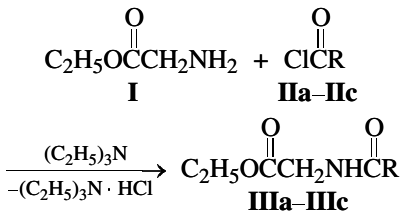
BRIEF COMMUNICATIONS

Synthesis and Aphicidal Activity of Ethyl *N*-Aroylaminoacetates

Zh. M. Kozhina, M. K. Ibraev, A. M. Gazaliev, and S. D. Fazylov

Institute of Organic Synthesis and Coal Chemistry of the Republic of Kazakhstan, Limited Liability Company, Karaganda, Kazakhstan



Received June 7, 2005

Abstract—Ethyl aminoacetate was acylated with various aroyl chlorides. The resulting ethyl *N*-aroylacetates were tested for aphicidal activity.

DOI: 10.1134/S1070427206020352

α-Amino acid derivatives and, in particular, *N*-acyl-α-amino acids containing amino and carboxy groups attract steady researchers' interest owing to a broad spectrum of their biological activity [1]. Some of amino acid derivatives exhibit antiphlogistic, antipyretic, antitumor, antiviral, and antibacterial properties, or affect the central nervous system [2, 3].

With the aim to prepare new potentially bioactive substances, we acylated ethyl aminoacetate **I** with carboxylic acid chlorides **IIa**–**IIc**:

where R = C_6H_5 (**a**), *m*-$CH_3C_6H_4$ (**b**), *o*-BrC_6H_4 (**c**).

The reaction was performed in absolute benzene at 0±5°C in the presence of triethylamine as HCl acceptor.

The yields of **IIIa**–**IIIc** depend on the type and position of substituents in the aryl moiety of aroyl chlorides. The electron-donor methyl group in **IIb** slightly decreases the positive charge on the carbonyl carbon atom, compared to unsubstituted benzoyl chloride **IIa**; as a result, the product yield slightly decreases. The *o*-Br substituent in **IIc** also somewhat decreases the product yield, hindering the reaction sterically.

Compounds **IIIa**–**IIIc** are colorless crystalline substances soluble in polar organic solvents and insoluble in water.

The composition and structure of the compounds were confirmed by elemental analysis and IR spectroscopy. The IR spectra of **IIIa**–**IIIc** contain characteristic absorption bands of the amide and carbonyl groups in the ranges 1630–1625 and 1755–1730 cm^{-1}, respectively; the NH group gives rise to a medium-intensity band at 3330–3270 cm^{-1}.

EXPERIMENTAL

The IR spectra were recorded on an AVATAR-320 device (KBr pellets).

The reaction progress and product purity were monitored by TLC.

Ethyl *N*-benzoylaminoacetate IIIa. Benzoyl chloride **IIa** (3.2 g) was slowly added to a solution of 2.4 g of **I** and 2.3 g of triethylamine in absolute benzene at 0±5°C. The mixture was stirred for 3 h. After distilling the solvent off, 3.76 g (90%) of **IIIa** was obtained; mp 59–60°C.

Ethyl *N*-(*m*-methylbenzoyl)aminoacetate IIIb was prepared similarly in 89% yield; mp 74–75°C.

Found, %: C 45.24, H 4.46, N 4.93.
$C_{12}H_{15}NO_3$.
Calculated, %: C 46.13, H 4.54, N 4.89.

Ethyl *N*-(*o*-bromobenzoyl)aminoacetate IIIc was prepared similarly in 72% yield; mp 53–54°C.

Found, %: C 65.26, H 6.52, N 6.41.
$C_{11}H_{12}NO_3Br$.
Calculated, %: C 65.15, H 6.78, N 6.33.

The compounds were tested for aphicidal activity in laboratory. Replicate specimens of cucumber and pea plants populated with pests (cucurbit and peach aphids, respectively) were sprayed from an atomizer with solutions of the test compounds of definite concentrations (1 ml) and placed in Petri dishes onto filter paper wetted with water. The pest mortality was evaluated 24 h after the treatment. The biological efficiency was calculated by Abbot's formula [4, 5] and corrected for the death rate in the control experiment performed with water.

The biological efficiency was assessed with cucurbit aphids in a laboratory box in isolated vegetation vessels on cucumber plants populated with the pests. Four replicate runs were performed. Aktellik agent was used as reference. Control runs were performed witn water. The living insects were counted before and 72 h after the treatment (spraying of a plant specimen with 5 ml of a working solution in a single run). The biological efficiency was calculated by Franz's formula [4, 5] taking into account an increase in the number of insects in the control run. In each replicate run, the insects were counted on three leaves of the model plant.

The laboratory assessment of the biological activity showed that treatment with **IIIa** in a concentration of 0.01 wt % reduced the number of cucurbit aphids by 88.3%.

CONCLUSIONS

(1) Ethyl *N*-aroylaminoacetates were prepared by acylation of ethyl aminoacetate with aroyl chlorides.

(2) It was found that ethyl *N*-benzoylaminoacetate exhibits aphicidal activity.

Abstract—The influence of metal-containing lubricants based on monoesters of glycerol and higher isomeric saturated monocarboxylic acids on characteristics of polyvinyl chloride was studied.

DOI: 10.1134/S1070427206020364

Mechanochemical stabilizers or lubricants are the imperative component of polyvinyl chloride formulations, especially those of rigid types [1]. In recovery of polyvinyl chloride (PVC), the presence of lubricants results in a decrease in their internal friction; as a result, the recovery temperature decreases, forming of PVC materials proceeds more smoothly and rapidly, and degradation of PVC decreases. In addition, the distribution of the formulation components becomes easier and the outward appearance of articles is improved.

A wide variety of chemicals are used as lubricants in processing of PVC. They differ in the influence on PVC characteristics, polarity, and compatibility with the polymer.

New metal-containing Vikol lubricants based on higher isomeric saturated monocarboxylic acids (HIAs) are the product of telomerization of ethylene with isobutyric acid.[1]

New metal-containing lubricants are produced in a single stage by the reaction of HIA and glycerol (1 : 1 molar ratio) in the presence of oxides of bivalent metals (Zn, Mg) or their two-component mixture in an amount of 0.6–0.8% relative to the total reaction mass at 180–190°C.

The lubricants traditionally used in industrial processing of PVC are glycerol monoesters based on saturated and unsaturated higher carboxylic acids, predominantly glyceryl monooleates, monostearates, and monorecinoleates [1, 2]. Contrary to acids with normal structure, HIAs have lower freezing points, infinite solubility in organic solvents, and higher viscosity due to the presence of short branchings in their molecules. It was of interest to study how lubricants prepared on the basis of HIAs affect the characteristics of PVC. The Vikol lubricants with various lengths of hydrocarbon chain were obtained and tested in comparison with the well-known surface lubricants, in particular, hydrocarbon wax and Glitserol.

[1] First obtained at the Kaustik Joint-Stock Company.

EXPERIMENTAL

As subjects of the study we used PVC of the S-6358M brand, Vikol metal-containing lubricants, whose characteristics are listed in Table 1, and also commercial Glitserol (ester of glycerol and synthetic fatty acids) and polyethylene wax PV-200. To study the influence of lubricants on the characteristics of PVC, the formulations were prepared as follows: 100 wt parts of suspended PVC, 3 wt parts of tribasic lead sulfate, 1 wt part of calcium stearate, and up to 5 wt parts of lubricant were homogenized in a laboratory mixer at 90°C for 30 min. The resulting mixture was rolled on a PD 320 laboratory roller at 175°C for 5 min. The ultimate tensile strength and the relative elongation were determined on an RMI-250 tensile-testing machine.

As can be seen from Table 1, the samples studied, which differ in the length of the hydrocarbon chain, have different densities, viscosities, and molecular mobilities (judging from the freezing point). It should be noted that these differences in the characteristics of metal-containing additives should affect their compatibility with PVC and, hence, affect the characteristics of the formulations containing these additives.

Table 1. Physicochemical characteristics of Zn-containing lubricants Vikol

Sample no.	Fraction of HIAs	Density at 20°C, g cm^{-3}	Acid number, mg KOH per gram	Temperature, °C		Kinematic viscosity, cSt, at indicated T, °C	
				flash point	freezing point	20	60
1	C_{22}–C_{24}	0.908	3.08	164	–10	328.99	39.3
2	C_{18}–C_{20}	0.937	2.52	145	–13	278.9	31.8
3	C_{12}–C_{14}	1.03	1.64	137	–36	121.14	3.58

The physicomechanical characteristics of rolled films (ultimate tensile strength and relative elongation) with the content of the Vikol lubricant equal to 0.8 wt parts per 100 wt parts of PVC are listed in Table 2 (contents of Glitserol and wax are similar).

As follows from Table 2, a distinctive feature of Vikol lubricants is the increase in the ultimate tensile strength and a certain decrease in the relative elongation of PVC films upon introduction of lubricants into the formulations. The shorter the length of hydrocarbon chain of the Vikol lubricant, the more pronounced this effect. The commonly used lubricants, such as Glitserol and wax, act similarly but to a lesser extent. Thus, at the standard temperature, addition of Vikol lubricants resulted in significant increase in the strength in the glassy state; hence, more rigid PVC films were obtained.

At the same time, the glass transition point T_g estimated on a PTB-1 PZh device from the inflection in the temperature dependence of the sample deformation decreases upon addition of the Vikol lubricant. The T_g values of the PVC formulations with the Vikol content of 1.2 and 5 wt parts per 100 wt parts of PVC are listed in Table 3. For comparison, polyethylene wax did not allow film preparation at its amount in PVC equal to 5 wt parts.

Thus, metal-containing lubricants exert a plasticizing effect on PVC; the performance of lubricants as plasticizers depends on their content in a PVC formulation and on the length of hydrocarbon chain of the Vikol lubricant. In the range of small amounts of lubricants (1.2 wt parts per 100 wt parts of PVC), the performance increases in the order Vikol-1 < Vikol-2 < Vikol-3. With the content of Vikol lubricant equal to 5 wt parts per 100 wt parts of PVC, the effect becomes the opposite. The significant increase in the strength with decreasing relative elongation of rigid PVC films in the presence of small amounts of metal-containing lubricants can be caused by ordering [3] or more complete relaxation of the internal stresses arising in fast cooling of the films [4]. In this case, their plasticizing effect is manifested, judging from the glass transition point of PVC in the presence of the Vikol lubricants (Table 3).

The plasticizing effect of the lubricants studied was also estimated by the broad-line NMR (RYa-2301, operating frequency 16.2 MHz, temperature 23°C) [5]. The molecular mobility of PVC in the presence of the Vikol lubricants was estimated from the second-order momentum of the NMR line ΔH_2^2 (content of Vikol lubricant 0.8 wt parts per 100 wt parts of PVC):

Lubricant type	ΔH_2^2, Oe^2	Lubricant type	ΔH_2^2, Oe^2
Without lubricant	14.4	Vikol no. 3	12.9
Vikol no. 1	13.4	Glitserol	14.1
Vikol no. 2	13.2	Wax PV-200	14.2

Table 2. Physicomechanical characteristics of PVC films containing lubricants

Lubricant type	Ultimate tensile strength, MPa	Relative elongation at break, %
Without lubricant	40	37
Vikol no. 1	51.6	32
Vikol no. 2	59.8	29
Vikol no. 3	72.4	26
Glitserol	44.6	34
Wax PV-200	42.5	35

Table 3. Glass transition point of PVC formulations in the presence of lubricants

Lubricant type	T_g, °C, at indicated lubricant amount, wt parts per 100 wt parts of PVC		
	0	1.2	5.0
Vikol no. 1	81	76	71
Vikol no. 2	81	77	70
Vikol no. 3	81	79	67
Wax PV-200	81	80	–

The data obtained show that all the additives increase the molecular mobility of PVC, i.e., they affect the structure and intermolecular interaction in the PVC samples studied. The increase in the molecular mobility (decrease in ΔH_2^2) is the most significant for Vikol-3, which has the shortest hydrocarbon chain (C_{12}–C_{14}) and, hence, a higher intrinsic molecular mobility. Addition of Glitserol and polyethylene wax decreases ΔH_2^2 only slightly, i.e., their plasticizing effect on PVC is insignificant.

CONCLUSION

A study of the influence of metal-containing lubricants Vikol on characteristics of polyvinyl chloride, judged from the glass transition point and broad-line NMR data, show that small amounts of metal-containing lubricants Vikol exert a plasticizing effect on polyvinyl chloride; the higher the intrinsic mobility of the lubricant, the more pronounced the effect. Due to this fact, formation of the polyvinyl chloride structure is facilitated, and a film material with a higher strength is formed.

BRIEF COMMUNICATIONS

The Role of Readily Hydrolyzable Polysaccharides of Larch Wood in Manufacture of Board Materials

O. S. Beusheva, N. P. Mus'ko, and M. M. Chemeris

Polzunov State Technical University, Barnaul, Russia

Received December 21, 2005

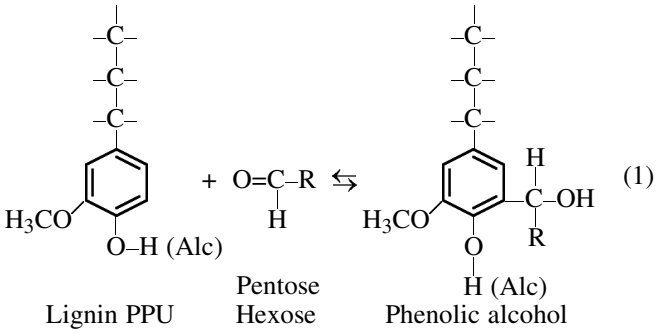
Abstract—Role of readily hydrolyzable polysaccharides of larch wood in production of board materials is studied.

DOI: 10.1134/S1070427206020376

The problem of development of environmentally friendly and cost-efficient board materials is now pressing as before. The reason is that thermosetting synthetic resins are mostly used in manufacture of board materials as binders, in addition to a wood filler and adhesive component, e.g., phenol-formaldehyde resol resin.

It was demonstrated in [1, 2] that all components required for production of board materials can be obtained through hydrothermal treatment of wood.

An equally important problem is utilization of large-scale waste of larch wood, which known to have limited application in wood-chemical processing.



Therefore, we examined in this study the possibility of manufacture of board materials from larch wood exposed to explosive autohydrolysis (EAH).

We examined the effects of temperature and pressure on the behavior of readily hydrolyzable polysaccharides of larch wood in production of board materials by hot pressing.

EXPERIMENTAL

As a raw material for production of boards, we used larch wood chips (25 × 15 × 5 mm) after extraction of bioactive components (arabinogalactan and dihydroquercitrin). Before exposure to explosive autohydrolysis, the chips were treated with water in a 2 : 1 volume ratio [3]. The explosive autohydrolysis was carried out in an autoclave at 220°C for 10 min. Then the resulting lignocarbohydrate material was air-dried, formed into a mat, and hot pressed.

Wood is composed of a complex set of macromolecular compounds, such as cellulose, hemicellulose, and lignin, cross-linked by chemical and hydrogen bonds and also by nonspecific physical interactions. The explosive autohydrolysis strongly modifies the structure of the initial material at the macro- and microlevels. Previously, we have demonstrated [4] that, under hydrothermal conditions, readily hydrolyzable polysaccharides of larch wood are hydrolyzed to give a large amount of reducing agents (RAs). The temperature of 220°C and treatment time of 10 min are the optimal conditions for the hydrolysis, under which the content of readily hydrolyzable polysaccharides in the wood pulp decreases from 22.9 to 3.2%. The content of reducing agents in the resulting aqueous extract is 15.4%. The UV spectra showed that the reaction mixture contains phenolic compounds [5]. Thus, the pulp obtained after explosive autohydrolysis of larch wood contains components that can enter into polycondensation reactions. It may be suggested that, similarly to the reactions of phenols with aldehydes yielding phenol-formaldehyde resins with liberation of water, the *p*-hydroxyphenylpropane units (PPUs) of lignin react with the aldehyde groups of sugars [6, 7]. A simplified scheme of the reaction can be written as

(1)

where R = $C_4H_5(OH)_4$, $C_5H_7(OH)_5$.

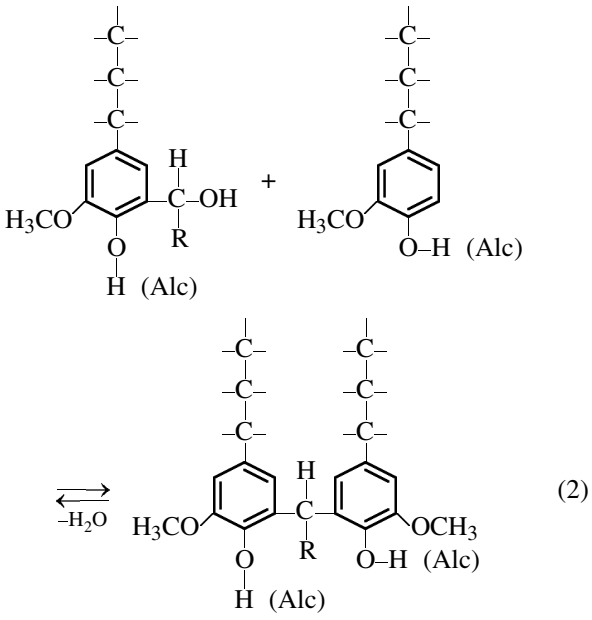


Table 1. Characteristics of board materials from larch wood and of commercial wood chipboards manufactured according to GOST (State Standard) 10632–89.

Parameter	Larch wood chipboards	Commercial chipboards
Density, kg m^{-3}	1200	550–830
Thickness swell, %	10	33–22
Static bending stress, MPa	30	14–16

Table 2. Weight loss in pressing (pressing time 5 min)

Parameter		Weight loss, %
Pressing temperature, °C	100	0.58
(P = 5.2 MPa)	110	0.60
	120	0.63
	130	0.85
	150	1.75
Pressure, MPa	1.2	0.75
(T = 140°C)	2.6	1.25
	5.2	1.58
	6.5	1.75

The resulting phenolic alcohol can enter into the reaction of polycondensation to give thermoplastic resins:

(2)

where R = $C_4H_5(OH)_4$, $C_5H_7(OH)_5$.

If the reaction between the reducing agents and lignin degradation products occurs, this will promote "self-adhesion" of wood particles in the course of hot pressing of wood pulp to give board materials.

The possibility of performing such a process was demonstrated in the preliminary experiments. Table 1 shows selected characteristics of the chipboards thus obtained from larch wood chips in comparison with those of the commercial wood chipboards currently produced in Russia.

As can be seen, the board material from larch wood surpasses the commercial wood chipboards in the basic characteristics. High strength and hydrophobic characteristics, as well as the lack of phenol-formaldehyde resins, make this composite material quite attractive for structural and building applications.

Thus, chemical transformations occurring in the basic components of larch wood in the course of explosive autohydrolysis open prospects for production of board materials without addition of binders.

Upon heating, phenolic alcohols enter into polycondensation to give cross-linked structures serving as a binder in the composite [Scheme (2)].

The formation of insoluble high-molecular-weight compounds (binders) by the reaction between the reducing agents and lignin fragments is confirmed by data on the weight loss in pressing. The weight loss depends on the pressing temperature and pressure (Table 2). The weight loss in the course of pressing can be attributed to the formation of volatile products, among them water.

As the pressing temperature is raised from 100 to 150°C, the weight loss increases from 0.58 to 1.75%.

In hot pressing of the pulp obtained by explosive autohydrolysis, the reducing agents and lignin fragments react to give thermosetting resins serving as binders in the composite. Therefore, the amount of the reducing agents should decrease. The resulting board material was analyzed for the residual reducing agents. The material was powdered and then treated with water to extract water-soluble compounds. The aqueous extract was analyzed for reducing agents. The amount of reducing agents in the wood pulp decreased after pressing as compared to that in the pulp after explosive autohydrolysis (15.4%). As the pressing temperature was raised from 120 to 160°C, the amount of reducing agents decreases from 9.0 to 4.3%

Table 3. Influence of pressing temperature on formation of reducing agents (pressure 5.2 MPa; pressing time 5 min)

Pressing temperature, °C	RA content in board material, %	RAs involved in formation of binders, %
120	9.0	6.4
130	8.7	6.7
140	7.4	8.0
150	5.5	9.9
160	4.3	11.1

Table 4. Influence of pressure on formation of reducing agents (temperature 140°C; pressing time 5 min)

Pressure, MPa	RA content in board material, %	RAs involved in formation of binders, %
1.2	11.8	3.6
2.6	11.2	4.2
3.9	8.9	6.5
5.2	7.4	8.0
6.5	6.8	8.6

(Table 3), suggesting that, in the course of pressing, the polycondensation takes place, and the amount of binders increases with temperature.

The manufacture of board materials involves impact of not only elevated temperature, but also high pressure on the initial mass. Data on the latter effect are listed in Table 4.

An increase in pressure also leads to a decrease in the content of reducing agents in board materials, suggesting their involvement in the formation of binders.

CONCLUSIONS

(1) The possibility of production of board materials from larch wood without addition of binders is demonstrated. These materials surpass commercial chipboards in strength and hydrophobic characteristics.

(2) Pressing of board materials obtained by explosive autohydrolysis of larch wood is accompanied by weight loss and decrease in the content of reducing agents.

OBITUARY

Oleg Grigor'evich Zarubitskii (1936–2005)

DOI: 10.1134/S1070427206020388

On December 29, 2005, in Kiev, died of severe illness, at the age of 69, Oleg Grigor'evich Zarubitskii. He was a prominent electrochemist, chairman of the Scientific Council of the National Academy of Sciences of the Ukraine for Electrochemistry, Honored scientist and technologist of the Ukraine, doctor of technical science, professor, corresponding member of the National Academy of Sciences of the Ukraine, and head of the Department of electrochemical refining of metals and metalloids (Vernadskii Institute of General and Inorganic Chemistry, National Academy of Sciences of the Ukraine). During many years, until very recently, O.G. Zarubitskii had been an active author of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry, Russian Academy of Sciences).

Zarubitskii was born on July 26, 1931, at a town of Borzna, Chernigov oblast, Ukraine. In 1950, he graduated from the Faculty of chemical engineering of Kiev Polytechnic Institute and, in the same year, commenced his scientific activities at the Institute of General and Inorganic Chemistry, Academy of Sciences of the Ukrainian SSR, where he made a career from an engineer to deputy director for science (1993–2001) and head of a department at the Institute. Zarubitskii was one of the most prominent representatives of the scientific school in electrochemistry of molten salt system, created in the Ukraine by V.A. Plotnikov (1873–1947), V.A. Izbekov (1881–1963), and Yu.K. Delimarskii (1904–1990).

An originally thinking talented scientist, Zarubitskii made a notable contribution to the development of quite a number of areas of high-temperature electrochemistry, his studies had always been closely related the demand of the technological practice. During his entire scientific activities, Zarubitskii paid a considerable attention to study of processes used to produce and refine heavy nonferrous and rare metals in molten electrolytes. Zarubitskii and co-workers were the first in the world to implement on the industrial scale methods for manufacture of bismuth, lead, and indium by electrolysis of molten salts. Zarubitskii was directly involved in the development of worldwide unprecedented apparatus for high-temperature chemical-metallurgical processes: high output capacity diaphragm

electrolyzers and electrolytic baths with bipolar electrodes and thin-layer electrolytes. Zarubitskii and coworkers made a remarkable contribution to investigation of the corrosion resistance of refractories, metals, and alloys used as construction materials in industrial installations that use molten electrolytes. Zarubitskii suggested advanced techniques for chemical, electrochemical, and chemical-thermal treatment of the surface of ferrous and nonferrous metals in ionic melts, performed original studies in the field of electrolytic metallurgy, and developed a technology for electrochemical deactivation of the surface of metals and alloys to remove radioactive contaminations.

Quite a number of Zarubitskii's recent studies were aimed to solve most important energy-related and ecological problems. He suggested an efficient method for production of hydrogen by electrolysis of hydrated melts and developed an economical technique for production of pure amorphous powdered silicon to be used in manufacture of solar cells.

Zarubitskii's scientific legacy is vast. Of particular scientific and practical importance are the monographs *Elektroliticheskoe rafinirovanie tyazhelykh metallov v ionnykh rasplavakh* (Electrolytic Refining of Heavy Metals in Ionic Melts) (together with Delimarskii,

Moscow, 1975) and *Ochistka metallov v rasplavakh shchelochei* (Purification of Metals in Alkali Melts) (Moscow, 1981). Zarubitskii was the author of more than 650 scientific works, including 5 monographs and 230 inventor's certificates and patents. His studies were recognized all over the world and reported at international scientific conferences in numerous countries.

Zarubitskii was distinguished by purposefulness, high working capacity, and position of principle in defending his scientific ideas and views. The Institute of General and Inorganic Chemistry, National Academy of Sciences of the Ukraine, and electrochemists of the Ukraine suffered a severe loss. Oleg Grigor'evich Zarubitskii died in the prime of his creativeness. His colleagues will preserve the memory of this very good person and scientists his ideas and designs will be further developed by his pupils and followers.

BOOK REVIEWS

Chekryshkin, Yu.S., Rozdyalovskaya, T.A., and Fedorov, A.A., *Gomogenno-kataliticheskoe glubokoe okislenie galogensoderzhashchikh organicheskikh veshchestv na rasplavakh elektrolitov* (Deep Homogeneous-Catalytic Oxidation of Halogen-containing Organic Substances in Electrolyte Melts),

Yekaterinburg: Ural'sk. Otd. Ross. Akad. Nauk, 2005, 124 pp.

DOI: 10.1134/S107042720602039X

In the brief preface (p. 3), the editor of the book, V.V. Lunin, Academician of the Russian Academy of Sciences, noted that it is the most appropriate, from both the economical and ecological standpoints, to use methods of catalytic hydration and catalytic oxidation in solving the problem of detoxication of halogen-containing waste. In this case, molten formulations containing salts of alkali metals and oxides of some other metals with variable degree of oxidation have important advantages over solid catalysts. Physicochemical characteristics of such melts allow their use in catalytic burning of organic wastes of varied composition and aggregative state. The monograph by Chekryshkin and co-authors presents the results of many years' investigations in the field of application of molten catalysts, which were mostly performed at the Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, (Perm) and at Perm State Technical University.

The book comprises an introduction, four chapters, conclusion, and bibliographic list. The introduction (pp. 4–7) notes that the development of ecologically safe methods for deactivation of halogen-containing wastes is necessitated by their high toxicity and possibility of their transformation into highly stable dioxins. The first chapter (pp. 8–27) contains general evidence about methods for utilization, detoxication, and elimination of halogen-containing organic substances. The authors rightfully note that the wide diversity of wastes in composition, amount, and territorial distribution makes impossible any versatile technology of their detoxication. Each of the techniques considered in this chapter has its own disadvantages and limitations. In the authors' opinion, the method of deep catalytic oxidation with the use of metal and salt oxides is to be considered an ecologically, economically, and technologically acceptable detoxication technique in the case of comparatively small amounts of highly toxic wastes of complex composition.

The second chapter (pp. 28–79) considers specific features of the use of molten oxides and salts as catalysts for oxidation processes. Particular attention is given to molten formulations containing vanadium(V) oxide and to deep oxidation of halogen-containing organic substances with catalysts of this kind. The reaction of oxidative destruction of halohydrocarbons is initiated by oxygen activated directly by V_2O_5 or by bronzes formed in interaction between V_2O_5 with the starting components of the catalysts (chlorides and carbonates of alkali metals).

The third chapter (pp. 80–104) presents the results of a study of reactions in systems constituted by sodium chloride, oxides of metals with a variable degree of oxidation (V, Cr, Mn, Co, Cu, Mo, Sb), and oxygen. In the presence of oxygen in the reaction medium, metal oxides act as catalysts for oxidation of chlorine atomd by oxygen. A small fourth chapter (pp. 105–108) considers particular examples of catalytic oxidation of a number of complex composites (rubbers, polymers, pesticides, etc.) with the use of molten catalysts. The main results obtained in studying the use of molten catalysts for deep oxidation of organic substances of various compositions and densities are summarized in the conclusion (pp. 109–111). The bibliographic list contains 263 references to works of domestic and foreign authors, mostly published in the last 10 years.

The monograph by Yu.S. Chekryshkin, T.A. Rozdyalovskaya, and A.A. Fedorov reflects the contribution made by the authors and by the scientific schools they represent to the solution of the important economical and ecological problem, utilization of technological and other wastes of complex organic substances. The book is distinguished by originality of formulation of the problem to be solved. It is of interest for researchers and engineers concerned with problems of ecologically and technologically safe elimination of organic substances of widely diverse origin.

Received July 4, 2005; in final form, January 2006

Abstract—Rounded nanosize particles of Co_3O_4 and NiO were prepared by precipitation with ammonium carbonate from cobalt and nickel nitrate solutions. Cobalt and nickel oxides and their precursors were characterized by thermal and X-ray phase analyses, electron microscopy, and IR spectroscopy.

DOI: 10.1134/S1070427206030013

Nickel and cobalt oxides and materials based on these compounds possess valuable dielectric, semiconducting, magnetic, and catalytic properties. They are used as electrode materials [1, 2], heterogeneous catalysts [3, 4], and materials for active units of gas sensors [5, 6]. Films of cobalt and nickel oxides can find application in electrochromic devices [7–9]. High-performance ultrahigh-frequency insulators are being developed on the basis of complex oxides of cobalt and nickel [10].

The properties of bulk and film materials largely depend on the morphology and size of particles. Extensive studies of nanosize materials in the last decade have shown that diminishing the particle size to the nanolevel leads to a dramatic increase in the activity of powders, which makes it possible to obtain high-quality materials on their basis.

Nanosize cobalt and nickel oxides are commonly produced by spraying pyrolysis [11–13], organometallic copolymerization [14], sol–gel process [15–17], hydrothermal synthesis [18], solid-state reactions [19], precipitation in microemulsions [20–22], and precipitation with urea [23, 24], carbonates of alkali metals [25, 26], and ammonia [27]. However, most of these methods require special equipment or expensive chemicals. Therefore, development of a comparatively simple method for synthesis of nanosize cobalt and nickel oxides, in which the powders obtained would not be contaminated with reaction products, is a topical task.

The aim of this study was to develop a simple and environmentally safe method for synthesis of nanosize cobalt and nickel oxides and to examine their properties.

EXPERIMENTAL

The synthesis was performed by precipitation from solutions. Chemically pure grade cobalt and nickel nitrates served as starting reagents, and ammonium carbonate of the same grade, as a precipitating agent. Cobalt and nickel carbonates were precipitated both at fixed pH values in the range from 6.2 to 7.8 and with gradual addition of the precipitant to a prescribed pH. At pH values exceeding 8, the precipitates started to appreciably dissolve because of the formation of soluble complexes $[Co(NH_3)_6]^{2+}$ and $[Ni(NH_3)_6]^{2+}$.

The precipitates obtained were transferred onto a porous glass filter and the filtration coefficient K_f (cm s^{-1}) was determined by the Darcy formula [28]

$$K_f = \frac{QL}{SH\tau},$$

where Q is the volume (cm^3) of a filtrate that passed through a precipitate layer of thickness L (cm) and surface area S (cm^2) at a rarefaction H (cm of water column) in a time τ (s).

To improve the reliability of data, the filtration coefficient was calculated for each batch of the precipitate as arithmetic mean of the results of three measurements. The carbonate precipitate was washed to remove NH_4^+ and NO_3^- ions with double-distilled water; the precipitate was twice resuspended, with intermediate washing with the same amount of water. After the second resuspending, cobalt and nickel carbonates were subjected to final washing with distilled water taken in an amount of 20 ml per gram of the precipi-

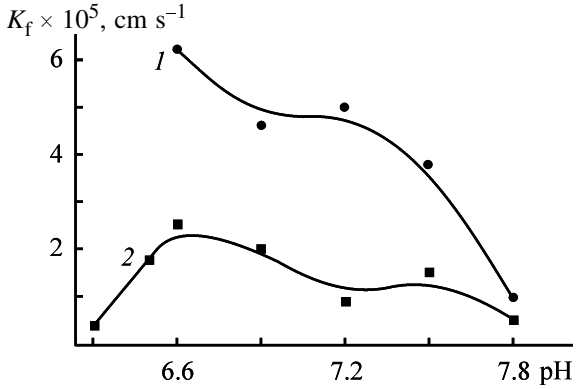

Fig. 1. Filtration coefficients K_f of products formed in precipitation of (*1*) nickel(II) and (*2*) cobalt(II) vs. the pH of precipitation.

tate. For further studies, samples of the precipitates were dried at 70–80°C in air.

Thermal analysis of the precipitation products was made on a Q-1000 OD-102 installation at a heating rate of 5 deg min^{-1}, with aluminum oxide as reference. IR spectra of samples pelletized with KBr were recorded on a Specord M30-1 spectrometer in the range 200–4000 cm^{-1}. X-ray phase analysis was performed with a DRON-3M X-ray diffractometer (CoK_α radiation, λ = 0.178897 nm). The phase composition was identified using the JCPDS (International Committee for Powder Diffraction Standards) database. The morphology of the powders was studied with a JEOL JCXA Superprobe 733 electron microscope (Japan).

The dependences of the filtration coefficients of nickel (light green) and cobalt (lilac-pink) carbonates on the precipitation pH are shown in Fig. 1. The filterability of cobalt precipitation products [K_f = (0.5–2.5) $\times 10^{-5}$ cm s^{-1}] was found to be several times smaller than that of nickel compounds [K_f = (1–6) $\times$ 10^{-5} cm s^{-1}], which may point to their higher dispersity and larger water content. Because both a decrease and an increase in the precipitation pH caused a significant solubility of the precipitate, the optimal precipitation conditions of nickel and cobalt carbonates were pH 7.2 and 7.5, respectively.

Figures 2a and 2b show the IR spectra of the products formed in precipitation of cobalt(II) and nickel(II), respectively, and subjected to thermal treatment at various temperatures. After thermal treatment at 80°C, both the products contain water. This is indicated by strong broad absorption bands with maxima at 3420 and 3410 cm^{-1} [ν(OH)] and by the band at 1630 cm^{-1} [δ(OH)]. The absorption spectrum of cobalt compounds shows a shoulder at 3490 cm^{-1} whose position and shape are characteristic of OH^- groups [29]. According to Bellamy's data [30], hydroxo carbonates have a more complex IR spectrum as compared to carbonates: the absorption band at 1430 cm^{-1}, which is associated with ν(CO) vibrations, is split in two. The number of bands in the range 700–1100 cm^{-1} also increases, which is confirmed by the spectra of the cobalt precipitation product; this feature is manifested by precipitated nickel carbonate to a lesser extent. The broad absorption bands at 370 and 350–425 cm^{-1} for cobalt and nickel products, respectively, are associated with stretching vibrations of the metal–oxygen bond. As the temperature of thermal treatment of cobalt carbonate is raised to 250°C, the bands related to CO_3^{2-} and OH^- groups disappear from the IR spectra, and the band with a maximum at 3420 cm^{-1}, which is associated with ν(OH) vibrations of crystallization water, is shifted to smaller wavenumbers and its intensity markedly decreases. The adsorption doublet at 565 and 660 cm^{-1} indicates that there exist Co^{3+} ions in an octahedral environment, which, combined with the band at 385 cm^{-1} associated with Co^{2+} ions in a tetrahedral environment, corresponds to formation of the spinel Co_3O_4 [31]. At a higher temperature (640°C), cobalt oxide contains no traces of water, and the shift of the absorption bands associated with stretching vibrations of the Co–O bond to 390, 570, and 670 cm^{-1} may indicate that aggregates grow and the number of point defects increases on the surface of a nanocrystal [32].

Nickel carbonate has a higher thermal stability than cobalt carbonate and contains a smaller amount of OH^- groups, and trace amounts of CO_3^{2-} groups (absorption band at 1465 cm^{-1}) are preserved after thermal treatment at 320°C. Another specific feature of the nickel precursor thermally treated at 320°C is that a sharp absorption band appears at 1385 cm^{-1} and the peak of the absorption band of ν(OH) vibrations of crystallization water is shifted to larger, rather than smaller, wavenumbers, to 3460 cm^{-1}. The absorption band of stretching vibrations of the Ni–O bond at 430 cm^{-1} indicates that the individual oxide NiO (bunsenite) exists at 320°C. After thermal treatment at 640°C, only a broad band at 430 cm^{-1}, with shoulders at 485, 512, and 560 cm^{-1}, is observed in the IR spectra of precipitated nickel carbonate, which points to cationic ordering of bunsenite [22]. The narrowing of the band associated with stretching vibrations of the metal–oxygen bond at 640°C indicates that the average size of NiO nanocrystals increases.

The results obtained in thermal analysis of precipitated nickel and cobalt carbonates are presented in Figs. 3a and 3b. Nickel carbonate typically shows two

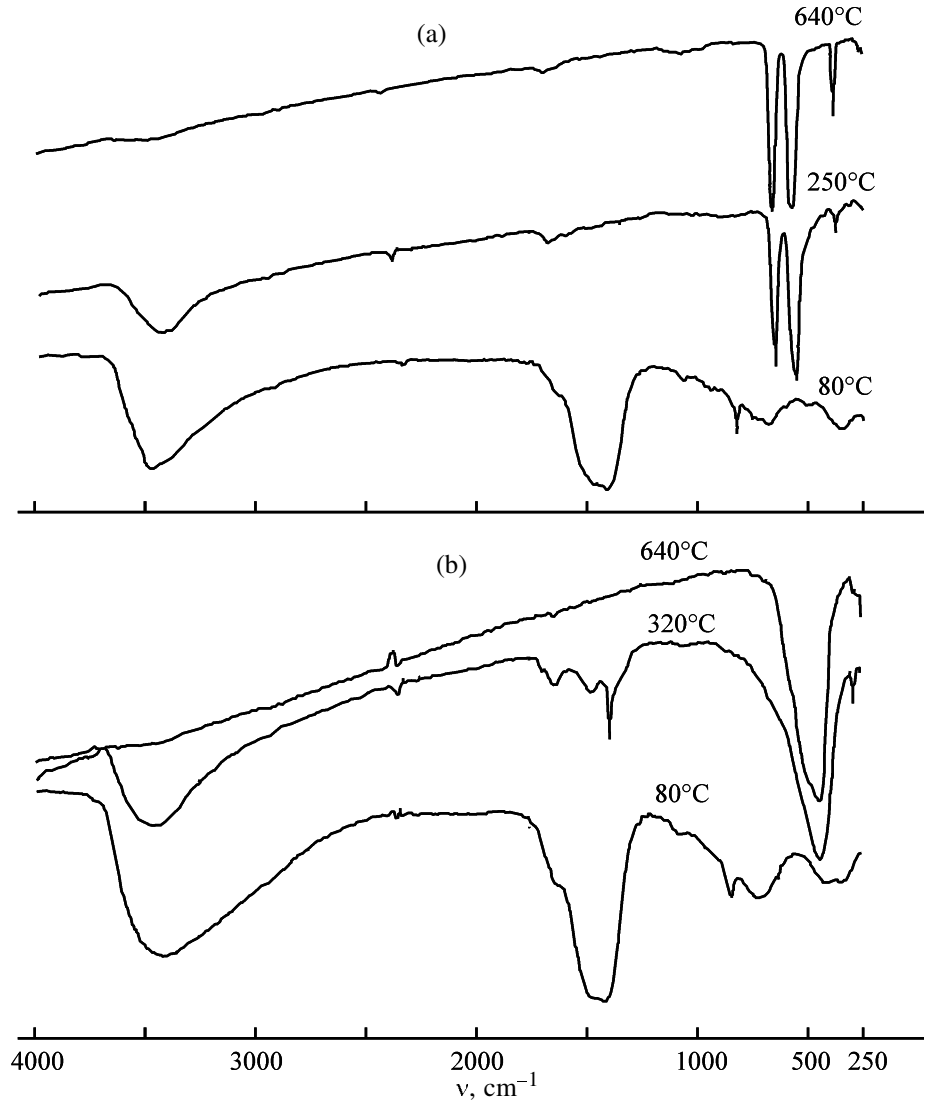

Fig. 2. IR spectra of products formed in precipitation of (a) nickel(II) and (b) cobalt(II) and subjected to thermal treatment at various temperatures for 2 h. pH: (a) 7.5 and (b) 7.2.

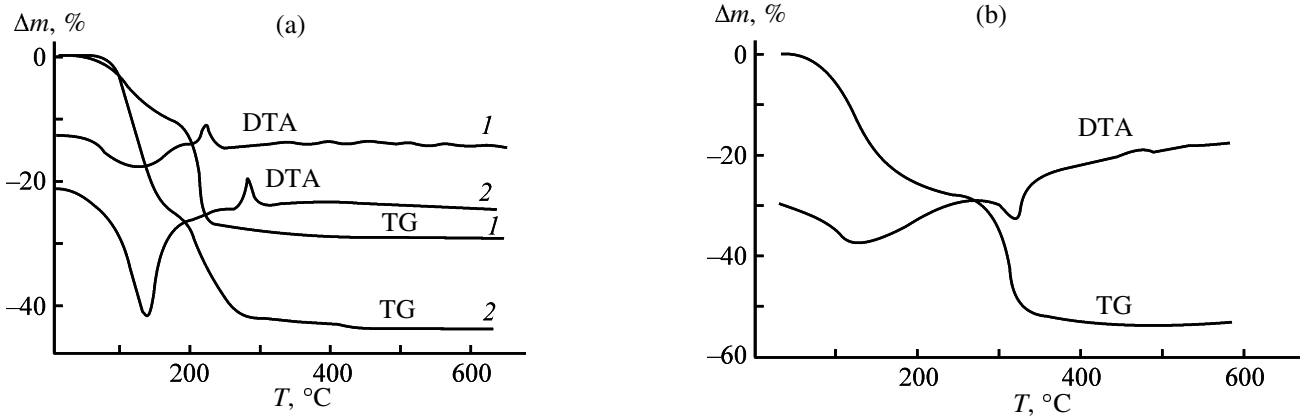

Fig. 3. Thermograms (a) of cobalt carbonate precipitated at (*1*) fixed pH 7.5 and (2) pH increasing to 7.5 in the course of precipitation and (b) of nickel carbonate precipitated at a fixed pH 7.2. (Δm) Weight loss and (T) temperature.

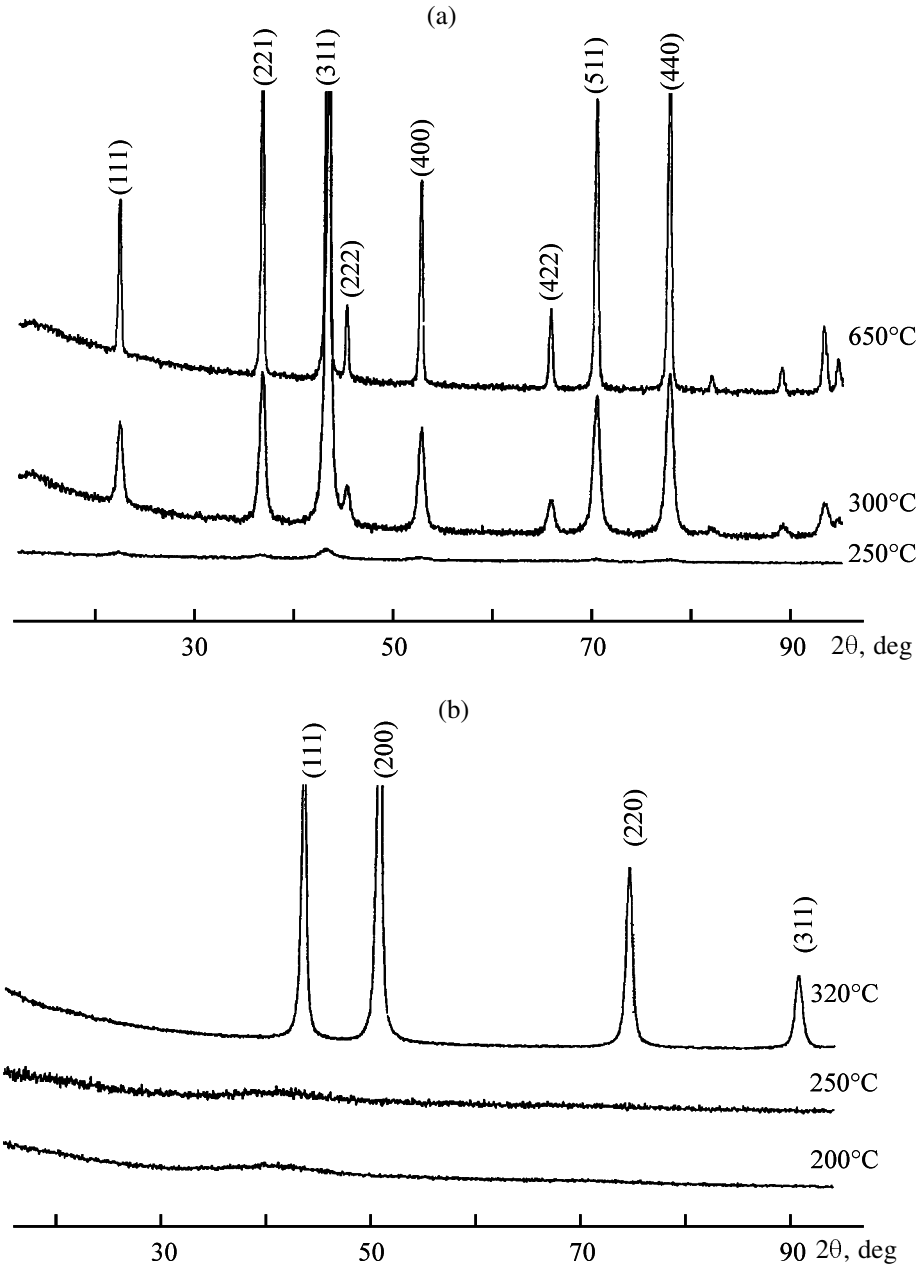

Fig. 4. X-ray diffraction patterns of products formed in precipitation of (a) cobalt(II) and (b) nickel(II) and subjected to thermal treatment at various temperatures for 2 h. (2θ) Bragg angle.

endothermic effects accompanied by weight of loss, with maxima at 120 (removal of absorbed and chemically bound water) and 320°C (removal of carbonate groups). This is in agreement with the data of [21, 23]. According to calculations based on the weight loss, the formula of precipitated nickel carbonate is close to $NiCO_3 \cdot 0.28Ni(OH)_2 \cdot 2.6H_2O$.

Cobalt carbonates precipitated from solution at fixed and varied pH values exhibit a strong difference in behavior under thermal treatment. In the former case, the endo- and exothermic effects have maxima at 120 and 225°C, respectively, whereas in the latter case, these peaks lie at 135 and 290°C, respectively. The shift of the peaks of the thermal effects to lower temperatures in the case of precipitation at a fixed pH value can be attributed to a higher dispersity of particles of the precipitate and to an increase in the content of the basic forms of hydroxo carbonates to give the active blue form of $Co(OH)_2$. At the same time, precipitation at a varying pH value leads to formation of the inactive pink form of $Co(OH)_2$ [34]. In

contrast to the case of nickel carbonate, the decomposition of cobalt carbonate to give Co_3O_4 is accompanied by an exothermic effect, which can be attributed to oxidation of a part of Co^{2+} ions to Co^{3+}. Judging from the results of thermal analysis, the formulas of cobalt carbonates precipitated at fixed and varying pH values can be represented as $CoCO_3 \cdot 0.83Co(OH)_2 \cdot 1.6H_2O$ and $CoCO_3 \cdot 0.75Co(OH)_2 \cdot 2.6H_2O$, respectively.

As can be seen in Figs. 4a and 4b, basic carbonates of cobalt and nickel are X-ray amorphous up to 250°C inclusive. Nevertheless, the presence of diffraction rings in electron diffraction patterns of the samples indicates that a long-range order in the atomic arrangement exists in these samples. The product formed in thermal treatment of cobalt carbonate crystallizes at 300°C to give a single-phase spinel Co_3O_4. All reflections of the Co_3O_4 phase can be identified in the cubic crystal system with a lattice constant a = 0.8052 nm (*Fd*3*m* space group). This is in agreement with the reference data of the JCPDS database [nos. 42-1467 (a = 0.8083 nm) and 43-1003 (a = 0.8084 nm)]. Further increase in temperature to 650°C does not give rise to other phases, but makes the degree of crystallinity of cobalt oxide higher and the lattice constant larger, a = 0.8072 nm; the latter circumstance may be due to an increase in the degree of structure filling by oxygen.

A transition from X-ray amorphous nickel carbonate to crystalline single-phase NiO is observed at 320°C. Nickel oxide (bunsenite) belongs to the cubic crystal system with a lattice constant a = 0.4193 nm (*Fm*3*m* space group), in agreement with the data of the JCPDS database [no. 47-1049 (a = 0.4177 nm)].

The results of thermal and X-ray phase analyses were used to choose, in order to obtain nanosize particles of cobalt and nickel oxides, the minimum possible decomposition temperatures of carbonates of these metals, equal to 300 and 320°C, respectively. According to electron microscopic data, basic cobalt carbonate is composed of needles combined into agglomerates 200–400 nm in size, and basic nickel carbonate, of 200–300-nm agglomerates. Particles of cobalt and nickel oxides, formed in thermal decomposition of basic carbonates, have a rounded shape and are 5–10 nm in size.

CONCLUSIONS

Nanosize particles of cobalt and nickel oxides were synthesized by precipitation from solution, with cobalt and nickel nitrates serving as starting reagents, and ammonium carbonate, as a precipitant agent. Rounded particles of cobalt and nickel oxides 5–10 nm in size were obtained.

Abstract—The influence exerted by the basicity of organic amines on hydrolytic polycondensation of zirconium tetraisopropoxide was studied in order to obtain nanodispersed ZrO_2 particles of various sizes.

DOI: 10.1134/S1070427206030025

Hydrolysis of tetraalkoxysilianes, leading to formation of SiO_2 nanoparticles with a narrow size distribution, has been studied in sufficient detail [1–5]. The influence exerted by the structure of the starting alkoxysilane and an alcohol used as a solvent, concentrations of the alkoxysilane and water, temperature of the sol–gel process, rate of addition of the alkoxysilane, and acidity of the medium has been examined [1–4]. As a result, suspensions of monodisperse SiO_2 particles have become commercially available and found wide use for synthesis of monolithic optical glasses and nanocomposite materials, in optoelectronics, etc. [6, 7]. Hydrosols of particles of this kind form periodic colloid structures, which are unique model systems for fundamental studies of interparticle interaction forces of varied nature [8, 9].

In contrast to the case of tetraalkoxysilanes, the formation of hydrosols of zirconium dioxide in hydrolytic condensation of its alkoxides has been studied to a considerably lesser extent. Let us consider chemical reactions (1)–(6) occurring in this process [10]:

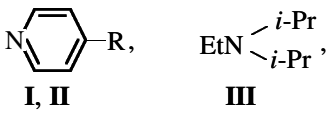
$$Zr(OR)_4 + nH_2O \underset{\text{Etherification (2)}}{\overset{\text{Hydrolysis (1)}}{\rightleftharpoons}} Zr(OH)_n(OR)_{4-n} + n\text{ROH},$$

$$\equiv Zr\text{–}OR + HO\text{–}Zr\equiv \underset{\text{Alcoholysis (4)}}{\overset{\text{Condensation (3)}}{\rightleftharpoons}} \equiv Zr\text{–}O\text{–}Zr\equiv + \text{ROH},$$

$$\equiv Zr\text{–}OH + HO\text{–}Zr\equiv \underset{\text{Hydrolysis (6)}}{\overset{\text{Condensation (5)}}{\rightleftharpoons}} \equiv Zr\text{–}O\text{–}Zr\equiv + H_2O.$$

Despite the apparent similarity of hydrolysis of Si and Zr alkoxides [reaction (1)] and of polycondensation of the forming compounds [reactions (3) and (5)], the formation of ZrO_2 nanoparticles has its distinctive features. This is due, on the one hand, to the tendency for zirconium atoms to increase their coordination number to eight and, on the other, to the markedly higher basicity of the oxygen atom in the ≡Zr–OH group, compared to that in ≡Si–OH (electronegativities of Zr and Si atoms by Pauling are equal to 1.2 and 1.8, respectively). Therefore, zirconium alkoxides have oligomeric structure in contrast to silicon alkoxides, which are monomeric. Zirconium alkoxides contain, as shown in detail for the example of zirconium tetraisopropoxide (ZTIP), alkoxy and oxo fragments in various combinations, with the relative amounts of these fragments dependent both on the preparation technique and on the storage duration of the samples synthesized [11, 12].

Owing to the increased basicity of the oxygen atom in the ≡Zr–OH group, compared to the ≡Si–OH group, the former is more labile in hydrolysis. As a result, the equilibrium of reactions (1) and (2) for zirconium alkoxides is strongly shifted to the right. The condensation reactions (3) and (5) are accompanied by formation of structures that contain a large number of hydroxy groups, which is quite untypical of silicon compounds. The reactions of alcoholysis (4) and hydrolysis (6) of these condensation products, which are responsible for the size ordering of oxide particles and for their growth, occur in the case of zirconium compounds by more complex mechanisms, compared to silicon compounds.



Until now, ZrO_2 hydrosols have been synthesized and the corresponding synthesis mechanisms have been studied in a weakly acidic medium [13–15]. Presumably, the forming suspensions of particles more than 1 μm in size [14] are poorly stable. It may be assumed that the sol–gel method for synthesis of

monodisperse ZrO_2 particles of various sizes by hydrolysis of zirconium tetrabutoxide [15] is seemingly preferable. However, the too complicated experimental procedure and the limited amount of water used for hydrolysis of zirconium tetrabutoxide cast doubt on the completeness of hydrolysis, i.e., on the purity of the oxide synthesized.

The influence exerted by the basicity and nucleophilicity of a number of organic amines on the hydrolysis of tetramethoxysilane (TMOS) and on the polycondensation of the compounds being formed has been studied previously in order to obtain monodisperse SiO_2 particles of prescribed size [5]. The simplicity of this process and of the apparatus involved, as well as the good reproducibility of the results obtained, stimulated studies of the hydrolytic polycondensation of zirconium alkoxides under similar conditions. It was intended to study fundamental aspects of formation of monodisperse ZrO_2 nanoparticles under similar conditions and to develop optimal conditions of their synthesis.

EXPERIMENTAL

The hydrolysis of ZTIP and the polycondensation of the forming compounds were studied under conditions of base catalysis. As catalysts served amines: pyridine (**I**), 4-(dimethylamino)pyridine (**II**), and ethyldiisopropylamine (**III**); as well as tetra-*n*-butylammonium hydroxide (**IV**) $(n\text{-Bu})_4N^+OH^-$:

I, II **III**

where R = H (**I**) and NMe_2 (**II**).

Zirconium tetraisopropxide was synthesized using the previously described method [16, 17] and purified by triple recrystallization from isopropanol. Amines **I** and **III**, preliminarily dried over BaO, were purified by distillation on a 10-TP column; they boiled within 0.2°C range. Amine **II** was recrystallized from ethanol. Hydroxide **IV** (Aldrich) was used without additional purification.

The sol–gel synthesis of ZrO_2 nanoparticles was performed in a glass reactor equipped with a double jacket for introduction of thermostating water, a magnetic stirrer, a dropping funnel, and a reflux condenser. The reactor was charged with ethanol, water, and an amine, and an isopropanol solution of ZTIP was added at 70°C under vigorous stirring in the course of 1 min. The total volume of the solution added was about 20 ml. A total of 12 sol–gel systems were prepared. The molar ratio alkoxide : water : ethanol : amine was $1 : 50 : 200 : X$, with the X values listed below:

Sol–gel system	Amine	X
1a	**I**	1.0
1b	**I**	5.0
1c	**I**	10
1d	**I**	20
1e	**I**	40
2a	**II**	1
2b	**II**	2
2c	**II**	3
2d	**II**	4
3	**III**	1
4	**IV**	1

The particle size in the sol–gel systems obtained was determined with an EM-125 electron microscope at an accelerating voltage of 75 kV. The samples studied were prepared by applying the suspensions obtained onto a carbon-reinforced collodion film substrate.

The choice of compounds **I**–**IV** is due to their different basicities, as characterized by the ionization constants of conjugated acids, pK_a:

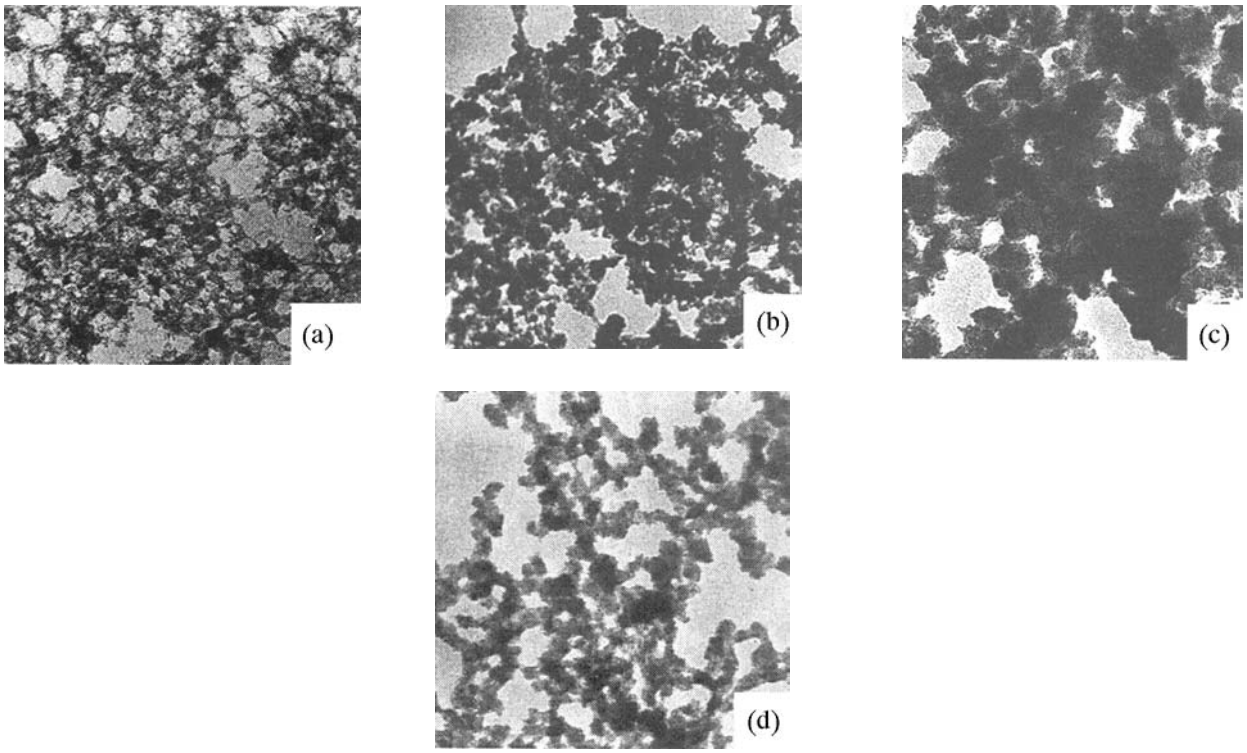
$$:NR_3 + H_2O \rightleftarrows HN^+R^- + OH^-. \quad (7)$$

At 20°C, the pK_a values of the compounds used are as follows [18]:

Amine	**I**	**II**	**III**	**IV**
pK_a	5.20	9.70	10.50	15.4

All the experiments performed can be conventionally divided into three groups. To the first of these belong experiments involving hydrolytic polycondensation of ZTIP in the presence of a nucleophilic base of medium strength, 4-(dimethylamino)pyridine (**II**) (sol–gel systems 2a–2e). The second group includes experiments with varied concentration of a weak base, pyridine (**I**) (sol–gel systems 1a–1e). Finally, to the third group belong experiments associated with hydrolysis of ZTIP in the presence of strong organic bases **III** and **IV**.

Figure 1 shows electron micrographs of particles in sol–gel systems 2a, 2c, and 2e. As the concentration of a base in the system increases, the forming ZrO_2 particles become coarser. However, the mechanism of their growth is apparently different from that in formation of SiO_2 particles in hydrolytic polycondensation of TMOS. In the latter case, the coarsening of



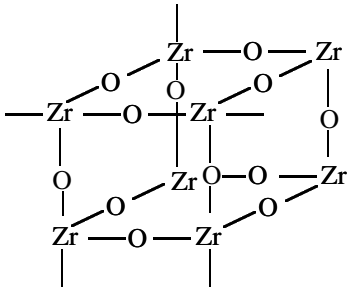


Fig. 1. Electron micrographs of particles in sol–gel systems (a) 2a, (b) 2b, (c) 2c, and (d) 3. Magnification 80000 (125 nm in 1 cm); the same for Figs. 2 and 3.

SiO_2 particles is accompanied by rupture of Si–O–Si bonds at places with an excess surface energy, specifically, at sharp projections and irregularities of the originally formed particles, which results in that they acquire a regular spherical shape [5]. According to Fig. 1, the coarsening of ZrO_2 particles is accompanied by aggregation of particles into a kind of clusters, rather than by growth of each separate particle. This involves sedimentation of the aggregated particles and the subsequent coagulation. As a result, loose nontransparent sediments are formed, with the rate of their formation being proportional to the concentration of the base. On passing from sol–gel system 2a to system 2e, the lifetime of the sol decreases from 10 days to several minutes. The difference between the processes of hydrolytic polycondensation of silicon and zirconium alkoxides can be understood as follows. According to Iler [19], silanols formed in hydrolysis of silicon alkoxides [reaction (1)] enter into condensation reactions (3) and (4). Successive elimination of water or alcohol molecules gives siloxanes of linear, cyclic, or polycyclic structure. After the polymerization is complete, particle of the dispersed phase of SiO_2 are formed and grow in solution. In the process, coarser particles grow by the condensation mechanism via dissolution of fine particles, with virtually only siloxane bonds formed within coarsening particles and silanol groups predominantly situated on the surface of the particles. Such particles with a hydroxylated surface show mutual repulsion and, therefore, cannot aggregate and grow via condensation with molecules of the $Si(OH)_4$ monomer or siloxane oligomers from a true solution [19]. In the case of hydrolytic polycondensation of zirconium alkoxides, the pattern is different. First, formation of linear or cyclic polyzirconoxane bonds $-(Zr-O)_{\overline{n}}$ is not characteristic of zirconium. Second, oxygen compounds of zirconium are never present in hydroxyl-containing solvents in the form of monomeric or low-molecular-weight oligomeric species of the type $[Zr(OH)_4]_n$. Despite that the hydrolysis of the ≡Zr–OR bond is considerably faster than the similar reaction for silicon, the ZrO_2 network

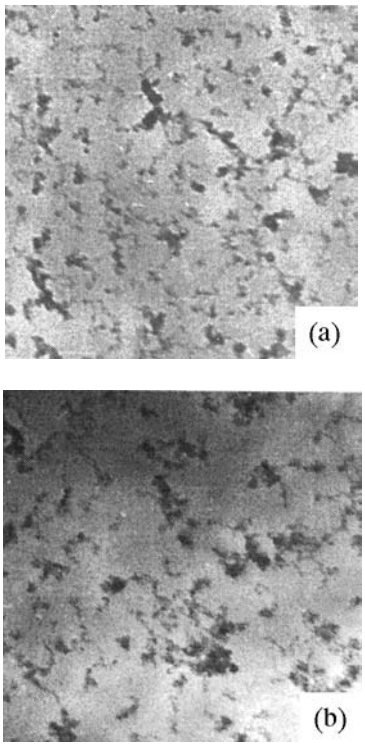

Fig. 2. Electron micrographs of particles in sol–gel systems (a) 1a and (b) 1d.

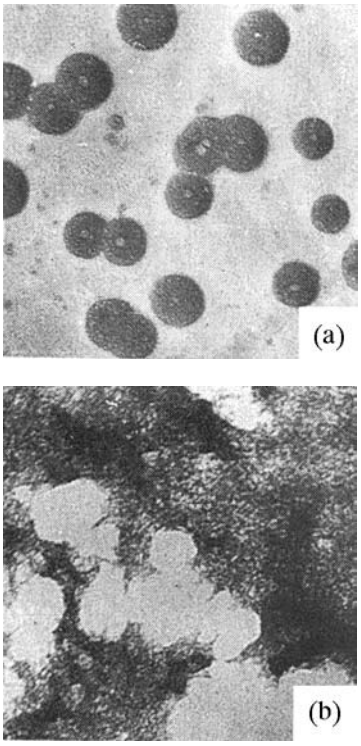

Fig. 3. Electron micrographs of particles in sol–gel system 4 (a) before and (b) after gelation.

does not commonly appear in pure form (in contrast to the case of the siloxane bond). In all cases, polycharged aqua structures, e.g., species of the type $[Zr_4(OH)_8(H_2O)_{16}]^{8+}$ [20], are formed in the course of polymerization. Because of the large number of water molecules in the coordination sphere of a zirconium atom, the content of hydroxy groups on the surface of growing particles is insignificant, which allows their successful aggregation to give jelly-like sediments of hydrated ZrO_2.

The course of the hydrolytic polycondensation of ZTIP is, undoubtedly, strongly affected by the pronounced nucleophilicity of the amine used (amine **II**). In hydrolytic polycondensation of ZTIP in the presence of base **III**, which has low nucleophilicity for steric reasons, but is considerably stronger, the degree of particle aggregation decreases (Fig. 1d).

The degree of aggregation of ZrO_2 particles and their size markedly decrease in the course of a sol–gel process catalyzed by a weak base **I**. The rate of their formation remains equally high, in contrast to the case of hydrolytic polycondensation of tetramethoxysiliane in the presence of pyridine, when many hours' boiling of the reaction mixture is necessary for hardly discernible SiO_2 particles to be formed. The growth of aggregates of ZrO_2 particles is presumably hindered by competition between the nitrogen atoms of pyridine and water molecules for the coordination sphere of a zirconium atom. An increase in the amount of pyridine in the reaction mixture does not make larger the size of the forming aggregates (Fig. 2), but only decreases the time in which a transparent, slightly opalescent gel is formed from tens of days to 1–2 days.

The formation of comparatively spherical ZrO_2 nanoparticles 100–150 nm in diameter (Fig. 3a) was only observed when a very strong base **IV** was used to catalyze the sol–gel process. In contrast to analogous SiO_2 particles, these nanoparticles have a rather loose structure (Fig. 3a) and, in a short time, disintegrate to give a gel-like structure (Fig. 3b).

CONCLUSIONS

(1) The mechanisms of formation and growth of nanodispersed ZrO_2 and SiO_2 particles synthesized by hydrolytic polycondensation of zirconium and silicon alkoxides in the presence of organic bases are different.

(2) The rate of formation of ZrO_2 particles in the sol–gel process of hydrolytic polycondensation of

zirconium tetraisopropoxide is independent of the basicity of the catalysts used.

(3) The coarsening of the ZrO_2 particles being formed occurs via aggregation of finer particles. This makes impossible synthesis of ensembles of monodisperse ZrO_2 particles in a protonic medium in the presence of organic amines.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of the Diffusion of Potassium Dichromate Aqueous Solutions in Porous Glass Membranes

Abstract—The diffusion coefficients of 0.1 M aqueous solution of potassium dichromate (pH 2–8) in a series of glass membranes with the prevailing pore radii from 4.5 to 70 nm were determined. Characteristic features of variation of the diffusion coefficient were correlated with the calculated content of chromium(VI) anionic species over a wide interval of pH of the solution.

DOI: 10.1134/S1070427206030037

The utility and efficiency of membrane filtration are determined by the relationship between the diffusion coefficients D of the solution components being separated or isolated [1, 2]. In this case, it is often necessary to consider the cases when the form of the dissolved substance depends on pH of the medium. Revealing the possibility and extent of manifestation of such dependences is a specific problem of the chemistry of solutions. Study of the diffusion in membranes can give certain grounds to judge the possibility for structural transformations in transported systems. In this connection, we have considered here the specific features of the diffusion of potassium dichromate aqueous solutions in porous glass membranes. It is universally accepted [3, 4] that in the pH range 2.0–4.5 dichromate anions, $Cr_2O_7^{2-}$, dominate in solutions, whereas in neutral and weakly alkaline media the monomeric chromate species CrO_4^{2-} prevail. A decrease in the acidity in the range 4.5–7.0 could be expected to result in a monotonic increase in the content of chromate ions, which will be accompanied by an increase in the measured diffusion coefficient and in the intensity of the membrane mass transfer as a whole.

First of all, it is necessary to refine the speciation of chromium(VI) in aqueous solutions. This problem remains controversial owing to differences in the pH intervals examined, in the concentrations of solutions under study, and in experimental methods used for detecting the anions. Thus, only monomeric CrO_4^{2-} and $HCrO_4^-$ ions were detected over a wide pH range (1–12) by computer processing of the electronic spectra of dilute potassium dichromate solutions [5]. At the same time, thorough examination of the IR spectra of solutions close in concentrations and pH [6, 7] revealed the presence of dichromate ions $Cr_2O_7^{2-}$ in the amounts reaching 30%, whereas the relationship between the fractions of chromate and dichromate ions was questioned. So far, reliably characterized [8] equilibria (1)–(3) have not been used to judge the influence of pH on the composition of the solutions.

$$H_2CrO_4 \rightleftarrows H^+ + HCrO_4^- \quad (K_1 = 0.16), \qquad (1)$$

$$HCrO_4^- \rightleftarrows H^+ + CrO_4^{2-} \quad (K_2 = 3.2 \times 10^{-7}), \qquad (2)$$

$$2HCrO_4^- \rightleftarrows Cr_2O_7^{2-} + H_2O \quad (K_{dim} = 35.5). \qquad (3)$$

Given the total concentration of the species taking part in equilibria (1) and (2)

$$c = [H_2CrO_4] + [HCrO_4^-] + [CrO_4^{2-}], \qquad (4)$$

their mole fractions can be calculated as

$$\alpha(H_2CrO_4) = \frac{[H^+]^2}{[H^+]^2 + K_1[H^+] + K_1K_2}, \qquad (5)$$

$$\alpha(HCrO_4^-) = \frac{K_1[H^+]}{[H^+]^2 + K_1[H^+] + K_1K_2}, \qquad (6)$$

$$\alpha(CrO_4^{2-}) = \frac{K_1K_2}{[H^+]^2 + K_1[H^+] + K_1K_2}. \qquad (7)$$

With regard to equilibrium (3), the concentration of dichromate ions in the solution is determined as

$$[Cr_2O_7^{2-}] = 0.5[HCrO_4^-]\alpha_{dim}, \quad (8)$$

where α_{dim} is the mole fraction of $HCrO_4^-$ ions that passed into the dimeric form.

Then the equilibrium concentration of $HCrO_4^-$ ions will be $(1 - \alpha_{dim})[HCrO_4^-]$, and the constant of equilibrium (3) will be written in the form

$$K_{dim} = \frac{\alpha_{dim}}{2[HCrO_4^-](1 - \alpha_{dim})^2}. \quad (9)$$

By transforming (9), we obtain quadratic equation (10):

$$\alpha_{dim}^2 - \{2 + 0.5(K_{dim}[HCrO_4^-])^{-1}\}\alpha_{dim} + 1 = 0. \quad (10)$$

As a result, α_{dim} can be found from Eq. (10) by substituting $HCrO_4^-$ concentrations obtained using the mole fraction $\alpha(HCrO_4^-)$ calculated by expression (6) for the pH interval 2–8. The results of our calculation give a quite definite pattern of the behavior of the system (Fig. 1). Thus, the mole fraction of $HCrO_4^-$ appears to be rather low, $\alpha(HCrO_4^-)$ ~0.1, and varies only slightly in the acid region. Chromic acid is formed in noticeable amounts only at a high concentration of protons (pH < 2), whereas the main part of hydrochromate ions, $HCrO_4^-$, passes into the dimeric form of $Cr_2O_7^{2-}$, which appears to dominate over a wide interval of pH 2–6. Approaching the neutral medium is accompanied by abrupt enhancement of the competition between reactions (2) and (3) in favor of the formation of chromate ions CrO_4^{2-}. Therefore, the results given in Fig. 1 refine the known views [3, 4, 8] and make it possible to predict a substantial increase in the fraction of mobile monomeric species in the solution at pH ≥ 6 and an increase in the rate of diffusion transfer in the membranes determined by this fraction.

The procedures for prepaation of membranes from porous glass and for adsorption determination of their structural parameters were published repeatedly [9–13]. The prevailing radii of the pores r_p and the porosity δ of the membranes used in the experiments are given below.

r_p, nm	4.5	19	30	38	45	70
δ, %	26.5	38.9	48.0	42.9	42.6	56.9

When studying the diffusion, we took the membranes as thin (about 1 mm) disks 25 mm in diameter. We fastened them hermetically at the outlets of glass tubes, thus serving as feed cells. These cells were filled with a 0.1 M aqueous solution of $K_2Cr_2O_7$. To

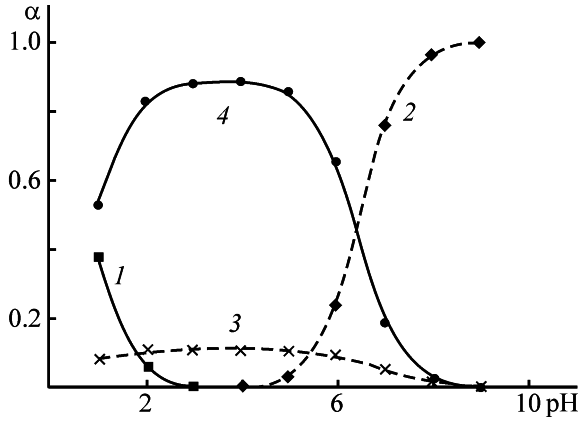

Fig. 1. Plots of equilibrium mole fractions α of (*1*) H_2CrO_4, (*2*) CrO_4^{2-}, and (*3, 4*) $HCrO_4^-$ in (*3*) monomeric and (*4*) dimeric forms vs. pH of the aqueous solution.

fix pH in the range 1–8, we acidified or alkalized the feed solution by adding hydrochloric acid or potassium hydroxide. Potassium dichromate that passed through the membrane was collected in beakers with distilled water, replaced at regular intervals. The concentration of the solutions in the samples did not exceed 10^{-3} M in all the tests, irrespective of pH of the medium and of structural parameters of the membranes in use. The samples were analyzed after bringing pH to 4 to ensure the presence of dichromate ions in them. The content of $Cr_2O_7^{2-}$ was then determined from the optical density at λ = 350 nm with the extinction coefficient ε = 2250 [14]. We carried out the tests under temperature control at 20°C with continuous stirring of the solutions. In all the cases, a steady-state flow through the membranes was attained no later than in 30 min after the beginning of the test. The dependences of the amount of the salt that passed through the membranes on time, *Q*–*t*, were always linear, which allowed us to determine the rates and the diffusion coefficients *D* from the first Fick's law:

$$dQ/d\tau = DS\delta\Delta c/h, \quad (11)$$

where $S\delta$ is the free section of a membrane, which is its geometric area corrected for the porosity; $\Delta c/h$ is the concentration drop at the inlet and outlet of the membrane of thickness *h*.

The resulting dependences of the diffusion coefficient on pH of aqueous 0.1 M solution of $K_2Cr_2O_7$ (Fig. 2) correspond to the steady-state overall transfer of the salt in the glass membranes. The character of *D* variation, the same in all the cases, distinctly reflects the speciation features found above (Fig. 1). In the range of pH 2–6, the diffusion mobility of the electro-

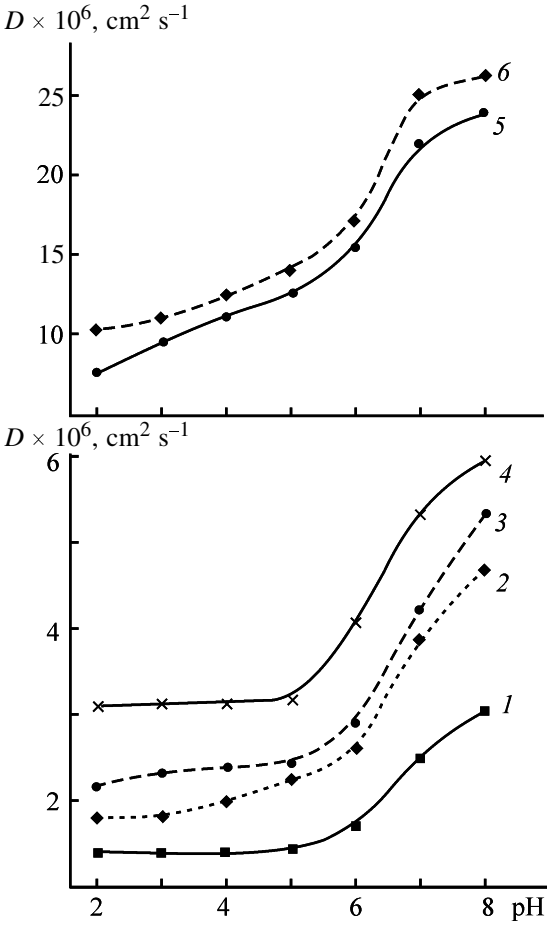

Fig. 2. Effect of pH of 0.1 M aqueous potassium dichromate solution on the diffusion coefficient D in glass membranes. Prevailing radius of membrane pores, nm: (*1*) 4.5, (*2*) 19, (*3*) 30, (*4*) 38, (*5*) 45, and (*6*) 70.

lyte remains almost constant or increases smoothly (in the membranes with pore radii of 45 and 70 nm), which corresponds to the prevalence of the anionic species $Cr_2O_7^{2-}$ in the solution. The further decrease in the acidity of the solution is accompanied by a distinct acceleration of the membrane transport. At pH 6, equilibria (2) and (3) start to rapidly shift toward formation of chromate ions CrO_4^{2-}; their intensive accumulation in the solution results in pronounced acceleration of the diffusion flow through the membranes. We emphasize once more that the diffusion coefficients determined characterize the membrane transfer as a whole. In this case, a substantial (by a factor of 2–3) increase in the diffusion coefficient resulting from pH increase is the consequence not only of higher mobility of CrO_4^{2-} ions compared to $Cr_2O_7^{2-}$ ions, but also of an increase in the number of particles at the membrane inlet, and, hence, in the $\Delta c/h$ gradient in Eq. (11). However, it is hardly possible to estimate the relative contributions of these factors.

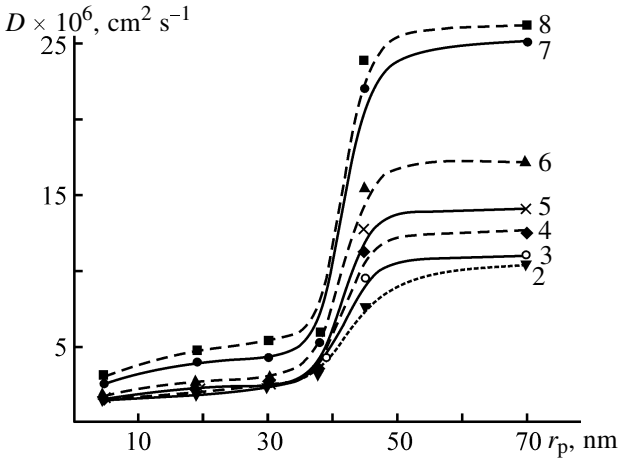

Fig. 3. Plot of diffusion coefficient D of potassium dichromate vs. pore radii r_p of the membranes. The figures at the curves are pH values of the solutions.

When the radius of transport channels of r_p = 45 nm is reached, the rate of diffusion in the glass membranes sharply increases in all the cases. The D–r_p dependences (Fig. 3) suggest that in a narrow interval of the radii of $38 < r_p < 45$ nm the inhibition of diffusion substantially decreases. This feature is most likely determined by the presence in the silica membranes of near-wall boundary layers of solution differing from the bulk of the solution in the structure, concentration, and properties [9–11]. We emphasize that this common factor, despite the difficulties in its detailed description, is distinctly manifested in the temperature dependences of the diffusion transfer of electrolytes [15], in the increased viscosity of boundary layers [1, 16, 17], and in the decreased dielectric permittivity and solvency of the bound water [18, 19]. Consequently, it is believed that low diffusion coefficients of an electrolyte in the pores of radius $r_p \leq$ 38 nm are determined by hindered ion motion in overlapping boundary layers, whereas in the channels of radius r_p = 45 nm a part of the pore solution remote from the silica surface ensures significantly accelerated membrane transfer. As for the uniform shape of the D–r_p curves, it suggests that the effective thickness of the near-wall boundary layer of the solution, in which the diffusion is hindered, remains constant within a wide pH range.

CONCLUSIONS

(1) A decrease in the acidity of an aqueous solution of potassium dichromate to pH ≥ 6 is accom-

panied by a substantial increase in the diffusion coefficient in the porous glass membranes. This feature is in agreement with the calculated pH dependence of the equilibrium composition of the solution.

(2) At any pH of the $K_2Cr_2O_7$ solution, a sharp increase in the diffusion coefficient is observed in the membranes with the pore radii $r_p > 38$ nm. This value can be considered as the effective thickness of the near-wall boundary layer of the solution, in which the diffusion is hindered.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Mutual Solubility of the Components in Systems RED-1 Diluent–Tri-*n*-butyl Phosphate Solvates of Rare-Earth Element(III) (Nd, Gd, Y, Yb, Lu) Nitrates–Escaid 100 Diluent

V. A. Keskinov, V. V. Lishchuk, A. K. Pyartman, and V. E. Skobochkin

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received June 9, 2005

Abstract—Phase diagrams of liquid binary systems RED-1 diluent–tri-*n*-butyl phosphate solvates of rare-earth element(III) (neodymium, gadolinium, yttrium, ytterbium, lutetium) nitrates were studied, and the binodal curves in the ternary systems $[Ln(NO_3)_3(TBP)_3]$ (Ln = Nd and Yb)–RED-1–Escaid 100 were determined at various temperatures.

DOI: 10.1134/S1070427206030049

Extraction of rare-earth elements(III) (REEs) with neutral organophosphorus compounds is widely used in separation and recovery processes. In saturation of the organic phase with coordination solvates of REE(III) nitrates in hydrocarbon diluents, second organic phase (so-called third phase) can be formed [1, 2]. Despite an obvious practical significance for REE separation processes, there are no available quantitative data on the mutual solubility of the components in the system RED-1 diluent–TBP solvates of REE(III) (Nd, Gd, Y, Yb, and Lu) nitrates––Escaid 100 diluent at various temperatures. Our goal was to fill this gap.

The density of the phases was studied by the bottle method. The initial solutions of REE(III) nitrates were prepared by dissolution of the corresponding oxides (ultrapure grade) in nitric acid (ultrapure grade). In the experiments we used vacuum-distilled tri-*n*-butyl phosphate (TBP) (ρ = 0.9727 g cm^{-3} at 298.15 K), RED-1 diluent (99% synthetic paraffin; ρ = 0.7395 g cm^{-3} at 298.15 K; dodecane fraction >50%; aromatics content <0.01 wt %), and Escaid 100 diluent (20 vol % aromatic hydrocarbons in paraffin; ρ = 0.8241 g cm^{-3} at 298.15 K). The coordination solvates $[Ln(NO_3)_3 \cdot (TBP)_3]$ (Ln = Nd, Gd, Y, Yb, and Lu) were prepared by triple extraction from saturated aqueous solutions of REE(III) nitrates [3]. The $[Ln(NO_3)_3(TBP)_3]$ "concentration" in pure solvates was 1.10±0.02 M (ρ = 1.275±0.001 g cm^{-3}). The binodal curves for the binary and ternary systems and the nodes for the binary systems were obtained using the procedure described in [4, 5]. The heterogeneous equilibria were monitored turbidimetrically using a Kernco 966 R instrument and a color filter (λ = 850 nm). The weight fractions of the components were determined to within 0.001–0.002, and the temperature, to within 0.2 K. It was demonstrated in the preliminary experiments that, in mixing the RED-1 solutions with $[Ln(NO_3)_3 \cdot (TBP)_3]$, the change in the volume of the organic phase is within 0.3 vol %. The compositions of the coexisting phases (vol %) were recalculated to the weight fractions taking into account the solution densities. The binodal curves were fitted by third-degree polynomials.

The phase diagrams of the ternary liquid systems, as influenced by the temperature, were constructed using the second-type Roozeboom triangle [rectangular coordinates for two components of the ternary liquid system with reference to the weight fractions (ω_i) of the components (for the third component, $\omega_3 = 1 - \omega_1 - \omega_2$)].

The results show that the $[Ln(NO_3)_3(TBP)_3]$–RED-1 binary systems (Ln = Nd, Gd, Y, Yb, and Lu) are incompletely miscible, forming two separate liquid phases I and II. Phase I is enriched in RED-1, and phase II, in $[Ln(NO_3)_3(TBP)_3]$. Increasing temperature increases the mutual solubility of the components, i.e., the phase separation region decreases (see table).

The binary systems are characterized by the upper critical temperature of solution (mixing) T_{cr} (K):

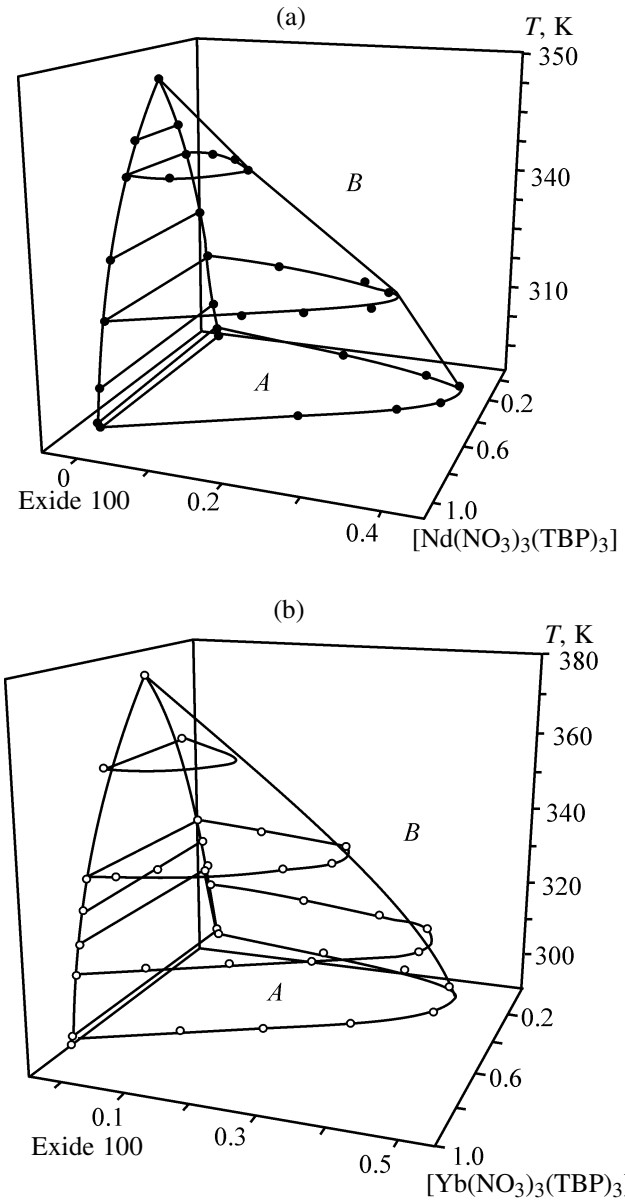

Fig. 1. Phase diagrams of ternary systems (a) $[Nd(NO_3)_3 \cdot (TBP)_3]$–RED-1–Escaid-100 and (b) $[Yb(NO_3)_3(TBP)_3]$–RED-1–Escaid-100. The concentrations are expressed in wt fractions. (*A*) Two-phase and (*B*) homogeneous regions.

346.25 ± 0.5 for the Nd(III) solvate, 349.05 ± 0.5 (Gd), 365.75 ± 0.5 (Y), and 375.55 ± 0.5 (Yb). As for Lu(III), the upper critical temperature of the binary system $[Lu(NO_3)_3(TBP)_3]$–RED-1 lies outside the experimental temperature range (further increase in the temperature above 383.15 K results in evaporation of the solvent from the liquid phase). In this case, T_{cr} was estimated by approximation of the section of the binodal curve by a third-degree polynomial to be 404 K (see table). In the series Nd–Gd–Y–Yb–Lu, the

upper critical temperature of solution for the binary systems increases with decreasing ionic radius of REE(III). The weight fractions of the components at T_{cr} are quite similar: Nd(III) 0.46, Gd(III) 0.45, Y, Yb(III) 0.47, and Lu(III) ~0.5. The observed considerable effect of the lanthanide nature on the upper critical temperature of solution, in our opinion, is caused by the dipole–dipole interaction between the REE solvates, which increases with decreasing ionic radius of REE(III). In the series Nd(III)–Lu(III), the difference in T_{cr} amounts to about 58 K.

The phase diagrams of the ternary systems $[Ln(NO_3)_3(TBP)_3]$–RED-1–Escaid-100 (Ln = Nd and Yb) demonstrate a homogeneous region (*B*) and a two-phase region (*A*) confined by the binodal curves corresponding to a given temperature (Figs. 1a, 1b). The upper critical temperatures of solution of the binary and ternary systems are practically coincident. In the case of $[Nd(NO_3)_3(TBP)_3]$, complete homogenization of the system at low temperature (293–298 K) requires introduction of up to 0.45 wt fraction of Escaid-100, and for $[Yb(NO_3)_3(TBP)_3]$, 0.52 wt fraction.

Finally, practical use of extraction systems based on TBP–RED-1–Escaid-100 mixtures under conditions of saturation of the organic phase with REE(III) nitrates with formation of $[Ln(NO_3)_3(TBP)_3]$ requires partial (about 0.6 wt fraction) replacement of the paraffinic diluent by the diluent containing up to 20% of aromatics. This ensures complete homogenization of the system at low temperatures.

CONCLUSIONS

(1) Binary systems $[Ln(NO_3)_3(TBP)_3]$–RED-1 (Ln = Nd, Gd, Y, Yb, and Lu) separate into two liquid phases I and II. Phase I is enriched in RED-1, and phase II, in $[Yb(NO_3)_3(TBP)_3]$. With increasing temperature the two-phase region decreases, i.e., the miscibility of the components increases.

(2) The binary systems are characterized by the upper critical temperature of solution T_{cr} (K): 346.25 ± 0.5 for the Nd(III) solvate, 349.05 ± 0.5 (Gd), 365.75 ± 0.5 (Y), 375.55 ± 0.5 (Yb), and about 404 (Lu). The upper critical temperature of solution of the binary systems increases in the order Nd < Gd < Y < Yb < Lu, i.e., with decreasing ionic radius of REE(III).

(3) The phase diagrams of the ternary systems $[Ln(NO_3)_3(TBP)_3]$–RED-1–Escaid-100 (Ln = Nd and Yb) demonstrate a homogeneous region and a two-phase region. Complete homogenization of the system at low temperatures (293–298 K) requires introduction of up to 0.6 wt fraction of Escaid-100.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Mercury(II), Zinc(II), and Iron(III) Thiocyanate Complexes on AV-17 Anion Exchanger and KU-2 Cation Exchanger Modified with Rhodamine Zh

E. A. Zauer

Volgograd State Engineering University, Volgograd, Russia

Received March 25, 2005

Abstract—Sorption of anionic mercury(II), zinc(II), and iron(III) thiocyanate complexes on KU-2 cation exchanger modified with Rhodamine Zh and on AV-17-8 strongly basic anion exchanger were studied in relation to the concentration of SCN^- ions and solution pH. Optimal conditions of sorption of metal complexes from dilute solutions were found.

DOI: 10.1134/S1070427206030050

Complex formation is widely used to increase the selectivity of metal ion sorption. Both usual and chemically and surface-modified ion exchangers are used as sorbents [1, 2].

The data on sorption of complex ions with usual and modified ion exchangers are lacking, although they are necessary to optimize sorption preconcentration and separation of elements and to develop technologies of industrial waste management. For instance, sorption of mercury(II) halide complexes with AV-17 anion exchanger was studied in [3]. Sorption of zinc complex ions from chloride solutions on various anion exchangers is described in [4]. Studies on sorption from mixtures of complexes are very few.

In this study, we examined the kinetics of sorption of mercury(II), iron(III), and zinc(II) thiocyanate anionic complexes on AV-17-8 strongly basic anion exchanger and on KU-2 strongly acidic sulfonic cation-exchange resin modified with a basic dye, Rhodamine Zh (RZh).

EXPERIMENTAL

The initial solution of iron(III) was prepared from ferric ammonium sulfate [5] and standardized complexometrically with sulfosalicylic acid [6]. A mercury(II)-containing solution was prepared from mercury sulfate [5] and standardized by complexometric back-titration with Eriochrome Black T indicator [6]. A solution containing Zn(II) was prepared by dissolving metallic zinc (chemically pure grade) in hydrochloric acid [5]. The working solutions were prepared by dilution of the initial solutions with distilled water. AV-17-8 anion exchanger in the chloride form was prepared as in [7].

To obtain modified KU-2 cation exchanger, the initial KU-2 resin in the hydrogen–salt form prepared as in [7] was stored in 0.2% aqueous solution of Rhodamine Zh for 24 h and then separated by filtration, washed with distilled water, and dried. Modification is the ion-exchange reaction

$$RSO_3^-H^+ + RZh^+ \rightarrow RSO_3^-RZh^+ + H^+.$$

It is known that basic dyes form ionic associates with halide and thiocyanate complexes of certain metal ions insoluble in water but soluble in organic solvents (e.g., toluene). This property of dyes is widely used in analytical chemistry for extraction-photometric determination of elements, including mercury(II) and zinc(II) [8, 9].

In this study, ionic associates of elements under consideration were obtained in the phase of the sorbent modified with Rhodamine Zh but not in a solution, and potassium thiocyanate was used as a complexing agent.

To study the sorption kinetics, a 0.50 ± 0.05-g portion of the sorbent was introduced into 100 cm^3 of a solution containing zinc, iron, or mercury after addition of a 25% aqueous solution of potassium thiocyanate. The mixture was stirred with a magnetic stirrer for definite time, and the sorbent was separated, washed with distilled water, and dried.

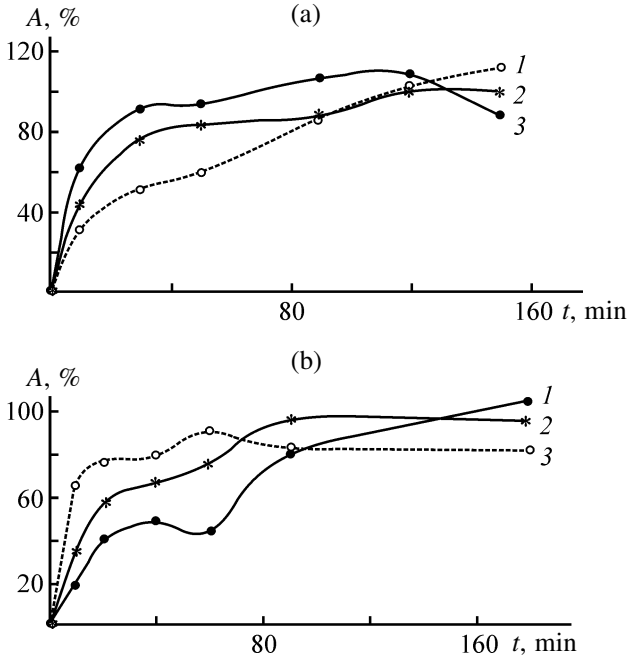

Fig. 1. Kinetics of sorption of (*1*) iron(III), (*2*) zinc(II), and (*3*) mercury(II) thiocyanate complexes from their mixture on (a) modified KU-2 cation exchanger and (b) AV-17 anion exchanger. $C_{KSCN} = 13 \times 10^{-5}$ M. Composition of the mixture of ions (μg cm^{-3}): (a) Fe 3.52, Zn 7.23, Hg 6.27 and (b) Fe 1.55, Zn 7.23, Hg 6.23. (*A*) Degree of sorption and (*t*) time.

Sorption was monitored with a Spektroskan crystal-diffraction scanning X-ray fluorescence spectrometer (Spektron Research and Production Association, St. Petersburg) [10, 11]; the contents of the metals were determined simultaneously on the surface of the solid concentrate at a 40 kV voltage on an X-ray tube with a copper anode at the time of signal accumulation of 40 s. The FeK_α (1936 mÅ), ZnK_α (1435 mÅ), and HgL_α (1241 mÅ) lines were used as analytical lines. The error of mercury, iron, and zinc determination was 3–10 rel. %.

In the presence of SCN^- ions, Hg^{2+}, Zn^{2+} and Fe^{3+} ions form complexes whose compositions depend on the concentration of the complexing ion. Zinc(II) and mercury(II) ions have the general composition $[M(SCN)_n]^{2-n}$ (M is zinc or mercury ion, n = 1–4). Iron(III) forms with thiocyanate ion complexes $[M(SCN)_n]^{3-n}$ (n = 1–6). Among the anionic complexes, the mercury complexes $[Hg(SCN)_3]^-$ ($\log\beta$ = 19.17) and $[Hg(SCN)_4]^{2-}$ ($\log\beta$ = 19.77) are the most stable. The iron {$[Fe(SCN)_4]^-$, $\log\beta$ = 4.53; $[Fe(SCN)_5]^{2-}$, $\log\beta$ = 4.23; $[Fe(SCN)_6]^{3-}$, $\log\beta$ = 3.23} and zinc {$[Zn(SCN)_3]^-$, $\log\beta$ = 2.2; $[Zn(SCN)_4]^{2-}$, $\log\beta$ = 3.7} complexes are moderately stable [12].

Sorption proceeds by the ion-exchange mechanism, when AV-17 anion exchanger is added into the solution containing the above thiocyanate complexes.

When KU-2 ion exchanger modified with Rhodamine Zh is used, the interaction of iron, mercury, or zinc anionic complexes with the dye in the sorbent phase is apparently similar to that in the solution, with the formation of ionic associates of the following composition: for zinc(II) and mercury(II), $(RZh)\cdot[M(SCN)_3]$ and $(RZh)_2[M(SCN)_4]$ and for iron(III), $(RZh)[M(SCN)_4]$, $(RZh)_2[M(SCN)_5]$, and $(RZh)_3\cdot[M(SCN)_6]$.

As seen from Fig. 1a, the rate of sorption of anionic complexes on the cation exchanger modified with Rhodamine Zh decreases in the order $Hg^{2+} > Zn^{2+} > Fe^{3+}$. This coincides with data of [2] showing that the sorbability increases with increasing stability of the complex. The time required to attain complete sorption is 40–60 min with mercury(II) and zinc(II) and 120–150 min with iron(III).

The rate of sorption on AV-17-8 anion exchanger (Fig. 1b) decreases in the same order as on modified KU-2 cation exchanger. The limiting sorption of anionic complexes is reached in 60 min with mercury(II) and in 90–120 min with iron(III) and zinc(II).

The results are presented in Fig. 2a and 2b. At low SCN^- concentrations, cationic iron(III), mercury(II) and zinc(II) complexes, which are not noticeably sorbed, dominate in the solution. As the concentration of SCN^- ions increases, the negatively charged complex ions appear in the solution. They are sorbed on the AV-17 anion exchanger by the ion-exchange reaction and are electrostatically attracted to modified KU-2 cation exchanger with formation of ionic associates with Rhodamine Zh. At a further increase in the SCN^- concentration, the SCN^- ions compete with anionic metal complexes for the sorption sites of the sorbent. However, thiocyanate ions are sorbed more weakly, since their charge is lower as compared to the charges of the complex ions at excess SCN^- ligands.

With the modified sorbent (Fig. 2a), the maximal degree of mercury(II) sorption is attained at a potassium thiocyanate concentration of 1.3×10^{-5} M. The further increase in its concentration does not change the sorption substantially. With Zn^{2+} and Fe^{3+}, the maximal sorption is observed at a KSCN concentration of $(10–13) \times 10^{-5}$ M. Probably, this is connected with the fact that mercury(II), as compared to zinc(II) and iron(III), forms stronger complexes with thiocyanate ions, which are better sorbed with the sorbent.

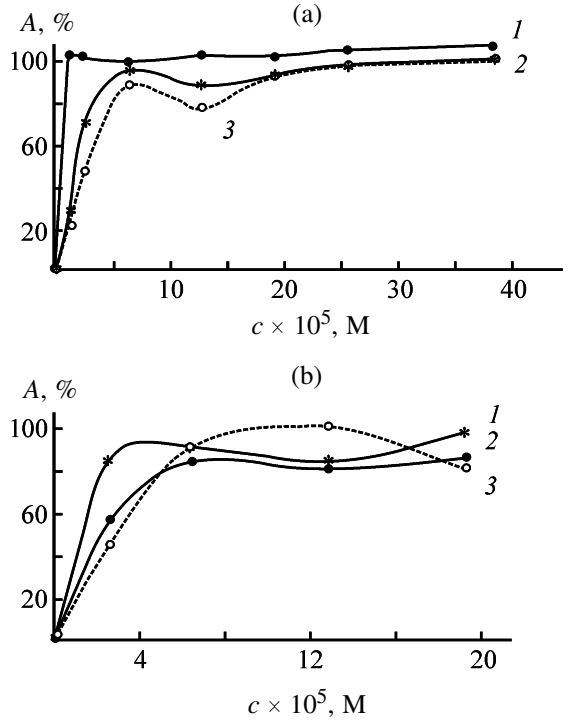

Fig. 2. Influence of KSCN concentration c on the degree of sorption A of (*1*) mercury(II), (*2*) zinc(II), and (*3*) iron(III) thiocyanate complexes on (a) modified KU-2 cation exchanger and (b) AV-17 anion exchanger. Sorption time 2 h. Composition of mixture of ions ($\mu g\ cm^{-3}$): Fe 1.76, Zn 7.23, and Hg 6.27.

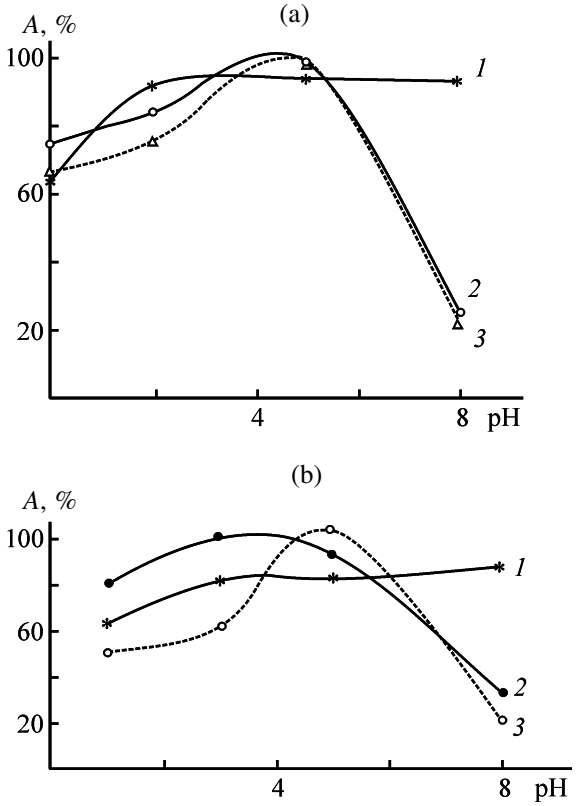

Fig. 3. Influence of solution pH on the degree of sorption A of (*1*) mercury(II), (*2*) zinc(II), and (*3*) iron(III) thiocyanate complexes on (a) modified KU-2 cation exchanger and (b) AV-17 anion exchanger. $c_{KSCN} = 13 \times 10^{-5}$ M, sorption time 2 h. Composition of mixture of ions ($\mu g\ cm^{-3}$): Fe 1.55, Zn 7.23, and Hg 6.27.

The maximal sorption of the metal ions studied on AV-17 resin is reached at a potassium thiocyanate concentration of $(8–13) \times 10^{-5}$ M (Fig. 2b).

Sorption of iron(III) and zinc(II) sharply decreases at pH > 5 on both AV-17 and modified KU-2 resins (Fig. 3a). Probably, this effect is a result of competing reactions of the metal ions with hydroxide ions with formation of hydroxo complexes. With iron(III), these complexes are $[Fe(OH)]^{2+}$ ($\log\beta$ = 11.87) and $[Fe(OH)_2]^{+}$ ($\log\beta$ = 21.17), which predominate in the solution even at pH 5 and prevent penetration of iron into the sorbent phase. In addition, with increasing pH the probability of formation of poorly soluble iron hydroxide $[Fe(OH)_3]^{0}$ increases. Zn^{2+} ions also form with OH^{-} ions hydroxo complexes $[Zn(OH)]^{+}$ ($\log\beta$ = 4.40), $[Zn(OH)_2]^{0}$ ($\log\beta$ = 11.30), $[Zn(OH)_3]^{-}$ ($\log\beta$ = 13.14), and $[Zn(OH)_4]^{2-}$ ($\log\beta$ = 14.66), which are more stable than complexes with thiocyanate ions. In contrast to iron(III) trihydroxide, zinc dihydroxide is amphoteric and forms negatively charged complex ions in the presence of excess hydroxide ions. However, within the pH range studied, cationic zinc complexes prevail; they are not sorbed on the surface of the modified cation exchanger.

At pH > 2 for modified KU-2 cation exchanger and pH > 3 for AV-17 anion exchanger, the acidity of solution does not noticeably affect the sorption of mercury(II), since only the anionic hydroxo complex can be sorbed with the ion exchangers studied among the complexes $[Hg(OH)]^{+}$ ($\log\beta$ = 10.30), $[Hg(OH)_2]^{0}$ ($\log\beta$ = 21.70), and $[Hg(OH)_3]^{-}$ ($\log\beta$ = 21.20) formed under these conditions[12]. Its stability is close to the stability of thiocyanate anionic complexes. Therefore, the decrease in the solution acidity probably causes sorption of mercury in the form of hydroxo but not thiocyanate complexes.

CONCLUSIONS

(1) The shapes of the pH dependences of sorption of mercury(II), iron(III), and zinc(II) with AV-17-8 anion exchanger and KU-2 cation exchanger modified

with Rhodamine Zh are similar. pH substantially affects the sorption of iron(III) and zinc(II) thiocyanate complexes. Sorption of mercury(II) complexes is essentially independent of pH.

(2) The order of sorption on modified cation exchanger and on anion exchanger is the same: initially mercury(II) complex anions, then zinc(II) complexes, and then iron(III) complexes are sorbed.

(3) The optimal conditions of simultaneous sorption of mercury(II), iron(III), and zinc(II) thiocyanate complexes from dilute solutions with modified KU-2 cation exchanger and AV-17-8 anion exchangers are as follows: sorption time 2 h, pH of solutions 4–5, and concentrations of thiocyanate ions $(10–13) \times 10^{-5}$ and $(8–13) \times 10^{-5}$ M in the case of KU-2 and AV-17-8 ion exchangers, respectively.

SORPTION AND ION-EXCHANGE PROCESSES

Isotherm of Strontium and Sodium Cation Exchange on Iron–Manganese Nodules

D. E. Chirkst, O. V. Cheremisina, M. V. Ivanov, A. A. Chistyakov, and I. T. Zhadovskii

St. Petersburg State Mining Institute, St. Petersburg, Russia

Received February 17, 2005

Abstract—The isotherm of ion exchange of Sr^{2+} and Na^{+} ions on iron–manganese nodules was obtained. It was suggested to describe the ion exchange by an equation analogous to the Langmuir isotherm equation. The limiting sorption and apparent ion exchange constant were calculated. The effective radius of sorbed strontium ions was determined.

DOI: 10.1134/S1070427206030062

Iron–manganese nodules (IMNs) as natural cation exchangers show promise for the recovery of strontium-90 from radioactively contaminated water and also from reactor conduits.

Radiation pollution of territories near nuclear plants is mainly caused by emergency emissions of cesium-l37 and strontium-90. Strontium is largely sorbed by the mineral component of soils [1–3], and its migratory activity is noticeably higher compared to cesium. A process for treatment of soils contaminated with ^{90}Sr [4] by flushing the soil with solutions of salts of multicharged cations was developed previously on the pilot scale. The study of the ion exchange on IMNs will make it possible to develop a procedure for the removal of strontium-90 from wash waters and also from underground waters.

In this study we examined the isotherm of the exchange of sodium and strontium ions on the IMN surface. As natural IMN samples contain various exchanging cations, iron–manganese nodules were converted to the sodium form.

According to the simplest Helmholtz model, the spatial separation of charges near a surface can be considered as an electrical double layer representing two parallel plates of a charged capacitor separated by a layer of a dispersing medium [5]. One capacitor plate is formed by potential-determining ions fixed on the solid surface and the other, by counterions contained in a liquid. Because of short range of action of adsorption forces, we can distinguish two main parts of an electrical double layer: a dense part (Stern–Helmholtz layer) and a more distant diffuse part (Gouy–Chapman layer). According to the Stern–Graham scheme, the dense part of an electrical double layer consists of internal and external parts. The internal part is formed by partially of completely dehydrated ions specifically adsorbed on the surface in question. The external part consists of hydrated ions, sodium ions in our case, which can exchange with strontium ions according to the Gedroits lyotropic series $Fe^{3+} > Al^{3+} > Cs^{+} > Sr^{2+} > Ca^{2+} > Mg^{2+} > Rb^{+} > K^{+} > Na^{+} > Li^{+}$ [5, 6]. The tendency of the cations to adsorption in this series increases in parallel with the ionic potential, which is equal to the ratio of the charge and radius of the hydrated ion.

It is known that ^{137}Cs is fixed in soils much more strongly than does ^{90}Sr, despite smaller ion charge [6]. As compared to strontium, cesium has a smaller Stokes radius of the hydrated ion. The higher ionic potential of cesium in aqueous solutions compared to strontium is indicated by the fact that the equivalent conductance of cesium ions, equal to 7.72×10^{-3} S m^2 equiv^{-1} at 298 K and infinite dilution, is higher than that of strontium ions, 5.94×10^{-3} S m^2 equiv^{-1} [7]. Owing to higher ionic potential in aqueous solution, cesium ions are bonded more strongly than strontium ions to negatively charged structural fragments on the surface of minerals.

An air-dry IMN sample with granules of size 0.10–0.25 mm was treated with a 5% NaOH solution for 5 days with intermittent stirring. The alkali solution was replaced daily by a fresh solution. The completeness of converting IMN into the sodium form was monitored by reaching the constant activity of Na^{+}

ions after treating IMN with an alkaline solution. The activity of Na^+ ions in alkaline solutions contacted with IMN and diluted using volumetric glassware to concentrations of 0.001–0.01 mol kg^{-1} was measured with an ion-selective electrode and an Anion ion meter. After that, IMN was multiply washed out with water to pH 7 of the aqueous extract and air-dried.

We studied the ion exchange from 0.013–0.500 M (with respect to Sr^{2+}) model aqueous solutions of $SrCl_2$. The value of sorption Γ_{Sr} (mol kg^{-1}) of strontium ions was determined under static conditions at the ratio of the liquid phase volume to the solid phase weight V/m = 10 ml g^{-1} and at the weight of an IMN sample of 5 g. The sorption value was calculated from the difference of concentrations of the starting (c_0) and equilibrium (c_{eq}) solutions by the formula

$$\Gamma = (c_0 - c_{eq})V/m.$$

A solution of strontium chloride was stirred with an IMN sample by a magnetic stirrer at 400 rpm to reach an equilibrium. The equilibration time required to reach a constant solution concentration was 5–6 h; in the experiments the time of phase contact was no less than 10 h.

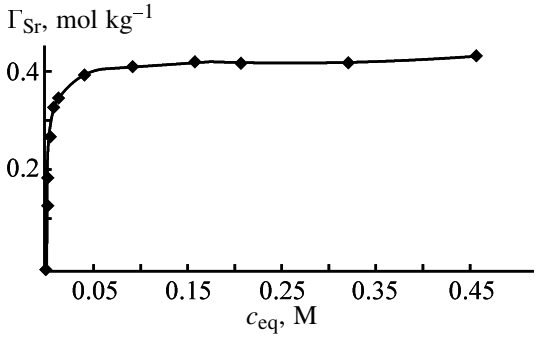

Fig. 1. Isotherm of sorption Γ_{Sr} of strontium cations on the IMN surface. (c_{eq}) Equilibrium concentration of strontium ions.

After experiments, the solution was filtered through a "blue band" filter, the equilibrium concentration of sodium ions was measured with an Anion pH meter equipped with an ion-selective electrode, and that of strontium ions was determined photometrically [8]. Solution aliquots of volume from 2 to 10 ml depending on the strontium(II) content were transferred into a 50-ml flask. The required pH 2.8–3.0 was adjusted by adding 10 ml of acetate buffere solution. Then 25 ml of a 60% aqueous solution of ethanol and 1 ml of a 0.1% solution of Nitroorthanilic C (Nitrochromazo) were added, and the solution in the flask was brought to the mark with distilled water. The strontium(II) content in the solution under study was determined by the intensity of the absorption band of the strontium complex with Nitrochromazo at λ 650 nm. This method allows determination of the strontium(II) content from 2 to 20 μg in 25 ml of solution. Under these conditions, Na^+ and NH_4^+ ions do not hinder up to 100-fold excess; K^+, up to a 30-fold excess; Ca^{2+}, up to 1/5-fold excess; and Mg^{2+}, up to 5-fold excess.

Table 1 shows the initial and equilibrium concentrations of strontium ions c_0 and c_{eq}, sorption values Γ_{Sr}, reciprocals of strontium ions sorption values $1/\Gamma_{Sr}$, equilibrium concentrations of sodium ions c_{Na^+}, and activity coefficients of single-charged cations γ_+ calculated by the Davies equation [9]. The measurements of the equilibrium concentration of sodium ions with an ion-selective electrode confirmed the equivalence of the exchange of sodium and strontium ions. The resulting isotherm of sorption of strontium ions on the IMN surface is given in Fig. 1.

The thermodynamic description of the exchange of strontium and sodium ions was carried out on the assumption of ideality of a solid phase, i.e. without taking into account the activity coefficients of sorbed ions. It was shown in [10] that the ion-exchange isotherm can be described by an equation of the Langmuir isotherm type. We used the linearization procedure suggested earlier [11] for an analog of Langmuir equation.

The equation of mass action law for the ion-exchange reaction

$$2Na^+_{sol} + Sr^{2+}_{aq} \rightleftarrows 2Na^+_{aq} + Sr^{2+}_{sol}$$

is of the form

$$\Gamma = \frac{\Gamma_{Sr^{2+}} a^2_{Na^+}}{\Gamma^2_{Na^+} a_{Sr^{2+}}}, \quad (1)$$

where K is the apparent exchange constant; $\Gamma_{Sr^{2+}}$ and Γ_{Na^+}, values of sorption of ions (mol kg^{-1}); a_{Na^+} and $a_{Sr^{2+}}$, activities of ions in solution (mol kg^{-1}).

The electroneutrality condition implies that the numbers of equivalents of exchanging ions in ion exchange should be equal. Therefore, the limiting sorption of ions should be expressed in equiv kg^{-1}. When calculating the thermodynamic functions by the mass action law, the value of sorption of ions should be expressed in mol kg^{-1}, as ion activities in solution have a dimension of mol kg^{-1} corresponding to the standard state. Thus,

$$\Gamma_\infty = \Gamma_{Na^+} + 2\Gamma_{Sr^{2+}},$$

where Γ_∞ is the limiting sorption of ions (equiv kg^{-1}), and the values of sorption of ions are expressed in mol kg^{-1}.

In view of the aforesaid, Eq. (1) can be reduced to form (2), as in the Debye–Hückel and also in the Davies approximations we have $\gamma_{z^+} = \gamma_+^{2z}$, where z is the cation charge:

$$K = \frac{\Gamma_{Sr^{2+}}[Na^+]^2\gamma_+^2}{\Gamma^2_{Na^+}[Sr^{2+}]\gamma_{2+}} = \frac{\Gamma_{Sr^{2+}} c^2_{Na^+}}{(\Gamma_\infty - 2\Gamma_{Sr^{2+}})^2 c_{eq}\gamma_+^2}. \quad (2)$$

Equation (2) is converted to formula (4) analogous to Langmuir isotherm equation (3).

$$\Gamma = \Gamma_\infty \frac{Ka}{1 + Ka}, \quad (3)$$

$$(\Gamma_{Sr^{2+}})^{1/2} = \Gamma_\infty \frac{(Kc_{eq})^{1/2}\gamma_+}{c_{Na^+} + 2\gamma_+(\Gamma_{Sr^{2+}} Kc_{eq})^{1/2}}, \quad (4)$$

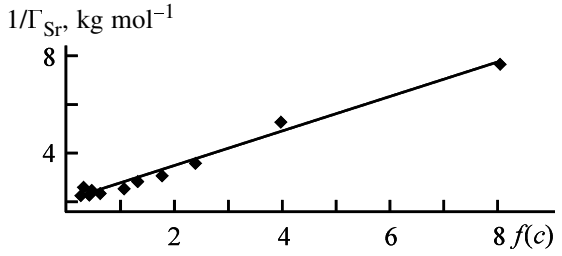

Fig. 2. Linearized isotherm of the exchange of Na^+ and Sr^{2+} ions. ($1/\Gamma_{Sr}$) Reciprocal of sorption of strontium cations; [$f(c)$], function depending on the equilibrium concentrations of sodium ions c_{Na^+} and strontium ions c_{eq}, the sorption value Γ_{Sr}, and the activity coefficients of single-charged cations γ_+ (dimensionless quantity).

where Γ and Γ_∞ are values of sorption and limiting sorption; K, equilibrium constant of the sorption process; and a, activity of sorbed ions.

The linear form of the equation looks like (5).

$$(\Gamma_{Sr^{2+}})^{-1} = \Gamma_\infty^{-1} + c_{Na^+}[\gamma_+\Gamma_\infty(\Gamma_{Sr^{2+}} Kc_{eq})^{1/2}]^{-1}. \quad (5)$$

It is similar to the linear Langmuir equation:

$$\Gamma^{-1} = \Gamma_\infty^{-1} + (\Gamma_\infty Ka)^{-1}.$$

The linear ion-exchange isotherm is shown in Fig. 2. The dependence of the reciprocal of the sorption of strontium ions on the argument

$$f(c) = c_{Na^+}[\gamma_+(\Gamma_{Sr^{2+}} c_{eq})^{1/2}]^{-1}$$

is approximated by the linear equation

$$(\Gamma_{Sr^{2+}})^{-1} = 0.72f(c) + 2.06$$

with $R^2 = 0.98$.

On this basis, using the formula $\Delta G^0_{298} = -RT\ln K$ (T = 298 K), we have calculated the limiting sorption of ions Γ_∞ = 0.97 equiv kg^{-1}, the apparent ion-exchange constant $K_{Na^+/Sr^{2+}}$ = 2.05, and the Gibbs energy of the exchange of strontium ions for sodium ions on the IMN surface ΔG^0_{298} = 1.78 kJ mol^{-1}. The thermodynamic data show that the ion-exchange equilibrium is shifted toward displacement of sodium ions from the IMN surface into the solution by Sr^{2+} ions.

The isotherm of the exchange of strontium and iron(III) ions described by a dependence similar to the Langmuir equation was obtained in [11] for a sample of Cambrian blue clay of the composition $K_2Al_4[Al_2Si_6O_{20}](OH,F)_4$. The resulting apparent exchange constant and the exchange Gibbs energy for

reaction (6) were $K_{Sr^{2+}/Na^+} = 5.28$ and $\Delta G^0_{298} = -4.13$ kJ mol^{-1}.

$$Sr^{2+}_{sol} + 2/3\,Fe^{3+}_{aq} \rightleftarrows Sr^{2+}_{aq} + 2/3\,Fe^{3+}_{sol}. \quad (6)$$

These data show that the equilibrium is shifted toward the displacement of strontium(II) from the solid phase by iron(III) ions.

The limiting sorption of strontium ions on the clay $\Gamma_0 = 0.068$ equiv kg^{-1} [11] is smaller by a factor of 14 than their limiting sorption of 0.97 equiv kg^{-1} on IMN. This is attributable to the fact that the specific surface area of IMN $S_{sp} = 41.81$ m^2 g^{-1} [12] is greater by a factor of 7 than that of Cambrian blue clay, $S_{sp} = 5.86$ m^2 g^{-1} [13], and the capacity of iron–manganese nodules $E = 7.66 \times 10^{-2}$ equiv kg^{-1}, determined by the sorption of Methylene Blue (MG) [12], is greater by a factor of seven than the capacity of the clay with respect to MG, $E = 1.03 \times 10^{-2}$ equiv kg^{-1} [13].

We have estimated the "landing area" of Sr^{2+} ions S_M (m^2) from the IMN specific surface area and limiting sorption of strontium ions of 0.485 mol kg^{-1}:

$$S_M = \frac{S_{sp}}{\Gamma_\infty N_A} = 14.3 \times 10^{-20}\ \text{m}^2,$$

where N is Avogadro's number.

Hence the radius of sorbed Sr^{2+} ions is 213×10^{-12} m or 213 pm, and it is larger than the Stokes crystallographic radius of 113 pm. This fact indicates that strontium ions are sorbed in the hydrated state in the Stern layer on the IMN surface. The found ionic radius of Sr^{2+} on the IMN surface is smaller than the ionic radius of 302 pm for strontium sorbed on the clay [11], which practically coincides with the Stokes ionic radius of Sr^{2+} (309 pm [7]) and is smaller that the radius of Fe^{3+} ions sorbed on a clay from an aqueous solution (348 pm [11]). Apparently, strontium ions are partially dehydrated when sorbed on IMN, and the number of hydration shells is reduced from two in an aqueous solution to one in the Stern layer. This fact indicates that the negative charge density on the IMN surface is higher than on the clay surface.

The Sr^{2+}_{aq} ions have a larger hydrated radius and higher charge than the Na^+ ions. However, the ionic potential, which is proportional to the ratio of the cation charge to the radius of the hydrated ion z/r_{aq}, is higher for Sr^{2+} ions; therefore, they displace Na^+ ions from the IMC surface in the ion-exchange reaction. According to the values of ion-exchange Gibbs energies, cations are ranked in the following order of the replacing power, which correlates with increasing ionic potential z/r_{aq} of hydrated cations:

	Na^+ <	Sr^{2+} <	Fe^{3+}
ΔG^0_{298}, kJ mol^{-1}		–1.78	–4.13 [11]
z/r_{aq}, nm^{-1}	5.46	6.48	8.62 [11]

CONCLUSIONS

(1) The isotherm of ion exchange of Na^+ and Sr^{2+} ions on iron–manganese nodules is described by a dependence analogous to Langmuir equation and can be presented in the linear form with $R^2 = 0.98$.

(2) The apparent ion-exchange constant $K_{Na^+/Sr^{2+}} = 2.05$ and the Gibbs energy of the exchange of strontium ions for sodium ions on the surface of iron–manganese nodules $\Delta G^0_{298} = 1.78$ kJ mol^{-1} were determined. A series of displacing power of ions based on the Gibbs energy of the ion exchange was constructed. It correlates with the growth of ionic potentials.

(3) The "landing area" of strontium ions on the surface of iron–manganese nodules was estimated at 14.3×10^{-20} m^2. The value of 213 pm of the radius of the sorbed cation suggests the sorption in the Stern layer with partial dehydration.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation and Study of Properties of Sulfonic Acid Ion Exchangers Based on Polypropylene Fibrous Material

Abstract—The possibility of raising the static exchange capacity of strongly acidic ion-exchange materials produced by grafting of styrene onto polypropylene fibers, with the subsequent sulfonation of the products synthesized, was analyzed. The chemical and osmotic stabilities of the sulfonic cation exchangers obtained and their frost resistance in freeze–thaw cycles were studied.

DOI: 10.1134/S1070427206030074

Chemical modification of materials by grafting of compounds with various functional groups onto their surface can impart to them prescribed properties. Directed control over the thickness, structure, and nature of the grafted layer yields dense or loose, monomeric or polymeric, and mono- or polyfunctional grafted layers. The distribution of molecules in these layers may be statistically uniform, chaotically disordered, or of "islet" type. In each particular case, the most appropriate supports and modifiers should be selected by "successive approximations." The modifiers should contain functional groups imparting the above-mentioned special properties (complexing, hydrophobizing, ion-exchange, catalytic, etc.) to the target product. A functional group is commonly bound to the support surface by the so-called anchor and linker, groups that provide firm fixation of a functional group to the support surface (in the first case) and combine the anchor and functional group into a unit (in the second). Schematically, this structure can be represented as follows: support–anchor–linker–functional group. If compounds containing groups that can form chemical bonds directly with the support surface are used, the modification can be performed in one step. In other cases, it is necessary to carry out the process of modification of a material in a desired direction in steps (two or more), i.e., by the method of surface assembly, which makes it possible to construct complex molecular structures on the surface of a starting material [1–7].

The strong recent rise in the production of nonwoven fibrous materials (NFMs) is due to the simplicity of their manufacture and their efficiency in practical use [8, 9]. NFMs predominate over textiles among technical fibrous materials (FMs) and are more and more frequently used in medicine. Among the methods used to produce NFMs (adhesive-bonding, needle-punching, stitch-bonding, and spun-bonding), the most promising is the last one, whose characteristics provide, in the aggregate, the lowest production cost of the target product. One of the principal tendencies in the manufacture of NFMs is that toward replacement of natural fibers with those synthesized, with increasing share of polypropylene fibers (PPF). These fibers took a leading position, as regards the amount of consumption, as far back as mid-1980s. Polypropylene fibers are regarded as fibers with one of the best values for money because they have low density, high mechanical strength and abrasion resistance, easy fibrillation, etc.

The main application field of NFMs is manufacture of consumer goods and medicinal and technical materials (geotextile, separation, and membrane materials, technical filters for purification of dyes, spinning solvents, and oil-containing emulsions). For example, Remay materials manufactured by Du Pont, which are used to filter oils and air, have a service life 2.5 times that of paper materials and can be easily regenerated. In addition, they are readily corrugated to give cartridge filters because of their rigidity and elasticity. Filtering-protective materials manufactured by Rhône Poulenc and Reifenhäuser companies are made of polypropylene, by needle-punching in the first case and by thermal fixation in the second. Separation and membrane materials are also being manufactured by

Vilene (Japan, Vilene brand), Carl Freudenberg (Germany, Viledon brand), and Saft (France). These NFMs are produced from polypropylene and polyamide with a fiber diameter of 5–15 μm [10–16].

Ion-exchange fibers (IEF) and nonwoven materials on their base, which can be used to treat gas–air and liquid media to remove toxic admixtures, aerosols of acids and alkalis, ions of heavy metals, surfactants, and dyes, have a highly developed surface, good mechanical strength, and chemical and osmotic stabilities. The main advantages of IEFs over granulated ion exchangers in gas and water treatment are the high degree of purification and sorption rate; possibility of production of various textile forms (staple, threads, fabrics, and nonwoven needle-punched or stitch-bonded cloth), which makes wider the choice of apparatus that can be used; possibility of multiple use in sorption–desorption cycles; and low aero- and hydrodynamic resistances [17–19].

Previously, PPFs with surface-grafted compounds (SGCs) have been developed for use as ion exchangers [20–26]. Weakly acidic IEFs were synthesized by grafting of acrylic acid onto PPF, and strongly acidic ones, by sulfonation of styrene-grafted polypropylene fibrous materials. Styrene was grafted in a single step. Further, it was suggested to use the sulfonic cation exchangers obtained to recover metals from water [24, 25].

The aim of this study was to analyze the possibility of improving the capacity characteristics of the sulfonic cation exchangers developed by grafting styrene to PPF in two steps and to examine some properties of the IEFs synthesized. As objects of analysis were chosen such characteristics of IEFs as the chemical and osmotic stability (including the stability in moistening–drying cycles) and frost resistance in freeze–thaw cycles.

EXPERIMENTAL

The starting PPFs were thoroughly washed to remove contaminations and oxidized with atmospheric oxygen (110°C, 30 h) [20]. Styrene was grafted in the presence of initiating agents [benzoyl peroxide (BP) and azobisisobutyronitrile (AIBN)] and without initiators (method 1). After the reaction was complete, the material was washed to remove the possibly formed homopolymer. Then the grafted product was sulfonated with an excess amount of concentrated H_2SO_4 (80°C, 2 h) with preliminary keeping (25°C, 2 h) in 1,2-dichloroethane (DCE) or without it, washed with H_2SO_4 of decreasing concentration, treated with ethanol, and finally washed with distilled water. The washed fiber was dried and its static exchange capacity (SEC) was determined using the standard procedure by titration with an indicator [22].

Further selection of conditions for synthesis of IEF with improved capacity characteristics resulted in the development of a procedure for two-step grafting of styrene (method 2): in the first stage, the starting PPF was treated with styrene without initiator at an elevated temperature; in the second stage, synthesis was performed in ethanol in the presence of an initiator. The conditions under which SGCs were sulfonated and the SEC was determined were the same as those in method 1.

The chemical and osmotic stabilities of IEF (including that to multiple cycles of moistening–drying) and the frost resistance in freeze–thaw cycles were studied. To determine the chemical stability, IEF samples were treated with 5 N H_2SO_4, 1 N HNO_3, and 5 N NaOH solutions (100°C, 6 h). To study the osmotic stability, IEF samples were alternately treated (5 min) with 1 N solutions of HCl and NaOH (the so-called acid-alkaline shock, a total of 100 cycles) and also were subjected to moistening–drying cycles (a total of 30 cycles). In the last case, the materials were moistened with distilled water at 20°C for 5 min and dried in air at 60°C for 1 h. To determine the frost resistance, IEF samples were placed in closed vessels with water and were frozen at –20°C for 22 h and then thawed at 25°C for 2 h (a total of 30 freeze–thaw cycles). The stability of the materials studied to the above treatments was evaluated by changes in their SEC in the course of tests.

The results obtained in the study (Tables 1, 2) confirm some of the previously made assumptions [21, 22]. First, keeping of a grafted product in DCE leads to improved diffusion of the sulfonating agent into the PPF. As a result of swelling of PPF in DCE, the efficiency of sulfonation increases, with the SEC of the final IEF naturally increasing. Thus, it is worth mentioning that the sulfonation conditions affect (as also do the grafting conditions) the type of distribution of functional groups (SO_3H groups in the given case) across the fibrous material. For example, if the duration of sulfonation is decreased or the stage of PPF keeping with SGC in DCE is excluded from the process of manufacture of sulfonic cation exchangers, SO_3H groups are mostly distributed over the surface of a fibrous material even in the case of volume distribution of the grafted copolymer. Thus, researchers can preset the type of distribution of functional groups in a material by choosing conditions of both grafting

and sulfonation (volume or surface sulfonation) and, consequently, can predetermine the nature, rate, and other characteristics of the processes that occur in the subsequent use of the products synthesized. Second, if initiating agents are used to ensure that the graft copolymerization occurs not only under the action of peroxides formed in preliminary oxidation of PPF, but also via chain-transfer reactions, use of BP is somewhat more efficient than that of AIBN.

It can also be seen that performing a two-step grafting of styrene onto PPF makes it possible to reduce the concentration of styrene in the reaction mixture in the second step from 20 to 10 wt % without any decrease in the SEC of IEF (Tables 1, 2). Presumably, the grafting occurs in this case with a higher efficiency for the following reason. Already in the first step (impregnation), the interfiber space of NWM itself, interfibrillar space in separate "threads," and other supra-

* Sample numbering corresponds to that in Table 2.

molecular structures (in the core, sheath, and surface of fibers) of the starting PPF are saturated with styrene. At the same time, the second stage involves styrene grafting proper over the entire cross section of a fiber, both within inner voids filled with styrene and on the surface of PPF.

The data of Table 2 confirm that production of IEF by two-step grafting is more efficient than the one-step process (Table 1) and leads to an increase in the SEC of the materials synthesized. As already mentioned above, a bulk polystructure is formed, with styrene penetrating through the entire cross section and all macro- and micromorphological formations of the fibrous material in the impregnation step. Presumably, the subsequent synthesis leads to an increase in the amount of grafted copolymer products and, in the end, to a higher SEC of the sulfonic cation exchangers obtained. In addition, the specific features of the mechanism by which the grafting develops in each step are governed by its conditions and primarily by temperature and presence of initiators. For example, an increase in temperature leads to decomposition of the hydroperoxy groups of oxidized PPF [20], which initiates grafting of styrene to PPF. If initiators of radical copolymerization (BP and AIBN) are introduced into the reaction zone, they start to affect these processes by making an additional contribution to the grafting efficiency.

There is no escape from mentioning that the total duration of two-step grafting of styrene to PPF is shorter than that for the single-step grafting. For example, the duration of single-step grafting is 4 (AIBN) and 5 h (BP) (Table 1). Use of two-step techniques makes it possible to reduce the total duration of grafting to 3 h with AIBN and to 4 h with BP (Table 2). Presumably, this is due to the already mentioned intensification of the occurring reactions by preliminary impregnation of the starting PPF with styrene.

Table 3 lists the results obtained in a study of the chemical and osmotic stabilities and frost resistance of some samples of the IEFs obtained, specifically, the effect of these tests on the SEC of the materials.

Table 3 shows that the IEFs synthesized have a high stability against aggressive media (acids and alkalis), which is presumably due to the chemical stability of the polypropylene matrix and sulfo groups and to resistance to washing-out of the grafted copolymer.

The slight decrease in the static exchange capacity of IEF, observed in moistening–drying and freeze–thaw cycles, is presumably due to development of some structural defects in the material. The appearance, development, and accumulation of microcracks may lead to subsequent partial disintegration of an insignificant part of fibers and to their rupture, with the possible removal of a part of the grafted product and the corresponding decrease in the SEC of the material. More demonstrative in this case are frost resistance tests, during which the volume of the aqueous phase changes as a result of freezing and thawing of the samples (in water–ice–water transitions). The stresses generated in the process may lead to partial degradation of the material and to a decrease in its capacity characteristics.

The SEC of ion exchangers as a result of the tests mentioned above may also somewhat decrease because of a certain loosening of the polymeric matrix on keeping PPF with SGC in dichloroethane prior to sulfonation (Table 3, sample nos. 6 and 8). As it frequently occurs, the same treatment of the material (with DCE in the given case) may further have a positive or negative effect. However, choice of the optimal conditions for all the processes makes it possible to obtain, in the end, materials with the necessary prescribed set of properties.

The IEFs studied, which were subjected to multiple

moistening–drying and freeze–thaw cycles, on the whole retain their structure and service characteristics.

CONCLUSIONS

(1) Grafting of styrene to a polypropylene fiber in two steps, including preliminary impregnation of the starting fibrous material with styrene, leads to an increase in the static exchange capacity of sulfonic cation exchangers produced by sulfonation of grafted products.

(2) The sulfonic cation exchangers obtained show a high resistance to acids and alkalis. The slight decrease in their static exchange capacity upon multiple moistening–drying and freeze–thaw cycles is due to the development of certain defects in the materials; nevertheless, they on the whole retain their working characteristics (recovery of metals from water) at a level sufficient for their exploitation.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Molybdoarsenates Reduced by Ascorbic Acid with Polyurethane Foams Based on Ethers, Esters, and Their Copolymers

O. M. Trokhimenko

Shevchenko Kiev National University, Kiev, Ukraine

Received June 20, 2004; in final form, June 2005

Abstract—Sorption of molybdoarsenates reduced by ascorbic acid from aqueous solutions with polyurethane foams based on ethers, esters, and their copolymers was studied in relation to the phase weight ratio and solution acidity.

DOI: 10.1134/S1070427206030086

Preconcentration is required to determine the total content of arsenic or the content of its separate species in the environment by physicochemical methods at concentrations close to the maximum permissible concentration (MPC) [1].

At present, the most widespread extraction methods give way to sorption methods, which provide higher distribution coefficients of microcomponents without using toxic organic solvents [2].

Arsenic(V) as molybdoarsenate is recovered on activated carbon [3] or on membrane nitrocellulose filters in the presence of quaternary ammonium bases [4]. It was shown in [1] that molybdoarsenate is efficiently recovered on an Amberlyte XAD-8 polyacrylate sorbent, or on thin-layer cellulose triacetate filters in the presence of tri-*n*-octylamine. Since polyurethane foams contain ether and amino groups [5, 6], i.e., functional groups of organic solvents recovering heteropoly complexes, they sorb such complexes with phosphorus, silicon [7, 8], and arsenic [9] as central atoms.

There is substantial difference between solvents and sorbents from the practical viewpoint: solvents are individual chemical substances, whereas sorbents are materials. The sorption properties of materials can somewhat vary depending on producer or even from one batch to another [10]. Therefore, the analytical characteristics should be studied for the same batch. In addition, materials based on organic polymers can undergo aging under the action of light, moisture, and air depending on storage conditions.

In this study, we examined sorption of molybdoarsenate reduced with ascorbic acid (RMA) on polyurethane foams based on ethers (PUF-1), esters (PUF-3), and their copolymers (PUF-2). We cannot guarantee the complete repeatability of the results because of the reasons mentioned above. However, general features of the behavior of these sorbents with respect to RMA can be revealed.

EXPERIMENTAL

The stock solution of sodium hydroarsenate [chemically pure grade, 100 μg As(V) in 1 cm^3] was prepared by dissolving an accurately weighed portion of the compound. The other solutions were prepared by dilution of the stock solution. The RMA solutions were prepared in the presence of excess molybdenum(VI) and ascorbic acid [11] taking into account that preliminarily synthesized and isolated heteropoly complexes, when dissolved in water, undergo irreversible acid–base transformations with formation of products with central atom : ligand ratio equal to 1 : 12, 1 : 11, 1 : 9, etc.

Acetone (chemically pure grade) was used to desorb complexes from the PUF surface.

Polyurethane foams based on ethers, esters, and their copolymers of 5-30, 35-98 and ER trademark, respectively, produced by Radikal plant (Kiev) were cut into 3 × 3 × 3 mm cubes and washed with sulfuric acid, water, and acetone before use [8].

Electronic absorption and diffuse reflection spectra were recorded on a Specord M-40 spectrophotometer (Germany).

Sorption was measured in the static mode. A PUF sample [(0.050 – 0.500) ± 0.001 g] was introduced into a beaker with an RMA solution (25–500 cm^3). A PUF cube was pressed to a glass bottom with a spatula to

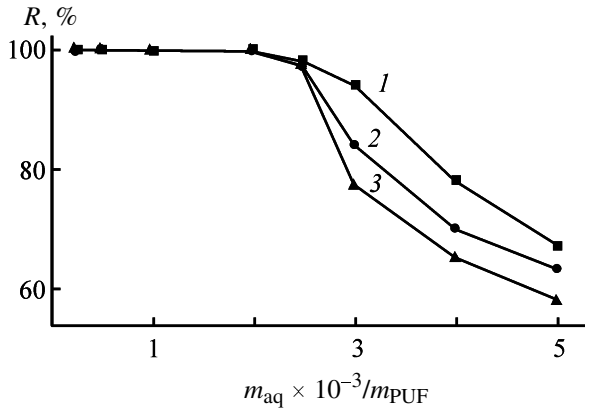

Fig. 1. Influence of phase weight ratio m_{aq}/m_{PUF} on degree of RMA sorption R. 40 μg of As(V), pH 1. Sorbent: (*1*) PUF-1, (*2*) PUF-2, and (*3*) PUF-3; the same for Figs. 2–4.

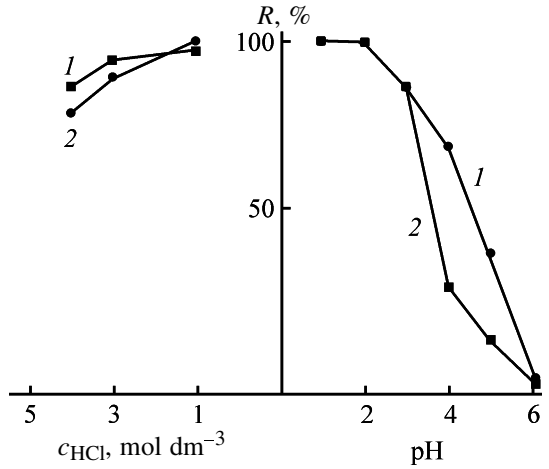

Fig. 2. Influence of solution acidity on the degree R of the recovery of RMA with various sorbents. $c_{As(V)} = 5 \times 10^{-5}$ mol dm^{-3}, $m_{aq}/m_{PUF} = 1000$. (c_{HCl}) HCl concentration.

remove air bubbles, and the solution was agitated with a magnetic stirrer to reach the sorption equilibrium. Then, PUF was separated from the solution, washed with distilled water, and dried between filter paper sheets and then in air. After that, the diffuse reflection spectrum of the sorbent with the sorbate and the absorption spectrum of the acetone desorbate were recorded. The effect of pH on RMA recovery was examined by adding a NaOH solution after complex formation under optimal conditions.

The preliminary experiments showed that the sorption equilibrium between RMA and the sorbent is attained in 10 (PUF-1), 15 (PUF-2), and 20 min (PUF-3).

The effect of the phase weight ratio m_{aq}/m_{PUF} on the RMA recovery was studied at a constant As(V) content. The recovery of the complex was quantitative at $m_{aq}/m_{PUF} < 2500$ (Fig. 1). At a further increase in this ratio, the degree of recovery gradually decreases due to less efficient contact between the sorbent and sorbate.

The state of the reduced heteropoly complexes in the solution depends on the absolute concentration of the central atom and the central atom : ligand ratio, on the type and concentration of the reductant, on pH, and on the solution ionic strength. Under the optimal conditions of formation, RMA is a reduced β-isomer of 12-molybdoarsenate with the formula β-$[AsMo_8^{VI}Mo_4^{V}O_{40}]^{7-}$ [12]. One of the main factors determining the state of the heteropoly complexes and hence their sorbability is the solution acidity.

The dependence of the degree of RMA recovery with polyurethane foams of various types on the solution acidity is shown in Fig. 2. As seen, the recovery of the complex is maximal at pH 0–2, which coincides with the pH range of its maximal extraction with oxygen-containing organic solvents (alcohols, ethers) [2]. In comparison with oxidized molybdoarsenate, RMA is sorbed within a wider pH range [9] due to higher stability with respect to acid and base hydrolysis. Within the entire range of acidity studied, the degree of RMA recovery with PUF-1 is somewhat larger than with PUF-3. This may be due to the fact that the ether groups form H bonds more readily than do ester groups [7, 13]. In addition, ethers are stronger electron donors than esters. This favors stronger donor–acceptor interactions of molybdenum atoms in RMA with oxygen atoms of PUF-1 polyether units. The decrease in the degree of RMA recovery from the acid solutions ($c_{HCl} > 2$ mol dm^{-3}) can be explained by the competition of Cl^- ions in anion-exchange binding of RMS and by partial decomposition of RMA with formation of molybdenum(V, VI) oxycations ($c_{HCl} >$ 4 mol dm^{-3}). A decrease in the recovery at pH 3–5 is caused by deprotonation of the sorbents (rather than by base hydrolysis of the sorbate), since RMA formed under optimal conditions is stable at pH increased to the above values.

Isotherms of RMA sorption are Langmuir-type isotherms (Fig. 3). The limiting sorption a_l and sorption constant K ($n = 5$, $P = 0.95$) calculated from them by the linear form of the Langmuir equation [14] are listed below:

PUF type	a_l, μmol g^{-1}	$K \times 10^{-6}$, dm^3 mol^{-1}
PUF-1	98	1.4
PUF-2	98	0.04
PUF-3	58	0.6

It is seen that a_l for PUF-1 and PUF-2 is actually

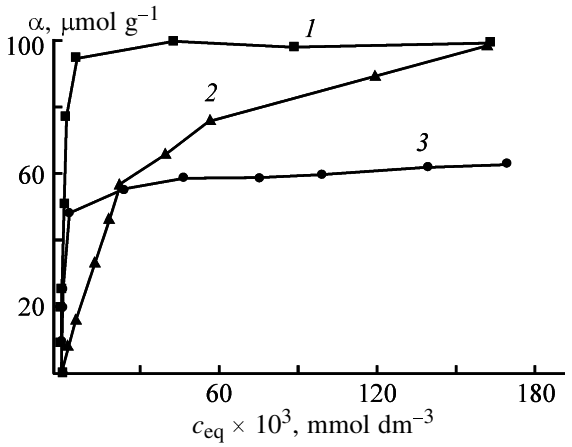

Fig. 3. Sorption isotherms of RMA. m_{aq}/m_{PUF} = 500, T = 293 K. (c_{eq}) RMA equilibrium concentration in aqueous solution and (α) concentration of RMA on PUF.

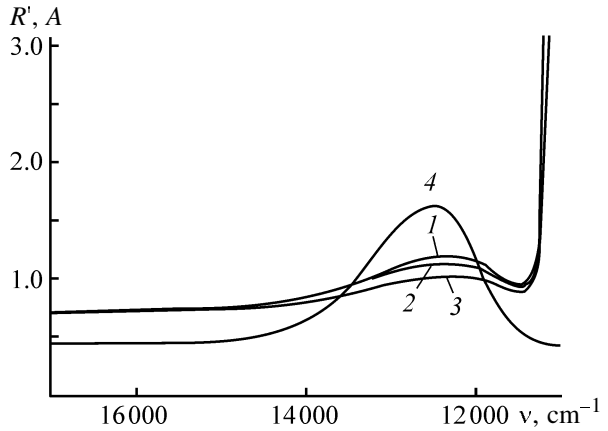

Fig. 4. Diffuse reflection spectra of RMA sorbed on the surface of (*1*) PUF-1, (*2*) PUF-2, and (*3*) PUF-3, and (*4*) its absorption spectrum in aqueous solution. m_{aq}/m_{PUF} = 500; 40 μg of As(V); Specord M-40. (*1–3*) (R') Diffuse reflection, (*4*) (A) optical density, and (ν) wavenumber.

the same, and for PUF-3 it is by a factor 2 lower. The sorption constant K decreases in the order PUF-1 > PUF-3 > PUF-2.

The state of RMA in the polyurethane foam phase was studied by diffuse reflection spectroscopy. The diffuse reflection spectra of RMA sorbed on various types of polyurethane foams and absorption spectrum of RMA aqueous solution are shown in Fig. 4. The band at 13500 cm^{-1} of the latter (Fig. 4, spectrum *4*) transforms into a shoulder, and a new band at ν < 11000 cm^{-1} (Fig. 4, spectra *1–3*) appears when RMA is sorbed on polyurethane foam. Bands within the 16500–12500 cm^{-1} range originate from charge transfer between Mo(V) and Mo(VI). A change in the energy of charge transfer of the complex sorbed on the polyurethane foam surface is indicative of a change in the energy of heteropolyanion molecular orbitals, which, in turn, suggests strong interaction (probably, through H bond) between RMA and the polymeric matrix. RMA is quantitatively recovered with acetone and other oxygen-containing solvents; λ_{max} of desorbates actually coincides with λ_{max} of RMA in aqueous solution.

CONCLUSIONS

(1) Comparative study showed that PUF-1 has higher sorption power with respect to molybdoarsenate reduced with ascorbic acid. This is also characteristic for heteropoly complexes with other central atoms (P, Si).

(2) The recovery of reduced molybdoarsenate by sorption on polyurethane foams is maximal at pH 0–2, and the concentration coefficient is 2.5×10^3.

(3) Isotherms of sorption of reduced molybdoarsenate are Langmuir-type isotherms. The sorption constants decrease in the order PUF-1 > PUF-3 > PUF-3.

SORPTION AND ION-EXCHANGE PROCESSES

Physicochemical and Rheological Properties of Thickeners Produced from Tunisian Clays[1]

M. Chtourou, M. Trabelsi, S. Baklouti, and M. Hedi Frikha

Laboratory of Applied Chemistry, Sfax, Tunisia
Laboratory of Industrial Chemistry, Sfax, Tunisia

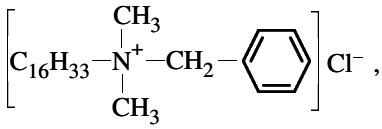
Received October 19, 2004

Abstract—Modification of two samples of Tunisian clays of the type of natural smectites with organic derivatives of ammonium salts was studied. The physicochemical properties of the modified products and the possibility of their use as components of lubricating oils were analyzed.

DOI: 10.1134/S1070427206030098

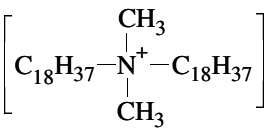
Natural clays find increasingly wide use. Their application fields include manufacture of ceramics, paints, printing inks, and lubricants [1–3]. Use of natural clays makes it possible not only to reduce the cost of articles, but also to impart to them plasticity and mechanical strength. These properties of clay are associated with the nature and structure of aluminosilicates. Because of their structure, clays can swell in polar solvents, e.g., water. However, they fail to do so in nonpolar solvents and do not acquire new rheological properties [4]. To use clays as thickeners in organic systems, natural hydrophilic materials should be modified by introduction of organic cations. The most widely used of these are cations of salts of quaternary ammonium bases, which contain at least one hydrocarbon chain with 12 to 18 carbon atoms [5–7]. It is the cation exchange of these ions for inorganic ions present on the surface of clay particles that imparts organophilic properties to the clay.

The thus modified organophilic clays are widely used as thickeners in manufacture of paints, printing inks, and lubricants [3, 4]. Introduction of modified clays into lubricants (e.g., into lubricating grease) can change their viscosity, make them pseudoplastic [3], and improve their mechanical properties and stability at elevated temperatures [1, 5–8].



The clays best suitable for modification with organic cations belong to smectites (montmorillonites): bentonite, hectorite, beidellite, stevensite, etc. [8]. These clays have a static exchange capacity (SEC) for cations of no less than 70 mmol-equiv per 100 g [1].

[1] This article was submitted by the authors in English.



Tunisian clays are widely used in manufacture of ceramic articles [9], but still find use neither in the paint-and-varnish industry, nor in production of lubricants. Here we consider clays suitable for modification with organic cations to enable their use as thickeners. Their physicochemical and rheological properties are studied in comparison with Bentones widely used in the industry. This study is a part of research work devoted to assessment of Tunisian clays.

EXPERIMENTAL

Two clay samples taken in southern Tunisia were chosen for the study. The raw samples were designated as B_{1r} and B_{2r}. The samples were modified with organic cations, using the following ammonium salts (Aldrich): dimethylbenzylhexadecylammonium chloride [BDMHA]Cl and dimethyldioctadecylammonium chloride [DMDOA]Cl:

[BDMHA]Cl

[DMDOA]Cl

The properties of the modified clays were compared with those of industrially modified clay Bentone 34 (RHEOX, Brussels, Belgium). The SEC of the clay samples was determined in the reaction with

bis(ethylenediamine)copper(II) sulfate prepared from copper(II) sulfate and ethylenediamine (both purchased from Aldrich).

The results obtained in a chemical analysis of the clays by the X-ray fluorescence technique are listed in Table 1; the clays studied contain a comparatively small amount of aluminum oxide (9–15 wt %) and are rich in silicon dioxide (40–50 wt %). It should be noted that presence of quartz in a clay impairs its plasticity. The calcination loss by the B_{1r} sample may reach 23%. So large values of the calcination loss are probably observed because of the presence of simple and(or) double carbonates and organic impurities in the clays.

The density ρ of the samples was determined by pycnometry. The specific surface area of the clays under study, S_{sp}, was found by BET on a Flow Sorb II 2300 instrument. The results of these measurements are listed in Table 2.

According to the results obtained, both the clays, B_{1r} and B_{2r}, have a density very close to that of pure montmorillonite (2.0 to 2.4 g cm^{-1}) and a large specific surface area. The value of S_{sp} for sample B_{2r} exceeds that for B_{1r}. Granulometric analysis of the clays (Fig. 1) shows that the constituent particles vary in size from 0.32 to 4.70 μm. However, most of clay particles have sizes falling within a very narrow range 0.32–1.00 μm. The particle sizes of sample B_{2r} are somewhat smaller compared to B_{1r}.

To determine the static exchange capacity of samples B_{1r} and B_{2r}, they were purified to remove mechanical impurities, sieved (~20 μm mesh), and converted into a form saturated with sodium cations. The SEC values of the clay samples were determined by the adsorption of the $[Cu(NH_2CH_2CH_2NH_2)_2]^{2+}$ cation [10]. This cation is highly selective toward clays and forms with them stable compounds [11]. In cation exchange, it can replace in clays most of other cations and even those of heavy metals [12].

In the experiments, 0.3-g samples of purified clays were treated in a 50-ml flask with a $[Cu(NH_2CH_2 \cdot CH_2NH_2)_2]SO_4$ solution of concentration 1.66×10^{-2} M, after which the pH value of the resulting mixture was measured. The adsorption equilibrium was attained in the system in 30 min, and then the mixture was separated by centrifugation. The content of the $[Cu(NH_2CH_2CH_2NH_2)_2]^{2+}$ cation in the supernatant was determined on a spectrophotometer from the absorption in the visible spectral range (550 nm). The SEC of the clays was determined from the difference between the added amount of the Cu(II) complex and that remaining in solution.

Table 1. Chemical composition of the starting clays

Composition	B_{1r}	B_{2r}
SiO_2	40.78	50.87
Al_2O_3	9.2	14.92
MgO	15.9	9.82
Fe_2O_3	2.06	1.36
CaO	5.51	3.28
K_2O	1.98	0.45
Na_2O	2.02	1.86
Calcination loss	22.92	17.37

Table 2. Density ρ and specific surface area S_{sp} of the starting clays

Clay	ρ, g cm^{-3}	S_{sp}, m^2 g^{-1}
B_{1r}	2.34	68.11
B_{2r}	236.0	110.52

Kinetic experiments on exchange of inorganic cations of the clays for organic ammonium cations were carried out by the method that is, in principle, similar to that used to determine the SEC for $[Cu(NH_2CH_2 \cdot CH_2NH_2)_2]^{2+}$. A suspension was prepared from a preliminarily purified clay taken in an amount of 2 wt % relative to the liquid phase (90 vol % H_2O + 10 vol % ethanol). The suspension was placed in a reactor with a reflux condenser and stirrer and was gradually heated to 80°C. After that, a solution of a quaternary ammonium salt (QAS) was added to the suspension. The presence of ethanol in the mixture facilitated dissolution of QAS. The suspension was sampled at regular intervals of time, the samples were separated

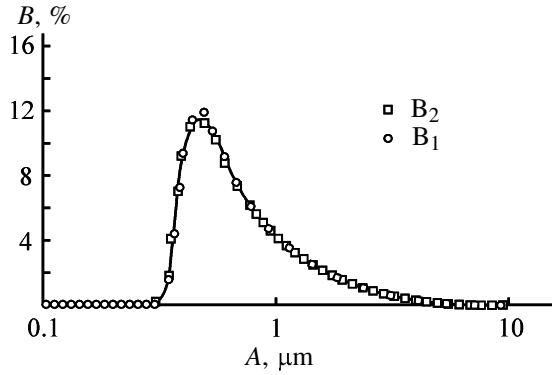


Fig. 1. Rersults of a granulometric analysis of the starting clays. (*B*) Content and (*A*) size of particles.

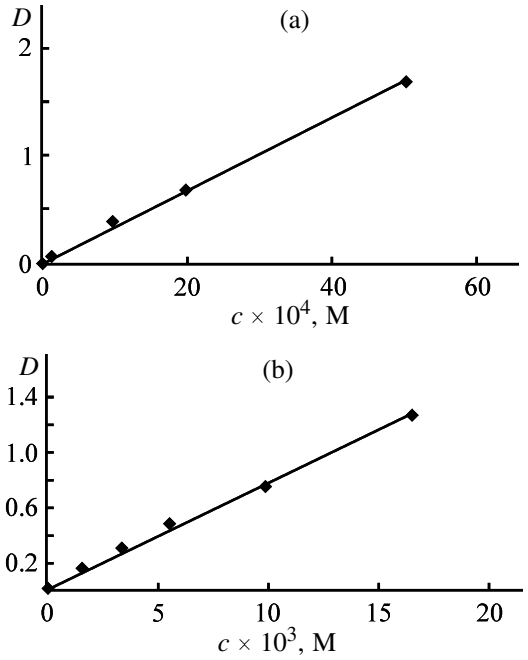

Fig. 2. Calibration plot for UV spectrophotometric determination of the concentration c of (a) $[BDMHA]^+$ and (b) $[Cu(NH_2CH_2CH_2NH_2)_2]^{2+}$ in solution. (D) Optical density. Wavelength λ, nm: (a) 262.5 and (b) 550.

by centrifugation, and the content of QAS was determined in the aqueous-alcoholic phase by two methods: UV spectroscopy and titration. In this way, the running concentration of QAS and the instant of time at which the reaction was complete were determined.

The UV spectroscopic studies of solutions were performed on a Shimadzu UV 2100 spectrophotometer. This method was used to study the kinetics of ion exchange between cations of clays B_{1r} and B_{2r} and the $[BDMHA]^+$ cation, because $[DMDOA]^+$ absorbs neither in the UV nor in the visible spectral range. The calibration plot used to determine the concentration of $[BDMHA]^+$ by UV spectroscopy is shown in Fig. 2a.

The titrimetric determination of the content of $[DMDOA]^+$ was performed by precipitation with a $NaB(C_6H_5)_4$ solution in the presence of Methyl Orange as indicator, in accordance with published recommendations [13].

Table 3. Static exchange capacity of the raw (r) and purified (p) clays

Clay	pH of suspension	Maximum absorbed amount, mmol per 100 g of clay	SEC, mmol-equiv per 100 g of clay
B_{1r}	10.04	32.24	64.48
B_{1p}	10.26	37.80	75.60
B_{2r}	10.26	42.53	85.06
B_{2p}	10.55	49.83	99.66

The IR spectra of modified clays were measured on a JASCO FT-IR 420 instrument. The X-ray phase analysis of the samples was made on a Philips PW 3710 instrument (CuK_α radiation).

The density of the samples was measured on a Helium Accu Pyc V_2 0.3N device.

To determine the rheological properties of the modified clays, the samples were ground in a Fritsch Pulverizer laboratory planetary mill and dispersed with ultrasound in a toluene–ethanol mixture. The resulting suspensions-gels were studied on a Reologica Instruments AB device with a C 40 4 measuring unit.

The composition of the suspensions being analyzed was, in accordance with the recommendations [3, 14], the following (wt %): modified clay 10, ethanol 10, toluene 80.

The static exchange capacity of the clays is the most important factor that predetermined their ability to be modified with organic cations. Clays with higher SEC more strongly swell in organic solvents and, as shown below, have better rheological properties. Figure 2a shows the calibration plot for determining the concentration of $[Cu(NH_2CH_2CH_2NH_2)_2]^{2+}$ ions in solution that is in contact with a clay. The results obtained in determining the SEC of the clays for the bis(ethylenediamine) complex of copper(II) are listed in Table 3. It can be seen that the $[Cu(NH_2CH_2CH_2 \cdot NH_2)_2]^{2+}$ cation is sorbed on the surface of the raw and purified samples of B_1 clays (B_{1r} and B_{1p}, respectively) less effectively than in the case of B_{2r} and B_{2p} samples. For both B_{1p} and B_{2p} samples, the SEC exceeds 70 mmol-equiv per 100 g of clay, which confirms that both the samples are rich in smectite (montmorillonite). Table 3 also shows that purification of clays enhances the adsorption of copper(II). In this case, the SEC increases by approximately 17%. This increase can be attributed to removal of impurities, free quartz and soluble mineral salts, from the clays in the course of their purification.

As follows from Fig. 3a, the rate of cation exchange between clay samples B_{1p} and B_{2p} and the $[BDMHA]^+$ cation is very high. In fact, the degree of replacement of the inorganic cation by the organic cation in 20 min is 90 and 50% for B_{1p} and B_{2p} samples, respectively. That is, the clays exhibit high affinity for organic cations. This primarily refers to B_{1p} sample. The cation exchange leading to modification

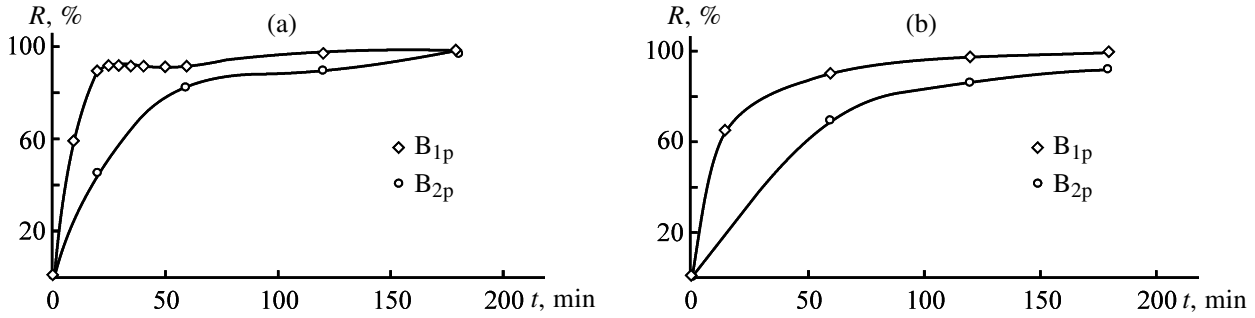

Fig. 3. Degree R of ion exchange with (a) $[BDMHA]^+$ and (b) $[DMDOA]^+$ cation for clays B_{1p} and B_{2p} vs. the time t of contact.

of clay samples with organic ammonium cations is complete in 1 h.

The kinetics of cation exchange between B_{1p} and B_{2p} samples and the $[DMDOA]^+$ cation can be judged from the data in Fig. 3b. Comparison of Figs. 3a and 3b shows that the rate of clay modification with $[BDMHA]^+$ cations is higher than that in the case of the $[DMDOA]^+$ cation. This can be attributed to structural differences between these ions. The $[DMDOA]^+$ cation contains two long hydrocarbon chains C_{18}. According to published data [15], the cation exchange in clays is the fastest when the organic cation contains aromatic groups capable of π-electron interaction with the surface centers of the material. For both the samples, the reaction of their modification with the $[DMDOA]^+$ cation is complete in 3 h.

According to Fig. 3, the saturation of the clays with organic ammonium cations on reaching the above values of SEC corresponds to replacement of approximately 96% of mineral cations with organic cations. Such an exchange makes it possible to raise the degree of hydrophobicity of a clay [16] and its compatibility with organic solvents.

Clays B_{1p} and B_{2p} modified with the organic cations $[BDMHA]^+$ and $[DMDOA]^+$ are designated in what follows as B_1H, B_2H, B_1D, and B_2D, respectively. These clays, obtained under preliminarily determined optimal conditions (time of contact between phases, solution temperature, concentration of an ammonium salt, SEC), were isolated by filtration. Then, they were several times washed on a filter with water and dried at 80–90°C. The products obtained were analyzed by various methods and compared with a commercial sample of Bentone 34.

The IR spectra of modified samples, compared to the raw samples, contain additional peaks (Fig. 4): one at 2851 cm^{-1} and another at about 2920 cm^{-1}. Both these peaks correspond to absorption by aliphatic CH_2 groups of the hydrocarbon chains of the modi-

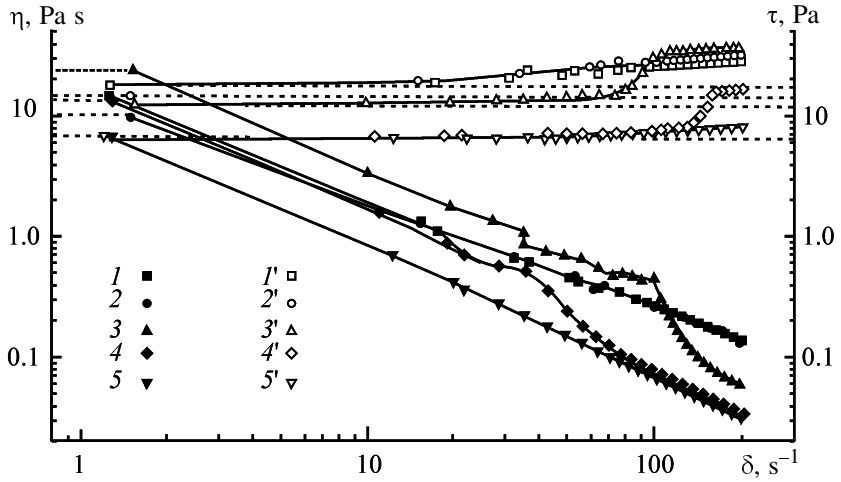

Fig. 5. Rheological characteristics of suspensions of modified clays (η) Dynamic viscosity, (τ) shear stress, and (δ) shear rate. Clay sample: (*1, 1'*) B_{34}, (*2, 2'*) B_2D, (*3, 3'*) B_2H, (*4, 4'*) B_1H, and (*5, 5'*) B_1D. (*1–5*) η and (*1'–5'*) τ.

fying cations [17–19], which confirms that organic cations are present in the clays. The same conclusion can be made on comparing the IR spectra of modified clays with that of Bentone 34.

The results obtained in studying the modified clays by X-ray phase analysis (Table 4) show that the interplanar spacings d_{001} are larger than those in the raw samples. Such an increase would be expected to occur upon intercalation of organic molecules between clay layers [20]. The magnitude of this increase probably corresponds to a monolayer arrangement of adsorbed organic particles [15, 21]. Modified clays, and especially B_1D and B_2D, have interplanar spacings comparable with those of Bentone 34, which is confirmed by their excellent properties in organic media (lubricants and solvents).

The results obtained in determining the densities of the modified clays are listed in Table 4. With the exception of sample B_1H, all other samples had densities close to that of Bentone 34. Comparison of these results with the densities of samples B_{1r} and B_{2r} (Table 1) shows that the density of modified clays decreases upon adsorption of organic cations on those parts of clays which are capable of ion exchange. This conclusion is in agreement with the authors' results that the interplanar spacings in clays increase because of the incorporation of bulky organic cations into their structure.

Table 4. Interplanar spacings *d* of the raw clays and those modified with organic cations and densities ρ of modified clays

Clay	d_{001}	ρ, g cm^{-3}
Raw:		
B_{1r}	15.0	–
B_{2r}	14.6	–
Modified:		
B_1H	17.6	2.002
B_2H	17.3	1.810
B_1D	19.5	1.736
B_2D	19.4	1.717
B_{34}	20.1	1.696

The rheological properties of organic suspensions of the modified clays B_1H, B_2H, B_1D, and B_2D in a toluene–ethanol mixture were compared with those of a suspension of Bentone 34, prepared under the same conditions. Figure 5 shows how the dynamic viscosity η and shear stress τ vary with the shear rate δ for the organic suspensions prepared. All of these are pseudoplastic fluids [15, 22] with dynamic stress values similar to those observed for aqueous suspensions of clays of medium concentration [23]. Such a behavior of the suspension may be associated not only with the formation of a gel of modified clay particles in an organic solvent [16, 24], caused by interparticle interactions, but also with the morphology of clay particles.

The apparent shear stresses (τ_a) for B_1H and B_1D samples (6.85 and 6.59 Pa), on the one hand, and for B_2H and B_2D (13.9 and 14.5 Pa), on the other, are virtually the same. The modified clays B_2D and B_2H are close in τ_a to Bentone 34 sample (18.0 Pa).

The results obtained demonstrate that the nature of a raw clay, morphology and size of its particles, and their specific surface area strongly affect τ_a [15],

depending on an organic ammonium cation adsorbed. This is confirmed by comparison of the specific surface area of the raw clay (Table 1) with its granulometric distribution (Fig. 3). According to published data [25], the area of the solid/liquid phase boundary increases as the particle size becomes smaller, and this makes stronger the interaction between the particles. As a result, the magnitude of the apparent shear stress τ_a increases.

With the exception of sample B_1D, all the other modified clay samples had a viscosity at a very low shear rate, η_{max}, that was comparable with, or exceeded the viscosity of the Bentone 34 suspension. This property is highly important for use of modified clays as thickeners in organic media [3]. The values of η_{max} of B_1H and B_2H clays (modified with the $[BDMHA]^+$ cation) exceeded those for B_1D and B_2D clays (modified with the $[DMDOA]^+$ cation). This phenomenon can be attributed to the specific configuration of adsorbed organic cations in solvents of the alkylbenzene type. The aromatic ring contained in the $[DMDOA]^+$ cation favors gelation [25]. An increase in the mechanical strength of a gel leads to a rise in its dynamic viscosity.

According to the results of this study, modified clays produced from material B_2 have rheological properties, η_{max} and τ_a, satisfactory for their use as thickeners in organic media.

CONCLUSIONS

(1) A study of the modification kinetics of two samples of Tunisian clay demonstrated that their treatment at 80°C with dimethyldioctadecylammonium chloride for 3 h or dimethylhexadecylbenzylammonium chloride for 1 h leads to incorporation of organic ammonium cations into the clay structure. This yields a high SEC for each clay sample and for each modifying cation.

(2) The study of the modified clays revealed their similarity, as regards the physicochemical properties, to products commercially manufactured in Europe, which enables their use as thickeners for lubricants.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Features of Impregnation of Nickel Metal–Ceramic Porous Supports for Electrodes of Alkaline Batteries

A. A. Bachaev and T. E. Kuzina

Received November 10, 2005

Abstract—The features of nickel oxidation in impregnation of nickel metal–ceramic porous supports for electrodes of alkaline batteries, which ensure their fabrication in a shorter time, were determined.

DOI: 10.1134/S1070427206030104

Nickel oxide electrodes (NOE) on a nickel metal–ceramic (MC) porous support have high specific characteristics and can be used in a wide range of current densities and temperatures. At the same time, their fabrication is a long power- and labor-consuming process consisting of a number of successive stages [1]. The time and a large number of multicycle stages in fabricating such electrodes are mainly caused by the fact that impregnating porous MC supports in a solution of nickel salts requires long time. The pores of the electrode are filled with a solution of nickel salts in the course of impregnation and then serve for the formation of an active substance. Filling pores takes 5–7% of the impregnation time [2]. The duration of the process is determined by the time necessary for obtaining the active substance by electrochemical oxidation of nickel from the support [3].

Reduction of the impregnation time in fabricating MC NOE should diminish the power consumption and increase the intensity of the process, which is an urgent and practically important problem.

In this study we elucidated the features of nickel oxidation under the impregnation conditions and chose on their basis the routes for reducing the time of fabricating MC NOE.

EXPERIMENTAL

The parameters of nickel etching were determined by analyzing two types of the electrochemical systems: Ni|$Ni(NO_3)_2$|Ni (I) and Pt|$Ni(NO_3)_2$|Ni (II) [4]. The polarization curves of the models studied were obtained in the galvanostatic mode. The progress of nickel oxidation was monitored by the values of the electrode polarizations. In studying the models, we used N0 nickel foil (nickel content 99.9%) and a 30 × 16 × 1-mm smooth platinum plate.

The phase composition of the oxidation products was determined by the X-ray diffraction analysis as in [4]. The densities of the deposit formed on platinum were calculated using the expression for the mass of the unit cell. To do this, the unit cell volume was identified with a crystal lattice constant estimated graphically by the method described in [5].

To test the performance of the system Ni|solution|NiO_x ($x > 1$), a NiO_x ($x > 1$) film was preliminarily deposited on platinum by the procedure described in [6].

The electrodes were fabricated on $30 \times 10 \times 1.6$-mm MC nickel supports with a bulk porosity of 70–75%. Nickel(II) hydroxide in the pores of the MC supports was obtained by the process described in [7, 8]. For impregnation we used $Ni(NO_3)_2$ and $NiSO_4$ solutions.

We analyzed the polarization curves obtained in system I (Fig. 1a) and used the results of the graphical analysis to determine the parameters of the nickel dissolution: the compromise nickel potential was found to be 0.00 V and the current density of the dissolution, 13×10^{-3} mA cm^{-2}. The results obtained in calculating the polarizability of the cathodic and anodic processes showed that nickel is oxidized with a cathodic control. The degree of cathodic control C_c is 75%.

Thus, the oxidation rate of nickel in impregnation of an MC support is determined by the hindrance of the cathodic process. However, studying it on nickel is rather complicated, because the Ni potential established in the system studied is a compromise rather than an equilibrium value. Therefore, it was suggested

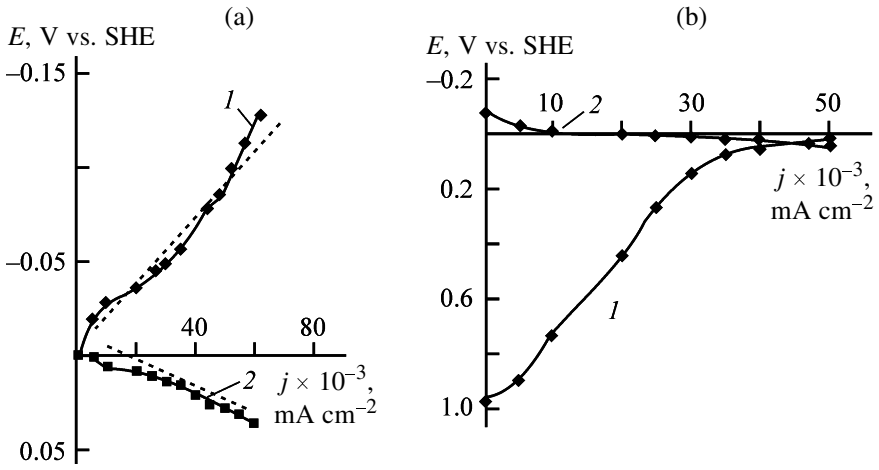

Fig. 1. Diagrams of nickel oxidation, obtained in a $Ni(NO_3)_2$ solution in the systems (a) Ni–Ni and (b) Ni–Pt. T = 80°C, $c_{Ni(NO_3)_2}$ = 950 g l^{-1}, pH 3; the same for Fig. 2. (*E*) Potential and (*j*) current density; the same for Figs. 2 and 3. Curves: (*1*) cathodic and (*2*) anodic.

to study the cathodic processes on a platinum electrode, which allows determination of the potential of a redox system and makes it possible to start a study from this potential. The graphical analysis of the results obtained for system II with a platinum cathode (Fig. 1b) shows that in this case nickel is also oxidized with a cathodic control (degree of cathodic control 92%). The values of the compromise potentials are approximately the same, E_{st} = 0.0 V, which indicates that the model suggested is qualitatively adequate and platinum can be used for studying cathodic processes.

It was shown previously [7] that in a $Ni(NO_3)_2$ solution the rate of reduction of nitrate ions on platinum is limited by their diffusion toward the electrode surface.

When system II, $Ni|Ni(NO_3)_2|Pt$, works under the short-circuit conditions, there occurs a fast decrease in the cathodic current with time. Because nickel is oxidized with a cathodic control, a decrease in the current density is due to the formation of a film of basic nickel compounds on the Pt surface. This film is formed when the pH of the near-electrode layer increases to 7.5 owing to the reduction of the oxidizing agent. According to the X-ray diffraction data, the films formed on Pt have the composition $Ni(NO_3)_2 \cdot Ni(OH)_2$ [4]. The resulting film of basic nickel compounds impedes the diffusion of the oxidizing agent toward the electrode surface. The rate of nickel oxidation in the presence of films on the platinum surface is determined by permeability of the film with respect to the oxidizing agent. Chloride ions are known to exhibit a strong depassivation effect [9].

Addition of $NiCl_2$ into the $Ni(NO_3)_2$ solution (concentration of Cl^- ions 193 g l^{-1}) changed the structure and composition of the above film. According to the X-ray structural analysis, the film formed on Pt at a volume ratio of $Ni(NO_3)_2$ and $NiCl_2$ solutions of 1 : 1 has the chemical composition $Ni(NO_3)_2 \cdot NiCl_2 \cdot Ni(OH)_2$ [4]. The film formed from a solution mixture has a density of 0.93 g cm^{-3}, and that formed from a $Ni(NO_3)_2$ solution, 1.45 g cm^{-3}. Thus, upon impregnation with the first film, the oxidation rate of nickel contained in the MC support is higher.

Examination of the influence of chloride ions showed that the properties of the film formed under the cathodic conditions govern the efficiency of nickel oxidation upon impregnation. The formed film decreases the rate of the process and simultaneously serves as target product, i.e., its growing is necessary for obtaining a large amount of an active substance [8]. In this case, the rate of nickel oxidation can be increased either by eliminating the concentration hindrance or by increasing the oxidizing power of the solution, or by transforming the obtained film into the oxidizing agent.

According to the data of [7], the introduction of 10 g l^{-1} $NaNO_2$ into a $Ni(NO_3)_2$ solution increases its oxidizing power. The $Ni(NO_3)_2$ solution contains, apart from the main oxidizing agent (nitrate ions), other nitrogen compounds having oxidative properties [10]. Therefore, the type of an oxidizing agent in the $Ni(NO_3)_2$ solution was identified by the chronovoltammetric method at a potential sweep rate of 100 mV s^{-1}.

The potentiodynamic curve obtained on Pt in a

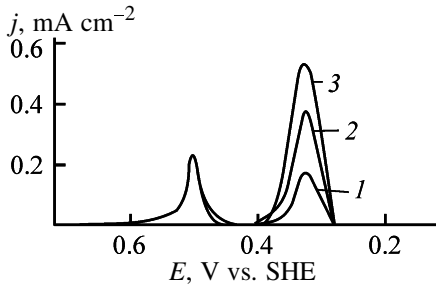

Fig. 2. Chronovoltammograms obtained on Pt in a $Ni(NO_3)_2$ solution (*1*) without additive, (*2*) with 10 g l^{-1} $NaNO_2$, and (*3*) purged with NO_2. V_p = 100 mV s^{-1}.

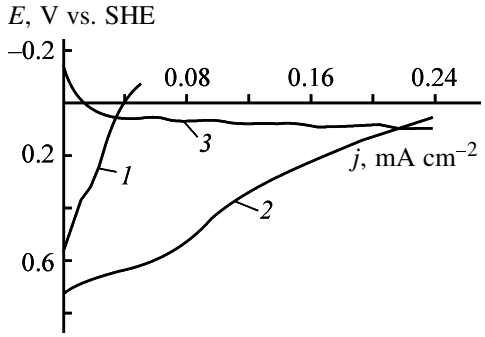

Fig. 3. Diagrams of nickel oxidation obtained in a $NiSO_4$ solution in the system Ni–Pt. $c_{Ni(II)}$ = 200 g l^{-1}, pH 2, T = 80°C. Curves: (*1, 2*) cathodic taken on (*1*) Pt and (*2*) Pt|NiOOH; (*3*) anodic taken on Ni.

$Ni(NO_3)_2$ solution shows at potentials of 0.35–0.1 V two peaks of the limiting current density (Fig. 2). Based on the data of [8, 10], the first peak was associated with reduction of HNO_3 to HNO_2. The latter substance disproportionates in an acid medium at high temperature to give a mixture $2NO_2 \rightleftarrows N_2O_4$ [11], whose components undergo reduction, which is reflected in the presence of the second peak on the curve. The occurrence of this successive transformation is confirmed by the fact that the introduction of sodium nitrite into a $Ni(NO_3)_2$ solution increases by a factor of 4 the current density of the second peak (Fig. 2). Purging a $Ni(NO_3)_2$ solution with NO_2 resulted in a further increase in the current density of the second peak (Fig. 2). All these facts confirm the suggestion that not only NO_3^- ions are responsible for the oxidation of Ni from the MC supports in a $Ni(NO_3)_2$ solution; the main oxidant is the $2NO_2 \rightleftarrows N_2O_4$ mixture.

Thus, to increase the oxidizing power of a $Ni(NO_3)_2$ solution, it is appropriate to introduce nitrites. Their disproportionation should favor the formation of a larger amount of the oxidant, i.e., $2NO_2 \rightleftarrows N_2O_4$ mixture, in the solution. The film formed in a $Ni(NO_3)_2$ solution with $NaNO_2$ added has the composition $Ni(NO_3)_2 \cdot Ni(OH)_2 \cdot NiO_x$ ($x > 1$) [4]. These films are looser than those formed in a $Ni(NO_3)_2$ solution, and, which is the most important, they contain NiO_x ($x > 1$), directly contacting nickel of the support and promoting the nickel oxidation [7].

The fact that the transformation of the film of basic nickel compounds formed on cathodic areas into NiO_x ($x > 1$) increases the oxidation rate of nickel of the porous MC supports [7] is also associated with the change in the composition and structure of the deposit. The time of impregnation of MC supports in the composition suggested decreased to 5 h, whereas in the case of the traditional process, the necessary amount of the active substance in an MC support is accumulated only after 18 h of impregnation in a $Ni(NO_3)_2$ solution. The active substance obtained in pores of MC supports is sufficiently active for operation in an alkaline battery, as indicated by its utilization factor [7].

To confirm the performance of the system Ni|solution|NiO_x ($x > 1$), we studied the similar system in which higher nickel oxides were formed without participation of nitrogen-containing compounds. As oxidant we chose $KMnO_4$, whose oxidative power is comparable with that of a $2NO_2 \rightleftarrows N_2O_4$ mixture. In operation of this system, the rate of nickel dissolution in a $NiSO_4$ solution increased by a factor of 5–6 (Fig. 3), with the control type preserved (C_c = 83%).

Thus, the system Ni|$NiSO_4$|NiO_x ($x > 1$), wherein higher nickel oxides are formed without participation of nitrogen-containing compounds, efficiently operates both in the subsequent impregnation cycles and, probably, in an alkali solution.

The results obtained suggest that the composition of the solution for treatment of the MC supports is as follows: a KOH solution (density 1.22 g cm^{-3}) with a 1% $KMnO_4$ additive. The process temperature is 70–80°C and time, 1 h. The electrodes are treated with a KOH solution containing 1% $KMnO_4$ only in the first cycle. The results showed that the treatment of the electrodes in all the subsequent cycles decreases the coefficient of utilization of the active substance.

When the KOH solution containing $KMnO_4$ is used for treatment, nickel of the MC support is actively oxidized, probably even in an alkali, with the formation of $Ni(OH)_2$ and NiO_x ($x > 1$), which is not the case of the traditional «sulfate» technology [8].

Upon the treatment in a KOH solution containing 1% $KMnO_4$, the basic nickel salts formed in pores of the MC support upon their impregnation in a $NiSO_4$ solution were oxidized. The resulting higher nickel oxides increased twofold the oxidation rate of nickel

contained in the MC supports in the subsequent impregnation cycles. The intermediate oxidation of basic nickel compounds present in pores of the MC supports with a KOH solution containing 1% $KMnO_4$, performed in the first cycle, makes it possible to fabricate the electrodes with a specific capacity of 0.3 A h cm^{-3} after five impregnation cycles.

The total time of fabrication of MC NOE by the method suggested was 18–20 h, which is approximately four times shorter than that of MC NOE fabrication by the traditional sulfate process.

CONCLUSIONS

(1) The revealed features of nickel oxidation in the impregnation of a metal–ceramic support allowed the etching rate to be decreased by a factor of 3–6 and the time of impregnation of nickel oxide electrodes on a metal–ceramic support, to 18–20 h instead of 50–80 h in the traditional processes (depending on solution composition).

(2) The capacity of pilot electrodes is the same as that of electrodes fabricated by the impregnation process applied in the practice.

Abstract—The yield of carbonyl compounds in treatment of river water and model solutions of humic acid as a function of the ozone uptake and conditions of UV irradiation was analyzed.

DOI: 10.1134/S1070427206030116

Formation and stability of the oxidation by-products is one of insufficiently studied aspects of application of ozone to potable water treatment. The primary products of the ozonolysis of organic impurities contained in natural water are aldehydes, ketones, and carboxylic acids [1, 2]. Ozonation of humic acid (HA) and fulvic acid (FA) solutions [3] and of natural water [1, 2, 4–7] leads to the formation of aliphatic aldehydes C_1–C_{14}, aliphatic carboxylic acids C_1–C_{24}, unsaturated aldehydes, dialdehydes, ketones, keto acids, dibasic aliphatic acids, hydroxy- and dihydroxybenzoic acids, esters, and other products.

Aldehydes, if present in a concentration of 0.2–12.5 μg dm^{-3}, impart to the ozonized water a specific smell (fruit, flower, or less pleasant), which then rapidly disappears [8]. Certain aldehydes and ketones are mutagenes and carcinogenes [2]. In addition, carbonyl compounds and chlorine react with the formation of trihalomethanes and other potentially hazardous organochlorine products. The concentration of some aldehydes and ketones in potable water is regulated on the basis of the Governmental Sanitation Rules and Regulations [9]. The presence of other compounds in water reservoirs is regulated by the maximum permissible concentration (MPC) [10]. The MPCs for aldehydes and ketones in potable water are as follows (mg dm^{-3}): formaldehyde 0.05, acetaldehyde 0.2, benzaldehyde 0.003, propenal 0.02, 2-butenal 0.3, 3-pentanone 0.1, and acetone 2.2. Aliphatic aldehydes C_1–C_{10}, glyoxal, methylglyoxal, and benzaldehyde are included into the list of by-products that are subject to monitoring in potable water in the United States [11].

The presence of 1–80 μg dm^{-3} carbonyl compounds in natural reservoirs results from the biochemical processes of oxidation of organic impurities [2, 4]. In ozonized water their total concentration exceeds many times the natural background [2, 4, 6, 7]. The formation of aldehydes in ozonation of natural water depends on a number of factors such as the structure of natural organic impurities, concentration of total organic carbon (TOC), ozone uptake, temperature, the pH of water, etc. [2–5]. The primary carbonyl compounds formed in ozonation of natural water are formaldehyde, acetaldehyde, glyoxal, and methylglyoxal. Aliphatic aldehydes C_4–C_{10}, benzaldehyde, and other substances are less common and are present in lower concentrations [4, 6].

Presently, the new combined oxidation processes, so-called Advanced Oxidation Processes (AOP), are being actively introduced into practical water treatment. Examples are combined application of ozone and hydrogen peroxide (O_3/H_2O_2) or of ozone and UV irradiation (O_3/UV). The composition of the by-products products formed by the AOP in preparation of potable water is studied insufficiently and the results obtained are controversial [12, 13].

This study is concerned with the composition of carbonyl compounds formed in ozonation, UV irradiation, and in the case of the O_3/UV treatment of river waters. We also studied how the yields of the above compounds are affected by the ozone uptake, conditions of UV irradiation, and by the quality of water.

EXPERIMENTAL

We studied the action of ozone alone and the combined action of ozone and UV radiation under the different irradiation conditions on the water from the

Table 1. Characterization of river water samples and model HA solutions

Water sample no.	T, °C	pH	Color index, deg	A_{254} (1 cm)	COD, mg O_2/dm^3	PO,* mg O_2/dm^3	TOC, mg dm^{-3}

Dnieper (sample nos. 1, 2) and Desna (sample no. 3) rivers in the summer period, as well as on model solutions of HA (Fluka, sample no. 4) (Table 1). The river water was preliminarily filtered through a paper filter.

The ozonation and joint treatment with ozone and UV radiation of the samples studied was performed on a laboratory installation in a bubbler-type reactor with a plunged UV source arranged in a quartz jacket [14, 15]. The ozonation parameters were recorded with a computer. The irradiation was performed in the continuous or batch mode with a low-pressure DRB-8 mercury-quartz lamp and in the pulse mode with an IFP-800 pulse xenon lamp. The total energy of the UV radiation of the DRB-8 lamp was 1.13 J s^{-1} and that of the IFP-800 pulse lamp, 2.32 J pulse^{-1} (including 1.15 J pulse^{-1} at 200–290 nm) at a pumping energy of 60 W s^{-1}, a pulse time of about 0.1 ms, and a pulse repetition frequency of 2.6 s [16]. The intensity of the UV radiation in the range 200–290 nm was 2.72 mJ cm^{-2} s^{-1} for DRB-8 lamp and 2.76 mJ cm^{-2} pulse^{-1} for IFP-800 lamp (at a total UV intensity of 5.58 mJ cm^{-2} pulse^{-1}). The ozone supply rate was 1.7–2.8 mg dm^{-3} min^{-1}.

In the course of the study, a portion of the solution (V = 0.625 dm^3) was ozonized until a certain amount of ozone (D_{oz}) was taken up. The time of the UV irradiation or O_3/UV treatment of the water was the same as the ozonation time. The UV irradiation of natural waters was done simultaneously with aeration to attain stirring conditions similar to those in ozonation or in the case of O_3/UV treatment. The methods of controlling the oxidation parameters and monitoring the water quality have been reported previously [14, 15].

Carbonyl compounds contained in water immediately after the treatment by the above methods were analyzed in the form of stable 2,4-dinitrophenylhydrazones (2,4-DNPH) and identified by gas chromatography/mass spectrometry (GC/MS) [17, 18]. To determine the amount of 2,4-DNPH by this method [18], we used the Supelco N 4 Carb Method 1004 Mix 2 reference mixture and mixtures of specially synthesized 2,4-DNPHs.

Nine aldehydes (formaldehyde, acetaldehyde, propanal, propenal, methylpropanal, butanal, 2-butenal, 3-methylbutanal, and pentanal) and six ketones (acetone, butanone, 3-methyl-2-butanone, 3-pentanone, 2-pentanone, and 2-hexanone) were identified by GC/MS in river waters and model HA solutions after ozonation and in the case of combined treatment with ozone and UV radiation. The major carbonyl compounds formed under all the treatment conditions used are formaldehyde, acetaldehyde, and acetone. The concentrations of propanal and 2-butenal were also determined by this method. The main problem for the water studied is associated with formaldehyde, since among the carbonyl compounds analyzed its concentration in potable water is regulated most strictly.

In comparison of the results obtained in ozonation of waters taken from different reservoirs or of HAs and FAs isolated from them, the concentrations of the forming oxidation products are given per milligram of TOC or per milligram of ozone taken up. The ratios of the O_3 amount to the TOC concentration in the ozonized waters varied from 0.2 to 3.0 mg mg^{-1} [3, 4]. The studies performed at a number of industrial water supply stations and pilot-plant installations in the United States using different water reservoirs and ozone doses showed [4] that the yields of formaldehyde and the total yield of four major aldehydes C_1–C_3 (formaldehyde, acetaldehyde, glyoxal, and methylglyoxal) in ozonation of natural waters are within 1.1–13.0 and 4.9–30.0 μg mg^{-1} TOC (Table 2). The statistic mean total yield of four major aldehydes in ozonation is approximately 12 μg mg^{-1} TOC, including 5 μg mg^{-1} TOC of formaldehyde. The ozonation of the model FA solutions containing 20 mg dm^{-3} TOC with an ozone amount of 1–3 mg O_3 mg^{-1} TOC produced even higher concentrations of C_1–C_3 aldehydes (~1.5–2.0 μmol mg^{-1} TOC) [3].

Table 2. Yield of carbonyl compounds in ozonation, UV irradiation, and O_3/UV treatment of the water samples studied

The yields of major carbonyl products in oxidation of initial sample nos. 1–4 are presented in Table 2 per milligram of TOC and per 1 mg dm^{-3} ozone uptake. The maximal total yields of formaldehyde, acetaldehyde, acetone, and C_1–C_3 carbonyl compounds in ozonation, UV irradiation, and O_3/UV treatment of the river waters studied (sample nos. 1–3) lie within the interval typical of potable water [4]. At ozone uptakes of 2–12 mg dm^{-3} (0.1–0.8 mg O_3/mg TOC), which are acceptable in potable water treatment, the yields of formaldehyde and acetaldehyde and the total yield of carbonyl compounds C_1–C_3 in ozonation and in O_3/UV treatment of sample nos. 1–3 (1–7, 1–6, and ~2–12 μg mg^{-1} TOC, respectively) do not noticeably exceed the statistic mean values for formaldehyde and the total yield of four major aldehydes in treatment of potable water from other reservoirs [4]. The yield of acetone is lower by approximately an order of magnitude (0.1–0.7 μg mg^{-1} TOC).

In ozonized sample no. 4 (HA solution), aldehydes were observed only after its decolorization, i.e., at D_{oz} > 2 mg mg^{-1} TOC. In this sample, the total yield of formaldehyde and carbonyl compounds per milligram of TOC does not differ from the typical values for river waters (Table 2). The maximal values of the total yields of formaldehyde, acetaldehyde, and major carbonyl compounds (formaldehyde, acetaldehyde, acetone, propanal, and 2-butenal) in the case of O_3/UV treatment of this sample (Table 2) somewhat exceed the values for potable water but are considerably lower than the values observed previously in ozonation of FA solutions [3].

The individual and total yields of carbonyl compounds per 1 mg dm^{-3} ozone uptake in ozonation of sample no. 4 are closer to the minimal values for potable water (Table 2). In the case of O_3/UV treatment of this sample, the maximal yield of acetaldehyde (61.5 and 44.5 μg mg^{-1} O_3) and the maximal total yield of aldehydes and ketones (89.0 and 59.6 μg mg^{-1} O_3) are observed at the minumal uptakes D_{oz} (2.1 and 4.4 mg dm^{-3}, respectively) (Fig. 1b). In the indicated ozone uptake range, this parameter is higher by a factor of at least 2–3 than that observed in the case of O_3/UV treatment at higher ozone uptakes and by an order of magnitude higher than that in ozonation (Table 2).

Also, the yields of formaldehyde and acetaldehyde and the total yield of carbonyl compounds per 1 mg dm^{-3} ozone uptake at D_{oz} < 4 mg dm^{-3} in ozonation and in O_3/UV treatment of river waters are mostly higher by a factor of about 1.5–2.5 as compared to those observed at higher ozone uptakes. Examples are the yield of acetaldehyde and the total yield of carbonyl compounds C_1–C_3 in O_3/UV treatment of sample no. 1 (Fig. 1a) and the yield of all major carbonyl compounds in ozonation of water sample no. 3 (Fig. 2). The total yields of primary carbonyl compounds per 1 mg dm^{-3} ozone uptake in ozonation of sample no. 3 (Figs. 2a, 2b) and in O_3/UV treatment of sample no. 4 (Fig. 1b) are considerably higher than the values typical of potable water only when the ozone uptakes D_{oz} are minimal.

The data obtained show that the O_3/UV treatment in the stage of the decolorization of natural water with

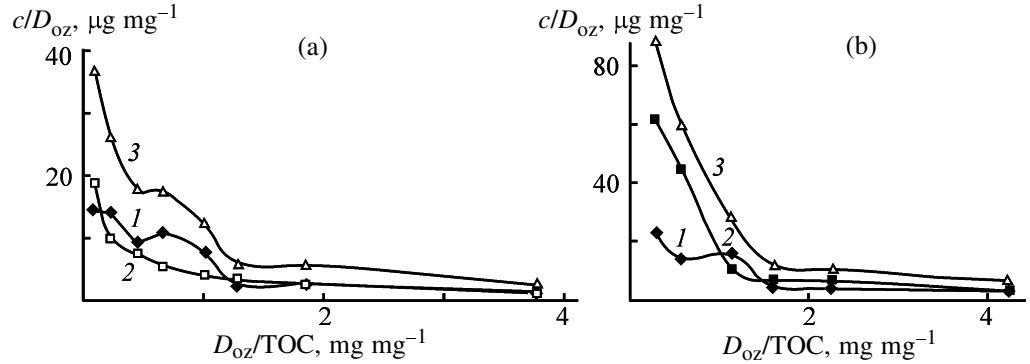

Fig. 1. Yields of (*1*) formaldehyde and (*2*) acetaldehyde, and (*3*) total yield of carbonyl compounds C_1–C_3 per 1 mg dm^{-3} ozone uptake c/D_{oz} vs. the ozone uptake D_{oz}/TOC in O_3/UV treatment of sample (a) no. 1 and (b) no. 4. Ozone feed rate: (a) 2.75 ± 0.05 and (b) 1.8 ± 0.1 mg dm^{-3} min^{-1}; I_{UV} = 2.72 mJ cm^{-2} s^{-1}.

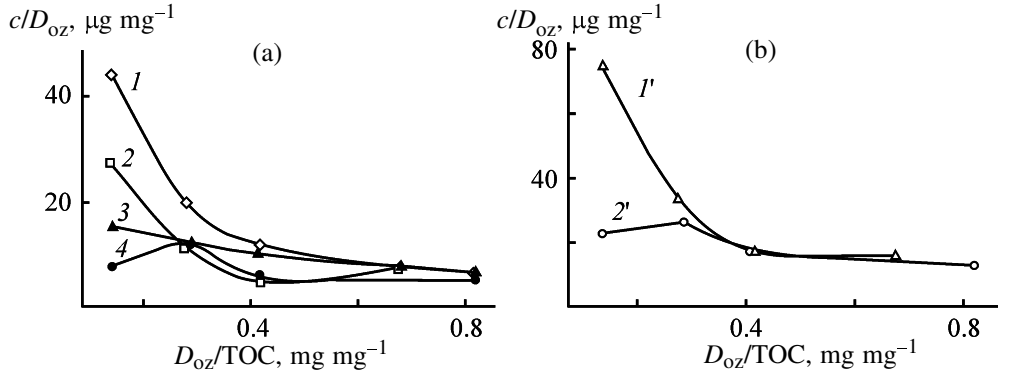

Fig. 2. (a) Yields c/D_{oz} of (*1, 3*) acetaldehyde and (*2, 4*) formaldehyde, and (b) (*1'*, *2'*) total yield of carbonyl compounds C_1–C_3 vs. the ozone uptake D_{oz}/TOC in (*1, 2, 1'*) ozonation and (*3, 4, 2'*) O_3/UV treatment of water sample no. 3. Ozone feed rate 1.95 ± 0.05 mg dm^{-3} min^{-1}, I_{UV} = 2.72 mJ cm^{-2} s^{-1}.

high concentration of HA and FA is undesirable, since it increases the yield of aldehydes in comparison with ozonation.

It has been shown previously [15] that a two-stage oxidation (first, ozonation and then, O_3/UV treatment) ensures more efficient removal of antropogenic microimpurities (pesticides and surfactants) from natural water. The indicated conditions of the treatment also significantly affect the yield of carbonyl products in oxidation of organic impurities (Fig. 3). The UV irradiation of ozonized sample nos. 4 or 1 after the decolorization with ozone ($\tau > 13.5$ and $\tau > 5.0$ min, respectively) significantly decreases both the yields of carbonyl compounds C_1–C_3 (Fig. 3a) and the yield of formaldehyde, which is the most strictly regulated major product, in comparison not only with the continuous combined O_3/UV treatment, but also with ozonation.

The effect exerted by the combined action of ozone and UV radiation on the individual and total yields of carbonyl compounds can differ dramatically, depending on the water source. For example, the O_3/UV treatment of sample no. 3 does not increase the yields of aldehydes in comparison with ozonation at the same ozone doses (Fig. 4b, 4c). The O_3/UV treatment of sample nos. 1 and 2 increases the yield of formaldehyde by a factor of 1.3–2.0 (Figs. 3b, 4a) and the yield of carbonyl compounds, by a factor of 1.3–1.5 (Figs. 3a, 4c).

The yields of carbonyl compounds in the case of the action of UV radiation on the river waters under study differ significantly depending on the radiation source. The radiation of a pulsed IFP-800 xenon lamp in the presence of oxygen increases the formaldehyde yield in sample nos. 2 and 3, whereas using the irradiation jointly with ozonation markedly decreases it in comparison with the case of irradiation with a bactericidal DRB-8 mercury-quartz lamp (Figs. 4a, 4b). The yields of acetaldehyde in the above samples differ by a factor of approximately 1.5–5, depending on the irradiation conditions.

Figure 4 also shows that the yields of formaldehyde in the case of UV irradiation of the water samples studied in the presence of oxygen are close, and frequently, the same as in ozonation and in O_3/UV treatment. For example, the formaldehyde yield in

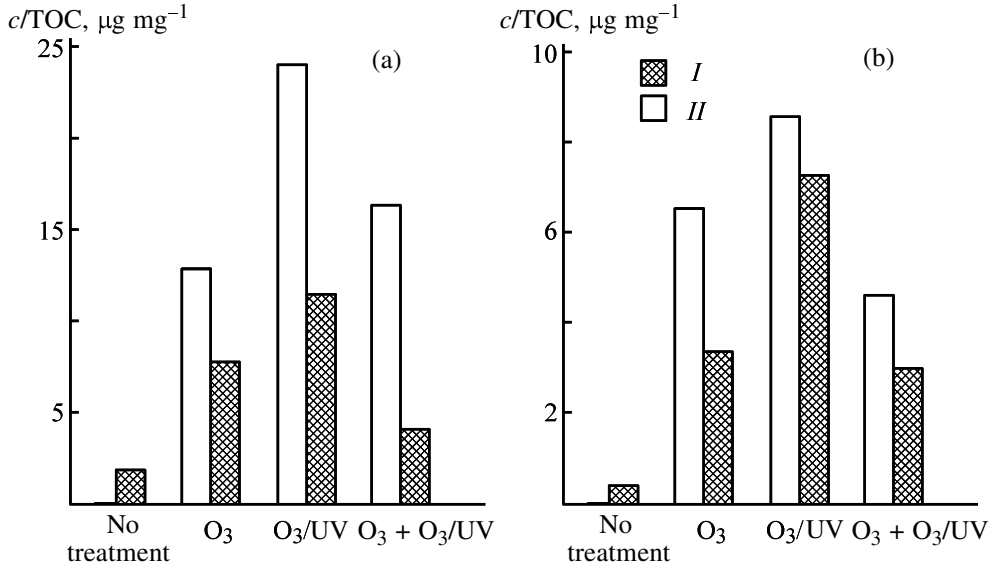

Fig. 3. Effect of ozonation, O_3/UV treatment, and two-stage oxidation (first, ozonation and then, O_3/UV treatment) of water sample (*I*) no. 1 and (*II*) no. 4 on the (a) total yield of carbonyl compounds and (b) yield of formaldehyde per milligram of TOC, *c*/TOC. Total treatment time τ (min) and specific ozone uptake D_{oz}/TOC (mg mg^{-1} TOC): 10.75 and 0.6–0.7 (no. 1), 19.0 and 2.1–2.3 (no. 4).

the combined action of pulsed UV irradiation and an oxidizing agent on water sample no. 2 is virtually independent of the kind of the oxidant (ozone or oxygen) and differs only slightly from the yield in ozonation (Fig. 4a). The yields of acetaldehyde in ozonation and under continuous UV irradiation of water sample no. 3 are equal (Fig. 4b).

Despite the fact that the yields of individual aldehydes differ by a factor of 1.3–6.3, the total yields of carbonyl compounds in two modes of UV irradiation or in O_3/UV treatment of water sample no. 2 are close (Fig. 4b). The individual and total yields of carbonyl compounds in ozonation and in combined treatment with O_3 and continuous UV radiation of water sample no. 3 are virtually equal. The combined treatment of this sample by O_3 and pulsed UV radiation decreases the yields of carbonyl compounds by 10–26% in comparison with the above treatments and by 75% in comparison with the pulsed UV irradiation of this sample in the presence of dissolved oxygen.

Analysis of the combined effect of ozone and UV radiation on the formation of carbonyl compounds in the river waters studied shows that the yield of individual products and the total yield under both conditions of O_3/UV treatment is considerably (by a factor of ~1.3–3.8) lower than their additive value, i.e., in ozonation and in UV irradiation. The additive or synergistic character of the combined action is observed only in a few cases. The additive effect is observed with the yield of formaldehyde in sample no. 2 upon combined treatment with O_3 and continuous UV radiation (Fig. 4a), and the synergistic effect, with the yield of acetone in the same sample irradiated in the pulsed mode.

The data presented show that, apart from oxidant dose and irradiation conditions, the concentration of carbonyl compounds is significantly affected by the quality of natural water, usually differing in the content of organic impurities. It may be suggested that carbonyl compounds are present in natural water as organic impurities of various structures or as various structural fragments of HA and FA. Intense formation of aldehydes at small doses D_{oz} is probably due to the decomposition of readily oxidizable compounds present in natural water or readily oxidizable groups in HA structure. As known, ozone most readily reacts with unsaturated and aromatic organic compounds. Predominance of polysubstituted aromatic nuclei, including polyhydroxy derivatives, and the presence of C=C bonds in aliphatic terminal groups and bridges between aromatic nuclei in the structure of the humic acid under study (Fluka) [19] facilitate its reaction with molecular ozone. The fraction of readily oxidizable compounds (PO/COD) in model HA solutions (0.7) is higher than in the natural waters studied here (0.5–0.6) (Table 1).

At the same time, in ozonation of aromatic compounds the carbonyl compounds C_1–C_3 are formed in the last stage of a complex chain of transformations, consisting of successive cleavage of aromatic nuclei

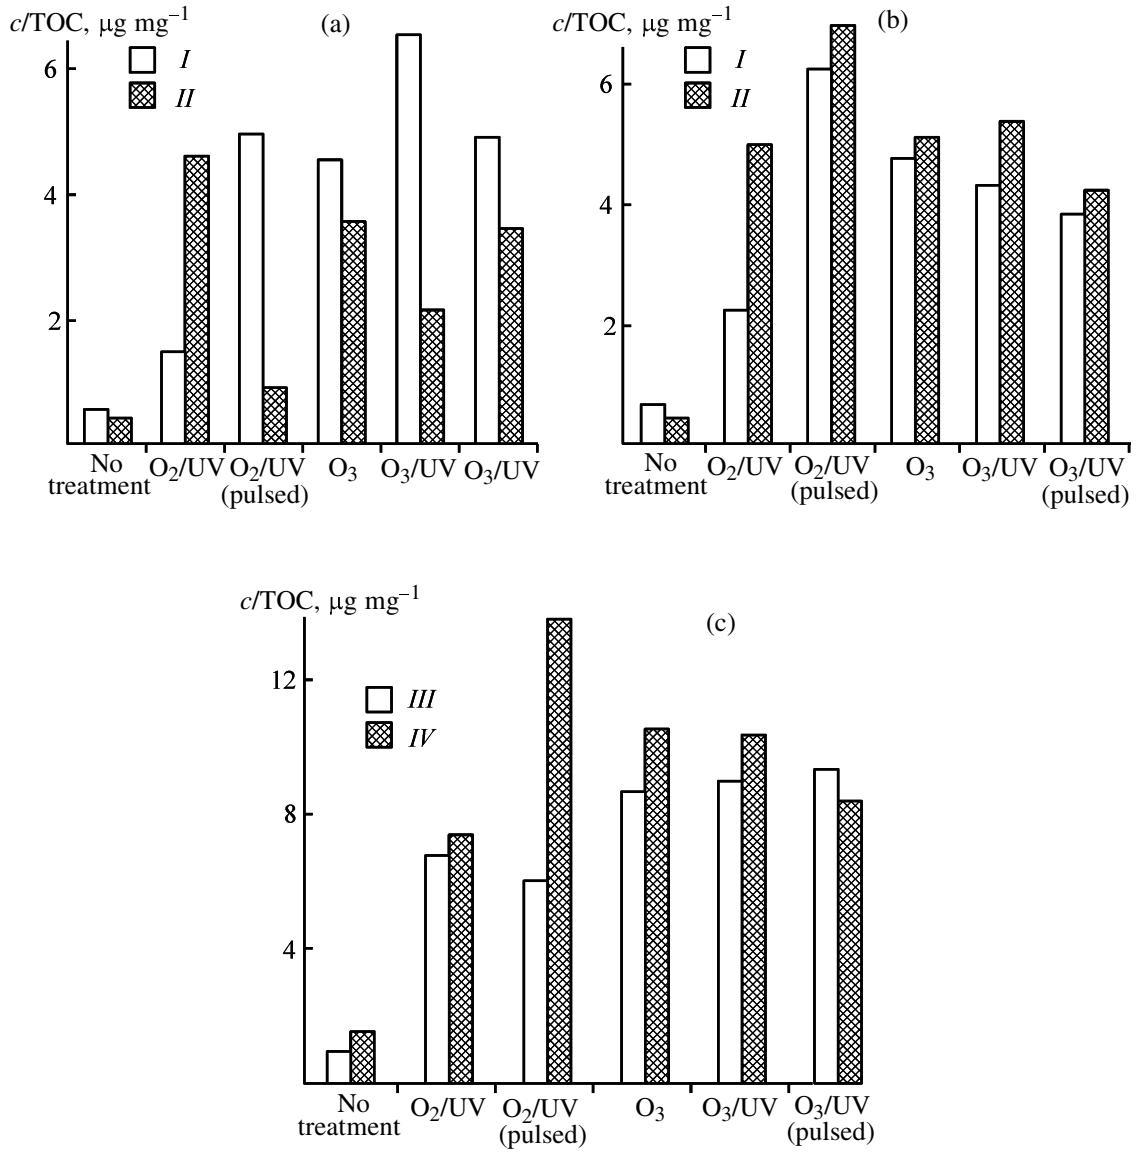

Fig. 4. Comparison of (a, b) yields of (*I*) formaldehyde and (*II*) acetaldehyde and (c) total yields of carbonyl compounds C_1–C_3, *c*/TOC, in ozonation and upon continuous or pulsed UV irradiation in combination with the effect of ozone or oxygen on water sample (a, c) no. 2 and (b, c) no. 3. $D_{oz} = 0.7 \pm 0.1$ mg mg^{-1} TOC, $\tau = 13$ min. (c) Sample: (*III*) no. 2 and (*IV*) no. 3.

and double C=C bonds of the primary products. In O_3/UV treatment, the oxidant species are highly active hydroxy radicals whose reactions are characterized by high rates and nonselectivity. The simultaneous reaction of OH radicals with various structural fragments of HA solutions (Fluka) and the high rates of the reactions predetermine the high yield of carbonyl compounds (per 1 mg dm^{-3} ozone uptake) at small D_{oz}.

Amines, amino acids, unsaturated carboxylic acids, and natural polyphenol compounds (flavones, flavanones, flavonoids, anthocyanes, etc.) should be classed with readily oxidizable compounds contained in natural water. The appearance of propenal and 2-butenal in ozonation and in the case of O_3/UV treatment of the waters studied is likely due to the presence of unsaturated compounds, for example, of higher carboxylic acids (C_{16}–C_{18}) containing two or three C=C bonds. At higher D_{oz}, the formation of aldehydes is associated with profound decomposition of HA and FA. Because the above acids are similar in

nature, the boundaries of the aldehyde yields per milligram of O_3 taken up, obtained for different reservoirs, become considerably narrower.

CONCLUSIONS

(1) Nine aldehydes and six ketones C_1–C_6 were identified by gas chromatography/mass spectrometry in river waters and model humic acid solutions treated with ozone alone and with ozone in combination with UV radiation.

(2) The yields of major carbonyl products (formaldehyde, acetaldehyde, and acetone) formed in oxidation of the samples studied depend on the ozone uptake, conditions of UV irradiation, and quality of water.

(3) The O_3/UV treatment of a natural water containing high concentration of humic and fulvic acids in the stage of decolorization is undesirable, because it results in a higher yield of aldehydes as compared to that in ozonation. It is reasonable to use two-stage oxidation (first, ozonation and then, O_3/UV treatment).

(4) The pulsed O_3/UV treatment of natural water decreases the yield of formaldehyde and the total yield of primary carbonyl compounds C_1–C_3 not only in comparison with the continuous O_3/UV treatment but also with the ozonation.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Water Treatment with a Shungite Sorbent and Biosorbents on Its Base

S. V. Efremova

National Center for Integrated Processing of Mineral Raw Materials of the Republic of Kazakhstan, Almaty, Kazakhstan

Received June 7, 2005; in final form, September 2005

Abstract—Physicochemical and sorption properties of a nonactivated shungite sorbent were studied. The immobilization of yeast cells of *Kluveramyces sp.* (strain 11 K) and *Candida sp*. (strain 10 K) and cells of oil-oxidizing bacterial cultures *Mycobacterium sp.* (strain 119-3 GM) and *Pseudomonas sp.* (strain 51 K) on this sorbent was examined. A comparative analysis of the accumulation of heavy metal ions and degradation of oil by free and immobilized cells of these microorganisms was carried out. The efficiency of application of biosorbents produced on the basis of the shungite support in water treatment to remove heavy metals and oil was studied.

DOI: 10.1134/S1070427206030128

There is a wide variety of materials used as adsorbents to purify water and aqueous solutions: ion-exchange resins, activated carbons, and natural and synthetic zeolites. The practical experience shows that use of natural dispersed materials is the most economically attractive. Numerous examples of their application in particular processes have been reported [1–3]. However, these studies are frequently either not systematic or failing to find wide practical use, and, therefore, a search for new types of raw materials and development of technologies for industrial manufacture of adsorbents on their base remain matters of current interest.

Studies of the sorption properties of shungite rocks from Karelia and their use in treatment of waste and recycled water have been reported [4–7]. Analysis shows that the specific surface area of these materials is comparatively small. However, various methods of modification of the starting rock (with alkali, with alkali under pressure in an autoclave, thermal treatment, etc.) make it possible to improve their sorption properties and to recommend shungite sorbents to be used instead of activated carbons in water treatment to remove mostly organic compounds and, in particular, petroleum products.

Similarly to that from Karelia, the Kazakhstan shungite rock is a multiphase system that contains a mineral component composed of quartzite and aluminosilicates and shungite proper, which differs from the Karelian material in a low degree of structural ordering and high particle dispersity [8–10]. These structural features of the Kazakhstan shungite should, in all probability, positively affect its sorption properties. The fact that a considerable amount of the rock in question is contained, in addition to natural deposits, in wastes formed in mining and dressing of polymetallic ores poses the question of processing of these materials.

Therefore, it was of interest to examine the possibility of using the Kazakhstan shungite rock to produce sorbents that could be used in water treatment to remove various contaminants.

EXPERIMENTAL

The shungite carbon–mineral sorbent (SCMS), whose main adsorption parameters are listed in Table 1, was prepared from a shungite concentrate produced from a homogenized sample of shungite rock[1] ($c \approx 20.0$ wt %) by foam flotation. The concentrate was mixed with an aqueous solution of sugar to the consistency of thick dough. The resulting paste was passed through a worm feeder with holes 0.3 cm in diameter. Grains 0.5–0.8 cm in size were dried in air first at room temperature and then at 110°C for 1 h, and after that were subjected to thermal treatment without access of air at 750°C for 20 min [11, 12].

* Shungite sorbent: SS, untreated; SSA activated with steam; SSM, treated with a NaOH solution [6]; SS-750, thermally treated at 750°C [7]; ACh, crushed activated charcoal for removing oil and other impurities from steam condensate; BAU-MF, crushed activated charcoal for adsorption from aqueous media in filtering installations [13].

The activation of the resulting sorbent, recommended in [12], was beyond the scope of this study.

Comparison of the physicochemical properties of SCMS with the characteristics of natural and modified Karelian shungite sorbents and those of activated charcoal shows that nonactivated SCMS is inferior in certain parameters (total pore volume, adsorption activity toward iodine) to commercial activated carbons but greatly surpasses various samples of sorbents produced from Karelian shungite rock in specific surface area and total pore volume (Table 1). In all probability, this is provided by structural features of the Kazakhstan shungite and by the method used to produce SCMS. In this technique, an aqueous solution of sugar serves as a binder, which favors carbonization of the sorbent in thermal treatment without access of air and thereby leads to an increase in its porosity. As regards the pore structure of the sorbent, it follows from experiments on the sorption of iodine, Methylene Blue, and acetone that nonactivated SCMS has a more developed microsctructure than the Karelian sorbents. For example, the pore volume of SCMS is 50 times the volume of micropores in the untreated Karelian shungite sorbent. At the same time, the volume of macropores in SCMS is nearly two times smaller than that in the Karelian sorbent. The volume of mesopores is somewhat larger than that in both untreated and modified Karelian shungite sorbents.

The shungite carbon–mineral sorbent was analyzed for product safety at Kazakh Republican sanitary-epidemiological station. It was found that the activity of natural radionuclides in the sample studied does not exceed the radiation background in various soils; the content of radionuclides in an aqueous extract does not exceed the level established by radiation safety regulations for water; the sorbent meets the sanitary-hygienic requirements.

The shungite carbon–mineral sorbent was tested in water treatment to remove heavy metal ions. The sorption was performed at room temperature by passing through a sorption column (d = 15 mm) at a rate of 75 cm^3 h^{-1} model solutions (pH 6–7) of $Pb(NO_3)_2$, $MnSO_4$, $CdCl_2$, and $ZnCl_2$ containing (mg l^{-1}): Pb^{2+} 0.15, 10; Mn^{2+} 0.15; Cd^{2+} 1, 10, 100; Zn^{2+} 0.15, 1.

The choice of the above solutions is due to the fact that lead(II), cadmium(II), and zinc(II) are the most toxic, and manganese(II) is predominant among heavy metals in the ecosystem of Kazakhstan [14].

The eluted fractions were collected in portions of 150 cm^3 every 2 h during 20 h until the ratio of the volume V of the solution passed to that of the sorbent (V_s) became 75. The content of heavy metal ions in the eluates was monitored with an atomic-adsorption spectrometer. The tests performed made it possible to determine how the sorption capacity of the shungite sorbent depends on the working time of the column and on the nature and concentration of a contaminant. Table 2 shows that SCMS exhibited a high activity in purification of solutions containing 0.15 mg l^{-1} of Pb^{2+} and Zn^{2+} each. Its operation is the most stable

Table 2. Sorption of metal ions by SCMS under dynamic conditions

Working time of column, *h*	Solution volume *V*, cm^3	V/V_s	Degree of recovery (%) of metal ions from their solutions at their indicated concentrations, mg l^{-1}

in a wide range of concentrations and large V/V_s in the case of Cd^{2+}.

An important characteristic of any sorbent is its ability to be regenerated and reused. A rather widely adopted way to regenerate natural sorbents used to remove heavy metal ions from water is alkaline treatment [1], which is also recognized as the most efficient method for modification of shungite sorbents [5, 6]. The worked-out SCMS was regenerated by treatment with a 0.4 N NaOH solution (s : l ratio 1 : 10), with boiling at atmospheric pressure for 30 min. In contrast to the autoclave method, such a treatment procedure has virtually no effect on the mechanical characteristics of the sorbent, because SiO_2 is either extracted from the existing pores or from microcracks, without disintegration of the silica skeleton [5]. Regenerated samples were tested in treatment of solutions containing 1.0 and 10 mg l^{-1} of cadmium. It was found that the regenerated material sorbs cadmium(II) from a solution with a concentration of cadmium ions of 10 mg l^{-1} with a lower efficiency than does the initial sorbent. In the case, however, of a solution containing 1 mg l^{-1} Cd^{2+}, the degree of recovery of cadmium(II) ions by a sorbent subjected to alkaline treatment markedly increases and constitutes 100% during the first 10 h of operation of the column. This fact indicates that the sorption capacity of SCMS can be controlled by some kind of modification or by selection of the optimal conditions of the sorption process.

As a method for modification of the sorbent surface can be considered immobilization of cells of microorganisms, e.g., those capable of selective sorption and accumulation of heavy metal ions and of oxidative degradation of oil [15–17].

Yeast cells of *Candida sp*. (strain 10 K) and *Kluveramyces sp*. (strain 11 K) were immobilized on a shungite support in the course of 1, 3, and 24 h (method I). The results obtained demonstrated that SCMS exhibits a higher activity toward cells of strain 10 K, compared with those of strain 11 K; during the first hour, 50 and 18%, respectively, were immobilized. At a longer time of culturing, cells are desorbed from the support surface. For example, the number of immobilized cells decreased to 31% in 3 h and to 25% in 24 h for strain 10 K; in the case of strain 11 K, the respective values were 11 and 6%.

Therefore, the cultures were preliminarily grown for 24 h in a Saburo liquid culture medium (glucose 40 g, peptone 10 g, water 1 l) to the logarithmic phase of active growth. After that the sorbent was introduced into the fermentation medium with these yeast cells, kept there for 24 h, and then separated (method II). The content of yeast cells of strain 11 K, sorbed on the shungite sorbent in this way, exceeded 40%. At the same time, the content of immobilized cells of strain 10 K was about 35%, which was lower than the content of cells fixed by method I during the first hour, but larger than that of cells fixed in 3 and 24 h.

Therefore, samples of modified sorbents were prepared in what follows by culturing of cells of strains 11 K and 10 K with SCMS by method II. The content of cells in finished biosorbents is listed in Table 3.

Table 3. Content of yeast cells adsorbed on the shungite sorbent

Strain	Number of cells in medium		Content of adsorbed cells, %
	without support	with support	
11 K	35.9×10^6	19.1×10^6	47
10 K	12.2×10^6	8.0×10^6	34

The sorption power of the sorbents obtained was studied for the example of aqueous solutions with 1 mg l^{-1} of cadmium and zinc ions each. The sorption of metal ions was observed at room temperature in the static mode at a 1 : 100 mass ratio of the sorbent and the solution being purified. It was found that the maximum degree of solution purification to remove Cd^{2+} and Zn^{2+} is observed after 24 h, with the highest sorption activity exhibited by immobilized cells of strain 11 K; the degrees of absorption by immobilized cells of strains 11 K and 10 K and by SCMS were 56, 55, and 52%, respectively, for cadmium ions, and 60, 55, and 50% for zinc ions.

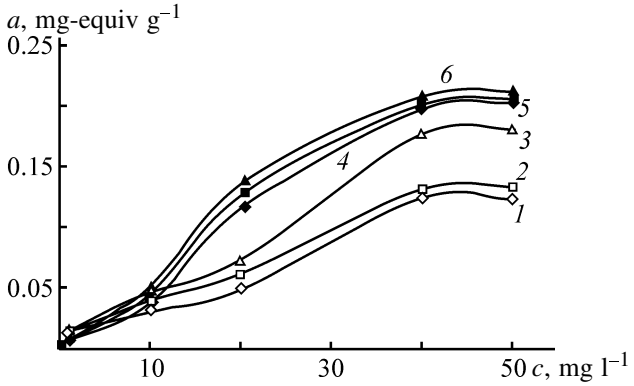

Fig. 1. Isotherms of sorption a of zinc and cadmium ions by shungite biological sorbents. (c) Concentration of metal ions in the solutions being purified. Sorption of Zn^{2+} by (*1*) SCMS, (*2*) immobilized cells of strain 10 K, and (*3*) immobilized cells of strain 11 K and of Cd^{2+} by (*4*) SCMS, (*5*) immobilized cells of strain 10 K, and (*6*) immobilized cells of strain 11 K.

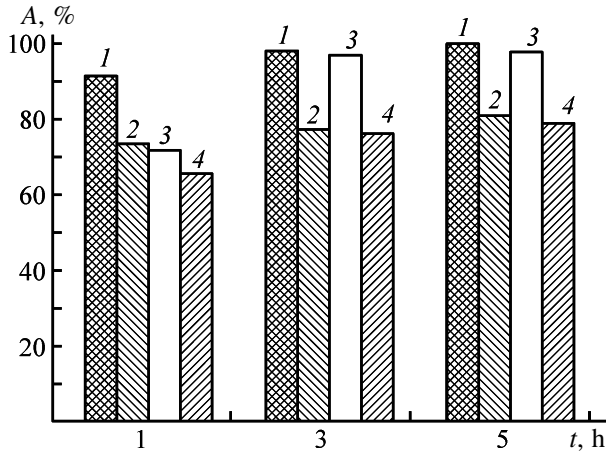

Fig. 2. Dynamics of sorption of cells of *Mycobacterium sp.* (strain 119-3 GM) and *Pseudomonas sp*. (strain 51 K) by granulated and powdered shungite sorbents. (A) Fraction of adsorbed cells and (t) immobilization time. Sorption by granulated sorbent: (*1*) strain 119-3 GM and (*2*) strain 51 K; sorption by powdered sorbent: (*3*) strain 119-3 GM and (*4*) strain 51 K.

Therefore, the absorption of metal ions from solutions with various initial concentrations (0.1 to 50 mg l^{-1} Cd^{2+} and 1 to 50 mg l^{-1} Zn^{2+}) was performed during 24 h. Figure 1 shows sorption isotherms, according to which the fraction of adsorbed ions of the contaminating metals increases with their concentration in solutions, and the sorption capacity of the sorbents tested for metal ions grows in the following order: shungite support, immobilized cells of strain 10 K, immobilized cells of strain 11 K, at a considerably higher sorption affinity for cadmium ions.

Cells of oil-oxidizing bacterial cultures *Mycobacterium* sp. (strain 119-3 GM) and *Pseudomonas sp.* (strain 51 KS) were immobilized on granulated and powdered (without binder) shungite supports in the course of 1, 3, and 5 h. The granulated SCMS (Fig. 2) exhibited a higher activity toward cells of the strains under consideration. Already in 1 h, the fraction of cells adsorbed on its surface reached 90% for strain 119-3 GM and 70% for strain 51 K, whereas for the powdered support, these figures were 72 and 64%, respectively. However, the optimal exposure time for immobilization of the bacterial cultures was 5 h. The fraction of cells of strain 119-3 GM, adsorbed during this interval of time, was 99% for the granulated support and 97% for that in the powdered state; for strain 51 KS, these figures were 80 and 78%, respectively.

On the basis of the results obtained, granulated SCMS was chosen as a support for laboratory experiments on water treatment to remove oil contaminations, and strain 119-3 GM, as hydrocarbon destructor. A shungite sorbent (SCMS) of mass 2 g, pasteurized at 1.5 atm for 1 h, was introduced into a vessel containing 100 cm^3 of a culture medium of the following composition (g): KH_2PO_4 1.0, K_2HPO_4 1.0, $MgSO_4 \cdot 7H_2O$ 0.2, $CaCl_2$ 0.02, $FeSO_4$ 0.002, NH_4NO_3 1.0, and H_2O up to 1 l. As a source of carbon and energy served 3 g of crude oil from the Tengiz oil field. A 10 cm^3 portion of a suspension of *Mycobacterium sp*. cells (strain 119-3 GM, concentration 10^9 cells per cm^3) was introduced into a flask. The culturing was performed on a rocker at 25°C and

a rocking rate of 220 rpm in the course of 3, 5, and 10 days. In a control run, bacterial cells were introduced into a culture medium with oil, but without any sorbent. The residual amount of the hydrocarbon contaminant, measured gravimetrically upon extraction with chloroform, was used to determine the efficiency of its consumption by free and immobilized cells of strain 119-3 GM.

Figure 3 shows that immobilized cells exhibit a stronger oil-oxidizing power than free cells. It should be noted that, after 3 days, the degree of oil oxidation by immobilized cells (78%) was 2.5 times that for free cells (30%). Longer exposure time favors an increase in the degree of degradation of the hydrocarbon contaminant by both immobilized and free cells of the bacterial culture *Mycobacterium sp.* (strain 119-3 GM). For example, the degree of oil degradation in 10 days reaches a value of 86% for immobilized cells of the culture under consideration and 78% for free cells.

A study of the dynamics of redistribution of the biomass of microorganisms in a system constituted by an aqueous medium and a support demonstrated that the fixation of microorganism cells on the shungite sorbent is decelerated in the presence of a hydrocarbon contaminant. As already noted, the fraction of cells adsorbed on the support in an oil-free medium in 1–5 h varied from 90 to 99% (Fig. 2), whereas in a contaminated medium, the fraction of adsorbed cells was only 67% in 3 days, 74% in 5 days, and 93% in 10 days. This behavior can be attributed to the high sorption affinity of SCMS for hydrocarbons, which results in that, in addition to immobilization of microorganisms, adsorption of oil occurs on its surface, with the subsequent degradation of oil by cells of the oil-oxidizing culture fixed on the sorbent. As a result, place for sorption of new portions of microorganism cells and hydrocarbon contaminants is freed, and this leads to an increase in the amount of adsorbed cells of *Mycobacterium sp.* (strain 119-3 GM) and in the degree of oil degradation.

This conclusion was confirmed by a model experiment in an aquarium containing 2 l of artificial Kaspian seawater (pH 8) of the following composition (g l^{-1}): NaCl 2.34, $MgSO_4 \cdot 7H_2O$ 24.6, KCl 1.5, $CaCl_2 \cdot 2H_2O$ 2.9, $FeSO_4$ 0.28, and NH_4Cl 1.0. A 40-g portion of a granulated shungite sorbent, 60 g of oil, and 200 cm^3 of a suspension of *Mycobacterium sp.* cells (strain 119-3 GM) with a concentration of 10^9 cells/cm^3 was introduced into one aquarium, and the same amounts of the contaminant and suspension of microorganism cells, into another. The

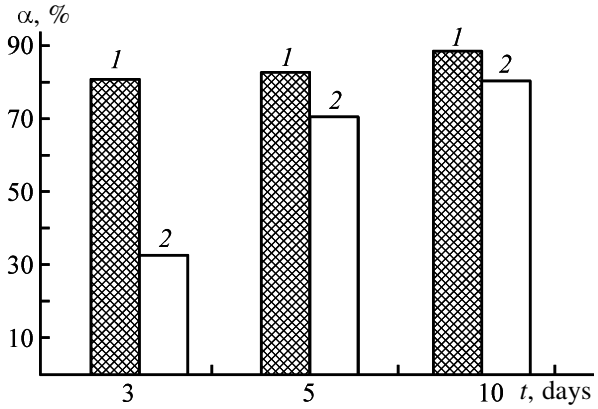

Fig. 3. Oil degradation by cells of the culture *Mycobacterium sp.* (strain 119-3 GM) immobilized on the sorbent and by free cells. (α) Degree of degradation and (*t*) time of degradation. Cells: (*1*) immobilized and (*2*) free.

experiment was carried out in the course of 30 days at 22°C without aeration; the degrees of oil consumption by cells of strain 119-3 GM, immobilized on the shungite sorbent and free, were compared. The data obtained (Fig. 4) indicate that the degree of oil consumption by immobilized cells (45%) markedly exceeds that by free cells (7%). Consequently, the shungite support enhances the oxidizing activity of immobilized cells. Adsorbing the hydrocarbon contaminant, it locally disrupts the integrity of the oil spot on the surface of water and thereby improves the aeration, and this enhances the oxidation of oil by immobilized oil-oxidizing microorganisms.

CONCLUSIONS

(1) The physicochemical properties of a nonactivated carbon–mineral sorbent based on Kazakhstan shungite rock were studied in comparison with natural and modified Karelian shungite sorbents and activated charcoals. It was demonstrated that, owing to the structural features of the Kazakhstan shungite and to

the method suggested for producing a carbon–mineral sorbent from this shungite, the sorbent markedly exceeds in sorption characteristics the known Karelian shungite sorbents, being, however, inferior to commercial activated charcoals.

(2) The dynamics of immobilization of cells of yeast cultures *Kluveramyces sp.* (strain 11 K) and *Candida sp.* (strain 10 K) on the shungite sorbent was studied and the optimal immobilization conditions were determined. Immobilized strain 11 K cells exhibit higher sorption aictivity toward heavy metal ions than do immobilized strain 10 K cells and straight shungite sorbent.

(3) It is preferable to use a granulated sorbent as a support for cells of *Mycobacterium sp.* (strain 119-3 GM) and *Pseudomonas sp.* (strain 51 KS).

(4) The possibility of using a shungite sorbent with immobilized oil-oxidizing microorganisms to treat natural water contaminated with oil products was assessed. These biosorbents provide an efficient adsorption-biological water treatment to remove oil.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Longitudinal Mixing in Fast Liquid-Phase Chemical Reactions in a Two-Phase Mixture

V. P. Zakharov and F. B. Shevlyakov

Bashkir State University, Ufa, Bashkortostan, Russia

Received June 16, 2005; in final form, November 2005

Abstract—The possibility of diminishing the diffusion limitations in the course of fast chemical reactions in liquid–gas systems by varying the reactant ratio and the rate of longitudinal mixing in the liquid phase and at the phase boundary (via changes in the geometry and hydrodynamic parameters of flow in tubular apparatus) was examined.

DOI: 10.1134/S107042720603013X

It is known that the driving force of the process in heat-and-mass exchange in classical apparatus of chemical technology and, consequently, the rate of this process are at a maximum at low coefficients of longitudinal mixing (that along the flow axis) [1]. If the hydrodynamic structure of flow of the reaction mixture approaches the plug-flow mode, this gives rise to the optimal, as regards the time of completion of the process, conditions for most of chemical reactions, which, as a rule, occur under the kinetic control. At the same time, intensive longitudinal mixing is necessary in performing fast liquid-phase chemical reactions in small-size high-output-capacity tubular turbulent apparatus [2]. In this case, the reactor is comparable in size with the region in which the fast chemical reaction occurs, which is essentially small, and longitudinal mixing leads to "smearing" of temperature, with quasi-isothermal conditions created [3]. Raising the rate of longitudinal mixing leads to intensification of the convective heat exchange, which occurs because of the increase in the heat-exchange coefficient of both the reaction mixture and the cooling agent, and to effective heat removal directly from the reaction zone in the case of external thermostating [4].

The previously revealed [5] fundamental aspects of longitudinal mixing in flow of a single-phase reaction mixture in tubular turbulent apparatus enable choice of the optimal conditions for fast liquid-phase chemical reactions in homogeneous media. At the same time, there is no evidence concerning the hydrodynamic mode of flow of two-phase reaction systems in tubular turbulent apparatus, which complicates the choice of the optimal conditions for fast chemical reactions that occur at the phase boundary, in particular in liquid–gas systems. In flow of a gas–liquid mixture in the turbulent mode, the interface is deformed, which should change the hydrodynamic structure of the flow and the conditions of occurrence of fast chemical reactions. A study of the fundamental aspects of the manner in which hydrodynamic structure of the flow of a gas–liquid mixture changes will enable a scientifically substantiated choice of the optimal geometry of an apparatus and of the process mode. In view of the fact that tubular turbulent apparatus are used to perform fast liquid-phase chemical reactions [3], it seemed appropriate to evaluate the longitudinal mixing in a continuous (liquid) phase.

The aim of this study was to analyze the fundamental aspects of variation of the efficiency of longitudinal mixing in the liquid phase in a flow of a two-phase reaction mixture for the example of a gas–liquid flow in tubular apparatus of the diffuser–confuser design.

The coefficient of longitudinal mixing was calculated using the single-parameter diffusion model, which describes the most precisely the curves of distribution over the residence time of the reagents in the reaction zone [5].The key parameter of this model is the Bodenstein number (Peclet number for the case of longitudinal mixing) $\mathrm{Bo} = L^2 w/v_r E$, where w is the flow rate; v_r, reactor volume; E, coefficient of longitudinal mixing; and L, apparatus length. It can be seen that the numerical values of the Bodenstein criterion make it possible to calculate the coefficient of longitudinal mixing E and to evaluate the extent of

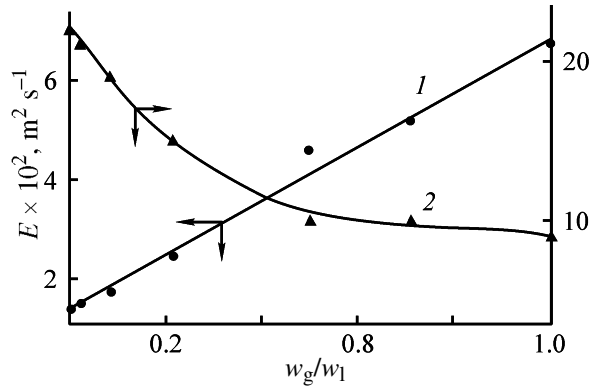

Fig. 1. (*1*) Coefficient of longitudinal mixing E and (*2*) Bodenstein number Bo vs. the ratio of the flow rates of the gas and liquid phases, w_g/w_l. w_l = 160 cm^3 s^{-1}, d_2 = 1.8 mm, d_d/d_c = 1.6.

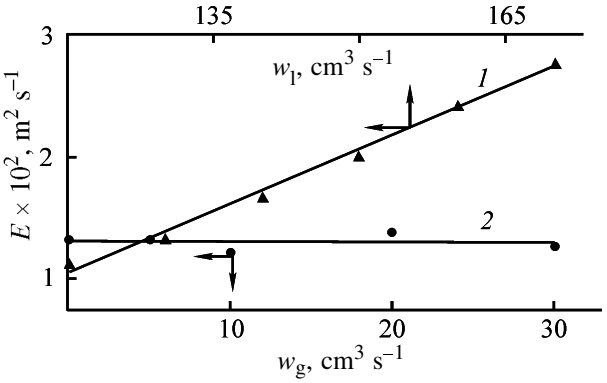

Fig. 2. Coefficient of longitudinal mixing E vs. the flow rate of (*1*) liquid (w_l, w_l/w_g = 5) and (*2*) gas (w_g, w_{l+g} = 160 cm^3 s^{-1}) phases. D_2 = 1.8 mm, d_d/d_c = 1.6.

deviation of the apparatus working mode from the idealized models of mixing (Bo $\to$ 0) and plug flow (Bo $\to \infty$). The design of the tubular turbulent apparatus and the procedure used to measure the curves of response to pulsed introduction of an inert indicator were described in [6].

The experimental setup for a study of the fundamental aspects of flow of two-phase systems comprises a six-section tubular turbulent apparatus of the diffuser–confuser design with inlet of the liquid phase through a coaxial pipe of diameter d_1 = 10 mm and gas feeding through a radially mounted pipe of diameter d_2 (0.8–7 mm). Length of the diffuser–confuser section, L_s = 72 mm; diameter of the wide part of the apparatus (diffuser), d_d = 24 mm; diameter of the narrow part of the apparatus (confuser), d_c = 15–24 mm. Tap water was used as the liquid phase. Its flow rate was measured with a rotameter installed at the line for flow feed into the turbulent apparatus. The flow rate of the gas phase was recorded with a gage installed at the outlet valve of a thick-walled metallic cylinder filled with compressed air (100–150 atm). The frequency curves of the size distribution of drops of the dispersed phase were measured by the method of photographing in high-intensity transmitted light with a SONY DSN-75 digital camera (exposure 1/1000 s, light sensitivity 400 units). To take into account the distortions associated with the bent shape of the apparatus shell, calibrating threads of a known size were introduced into its volume. The calculations used the central part of the longitudinal cross section of the apparatus ($0.75 \times d_d$), in which the discrepancy between the size of the calibration threads, calculated from the image obtained, and the true values was less than 1%. This procedure also made it possible to eliminate the possible image distortions associated with the refractive index of the glass apparatus shell and to take into account the fixed error [7].

As the content of gas in the gas–liquid flow increases, the coefficient of longitudinal mixing E grows (Fig. 1, curve *1*). This leads to a corresponding decrease in the Bodenstein number, with the result that the hydrodynamic structure of the moving reaction mixture approaches the ideal-mixing mode (Fig. 1, curve *2*). Thus, if fast chemical reactions occur under the conditions when a phase boundary exists in the liquid–gas system, including the case of boiling of the reaction mixture, the working mode of the apparatus approaches the ideal mixing mode with a high rate of longitudinal mixing. The high rate of longitudinal mixing results in that the distribution of the residence time of reagents in the reaction zone is broadened, which should be kept in mind when performing fast chemical reactions under real conditions. The coefficient of longitudinal mixing is strongly affected by an increase in the motion velocity of the liquid phase at a fixed gas content of the flow (Fig. 2, curve *1*). At the same time, changes in the ratio of flow rates of the gas and liquid phases, w_g/w_l, at a constant total rate of the gas–liquid flow has virtually no effect on the efficiency of longitudinal mixing (Fig. 2, curve *2*).

The longitudinal mixing in a tubular apparatus can be substantially intensified by changing the geometry of the gas–liquid flow. On passing from a cylindrical apparatus (d_d/d_c = 1) to that of a diffuser–confuser design (d_d/d_c = 3), the coefficient of longitudinal mixing increases by a factor of about 3 (Fig. 3, curve *1*). All other conditions being the same, changing the diameter of the inlet pipe of the gas phase does not affect the rate of longitudinal mixing (Fig. 3, curve *2*).

Generalization of the experimental data obtained made it possible to derive relations that could account for the influence exerted by various process parameters on the rate of longitudinal mixing in a two-phase flow in a tubular turbulent apparatus (Fig. 4). As the volume–surface diameter of particles of the dispersed phase increases to $d_{32} \approx 2$ mm ($d_{32} = \Sigma m_i d_i^3 / \Sigma m_i d_i^2$, where m_i is the number of particles of diameter d_i), the coefficient of longitudinal mixing decreases (Fig. 4, curve *2*). Further coarsening of particles of the dispersed phase has virtually no effect on the rate of mixing of the liquid phase along the apparatus axis. It was found that the coefficient of longitudinal mixing in the liquid phase is largely determined by the number of particles of the dispersed phase. The formation of a gas–liquid flow with a large specific surface area via breakup of the dispersed phase results in that the rate of longitudinal mixing in a continuous medium increases and the working mode of the apparatus closely approaches the ideal-mixing mode (Fig. 4, curve *1*). This makes it possible to create uniform reagent concentration fields directly in the reaction zone in the case of local occurrence of fast chemical processes in liquid–gas systems. If a fast chemical reaction occurs in a single-phase mixture, boiling in the reactor volume, with a two-phase flow formed, will intensify reagent mixing along the apparatus axis.

The competing influence of the particle size in the dispersed phase and the particle number on the rate of longitudinal mixing (Fig. 4) accounts for the dependences obtained in the study (Figs. 1–3). As the gas content of the flow (i.e., the w_g/w_l ratio) increases, particles of the dispersed phase become coarser and their number grows, which intensifies the longitudinal mixing (Fig. 1). Flow of the reaction mixture with a high velocity at a fixed gas content of the flow leads to an increase in the number of particles of the dispersed phase via its breakup and to a rise in the rate of mixing along the apparatus axis (Fig. 2, curve *1*). Apparently, this is the main reason why the reaction zone is "densified" when fast chemical processes are carried out in tubular turbulent apparatus in both single- [3] and two-phase [8] systems. As the residence time of reagents in the reaction zone decreases as the output capacity of the apparatus becomes higher, the yield of the product (process rate) increases, which is determined by intensified homogenization of the reaction mixture, including that in longitudinal mixing. Changing the content of the gas phase at the same total gas–liquid flow rate leads to a slight change in the number of particles of the dispersed phase and, accordingly, in the coefficient of longitudinal mixing (Fig. 2, curve *2*). The rise in the number of particles

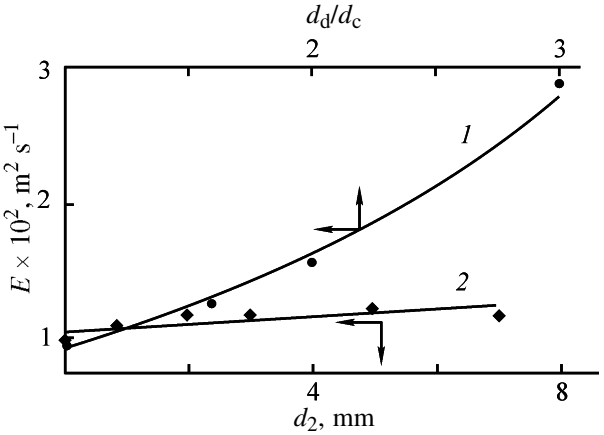

Fig. 3. Coefficient of longitudinal mixing E vs. (*1*) d_d/d_c ratio (d_2 = 3 mm) and (*2*) diameter of the inlet pipe for the gas phase d_2 (d_d/d_c = 2). w_l = 150 cm^3 s^{-1}, w_l/w_g = 3.

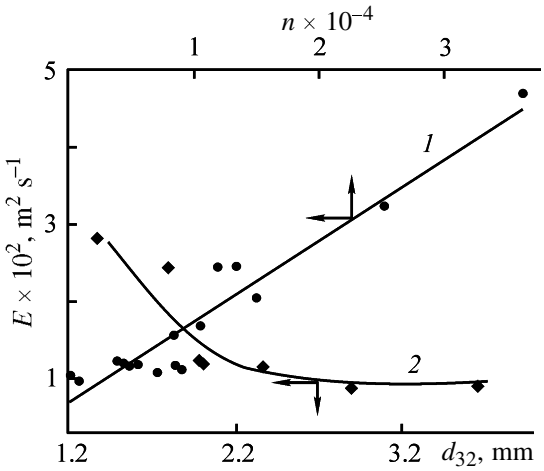

Fig. 4. Generalized dependences of the coefficient of longitudinal mixing E, on (*1*) number n and (*2*) volume–surface diameter d_{32} of particles of the dispersed phase in a gas–liquid flow in a tubular turbulent apparatus.

of the dispersed phase via dispersion predetermines an increase in the rate of longitudinal mixing on passing from a cylindrical apparatus to that of the diffuser–confuser type (Fig. 3, curve *1*).

The hydrodynamic mode of flow of the gas–liquid reaction mixture is affected by the spatial position of a tubular turbulent apparatus of the diffuser–confuser design. In the case of a flow of a single-phase reaction mixture, the position of the apparatus has virtually no effect on the rate of longitudinal mixing (Fig. 5, curve *1*). The gas–liquid flow is characterized by the minimum value of the coefficient of longitudinal mixing at apparatus inclination angles α from –40° to 0°. A vertical position of the tubular apparatus (α = –90°) with a downward direction of the gas–liquid flow determines the maximum value of the coefficient of

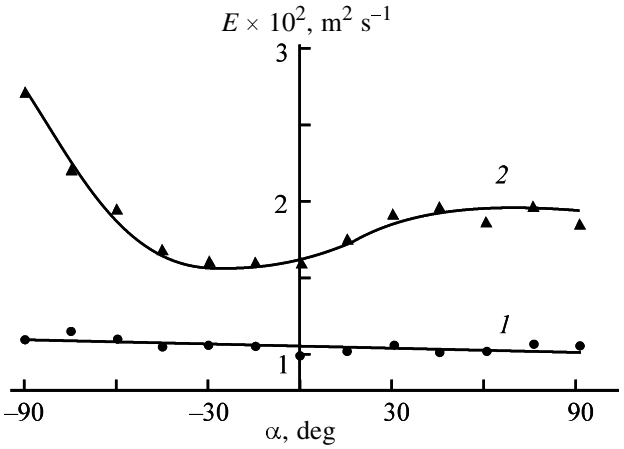

Fig. 5. Coefficient of longitudinal mixing E for (*1*) single- and (*2*) two-phase flows vs. the inclination angle α of the apparatus. d_2 = 3 mm, d_d/d_c = 2, w_l = 170 cm^3 s^{-1}, w_g = 40 cm^3 s^{-1}; position of the apparatus: α = 0°, horizontal; α = 90°, vertically upwards; and α = –90°, vertically downwards.

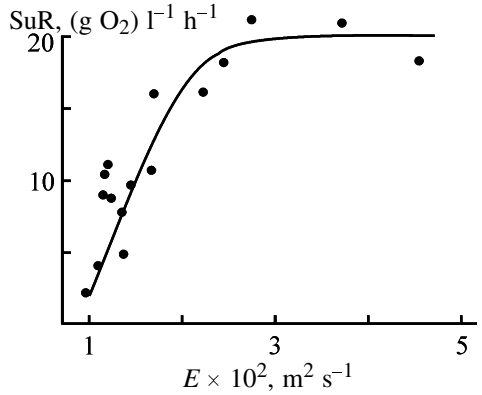

Fig. 6. Generalized dependence of the sulfite number of the reactor SuR on the coefficient of longitudinal mixing E in a gas–liquid (water–air) flow in a tubular turbulent apparatus.

longitudinal mixing. It should be noted that, in this case, the size of particles of the dispersed phase and, accordingly, their number remain unchanged. Apparently, the rate of longitudinal mixing of the gas–liquid flow changes on varying the position of the apparatus by applying to the flowing reaction mixture gravitational forces complicated by strong differences in the density of the constituent components. The dependence of the hydrodynamic mode of flow of the gas–liquid mixture on the position of the apparatus creates additional opportunities for varying the conditions of fast chemical reactions in liquid–gas systems. When carrying out fast chemical reactions in two-phase systems, it is preferable to mount the tubular turbulent apparatus vertically, with the reagents fed from the top. This makes it possible to create an intensive longitudinal mixing and to simplify the discharge of the reaction mixture on terminating the process.

The formation of a reaction mixture with a developed phase boundary and intensive longitudinal mixing in tubular turbulent apparatus predetermines a pronounced increase in the mass-exchange coefficient in the liquid phase. In this case, it becomes possible to effectively diminish the diffusion limitations in the course of fast chemical reactions in liquid–gas systems. This is confirmed by the dependence of the intensity of liquid-phase oxidation, characterized by the "sulfite number of reactor" SuR (amount of oxygen absorbed by unit reaction volume in unit time [8]), on the hydrodynamic structure of flow of the reaction mixture (Fig. 6). It can be seen that raising the coefficient of longitudinal mixing by any of the methods considered in this study leads to an increase in the specific rate of dissolution of atmospheric oxygen in water and, as a result, causes acceleration of the liquid-phase oxidation. In addition, the dependence SuR = $f(E)$ (Fig. 6) has the form of a curve that levels off, and there is no need to make the rate of longitudinal mixing higher than $E = (2–3) \times 10^{-2}$ m^2 s^{-1}.

The fundamental aspects of how the efficiency of longitudinal mixing varies in gas–liquid flows in tubular turbulent apparatus of diffuser–confuser design enable a scientifically substantiated choice of the optimal geometry of the zone of reagent mixing and of the process mode. The formation of disperse systems with a developed phase boundary and, consequently, with a high rate of longitudinal mixing makes it possible to create uniform profiles of reagent concentrations and temperature in a local region in which fast chemical reaction occur and to diminish the diffusion limitations. The correlation between the rate of longitudinal mixing and the efficiency of convective heat exchange in tubular apparatus predetermines the possibility of controlling the process by external thermostating in the course of fast chemical reactions in liquid–gas systems. Apparently, the dependence of the rate of longitudinal mixing in the liquid phase on the particle size of the dispersed phase and particle number, obtained for liquid–gas systems, will be also applicable to description of fast chemical reactions in liquid–liquid and liquid–solid systems.

CONCLUSIONS

(1) The coefficient of longitudinal mixing in the liquid phase in flow of gas–liquid reaction systems in tubular turbulent apparatus of diffuser–confuser

design decreases as particles of the dispersed phase become coarser and is directly proportional to their number.

(2) The rate of a fast (diffusion-controlled) chemical process in a gas–liquid flow depends on the coefficient of longitudinal mixing. Raising the rate of longitudinal mixing in tubular apparatus by changing the geometry and hydrodynamic parameters of flow and the ratio of the reacting components makes it possible to effectively diminish the diffusion limitations in performing fast chemical reactions in liquid–gas systems.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Aromatic Alcohols and Their Alkanoic Acid Esters

M. K. Mamedov

Institute of Petrochemical Processes, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received July 26, 2005; in final form, January 2006

Abstract—The reaction of benzene with ethylene and propylene oxides in a helium atmosphere with aluminum chloride as a catalyst and the esterification of the resulting alcohols with saturated monocarboxylic acids in the presence of the heterogeneous catalyst KU-2-8 were studied.

DOI: 10.1134/S1070427206030141

Aldehydes, ketones, and higher alcohols have usually pleasant odor and are synthetic fragrance compounds [1–3]. Some aromatic alcohols and their esters are successfully used in perfume industry as components in preparation of perfume compositions, eau de Colognes, food essences, and odorants for detergents [4–6].

The procedures of synthesis of aromatic alcohols by the reaction of benzene with ethylene and propylene oxides [7, 8], hydrogenation of styrene oxide [9] and cinnamic aldehyde [10], and oxidation of cumene [11] are well known.

Taking account a great practical significance of aromatic alcohols, we developed an efficient procedure of synthesis of 2-phenylethanol and 1-phenyl-2-propanol by hydroxyalkylation of benzene with ethylene and propylene oxides in the presence of aluminum chloride as a catalyst [12].

The reaction proceeds in two steps. In the first step, complexes **A** and hydrogen chloride are formed:

$$C_6H_6 + 3CH_2\overset{O}{\diagdown\diagup}CHR + AlCl_3 \rightarrow \underset{\mathbf{A}}{(C_6H_5CH_2\underset{R}{\underset{|}{C}}HO)_3Al} + 3HCl.$$

In the second step, decomposition of complexes **A** with water yields aromatic alcohols **I** and **II**:

$$\mathbf{A} + H_2O \rightarrow \underset{\mathbf{I, II}}{C_6H_5CH_2\underset{R}{\underset{|}{C}}HOH} + Al(OH)_3,$$

where R is H (**I**) and CH_3 (**II**).

Hydrogen chloride formed in the first step reacts with the initial oxides to give as by-products chlorohydrins **III**–**VI**:

$$HCl + RCHCH_2 \rightarrow \underset{\mathbf{III, IV}}{RCH(OH)CH_2Cl}, \quad \underset{\mathbf{V, VI}}{RCH(Cl)CH_2OH}$$

where R is H (**III, V**), CH_3 (**IV, VI**).

Chlorohydrins **III**–**VI** adversely affect the yield of alcohols **I** and **II**; therefore, to remove hydrogen chloride from the system we used an inert gas (helium); by so doing, we significantly increased the yield of the target products **I** and **II**.

The influence of various factors on the yields of **I** and **II** was studied. We found that the optimum conditions for hydroxyalkylation of benzene are the temperature of 6–7°C, helium flow rate of 2 l min^{-1}, and molar ratio benzene : organic oxide : $AlCl_3$ equal to 5 : 3 : 1. Under these conditions, the yield of alcohols **I** and **II** reaches 90–95% based on organic oxides (compare to the yield of 30–41% for the procedure described in [13]).

To make the process waste-free, hydrogen chloride was passed through aluminum hydroxide to obtain aluminum chloride and helium was purified to remove HCl and repeatedly used in the process.

The composition and structure of **I** and **II** were proved by elemental analysis and IR and ^1H NMR spectra. In the IR spectra the bands at 3300, 3020, 1610, 1500, 745, and 695 cm^{-1} are assigned to the skeleton vibrations of monosubstituted benzene; the absorption at 900 cm^{-1} corresponds to bending modes of the C–H bond; at 1380 cm^{-1}, to methyl groups; at

3440 cm^{-1}, to hydroxy groups; at 1060 cm^{-1}, to primary hydroxy groups; the absorption in the range 1400–1250 cm^{-1} belongs to in-plane bending mode of the bound OH group.

In the ^1H NMR spectra, phenyl protons give signals in the range 6.8–7.28 ppm; methyl protons, at 1.38 ppm; and protons at the tertiary carbon atom and OH group, at 4.75 and 2.60–2.70 ppm, respectively.

With the aim to synthesize esters of the aromatic alcohols synthesized, we studied their esterification with saturated monocarboxylic acids. Contrary to the existing procedures, in this reaction we used a heterogeneous catalyst, ion-exchange resin KU-2-8:

$$\mathbf{I},\ \mathbf{II} + R'COOH \xrightarrow[-H_2O]{\text{KU-2-8}} C_6H_5CH_2\underset{\displaystyle R}{\underset{|}{C}}HOC\overset{\displaystyle O}{\overset{\|}{}}R',$$

VII–XIX

where R is H (**VII**–**XII**), CH_3 (**XIII**–**XIX**); R' is CH_3 (**VII**, **XIII**), C_2H_5 (**VIII**, **XIV**), $CH_3(CH_2)_2$ (**IX**, **XV**), $(CH_3)_2CH$ (**X**, **XIV**), $CH_3(CH_2)_3$ (**XI**, **XVII**), $(CH_3)_2CHCH_2$ (**XII**, **XIX**).

The use of the KU-2-8 catalyst significantly simplifies synthesis of esters (**VI**–**XIX**), since in this case neutralization of the catalyzate, its washing, and drying before distillation are eliminated from the flowsheet.

Removal of water formed in the course of esterification from the system prevents the reverse reaction and significantly increases the yield of the target compounds (to 82–95%).

The structure of the synthesized esters **VI**–**XIX** was proved by the IR spectra. The strong absorption bands at about 1720 and 1200 cm^{-1} suggest the presence of the ester group. In the ^1H NMR spectra, the phenyl protons give a singlet at 7.20 ppm; methyl protons, at 2.10 ppm; and ethylene (CH_2CH_2) protons, at 2.75 and 3.82 ppm.

EXPERIMENTAL

The initial substances were freshly distilled chemically pure grade compounds, whose physicochemical characteristics corresponded to published data [14].

The composition and purity of alcohols **I** and **II** and their esters **VI**–**XIX** were determined by gas–liquid chromatography on an LKhM-8 MD chromatograph; stationary phase polyethylene glycol adipate applied to Sferokhrom (10 wt %), column length 2 m, vaporizer temperature 250°C, column temperature 120–170°C, detector temperature 120–170°C, and current 100 mA. The purity of alcohols **I** and **II** and esters **VI**–**XIX** was 99.0–99.5%.

The IR spectra were recorded on a UR-20 device in CCl_4. The ^1H NMR spectra of solutions of compounds in CCl_4 were recorded on a Tesla BS-487 spectrometer operating at 80 MHz at 25°C; HMDS was used as an internal reference; the accuracy of measuring chemical shifts was ±0.05 ppm.

Hydroxyalkylation of benzene was performed as follows. Benzene was charged into an enameled reactor and anhydrous $AlCl_3$ was added in portions over a period of 1 h; then, a helium from a cylinder was passed through the mixture at a flow rate of 2 l min^{-1}. The released gas was passed through the other reactor containing a suspension of aluminum hydroxide. Then, the calculated amount of ethylene or propylene oxide was fed into the enameled reactor over a period of 3 h. The reaction was carried out at 6–7°C; this temperature was maintained up to the end of the process by passing cooled water through the reactor jacket, since the process is exothermic. After completion of feeding the oxide, the reaction mixture was stirred for 1 h and cold distilled water was added to decompose the resulting complex **A**. In so doing, the upper layer was separated, dried over silica gel, and aromatic alcohols **I** and **II** were isolated by fractional distillation.

2-Phenylethanol (I). From 1560 g of benzene, 528 g of ethylene oxide, and 534 g of $AlCl_3$, 1317.6 g of alcohol **I** was obtained (90%); bp 91–92°C (8 mm Hg), d_4^{20} = 1.0209, n_D^{20} = 1.5306. IR spectrum, ν (cm^{-1}): (CH of phenyl radical) 3330, 3020, 1610, 1500, 900, and 745; (CH_2CH_2) 1440–1470; (OH) 3440, 1060. ^1H NMR spectrum (δ, ppm): (OH) 2.60, (CH_2) 2.85, (CH_2) 3.26, (CH of phenyl radical) 7.20.

Found, %: C 78.45, H 8.25.
$C_8H_{10}O$. Calculated, %: C 78.65, H 8.25.

1-Phenyl-2-propanol (II). From 1170 g of benzene, 522 g of propylene oxide, and 400.5 g of $AlCl_3$, 1138.2 g of alcohol **II** was obtained (93%); bp 92–93°C (2 mm Hg), d_4^{20} = 1.0047, n_D^{20} = 1.5218. IR spectrum, ν (cm^{-1}): (CH of phenyl radical) 3330, 3018, 1605, 900, and 740; (CH_3) 1380, (CH_2 and CH) 1440, 1340; (OH) 3440, 1056. ^1H NMR spectrum (δ, ppm): (OH) 2.60, (CH_2) 1.85, (CH_2) 2.80, (CH) 4.58, (CH of phenyl radical) 7.25.

Found, %: C 79.36, H 8.81.
$C_9H_{12}O$. Calculated, %: C 79.37, H 8.88.

* Odor: **VII**, fruit (tint of greens); **VIII**, fruit (rose tint); **IX**, fruit (rose tint); **X**, weak fruit; **XI**, delicate fruit; **XII**, apricot (rose tint); **XIV**, grass; **XVI**, weak flower; **XVII**, weak fruit; **XIX**, flower fruit.

Organoleptic tests[1] of the synthesized alcohols show that 2-phenylethanol has rose odor, and 1-phenyl-2-propanol, hyacinth odor.

Esters **VI**–**XIX** of alcohols **I** and **II** (see table) were prepared using a Dean–Stark trap with KU-2-8 catalyst in an amount of 10 wt % based on the raw materials in benzene at 80–85°C. The water release was complete in 4–5 h. The molar ratio of reacting components **I**, **II** : carboxylic acid : solvent was 1 : 1 : 2.

CONCLUSIONS

(1) Aromatic alcohols that are synthetic fragrance compounds were synthesized by hydroxyalkylation of benzene with ethylene and propylene oxides in an inert medium with aluminum chloride as a catalyst (yield 90–93%).

(2) Esterification of the aromatic alcohols synthesized with saturated aliphatic monocarboxylic acids in the presence of a heterogeneous catalyst, KU-2-8 ion-exchange resin, yields esters (yield 82–95%) with pleasant odor, which can be used as a component of perfumes and essences.

[1] Organoleptic tests were performed at the All-Russian Research Institute of Synthetic and Natural Fragrance Compounds (Moscow).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Tetraalkylammonium Salts of Naphthimide and Its Halo and Nitro Derivatives

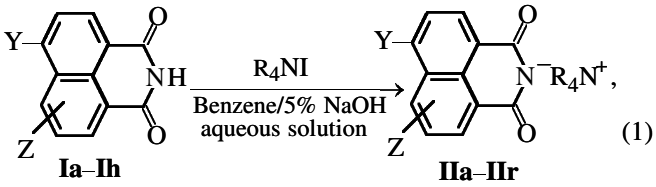
V. F. Anikin and N. F. Fed'ko

Mechnikov National University, Odessa, Ukraine

Received July 26, 2005

Abstract—Synthesis of tetraalkylammonium salts of naphthimide and its derivatives was studied.

DOI: 10.1134/S1070427206030153



Being efficient phosphors, derivatives of naphthimide {1*H*-benzo[*de*]isoquinoline-1,3(2*H*)dione} are widely used in preparing dyes [1], optical brighteners for natural and synthetic materials [2], day fluorescent pigments [3], blends for crack detection on solid surfaces [4], and active compositions for radioelectronics [5]. Several N-substituted naphthimides are biologically active compounds, which can be used as precursors of antitumor and antiviral preparations [6].

N-Alkylnaphthimides are mainly prepared by one-step acylation of primary amines with the corresponding naphthalic anhydrides. However, side reactions proceeding at the aromatic ring in the course of aminolysis of 4- and 4,5-halo- and nitro-substituted naphthalic anhydrides decrease the yield of the final products. Moreover, because of low solubility of mono- and especially disubstituted anhydrides in organic solvents, acylation should be performed under rather rigid conditions [7].

Since six-membered imide ring in the naphthimide molecule is fairly stable in alkaline solutions, its sodium and potassium salts [8] can be used as nucleophilic reagents. However, the salts of halo- and nitro-substituted naphthimides are also poorly soluble in organic solvents. Certain disadvantages are also typical for acylation of preliminarily prepared potassium and sodium naphthimides under the conditions of phase-transfer catalysis using tetraalkylammonium salts [9, 10]. For example, concentrated alkaline solutions cause hydrolysis of halogenated alkanes.

Assuming that the above disadvantages of known acylation procedures can be eliminated using tetraalkylammonium salts of naphthimide, we developed a new method for preparing these compounds.

The synthesis was performed in benzene–5% NaOH aqueous solution at room temperature by anion exchange and subsequent extraction of the desired salt into the organic solvent; the molar ratio of the corresponding naphthimide and tetraalkylammonium salt was 1.5 : 1. Using this procedure, we prepared tetraalkylammonium naphthimides **IIa**–**IIq**:

Ia–**Ih** **IIa**–**IIr** (1)

I: Y = H, Z = H (**a**), 2-Br (**b**), 3-NO_2 (**c**), 4-Cl (**d**), 4-Br (**e**), 4-NO_2 (**f**), 4-morpholino (**g**); Y = Cl, Z = 4-Cl (**h**); **II**: R = C_8H_{17}, Y = H, Z = H (**a**), 2-Br (**b**), 3-NO_2 (**c**), 4-Cl (**d**), 4-Br (**e**), 4-NO_2 (**f**), 4-morpholino (**g**); Y = Cl, Z = 4-Cl (**h**); R = C_6H_{13}, Y = H, Z = H (**i**), 2-Br (**j**), 3-NO_2 (**k**), 4-Cl (**l**), 4-Br (**m**), 4-NO_2 (**n**); Y = Cl, Z = 4-Cl (**o**); R = C_4H_9, Y = H, Z = H (**p**), 4-Cl (**q**); and Y = Cl, Z = 4-Cl (**r**).

Tetraalkylammonium iodides are available reagents allowing reliable control of the reaction completeness because, in contrast to nitric and hydrochloric acids and to naphthimide, HI acts as a strong acid in the acetic acid solution [11]. This allowed evaluation of the content of tetraalkylammonium naphthimides in the presence of iodide ions in glacial acetic acid using perchloric acid, which is consumed in titration of acetate ions (in amounts equivalent to naphthimide ions) in accordance with the following reactions:

$$\textbf{IIa–IIr} + AcOH \rightarrow \textbf{Ia–Ih} + R_4N^+AcO^-,$$
$$R_4N^+AcO^- + HClO_4 \rightarrow R_4N^+ClO_4^- + AcOH. \quad (2)$$

The degree of anion exchange depends on the structure of the tetraalkylammonium cation. With decreas-

Table 1. Alkylation time τ, yield of naphthimides **IIIa**–**IIIf**, and their melting points

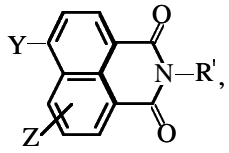
ing number of carbon atoms bound to the central nitrogen atom of tetraalkylammonium cations, their lipophilicity decreases, thus decreasing the extraction constant. Under similar conditions (vigorous stirring of the reaction mixture for 2 h at room temperature), tetraoctylammonium iodide is converted into the corresponding naphthimide salt in one treatment cycle, whereas the degrees of conversion of tetrahexyl- and tetrabutylammonium iodides are 70 and 45%, respectively. Therefore, in the last two cases the organic phase was separated and repeatedly treated with an aqueous alkaline solution of naphthimide of the same concentration up to complete conversion of the initial salt.



Tetrahexyl- and tetrabutylammonium salts of naphthimide can also be prepared in high yields by conversion of tetraalkylammonium iodide (remaining after extraction) into nitrate using lead or silver nitrate. Nitrate ion is more hydrophilic than iodide [12], and thus its exchange for the naphthimide ion is easier. Since in this case the completeness of extraction of naphthimide ions cannot be monitored because both nitrate and naphthimide anions are titrated with perchloric acid, the reaction completion was judged from the content of unchanged naphthimide in the aqueous phase.

The composition and structure of the resulting compounds **IIa**–**IIr** were determined by elemental analysis and ^{1}H NMR spectroscopy. As compared to the corresponding naphthimides, the signal of aromatic protons in the ^{1}H NMR spectra of the resulting products is shifted upfield and the greatest shielding (by 0.15–0.30 ppm) is observed for protons occurring in the *ortho* and *para* positions to the imide ring. This is probably due to the increased electron density on these carbon atoms owing to the effect of the negatively charged imide fragment and corresponding increase in the shielding constant. The signals of aromatic and aliphatic protons are observed at 7.7–8.9 and 0.8–3.2 ppm, respectively. The spin–spin coupling constants of aromatic protons are typical of naphthimide derivatives [7, 10, 13].

Salts **IIa**–**IIr** are crystalline compounds with distinct melting points (mp); they are readily soluble in polar and nonpolar aprotic solvents and can be stored for a long time. These compounds are convenient reagents for introduction of naphthimide fragment under the mild conditions. For example, *N*-alkylnaphthimides **IIIa**–**IIIf** are formed in nearly quantitative yields in reactions of salts **IId, IIf, IIh, IIl, IIn, IIo, IIq,** and **IIr** with alkylating agents in benzene at 40°C within 25–45 min. Salts of 4-chloro- (**IId, IIm, IIq**), 4-nitro- (**IIf, IIn**), and 4,5-dichloronaphthimides (**IIh, IIo, IIr**) were used to study the possibility of preparing various derivatives of *N*-alkylnaphthimide:

IId, **IIf**, **IIh**, **IIl**, **IIn**, **IIo**, **IIq**, **IIr**

III: Y = H, Z = Cl; R' = C_4H_9 (**a**), C_8H_{17} (**b**); Z = NO_2, R' = C_4H_9 (**c**), C_8H_{17} (**d**); Y = Z = Cl, R' = C_4H_9 (**e**), C_8H_{17} (**f**); X = Cl, Br, I.

The conditions of alkylation of salts **IId, IIf, IIh, IIl, IIn, IIo, IIq**, and **IIr** and the yields and melting points of the resulting products **IIIa**–**IIIf** are given in Table 1. As seen, the reaction rate and yield of *N*-alkylnaphthimides are almost independent of the lengths of hydrocarbon chain in the alkylating agent and tetraalkylammonium cation. On passing from chloro- to iodoalkanes, the reaction rate increases, which agrees with theoretical data [14].

Tetraalkylammonium salts can also be used to prepare bisnaphthimides under mild conditions in high yields. Kupriyan *et al.* [15], when preparing these compounds by alkylation of halogen-substituted

naphthimides with dibromoalkanes under the conditions of phase-transfer catalysis, observed hydrolysis of bromoalkylnaphthimide formed in the first step and a decrease in the yields of the desired bisnaphthimides [from 66% (1,6-dibromohexane) to 24% (1,3-dibromopropane)] with decreasing length of the hydrocarbon chain in the alkylating agent. At the same time, alkylation of tetraoctylammonium salts of 4-chloro- (**IId**) and 4-nitronaphthimide (**IIf**) in benzene proceeds without hydrolysis, with nearly quantitative yields (90–95%) of 4-chloro- (**IVa**–**IVc**) and 4-nitrobisnaphthimides (**IVd**–**IVf**).

(4)

IV, Y = Cl, *n* (**a**) 3, (**b**) 4, (**c**) 6; Y = NO_2, *n* (**d**) 3, (**e**) 4, and (**f**) 6.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker WM-400 device (DMSO-d_6, TMS internal reference). The reaction progress and purity of the resulting compounds were monitored by thin-layer chromatography (TLC) using Silicagel 60 F_{254} plates (Merck), with subsequent UV development.

The starting naphthimides **Ia**–**Ih** were obtained by the procedure presented elsewhere [16]; the required (0.1 M) solution of perchloric acid in glacial acetic acid was prepared; the actual content of perchloric acid was determined by titration with sodium biphthalate [17].

Tetraoctylammonium iodide. Octylamine (26 g), octyl iodide (168 g), and potassium carbonate (55 g) were heated with stirring on a water bath at 90°C for 20 h. After cooling, water was added to the reaction mixture to dissolve inorganic salts, and the product was extracted with chloroform. The organic layer was separated, washed several times with a 10% aqueous ammonia solution and with water, and then dried with sodium sulfate. The solvent was distilled off, and after recrystallization from ethanol tetraoctylammonium iodide was obtained as colorless plates; yield 84 g (70%), mp 121–122°C.

Tetrahexylammonium iodide. Trihexylamine (32.4 g) and hexyl iodide (38.2 g) were heated with stirring on a water bath at 90°C for 18 h. The reaction product was isolated as described above. Tetrahexylammonium iodide was obtained as colorless plates; yield 55.2 g (78%), mp 132–134°C.

Tetraoctylammonium salts of naphthimides IIa–IIh (Table 2). Appropriate finely dispersed naphthimide (1.5 mmol) was mixed with a 5% NaOH aqueous solution (50 ml) and a solution of tetraoctylammonium iodide (1 mmol) in benzene (50 ml). The reaction mixture was vigorously stirred at room temperature for 2 h and filtered. The organic layer was separated, washed with water to neutral reaction, and dried with sodium sulfate; the solvent was distilled off. The aqueous solution was acidified, and unchanged naphthimide was regenerated.

Tetrahexyl- and tetrabutylammonium salts of naphthimides IIi–IIr. *Procedure A.* Appropriate finely dispersed naphthimide (1.5 mmol) was mixed with 5% NaOH aqueous solution (50 ml) and a solution of tetrahexyl- or tetrabutylammonium iodide (1 mmol) in benzene (50 ml). The reaction mixture was vigorously stirred at room temperature for 2 h, filtered, and the organic layer was separated. Then the treatment of the organic phase with aqueous alkaline solution of naphthimide of the same concentration was repeated under similar conditions two times (tetrahexylammonium salts **IIi**–**IIo**) and five times (tetrabutylammonium salts **IIp**–**IIr**). Further treatment of the organic and aqueous layers was performed as described above.

Procedure B. After the first extraction of appropriate naphthimide anion (procedure A), the reaction mixture was mixed with $AgNO_3$ (0.34 g) or $Pb(NO_3)_2$ (0.66 g), and the precipitate was filtered off. Further treatment of the organic and aqueous layers was performed as in procedure A.

To determine the molecular weights of salts **IIa**–**IIr**, a portion of salt **IIa**–**IIr** (0.2 g) was dissolved in acetic acid (25 ml), two drops of Crystalline Violet solution were added, and the resulting solution was titrated with a 0.1 M $HClO_4$ solution up to change of the solution color from violet to blue-green. The molecular weight of compounds **IIa**–**IIr** was evaluated from the following expression:

$$M = m \times 1000/V_a c_m,$$

where m is the weighed portion of salt **IIa**–**IIr** (g), c_m is the concentration of $HClO_4$ solution (M), and V_a is the volume of perchloric acid consumed in titration (ml).

The reactions of tetraalkylammonium salts of naphthimides with alkyl halides (Table 1) were performed as follows. A solution of tetraalkylammonium salt of naphthimide (1 mmol) in benzene (50 ml) was mixed with appropriate alkyl halide (1 mmol). The reaction mixture was stirred at 40°C for 20–45 min, and then the benzene solution was filtered through an alumina bed to remove tetraalkylammonium halide. Then the solvent was evaporated, and the reaction product was recrystallized from ethanol.

To prepare bisnapthimides, a solution of tetraalkylammonium salt of naphthimide (1 mmol) in benzene (50 ml) was mixed with appropriate dibromoalkane (2 mmol). The reaction mixture was stirred at 40°C for 30 min, and the reaction product was filtered off and washed with ethanol; the yields of the final products were 90–95%.

CONCLUSIONS

(1) Tetraalkylammonium salts of naphthimides, which are convenient precursors for introduction of naphthimide fragment, were prepared in high yield (94–99%) by anion exchange and extraction of the desired product into the organic phase.

(2) Tetraalkylammonium salts of naphthimides are alkylated under the mild conditions to form *N*-alkylnaphthimides in high yields (90–98%).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Formation of Formic Acid and Cyclohexyl Formate in Oxidation of Cyclohexane

Kuznetsk Coal Fields State Technical University, Kemerovo, Russia

Received December 16, 2005

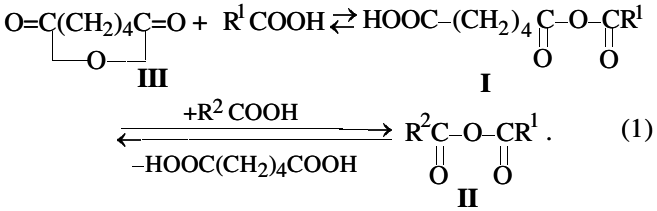
Abstract—The consistency of the suggested mechanisms of formic acid formation with the composition of products formed in the industrial process of cyclohexane oxidation was examined. The role of formic acid in the formation of cyclohexyl esters of mono- and dicarboxylic acids was elucidated.

DOI: 10.1134/S1070427206030165

Mono- and dicarboxylic acids and their cyclohexyl esters are among the main by-products of cyclohexane oxidation to cyclohexanol and cyclohexanone [1, 2]. It is known [1–4] that carboxylic acids are formed by oxidative cleavage of the C–C bond along numerous pathways, mainly in steps following the formation of a ketone. The pathways of formation of formic acid are, apparently, among the least understood. The main pathway of formation of esters derived from secondary alcohols (including cyclohexanol) is alcoholysis of mixed anhydrides of carboxylic acids with secondary alcohols present in the reaction mixture [4–6]. Fast reactions of acyl interchange result in formation of esters containing acyl residues not only from the anhydride initially formed by oxidative degradation (e.g., adipic anhydride), but also from all mono- and dicarboxylic acids present in the reaction medium [4, 6, 7]. Although it was suggested [7] that in alcoholysis of mixed anhydrides two esters are formed with equal probability, irrespective of the structure of the carboxylic acid residue, there are indications [8] that in alcoholysis of mixed formic acid anhydrides the formates are formed preferentially; therefore, increased yield of formates in autooxidation can be expected. This assumption is well consistent with the fact [1] that cyclohexyl formate is the major product among cyclohexyl esters of monocarboxylic acids formed by oxidation of cyclohexane.

This study concerns the pathways of formic acid formation in the industrial process of cyclohexane oxidation to cyclohexanol and cyclohexanone and elucidation of the role of formic acid in ester formation.

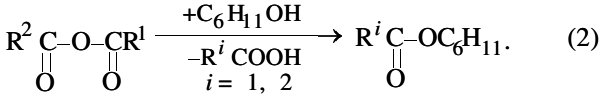
EXPERIMENTAL



Samples of oxidized cyclohexane (150–155°C, 0.04% cobalt naphthenate, 0.8 MPa) were taken from the oxidation shop of caprolactam production plant of Azot Joint-Stock Company (Kemerovo).

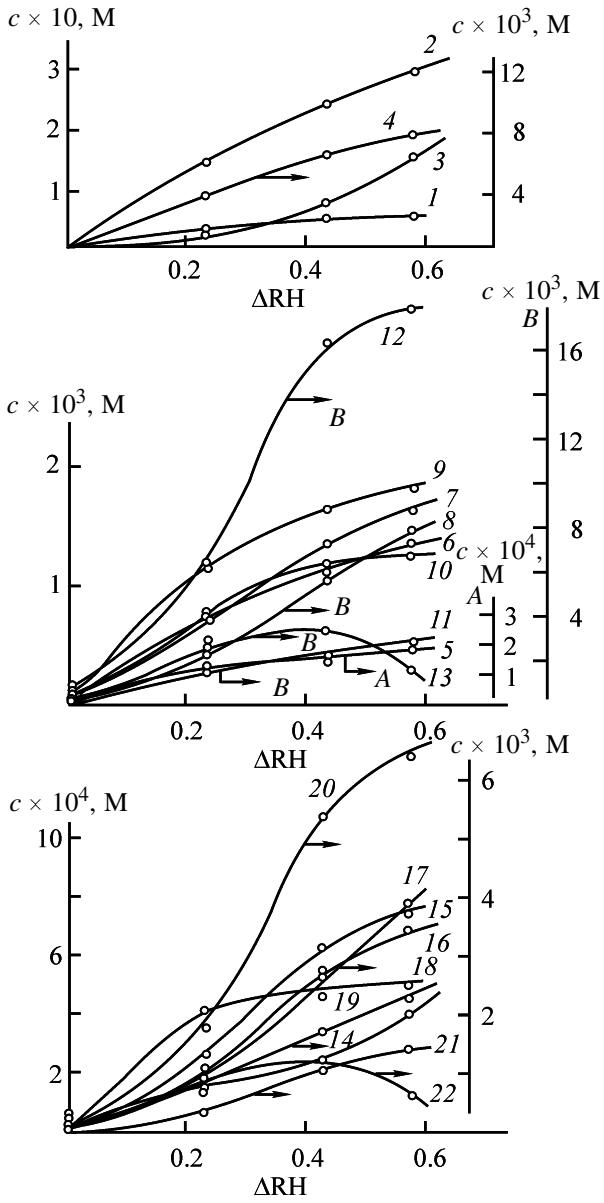
The products of cyclohexane oxidation were determined by GLC. The products were identified by comparison of the retention times of the components with those of reference substances in columns with stationary phases of various polarities. Glutaric acid monoaldehyde was prepared by oxidation of excess glutaraldehyde with aqueous $KMnO_4$ at 0°C. Compounds containing carboxy groups were converted prior to determination to the methyl esters by treatment with diazomethane. Formic acid in cyclohexane oxidation products was determined by a specially developed procedure [8]. After the extraction of water-soluble acids with water from the mixture of oxidation products, these acids were converted to potassium salts by treatment with an alcoholic solution of alkali followed by vacuum evaporation. The dry residue of the salts was treated successively with acetyl chloride and benzyl alcohol in pyridine. Then the content of benzyl formate, corresponding to the concentration of formic acid, was determined. The determination of the total content of mixed anhydrides in oxidized cyclohexane was based on the same principle. Samples were treated with a mixture of formic acid and dodecyl alcohol in pyridine. The amount of dodecyl formate formed in the process (determined by GLC) corresponded to the total content of mixed anhydrides in the sample. Prior to determination of cyclohexanol and cyclohexanone in oxidized cyclohexane, samples

were reduced with triphenylphosphine [9]. The oxidation products were analyzed by GLC using the following stationary phases: Carbowax 6000 on Chromaton N-AW-DMCS 0.250–0.315 mm and 5% XE-60 on Chromaton N-AW 0.20–0.25 mm. Peroxy compounds were determined colorimetrically with a reagent containing Fe^{2+} ions and *N*,*N*-dimethyl-*p*-phenylenediamine [10].



We determined the content of mono- and dicarboxylic acids and their cyclohexyl esters in samples of oxidized cyclohexane taken from the cascade of industrial reactors of the cyclohexane oxidation shop and of recycled cyclohexane (see figure). The qualitative composition of carboxylic acids and cyclohexyl esters is, on the whole, well consistent with published data [1, 2]. The absence of acetic and propionic acids and their esters in oxidized cyclohexane is due to low conversion of cyclohexane. According to [1], these acids appear only at a cyclohexane conversion of 7% and over. We detected for the first time in oxidized cyclohexane glutaric acid monoaldehyde and cyclohexyl ester of adipic acid monoaldehyde. The ratio of the yields of cyclohexyl esters to the content of the corresponding acids in oxidized cyclohexane (Table 1) varies within narrow limits, except for cyclohexyl formate and formic acid. With increasing conversion, this ratio in some cases slightly increases and in other cases slightly decreases. For cyclohexyl formate and formic acid, this ratio is considerably higher than for other mono- and dicarboxylic acids and their cyclohexyl esters.

According to the existing views [4, 6, 7], esters of secondary alcohols are formed in the course of oxidation processes mainly by alcoholysis of mixed anhydrides with secondary alcohols present in the reaction medium. In oxidation of cyclohexane, mixed anhydrides (including those containing a formic acid residue) arise from fast reactions of acyl interchange of adipic anhydride (initial product of oxidative degradation of cyclohexane ring [4]) with carboxylic acids:



(1)

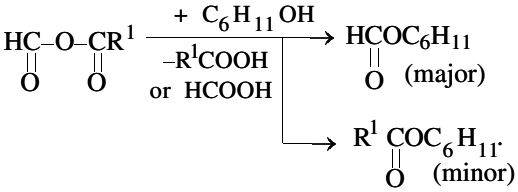
The reaction of mixed anhydrides with cyclohexanol yields a mixture of esters:

(2)

Content *c* of cyclohexane oxidation products as a function of conversion ΔRH. 150–155°C, 0.8 MPa, 0.04% cobalt naphthenate. (*1*) Peroxy compounds, (*2*) cyclohexanol, (*3*) cyclohexanone, (*4*) adipic anhydride, (*5*) formic acid, (*6*) butyric acid, (*7*) valeric acid, (*8*) caproic acid, (*9*) succinic acid, (*10*) glutaric acid, (*11*) glutaric acid monoaldehyde, (*12*) adipic acid, (*13*) adipic acid monoaldehyde, (*14*) cyclohexyl formate, (*15*) cyclohexyl butyrate, (*16*) cyclohexyl valerate, (*17*) cyclohexyl capronate, (*18*) cyclohexyl hydrogen succinate, (*19*) cyclohexyl hydrogen glutarate, (*20*) cyclohexyl hydrogen adipate, (*21*) dicyclohexyl adipate, and (*22*) cyclohexyl ester of adipic acid monoaldehyde.

Presumably, the reactions of type (2) with mixed anhydrides containing a formic acid residue will preferentially yield cyclohexyl formate:

Table 1. Ratio *B* of yields of cyclohexyl esters of mono- and dicarboxylic acids to the yield of free acids in oxidation of cyclohexane at 150°C to various conversions



Acid	*B* at indicated conversion,* %

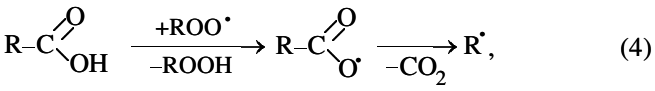
Table 2. Yield of cyclohexyl esters in reactions of carboxylic acids and acetic anhydride with cyclohexanol at 90°C

Acid	Concentration of acid residues, M	Yield of cyclohexyl esters	
		M	mol mol^{-1}*
Formic	1.41	0.64	0.45
Acetic	1.90	0.12	0.06
Propionic	2.18	0.12	0.05
Valeric	1.81	0.07	0.04

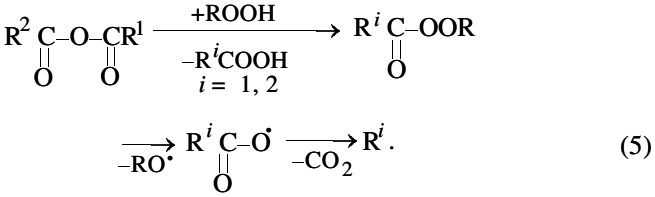
* Per mole of starting acid.



(3)

This assumption is confirmed by the results obtained in the reaction of a mixture of formic, propionic, and valeric acids (for concentrations, see Table 2) and acetic anhydride (0.95 M) with cyclohexanol (4.9 M) in a glass ampule at 90°C. A GLC analysis of the reaction mixture, performed 60 min after the start of the reaction, revealed the presence of cyclohexyl esters of all the acids present in the mixture (Table 2).

Table 2 shows that the yield of the ester per mole of the acid for formic acid is almost an order of magnitude higher than for the other acids. Therefore, reactions (1) and (3) can account for the features of cyclohexyl formate accumulation in the course of cyclohexane oxidation.



A question naturally arises: Can the increased yield of cyclohexyl formate be partially due to the higher rate of esterification of formic acid with cyclohexanol, compared to other acids formed by cyclohexane oxidation? The initial rate of esterification of formic acid with methanol at 20–40°C is approximately 30 times higher than that of butyric acid [11], which even exceeds the ratio of the rates of formation of the corresponding esters in the alcoholysis of mixed anhydrides (Table 2). This matter undoubtedly requires a special study. At the same time, it should be noted that esterification, in contrast to alcoholysis of anhydrides with alcohols, is reversible and can result not only in formation of etsters in early steps, but also in their hydrolysis if the equilibrium concentration of these compounds will be exceeded as a result of reactions (1) and (3).

The pathways of formation of formic acid in liquid-phase oxidation processes are the least understood, which may be caused by multistep mechanisms of its formation and by problems with analytical determination of this compound [8] because of low sensitivity of a flame ionization detector to formic acid. One of pathways of formic acid formation in the course of cyclohexane oxidation, suggested even in [1], involves successive decarboxylation of monocarboxylic acids, yielding methyl radical and then formic acid. The decarboxylation may occur both with the participation of the peroxy radicals {reactions of type (4) [1, 3]}:

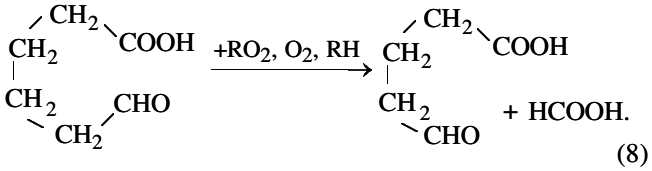
(4)

or via mixed anhydrides [reactions of type (1)], which form peroxy esters in the reactions with hydroperoxides. The homolytic cleavage of peroxy esters can lead to the decarboxylation [4]:

(5)

If reactions (4) and (5) really occur, the reaction products should contain the whole set of monocarboxylic acids from C_6 to C_1, and their content should

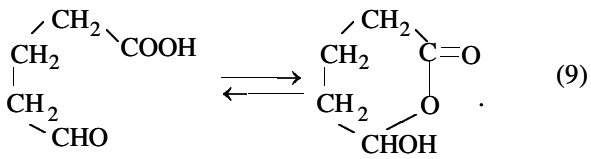
decrease with decreasing number of C atoms [1]. As already noted, acetic and propionic acids appear in oxidized cyclohexane only in late oxidation steps, whereas formic acid appears considerably earlier (see figure; Table 1). Therefore, an additional pathway of formation of formic acid was suggested in [1]: from a primary carbon-centered radical formed by reactions of types (4) and (5):



$$R^1\dot{C}H_2 \xrightarrow{+O_2,\ RH} R^1CH_2OOH \xrightarrow[-HO^{\bullet}]{} R^1CH_2O^{\bullet} \xrightarrow[-R^{1\bullet}]{} HCHO \longrightarrow \cdots \longrightarrow HCOOH. \quad (6)$$

However, scheme (6), like schemes (4) and (5), implies multistep formation of formic acid from other monocarboxylic acids and thus its successive, rather than parallel, accumulation, which is inconsistent with the experiment.

Analysis of published data on the mechanisms of oxidation of organic compounds [3] shows that formic acid can form by oxidation of aldehydes at α-CH bonds relative to the carbonyl group [reaction (7), pathway a] [12]:



$$RCH_2C(=O)H \xrightarrow{+RO_2,\ O_2,\ RH} \begin{cases} \xrightarrow{(a)} RCH_2C(=O)OOH \\ \xrightarrow{(b)} RCHC(OOH)(=O)H \end{cases} \longrightarrow RCHO + HCOOH. \quad (7)$$

Since one of major aldehyde components of cyclohexane oxidation products is adipic acid monoaldehyde, its oxidative transformations [reaction (7), pathway b] should presumably yield formic acid and glutaric acid monoaldehyde:

(8)

The latter compound was indeed detected in cyclohexane oxidation products; it is accumulated in amounts comparable with those of adipic acid monoaldehyde (see figure, curve *11*). This fact, along with the trend in variation of the adipic acid monoaldehyde content with cyclohexane conversion, typical of intermediates, counts in favor of formation of glutaric acid monoaldehyde by reaction (8). It could be expected that glutaric acid monoaldehyde, in turn, would be oxidized to formic acid and succinic acid monoaldehyde by the reaction of type (8). However, succinic acid monoaldehyde was not detected among cyclohexane oxidation products. Furthermore, the trend in variation of the glutaric acid monoaldehyde content with cyclohexane conversion essentially differs from that observed with adipic acid monoaldehyde (see figure, curves *11*, *13*). This feature may be associated with the possibility of cyclization of 4-acylcarboxylic acids [13] to 5-hydroxy lactones with a stable pyranose ring:

(9)

The cyclization is favored by the presence of free carboxy groups [13]. Presumably, 5-hydroxy-δ-valerolactone is oxidized considerably more difficultly than the open-chain form containing a free aldehyde group. It is known [14] that α-ethylacrolein dimethyl acetal is oxidized with oxygen considerably more difficultly than free α-ethylacrolein.

The hypothesis that formic acid is formed from adipic acid monoaldehyde is also supported by data on the yield of formic acid and some other products in oxidation of neat cyclohexanol and cyclohexanone at 120°C (Table 3).

The ratio of the yields of formic and adipic acids (taking into account their content in the corresponding cyclohexyl esters), calculated from data in Table 3, is 0.54 for cyclohexanol and 0.95 for cyclohexanone.

Table 3. Content of some products in oxidized cyclohexanol and cyclohexanone

Acid	Cyclohexanol	Cyclohexanone
	$c \times 10^3$, M	
Oxygen uptake	82.1	44.6
Formic acid	2.1	3.25
Cyclohexyl formate	2.38	–
Glutaric acid	0.58	0.41
Glutaric acid monoaldehyde	1.25	1.31
Adipic acid	7.52	3.32
Cyclohexyl hydrogen adipate and dicyclohexyl adipate	0.97	–
Adipic acid monoaldehyde	0.82	1.4

The higher yield of formic acid in the oxidation of cyclohexanone, compared to the oxidation of cyclohexanol, correlates with an increase in the content of adipic acid monoadlehyde in going from cyclohexanol to cyclohexanone. Despite milder conditions, the relative yield of formic acid in the oxidation of the alcohol and ketone is appreciably higher than in the oxidation of cyclohexane for which this ratio is about 0.022 (see figure). This fact may be due both to thermal decomposition of formic acid under the conditions of cyclohexane oxidation at elevated temperature and to the loss of formic acid with off-gases under the conditions of the industrial process. It is significant that in all the cases we detected in the reaction mixture glutaric acid monoaldehyde whose formation is not implied by the existing concepts of cyclohexane oxidation.

CONCLUSIONS

(1) In oxidation of cyclohexane under the conditions of the industrial process, the ratio of the yields of cyclohexyl formate and formic acid is considerably higher than the corresponding ratios for the other mono- and dicarboxylic acids and their cyclohexyl esters. The increased relative yield of cyclohexyl formate is due to specific features of alcoholysis of mixed anhydrides containing a formic acid residue.

(2) One of probable pathways of formic acid formation in the oxidation of cyclohexane involves oxidative transformations of adipic acid monoaldehyde, yielding formic acid and glutaric acid monoaldehyde.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Catalytic Synthesis of *N*-Benzoyl (*N*-Nitrobenzoyl) Derivatives of ε-Aminocaproic Acid Oligomers

Abstract—The synthesis of *N*-benzoyl [*N*-(*m*-nitrobenzoyl)] derivatives of ε-aminocaproic acid oligomers by the reaction of ε-caprolactam with benzoic (nitrobenzoic) acid in the presence of *p*-toluenesulfonic acid as catalyst was studied.

DOI: 10.1134/S1070427206030177

It is known that ε-aminocaproic acid oligomers inhibit reproduction of respiratoric viruses. Acid-catalyzed oligomerization of ε-caprolactam with carboxylic acids yields *N*-acyl derivatives of ε-aminocaproic acid oligomers [1–5].

In this study, *N*-benzoyl (BACA) and *N*-nitrobenzoyl (*m*-NBACA) derivatives of ε-aminocaproic acid oligomers were prepared by the reaction of ε-caprolactam (CL) with benzoic (BA) and nitrobenzoic (*m*-NBA) acids in the temperature range 150–210°C. *p*-Toluenesulfonic acid (TsOH) was used as catalyst.

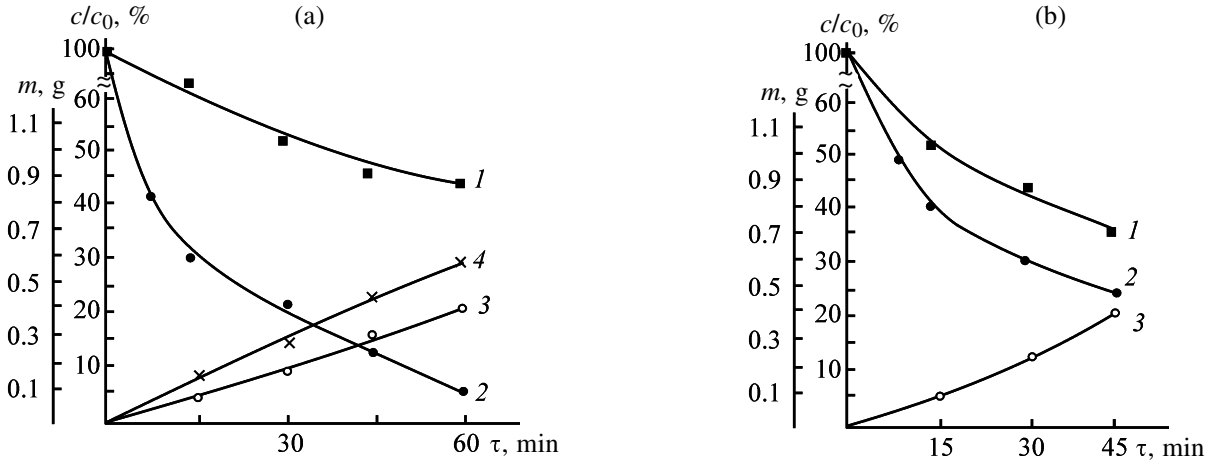
where R = H (BA), *m*-NO_2 (*m*-NBA) (**I**); R' = H (BACA), *m*-NO_2 (*m*-NBACA) (**II**); n =1, 9, 10.

EXPERIMENTAL

The IR spectra (KBr pellets or a mulls in Vaseline oil) were recorded on a Specord M-82 IR spectrometer. The ^{1}H NMR spectra were recorded on a Varian Mercury Plus spectrometer (300 MHz) in DMSO-d_6 with TMS as internal reference. The reagent consumption rate was determined by an ampule technique.

N-Benzoyl derivatives of ε-aminocaproic acid oligomers, R = H (BACA) (**II**). Ampules filled with the reaction mixture (CL 1.9 g, BA 2 g, and TsOH 0.30 g; reactant molar ratio 1 : 1 : 0.1) were kept in a thermostat at 150°C. At 15-min intervals these ampules were successively removed, and chloroform was added. Unchanged CL and BA dissolved in chloroform and were separated from the insoluble residue of BACA oligomer mixture containing oligomers with 9 and 10 monomeric units. To separate these oligomers, the solid residue was mixed with ethanol and heated to boil. The resulting solution was filtered and then cooled. Under these conditions $BACA_{n=10}$ precipitates and $BACA_{n=9}$ remains in ethanol. $BACA_{n=10}$ was separated from $BACA_{n=9}$ by filtration. $BACA_{n=9}$ was isolated from the filtered solution by ethanol evaporation and then recrystallized. $BACA_{n=9}$: yield 0.66 g (35%), mp 165– 167°C. Found, %: N 10.92. Calculated, %: N 11.05. $BACA_{n=10}$: yield 0.85 g (45%), mp 188–190°C. Found, %: N 11.20. Calculated %: N 11.27.

The molecular structures of $BACA_{n=9}$ and $BACA_{n=10}$ were characterized by IR and ^{1}H NMR spectroscopy. The IR spectrum of $BACA_{n=9}$ contains the amide I and amide II absorption bands (1638 and 1584 cm^{-1}, respectively) and the absorption bands of the stretching vibrations of the NH groups at about 3292 cm^{-1}. The IR spectrum of $BACA_{n=10}$ contains the amide I and amide II absorption bands (1636 and 1536 cm^{-1}, respectively) and the absorption band of the stretching vibrations of the NH group at about 3200 cm^{-1}.



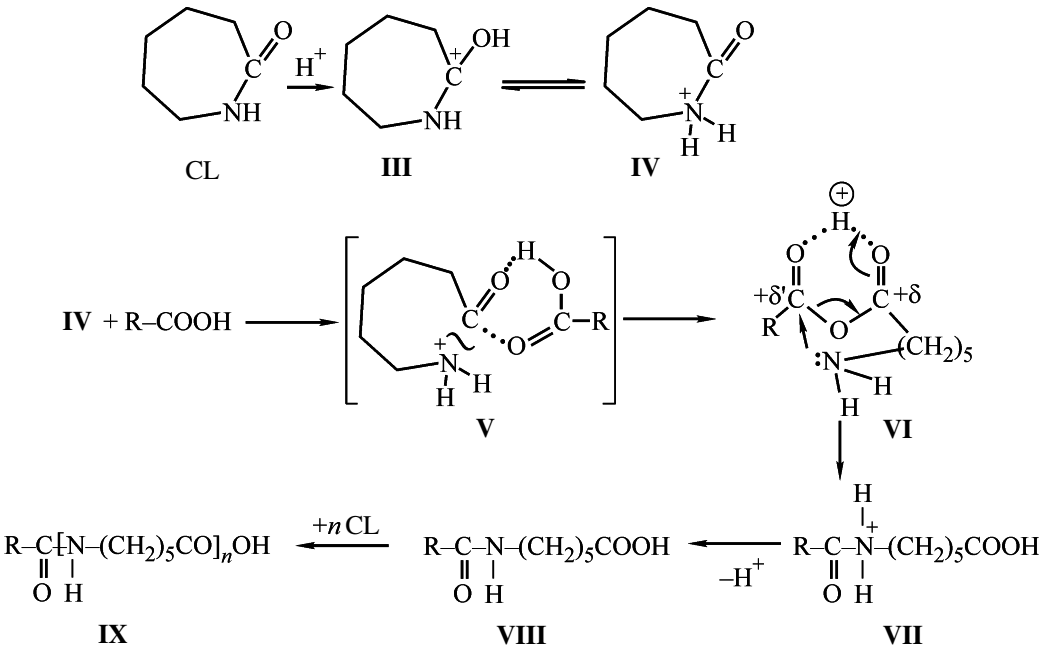


Fig. 1. Time dependence of the reagent consumption (c/c_0) and oligomer formation m in the course of reaction between (a) CL and BA and (b) CL and *m*-NBA. (τ) Time. 150°C (a) (*1*) BA, (*2*) CL, (*3*) $BACA_{n=9}$, and (*4*) $BACA_{n=10}$; (b) (*1*) *m*-NBA, (*2*) CL, and (*3*) *m*-NBACA.

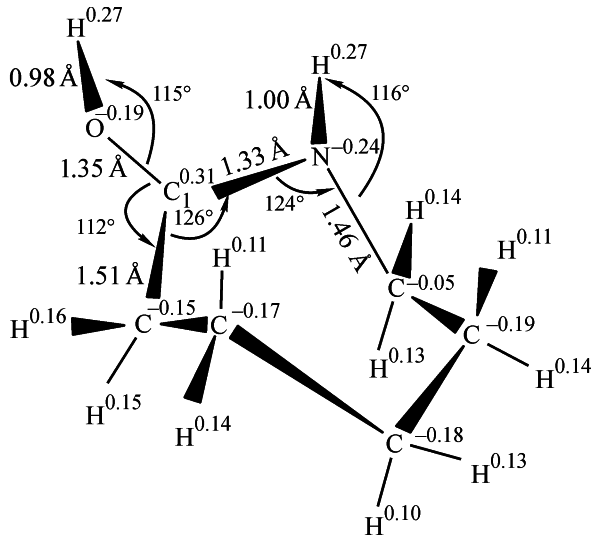
^{1}H NMR spectrum of $BACA_{n=9}$ in DMSO-d_6, δ, ppm: 8.22 s [9H, NH], 2.99 m [18H, CH_2NH], 2.22 m [18H, $CH_2C(O)$], 7.08–7.89 m [5H, Ph], and 1.16–1.98 m [46H, $(CH_2)_{23}$].



N-(*m*-Nitrobenzoyl)-ε-aminocaproic acid, R = *m*-NO_2 [*m*-NBACA (**II**)], was prepared similarly. After the reaction completion, the product was treated with diethyl ether to remove unchanged CL and *m*-NBA. The insoluble residue was filtered off and then recrystallized from chloroform. *m*-NBACA yield 1.2 g (65%), mp 89–100°C. Found, %: N 9.90. Calculated, %: N 9.96.

^{1}H NMR spectrum of *m*-NBACA in DMSO-d_6, δ, ppm: 8.57 s (H, NH), 3.03 m (2H, CH_2NH), 2.99 m [2H, $CH_2C(O)$], 7.08–8.41 m [4H, Ph], and 1.24–2.98 m [6H, $(CH_2)_3$].

The oligomerization mechanism involving a six-membered intermediate complex of protonated CL with carboxylic acid was suggested:

R = Ph [BA, BACA (**IX**)]; *m*-NO_2Ph [*m*-NBA *m*-NBACA (**VIII**)], n = 9, 10.

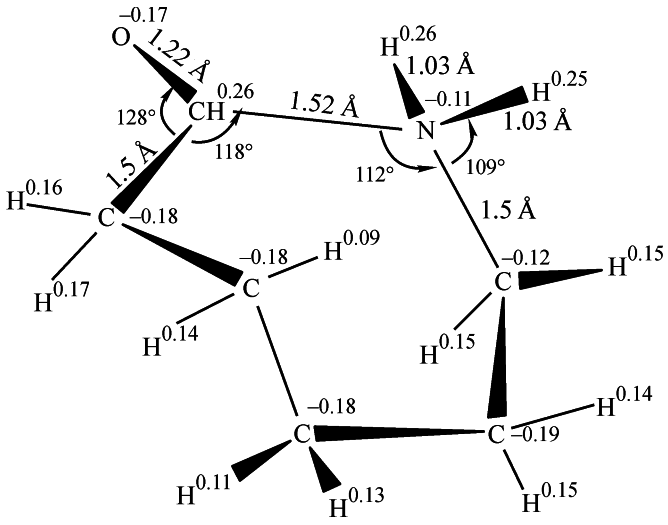


Figure 1 shows the time dependence of c/c_0 (current amount of a reactant relative to its initial amount) and m (oligomer yield, g). In Fig. 1a c/c_0 refers to BA and CL, and m, to $BACA_{n=9}$ and $BACA_{n=10}$. In Fig. 1b, c/c_0 refers to *m*-NBA and CL, and m, to *m*-NBACA.

As seen from these kinetic curves, in the early stage of the reaction, the reactant consumption ratio $V_0(CL)/V_0(m\text{-NBA})$ decreases by a factor of 1.4, whereas the ratio $V_0(CL)/V_0(BA)$ decreases by a factor of 2.

The larger reactant consumption in formation of *m*-NBACA (isolated in 65% yield) can be attributed to acyl rearrangement.

The AM1 quantum-chemical calculations [6] showed that, in the presence of acid catalyst, the activation energy of formation of anhydride via protonation of the amide group of ε-CL (**IV**) is 134 kJ mol^{-1}. The energy gain in acyl rearrangement is no lower than 83.8 kJ mol^{-1}.

The energy of structure **IV** is close to that of structure **III** in which proton is bound to the carbonyl oxygen atom of the ε-CL molecule. However, the protonation of the NH group is accompanied by lengthening of the NC(O) bond from 1.38 Å in **III** to 1.52 Å in **IV**, which facilitates cleavage of the amide ring.

The structural and electronic characteristics of the ε-CL molecule (see below) were calculated with AM technique [1]. Total charge of molecular system (OH cation) Q = 1; bond lengths: $R_{C–C}$ 1.51, $R_{C–H}$ 1.09 Å; bond angles ∠CCC 114°, ∠CCH 109°, $\angle CCC_1$ 112°, ∠CCN 115°; bond order $P_{C_1–N}$ 1.482; total energy E_0 = –33 555 kcal mol^{-1}, and dipole moment μ 3.82 D.

CONCLUSIONS

(1) The rate of consumption of ε-caprolactam and benzoic and *m*-nitrobenzoic acids in the course of synthesis of *N*-benzoyl (*N*-*m*-nitrobenzoyl) derivatives of ε-aminocaproic acid oligomers and the quantum-chemical calculations show that these reactions involve acyl rearrangement in which a mixed anhydride is formed.

(2) The acyl rearrangement is facilitated by appearance of a positive charge on the carbonyl carbon atom of the benzoyl group and an unshared electron pair on the nitrogen atom of the amino group.

(3) Introduction of the electron-acceptor nitro group into the benzoic acid molecule facilitates the acyl rearrangement and, as a result, increases the consumption rate of nitrobenzoic acid.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Separation of 2,4'- and 4,4'-Dihydroxydiphenyl Sulfones

Abstract—To develop a procedure for separating 2,4'- and 4,4'-dihydroxydiphenyl sulfones, their acidity and solubility in water were studied.

DOI: 10.1134/S1070427206030189

Bisphenol S prepared by the reaction of 2 mol of phenol with 1 mol of sulfuric acid is a mixture of 4,4'- (**I**) and 2,4'-dihydroxydiphenyl sulfone (**II**) with small amounts of 2,4',4"-trihydroxytriphenyl disulfone (**III**) and unidentified colored and colorless impurities.

Previously crude bisphenol S was used for preparing macromolecular components of heat-developable mixtures and photoconductors. At present, only pure sulfones **I** and **II** are used for this purpose. Sulfone **III** does not find practical application so far. Most of the procedures for separating sulfones **I** and **II** are based on their different solubilities in organic solvents. Since only isomer **I** was used in practice, these methods consisted in its separation from concomitant impurities. Isolation of individual sulfones **I** and **II** by treatment of bisphenol S with a boiling mixture of *p*-xylene and isopropanol or methyl ethyl ketone was described in patent [1].

Procedures involving no organic solvents are more convenient for industrial applications. Components of bisphenol S were separated in the form of their monosodium salts [2] by the following procedure. An isomer mixture was dissolved in approximately 2 equiv of aqueous alkali to form the disodium salts readily soluble in water. Only the monosodium salt of **I** was precipitated after partial neutralization of the solution. As stated in patent [2], under these conditions isomer **II** is in the solution in the form of its disodium salt. The suspension was filtered. Monosodium salt of isomer **II** was crystallized after partial neutralization of the filtrate. The salt was separated from the solution. Acidification of an aqueous suspension of this salt gave pure sulfone **II**. Monosodium salts of sulfones **I** and **II** were recovered in 97 and 83% yields respectively, from a mixture containing 79 wt % sulfone **I**, 20 wt % sulfone **II**, and 1 wt % impurities [2]. The purity of both isolated salts was no less than 90%. Thus, this method seems promising for develop a high-performance industrial process for separating isomers **I** and **II** without using organic solvents.

We experimentally tested the procedure described in patent [2]. The results of separation of bisphenol S are presented in Table 1. Isomer **I** was isolated in a yield of 93 wt %, which is close to the yield reported in the patent. However, instead of pure isomer **II** we obtained only a mixture containing 48 wt % target product.

To exclude the possible influence of impurities which can be different in bisphenol used in [2] and in our sample, we prepared a model mixture containing pure isomers **I** and **II** in the ratio equal to that in the bisphenol described in patent [2] (Table 1, run no. 2). The results of separation of this mixture also differed from those reported in the patent.

Since, according to patent [2], monosodium salt of isomer **I** is formed and crystallizes in a solution in which isomer **II** is in the form the disodium salt, the acidity of sulfone **II** should be substantially higher

Table 1. Results of separation of a mixture of dihydroxydiphenyl sulfone isomers

Run no.	Sample	Weight, g	Component content, wt %		
			I	**II**	**III**
1	Bisphenol S	50	82.0	16.5	1.5
	Isomer **I**	40.5	93.2	6.6	0.2

* V_{equiv} is the equivalent volume of 0.1251 N NaOH.

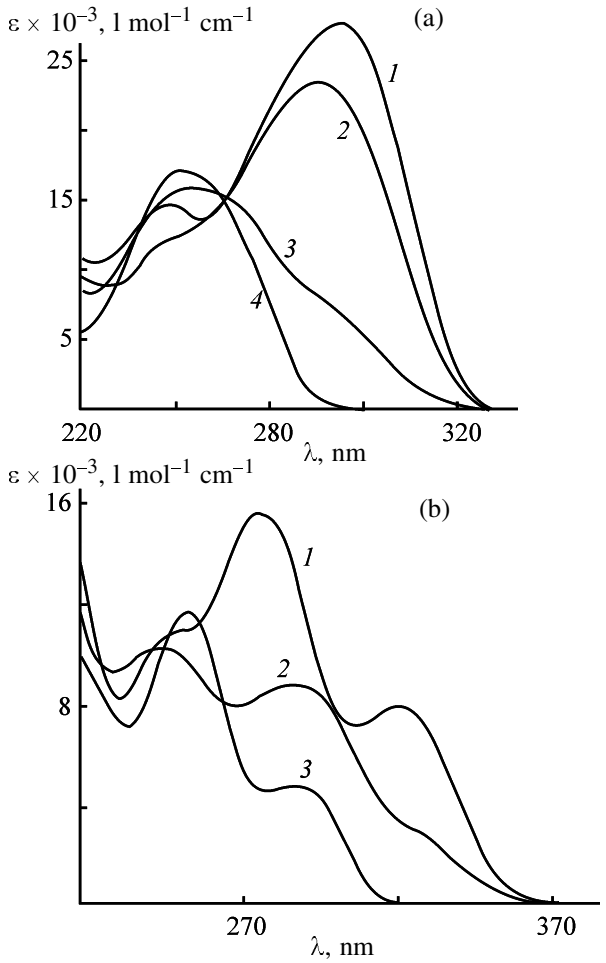

Fig. 1. UV spectra of aqueous solutions of (a) isomer **I** at pH (*1*) 9.95, (*2*) 8.42, (*3*) 7.12, and (*4*) 5.16 and (b) isomer **II** at pH (*1*) 10.12, (*2*) 7.05, and (*3*) 5.24. (ε) Molar extinction coefficient and (λ) wavelength.

than that of sulfone **I**. pK_{a1} and pK_{a2} of sulfone **I** in 71.9 wt % aqueous ethanol at 24°C is 9.01 and 9.93, respectively [3]; in water at 24°C, 7.57 and 8.53, respectively [3]; in 48% aqueous ethanol, 8.79 and 9.41, respectively [4]; and in 70 wt % aqueous ethanol, 8.87 and 10.44, respectively [5].

In addition, the acidity of chlorinated [5] and hydroxymethyl-substituted [6] 4,4'-dihydroxydiphenyl sulfone and 2,2'-dihydroxydiphenyl sulfone [4] is known. No data on acidity of sulfone **II** are reported.

Thus, the published data on isomer **I** are contradictory. This can be due to the influence of the solution composition of the acid properties. Since the acidity of compound **I** in water [3] was measured using an insufficiently pure sample (a mixture of isomers with mp 236–238°C was studied, whereas the mp (melting point) of pure **I** was 249.5°C [7]) and no data on the acidity of sulfone **II** under the comparable conditions were reported, in this study we performed parallel measurements of the acidity of isomers **I** and **II** in an aqueous solution. The potentiometric titration curves of ~0.004 M aqueous solutions of these compounds are similar and typical of dibasic acid. The acidity constants calculated by the Neues procedure [8] are presented in Table 2.

The pK_{a1} (negative logarithm of the dissociation constant for the first step) values of isomers **I** and **II** are almost the same (7.52 and 7.54, respectively). Since the structure of the aromatic ring of the $ArSO_2$ groups insignificantly affects the acidity of the 4-hydroxy group [3], the first dissociation step of compounds **I** and **II** is deprotonation of the 4-hydroxy group. At the same time, the pK_{a2} values of isomers **I** and **II** differ substantially (8.57 and 8.83, respectively). This is due to the fact that the second dissociation step of isomer **I** involves deprotonation of the 4-hydroxy group whereas the second dissociation step of isomer **II** is deprotonation of the 2-hydroxy group.

We found that pK_{a2} of isomer **II** is somewhat larger than that of isomer **I**. This is consistent with the ratio of acidities of other *o*- and *p*-substituted phenols. For example, *o*-nitrophenol is weaker acid than *p*-nitrophenol (pK_a 7.23 and 7.15, respectively [8]).

Our experiments on the influence of the pH on the absorption spectra of aqueous solutions of compounds **I** and **II** additionally confirmed their similar acid properties. Unlike the spectra of the molecular compounds [9], dianions of **I** and **II** strongly absorb in the relatively long-wave range (Fig. 1). The spectrum of dianion **I** contains a band with a maximum at λ = 295 nm (ε = 27400 l mol^{-1} cm^{-1}); two

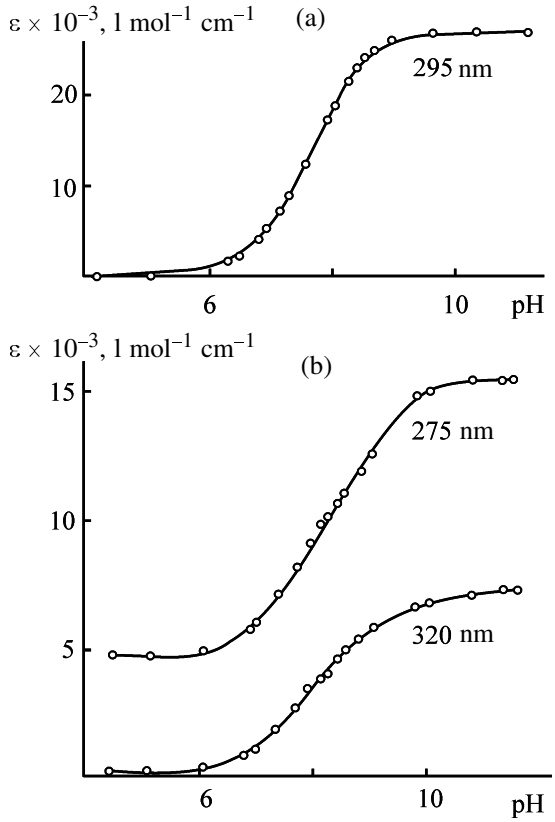

Fig. 2. Molar extinction coefficient ε as a function of pH of solutions of (a) **I** and (b) **II** (analytical wavelengths are indicated).

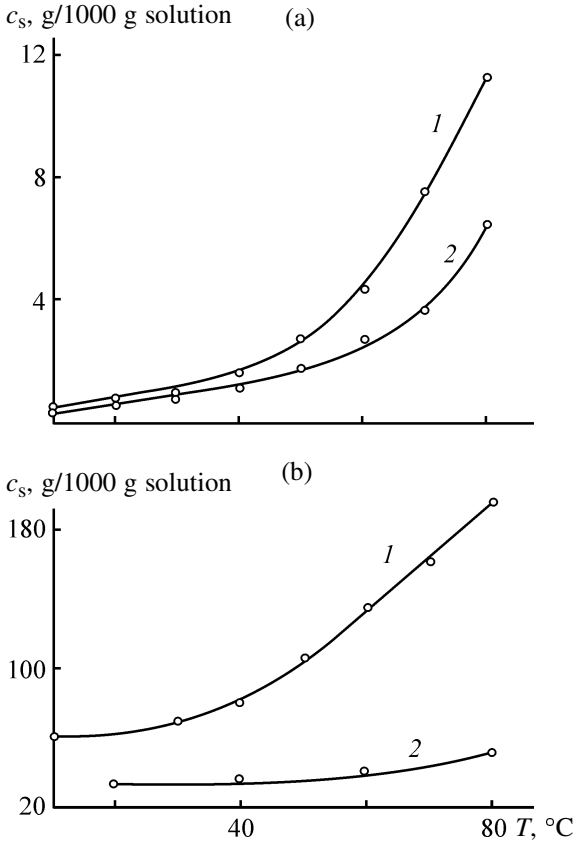

Fig. 3. Solubility c_s of (a) (*1*) sulfone **I** and (*2*) **II** and (b) their monosodium salts as a function of temperature *T*.

bands at λ = 275 nm (ε = 15 400 l mol^{-1} cm^{-1}) and λ = 320 nm (ε = 8000 l mol^{-1} cm^{-1}) are observed in the spectrum of dianion **II**. When pH of solutions of these compounds increases from 6 to 9, the absorption in these ranges increases (Fig. 2). The pH dependence of the molar absorption coefficient has a usual S-shape and reflects an increase in the degree of dissociation with pH. Since the absorption spectra of conjugated acids **I**, **II**, and their mono- and dianions overlap in the whole range, it is impossible to determine pK_{a1} and pK_{a2} from the spectra data. However, the pH of half-neutralization of isomer **I**, calculated from the spectral data, is 7.71. For isomer **II**, this value calculated from the absorption at λ = 275 nm and λ = 320 nm was 8.09 and 8.05, respectively. Thus, these results also show that the acidity of isomer **II** is noticeably lower than that of isomer **I**. Therefore, the statement [2] that monosodium salt of **I** precipitates and the readily water-soluble disodium salt of **II** remains in the solution after acidification of solutions containing disodium salts of **I** and **II** is incorrect.

Selective crystallization of one of the isomers may also be due to its lower solubility. The data on solubility of isomers **I** and **II** are contradictory. Zehenter and Fauzer reported [10] that the solubility of isomer **II** (0.32 g in 100 g of water) at 22°C is higher by a factor of approximately 1.5 than that of isomer **I** (0.24 in 100 g of water). At the same time, isomer **I** was recrystallized from an aqueous solution to remove less soluble isomer **II** [7]. To clarify this point, we studied the solubility of sulfones **I** and **II** in water in a wide temperature range. As seen from Fig. 3, the solubility of isomer **II** at 10–80°C is lower by a factor of 2 than that of isomer **I**. Hence, although the content of isomer **I** in its mixture with isomer **II** is high, it is difficult to isolate isomer **I** by recrystallization from water.

Crystallization of monosodium salt of **I** form an acidified aqueous solution of a mixture of disodium salts of **I** and **II**, described in patent [2], could be due to substantial difference in the solubilities of the monosodium salts of these isomers. Since no data on the solubilities of monosodium salts of **I** and **II** are reported, we determined the concentrations of their saturated aqueous solutions at different temperatures (Fig. 3). As seen from Fig. 3, the solubility of mono-

sodium salt of **II** is lower than that of monosodium salt of **I** in the whole temperature range. These data clarify the experimental results on separation of mixtures of isomers **I** and **II**.

Since separation of sulfone **I** from impurities of isomer **II** was performed by treatment of their ammonium salts [11], we studied the solubility of monoammonium salt of **I** in water at different temperatures. The solubility of this salt in water is noticeably lower than that of the monosodium salt, with the difference being the most pronounced at low temperatures. The solubility c_s (wt %) of the sodium salt at 10, 30, 40, 50, 60, 70, and 80°C is 6.0, 7.0, 8.2, 11.1, 14.6, 16.6, and 20.1, respectively; the solubility of the ammonium salt at 20, 30, 40, 50, 60, and 70°C is 3.4, 3.6, 4.8, 7.1, 11.0, and 15.0, respectively. Thus, isomer **I** can be purified more efficiently in the form of monoammonium salt as compared to its sodium analog.

Thus, separation of isomers **I** and **II** in the form of their monosodium salts based on the difference both in their acidities and in solubilities in water at a usual content of isomer **II** in the mixture (15–20 wt %) is ineffective. However, if the content of isomers **I** and **II** in the mixture substantially differs (~85 and ~2 wt %, respectively), the salts of these compounds can be separated by the procedure described in [11]. This procedure is unsuitable for isolation of pure **II**.

EXPERIMENTAL

Crude bisphenol S was prepared by sulfonation of phenol in the presence of *o*-dichlorobenzene. A 250-ml three-necked flask equipped with a thermometer, a mechanical stirrer with a seal, and a Würtz adapter with a descending condenser was loaded with phenol (120 g) and dichlorobenzene (80 ml). To this solution, 92% sulfuric acid (68 g) was added with stirring at 100–110°C within 10 min. The mixture was kept at 100–110°C for 1 h and then was heated to boil at 140–145°C. The aqueous azeotrope of *o*-dichlorobenzene was separated and the organic layer was returned to the reaction mixture. The temperature of the reaction mixture increased to 180°C within 5 h. Then the reaction mixture was cooled, and *o*-dichlorobenzene was decanted. A solution of sodium hydroxide (51 g) in water (150 ml) was added to the residue. The resulting suspension was heated at 90–95°C with stirring until a solution was formed. The residual organic solvent was separated, and the solution was diluted to 600 ml with distilled water and acidified with 70% sulfuric acid to pH ~3. After cooling of the reaction mixture, the precipitate was filtered off, washed with distilled water, and dried at 110–120°C. The yield of crude bisphenol S containing 82, 16.5, and 1.5 wt % of sulfones **I**, **II**, and **III**, respectively, was 143 g (90%).

Individual isomers I and II were obtained by separation of crude bisphenol using a benzene–acetone mixture by the procedure described in [7]. The melting points of isomer **II** and **I** recrystallized from 5% aqueous ethanol were 185–186 and 248–249°C, respectively, which is close to the published data (186.7 and 249.5°C, respectively [7]).

Monosodium salts of sulfones I and II and monoammonium salt of I were prepared by dissolution of these sulfones in 1 equiv of aqueous solution of the appropriate base on heating. The precipitates of these salts formed on cooling were filtered off and dried at 105–110°C. As determined by UV spectroscopy, the content of the target product was no less than 99.5%.

Chromatographic analysis of crude bisphenol S and the isomer mixtures was performed on a Milikhrom chromatograph using columns packed with Sil 600. A mixture of hexane (40 ml), ethyl acetate (20 ml), acetic acid (2 ml), and trifluoroacetic acid (0.5 ml) was used as the eluent. The wavelength used for detection was λ = 260 mn.

The content of individual isomers in aqueous solutions was determined by their absorption measured in 1-cm quartz cells on an SF-26 spectrophotometer. The molar extinction coefficient of isomers **I** (λ = 295 nm) and **II** (λ = 275 nm) measured in solution with pH 11.0–11.5 was 27400 and 15450 $l\,mol^{-1}\,cm^{-1}$, respectively.

Crude bisphenol S was separated by the procedure in [2]. Crude bisphenol S (50 g) was placed in a 250 ml three-necked flask equipped with a thermometer, a mechanical stirrer, and a reflux condenser. A solution of NaOH (17 g) in water (75 ml) was added. The resulting suspension was refluxed until a solution was formed. 72% sulfuric acid (12.6 g) was added. The suspension was slowly cooled to 40°C. A precipitate of monosodium salt of isomer **I** was filtered off and the liquid phase was thoroughly removed by pressing. The filtrate was heated to 90– 95°C with stirring and acidified to pH 3–4. After cooling, the precipitate of isomer **II** was filtered off, washed with distilled water, and dried at 105–110°C. Isolated monosodium salt of isomer **I** was suspended in distilled water (120 ml). The suspension was heated to 90–95°C with stirring and acidified to pH 4–5. After cooling, the precipitate of isomer **I** was filtered off, washed with distilled water, and dried at 105–110°C.

A mixture containing 80 wt % isomer **I** and 20 wt % isomer **II** was separated similarly.

To determine the solubility of sulfones **I** and **II** and their salts in water, weighed portions of these compounds were mixed with water in a flask equipped with a thermometer and a reflux condenser. The resulting suspensions were heated to a temperature higher by 5–10°C than the required temperature. The system was thermostated with an accuracy of ±0.2°C for 5–6 h with stirring. Samples of the saturated solution were taken with a sampler equipped with a glass frit, placed in a weighing bottle, cooled to room temperature, weighed on an analytical balance with an accuracy of ±0.00005 g, and analyzed spectrophotometrically.

CONCLUSION

The relative acidities of 2,4'- and 4,4'-dihydroxydiphenyl sulfones and the solubilities of their salts do not allow isolation of the pure 2,4'-isomer by precipitation of its monosodium salt but allow removal of impurities of the 2,4'-isomer from 4,4'-dihydroxydiphenyl sulfone.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Rearrangement of Polyarylene Benzimidates into Poly(*N*-arylenebenzamides)

V. F. Burdukovskii, D. M. Mognonov, S. O. Botoeva, and Zh. P. Mazurevskaya

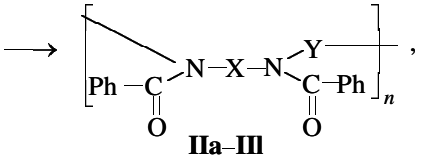
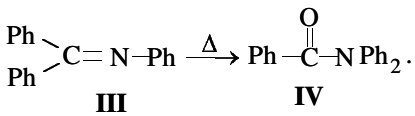
Received June 8, 2005



Abstract—The transformation of polyarylene benzimidates prepared by polycondensation of bisphenols with benzimidoyl chlorides in *N*-methyl-2-pyrrolidone into poly(*N*-arylenebenzamides) was studied.

DOI: 10.1134/S1070427206030190

Polyarylene benzimidates (PBIs) prepared by polycondensation of imidoyl chlorides derived from aromatic mono- and dicarboxylic acids with bisphenols [1] exhibit high heat resistance and large interval between the decomposition onset and softening points. Specific features of the imidate bond and available data on its reactivity [2] allowed us to suggest the possibility of the following rearrangement in the polymer chain:



Ia–**Im**

IIa–**III**

Ia, X = *p*-C_6H_4, Y = *m*-C_6H_4; **Ib**, X = *p*-C_6H_4, Y = (*p*-$C_6H_4)_2CMe_2$; **Ic**, X = *p*-C_6H_4, Y = (*p*-$C_6H_4)_2SO_2$; **Id**, X = *m*-C_6H_4, Y = *p*-C_6H_4; **Ie**, X = Y = *m*-C_6H_4; **If**, X = *m*-C_6H_4, Y = (*p*-$C_6H_4)_2CMe_2$; **Ig**, X = *m*-C_6H_4, Y = (*p*-$C_6H_4)_2SO_2$; **Ih**, X = (*p*-$C_6H_4)_2O$, Y = *p*-C_6H_4; **Ii**, X = (*p*-$C_6H_4)_2O$, Y = *m*-C_6H_4; **Ij**, X = (*p*-$C_6H_4)_2O$, Y = (*p*-$C_6H_4)_2SO_2$; **Ik**, X = (*p*-$C_6H_4)_2 \cdot CH_2$, Y = *p*-C_6H_4; **Il**, X = (*p*-$C_6H_4)_2CH_2$, Y = *m*-C_6H_4; **Im**, X = (*p*-$C_6H_4)_2CH_2$, Y = (*p*-$C_6H_4)_2CMe_2$; **IIa**, X = Y = *m*-C_6H_4; **IIb**, X = *p*-C_6H_4, Y = (*p*-$C_6H_4)_2CMe_2$; **IIc**, X = *p*-C_6H_4, Y = (*p*-$C_6H_4)_2SO_2$; **IId**, X = *m*-C_6H_4, Y = *p*-C_6H_4; **IIe**, X = Y = *m*-C_6H_4; **IIf**, X = *m*-C_6H_4, Y = (*p*-$C_6H_4)_2CMe_2$; **IIg**, X = (*p*-$C_6H_4)_2O$, Y = *m*-C_6H_4; **IIh**, X = (*p*-$C_6H_4)_2O$, Y = (*p*-$C_6H_4)_2SO_2$; **IIi**, X = (*p*-$C_6H_4)_2CH_2$, Y = *p*-C_6H_4; **IIj**, X = (*p*-$C_6H_4)_2CH_2$, Y = *m*-C_6H_4; **IIk**, X = (*p*-$C_6H_4)_2CH_2$, Y = (*p*-$C_6H_4)_2CMe_2$; **III**, X = (*p*-$C_6H_4)_2CH_2$, Y = (*p*-$C_6H_4)_2SO_2$.

Initially we studied the rearrangement of a model compound, phenyl *N*-phenylbenzimidate **III**, into *N*,*N*-diphenylbenzamide **IV**, known as Chapman rearrangement [3]:

III **IV**

We found that heating of **III** at 250°C for 13 h leads to its complete transformation into **IV**. The structure of the product was proved by IR and ^{13}C NMR spectroscopy. The IR spectrum of **IV** contains a C=O absorption band at 1657 cm^{-1}, whereas the C–O band at 1210 cm^{-1} is absent. In the ^{13}C NMR spectrum of **IV**, a carbonyl carbon signal appears at 170.53 ppm.

Having obtained the positive result in the model reaction, we examined the possibility of the similar rearrangement in PBIs.

The possibility of thermal rearrangement of the polymers was checked with **Ie** as example (Fig. 1). The first evidences of the transformation in the melt appear in 3 h, after which the reaction accelerates and is complete in 18 h at 86% conversion. The rearrangement in a film and in the glassy state involves a long induction period and therefore takes more than 30 h. The rearrangement of **Ie**, according to viscosity measurements, is not accompanied by significant changes in the molecular weight. The conversion was esti-

mated from the IR spectra (absorption of the imido ester bond).

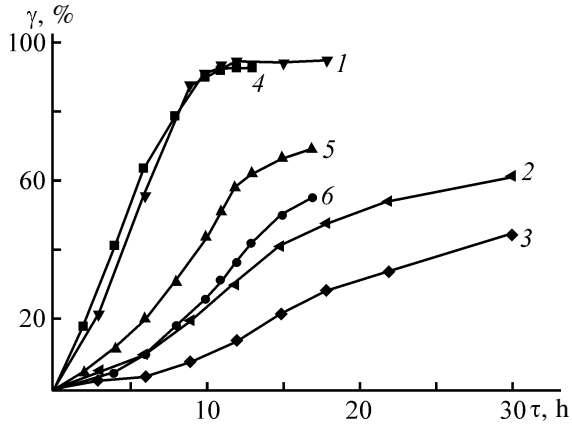
Figure 1 shows the conversion curves of **If** in nitrobenzene (NB) and diphenyl ether (DPE). The behavior of **If** in these solvents was different. In NB, compound **If** dissolved immediately without swelling, whereas in DPE the dissolution occurred only on heating above 150°C. Nevertheless, at equal other conditions, the rearrangement in DPE was faster.

We found that the molecular weight of PBI did not noticeably affect the kinetic parameters of the reaction.

Our results show that the rearrangement of PBIs into poly(*N*-arylenebenzamides) (PBAs) occurred considerably more readily in the melt and in DPE at 240°C. The conditions for preparing some PBAs are given in Table 1.

For more flexible PBIs **Ie**, **If**, **Il**, and **Im**, the transformation occurs to a greater extent in DPE, and for more rigid PBIs, in the melt.

The structures of PBAs were confirmed by IR spectroscopy: The C=N absorption band in PBIs at 1658 cm^{-1} shifted to 1672 cm^{-1}, and the C–O band at 1220 cm^{-1} virtually disappeared. The most convincing proof is furnished by ^{13}C NMR spectroscopy: In the spectra of PBAs, a signal of the carbonyl carbon atom appears at 174.7 ppm.



The PBAs obtained, like the starting PBIs, are soluble in DMF, *N*,*N*-dimethylacetamide, DMSO, *m*-cresol, and pyridine, but, in contrast to the starting polymers, dissolve in chloroform only on heating.

The glass transition point of the polymers changes insignificantly upon PBI → PBA rearrangement: from 275–318 to 210–252°C, respectively. The PBAs prepared significantly surpass the PIDs in the heat resistance: The 10% weight loss (TGA in air, 5 deg min^{-1}) is observed at 454–487°C (for the starting PIDs, at 360–415°C).

The PBAs obtained exhibit good film-forming properties; the physicomechanical characteristics of the films are given in Table 2. The properties of the press materials prepared by pressing PBA powders at 70–75 MPa/250–350°C are also given in Table 2.

EXPERIMENTAL

The IR spectra were recorded on Specord IR-75 and UR-20 spectrophotometers (4000–400 cm^{-1}) in KBr. The ^{13}C NMR spectra were taken on a Varian VXR-500S spectrometer (400.0 MHz for ^{1}H) in DMSO-d_6, internal reference TMS.

PBI conversion γ as a function of time τ in (*1*) melt, (*2*) glassy state, (*3*) film, (*4*) DPE at 240°C, (*5*) DPE at 200°C, and (*6*) NB at 200°C.

Dynamic thermogravimetric analysis was performed with a Q-1000 derivatograph in air at a heating rate of 5 deg min^{-1}, with Al_2O_3 as reference. The thermomechanical analysis was performed with a Tsetlin device at a constant load of 0.08 MPa and a heating rate of 100 deg h^{-1}.

Film materials were obtained by casting an 18–20% solution of a polymer in DMF onto a glass support. Physicomechanical tests of film samples were performed according to GOST (State Standard) 14236–81 (COMECON Standard 1490–79), and those of press materials, according to GOSTs 4647–80 and 4648–71.

Phenyl *N*-phenylbenzimidate. A flask equipped with tubes for argon inlet and outlet was charged with

250 ml of absolute ethanol and 0.3 mol of phenol; 0.25 mol of Na was added in small portions while purging with Ar. After the reaction completion, a solution of 0.25 mol of *N*-phenylbenzimidoyl chloride in dioxane was slowly added. After stirring for 15 h, the mixture was poured onto 300 ml of ice and placed in a freezing chamber for 10 h, after which it was allowed to warm up to room temperature. The precipitate was filtered off and recrystallized from absolute ethanol; yield 87.4%.

***N*,*N*-Diphenylbenzamide** was prepared by rearrangement of phenyl *N*-phenylbenzimidate in an inert atmosphere at 250°C for 13 h; mp 179.5–179.8°C (cf. 179.6°C [4]).

Polyarylene benzimidates were prepared in a 50-ml three-necked flask equipped with a stirrer and with tubes for argon inlet and outlet. A mixture of 0.01 mol of bisphenol with *N*-methyl-2-pyrrolidone was added while purging with argon, and the mixture was homogenized. Then 0.02 mol of triethylamine and 0.01 mol of appropriate imidoyl chloride were added with vigorous stirring. The homogenized reaction mixture was heated to 170–180°C for 17–18 h, after which the product was precipitated by pouring the mixture into 2% aqueous ammonia, filtered off, washed with a 1% solution of sodium bisulfite in water and with water, and dried in a vacuum at 60–70°C to constant weight.

Poly(*N*-arylenebenzamides) were prepared by rearrangement of the corresponding PBIs under Ar in the melt and in DPE (Table 1).

CONCLUSION

Film-forming poly(*N*-arylenebenzamides) were prepared by rearrangement of polyarylene benzimidates in the melt and in diphenyl ether at 240°C. The polymers obtained exhibit good solubility, high resistance to thermal oxidative degradation, and relatively low softening points.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Cocarbonization of Polymers as a New Concept for Synthesis of Carbon Composites

Yu. N. Sazanov and A. V. Gribanov

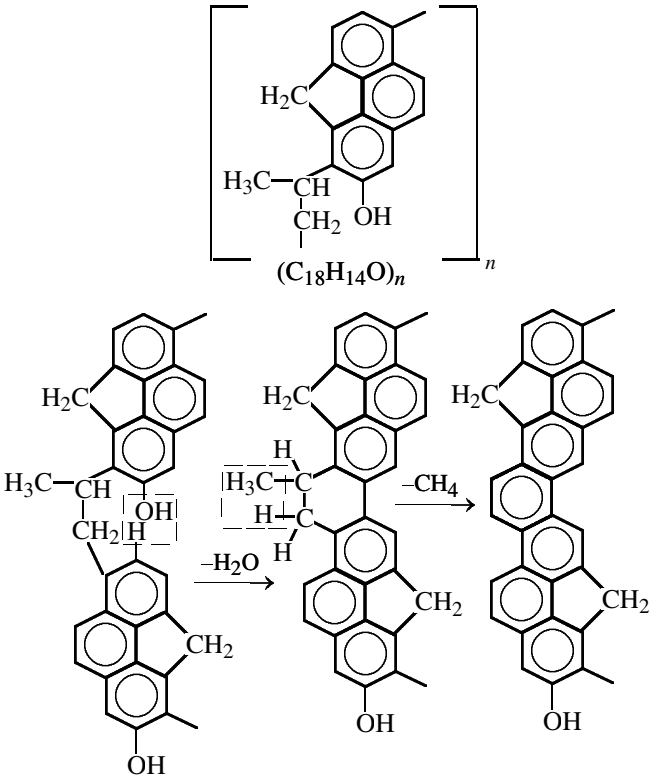
Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received December 28, 2005

Abstract—Foundations of cocarbonization of a series of carbon-chain and heterochain polymers in the solid phase and in solution were considered; the concept of this process was formulated. The temperature and kinetic parameters of the maximal thermal activity were determined. The possibilities of intermolecular interactions of compatible macromolecular compounds depending on the chemical structure of the initial components of composites and concentration and temperature–time parameters were studied.

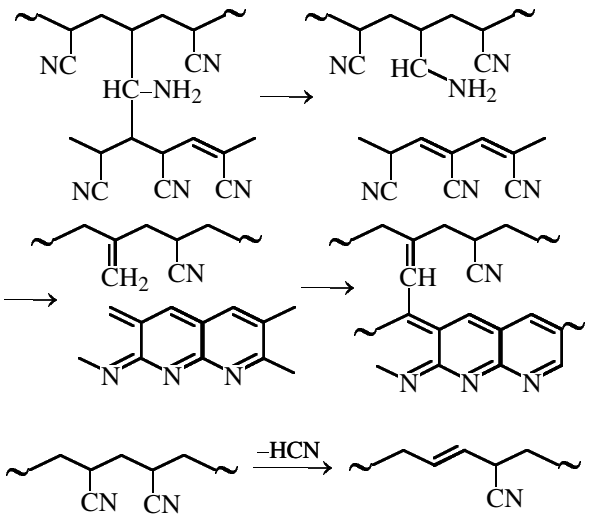
DOI: 10.1134/S1070427206030207

An interest in carbonization of polymers arose from studies of synthesis and characteristics of highly heat-resistant polymers and various materials based on these. It was shown [1] that the attainment of high heat resistance requires formation of macromolecules with carbo- and heterocyclic structure, in which the concentration of carbon atoms approaches 100%. Depending on the specific requirements to the materials, polymers can contain various heteroatoms, whose introduction allows preparation of various heat-resistant compounds having unique characteristics.



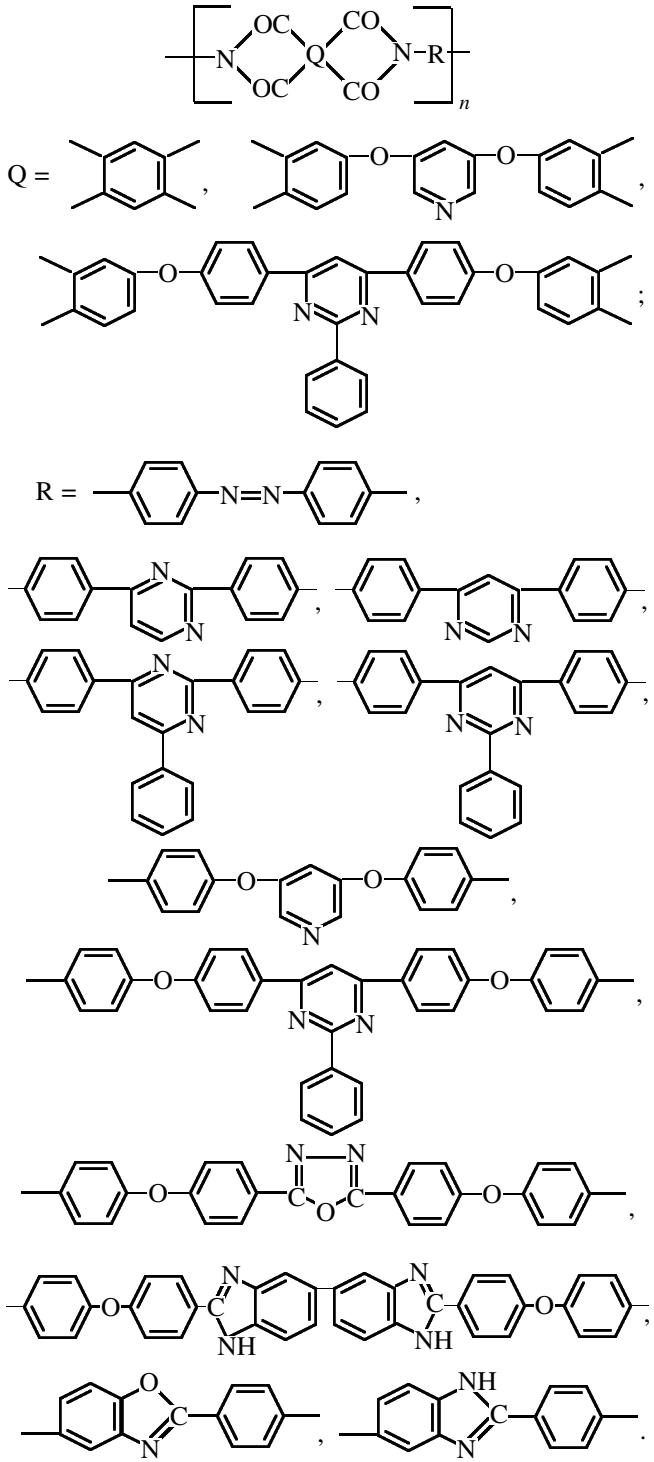
Polymers with carbon-chain, heterochain, and mixed structure, whose heat resistance under certain conditions reaches 500–600°C, were synthesized under laboratory conditions. Many representatives of these polymers are produced on the industrial scale and serve as indispensable materials operating for a long time under extreme thermal conditions [2, 3]. The examples of these polymers are polyphenylenes, cyclic polyacrylonitrile, polyimides, polybenzimidazoles, polybenzoxazoles, polyphenylquinoxalines, and other polyheterocyclic compounds.

During the studies and industrial tests of materials and items based on heat-resistant polymers, problems related to variation of their parameters as a result of thermal overload arose: the characteristics of materials irreversibly changed, which resulted, as a rule, in degradation of polymers and destruction of items based on these.



Studies aimed to solving these problems were pursued in two directions: (1) search for pathways of synthesis of new heat-resistant structures, development of various stabilizing agents preventing thermal degradation and composite materials [4–7]; (2) study of the characteristics of polymers altered as a result of thermal overload.

The studies of carbonization of polymers initially concerned carbon fibers based on cellulose hydrate, polyacrylonitrile, and partially carbon and oil distillation residues. It was shown that a number of regular trends well-known in carbon chemistry and coke chemistry are applicable to carbonization of polymers [8]. We can say that the terms "coke" and "coking" were prototypes of the term "carbonization," since they are based on thermochemical reactions related to gradual condensation of organic compounds, formation of rings, their subsequent aggregation [4], and elimination of hydrogen and heteroatoms (oxygen, nitrogen, sulfur, etc.). The similarity of these processes is evident from a comparison of the schemes of transformation of so-called carbon monomer used in coke chemistry (a) and cyclization of polyacrylonitrile (b).



Despite the fact that the residues of carbonized products of cellulose do not exceed 15–20%, carbon fibers based on these are of great practical value especially as highly active sorbents used in medicine. Of even greater value among polymer carbon materials are carbonizates of polyacrylonitrile (PAN); in its carbonization the carbon residue (CR) increases to 60%. The fields of application of carbonized and graphitized PAN are so wide that in dozens of leading branches of industry many of materials and items

based on these are indispensable for numerous structures, devices, and apparatus [9, 10].

Beginning from the 1980s, once the most heat-resistant polymers, polyimides, became commercially available as films and fibers, the need in studying the processes of their carbonization arose. The first studies of the influence of the polyimide unit structure on its thermal stability and some other characteristics showed a certain influence of nitrogen atoms on thermochemical conversion of polyimide to carbonizate

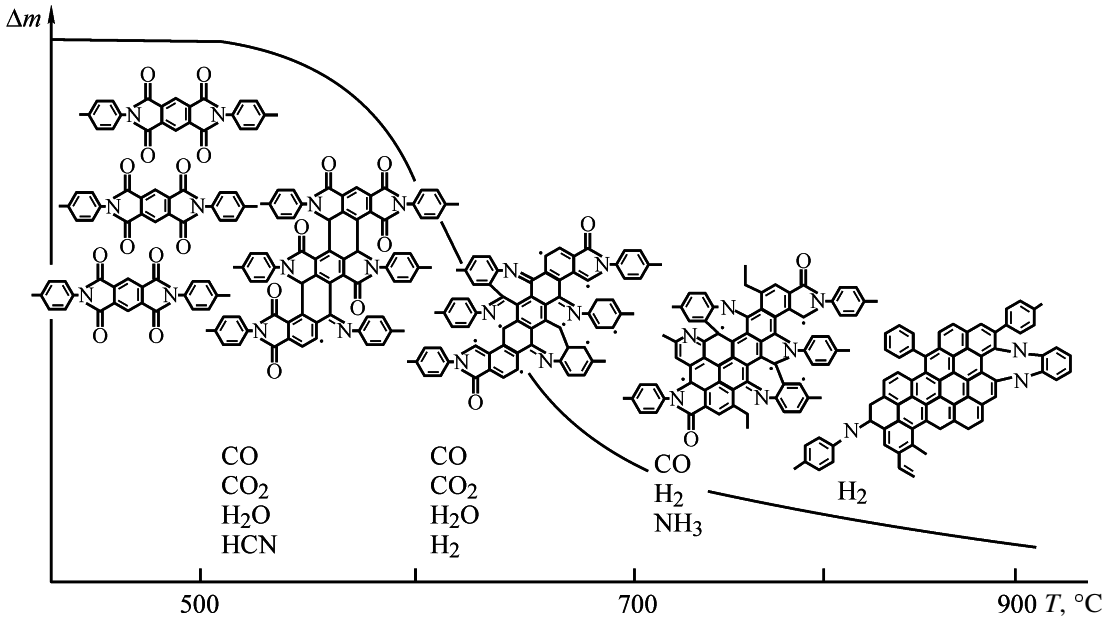

Fig. 1. Schematic thermogram of thermochemical reactions of polyimide PM carbonization in the range 500–900°C. (Δm) Weight loss and (T) thermal treatment temperature; the same for Fig. 3.

at a temperature of 500°C and above. In a series of runs, the yield of coke residue as high as 70–75% was attained; in so doing, a correlation was observed between the ratio of nitrogen atoms and their bonds with neighboring atoms, and on the one hand, and carbon residue (CR), on the other hand [11, 12]. Scheme (c) shows the structures studied, for which it was found that polyimides based on *p*-phenylenediamine, benzoxazole, and pyrimidine derivatives, i.e., polymers containing more nitrogen atoms in the chain, have the highest CR at 900°C. More recent studies [13, 14] showed that nitrogen atom in the polyimide chain plays a crucial role in thermal transformation of this polymer in a wide temperature range. For polyimide PM as example, it was shown that, beginning from the stage of conversion of the polyimide prepolymer into the cyclic polymer, in which nitrogen plays the role of creating factor, up to conversion of the polymer to highly carbonized product above 1200°C, when nitrogen leaves the intermediate cyclic structures (Fig. 1), this atom permanently participates in gradual rearrangement of polyheterocyclic structure to carbocyclic structure. In energy terms, this process is more favorable than the direct carbonization of carbon-chain polymers. The similar "relay" character of thermal transformations of polyimides is observed on introduction of fragments containing pentavalent phosphorus atoms, close in structure to some nitrogen compounds [15].

Further studies on the synthesis of carbonized materials from commercial polyimide film (polyimides PM and VM) involving variation of the conditions of thermal treatment showed that the products with increased content of carbon, exhibiting the stability of shape and increased conductivity, are formed only in a block or thick film under isothermal heating. However, CR values for such a film do not exceed 40–50%.

To minimize the above drawbacks we performed carbonization of copolyimides incorporating, along with the initial dianhydrides of tetracarboxylic acids, two diamines of various isomer compositions based on pyrimidine derivatives. The results of this study [16] showed a noticeable increase in the thermal stability and strength of these polyimides in comparison with polyimide PM. For a series of samples, carbonizates were obtained in a yield of 70–80% with respect to carbon residue. The similar studies were performed with combination of polyimides with other polyheterocyclic compounds. For example, based on phenylquinoxaline, the difference in the structure of the resulting carbonizates depending on the three-dimensional packing of the reactants was revealed [17].

However, the three-dimensional packing of branched polymers does not allow CR to be increased in comparison with PM polymer. The other way of introduction of nitrogen-containing fragments into the polyimide structure was formation of interpolymeric complexes based on common solvent. For this pur-

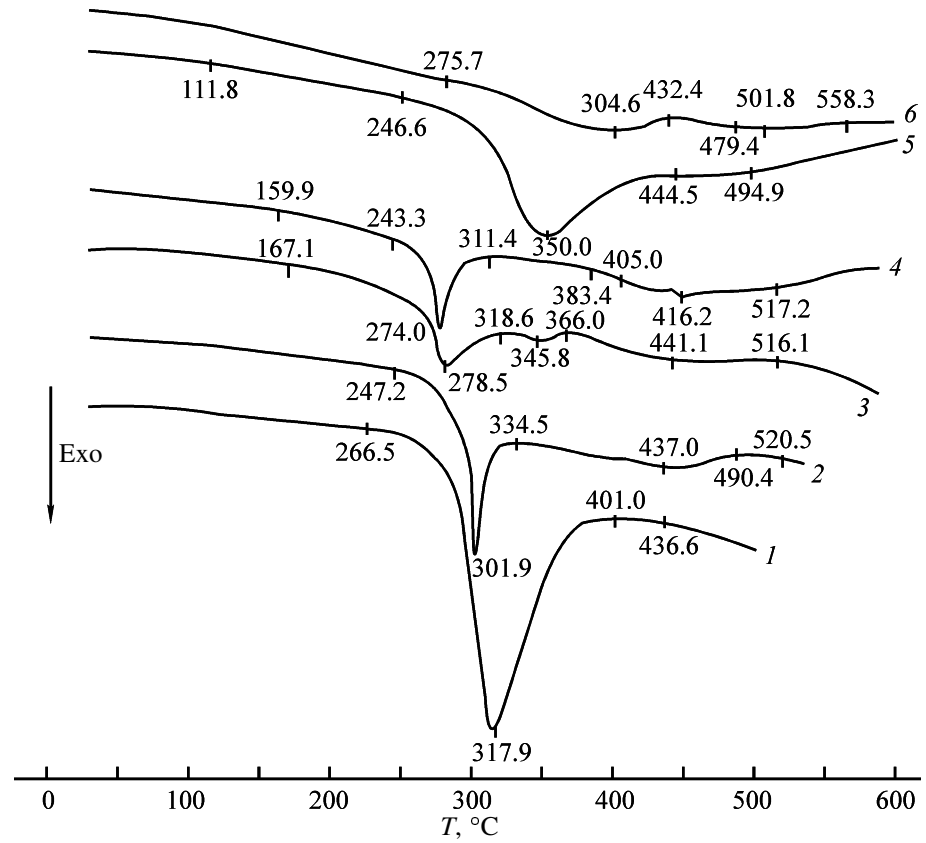

Fig. 2. DSC curves for the samples of PAN, chitin, and PAN + chitin film prepared from DMF. Heating rate 10 deg min^{-1}, weighed portion 5 mg. (*T*) Temperature of thermal treatment. pose, the solutions of prepolymers of polyimide PM, polybenzimidazole, polyacrylonitrile (PAN), polyvinylpyridine, polyvinylpyrrolidone, and polyvinyltetrazole in dimethylformamide or dimethylacetamide were used [18–21].

Among the studied polymer pairs polyamido acid–nitrogen-containing polymer, the products of thermal treatment of mixed solutions of polyamido acid (PAA) with PAN are of the most interest for the cocarbonization process. The specific feature of this pair is that the main cyclization reactions of both polyamido acid and polyacrylonitrile are suppressed. Competition of these reactions under ordinary conditions of thermal cyclization prevents formation of copolymer and yields a blend of polyimide with PAN, whose carbonization under subsequent heating does not yield a carbonizate with a new structure different from polyimide and PAN. Only in the case of prolonged heating of a mixture of solvate complexes of the initial polymers at 150–200°C, copolymer can be formed through an interpolymer complex. In some characteristics, this product differs from the initial polymers (increased chemical stability, prolonged thermal stability, improved flexibility and elongation at break). Further heating of this compound at 400–500°C yields a carbonizate whose structure in its spectral characteristics differs from those of both polyimide carbonizate and PAN carbonizate. At 900°C, the carbonized residue retains the shape of the initial material, has metallic luster, conductivity comparable with that of the carbonized polyimide, and CR varying from 60 to 80% depending on the carbonization conditions.

Since synthesis of the above carbonizate presents some problems caused by instability of PAA solutions and prolonged synthesis of the initial copolymer, subsequent experiments on studying cocarbonization were performed with PAN. As the second component of the initial blend we used cellulose and its derivatives. These macromolecular compounds have rich resources and are widely used in industry; thermal degradation and carbonization of these compounds were studied theoretically and experimentally [9, 10]. According to our observations and hypothesis [22] on the role of nitrogen in formation of carbon cyclic-chain structures, we chose nitrogen-containing polysaccharides, chitin and chitosan.

Based on the studies on carbonization of polyimides and their reactions with polymers in a wide temperature range (20–1000°C) in various gaseous media and at various temperature–time modes of thermal treatment, we can postulate the following principles of thermal reactions of polymers (cocarbonization).

(1) Performing cocarbonization in the temperature range in which the reacting polymers exhibit the highest thermal activity (thermal degradation, cross-linking).

(2) Providing conditions favorable for mutual thermochemical cross-linking of polymers.

(3) Using polymers tending to ring formation on the level of polycarbo- and heterocycles.

(4) Using catalytic polymerization and polycondensation applied in chemistry of heat-resistant macromolecular compounds.

(5) Taking into account steric orientation of macromolecules for realization of intermolecular bonds.

The pairs of polymers polyacrylonitrile–chitin and polyacrylonitrile–chitosan, chosen as an example, in their thermochemical characteristics meet the formulated requirements. The DSC curves of the initial polymers PAN and chitin and their blends in various modifications are shown in Fig. 2. It is seen that each of the compounds studied shows the highest thermal reactivity in the same temperature range, 250–400°C (first principle), and thermal effects of formation of carbonizates through interpolymeric complexes suggest the presence of structures different from those of the initial polymers. The TGA data of the same samples (Fig. 3) suggest formation of cocarbonizates (curves *3, 4*) with CR close to that of polyacrylonitrile (70–80%), i.e., the second principle of the cocarbonization concept is realized.

The structure of the initial polymers corresponds to the third principle of the concept. It is well known that in heating the dominating reaction of PAN cross-linking is cyclization, and the initial chitin and chitosan contain glucopyranose rings opening in the above temperature range (250–400°C). In addition, spatial organization of the PAN polymers used is energetically and sterically favorable for their intermolecular interaction (realization of the fifth principle). As regards fourth principle of the concept, it is manifested in the difference in the thermochemical activity of PAN samples synthesized by the radical and anionic mechanisms of acrylonitrile polymerization [22].

The experiments on cocarbonization of polyacrylonitrile with chitin and chitosan and also model studies of the heat resistance and carbonization of cyano derivatives of cellulose [23, 24] confirmed once again the special role of nitrogen atoms in formation of cyclic carbon structures in the early stage of carbonization of nitrogen-containing polymers.

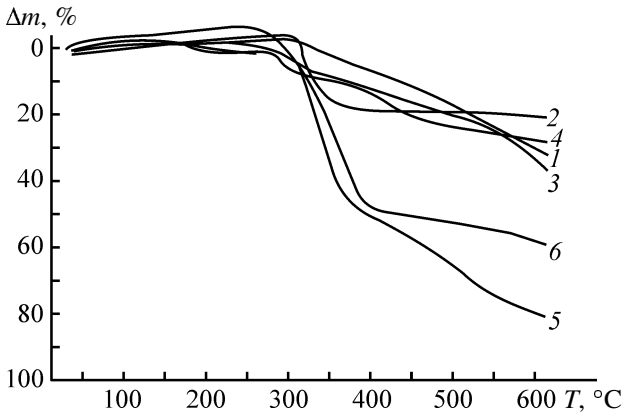

Fig. 3. TG curves for the samples of PAN, chitin, and PAN + chitin film prepared from DMF. The experimental conditions and legend are the same as for Fig. 2.

Thus, the use of the suggested concept of cocarbonization of polymers can promote development and application of new carbon materials.

CONCLUSIONS

(1) A concept of formation of carbon composites, termed cocarbonization of polymers, was suggested. This concept is based on realization of thermochemical reactions of reacting polymers in the range of temperatures of their maximal thermal activity.

(2) The basic principles of cocarbonization are close coincidence of the temperature boundaries of heat resistance, reactions in the diffusion area, and prolonged period of thermal treatment under isothermal conditions.

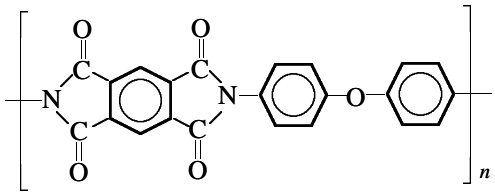
Abstract—A series of foamed organoplastics based on a combination of foamed fully aromatic polyimide binders and Arimid T polyimide felt were prepared. New composite foamed organoplastics reinforced with montmorillonite nanoparticles were prepared using commercially available aromatic monomers.

DOI: 10.1134/S1070427206030219



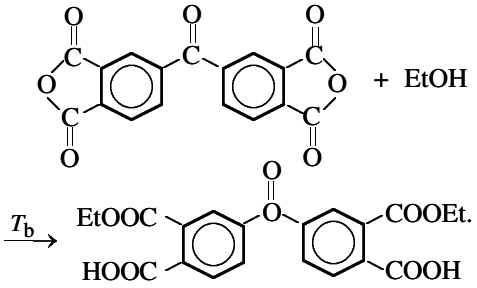
The preparation of strong and light heat-resistant structural materials is one of the most urgent problems of modern engineering. Among these materials the most promising are polymeric composites based on a combination of continuous carbon or organic fibers with heat-resistant polymeric binders. The density of these materials, depending on the kind of filler and its volume fraction, varies, as a rule, from 1100 to 1500 kg m^{-3}. The progressively growing industrial application of highly thermostable composite materials allowed the development of power and fuel-saving technologies and light-weight installations. These materials are successfully used in aircraft industry, ship building, and automobile construction [1].

A great body of data on nanocomposite materials based on a polymeric matrix reinforced with inorganic nanofillers, in particular, montmorillonite (MMT), were published in the last decade. The montmorillonite lamellar structure consists of aluminosilicate layers with a thickness not exceeding 1 nm. Owing to good mechanical and barrier characteristics and high refractoriness [2, 3], composites of this kind are of great scientific and practical interest.

In this study we attempted to prepare lighter polymeric composites based on a combination of polyimide felt and elastic foamed polyimide binder [4–6]. These materials have density ranging from 200 to 500 kg m^{-3}. Their strength and elasticity exceed those of modern foamed polyimides developed in the United States (Skybond, Illmid, Solymide) [7, 8] and of EPPI foamed polyimide produced in Russia [9]. The foamed composites can be prepared with equipment commonly used for preparing carbon-reinforced and organoplastics [10]. It is believed that in future these organoplastics can find wide technical application as efficient heat shielders and light, strong, and nonflammable structural materials [11].

EXPERIMENTAL

In this study the influence of the chemical structure of polyimide binders on the thermomechanical characteristics of foamed composites was examined for foamed composites based on a combination of various polyimide binders (Table 1) and Arimid T polyimide felt prepared from wastes from production of Arimid T polyimide fiber.



The use of polyimide binders in combination with polyimide fibers of similar chemical and structural type in preparing foamed composites ensures their efficient mutual adhesion and high integrity of the final material. The foamed polyimide binders were prepared from commercially available monomers widely used in production of polyimides: 3,3',4,4'-benzophenonetetracarboxylic acid dianhydride (BP), 3,3',4,4'-(diphenyl

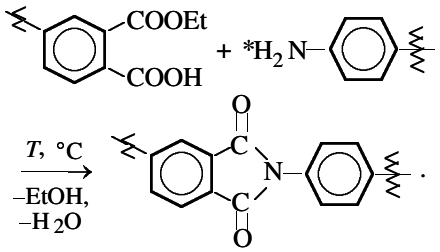
oxide)tetracarboxylic acid dianhydride (DPO), 3,3',4,4'-diphenyltetracarboxylic acid dianhydride (DP), 4,4'-diaminodiphenylmethane (DADPM), 4,4'-diaminodiphenyl ether (DADPE) and *m*-phenylenediamine (*m*-PDA). Ethyl alcohol and, in some cases, alcohol–water mixtures were used as solvents. It is known that polyimide foamed composites are formed by thermal imidization of H complexes of 3,3',4,4'-(diphenyl oxide)tetracarboxylic acid diesters with aromatic diamines. The chemical reactions and procedures for preparing the initial H complexes were thoroughly analyzed in [12]. The simplified scheme of this process includes three main steps.



(1) Preparation of 3,3',4,4'-benzophenonetetracarboxylic acid diester (BPE) by esterefication of 3,3',4,4'-benzophenonetetracarboxylic acid dianhydride (BP) with alcohol in solution:

(2) Preparation of H complex of BPE with diamine in the cooled solution.

(3) Conversion of H complexes into polyimide by thermal imidization. In this step, the volatile products (water, alcohol) are evolved to form a porous structure of foamed composite:

To optimize the conditions for preparing foamed composites and ensure efficient impregnation of the prepreg, we studied the rheological features of H complexes. The viscosity of the molten H complexes was measured on a PIRSP flowmeter [13] of cone-plane type (angle at cone apex 1°, cone diameter 40 mm) at 95°C at a constant shear rate of 0.013 s^{-1}. Figure 1a shows the time dependence of viscosity of several molten H complexes prepared under identical conditions in 10% solution of water in ethanol. Comparison of curves *1–3* (Fig. 1) shows how the dianhydride structure affects the initial viscosity of the molten H complex and its subsequent thickening due to thermolysis. It is seen that H complexes under consideration show different impregnation capability. The H-complex based on DPO shows the lowest initial viscosity (approximately 300 Pa s) which in the first 20 min increases only slightly. On the contrary, the viscosity of molten H complex based on BP sharply increases with time. We suggest that this rheological behavior is caused either by structural (ordering of supramolecular structure of H complexes) or chemical (increase in molecular weight of polymer) reasons.

The structural hypothesis is consistent with the dependence of the viscosity of the molten H complexes on the shear rate in the range 0.02–100 s^{-1} (Fig. 1b). The larger slope in the plot of viscosity vs.

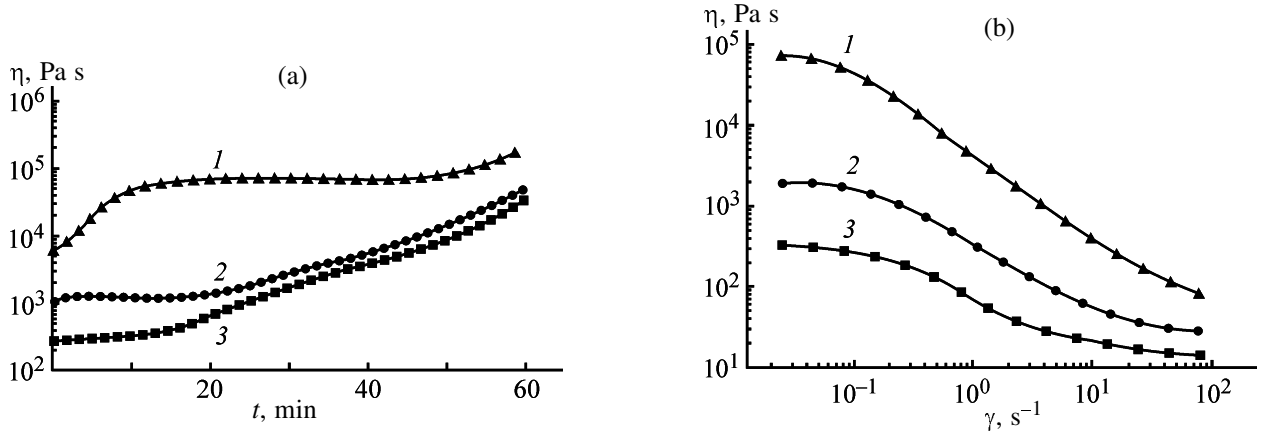


Fig. 1. Dependence of viscosity η of molten H complex on (a) time and (b) shear rate γ at 95°C. (*1*) BP : *m*-PDA : DADPM, (*2*) DP : *m*-PDA : DADPM, and (*3*) DPO : *m*-DPA : DADPM.

shear rate for H complex based on BP dianhydride is indicative of higher ordering of its supramolecular structure at 95°C. At the highest shear rate (about 100 s^{-1}), the viscosity of all the molten H complexes becomes close. We believe that this effect is caused by the fact that the shear stress breaks the supramolecular structure of H complexes. Our results show that only the H complex based on DP allows efficient impregnation of felt at relatively low temperature because this H complex remains low-viscous (~300 Pa s at 95°C) during sufficiently long time (20 min).

The preparation of foamed composite involves two main stages: (1) Preparation of a prepreg based on a combination of polyimide felt and H complex and (2) preparation of foamed composite by hot pressing. A prepreg is prepared by impregnating felt with a molten H complex. This procedure is carried out as follows. An H complex powder is uniformly applied to the felt surface by electrostatic deposition. This intermediate product is placed on an electric plate heated to 120–140°C and rolled for several seconds to ensure uniform distribution of the molten H complex throughout felt. The resulting prepreg is a flexible material suitable for packing into molds. The weight ratio of the H complex and felt in the prepreg is 1 : 1. The multilayer prepreg is packed into a mold of appropriate configuration. The mold is hermetically sealed and placed between slabs of a heated press. Hot pressing is provided by the internal pressure developed in the foaming binder. Therefore, with hermetically sealed molds, a foamed composite can be prepared by heating a prepreg in a thermostat (without external pressure) at 200–220°C for 1–2 h.

This mode of curing and foaming polyimide binders was chosen taking into account that these conditions ensure the maximal degree of imidization for the majority of H complexes. The resulting foamed organoplastics have increased heat-insulating characteristics and high heat resistance. The density of these foam composites can be varied by varying both the degree of felt impregnation with H complex and the number of prepreg layers in a mold. In this study we used four-layered prepreg packing ensuring the preparation of foam composites with approximately equal density of 500 kg m^{-3}.

The failure surface of foamed composites in the zone of its bending was examined with a scanning electron microscope (SEM, Cambridge S-200, the United States). The electron-microscopic pattern of the surface of a foamed composite based on H complex BP : *m*-PDA : DADPM subjected to triple-point bending is shown in Fig. 2. The electron micrograph (Fig. 2c) distinctly shows the porous structure of the composite and uniform distribution of Arimid T fibers throughout the polymeric matrix. Figure 2d shows that the fiber–matrix interface contains specific stitches causing the efficient adhesion. We believe that these interface interactions are responsible for high strength and elasticity of the foamed composite.

The bending tests were carried out with three-point bending technique on a 1958 U-10-1 tensile-testing mashine (distance between supports 30 mm). The tested plates of the foamed composite were 4–5 mm thick and 10 mm wide. The loading rate was 5 mm min^{-1}.

The compression tests of foamed composites was carried out under uniaxial compression on a UTS-10 (Gemany) universal mechanical testing installation. The tested samples were square prisms of 10×10 mm base and 8.5–8.7 mm height. The modulus of elasticity in compression was determined from the initial portion of the loading diagram. The modulus of

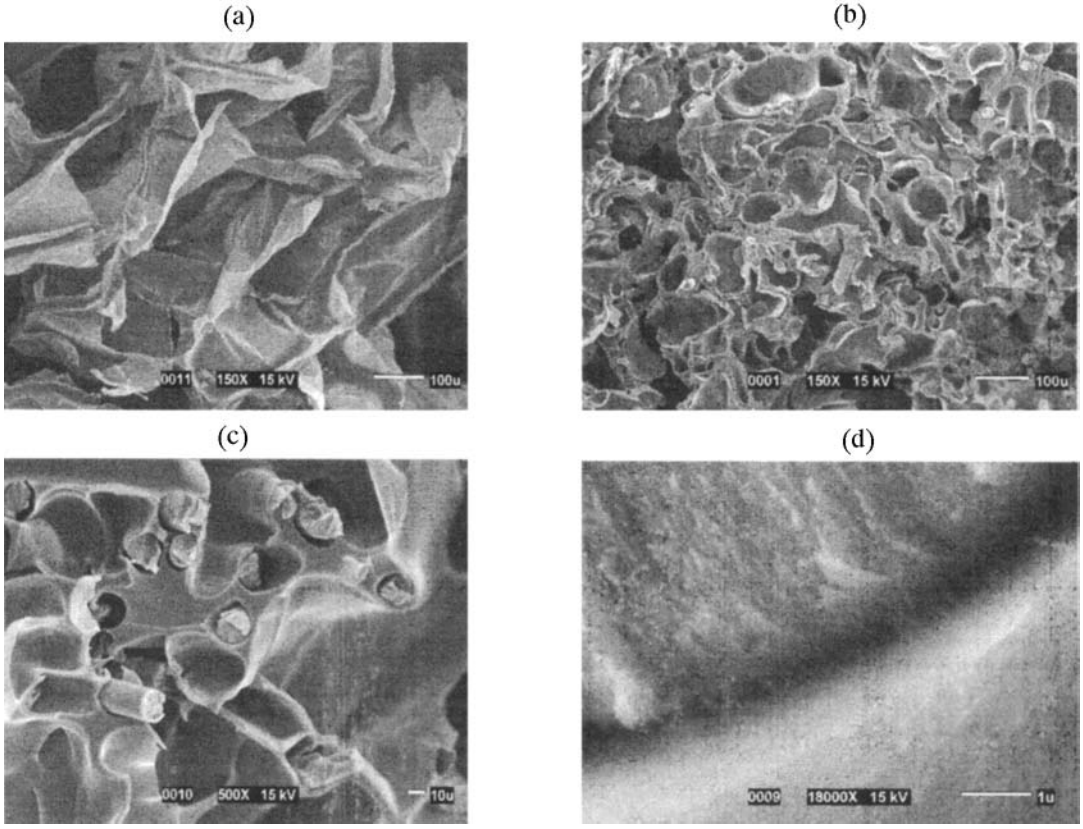

Fig. 2. Electron-microscopic patterns of the failure surface of foamed composites based on BP : *m*-PDA : DADPM H complex. (a) Initial foam and (b–d) failure surface of foamed composite. Magnification: (a, b) × 150, (c) × 500, and (d) 18000.

elasticity in shearing G' and the modulus of shear loss G'' were determined in the temperature range 20–400°C by a method based on free attenuation of torsion vibrations of an MK-003 torsion pendulum developed at the Institute of Macromolecular Compounds, Russian Academy of Sciences. The tested samples were plates of 3 mm thickness, 10 mm width, and 40 mm length. The glass transition point T_g of foamed composites was determined as the temperature corresponding to maximal modulus of shear loss G''. The density of foamed compositions was determined gravimetrically.

The main thermomechanical characteristics of the tested foamed composites are listed in Table 1. These data show that the strength of foamed composites prepared with the H complex based on DPO (sample nos. 5, 6, 8) exceeds that of the foamed composites prepared with the H complex based on BP (sample nos. 1–4). Another advantage of foamed composite based on DPO is decreased softening point. It should be noted that, in a bending test, the foamed composites based on DPO, owing to their higher elasticity, were not broken but only bended. We believe that the better mechanical properties of foamed composites based on DPO dianhydride are mainly due to more efficient impregnation of the felt with molten H complex based on this polyimide binder.

It was found that, in synthesis of foamed composites, the toxic DADPM can be replaced by less toxic and commercially available DADPE [14]. Table 1 shows (sample nos. 6, 8) that this substitution does not deteriorate the mechanical characteristics of foam composites prepared with H complexes based on BPE with addition of water (10 vol %). The composite based on DP (Table 1, sample no. 7) has lower bending strength than the composites based on DPO and BP. At the same time, introduction of DP into the foamed composite matrix considerably increases the glass transition point T_g (Fig. 3).

The optimal thermochemical properties are exhibited by the foamed composite based on DPO : *m*-PDA : DADPE H complex (Table 1, sample no. 8). This composite was subjected to modification with montmorillonite nanoparticles to elucidate their effect on thermomechanical characteristics. Two kinds of

* Solvent C_2H_5OH/H_2O.

montmorillonite were used: (1) untraeated montmorillonite in the Na form and (2) commercially available montmorillonite treated with a quaternary ammonium salt MMT 15A (Cloisite 15A, Southern Clay Products).

In preparation of foamed composites modified with montmorillonite nanoparticles, the latter were introduced under ultrasonic treatment (a Sapfir ultrasonic generator, 40 kHz, 1.5 h, room temperature) into the reaction mixture in an amount of 5 or 10 wt % after completion of formation of H complex.

Thermomechanical characteristics of foamed polyimide composites modified with montmorillonite are listed in Table 2. These results show that introduction of montmorillonite significantly affects the properties of foamed polyimides. The addition of montmorillonite, depending on its kind and content, differently influence the particular thermomechanical properties.

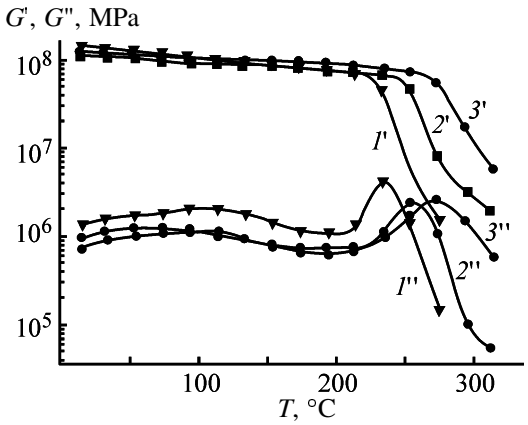

Fig. 3. Temperature dependence of the (*1'–3'*) modulus of elasticity in shear G' and (*1"–3"*) modulus of shear loss $G"$ of foamed composites based on a combination of Arimid T polyimide felt and H complexes based on diamines *m*-PDA and DADPM and dianhydrides. Dianhydride: (*1'*, *1"*) DPO, (*2'*, *2"*) BP, and (*3'*, *3"*) DP.

In our compression tests, the maximal accessible pressure was 90 MPa. Under this pressure, all the samples maintained their integrity. With increasing montmorillonite content from 5 to 10 wt %, the modulus of elasticity in compression of foamed composites modified with untreated montmorillonite increases (Table 2, sample nos. 2, 4). At the same time, the three-point bending test did not show increase in the bending strength. We believe that this result is caused by the fact that the rigid inorganic montmorillonite nanoparticles accumulate stresses, and, as a result, make the composites more brittle. This hypotheses is confirmed by easier brittle failure of the composite modified with nanoparticles as compared to the initial composite (Table 2, sample 1). In shear tests, the modulus of elasticity somewhat increased but only for the composites modified with the untreated montmorillonite (Table 2, samples 2, 4). The addition of montmorillonite did not affect the softening point of the foamed composites.

In contrast to untreated montmorillonite (MMT), MMT 15A nanoparticles exert a plasticizing effect on the foamed composite: the modulus of elasticity in compression decreases by a factor of 4 as compared to initial sample. This modulus somewhat increases with increasing MT concentration to 10% but, nevertheless, remains considerably lower than that of the initial sample. Thus, modification of the foamed composite with untreated montmorillonite MMT is preferable, since this treatment increases the modulus of elasticity, i.e., rigidity.

CONCLUSIONS

(1) Organoplastics of a new kind, based on a combination of foamed polyimide binders and Arimid T polyimide felt, were prepared using commercially available aromatic monomers.

(2) The H complex based on 3,3',4,4'-(diphenyl oxide)tetracarboxylic acid melts to form low-viscous liquid whose viscosity at 95°C remains low and practically constant (300 Pa s) for 20 min.

(3) Thermomechanical characteristics of foamed composites prepared with H complex based on 3,3',4,4'-(diphenyl oxide)tetracarboxylic acid dianhydride exceed those of foamed composites based on 3,3',4,4'-benzophenonetetracarboxylic acid dianhydride by a factor of 1.5. In bending test, the composites based on 3,3',4,4'-(diphenyl oxide)tetracarboxylic acid bend without failure, which makes them promising for preparing new flexible foamed materials.

(4) Modification of foamed polyimide composites with montmorillonite nanoparticles, particularly with untreated montmorillonite, increases their rigidity.

Abstract—Influence of low-temperature plasma on the polymer surface was studied with the aim of preparing polymers with required surface properties.

DOI: 10.1134/S1070427206030220

The surface properties of most of polymers, even with a high level of bulk physicomechanical parameters, do not meet the industrial, especially aviation, requirements. Polymer composites based on polyurethanes find expanding application. The composites with required performance can be prepared by variation of the polyurethane formulation and by introduction of modifying additives [1–4].

Since urethane formation in a multicomponent system is a complex process, the performances of polyurethanes of different batches, even produced by the same procedures, can differ essentially. In addition, for each particular polyurethane, the composition of the reaction mixture and the type of modifying additive should be optimized.

A feasible procedure for modifying the structure and hence for altering the performances of polymer composites is radiochemical treatment.

Under exposure to ionizing radiation, polymer composites undergo chemical transformations including cross-linking, degradation, and oxidation, which change their physicomechanical parameters. These changes can be negative or positive depending on the radiation dose and the macromolecular structure.

Polymer composites can be modified in a low-temperature plasma [5–10].

A gas-discharge low-temperature plasma affects only the surface layer of a polymer and hence affects bulk physicomechanical properties of the polymer as whole to a lesser extent then do other kinds of radiation. However, the surface transformations of the polymer treated with a low-temperature plasma are stronger. Therefore, treatment of a polymer composite with a low-temperature plasma modifies the surface properties of a composite and has virtually no effect on its main physicomechanical parameters.

Here we studied the effect of a low-temperature gas-discharge plasma on the surface properties of polyurethane composites.

EXPERIMENTAL

We studied a polyurethane composite containing saponified vinyl chloride–vinyl acetate copolymer, urethane prepolymer, and triisocyanate.

The treatment with a low-temperature plasma was performed on a UVN-2M-1 standard vacuum unit. A quartz cylinder 60 mm in diameter was used as the reaction chamber. The reaction chamber was equipped with side inlets for feeding the reaction gas directly in the discharge area. To renew the gas phase in the reactor, its was continuously pumped off through face slits.

A standard generator with a carrier frequency of 40.68 MHz was used as an ac source for the plasma discharge. The maximal power was obtained by varying the output resistance.

The structural transformations of the surface of the polyurethane composites were studied by IR multiple attenuated total internal reflection spectroscopy (IR MATIR), electron microscopy, and NMR. The surface properties of the polyurethane composites were determined from the changes in their adhesion and triboadhesion parameters.

The MATIR spectra were recorded using a conventional unit containing KRS-5 crystals (14 reflections). The apparent thickness of the examined layer calculated by the known equation was 3–5 μm. The electron microscopic studies were performed on an elec-

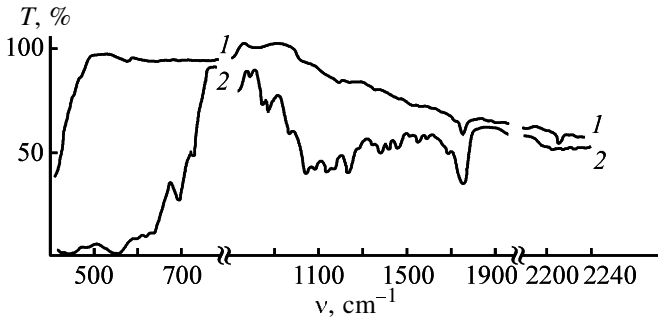

Fig. 1. IR MATIR spectra of the (*1*) initial and (*2*) modified polyurethane composite. (*T*) transmission and (ν) wavenumber.

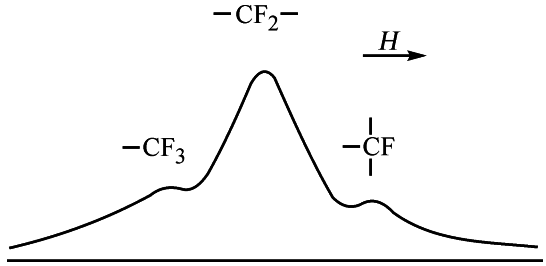

Fig. 2. NMR spectrum of plasmochemically obtained polytetrafluoroethylene.

tron scanning microscope. To increase the picture contrast, a 0.03-μm gold layer was sprayed on the sample surface.

The adhesion was determined as tangential shear strength required for rupture of the adhesion bonds of the polyurethane composite with a model support. These measurements were performed on a special strain-gage unit.

The triboadhesion properties of the polyurethane composites were determined as a change in the transportation strength (F_i and F_f are the initial and final strengths, respectively) as influenced by the number of the passage cycles relative to a stationary counterbody. These experiments were performed on a tribometer under normal (NCC: 40% humidity and 25°C) and extreme (ECC: 98% humidity and 40°C) climatic conditions.

It is known that organic monomers polymerize in a gas-discharge plasma to form cross-linked polymers strongly bound to the support surface.

Plasma polymerization on electrodes was extensively studied. The conditions of plasma polymerization on a polyurethane composite film fixed in the middle of the interelectrode space were studied. To deposit a uniform film, we used a mobile support compensating the nonuniformity of the gas-discharge plasma. The initial monomer was tetrafluoroethylene. We suggested that the antifriction properties of the polymer deposited in plasma from this monomer would be similar to those of Teflon.

Treatment of polyurethane composites in a low-temperature plasma in the presence of tetrafluoroethylene yields a 0.3–0.8-μm film on the support surface. The IR MATIR spectra (Fig. 1) of this coating contain the strong $–CF_2–$ bands at 680, 740, 1242, and 1380 cm^{-1}. In addition, the bands of –CF=, –CF=CF–, $–CF_3$, and SiF_6^{2-} groups were observed at 1230, 1789, 1640, and 540 cm^{-1}, respectively.

These data show that plasma-deposited polytetrafluoroethylene is cross-linked and its structure differs from that of polytetrafluoroethylene formed by polymerization of the double bonds. The branching and cross-linked fragments of the polymer contain the ≡CF groups. The degree of branching and the content of cross-links in the plasma-deposited polymer can be estimated from the content of $–CF_2–$ and ≡CF groups.

Under conditions of gas-discharge polymerization of tetrafluoroethylene, the ≡CF group can be formed without rupture of the C–F bond. This fact suggests that the polymerization involves both addition to the double bonds and rupture of the CF bond. The rupture of this bond is confirmed by the presence of the SiF_6^{2-} band (540 cm^{-1}) in the spectra of the examined polymers. This groups is formed by reaction of fluorine atoms with the glass walls of the reaction chamber.

These data agree well with the results of an ESCA study of plasma-deposited organofluorine polymers [5].

It should also be noted that the band of urethane groups at 1750 cm^{-1} in the spectrum of the polyurethane composites modified in gas-discharge plasma contains a shoulder at 1700 cm^{-1} which can be assigned to CO···HCF hydrogen bonds. This suggests that the plasma-deposited polymer is grafted to the polyurethane matrix.

Our electron microscopic studies show than the surface structure of the polyurethane composite changes after the plasmochemical treatment. The surface of the initial polyurethane composite is loose and highly porous. The number of pores on unit surface is 20 and more; the pore size is 0.7×0.7 μm^2. The surface porosity of the polyurethane composite decreases after the plasmochemical treatment: the number of pores on unit surface decreases to 8 and the pores become narrower: 0.4×0.3 μm^2. This is due to formation of polytetrafluoroethylene film on the composite surface.

The IR and NMR spectra (Fig. 2) of the plasma-deposited coatings show that the polymer with the

Adhesion and triboadhesion properties of polyurethane composites

* F_i and F_f are the initial and final shear strengths, respectively.

maximal content of $-CF_2-$ groups is formed by plasma polymerization of tetrafluoroethylene under the best conditions. As the power increases, the content of the ≡CF groups increases owing to formation of strongly cross-linked polymer. The low fluorine content (C/F ratio) in the polyfluorinated polymer prepared under these conditions substantially decreases its hydrophobicity, which affects the physicochemical (adhesion and triboadhesion) properties of the polymer [6, 8]. In particular, the adhesion of the polyfluorinated polymer to the composite is lower. The wetting angle of water on the surface of the film deposited on the polyurethane composite by plasma polymerization of tetrafluoroethylene under the best conditions is 82°, whereas for the polymer film deposited at a high discharge power (low F/C ratio) this angle is as low as 78°C.

The adhesion and triboadhesion properties of the initial polyurethane composites and the composites modified in gas-discharge low-temperature plasma are presented in the table.

As seen from the table, the adhesion and triboadhesion properties of the polyurethane composite are improved after plasmochemical modification, with the physicomechanical parameters remaining the same.

CONCLUSION

The surface properties of the polyurethane composite can be modified by treatment in gas-discharge low-temperature plasma. The physicochemical properties of the composite which determine its performances remain within the required range.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Amphiphilic Block Copolymers Polystyrene–*block*-Polyvinylpyrrolidone from Active Polystyrene

O. A. Shamenkova, L. K. Mokeeva, N. A. Kopylova, and Yu. D. Semchikov

Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

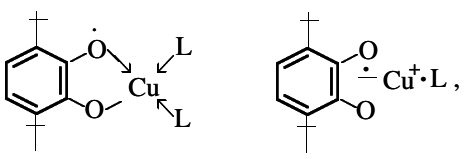
Abstract—A new method was developed for preparing amphiphilic block copolymers polystyrene–*block*-polyvinylpyrrolidone. The colloid-chemical properties of the copolymers were studied by probe microscopy and wetting. The possibility of modifying the properties of surfaces by the block copolymers synthesized and of preparing inverse emulsions based on them was demonstrated.

DOI: 10.1134/S1070427206030232



Pseudoliving radical polymerization allows preparation of block copolymers with controllable block length and narrow molecular-weight distribution [1]. However, this process is applicable only to a very limited range of monomers, primarily to so-called inactive monomers (monomers with no π–π conjugation).

Previously we prepared styrene–butyl methacrylate block copolymer based on active polystyrene (PS) containing at the chain end a copper semiquinolate complex activated by UV irradiation [2]. The goal of this study was to reveal the possibility of preparing by this method a block copolymer of styrene (ST) with an inactive water-soluble monomer, *N*-vinylpyrrolidone (VPD). This block copolymer is of doubtless practical interest because of its amphiphilic nature.

EXPERIMENTAL

The commercial monomers were additionally purified prior to use. Styrene was dried over anhydrous sodium sulfate, and VPD, over anhydrous KOH and CaH_2; 0.1 wt % toluene diisocyanate was added to bind the impurities. Then the monomers were distilled under reduced pressure (bp 35°C/0.8 kPa for ST and 78°C/2 kPa for VPD).

Polystyrene (PS) was prepared in the presence of a stable radical, bis(triphenylphosphino)(3,6-di-*tert*-butylbenzo-1,2-semiquinolato)copper(I) (SQCu):

where L is triphenylphosphine.

The SQCu concentration was 1.5×10^{-3} M. AIBN (10^{-2} M) was used as initiator. The mixtures were charged into ampules, deoxygenated by threefold freezing in liquid N_2–pumping–thawing, and the ampules were sealed off. Then the ampules were preheated at 70°C to completion of the induction period, cooled, placed in a thermostat, and UV-irradiated with a PRK lamp at 25°C. The polymerization was performed to 7% conversion. Polystyrene was purified by threefold reprecipitation with methanol from a chloroform solution and dried to constant weight. To perform block copolymerization, 5 wt % solutions of PS and VPD were placed in dilatometric ampules, degassed at a reduced pressure, and exposed to UV radiation at 25°C. The molecular-weight characteristics of the samples were determined by gel permeation chromatography on a Waters chromatograph equipped with a refractometric detector. The supramolecular structure of the polymers was examined by scanning probe microscopy with a Solver Bio NT-MDT device in the continuous mode; weighed portions of the polymers were dissolved in chloroform, the solutions were applied to clean silicon supports, and the specimens were dried at room temperature. The modification of a solid surface with the block copolymers synthesized was studied by the wetting method [3], with measuring the contact angle; a 0.035-g copolymer sample was dissolved in 10 ml of chloroform, and the solution was cast onto a silicon support. Water was used as wetting fluid.

The kinetic curve of VPD polymerization in the presence of active PS is shown in Fig. 1. The poly-

merization involved an induction period (170 min); the mean process rate was 2.2×10^{-5} mol l^{-1} s^{-1}. It should be noted that VPD does not spontaneously polymerize under these conditions. By the copolymerization we obtained two samples (7 and 17% conversion; samples I and II, respectively). Their composition was determined by the Kjeldahl method [4]. The mole fraction of VPD in samples I and II was 0.5 and 0.75, respectively.

Sample II was studied in the most detail. Sequential extraction with methanol and then with cyclohexane in a Soxhlet apparatus showed that this sample contained 2.3% PS, 30.8% polyvinylpyrrolidone (PVPD), and 66.0% block copolymer with the mole fraction of VPD units of 0.65. The following scheme of the block copolymerization can be suggested within the framework of the controlled chain propagation:

$$\text{P–(ST)}_n\text{–SQCu} \overset{h\nu}{\rightleftharpoons} \text{P–(ST)}_n^{\bullet} + \text{SQCu}$$

$$\overset{m\text{VPD}}{\rightleftharpoons} \text{P–(ST)}_n\text{–(VPD)}_m\text{SQCu}.$$

The VPD polymerization is initiated by absorption of a light quantum through reversible dissociation of the macromolecule–semiquinolate complex bond at the end of an active PS macromolecule [P–$(ST)_n$–SQCu(I)]. The PVPD block propagates on the thus generated radical until it recombines with the SQCu molecule.

Let us discuss the cause of formation of homopolymers under these conditions. A GPC analysis of sample II showed that the molecular-weight distribution of the polymer was unimodal; however, despite appreciable conversion, the weight-average molecular weight did not noticeably change relative to the starting active PS (Fig. 2). From the standpoint of pseudo-living block copolymerization, this fact can be attributed only to the parallel occurrence of photochemical degradation. Indeed, Figure 3 shows that, upon UV irradiation of PS in an inert solvent (benzene) for 9 h, the viscosity-average molecular weight of PS decreases by 30%. Irradiation of PVPD in methanol for the same time also decreases its molecular weight, but insignificantly. It was also shown that VPD polymerized upon UV irradiation at 25°C in the presence of PVPD at a rate of 4.9×10^{-4} mol l^{-1} s^{-1}; in the process, the viscosity-average molecular weight of PVPD increased from 96×10^3 to 270×10^3. As VPD does not spontaneously polymerize upon UV irradiation, it can be assumed that the polymerization of VPD is initiated by photochemical degradation of PVPD

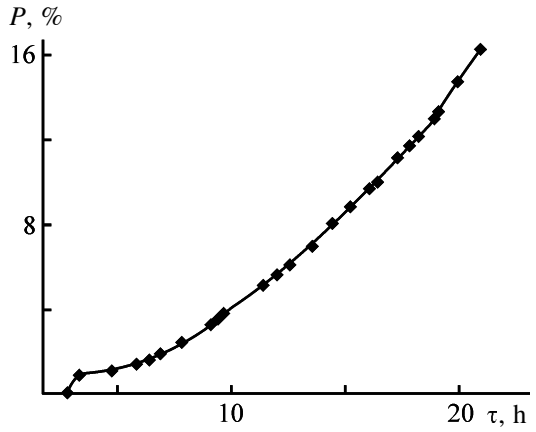


Fig. 1. Conversion P of VDP as a function of time τ in the UV-induced block copolymerization with PS (25°C, PS concentration 5%).

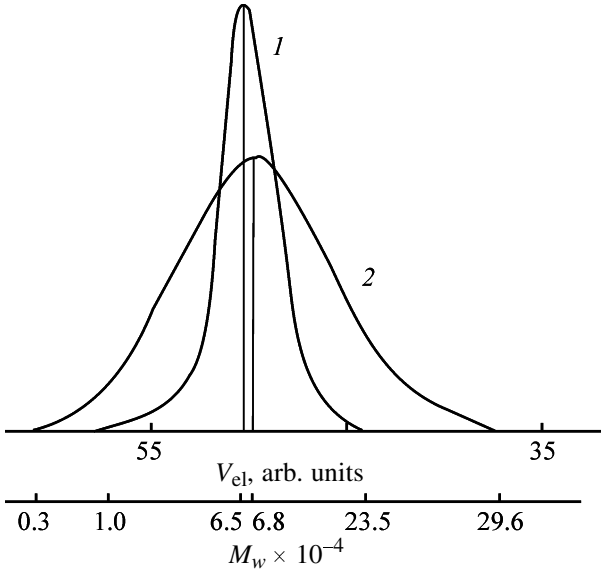

Fig. 2. Gel chromatograms of the (*1*) initial macroinitiator PS and (*2*) product of block copolymerization (sample II). (V_{el}) Eluent volume and (M_w) weight-average molecular weight.

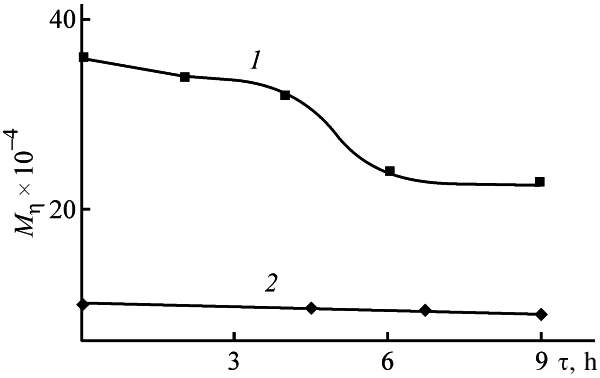

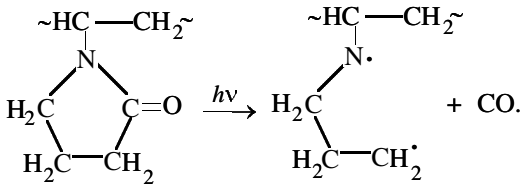

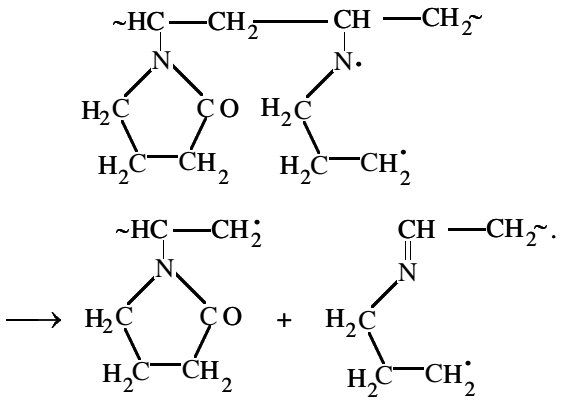

Fig. 3. Viscosity-average molecular weights M_η of (*1*) PS and (*2*) PVPD as functions of UV irradiation time τ. Solvent: (*1*) benzene and (*2*) methanol; 25°C.

(Norrish reaction):

The generated radicals can initiate the process without cleavage of the polymer backbone; also, this reaction can be followed by the chain β-cleavage:

Thus, the general pattern of formation of the block copolymer is as follows. The polymerization of VPD requires the presence of PVPD, which can be formed only by pseudoliving polymerization initiated by active PS. The subsequent polymerization can occur at the expense of degradation of PVPD units.

It is known that the supramolecular structures of block copolymers and homopolymers cardinally differ. Therefore, an obvious evidence of formation of block copolymers is furnished by scanning probe microscopic examination of the surface topography of films prepared from the isolated block copolymer and blends of the homopolymers taken in the corresponding ratio. Figure 4 shows that the topography of the films prepared from the blends (Figs. 4b, 4d) cardinally differs from that of of the films prepared from the block copolymers (Figs. 4a, 4c). Blend films demonstrate complete microphase segregation; at a VPD mole fraction of 0.5 (Fig. 4b), PS is apparently a continuous phase and PVPD forms discrete spherical particles of ~2.3 μm size. This is consistent with the estimated Hildebrand solubility parameter of the solvent and polymers: it is close for $CHCl_3$ and PS [$\delta(PS) = 18.2 \times 10^3$, $\delta(CHCl_3) = 18.6 \times 10^3$ $(J\ m^{-3})^{0.5}$] but significantly different for PVPD [$\delta(PVPD) = 22.2 \times 10^3$ $(J\ m^{-3})^{0.5}$] [5]. The surface topography of a film of a sample prepared in the presence of active PS (Fig. 4a) also contains spherical domains of almost the same size (2.4 μm), but the interphase boundaries are diffuse, up to mutual penetration of the phases.

In the blend with a PVPD mole fraction of 0.75 (Fig. 4d), PVPD is a continuous phase, and PS macromolecules form spherical particles of size 0.4 μm. The topography of sample II of similar composition (Fig. 4c), which is a blend of homopolymers and block copolymer, shows a tendency toward further diffusion of VPD units.

The block copolymer isolated from sample II has a microheterogeneous structure with pronounced supramolecular formations (Fig. 4e). Thus, as expected, films of homopolymer blends, crude block copolymerization products, and isolated block copolymer essentially differ in the topography.

It was interesting to study the surfactant properties of the amphiphilic block copolymer synthesized. For this purpose, we performed two experiments.

Sample II is soluble in chloroform; therefore, it was tested as emulsifier for preparing a water-in-chloroform emulsion. We prepared a 1 wt % solution of the polymer in chloroform, which was then mixed with water in 4 : 1 volume ratio. After shaking the system, the settling took 15 h (without adding the polymer it occurred within 3 s). The lower chloroform layer remained turbid, despite the fact that in the absence of water the sample solution was transparent. This fact is indicative of formation of water-containing micelles (owing to conjugate solubility). Because of a low resolving power of the photocolorimeter, the micelle size was determined after dilution of the system with chloroform to a concentration of 0.03%; it was estimated at 53.7 nm using the tables of characteristic light scattering functions [6].

The possibility of modification of the solid surface was demonstrated by the wetting method with a block copolymer containing 65 mol % VPD units. The silicon support is hydrophilic owing to the presence of OH groups on its surface. In the molecules of the block copolymer, the hydrophilic VPD units are oriented toward the support, and hydrocarbon "tails" of PS are oriented outwards and determine the properties of the surface. As a result, the surface becomes hydrophobic, and the contact angle θ on wetting with water becomes 72°, which is close to the contact angle with PS films (76°). It should be noted that the contact angle of a PVPD film with water is 7°. The blend of a similar composition is characterized by a contact angle of 14°, which differs from the value characteristic of the block copolymer and is one more evidence of formation of a new chemical compound.

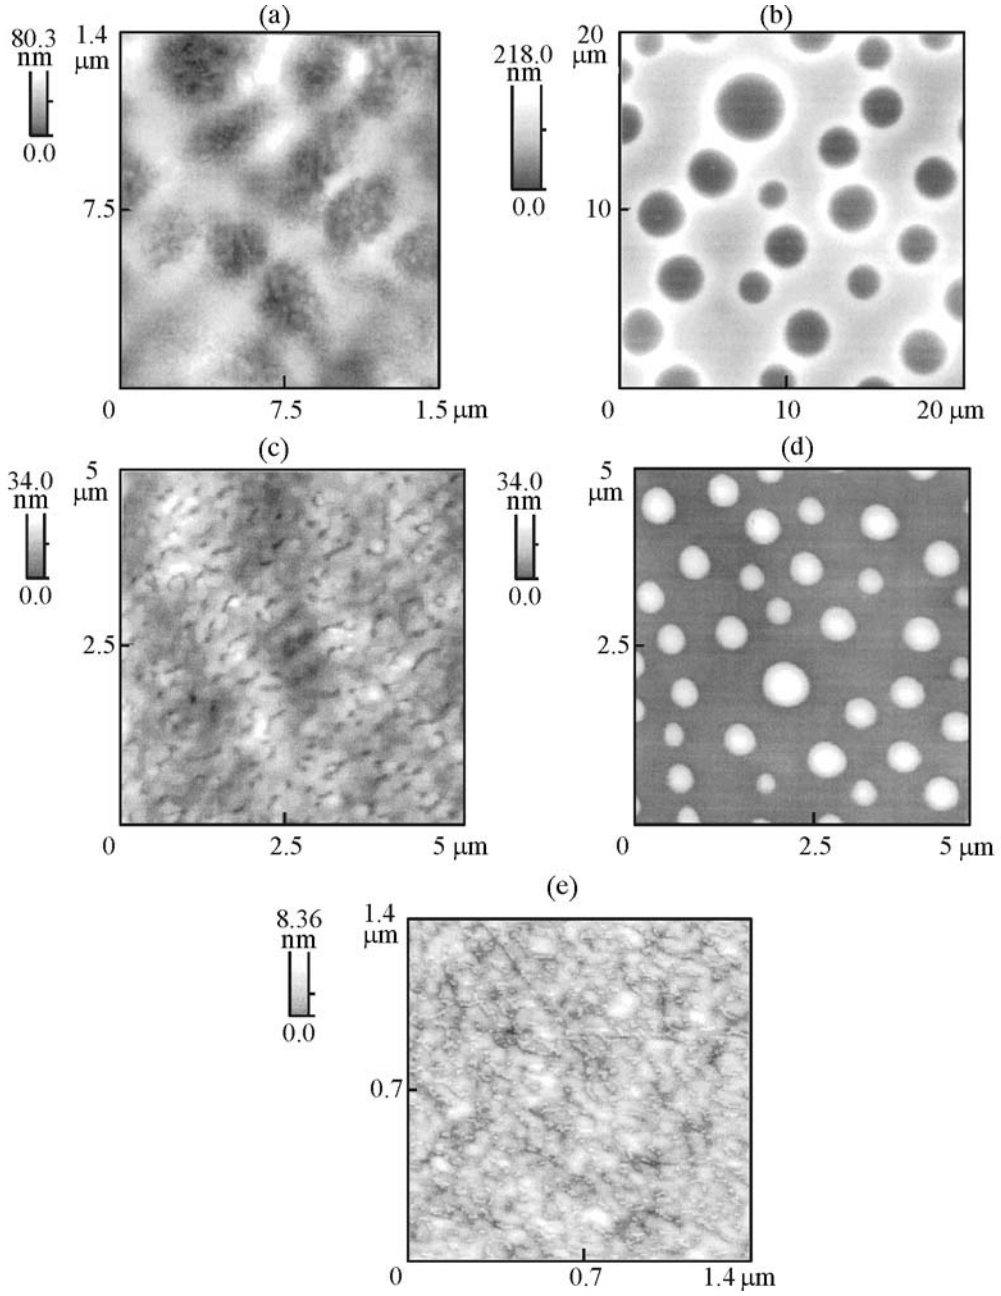

Fig. 4. Topography of the surface of films prepared from (a, b) block copolymerization products [(a) 0.5 PS–0.5 PVPD, (b) 0.25 PS–0.75 PVPD], (c, d) homopolymer blends of respective compositions, and (e) PS–*block*-PVPD copolymer 0.35 PS–0.65 PVPD.

CONCLUSIONS

(1) Amphiphilic copolymers polystyrene–*block*-polyvinylpyrrolidone were prepared by controlled radical polymerization under mild conditions using active polystyrene. The possible effect of the degradation of the macrochain units on formation of the block copolymers was demonstrated.

(2) The supramolecular structure of the surface of films prepared from the copolymers in hand indirectly confirms their block structure.

(3) The block copolymer prepared can be used as an emulsifier and for modification of a solid surface.

Abstract—The effect of silver ions on the physicochemical properties of methyl methacrylate–methacrylic acid copolymer films, namely, film-forming properties and resistance to fluorine-containing plasma, acid etchers, and temperature, was studied by lithography, derivatography, atomic-force microscopy, and optical spectroscopy. The activation energies were calculated for thermal transformations in the copolymer with and without silver ion additions, when heated in air to 300°C.

DOI: 10.1134/S1070427206030244

Methyl methacrylate–methacrylic acid copolymers form the basis of many positive resists having high resolution powers and good adhesion to metallic and semiconducting supports [1]. However, they exhibit inadequate stability in plasma treatment [2].

This study was aimed to enhance the resistance of methyl methacrylate–methacrylic acid copolymer (MMA–MAA CP) to fluorine-containing CF_4–NH_3 plasma via adding a silver salt. Also, we elucidated how the silver salt affects the film-forming properties and the resistance to acid etchers and temperature and by what mechanism the modifying addition affects the properties of the MMA–MAA CP.

EXPERIMENTAL

Our study was concerned with a commercial solution of MMA–MAA CP in organic solvents, known as ELP-9 electron resist. Silver trifluoroacetate (TFA-Ag) served as modifier. It was prepared by the procedure [3] involving dissolution of freshly precipitated silver oxide in an excess of trifluoroacetic acid and evaporation to dryness of the resulting solution on a water bath, washing of the product with CCl_4 to remove excess acid, drying to constant weight, and storage in a vacuum desiccator in the dark. The silver salt (0.001 to 0.1 mol per liter of the copolymer solution) was introduced by homogenic dissolution via mixing in a WU-4 vibromixer. The resulting solutions were freed from mechanical inclusions by filtration through a polyamide filter with a pore diameter of 0.2 μm.

For lithographic, microscopic, and IR- and UV-spectroscopic studies, thin polymer films (0.4–0.7 μm) were formed by centrifugation on preliminarily degreased supports (silicon and gallium arsenide with a silicon oxide layer applied, optically transparent glasses). For studies of the resistance to high temperatures, thicker copolymer films (14–16 μm) on polyethylene supports were prepared by casting. The resulting coatings were dried at 130, 165, and 180°C (±5°C) for 5, 15, and 30 min, respectively.

The film thickness was determined on an MII-4 interference microscope and a micrometer. The image in the films was formed by exposure to the UV irradiation from a DRKs-500 ultrahigh-pressure mercury–xenon lamp via a quartz template with the element having a minimal size of 0.57 μm, followed by dissolution of the polymer that decomposed under irradiation in a mixture of isopropyl alcohol and methyl ethyl ketone. The quality of the resulting relief was estimated upon exposure to organic solvents, acid etcher for silicon oxide HF–NH_4F–H_2O, CF_4–NH_3 gas mixture (in an Alcatel RDE-300 reactive ionic etching setup). The quantitative characteristic was the time of exposure to an aggressive medium until appearance of defects in the masking layer of the copolymer. The defects were revealed with a Latimet microscope under ×100, ×200, and ×500 magnifications.

The MMA–MAA CP film morphology was studied in a Solver P-47 atomic-force microscope (AFM) in the contact scanning mode. The IR spectra were recorded on a Specord M80 spectrophotometer at 4000–

Characteristics of etching of the polymer films in the CF_4–NH_3 plasma in relation to the content of silver trifluoroacetate in MMA–MAA CP

400 cm^{-1}. The absorption bands were assigned using the reference data [4, 5]. The electronic spectra were recorded on a Specord M40 spectrophotometer at 260–900 nm.

The thermal stability of the polymer films in air was studied with an MOM Q-1500 derivatograph (Hungary) at a heating rate of 6–10 deg min^{-1} in platinum crucibles. We used 100-mg weighed portions of the ground polymer films and silver trifluoroacetate powder. Aluminum oxide served as the reference.

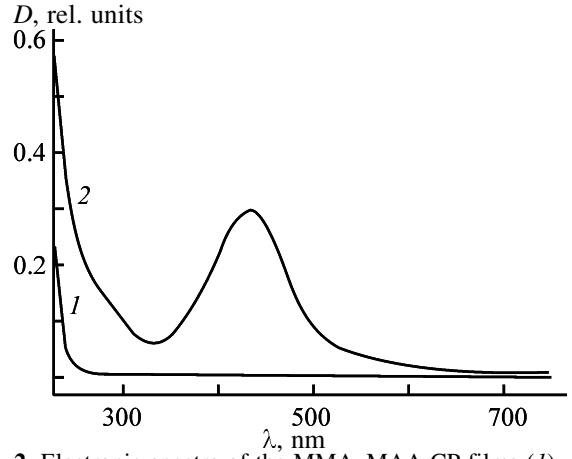

Fig. 2. Electronic spectra of the MMA–MAA CP films (*1*) without and (*2*) with addition of 0.05 M CF_3COOAg after heat treatment at 160°C. (*D*) Absorption and (λ) wavelength.

Our studies showed that the solutions with silver salt additions had good film-forming properties. Films thereof exhibit good adhesion to the support surface and withstand exposures to acid etchers for 10 min and more. This period is required for creation of images in the layers of passivating dielectric coatings (silicon oxide and nitride) and metals (titanium, aluminum, copper, gold) [6]. More precise reproduction of the sizes of the topological elements in production of integrated circuits is provided by reactive ionic etching methods.

The resistance of the silver salt modified MMA–MAA CP to etching in the fluorine-containing plasma increases relative to the initial composition by a factor of 1.3–2.5 (see table). Increased resistance of the copolymer films to an active medium based on CF_4–NH_3 increases the selectivity during etching of silicon oxide, which allows more precise reproduction of the critical sizes of the topological elements of integrated circuits.

The enhanced resistance to plasma, exhibited by the films, can be due to reinforcement of the structure of the polymer via reactions of the functional carbonyl and carboxy groups of the MMA–MAA CP with silver trifluoroacetate. Intermolecular interaction in the polymer–salt system is suggested by the optical spectroscopic data. In the IR spectra of the film with TFA-Ag additions (Fig. 1, curve *1*), the absorption bands at 1530 (asymmetric stretching vibrations of the carboxylate ion) and 1730 cm^{-1} (stretching vibrations of the carbonyl group) [5] exhibit increased intensity and are shifted and broadened. The observed changes in the IR spectra can be due to an increased degree of ionization of the carboxy groups of the macromolecules because of their coordination by the silver ions.

The electronic spectra of the silver salt modified MMA–MAA CP contain an absorption band at 330–600 nm with a maximum at 435 nm (Fig. 2, curve *2*), characteristic for silver compounds [7] and silver nanoparticles in methacrylate matrices [8–10]. Silver nanoparticles in the copolymer films can arise from thermal decomposition of the salt in the presence of the copolymer, e.g., by the scheme

$$4CF_3COOAg \rightarrow 4CO_2\uparrow + C_4F_{10}\uparrow + 2AgF + 2Ag.$$

Evolution of gaseous products from the films and formation of the silver particles on the film surface

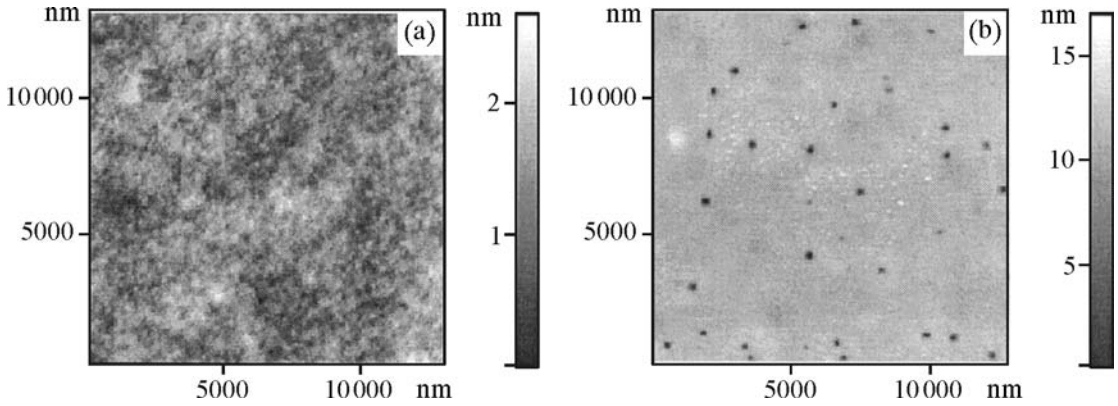

Fig. 3. AFM images of the MMA–MAA CP films (*1*) without and (*2*) with addition of 0.05 M CF_3COOAg after heat treatment at 160°C.

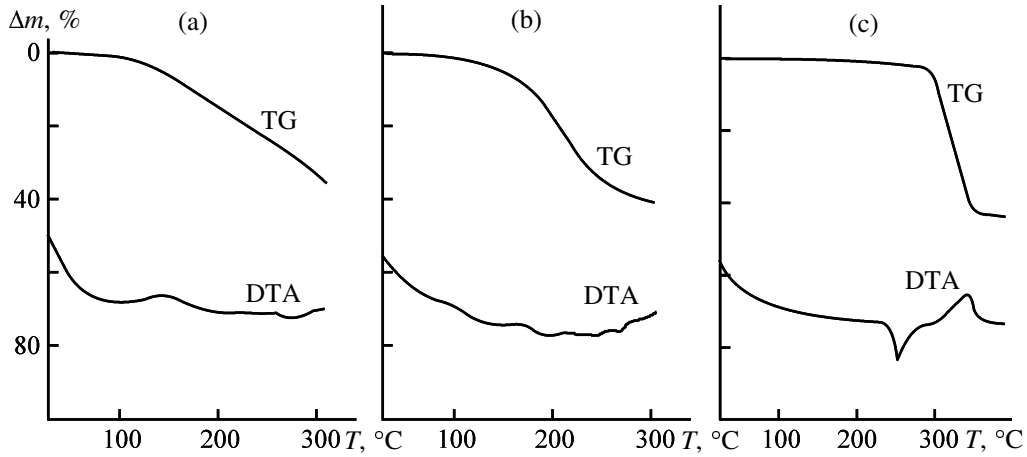

Fig. 4. Derivatograms of (a, b) MMA–MAA CP films (a) without silver trifluoroacetate and (b) containing 1.25×10^{-1} M silver trifluoroacetate and (c) neat silver trifluoroacetate. Heating rate 10 deg min^{-1}. (Δm) Weight loss and (T) heating temperature.

were evidenced by the AFM studies which revealed lustrous silver metal sections, 50–200 nm in size and 1–2 nm in height, around the pits in the films with TFA-Ag additions (Fig. 3b). In films without silver salt additions (Fig. 3a), such phenomena were not observed. Increase in the salt content to 0.1 M favors formation of a uniform lustrous layer over the entire film surface [6].

Thus, the resistance of the silver salt modified copolymer films to the CF_4–NH_3 plasma is due to reinforcement of the polymer structure via formation of additional metal–polymer bonds and formation in the film of silver particles and silver fluoride AgF. The latter can arise from the heat treatment of the modified copolymer and etching in the fluorine-containing plasma [1, 11].

Formation of conducting silver nanoparticles in the bulk and on the surface of the polymer is responsible for electrical conductivity of the polymer material [6]. The MMA–MAA CP films with silver trifluoroacetate (0.1 M) have an electrical conductivity of 1.8×10^{-4} S m^{-1}. This is essential for preventing the charge accumulation and ensuring conditions for discharge during exposure.

Of special interest is the thermal stability of the MMA–MAA CP films with TFA-Ag, specifically, their ability to withstand heating to 200°C. This is essential for preserving the configuration of the image elements during thermal impact (postbaking, ion-plasma processes) [1]. In this connection, we studied how the silver salt affects the resistance of MMA–MAA CP during heating in air to 300°C. The nature of the chemical transformations in the copolymer during heating was judged from the IR spectra.

The MMA–MAA CP without silver salt additions at 60–150°C was characterized by a minor weight loss (to 4 wt %), accompanied by a weak endothermic effect (Fig. 4a). This can be due to removal from the material of low-molecular-weight solvents (butyl acetate, methyl Cellosolve), strongly retained by the

polymer via intermolecular bonds. From the thermogravimetric (TG) data (Fig. 4), we estimated by the Freeman–Carroll method [12, 13] the activation energy of the polymer desolvation at 42.6 kJ mol^{-1}. There were no visible changes in the IR spectra of the copolymer heated to the temperatures mentioned. Further heating to 200°C increases the weight loss to 10%. We showed previously [14] that this is accompanied by appearance of two new absorption bands, at 1760 and 1800 cm^{-1}, in the IR spectra of the copolymer. They suggest formation of anhydride rings by intra- and intermolecular condensation of the ester and carboxy groups, with the elimination of methanol [15]. In the presence of the silver salt, the behavior of the polymer when heated to 250°C remains virtually unchanged (Fig. 4b); at 50–160°C, like in the case of MMA–MAA CP without additions, the residual solvents are removed with the activation energy of 36.4 kJ mol^{-1}. A minor decrease in the activation energy of this process can be due to easier release of the solvents from the copolymer films because of the competing reaction of the silver ion with the reactive centers of MMA–MAA CP. As to silver trifluoroacetate, in the absence of the polymer surrounding it withstands heating in air to 220°C without major changes and decomposes at 250°C (Fig. 4c), possibly, by the above-mentioned scheme. The activation energy of this process was estimated at 167.3 kJ mol^{-1}.

CONCLUSIONS

(1) The additions of silver trifluoroacetate, depending on the content, increase the resistance of methyl methacrylate–methacrylic acid copolymer to fluorine-containing plasma by a factor of 1.3–2.5 and increase the electrical conductivity to 1.8×10^{-4} S m^{-1}.

(2) The changes in the composition of methyl methacrylate–methacrylic acid copolymer and silver trifluoroacetate are due to formation in the bulk of the copolymer of silver particles, followed by formation on the polymer film surface of a metal layer. In the presence of the salt, the basic characteristics of the copolymer are preserved, namely, the ability of forming thin high-quality films, adhesion to various surfaces, ability of forming a masking relief resistant to aggressive acid media, and thermal stability up to 200°C.

ACKNOWLEDGMENTS

The authors are grateful to T.A. Kurmaev for carrying out plasma etching and to K.V. Oskomov for the atomic-force microscopic study of the samples.

Abstract—The sorption properties of natural polysaccharide (apple pectin) with respect to heavy metals in a Ringer salt solution were studied as influenced by the procedures and process parameters of its chemical modification.

DOI: 10.1134/S1070427206030256

Pectins are vegetable polymers of *L,D*-galacturonic acid partially esterified with methoxy groups. These polymers are commercial products used as gel-forming agents and fillers in food industry [1–3]. Heavy metal ions react with free carboxy groups of pectins to form difficultly soluble complexes [4–6]. The reactivity of pectins with respect to heavy metal ions strongly depends on the degree of esterification, content of ballast agents, and content of free and bound carboxy groups and can be substantially increased by partial hydrolysis of the ester groups.

Pectins can be modified by saponification catalyzed by mineral acids, bases, salts of weak acids, enzymes, concentrated ammonium systems, and primary aliphatic amines [7–9]. The acid and base (ammonium) hydrolysis are the simplest and most efficient procedures for modifying pectins.

The aim of this study was to develop a procedure for preparing low-esterified pectin with increased sorption capacity for heavy metal ions, which could be used as a detoxicant additive to pharmaceuticals and as a therapeutic and prophylactic agent.

EXPERIMENTAL

We used fresh pomace as the raw material. Wet pectic coagulate was prepared from pomace by the known procedure [10, 11]. The coagulate was saponified with hydrochloric or nitric acid by the following procedure. The coagulate was mixed with an aqueous alcoholic solution of an appropriate acid (the alcohol concentration in the solution was 60–70 wt %) at the coagulate : solution volume ratio of 1 : (3–5). The mixture was heated at 40–50°C for 24–72 h. The precipitate was filtered off and washed with several portions of aqueous alcohol with the alcohol concentration increasing from 60 to 96%. The product was dried at 50°C to constant weight. Saponification of powdered pectins was performed similarly, however, in this case the mixture was heated for 120 min. It should be noted that the treatment of the wet coagulate is faster and is characterized by a lower consumption of alcohol, acid, and energy.

Base (ammonia) saponification of wet pectin coagulate was performed by the following procedure. The coagulate was cooled to 5–7°C and poured over with a mixture of 60% isopropanol and 1.5–1.8 M NH_4OH cooled to 5–7°C. The mixture was kept at 5–7°C for 1–3.2 h. The saponified pectin was filtered off, washed, and dried as in the case of the acid treatment. The content of uronic acid, of free and esterified carboxy groups, and of ballast substances was determined by titration [12]. The degree of esterification was calculated from these data. The degree of esterification of the initial (unmodified) apple pectin was 78.5%. The content of methoxycarbonyl and carboxy groups and of uronic component was 11.9, 3.2, and 64%, respectively. Thus, low-esterified pectin with decreased content of methoxy groups and nonuronic (ballast) compounds (see table) was prepared by acid and ammonia modification of wet or dry apple pectin.

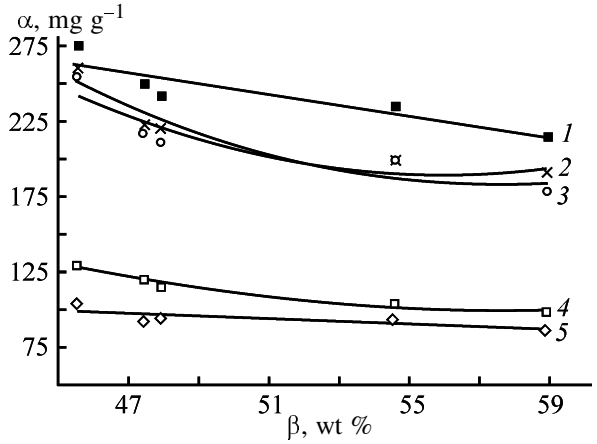

Fig. 1. Sorption capacity of apple pectins α for (*1*) lead(II), (*2*) cadmium(II), (*3*) copper(II), (*4*) nickel(II), and (*5*) strontium(II) as a function of the degree of esterification of the carboxy groups in the pectin β.

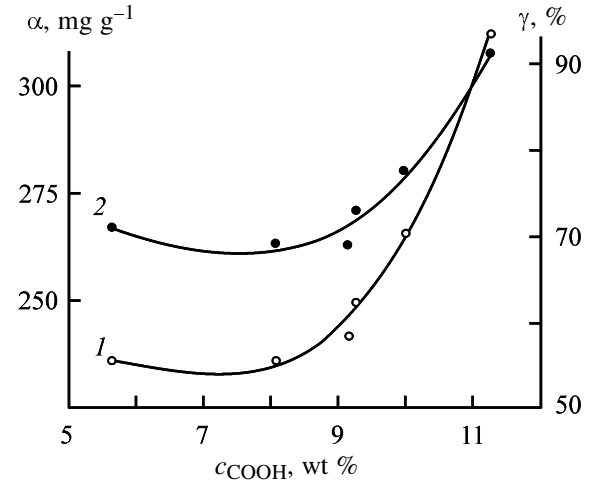

Fig. 2. (*1*) Sorption capacity of pectins α for lead(II) and (*2*) degree of lead sorption from a salt solution γ as functions of the content of free carboxy groups c_{COOH} in the pectin.

The main aim of the modification was to improve the sorption properties of pectin with respect to heavy metal ions. The maximal sorption capacity of modified pectin for lead(II), cadmium(II), nickel(II), copper(II), and strontium(II) ions was experimentally determined by the procedure described in our previous study [13]. The sorption was performed from solutions of appropriate salts of these metals with the initial metal concentration of 1500–1800 mg l^{-1}. A salt mixture simulating the composition of the Ringer's solution was used as the supporting electrolyte. The initial and equilibrium concentrations of heavy metals were measured by atomic absorption spectroscopy on a KAS-120 spectrometer (Selma, Ukraine).

The dependence of the sorption of metal ions by the modified apple pectin on its degree of saponification is shown in Fig. 1. The maximal sorption capacity of unmodified apple pectin for lead(II), cadmium(II), copper(II), nickel(II), and strontium(II), determined under the similar conditions, was 147–180, 61–85, 97–102, 76–89, and 37–43 mg g^{-1}, respectively.

It is seen that the sorption of heavy metal ions from multicomponent salt solutions depends on the degree of esterification of the modified pectin. As the degree of esterification of the carboxy groups decreases, the sorption of lead(II), copper(II), and cadmium(II) from the model salt solutions increases to the greatest extent; the sorption of nickel(II) changes to a lesser extent; and the maximal sorption of strontium(II) remains virtually the same.

To illustrate how the content of free carboxy groups in the modified pectin affects its sorption properties, the dependences of the maximal sorption capacity α (mg g^{-1}) for lead(II) and degree of lead sorption γ (%) from the model solution are shown in Fig. 2. As seen

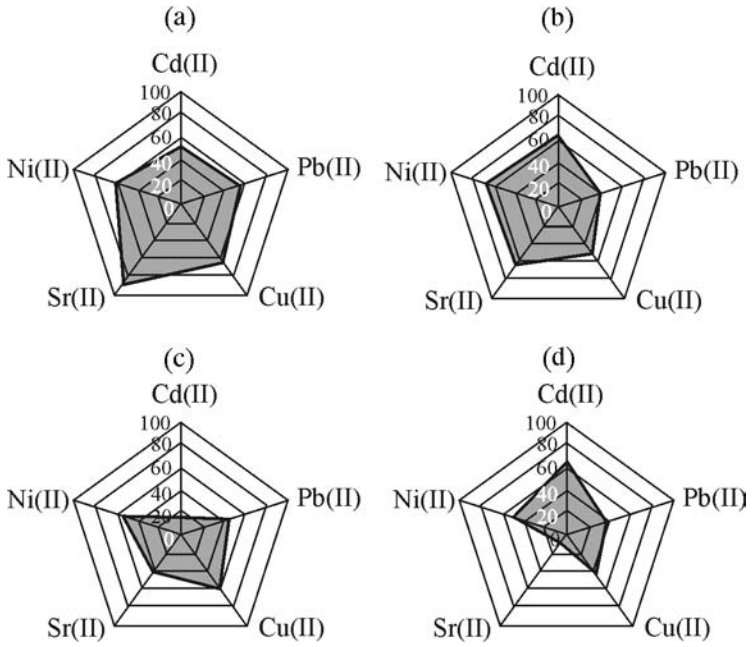

Fig. 3. Degrees of metal sorption from a salt solution γ (%) on (a) initial pectin and pectin modified with (b) HCl, (c) HNO_3, and (d) NH_4OH.

from Fig. 2, the content of free carboxy groups has a critical effect on the sorption properties of pectin. It should be noted that the mechanism of reaction of heavy metal ions with pectin is a matter of discussion. At the qualitative level, this reaction consists in formation of pectates, metal complexes with carboxy groups of the polysaccharide matrix. These compounds contain both chemically bound (coordinated) metal and metal ions occluded by a strongly swollen polysaccharide macromolecule. Ion exchange of metal ions with functional groups of the polysaccharide is also possible.

The degree of sorption of various metal ions by unmodified and modified pectins is shown in Fig. 3. As seen from Fig. 3, the best sorbent for removal of cadmium(II) from biological solutions is pectin modified with HCl; pectin modified with HNO_3 should be used to remove lead(II) and copper(II); and pectin modified with NH_4OH is favorable for removal of strontium(II). When all these ions are present in the solution, pectin saponified with HNO_3 should be used.

Thus, sorption of toxic metal ions (lead, cadmium, etc.) on wet pectin coagulate from multicomponent salt solutions simulating the electrolyte composition of a human body can be substantially increased by partial saponification of methoxycarbonyl groups of pectin by the suggested procedures.

CONCLUSIONS

(1) The content of methoxycarbony groups of wet pectin coagulate can be decreased from 70–75 to 40–45 wt % by saponification with hydrochloric acid, nitric acid, and ammonium hydroxide using the suggested procedures. The content of free carboxy groups after this modification increases from 2–4 to 8–12 wt %.

(2) This chemical modification increases the sorption capacity of the pectins for lead(II), copper(II), and cadmium(II) in multicomponent salt solutions simulating the electrolyte composition of a human body.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Mg/Na Selectivity of Sulfonic Cation-Exchange Membrane Modified with Poly(4-Vinyl-*N*-Propylpyridinium) Bromide

V. P. Greben' and I. G. Rodzik

Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received October 4, 2005

Abstract—Mg/Na selectivity of sulfonic cation-exchange membrane modified with poly(4-vinyl-*N*-propylpyridinium) bromide by surface electrodeposition, influenced by the electrodialysis conditions, is studied.

DOI: 10.1134/S1070427206030268

Cations can be separated by electrodialysis with a cation-exchange membrane using various techniques. The most practicable approach involves complexation of cations of one or several sorts with formation of compounds poorly penetrable through the membrane. In particular, Na and K ions were separated by electrodialysis in the presence of 18-crown-6 as a strong complexant for potassium [1]. Silver was separated from zinc and copper in the presence of EDTA [2]. Malonic, oxalic, and citric acids were used as complexants in separating Cu, Ni, and Co [3]. The drawback of this approach is in a large consumption of chemicals.

Another approach involves bulk or surface modification of the membrane by soaking in solutions of reagents, which are mostly high-molecular-weight cationic surfactants or complexants. For example, impregnation of a cation-exchange membrane with crown ethers increases the permeability with respect to alkali cations as compared to alkaline-earth elements, and also to Na relative to K [4]. Modification with polyethylenimine was used to increase the proton transfer relative to that of divalent cations [5]. The most widely used method is modification of cation-exchange membranes by direct introduction of reagents into the solution to be electrodialyzed. In this case, the modifier, having, as a rule, a positive charge, e.g., cyclodextrin [6], polyethylenimine [7, 8], or crown ether [4], is electrodeposited on the membrane surface from the side of the solution being dialyzed, thus increasing the transmembrane transfer of alkali metals as compared to alkaline-earth elements.

All the above-mentioned methods require regular repeated modification of membranes, because of gradual desorption of modifiers from the surface. Therefore, it is advisable to chemically bind a modifier to the membrane. Takata *et al*. [9] have bound polyethylenimine to the surface of cation-exchange membranes through interaction with sulfochloride groups introduced into the membrane.

In this study we examined the effect of modification of MK-40L membrane with poly(4-vinyl-*N*-propylpyridinium) bromide (PVPPB) on the Mg/Na selectivity of transmembrane transport.

EXPERIMENTAL

The selectivity coefficient of transmembrane transport $P_{Na^+}^{Mg^{2+}}$ is written as

$$P_{Na^+}^{Mg^{2+}} = \bar{t}^{Mg^{2+}} c_{Na^+} / \bar{t}^{Na^+} c_{Mg^{2+}}, \quad (1)$$

where $\bar{t}^{Mg^{2+}}$ and $\bar{t}^{Na^+}$ are the transport numbers of Mg and Na cations across the membrane and $c_{Mg^{2+}}$ and c_{Na^+}, Mg and Na concentrations in the solution (g-equiv l^{-1} or N).

The cell and the procedure of determination of the transport numbers of the cations were the same as in [10]. The middle compartment of the cell between an ideally selective anion-exchange membrane and the investigated cation-exchange membrane was charged with 0.25 N NaCl + 0.25 N $MgCl_2$ with or without addition of PVPPB. Three different procedures were used for modification of the cation-exchange membrane.

(1) The membrane was held for a fixed time in a PVPPB solution, washed with distilled water several times for 3–5 s, and arranged in the cell. The middle compartment was filled with the NaCl and $MgCl_2$

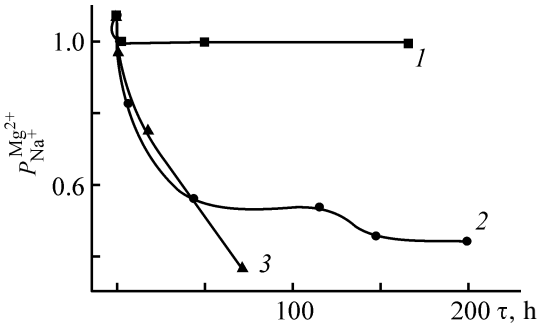

Fig. 1. Selectivity coefficient $P_{Na^+}^{Mg^{2+}}$ as a function of the time of treatment of the cation-exchange membrane in the PVPPB solution τ. Current density (A dm^{-2}): (*1, 2*) 1.0 and (*3*) 2.0. PVPPB concentration (g l^{-1}): (*1*) 0.23 and (*2, 3*) 2.16.

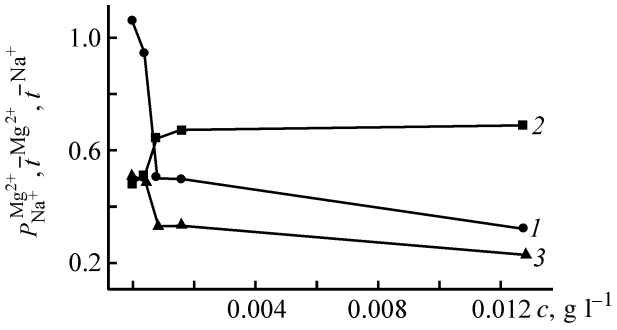

Fig. 2. (*1*) $P_{Na^+}^{Mg^{2+}}$, (*2*) $\bar{t}^{Na^+}$, and (*3*) $\bar{t}^{Mg^{2+}}$ as functions of the PVPPB concentration c in the solution being dialyzed at a current density of 1 A dm^{-2}.

solutions, and electrodialysis was carried out to determine the transmembrane transport numbers of Na and Mg.

(2) The membrane was arranged in the cell. The middle compartment was filled with 0.25 N NaCl + 0.25 N $MgCl_2$ containing a fixed concentration of PVPPB. After electrodialysis the solution was removed, and the compartment was washed with distilled water. All the solutions were combined and analyzed. Then the next run was performed in the same manner.

(3) As in method no. 2, but using PVPPB-free solution in the runs following the first one.

As seen from Fig. 1, increasing time of treatment of the cation-exchange membrane in the PVPPB solution, as well as increasing PVPPB concentration and current density decrease the transmembrane transport of Mg ($P_{Na^+}^{Mg^{2+}}$ decreases).

In the course of soaking in the PVPPB solution, an adsorption layer is formed on the surface of the cation-exchange membrane, which is positively charged, while the polymer matrix (bulk) of the membrane is charged negatively. Therefore, an electrostatic barrier is formed on the membrane surface, whose effect is stronger with respect to double-charged cations as compared to single-charged cations. Most likely, increasing PVPPB concentration and soaking time increase the thickness of the adsorption layer, and increasing current density makes this layer more compact, thus decreasing the transmembrane transport of Mg.

Figure 2 shows how the PVPPB concentration in the dialyzable solution influences the Mg/Na selectivity of the transmembrane transport and the Mg and Na transport numbers in electrodialysis. In the case in hand, a PVPPB film was formed on the membrane surface through migration of PVPPB from the bulk of the solution to the membrane followed by its electrodeposition. It is most likely that, with increasing PVPPB concentration in the solution being dialyzed to 0.0015–0.002 g l^{-1}, the film thickness on the membrane surface increases rapidly, providing the most significant changes in the selectivity coefficient and transport numbers. In the indicated PVPPB concentration range, the sum of the Mg and Na transport numbers approaches unity (0.99 ± 0.01), suggesting the lack of poisoning of the membrane with PVPPB polycations. However, with increasing PVPPB concentration to 0.013 g l^{-1}, this value decreases to 0.92.

The trends in the dependences of the Na and Mg transport numbers and of the selectivity of the transmembrane transport on the current density are similar without (Fig. 3a) and with addition of PVPPB to the solution being dialyzed (Fig. 3b), but their values are strongly different. In both cases, at i < 1 A dm^{-2}, $P_{Na^+}^{Mg^{2+}}$ and transport numbers of Mg and Na increases with increasing current density, but the sum of the Mg and Na transport numbers remains unchanged (0.92 ± 0.01), which can be attributed to some redistribution of Mg and Na fluxes among the membrane areas, depending on the density of functional groups [10] without change in the total transport number of the cations.

Our results show that deposition of a modifier, particularly, PVPPB on the membrane surface can be realized at relatively low modifier concentrations, i.e., its consumption is low. It was interesting to determine the useful life of the PVPPB layer. Figure 4 shows that, in electrodeposition at low PVPPB concentration (0.0016 g l^{-1}), $P_{Na^+}^{Mg^{2+}}$ rapidly increases, and the Na transport number decreases with increasing time of electrodialysis, suggesting small initial thickness of

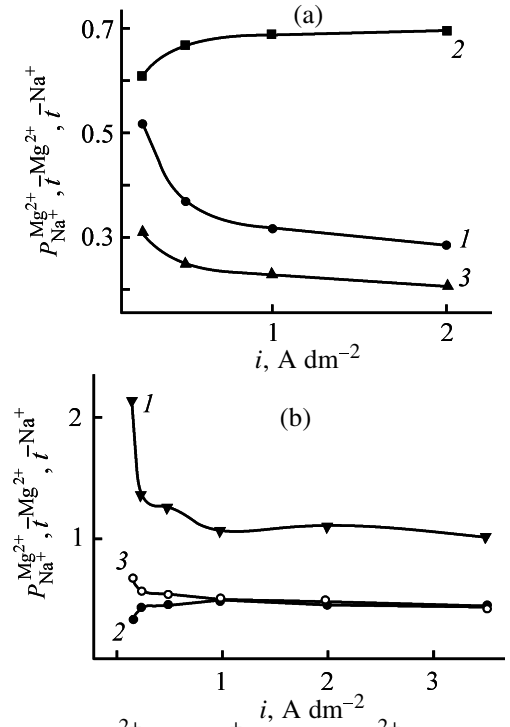

Fig. 3. (*1*) $P_{Na^+}^{Mg^{2+}}$, (*2*) $\bar{t}^{Na^+}$, and (*3*) $\bar{t}^{Mg^{2+}}$ as functions of the current density i. Solution: (a) 0.25 N NaCl + 0.25 N $MgCl_2$ and (b) 0.25 N NaCl + 0.25 N $MgCl_2$ + 0.0128 g l^{-1} PVPPB.

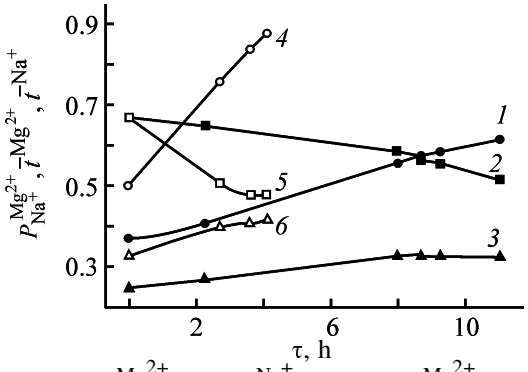

Fig. 4. (*1, 4*) $P_{Na^+}^{Mg^{2+}}$, (*2, 5*) $\bar{t}^{Na^+}$, and (*3, 6*) $\bar{t}^{Mg^{2+}}$ as functions of the electrodialysis time τ with the cation-exchange membrane preliminarily modified by electrodeposition of PVPPB for 30 min. Current density (A dm^{-2}): (*1–3*) 0.5 and (*4–6*) 1. PVPPB concentration (g l^{-1}): (*1–3*) 0.0128 and (*4–6*) 0.0016.

the electrodeposited PVPPB layer. Increasing PVPPB concentration by about an order of magnitude (0.0128 g l^{-1}) results in a considerable decrease in the initial selectivity coefficient, and the dependences of the membrane selectivity and Na transport numbers on the electrodialysis time become weaker.

It should be pointed out that, generally, at optimal conditions, modification of the membrane through addition of PVPPB to the initial solution containing Mg and Na chlorides decreases the membrane selectivity with respect to magnesium by a factor of about 3 (Figs. 2, 4).

CONCLUSIONS

(1) Soaking of the sulfonic cation-exchange membrane in the solution containing poly(4-vinyl-*N*-propylpyridinium) bromide or its electrodeposition on the membrane surface results in the formation of an adsorption layer representing an electrostatic barrier for cations, the effect being stronger with respect to double-charged cations as compared to single-charged cations.

(2) The Mg/Na selectivity of the membrane can be reduced by a factor of about 3 through modification of the membrane with PVPPB.

(3) Over the PVPPB concentration range 0.0015–0.002 g l^{-1} in the solution being dialyzed, the modification significantly decreases the Mg/Na selectivity of the membrane without poisoning.

(4) The Mg/Na selectivity of the sulfonic cation-exchange membrane is studied, as influenced by the current density, electrodialysis time, and PVPPB concentration.

Abstract—Interaction of polyethylenimine with aluminum salts in aqueous solutions was studied; in the process, polymer–colloid complexes exhibiting elevated activity in separation of dispersions with low pH are formed.

DOI: 10.1134/S107042720603027X

Polymer–colloid complexes (PCCs) are new specific macromolecular compounds formed by interaction of water-soluble organic polymers with the surface of colloidal particles [1–3]. Though PCCs may have different structures, depending on both the nature of colloidal particles and type of functional groups in the polymer macromolecules, they are all water-soluble. These complexes are of particular importance for flocculation of colloidal dispersions and can be used in treatment of wastewater and in design of closed environmentally safe treatment cycles [4, 5].

Aluminum aquahydroxo complexes are formed as colloidal particles in concentrated aqueous solutions of aluminum pentahydroxochloride (APHC) [6]. It was found [7, 8] that the reaction of APHC with polyacrylamide (PAA) in aqueous solution yields PCCs exhibiting high flocculation activity in separation of model and real aqueous dispersions. Along with PAA, numerous water-soluble polymers with ionizable functional groups [including polyethylenimine (PEI)] can be used to prepare PCCs.

In this study we examined the flocculation properties of the compounds formed in aqueous solutions by APHC colloidal particles with PEI in separation of model and real dispersions.

EXPERIMENTAL

In this study we used APHC prepared by the known procedure [9] (Al^{3+} content 12.8 wt %, Cl^-/Al^{3+} atomic ratio 0.48, pH 4.5, ρ 1330 kg m^{-3}, dry residue 46.8 wt %) and PEI (molecular weight 30 000–40 000) purchased from Serva (the United States).

The composition of PCC of the polymer with APHC was studied with an Ubbelohde viscometer (Cannon, d_c 0.25 mm) at 30 ± 0.1°C. For this purpose, the solution pH was adjusted to 4.5 with 0.1 N HCl; the pH measurements were carried out with a pH-300 pH-meter (Hanna Instruments, the United States) equipped with an HI 1131 combined electrode. Before the viscosity measurements, the solutions were aged for 2 days.

The polymeric complexes were prepared by mixing the aqueous solutions of PEI (1 wt %) and APHC at room temperature; the Al^{3+} : PEI unit ratio was varied from 0.25 to 10.0. To prepare PCC, the resulting solution was stored for 2 days at room temperature.

A model kaolin dispersion (0.8 wt %) was prepared using kaolin [technical grade, GOST (State Standard) 19.608–84] and tap water (pH 7.8) and swollen for 3 h. Before the experiments, the dispersion was thoroughly mixed and poured in 250-ml glass cylinders. Then the required amounts (charges) of the flocculant solution with a concentration from 2 to 20 mg l^{-1} were added, and the resulting suspensions were stirred with disc stirrers for 30 min. After storage for 20 min, the optical density D of the supernatant was measured on a KFK-3 device (λ = 460 nm, l = 1–5 cm). Using the spectrophotometric procedure [9, 10], the clarification effect E_c was calculated as a dimensionless parameter characterizing the flocculation process:

$$E_c = \tau_D^0/\tau_D - 1,$$

where τ_D^0 and τ_D are the supernatant turbidities in

the absence of additives and after flocculant addition, respectively.

The precipitation curves of the kaolin suspension were plotted using the data on changes in the weight of the precipitate accumulated on the pan placed in the suspension using an AUX120 electronic balance with a bottom hook (Shimadzu, Japan). For this purpose, the suspension (600 ml) poured in the cylinder was stirred with the flocculant solution for 30 s with a disc stirrer, and the pan hanged on the hook was submerged in the suspension. Changes in the precipitate weight were recorded in certain periods using a stopwatch.

The rate parameter of the flocculation (flocculation effect) was calculated using the expression given in [11]:

$$D = v/v_0 - 1 = t_0/t - 1,$$

where v and v_0, and t and t_0 are the average precipitation rates and precipitation half-times (Q 0.5) in the presence of the flocculant and without it, respectively.

The constant of the precipitate compaction γ was calculated from the slope of the sedimentation curves at high degrees of clarification ($Q > 0.6$); the curves were plotted in the $\log[Q_{max} - Q(t)] = e^{\gamma t}$ coordinates [12].

The density of the resulting precipitates was calculated from the following equation [13]:

$$\rho_p = \frac{m + [(1 - Q_{max})V_0 - m/\rho]\rho_0}{(1 - Q_{max})V_0}.$$

The flotation of petroleum-containing and dairy wastewaters was performed in a glass column (40 mm in diameter and 350 mm high) stoppered from the bottom with a glass frit (Schott filter no. 4). The wastewater was sampled from a pipe that led to the flotation unit. The emulsion sample (300 cm^3) was placed in the column, and after addition of the reagent solution the column was purged with air supplied from the bottom at a constant rate of 120 $cm^3\ min^{-1}$. After 10 min, a sample was taken from the bottom stopcock of the column and analyzed for the content of petroleum products [14].

The flocculation of the kaolin dispersion was performed in the mode of free (unhindered) sedimentation (content of the dispersed phase c_d 0.8 wt %). As seen from Fig. 1, PEI is characterized by small clarification effect (curve *1*), but after protonation with HCl its flocculation power slightly increases (curve *2*). This is probably due to the opening of the macromolecular globules in the course of ionization of the imine groups. The PEI + APHC compounds exhibit significantly higher flocculation effect, as compared to initial PEI; and the highest effect is attained at Al^{3+}/PEI unit molar ratio of 1.2 (Fig. 1, curve *4*).

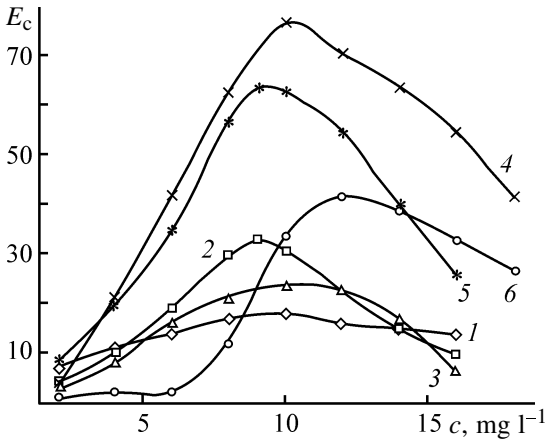

Fig. 1. Clarification effect E_c of a kaolin dispersion (c_d 0.8 wt %) as influenced by the content c and type of the flocculant. (*1*) PEI; (*2*) PEI (pH 4.5); (*3*–*6*) PEI + APHC PCC at Al^{3+}/PEI unit molar ratio of (*3*) 0.8, (*4*) 1.2, (*5*) 1.5, and (*6*) 2.2.

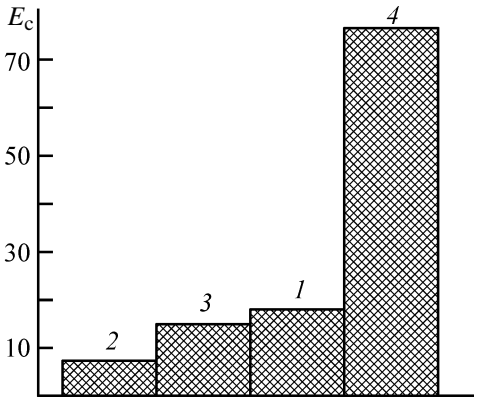

Fig. 2. Clarification effect E_c of a kaolin dispersion (c_d 0.8 wt %) as influenced by the type of the flocculant; Al^{3+}/PEI unit molar ratio 1.2; the same for Fig. 3. (*1*) PEI, (*2*) PEI + $Al_2(SO_4)_3$, (*3*) PEI + $Al(NO_3)_3$, and (*4*) PEI + APHC PCC.

In contrast to APHC, the reactions of PEI with aluminum sulfate and nitrate yield PCCs with a weaker flocculation effect as compared to PEI (Fig. 2). This fact agrees with the ionic-coordination mechanism of formation of the PEI chelate complexes with metal ions, which increases compaction of macromolecules and decreases their flocculation power [15]. In contrast to the complex based on APHC + PAA, formation of the polymer–colloid complexes of APHC and PEI cannot be confirmed by recovery of the product. However, certain increase in the flocculation power of

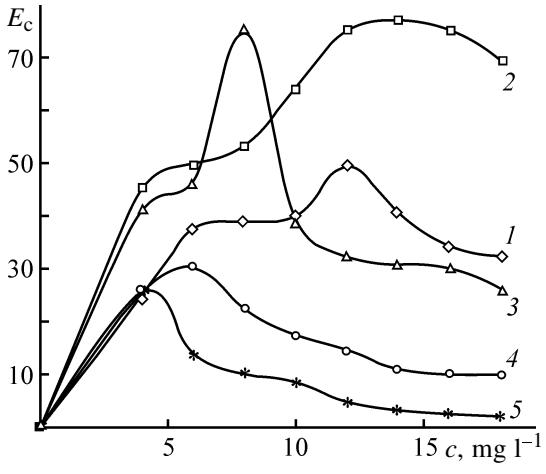

Fig. 3. Clarification effect E_c of a kaolin dispersion (c_d 0.8 wt %) as influenced by the PEI + APHC PCC content c. Solution pH: (*1*) 7.62, (*2*) 6.5, (*3*) 5.5, (*4*) 3.85, and (*5*) 2.

the product of interaction of APHC and PEI in comparison with the individual components indirectly confirms the formation of a PCC.

The data on PCC formation as influenced by the solution pH are of particular importance. To study this effect, PCCs were prepared by mixing the initial components, and then the solution pH was adjusted with 0.1 M HCl. As seen from Fig. 3, the strongest flocculation effect is observed at pH 6.5–5.5 (curves *2, 3*), because in this pH range the macromolecule occurs in the most open conformation [16]. Further acidification of the PCC solution decreases the flocculation effect, probably due to partial degradation of PCC via decomposition of aluminum aquahydroxo complexes [17].

It is known that the performance of an ionic flocculant is determined by the wastewater pH. The data on the clarification effect as influenced by the kaolin dispersion pH (PCC content 6 mg l^{-1} with respect to PEI, Al^{3+}/PEI unit molar ratio 1.2) are given below:

pH	E_c
1.5	2.0
3.0	5.0
4.5	28.4
6.0	30.8
7.4	27.6
9.5	14

As seen, the flocculation effect of PCC is the strongest at pH from 4.5 to 7.5. In this pH range, the PEI macromolecule occurs in the most open conformation, i.e., neutral and acidic solutions are the best for efficient flocculation using PCC.

The kinetics of the dispersion clarification are also of particular importance. The kinetic sedimentation curves of a kaolin suspension in the presence of PEI and PCC at an optimal flocculant content of 8 mg l^{-1} (with respect to polymer) are shown in Fig. 4. As can be seen, the solution pH and PCC composition strongly affect the flocculation kinetics. To obtain more detailed kinetic data, the quantitative parameters [such as the rate parameter of flocculation (flocculation effect) D, the constant of precipitate compaction γ, and the precipitate density ρ_p] were evaluated (Table 1). With decreasing pH to 4.5, the process rate decreases by a factor of 2, but this is accompanied by changes in the precipitate structure, which at the final stage deforms and becomes more compact. Further acidifica-

tion of the initial solutions causes an opposite affect. Our study of the effect of PCC composition on the kinetic parameters of flocculation shows that the most compact precipitate at the smallest rate of the floccule precipitation is formed at the Al^{3+}/PEI unit molar ratio of 1.25.

To explain this behavior of the flocculation system, we examined the effect of the reagent molar ratio on the parameter *F* (Fig. 5):

$$F = \eta_{sp}^{exp}/\eta_{sp}^{cal} - 1,$$

where η_{sp}^{exp} is the specific viscosity of the mixture of PEI and APHC solutions and η_{sp}^{cal} is the sum of the specific viscosities of the individual aqueous solutions of PEI and APHC.

These data show that the interaction of PEI macromolecules with APHC particles proceeds in the entire range of the reagent molar ratios (from 0.25 to 4.0); with increasing Al^{3+}/PEI unit molar ratio from 0 to 1.25, *F* decreases. This confirms formation of PCC; moreover, in the course of addition of APHC to the Al^{3+}/PEI unit molar ratio of 1.25, the reaction mixture contains PCC of the primary composition and excess PEI. In this case, the composition means the number of particles linked with one macromolecule. It should be noted that with formation of PCC of the primary composition the size of the PEI globules decreases, which is confirmed by the decrease in parameter *F*. At Al^{3+}/PEI unit molar ratio of 1.25, all the PEI macromolecules are linked in a polycomplex of the primary composition and this stage is characterized by the smallest parameter *F*. Further increase in the APHC content (Al^{3+}/PEI unit molar ratio >1.25) changes the PCC composition, i.e., the number of APHC particles linked with one macromolecule in-

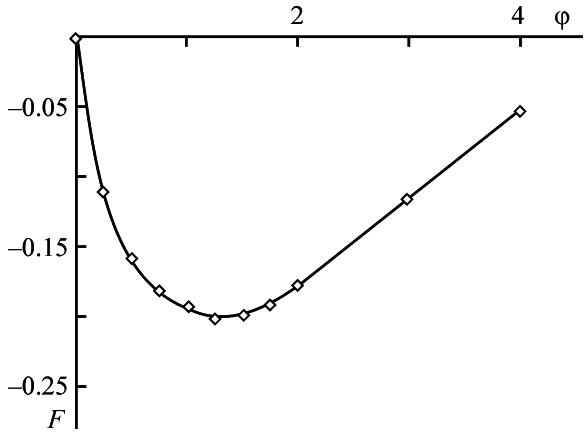

Fig. 5. Parameter *F* as a function of the Al^{3+}/PEI unit molar ratio φ in aqueous solution; PEI content 1 g dl^{-1}, pH 4.5, 30°C.

Table 2. Efficiency of purification of oily wastes as influenced by the reagent composition

Reagent	Al^{3+}/PEI unit molar ratio	Charge, mg l^{-1}	Optical density	Degree of purification
–	–	–	1.210	0
$Al_2(SO_4)_3$	1 : 0	20	0.240	80.1
APHC	1 : 0	20	0.210	82.6

PCC-2	2 : 1	5	0.224	81.5
PCC-4	4 : 1	5	0.145	88.0
PCC-6	6 : 1	5	0.110	90.4
PCC-8	8 : 1	5	0.091	92.4
PCC-10	10 : 1	5	0.091	92.4

creases. Simultaneously, the macromolecular globules open owing to electrostatic repulsion between the APHC particles (charged dispersed particles) linked with PEI macromolecule.

The data obtained using the model systems are of particular importance for preliminary evaluation of the PCC flocculation power. Under the real conditions, the reagent performance is determined by the properties of the solution in which it is used as flocculant.

The results of treatment to remove pollutants of wastewaters from an oil refinery containing emulsified oil products (pH 3.5) are listed in Table 2. PCCs with various reagent molar ratios were tested, and the treatment was performed by pressure flotation. For comparison, straight PEI, aluminum sulfate, and APHC were used. As seen, the performance of straight PEI is low. Common inorganic emulsion breakers such as $Al_2(SO_4)_3$ and APHC are more active, but the performance of PCC is significantly higher at even smaller charges. The flocculation activity increases with increasing content of APHC in PCC on passing from PCC-2 to PCC-10, which is due to the appearance of excess particles of aluminum aquahydroxo complexes (not involved in complexation with the polymer), providing degradation of the emulsion particles and their coalescence [18]. The degree of purification also depends on the solution pH (Table 3).

Table 3. Efficiency of purification of oily wastes using PCC-8 flocculant as influenced by the solution pH; reagent charge 6 mg l^{-1}

Wastewater pH*	Optical density**	Degree of purification, %
0.95	0.054	95.5
2.10	0.068	94.3
3.55	0.091	62.4
5.95	0.081	93.3
7.20	0.061	94.8

* The wastewater pH was adjusted with HCl and NaOH solutions.

** Optical density of the initial wastewater 1.210.

As seen from Table 3, owing to high performance in a wide pH range, PCC-8 can be used as specific reagent for treatment of wastewaters with elevated acidity.

The wastewaters from the Volgomyasomoltorg Joint-Stock Company are characterized by high content of the dispersed phase and by complex composition. Similarly to the case of oily wastes, the treatment was performed by pressure flotation. The reagent performance was judged from the degree of purification and such parameters as content of fats and dry residue, chemical oxygen demand (COD), and pH before and after treatment, determined by the procedures given in [19] (Table 4).

Our experimental data show that PCC is more efficient than widely used VPK-402 and KF flocculants and operates at charges smaller by a factor of 4 as compared to weakly basic aluminum oxychloride (AOC) and APHC. It should be noted that PCCs based on PAA and APHC are almost inefficient in dispersions containing fat-and-oil particles, i.e., polymer–colloid complexes of APHC and PEI are the specific reagents for treatment of dairy wastewaters.

CONCLUSIONS

In contrast to other aluminum compounds, aluminum polyhydroxychloride reacts with polyethylenimine in aqueous solutions to form polymer–colloid complexes acting as coagulants destabilizing colloidal and emulsified systems and as cation-active flocculants promoting rapid and complete separation of

dispersions. These complexes exhibit high performance in acidic solutions, which is due to conformation behavior of polyethylenimine. The resulting polycomplexes can be used as highly efficient reagents for water treatment.

Abstract—Influence of short-chain soda soap (sodium pentanoate) on the foaming and stabilizing activity of long-chain sodium carboxylates (laurate, myristate, and palmitate) is studied.

DOI: 10.1134/S1070427206030281

Mixtures of sodium salts of homologous carboxylic acids are produced at many chemical works as by-products and wastes: alkaline waste from caprolactam production (adipates), adipose tar (fat work waste), sulfate soap and tall oil (products from distillation of sulfate lye formed in pulping), etc. Generally they are used as foaming agents or collectors in flotation of potash, phosphorite, and other ores.

To understand the effect of these products on flotation, we studied the foaming activity of mixtures consisting of sodium salts of carboxylic acids with different chain length, particularly, of the short-chain pentanoate with long-chain laurate, myristate, and palmitate.

The experimental procedure was as follows. A mixed aqueous solution containing fixed concentrations of reagents (V = 20 ml) was foamed for 30 s in a graduated cylinder. The foaming activity was estimated by the foam volume and lifetime.

For comparison, initially we examined the foaming activity of aqueous solutions of the individual sodium salts of butyric (C_5), octanoic (C_8), lauric (C_{12}), myristic (C_{14}), and palmitic (C_{16}) acids. The foaming activity of these compounds depends on their chain length and concentration (Fig. 1). The foam formation in the solutions considerably increases as the reagent concentration approaches the critical micelle concentration (CMC): 2.28×10^{-2}, 6.96×10^{-3}, and 2.1×10^{-3} M for the laurate, myristate, and palmitate, respectively. The maximum of foaming activity near CMC can be attributed to the completion of the formation of the adsorption layer with the maximal mechanical strength. With a further increase in the reagent concentration above CMC, association (micelle formation) occurs in the bulk of the solution, which decreases the diffusion rate of the molecules to the adsorption layer, thus reducing the foaming activity.

Increase in the length of the hydrocarbon chain in the homologous series of the soaps initially increases their foaming activity from the octanoate to myristate and then decreases on passing to the palmitate (foam head height is 15.5, 18.0, 19.0, and 3.5 cm for the aqueous octanoate, laurate, myristate, and palmitate solutions, respectively). It should be pointed out that the short-chain butyrate and pentanoate do not form foam even in concentrated 25–50% solutions. With increasing chain length, the soap concentration corresponding to the maximal foaming activity decreases from 0.6 M for the octanoate to 2.28×10^{-2} and 6.96×10^{-3} M for the laurate and myristate, respectively.

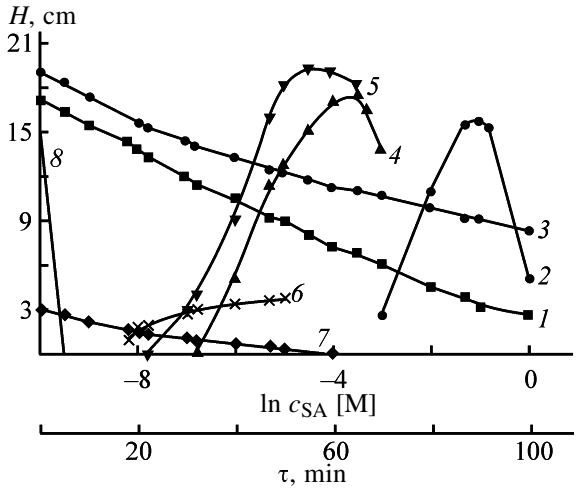

Fig. 1. (*2*, *4–6*) Foaming activity H and (*1*, *3*, *7*, *8*) foam stability τ as functions of the sodium carboxylate concentration c_{SA}: (*1*, *4*) laurate, (*2*, *8*) octanoate, (*3*, *5*) myristate, and (*6*, *7*) palmitate.

The foam stability is among the most important performance characteristics. It was demonstrated that the stability of foam formed by sodium soaps is also controlled by the nature and concentration of the surfactant, approaching the maximum at CMC. For example, for the sodium laurate solutions with the concentrations of 5.6×10^{-3} (below CMC), 2.28×10^{-2} (CMC), and 3.3×10^{-2} M (above CMC), the foam lifetime was found to be 17, 100, and 40 min, respectively.

With increasing chain length in the homologous series of sodium carboxylates, the foam stability increases from the lower carboxylates to the myristate and then decreases. Thus, for the myristate and laurate, the foam head height decreased in 100 min by 50 (Fig. 1, curve *3*) and 83% (Fig. 1, curve *1*), respectively, while with the palmitate the foam fully broke in 50 min (Fig. 1, curve *7*).

We studied the foaming activity of binary solutions of short-chain sodium pentanoate and long-chain sodium soap (laurate, myristate, or palmitate). It was demonstrated that the pentanoate has a positive effect on the foaming activity of the long-chain soaps, depending on their nature and concentration. The dependence of the foaming activity of the laurate, myristate, and palmitate on the pentanoate concentration passes through a maximum, which shifts toward lower pentanoate concentrations on passing from the laurate to the palmitate. For example, at a concentration of the long-chain soap C_{12}, C_{14}, and C_{16} of 5.7×10^{-3}, 2.0×10^{-3}, and 1.6×10^{-3} M, the maximal foaming activity was attained at a pentanoate concentration of 3.2×10^{-2}, 4.0×10^{-3}, and 3.0×10^{-3} M, respectively, and the foam head was 12.0, 5.0, and 4.2 cm against 0.5, 3, and 2.1 cm without the pentanoate.

It should be pointed out that, while for the laurate and myristate this trend is observed over a fairly wide concentration range (up to CMC and even more), in the case of the palmitate, some increase in the foaming activity takes place only below CMC. At higher concentration, addition of the pentanoate decreases the foaming activity (note that in individual pentanoate solutions with the concentrations corresponding to those of the pentanoate additive in the binary solutions studied, no foaming was observed at all).

The positive effect of the short-chain pentanoate on the foaming activity of the long-chain soaps can be attributed to the fact that, when entering the laurate or myristate micelles, the molecules of readily soluble pentanoate weaken the interchain interaction in the micelles and strengthen the electrostatic repulsion

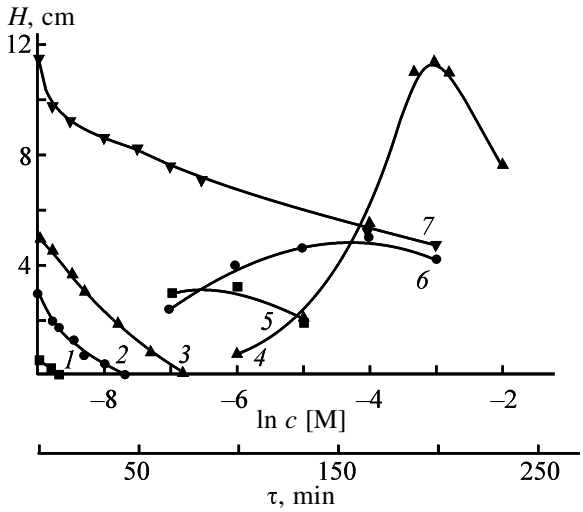

Fig. 2. (*4–6*) Foaming activity H and (*1–3, 7*) foam stability τ as functions of the sodium pentanoate concentration c in the solutions of long-chain sodium carboxylates: (*1, 4, 7*) laurate, (*2, 3, 6*) myristate, and (*5*) palmitate. Curves *1* and *2* were obtained without addition of the pentanoate.

in their surface layer. As a result, the coarse micelles of the poorly soluble long-chain surfactant become more finely dispersed, thus favoring its uniform distribution throughout the bulk of the solution and facilitating the formation of a sufficiently stable adsorption layer at the gas/liquid interface. As for the more hydrophobic palmitate molecules, the effect of the pentanoate is reduced essentially to the role of a supplier of counterions providing coagulation and salting-out of the surfactant at the concentration near its CMC.

Introduction of the pentanoate into the solutions of the long-chain laurate, myristate, and palmitate considerably improves the stability of foam. Figure 2 shows data on the stability in time for the foam formed in the laurate and myristate solutions with addition of the pentanoate. It was demonstrated that, while in the case of individual laurate solution ($c = 5.6 \times 10^{-3}$ M), the foam lifetime was 15 min (Fig. 2, curve *1*), after addition of pentanoate (3.3×10^{-2} M) to this solution, even in 200 min, the foam head decreased only by half (Fig. 2, curve *7*). After addition of pentanoate (1.2×10^{-2} M) to the myristate solution ($c = 2.0 \times 10^{-3}$ M), the foam was broken in 75 min against 48 min without pentanoate (curves *3, 2*) (pentanoate concentrations corresponded to those at which the maximal foaming activity was observed).

Since foam formation often occurs in the presence of some inorganic salts, it was advisable to examine the salt effect on the foaming activity in the laurate–

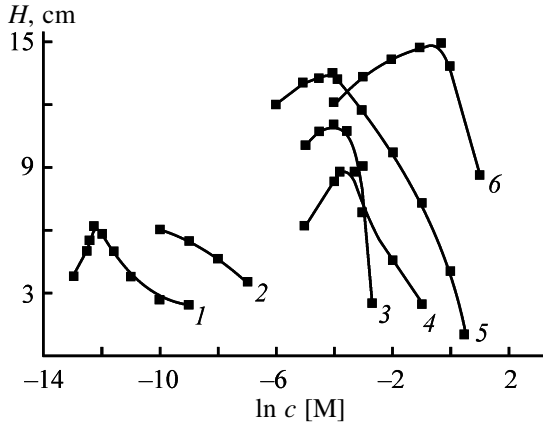

Fig. 3. Foaming activity H of (*1, 4*) myristate–pentanoate and (*2, 3, 5, 6*) laurate–pentanoate binary solutions as a function of the electrolyte concentration c: (*1, 2*) $AlCl_3$, (*3*) KCl, and (*4–6*) NaCl. Pentanoate concentration (M): (*3, 6*) 0.003, (*1, 4*) 0.012, and (*2, 5*) 0.034.

pentanoate and myristate–pentanoate binary solutions. As inorganic salts we used sodium, potassium, and aluminum chlorides. It was demonstrated previously [1] that the foam formation starts at the surfactant bulk concentration c_m corresponding to the saturation of the adsorption layer. It is well known also that, in the presence of electrolytes, this saturation is attained at lower surfactant concentration. Chistyakov and Chernin have shown [2] that, for micelle-forming surfactants, the decrease in c_m with increasing counterion concentration c_i is described by the following relationship:

$$\log c_m = -a \log c_i + \text{const},$$

i.e., increasing electrolyte concentration decreases the surfactant concentration at which the foam formation starts.

Our results show that addition of inorganic electrolytes strongly increases the foaming activity of the investigated surfactants, depending on the nature and concentration of both the surfactants and inorganic salts (Fig. 3). We studied the effect of the NaCl concentration on the foaming activity in 5.6×10^{-3} M laurate and 2.0×10^{-3} M myristate solutions containing 3.0×10^{-3} and 1.2×10^{-2} M pentanoate, respectively. With increasing NaCl concentration, the foaming activity passes through a maximum. In this case, with increasing hydrophobicity of the surfactant, the maximum of the foaming activity is observed at lower electrolyte concentration (0.85 and 0.034 M in the laurate–pentanoate and myristate–pentanoate solutions, respectively). The foam head in these solutions was, respectively, 14.9 and 9.6 cm against 4.7 and 7.1 cm without NaCl.

It was demonstrated in studying the effect of the electrolyte nature on the foaming activity of the sodium soaps that NaCl and KCl, having the same cationic charge, differently influence the foaming and stabilizing properties of the investigated binary solutions. For example, in the laurate–pentanoate system with NaCl, the maximal foaming activity was observed over a wide concentration range (1.8×10^{-2}–1.6 M), whereas with KCl, only near 1.7×10^{-2} M. This is due to different hydrability of the cations (positive for Na^+ and negative for K^+), resulting in different interaction of this cations with the surfactant molecules and micelles. The K^+ ion, having a smaller radius in the hydrated state compared to Na^+, more readily penetrates the Stern layer and more efficiently neutralizes the ionized polar groups of the surfactant, thus facilitating the micelle formation and salting-out.

In the case of trivalent aluminum, the maximal foaming activity was observed at an electrolyte concentration of 4.6×10^{-6} M, which is considerably lower than with the monovalent cations. The reason is that multivalent cations, even taken in low concentration, form complexes with the sodium soaps, initiating aggregation of the micelles followed by salting-out of the surfactant, thus decreasing its foaming activity.

Addition of the inorganic salts into the binary solutions also improves the foam stability (Table 1). For example, addition of NaCl (8.5×10^{-2} M) to the 5.6×10^{-3} M laurate solution containing 3.0×10^{-3} M pentanoate increased the foam lifetime from 20 to 30 min. Increasing pentanoate concentration slightly expands the range of electrolyte concentrations at which foam is formed. For example, at a pentanoate concentration of 3.4×10^{-2} M, after introduction of even 8.5×10^{-2} M NaCl, the foam head height in 2 h remained 85.7% of the initial. The foam formed in the system laurate–pentanoate–water in the presence of KCl taken in concentration corresponding to the maximal foaming activity (3.4×10^{-2} M) is characterized by low stability (8 min).

The increase in the foam stability in the presence of inorganic electrolytes was observed also in the system myristate–pentanoate. For example, the foam formed in the system 2.0×10^{-2} M myristate–5.6×10^{-3} M pentanoate without and with addition of NaCl (3.4×10^{-2} M) was broken in 2 h to 55.5 and 24%, respectively.

As known, the foam break follows the escape of the liquid from it (foam bleeding), which is quantita-

Table 1. Effect of the sodium pentanoate concentration and of inorganic electrolytes on the foaming activity of sodium laurate and myristate (laurate and myristate concentrations 5.6×10^{-3} and 2.0×10^{-2} M, respectively)

Concentration, M × 10²			Foam head, cm		Foam stability in 2 h, %
sodium pentanoate	NaCl	KCl	initial	after 2 h	
Sodium laurate					
0.3	–	–	2	Foam was broken in 20 min	
0.3	8.5	–	15	Foam was broken in 30 min	
3.4	–	–	7	6	64.0

Table 2. Effect of NaCl and KCl concentrations on W_0 and K_1 for foam formed in the laurate–pentanoate systems (laurate and pentanoate concentrations 5.6×10^{-3} and 3.0×10^{-3} M, respectively)

NaCl			KCl		
concentration × 10², M	$W_0 \times 10^3$, s^{-1}	K_1, m^{-1}	concentration × 10², M	$W_0 \times 10^3$, s^{-1}	K_1, m^{-1}
–	11.0	32.0	–	11.0	32.0
2.1	5.0	45.0	1.7	3.3	39.0
4.3	1.4	31.0	3.4	3.6	39.2
50.0	1.0	32.0	6.7	10.0	27.5
85.0	1.4	31.0	–	–	–

Note: For the laurate solution with $c = 5.6 \times 10^{-3}$, $W_0 = 2.67 \times 10^{-2}$ m s^{-1} and $K_1 = 34.0$ m^{-1}.

tively characterized by the volume of the liquid accumulated below the foam/solution interface in a fixed time, i.e., by the initial rate of foam bleeding W_0. It was interesting to study the effect of the electrolyte (KCl, NaCl) concentration on the foam bleeding rate in the laurate–pentanoate binary solutions. The experimental data were fitted by the following equation [3]:

$$(K_1\tau)/2 = \tau/V' - 1/W_0,$$

where K_1 is a constant; V', volume of the liquid related to the unit cross-section area of the vessel (m^2); W_0, initial rate of foam bleeding (m s^{-1}); and τ, time (s).

The applicability of this equation to foams was demonstrated in [3–5] and in our previous studies. Table 2 shows that addition of the pentanoate to the laurate solution decreases W_0 practically by half from 2.67×10^{-2} to 1.10×10^{-2} m s^{-1}.

Introduction of NaCl and KCl in the laurate–pentanoate system decreases W_0 to 1.4×10^{-3} and 3.3×10^{-3} m s^{-1}, respectively.

To conclude, small concentrations of the electrolytes favor the formation of a more compact adsorption layer of the surfactant at the gas/liquid interface, thus improving the foaming activity of the surfactant solutions and foam stability. Further increase in the inorganic salt concentration results in salting-out of the surfactant and in decrease in its concentration in the solution, foaming activity of the system, and foam stability.

The positive effect of sodium pentanoate and inorganic electrolytes on the foam formation in solutions of long-chain carboxylates is attributed to the facts that the pentanoate tends to be solubilized in the soap micelles and also that introduction of the electrolyte decreases the surfactant concentration corresponding to the saturation of the adsorption layer, thus providing compaction of the adsorption layer

at the gas/liquid interface and increasing the foaming activity and foam stability.

Finally, introduction of the short-chain sodium soap (pentanoate) and inorganic electrolytes into solutions of sodium salts of long-chain carboxylic acids allows control of the foam formation in their solutions.

CONCLUSIONS

(1) The dependence of the foaming activity of long-chain sodium carboxylates (laurate, myristate, and palmitate) on the sodium pentanoate concentration passes through a maximum, which shifts toward lower concentrations on passing from the laurate to palmitate.

(2) Addition of inorganic electrolytes favors the formation and stability of foams formed in binary carboxylate solutions.

(3) Introduction of the electrolytes (KCl, NaCl) into the system sodium pentanoate–water decreases the initial rate of foam bleeding, which is consistent with data on their effect on the foaming.

Abstract—The possibility of preparing a new fluorosiloxane elastomer by hydrolytic copolycondensation of the hydrosilylated derivative of 1-vinyl-2,2,3-trifluoro-3-trifluoromethylcyclobutane with dimethyldichlorosilane was examined.

DOI: 10.1134/S1070427206030293

Development of new elastomers combining high oil and benzine resistance with a low glass transition point remains urgent in the modern chemistry of polymers. Among the best materials having such a set of properties are polyfluoroalkylsiloxanes. However, production of commercial rubbers based on poly(methyl-3,3,3-trifluoropropyl)siloxanes such as SKTFT requires expensive and relatively difficultly accessible 3,3,3-trifluoropropene. Thus, an important task is to develop methods for preparing polymers similar in their characteristics to poly(methyl-3,3,3-trifluoropropyl)siloxane from fluoroalkenes that are more readily available and convenient in handling.

In this respect, one of the most promising compounds is 1-vinyl-2,2,3-trifluoro-3-trifluoromethylcyclobutane **I**, whose preparation by a simple procedure from commercial buta-1,3-diene and hexafluoropropene was described in [1, 2].

Patent [3] reported for the first time on hydrosilylation of fluoroalkene **I** with methyldichlorosilane **II**, giving methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]dichlorosilane **III** in 90% yield.

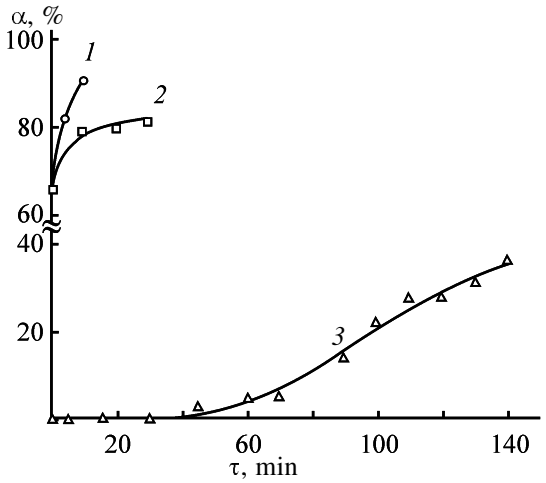
Dichlorolisane **III** was further used for preparing 1,3,5-trimethyl-1,3,5-tris[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]cyclotrisiloxane, a monomer in synthesis of the corresponding polysiloxane [4]. Anionic polymerization of the latter yields a high-quality polymer [5], but this method requires isolation of the pure trimer by vacuum distillation [bp 220°C (2 mm Hg)].

The goal of this study was to optimize the process in the hydrosilylation stage, and one of pathways was to choose a catalyst with a high activity and selectivity, as well as to take advantage of the possibility of synthesizing polysiloxanes directly from dichlorosilane **II** without isolation of the high-boiling trimer.

Hydrosilylation of fluoroalkenes was the subject of numerous studies [3, 6–8], most of which mention the commonly used Speier's or Karstedt's catalysts [1, 6, 7]. The only exception is a study by Ojima *et al.* [8] describing in detail hydrosilylation of 3,3,3-trifluoropropene and pentafluorostyrene, catalyzed by palladium, rhodium, and ruthenium complexes. With Rh and Ru catalysts, the reaction proceeds nonselectively, which rules out their practical application.

As shown previously [9–11], the catalytic activity of transition metal complexes in hydrosilylation is substantially affected by the nature of the ligand surrounding, in particular, by the balance of the σ-donor and π-acceptor properties of neutral ligands. In a series of Pt(II) complexes whose ligands have more prominent π-acceptor properties, the catalytic activity in adding hydrosilanes and hydrosiloxanes at the C=C bond tends to increase, as confirmed by kinetic studies [9, 10].

To extend the relationships revealed to reactions of fluoroalkenes, as well as to find new highly efficient catalysts for the process under study, we carried out hydrosilylation of cyclobutane **I** with hydrosilane **II** in the presence of platinum(II) bisphosphine complexes, *cis*-[$PtCl_2L_2$] [L = Et_3P, $Ph_2PCH{=}CH_2$, Ph_3P, *cyclo*-



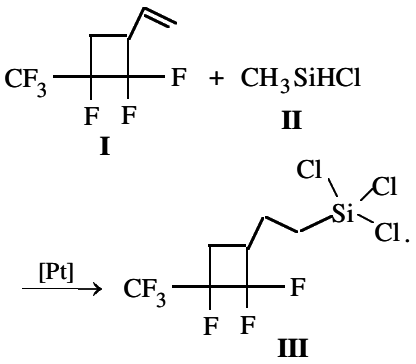


Fig. 1. Kinetic plots for the reaction of cyclobutane **I** and chlorosilane **II** in the presence of Pt(II) complexes. c_{cat} = 4×10^{-4} mol mol^{-1} ≡SiH, T = 50°C. (α) Cyclobutane **I** conversion and (τ) time. (*1*) *cis*-[$PtCl_2(Ph_2PC_6H_9)_2$], (*2*) *cis*-[$PtCl_2(Ph_3P)_2$], and (*3*) *cis*-[$PtCl_2(Ph_2PCH{=}CH_2)_2$].

$C_6H_9PPh_2$ (*cyclo*-C_6H_9 is cyclohex-1-enyl]. The selectivity of the reaction was monitored by ^1H and ^{29}Si NMR spectroscopy.

We found that hydrosilane **II** is added regioselectively; in accordance with the Farmer rule, the only reaction product is methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]dichlorosilane **III**, which was isolated from the reaction mixture by vacuum distillation:

The nature of the phosphine in the complex strongly affects its catalytic activity (Fig. 1). We found that, for [$PtCl_2L_2$] complexes, the catalytic activity increases in the ligand series as $Et_3P \ll Ph_2PCH{=}CH_2 \ll Ph_3P < Ph_2PC_6H_9$ and it determined by the combined effect or electronic and steric factors.

Dichlorobis(triethylphosphine)platinum(II) does not noticeably catalyze the reaction under the experimental conditions. With dichlorobis(vinyldiphenylphosphine)platinum(II), there was a significant induction period (30 min), and conversion of cyclobutane **I** within 2 h did not exceed 30%. At the same time, dichlorobis(triphenylphosphine)platinum(II) and dichlorobis(diphenylcyclohex-1-enylphosphine)platinum(II) are very active catalysts.

The ligand "activity series" that we derived shows that the π-acceptor properties of the phosphines are enhanced in going from electron-donating alkyl to alkenyl and aromatic substituents at the phosphorus atom. At the same time, a sharp increase in the catalytic activity in going from the vinyl to a bulky cyclohex-1-enyl substituent suggests a substantial contribution from the steric factors to the catalytic properties of Pt(II) phosphine complexes.

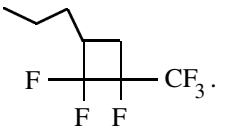
Our kinetic studies showed that the relationships in variation of the catalytic properties of Pt(II) complexes in the reaction of cyclobutane **I** with hydrosilane **II** correspond to those in hydrosilylation of alkenes [9, 10], which facilitates a search for the best reaction catalysts. In the series of the metal complexes considered, the most efficient are dichlorobis(triphenylphosphine)platinum(II) and dichlorobis(diphenylcyclohex-1-enylphosphine)platinum(II).

Patent [5] reports on preparation of polymethyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]- and polymethyl[2-(2,2,3-trifluoro-2-trifluoromethylcyclobutyl)ethyl]siloxanes by anionic polymerization. It was found that vulcanizates of such a polymer are resistant to swelling in hydrocarbon solvents (somewhat more resistant than those based on SKTFT-100 rubber) and have a high thermal stability (13% weight loss occurs at 430°C) [5]. However, the glass transition point of such material proved to be unacceptably high, from –36 to –32°C. Borisov [12] showed previously with poly(dimethyl)(methylphenyl)siloxane and poly(dimethyl)(diphenyl)siloxane as examples that introduction of dimethylsiloxane units into the macromolecular chain substantially lowers the glass transition point of the polymer. Therefore, in the context of the task of increasing the frost resistance, it was of interest to prepare a polymer with a mixed structure, containing both methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]siloxane and dimethylsiloxane units in a ratio such that the fluorine content was as close as possible to that in SKTFT-50 rubber, since this characteristic governs the resistance of the material to nonpolar solvents.

Cazacu *et al*. [13, 14] described a two-step process for preparing mixed polydimethylpolydiphenylsiloxane copolymer by condensation of an equimolar mixture of tetramethyldisiloxanediol in the presence of a polymeric sulfonic acid (Vionit CS-34C). These

silanediols are formed by hydrolysis of the corresponding chlorosilanes, the rate constant of hydrolysis of the Si–Cl bond being virtually independent of the nature of other substituents at the silicon atom [15]. This fact suggested that three different reactions can be integrated into one step (hydrolysis of a mixture of chlorosilanes, condensation of the resulting silanediols and siloxanediols with one another, and opening of the cyclic siloxanes formed by hydrolysis, in the presence of an acid catalyst).

We found that dichlorosilane **III** synthesized by hydrosilylation in the presence of fluoroalkanesulfonic acids enters into the copolycondensation reaction with dimethyldichlorosilane **IV** to form poly(dimethyl)-{methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]}siloxane **VI**. According to the ^{29}Si NMR data, it contains about 30% siloxane units with fluorine-containing substituents. To enable vulcanization of the polymer with peroxide initiators, we introduced into the polymer about 0.3% methylvinylsiloxane units. The overall equation of the process can be represented as follows:



$$x\mathrm{R_FMeSiCl_2} + y\mathrm{Me_2SiCl_2} + z\mathrm{CH_2{=}CH(Me)SiCl_2}$$
III **IV** **V**

$$+ (x + y + z + 1)\mathrm{H_2O}$$

$$\rightarrow \mathrm{HO{-}[(R_FMeSiO)_x(MeOSiO_2)_y(CH_2{=}CH(Me)SiO)_z]{-}H}$$
VI

$$+ 2(x + y + z)\mathrm{HCl},$$

where R_F =

A study of the sample by gel-permeation liquid chromatography showed that it contained about 10% low-molecular-weight cyclic products. The polydispersity index of the polysiloxane was 7.3, and the weight-average molecular weight, 606000.

The resulting polymer is significantly superior to commercial rubbers like SKTFT in the thermal stability. According to thermogravimetric data, for the sample synthesized a 5% weight loss is observed only at 350°C, while for SKTFT-50 rubber even at 270°C a 13% weight loss was observed.

The low-temperature properties of the polymer were studied by the low-temperature dielectric spectroscopy. The maximum in the temperature dependence of the dielectric loss tangent (Fig. 2) corresponds to the temperature of the dielectric α-transition, which is typically 5–10 K higher than the glass transition point of the corresponding polymer [17]. Introduction into the macromolecular chain of a significant number of dimethylsiloxane units, as expected, sharply improved the low-temperature properties relative to the homopolymer. Comparison of our data with the results of similar studies of commercially produced SKTFT-50 rubber (Fig. 2) shows that the polymer that we synthesized is close in the low-temperature properties to SKTFT-50 rubber.

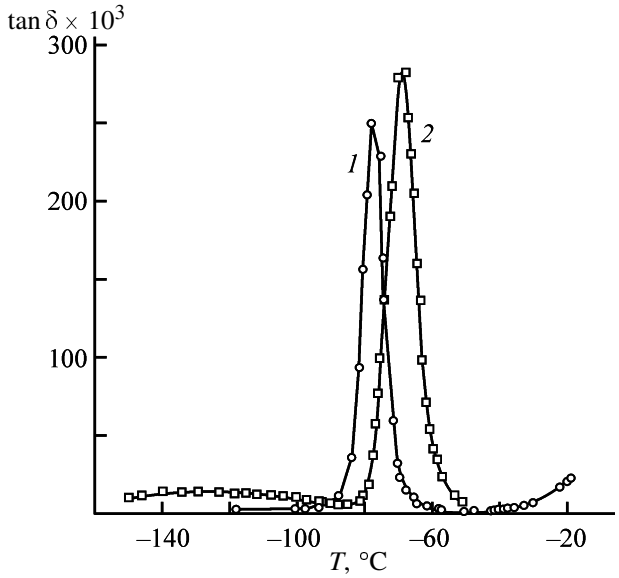


Fig. 2. Temperature dependence of the dielectric loss tangent tan δ for (*1*) SKTFT-50 rubber and (*2*) polysiloxane **VI**.

EXPERIMENTAL

The ^{1}H and ^{29}Si NMR spectra were recorded on a Bruker AC-500 spectrometer (working frequencies 500.142 and 99.361 MHz, respectively) with TMS as internal reference and $CDCl_3$ and $(CD_3)_2CO$ as solvents.

The molecular-weight distribution was determined on a Waters gel chromatograph at 25°C using a column packed with Microstyrogel stationary phase with a permeability of 10000, 500, and 100 Å; mobile phase (THF) flow rate 1 ml min^{-1}.

Thermogravimetric studies were carried out on a Du Pont 951 instrument (heating rate 10 deg min^{-1}).

The dielectric properties of the polysiloxane synthesized were studied with an Orion TR-9701 dielectric bridge using a three-electrode cell temperature-controlled in the range from –150 to 150°C.

Chromatographic analysis was carried out on a Tsvet-100 instrument with a thermal conductivity

detector; stationary phase Chromaton N-AW (0.315–0.400 mm), impregnated with 10% SE-30; carrier gas helium, flow rate 4 $l\,h^{-1}$, bridge current 100 mA; column temperature 150°C.

The kinetics of hydrosilylation of cyclobutane **I** was monitored by chromatographic analysis of the regularly taken samples of the reaction mixture.

Into a temperature-controlled reactor with a magnetic stirrer, 4.9 mmol of cyclobutane **I** and 5.0 mmol of hydrosilane **II** were introduced. When the temperature of the mixture reached 50°C, 20 μl of 0.1 M solution of the catalyst in dichloromethane was added, from which moment the time was counted. The catalyst concentration in the reaction mixture was 4×10^{-4} mol mol^{-1} of hydrosilane **II**.

Dichlorobis(triethylphosphine)platinum(II) and dichlorobis(triphenylphosphine)platinum(II) [18], dichlorobis(vinyldiphenylphosphine)platinum(**II**) [19], and dichlorobis(diphenylcyclohex-1-enylphosphine)-platinum(**II**) [20] were prepared by published procedures.

Methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]dichlorosilane III was isolated from the reaction mixture by vacuum distillation, bp 55°C (2 mm Hg), n_D^{20} 1.4039, d_{20}^{20} 1.3573. ^{1}H NMR spectrum, δ, ppm ($CDCl_3$): 0.80 s (3H, CH_3Si); 1.10 t (2H, CH_2Si), J_{HH} 8 Hz; 1.65–2.10 m (2H, CH_2); 2.33 m (1H, CH); 2.65 m (2H, CH_2). ^{29}Si NMR spectrum: δ_{Si} 29.7 ppm.

Found (%): Si 9.05, C 30.02, F 35.60, Cl 22.06, H 3.10.

Calculated (%): Si 9.09, C 30.09, F 35.74, Cl 21.94, H 3.14.

Poly(dimethyl){methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]}siloxane VI. Into a four-necked round-bottomed flask equipped with a wide-blade stirrer, glycerol seal, a thermometer, and a dropping funnel, 0.333 mol of dichlorosilane **III**, 0.671 mol of dichlorosilane **IV**, and 3.17 mmol of methylvinyldichlorosilane and then a solution of 0.03 mol of fluoroalkanesulfonic acid in 3 ml of nitromethane were added. To the resulting mixture, a mixture of 1.00 mol of water and 1,2-dimethoxyethane was added dropwise with stirring. Hydrolysis was carried out for 72 h. Then the reaction mixture was stirred in a vacuum (20 mm Hg) for 16 h, dissolved in chloroform, and 0.10 mol of ammonium hydrocarbonate was added to the resulting solution. The solution was stirred for 8 h, the precipitate was separated, the solvent was removed in a water-jet-pump vacuum, and the reaction product was kept in a vacuum oven at 120–150°C and 1.5 mm Hg until frothing ceased. After the treatment, the polymer was once again dissolved in chloroform. To a solution, 0.10 mol of finely pulverized anhydrous sodium hydrocarbonate was added, whereupon the solution was filtered. The polymer was precipitated with ethanol, and the reprecipitated polymer was once again kept in an oven for 6 h at 200°C (1 mm Hg). Yield of polymer **VI** 80%. ^{29}Si NMR spectrum, δ_{Si}, ppm [$(CD_3)_2CO$]: 2.16 [$(CH_3)_2SiO$], 23.8 [$(CH_3)R_FSiO$].

CONCLUSIONS

(1) The cycloaddition product of commercially available buta-1,3-diene and hexafluoropropene, 1-vinyl-2,2,3-trifluoro-3-trifluoromethylcyclobutane, was hydrosilylated with methylchlorosilane to form methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)-ethyl]dichlorosilane. *cis*-Dichlorobis(triphenylphosphine)platinum(II) and *cis*-dichlorobis(diphenylcyclohex-1-enylphosphine)platinum(II) were suggested as efficient hydrosilylation catalysts.

(2) Methyl[2-(2,2,3-trifluoro-3-trifluoromethylcyclobutyl)ethyl]dichlorosilane was used as comonomer in synthesis of poly(dimethyl){methyl[2-(2,2,3-trifluoro-2-trifluoromethylcyclobutyl)ethyl]}siloxane by hydrolytic polycondensation, which eliminates a labor- and power-consuming step of isolation of cyclosiloxanes.

(3) The points of dielectric α-transition of commercial SKTFT-50 rubber and of the elastomer synthesized are close, but the latter is superior in the thermal stability, which makes it promising for production of specialty rubbers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Bleaching of Buckwheat Straw and Peel with Potassium Peroxoborate

Abstract—The use of potassium peroxoborate for bleaching buckwheat production waste, straw and peal, both untreated and treated with water, mineral acids, sodium hydroxide, and organic solvents, is examined.

DOI: 10.1134/S107042720603030X

Complex utilization of plant raw materials is urgent today. Of special value is renewable waste of cereals, accumulated at plants during corn peeling. Among promising raw materials for preparation of a number of chemical substances is large-tonnage waste from buckwheat production, such as flower shells, peel (BP) or husk, and straw (BS), most of which is currently burned in fields or used as fuel.

Here we continue a study of the waste from buckwheat production as a candidate raw material for chemical industry [1–3] and examine the suitability of potassium peroxoborate (PPB) (whose synthesis procedure was developed previously [4]) for bleaching BP and BS and their residues (after recovery of polysaccharides of various compositions) for pulp production. It should be noted that highly efficient inorganic high-peroxide boron compounds [4] successfully passed laboratory and semicommercial tests as bleaching agents for textile materials (cotton and flax) and mulberry silkworm threads in China.

EXPERIMENTAL

Our study was concerned with BS and BP from various regions of Russia (Primorskii, Krasnodar, and Altai krais, Amur oblast). The straw was ground to 5-cm-long particles, and the peel was separated into fractions, whereupon particles ≥2 mm in size were selected. The raw material was washed with water and dried at 60°C.

We studied how the bleaching agent PPB affects the samples of the initial raw material and its residue after treatment (extraction) with water, mineral acids (1 N HCl, H_2SO_4, HNO_3), sodium hydroxide (0.1 and 1 N solutions), and organic solvents (a chloroform–ethanol mixture, 1 : 1 by volume) at the solid : liquid volume ratio of 1 : 10, extraction time of 1 h, and temperature of 95°C. The raw material residue after extraction of soluble substances was filtered off, washed with water, and dried to constant weight at 60°C.

Table 1 presents the samples of the initial raw ma-

Table 1. BS and BP samples studied*

Raw material	Sample no.	Solvent	Raw material residue, wt %
BS-1	1	–	
	2	H_2O	79.0
	3	1 N HCl	64.0
	4	1 N H_2SO_4	82.0
	5	1 N HNO_3	43.0
	6	$CHCl_3$ + C_2H_5OH (1 : 1)	61.3
	7	0.1 N NaOH	73.0
	8	1 N NaOH	99.0
BS-2	9	0.1 N NaOH	73.0
	10	1 N NaOH	99.0
BS-3	11	0.1 N NaOH	73.0
	12	1 N NaOH	99.0
BP-1	13	–	
	14	H_2O	73.0
	15	1 N HCl	43.0
	16	1 N NaOH	49.0
	17	$CHCl_3$ + C_2H_5OH (1 : 1)	80.5

* BS and BP samples, plant strain, place and time of collection of the raw material: BP-1, Ekaterinoslavka settlement, Amur oblast, 2001; BS-1 and BS-2, town of Ussuriisk, Primorskii krai, Izumrud strain, 2000–2001, respectively; BS-3, town of Ussuriisk, Primoskii krai, strain P-312, 2001.

terial and the weight of its residue after extraction. We determined the composition of the extracts in [2].

The action of PPB containing 20% available oxygen O_{av} on the BS and BP samples under study was examined in relation to pH of the solution (created by the bleaching composition components in the case of PPB and adjusted with alkali in the case of H_2O_2), bleaching agent concentration, and temperature and time of the process. For comparison, we carried out a series of experiments on bleaching of BS and BP with hydrogen peroxide.

The decomposition rate for PPB and H_2O_2 was estimated from the change in the content of O_{av} in solution, determined by permanganatometric titration [5], and calculated as $\ln[c_0/(c_0 - c_x)]$, where c_0 is the initial concentration of available oxygen in solution and $(c_0 - c_x)$, concentration of the available oxygen that did not decompose by the time τ.

The decomposition rate constants of available oxygen in solution were calculated by the rate equation of the first-order reaction [6]. The bleaching power of PPB was determined on a Specol instrument by the technique described in [7] relative to freshly calcined magnesium oxide as the reference. We analyzed the spectrophotometric curves of the reflection coefficient ρ at 400–700 nm and the whitenesses of the raw material samples studied. The results are presented in Figs. 1–4 and Tables 1–3.

Preliminary studies showed that BP (Table 1, sample nos. 13–17) was bleached with PPB much less efficiently than BS, and we chose BS as the primary object of our study.

The initial BS, both ground and nonground (Table 1, sample no. 1), was bleached with PPB and H_2O_2. Figure 1 presents the kinetic curves of thermal decomposition of aqueous solutions of PPB and H_2O_2 during bleaching of BS.

Our data show that, with PPB as the bleaching agent (Fig. 1, curves *1, 2*), decomposition of available oxygen proceeds uniformly at a low rate, which allows a "softer", compared to H_2O_2, bleaching of the raw material (Fig. 1, curves *3, 4*). With PPB as the bleaching agent, the initial concentration of O_{av} within the initial 30 min decreases by 17–27% (Table 2). Further, the decomposition rate of O_{av} remains virtually unchanged. The degree of decomposition of O_{av} within 60 min of bleaching was estimated at 22.7–31.9%.

We calculated the rate constants of O_{av} decomposition in solution and estimated the whiteness of the bleached BP and BS samples (Table 2). The initial

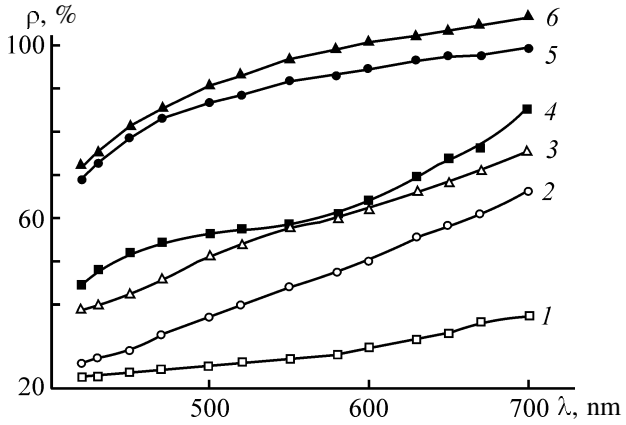

Fig. 4. Spectrophotometric curves of the reflection coefficient ρ for the raw material samples with and without bleaching. (λ) Wavelength. Sample no., bleaching agent: (*1*) 13, none, (*2*) 13, H_2O_2; (*3*) 13, PPB; (*4*) 1, none, (*5*) 1, H_2O_2; and (*6*) 1, PPB.

BS, bleached with PPB, undergoes the most profound oxidation, the whiteness being 69%, and with H_2O_2 the whiteness was no greater than 58%.

Grinding of BS insignificantly accelerated decomposition of O_{av}, leaving the whiteness virtually unaffected (68.8 against 69.1%). Replacement of PPB by H_2O_2 sharply (fivefold) accelerated decomposition of O_{av} (Fig. 1, curves *3* and *4*), with the linear run of the kinetic plots preserved. The degree of decomposition of the available oxygen is 82.98% within the initial 30 min and only slightly changes within the subsequent 30 min. It should be noted that, in this case, grinding of the straw affects the whiteness, namely, increases by 10% (45.3 and 58.7%), leaving the O_{av} decomposition rate virtually unaffected (Table 2).

Figure 2 and Table 2 show how PPB and H_2O_2 affect the BS residue after treatment with alkali solution

(0.1 N for sample nos. 7, 9, 11 in Table 1 and 1 N for sample nos. 8, 10, 12). Like in Fig. 1, the kinetic plots exhibit linear sections, corresponding to decomposition of O_{av} in solution within the initial 30 min. The major loss of O_{av} in solutions with PPB and H_2O_2 was estimated at 72.8–79.6% in the former case and 83.7% in the latter. The degree of decomposition of available oxygen in solutions with PPB and BS residues after hydrolysis of the raw material with 0.1 N NaOH was estimated at 76.2–96.0% (after hydrolysis with 1 N NaOH, 77.5–98.8%) (Table 2). The whitenesses for these samples are close, 29.0–30.3% (after hydrolysis with 1 N NaOH, 23.4–29.9%).

With H_2O_2 as the bleaching agent, the degree of decomposition of O_{av} is higher (92.0%), but the whiteness of the straw does not exceed 20.1–22.8%.

The rate constants of O_{av} decomposition in solutions are independent of the composition of the bleaching agent; they attain a maximum after 30 min and then tend to decrease. In the case of PPB, the rate constant of O_{av} decomposition is 8.5×10^{-4} s^{-1} on the average, and in the case of H_2O_2 it increases to 10.0×10^{-4} s^{-1} (Table 2).

Acid treatment of BS before bleaching with PPB accelerates the O_{av} decomposition in solution compared to the above-mentioned systems. Figure 3 presents the bleaching kinetic curves for BS sample nos. 2–6 (Table 1), and Table 3, the bleaching parameters.

The O_{av} decomposition rate in solution with PPB was at a maximum for the BS residue after extraction with HNO_3 (Fig. 3, curve *5*), and at a minimum, for the BS treated with an organic solvent (Fig. 3, curve *6*). Even within the initial 10 min, the degree of decomposition of O_{av} in solutions for all the systems was 40–66%. The calculated decomposition rate constants (Table 3) suggest that pretreatment of BS with water, acids, or organic solvents decreases this parameter when PPB is used as the bleaching agent.

Going from PPB to H_2O_2 as the bleaching reagent decelerates decomposition of O_{av} in solution with the same BS samples within the initial 10 min: The degree of decomposition of O_{av} was estimated at 17.4–36.9%. However, at the end of the peroxide bleaching (after 60 min) the O_{av} decomposition rate becomes comparable with those of the analogous solutions with PPB, and the degree of decomposition of O_{av} reaches 96%. The O_{av} decomposition rate constants at the end of bleaching of the BS samples with H_2O_2 are close to those for the systems with PPB, namely, 7.2×10^4 and 7.8×10^4 s^{-1}, respectively.

The spectrophotometric curves (Fig. 4) taken for BS and BP before and after bleaching with PPB and H_2O_2 at 400–700 nm suggest that the reflection coefficient ρ of the bleached raw material increases after bleaching. The reflection coefficients for the BS and BP bleached with PPB exceed those attained with H_2O_2.

CONCLUSIONS

(1) The kinetics of thermal decomposition of potassium peroxoborate and hydrogen peroxide during bleaching of buckwheat peel and straw was studied in relation to the kind of the raw material, method of its pretreatment (with water, mineral acid solutions, sodium hydroxide, or a mixture of chloroform with ethanol or its derivatives), and bleaching time. The decomposition rate constant of available oxygen in the case of potassium peroxoborate varies from 10^{-4} for the initial straw to $(7.8–8.7) \times 10^{-4}$ s^{-1} for the straw treated with the solvents, and in the case of hydrogen peroxide, from 5×10^{-4} to 10^{-3} s^{-1}, respectively.

(2) Potassium peroxoborate containing 20% available oxygen is suitable for bleaching of buckwheat straw. The most profound oxidation is characteristic for the initial (untreated) straw, whose whiteness reaches 69.1% (with hydrogen peroxide, 45.3%). The optimal time of bleaching of the straw with hydrogen peroxide was estimated at 30 min.

Abstract—The structure of oxidized atactic polypropylene was studied.

DOI: 10.1134/S1070427206030311

Previously [1] we reported on preparation of oxidized atactic polypropylene (OAPP) under laboratory conditions and on the properties and applications of this product. Today Ataktika Limited Liability Company (Tomsk) produces OAPP in an amount of 400 t annually on a semicommercial installation by a continuous process of oxidation of atactic polypropylene (APP) melt with atmospheric oxygen.

In this study we analyzed the structure of the polymeric product formed by thermal oxidative degradation (TOD) of APP.

EXPERIMENTAL

APP, a raw material for OAPP production, is a by-product from the polypropylene plant of Tomskneftekhim Limited Liability Company. The properties of the APP-G grade polymer meet TU (Technical Specifications) 2211-056-05 796 653–98 (Table 1).

The viscosity-average molecular weight was calculated from the intrinsic viscosity measured in benzene at 23°C with an Ubbelohde viscometer:

$$[\eta] = 2.7 \times 10^{-4} \overline{M}_{\eta}^{0.71}.$$

The dynamic viscosity of the polymer melt was determined with a programmable Brookfield viscometer. The polydispersity index of the polymers was calculated from the data obtained by centrifugal sedimentation on an MOM analytical ultracentrifuge (for the procedure, see [2]). The amount of impurity isotactic fraction insoluble in boiling heptane was determined by extraction of commercial APP in a Soxhlet apparatus for 6 h. Atactic polypropylene was purified by extraction with heptane at 20°C, followed by repre-

Table 1. Properties of atactic polypropylene

Mean number of double bonds per polymer molecule	0.4	0.4	1.3	1.5

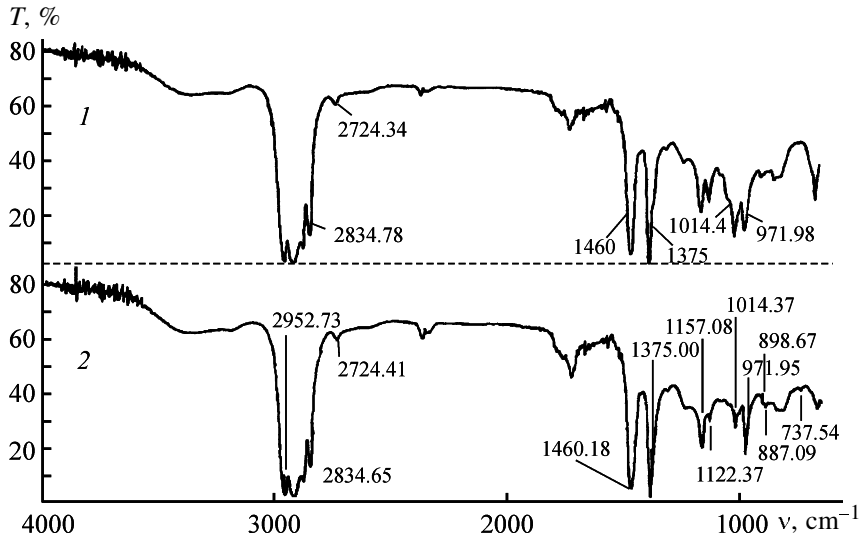

Fig. 1. IR spectra of OAPP: (*T*) transmission and (ν) wavenumber. Oxidation conditions: (*1*) APP sample no. 1, 180°C, 2 h; (*2*) sample no. 4, 250°C, 5 h.

cipitation with alcohol. The content of double bonds was determined by the Kaufman–Baltes method [3] from the iodine number. The IR spectra of APP were recorded on an Impact 410 Nicolet IR Fourier spectrometer using the multiple attenuated total internal reflection (MATIR) technique on a zinc selenide crystal [4]. The polymer was applied to the crystal at 20°C as a film and then kept for 3 h at room temperature.

The content of functional groups in OAPP was determined from the reduced intensities of absorption bands at 1720 (>C=O groups), 3180 (hydrogen-bonded alcoholic OH groups), and 3469 cm^{-1} (non-associated OH groups) [5]. As reference band we used the band at 1460 cm^{-1} whose intensity is insensitive to the OAPP composition and to the structure of its chains but monotonically varies with the sample thickness. The IR spectra of OAPP are shown in Fig. 1.

When calculating the concentrations of carbonyl and hydroxy groups, we used the molar extinction coefficients of 220 and 70 kg mol^{-1} cm^{-1}, respectively [5]. The amount of hydroxy groups at the secondary C atom was determined by acylation with acetic anhydride in pyridine [6].

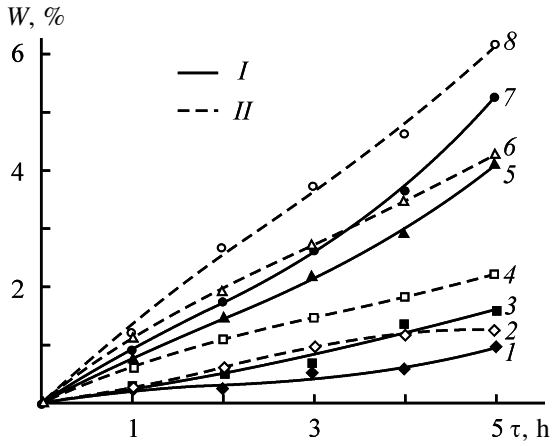
The kinetic parameters of thermal oxidative degradation of the polymers were determined according to [7] using data obtained with a Q-1000 derivatograph in the range 20–500°C (Table 2).

Oxidized atactic polypropylene was prepared on a semicommercial installation consisting of three series-connected oxidation reactors of bubbler type with a working volume of 180 l and of two separating condensers for isolation of low-molecular-weight condensable liquid degradation products. The synthesis temperature was 150–250°C depending on the grade of OAPP to be obtained and on the properties of the starting polymer; the reaction time was 1.0–8.0 h, and the air flow rate, 0.6–1.9 l min^{-1} kg^{-1}. The yield of low-molecular-weight by-products depends on the oxidation conditions and varies within 0.3–5.0 wt % (Fig. 2). The variation of the molecular weight with time in the course of TOD of commercial APP samples of various quality (Table 1) is shown in Fig. 3.

The composition and properties of commercial APP vary in a wide range (Table 1), which means that the properties of this by-product depend on the grade of the main product, isotactic polypropylene (IPP). Sample nos. 1 and 4 differ in the composition and properties most significantly, and these samples were chosen for further studies. Low-molecular-weight APP has a lower content of the isotactic fraction, a higher content of double bonds, broader molecular-weight distribution, lower softening point, and lower melt viscosity; the latter two properties allow the TOD to be performed at 150°C.

Table 2. Kinetic parameters of thermal oxidative degradation of atactic polypropylene

Parameter	Sample	
	no. 1	no. 2
Activation energy, kJ mol^{-1}	62.4	56.3
Pre-exponential term, s^{-1}	5.0×10^2	1.4×10^2
Thermal effect of reaction, kJ kg^{-1}	–2000	–1306
Apparent reaction order	1.5	1.5



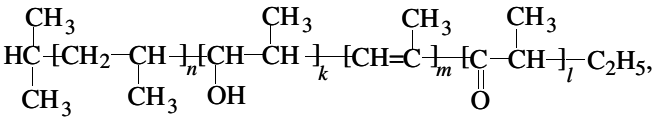


Fig. 2. Yield W of (*I*) low-molecular-weight organic compounds and (*II*) water in APP oxidation. Air flow rate 1.0 l min^{-1} kg^{-1}; the same for Figs. 3–5. (τ) Time; the same for Figs. 3 and 5. Oxidation conditions: (*1*, *2*) APP sample no. 1, 180°C; (*3*, *4*) sample no. 1, 250°C; (*5*, *6*) sample no. 4, 180°C; (*7*, *8*) sample no. 4, 250°C.

Low values of the activation energy and thermal effect of TOD of the lower-molecular-weight polymer confirm significant structural differences between the polymer samples, affecting their reactivity in oxidation (Table 2, sample no. 4).

The IR spectra of OAPP samples (Fig. 1) contain stretching vibration bands of >C=O groups of ketones in the region of 1720 cm^{-1}; at 3400–3200 cm^{-1}, there are characteristic weak broad absorption bands of stretching vibrations of alcoholic OH groups involved in hydrogen bonding and nonassociated OH groups. Weak bands of stretching vibrations of double >C=C< bonds in combination with bending vibration bands at 830, 887, 898, and 971 cm^{-1} are indicative of a high content of vinyl and vinylidene double bonds.

With an increase in the reaction temperature, the yield of water and low-molecular-weight condensable TOD products increases (Fig. 2). The yield of water at 250°C increases to 5.5% owing to dehydration of tertiary alcoholic groups with the formation of olefinic fragments. The reaction temperature and molecular weight of the starting APP affect the structure and properties of OAPP (Fig. 3). The extent of TOD of the polymer is fairly efficiently controlled by the reaction conditions, and three grades of OAPP can be produced (low-oxidized, intermediately oxidized, and highly oxidized) for various applications. The kinetic curves of accumulation of carbonyl and hydroxy groups in the polymer are shown in Figs. 4 and 5. After 1.5-h oxidation, the rate of accumulation of oxygen-containing groups sharply decreases, suggesting that the rates of polymer oxidation and its degradation with the elimination of low-molecular-weight oxygen-containing products (water, ketones) becomes equal. The concentration of hydroxy groups at the tertiary carbon atom considerably decreases with increasing temperature (Fig. 5, curves *1*, *3*), due to their dehydration. The mean content of olefinic double bonds in OAPP increases only slightly (to no more than two bonds per polymer molecule) relative to the starting polymer. The general formula of OAPP obtained on a semicommercial installation by oxidation of a polymer melt at 150–250°C is as follows:

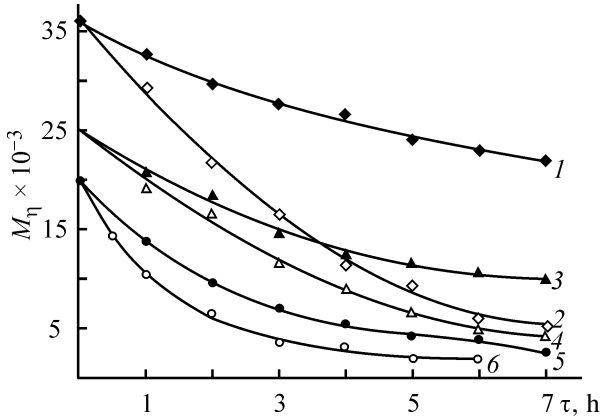

Fig. 3. Variation with time τ of the viscosity-average molecular weight M_η of APP in the course of its thermal oxidative degradation in melt. Oxidation conditions: (*1*, *2*) APP sample no. 2, (*3*, *4*) sample no. 3, and (*5*, *6*) sample no. 4. (*1*, *3*, *5*) 180 and (*2*, *4*, *6*) 250°C.

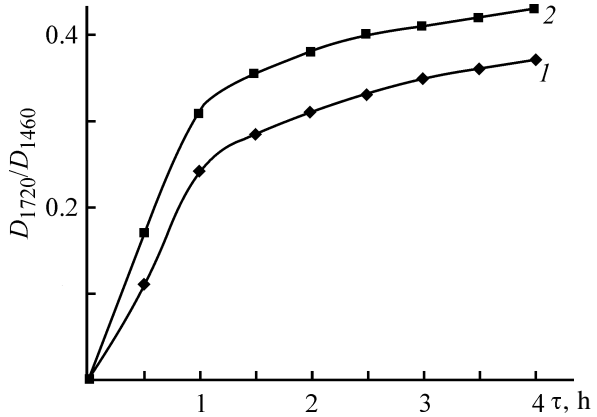

Fig. 4. Kinetic curves of accumulation of carbonyl groups in APP (sample no. 4) in the course of its thermal oxidative degradation. (D_{1720}, D_{1460}) Optical densities at 1720 and 1460 cm^{-1}, respectively; (τ) time. Oxidation temperature, °C: (*1*) 180 and (*2*) 250.

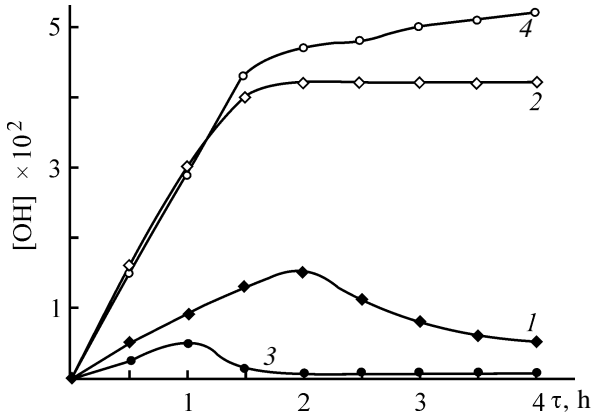

Fig. 5. Kinetic curves of the accumulation of hydroxy groups in APP (sample no. 4) in the course of its thermal oxidative degradation. OH groups: (*1*, *3*) at tertiary and (*2*, *4*) at secondary carbon atoms. Oxidation temperature, °C: (*1*, *2*) 180 and (*3*, *4*) 250.

where n = 123.0–898.0, m = 1.1–2.0, k = 1.0–1.9, l = 1.6–2.0.

Oxidation of APP methylene groups is caused by formation in a polymer melt of active radicals (hydroxy, methyl, primary alkyl), which are low-selective in hydrogen atom abstraction.

CONCLUSIONS

(1) Oxidized atactic polypropylene was prepared under semicommercial conditions by a three-reactor continuous process.

(2) The general formula of oxidized atactic polypropylene prepared by oxidation of atactic polypropylene melt with atmospheric oxygen at 150–250°C was determined.

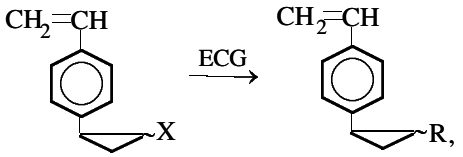
Abstract—The capability of polymers synthesized from new monomers, 2-glycidyloxymethyl- and 2-glycidyloxycarbonyl-1-(*p*-vinylphenyl)cyclopropane, to photochemical cross-linking was evaluated from variation of their solubility after UV irradiation. The dependence of the photosensitivity of the polymers on the structure of substituents was studied.

DOI: 10.1134/S1070427206030323

The prospects for practical use of functional polymers, in particular, in negative photoresists, cause an interest in their study. The presence of functional groups and also their chemical nature affect appreciably such important photolithographic parameters of a resist as photosensitivity and resolution [1–7].



The practice of using some resists in photolithographic processes revealed a number of significant drawbacks, one of which is low photosensitivity. Hence, to improve the photosensitivity and other lithographic characteristics of negative photoresists based on functional polymers, radically new approaches to the synthesis of new monomers and polymers based on these are required.

We studied previously [8] the photochemical characteristics of polymers of functionally 2-substituted cyclopropylstyrenes.

Here we studied how the structure of functional groups affects the photosensitivity of polymers prepared from 2-glycidyloxymethyl- and 2-glycidyloxycarbonyl-1-(*p*-vinylphenyl)cyclopropanes.

The monomer for preparing the polymer was synthesized as follows. First, 2-ethoxycarbonyl-1-(*p*-vinylphenyl)cyclopropane was prepared by the reaction of ethyl diazoacetate with *p*-divinylbenzene in the presence of a catalytic amount of anhydrous $CuSO_4$. Then, 2-ethoxycarbonyl-1-(*p*-vinylphenyl)cyclopropane was saponified to obtain 2-carboxy-1-(*p*-vinylphenyl)cyclopropane and reduced to obtain 2-hydroxymethyl-1-(*p*-vinylphenyl)cyclopropane [9].

To prepare 2-glycidyloxymethyl- and 2-glycidyloxycarbonyl-substituted cyclopropanes, we chose the following pathway:

where X = $-CH_2OH$, $-COOH$;

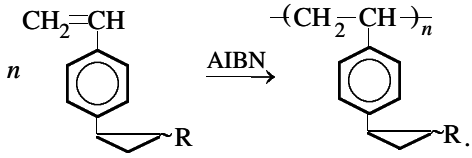
R = $-CH_2OCH_2-CH(O)-CH_2$ (**I**), $-C(=O)-OCH_2-CH(O)-CH_2$ (**II**).

Chromatographic analysis and spectral data showed that the synthesized monomers I and **II** were mixtures of two individual compounds. We found that these compounds were geometric *cis* and *trans* isomers (ratio *cis* : *trans* = 30 : 70). The purity of the monomers synthesized was monitored by gas-liquid chromatography. In all cases it was 99.9%.

In the IR spectra of **I** and **II**, there are absorption bands at 830–850, 990–1000, 1640–1645, 1035–1045, and 1105–1110 cm^{-1}, characteristic of epoxy ring, vinyl group, three-membered carbon ring, and ether bond, respectively. In addition, in monomer **II** there is an absorption band at 1720 cm^{-1} characteristic of the carbonyl group. The absorption bands at 1500 and 1605 cm^{-1} characteristic of the benzene ring are preserved.

The ^1H NMR spectra of **I** and **II** contain signals characteristic of protons of aromatic ring (δ = 6.60–7.30 ppm), cyclopropane ring (0.65–1.66 ppm), and vinyl group (5.10–6.65 ppm). The epoxy ring protons give signals at 2.30–2.60 ppm (CH_2), and 2.96 ppm

(CH). These results suggest that the reactions in all steps proceed smoothly and with quantitative yields of the target products, leaving the vinyl group and three-membered ring intact.



Polymerization of **I** and **II** was performed in the bulk and in benzene solution at 70°C in the presence of azobis(isobutylonitrile) (AIBN).

It was shown that, under the conditions studied, polymerization proceeds via scission of the double bond of the vinyl group to form macromolecules with reactive cyclopropane and epoxy side groups. This fact is confirmed by examination of the structure of the resulting polymers.

A comparison of the IR spectra of the initial monomers and polymers synthesized from them shows that the absorption bands at 990 and 1640 cm^{-1} observed in the spectra of the initial monomers and assigned to the bending and stretching modes of the vinyl bond, respectively, disappear after polymerization. The absorption bands at 1500 and 1605 cm^{-1} and in the range 1035–1045 cm^{-1} characteristic of the benzene ring and cyclopropane group, respectively, are retained during polymerization.

The absorption bands in the spectra of polymers at 1720 and in the ranges 840–850, 1105–1110 cm^{-1}, assigned to vibrations of the C–O, epoxy, and ether groups, are completely retained after the polymerization.

The IR data and elemental analysis suggest that the polymers synthesized have the following structure:

First of all, we should note some features of the structure of the resulting polymers containing two reactive groups, cyclopropane and epoxy, in the side chains of macromolecule. Due to easy rupture of the C–C and C–O bonds under irradiation [10–12], these functional groups impart to the resulting polymers high sensitivity to UV irradiation: under UV irradiation, these polymers easily transform into the insoluble form.

To elucidate the mechanism of photochemical cross-linking, we performed a spectroscopic study. For this purpose, we studied cross-linking of the resulting epoxy and cyclopropane-containing polymers by IR spectroscopy in various stages of UV irradiation. The results of UV irradiation are presented in Table 1.

Table 1. Data on UV irradiation of polymers based on monomers **I** and **II**

Monomer	Amount of polymer, %, after irradiation for indicated time, min				
	1	2	6	10	12
I	17	45	65	88	93
II	23	50	70	91	97

Table 1 shows that the maximal degree of photochemical conversion (the maximal amount of insoluble fractions) is observed with the polymer obtained from monomer **II**. This fact is undoubtedly associated with the structure of the macromolecule: along with cyclopropane and epoxy groups, it contains strongly absorbing carbonyl group, which significantly enhances the uptake of the UV energy.

The spectral analysis of the polymers showed that after UV irradiation the absorption bands characteristic of cyclopropane ring (1030–1040 cm^{-1}) and epoxy fragment (840–850, 917, 1250–1260 cm^{-1}) decrease or disappear. It was shown that the intensities of the absorption bands characteristic of cyclopropane and epoxy fragments decrease to a similar extent during UV irradiation in the initial stages. The clearest results were obtained at irradiation duration of 30 min, when the absorption bands of the above fragments virtually completely disappeared. Since the spectrum of the polymer after irradiation contained no absorption bands corresponding to cyclopropane and epoxy rings, it is evident that these groups participate in the subsequent photochemical reactions and these reactions are apparently resposible for the high capability of the polymer for photochemical cross-linking.

As seen from Table 2, the polymers synthesized have high lithographic characteristics, which allows these polymers to be used as a photosensitive base of photoresists. Thus, our studies demonstrated the possibility of developing a new class of photosensitive materials having high film-forming ability, elasticity, achromatism, and good adhesion characteristics appropriate for formation of photoresist films.

EXPERIMENTAL

2-Glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane was prepared in a three-necked flask charged with 14.4 g (0.1 mol) of 2-hydroxymethyl-1-(*p*-vinylphen-

Table 2. Characteristics of polymers based on epoxy-substituted vinylphenylcyclopropanes

Copolymer	Concentration of polymer in benzene, %	Content of microdefects, def cm^{-2}	Film thickness, μm	Exposure time, s	Photosensitivity, $cm^2\ J^{-1}$

yl)cyclopropane in 50 ml of dehydrated ethanol, 0.2 g of hydroquinone, and 8 g (0.2 mol) of powdered sodium hydroxide. Then, 14 g (0.15 mol) of epichlorohydrin (ECH) was added with vigorous stirring. The reaction mixture was stirred for 4 h. The NaCl precipitate was filtered off, and ethyl ether was removed. Then the reaction mixture was distilled to isolate the reaction product: bp 150–153°C at 1 mm Hg, yield 18.86 g (82%), n_D^{20} = 1.5220, d_4^{20} = 1.04, MR_{Dcalc}/MR_{Dfound} = 67.07/67.45.

Found (%): C 78.30, H 7.80.
Calculated (%): C 78.26, H 7.83.

2-Glycidyloxycarbonyl-1-(*p*-vinylphenyl)cyclopropane was prepared in a three-necked flask equipped with a stirrer, a reflux condenser, and a dropping funnel. The flask was charged with 18.8 g (0.1 mol) of 2-carboxy-1-(*p*-vinylphenyl)cyclopropane, 50 ml of anhydrous ether, and 1.2 g of hydroquinone, and 2.3 g (0.1 g-atom) of finely cut sodium metal was added with stirring in a nitrogen atmosphere. After complete dissolution of sodium, 14 g (1.15 mol) of ECH was added dropwise. The mixture was heated to 40°C for 1 h; after reaction completion, NaCl was filtered off, and the ether and unchanged EPC were removed. The residue was distilled in a vacuum; bp 160–162°C at 1 mm Hg, yield 22.21 g (91%), n_D^{20} = 1.5310, d_4^{20} = 1.12, MR_{Dcalc}/MR_{Dfound} = 67.09/67.36.

Found (%): C 78.30, H 7.80.
Calculated (%): C 78.26, H 7.83.

Polymerization was carried out both in the bulk and in a benzene solution in the presence of 0.2 mol % AIBN at 70°C. The resulting polymers were purified by twofold precipitation from a benzene solution with methanol and dried at 30°C in a vacuum (15–20 mm Hg).

After purification, all the polymers obtained are soluble in aromatic and chlorine-containing hydrocarbons and insoluble in alcohols.

The molecular weight was estimated from the intrinsic viscosity determined in benzene in an Ubbelohde viscometer: [η] = 1.05 (**I**) and 1.1 dl g^{-1} (**II**).

The IR spectra of the polymers were recorded on a UR-20 spectrometer.

To study the photochemical cross-linking of polymers, we prepared 2–10% solutions of polymers, which were applied to a glass support (K-8) 60 × 90 mm in size by centrifugation at 2500 rpm. The thickness of the resulting resist film was measured with an MII-4 Linnik microinterferometer. It was 0.15–0.20 μm.

The layer was dried for 10 min at room temperature and for 20 min at 40–45°C at a pressure of 10 mm Hg.

A DRT-220 mercury lamp (current strength 2.2 A) was used as a UV source, the distance from the radiation source was 15 cm, the velocity of moving the exposure meter gate was 720 mm h^{-1}, and the exposure time was 5–20 s. The content of insoluble polymer was determined from the ratio of the polymer weight to the initial weight of the film.

CONCLUSION

New monomers, 2-glycidyloxymethyl- and 2-glycidyloxycarbonyl-1-(*p*-vinylphenyl)cyclopropane, and polymers based on these were synthesized and characterized. The photosensitivity of the resulting polymers and its dependence on the substituent structure were studied. Participation of cyclopropane and epoxy groups in photochemical cross-linking was established.

BRIEF COMMUNICATIONS

On the Term "pH of the Precipitation Onset of Heavy Metal Hydroxides"

Yu. P. Perelygin and I. V. Rashevskaya

Penza State University, Penza, Russia

Received September 28, 2005; in final form, January 2006

Abstract—It is suggested to take as pH of the precipitation onset of metal hydroxides the pH at which 10% of the initial amount of metal ions has precipitated. An equation for calculating this quantity is presented.

DOI: 10.1134/S1070427206030335

Precipitation of metals in the form of hydroxides is used in hydrometallurgy [1], analytical chemistry [2], and wastewater treatment [3, 4].

The pH values of the onset and completion of the precipitation of hydroxides are determined using the data of the reference book [5]. Whereas by pH of complete precipitation is meant a pH value at which the concentration of metal ions in solution over the precipitate does not exceed 10^{-5} M, the term "pH of the precipitation onset" has no clear definition [5].

In [6], it was suggested to understand by pH of the precipitation onset of metal hydroxides a pH value at which the concentration of metal ions in solution over a precipitated hydroxide is 1 M. However, the initial concentration of the metal ion in solution, which should exceed 1 M, remains unknown and, consequently, it is unclear what part of the initial amount of metal ions has precipitated. In [6], no dependence of pH of the precipitation onset of metal hydroxides on the initial concentration of a salt in solution was demonstrated, whereas in [5], a dependence of this kind was observed.

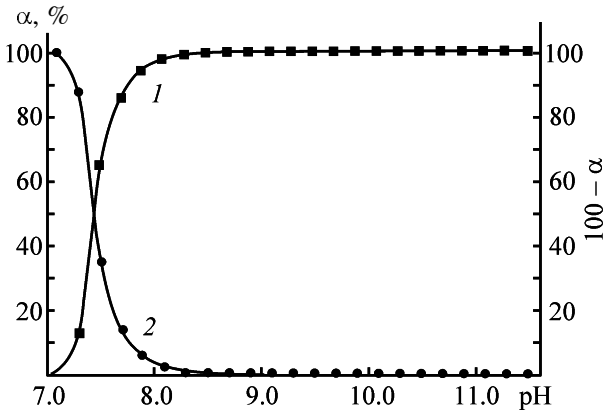
Thus, the reported pH values of the precipitation onset of hydroxides [5, 6] can hardly be used for practical purposes for the reasons mentioned above. This circumstance initiated the present study.

The concentration of the metal ion in solution, $[M^{+z}]$, over a precipitated metal hydroxide $M(OH)_z$ can be found, if the solubility product (SP) of the metal hydroxide is known, by the equation

$$[M^{+z}] = SP/[OH^-]^z. \quad (1)$$

According to the material balance, the sum of the amounts of the metal ion in the precipitate and solution is equal to the initial amount of the metal ion in solution:

$$c_M V = m/M + [M^{+z}]V, \quad (2)$$



where z is the valence of the metal; V, solution volume; m and M, mass of the precipitate and the molecular weight of the metal hydroxide, respectively; and c_M, initial concentration of the metal ion in solution.

Substituting Eq. (2) into (1) and taking into account that $[OH^-] = K_w/[H^+]$ (K_w is the ionic product of water), we obtain the equation

$$c_M V = m/M + (SP\,V[H^+]^z)/K_w^z. \quad (3)$$

Dividing the left- and right-hand parts of Eq. (3) by the initial amount of the metal ion in solution ($c_M V$), we obtain an equation that can be used to determine the relative fractions of the metal hydroxide [$\alpha = (m/c_M V) \times 100\%$] and metal ion ($100 - \alpha$) in solution as functions of the solution pH:

$$\alpha = [1 - (SP[H^+]^z)/(c_M K_w^z)] \times 100\%. \quad (4)$$

Relative fractions of cadmium ions (*1*) in the precipitate (α) and (*2*) in solution ($100 - \alpha$) vs. pH. Initial concentration of cadmium ions 1 M.

pH values calculated by Eq. (4) and taken from [5, 6]

Hydroxide	pH	
	10% metal hydroxide	[5, 6]
Initial concentration of metal ion 1 M		
$Cd(OH)_2$	7.2	7.2 [5]
$Ni(OH)_2$	6.7	6.7 [5]
$Fe(OH)_2$	6.5	6.5 [5]
$Mn(OH)_2$	7.7	7.8 [5]
$Pb(OH)_2$	6.47	6.4 [6]
$In(OH)_3$	1.7	2.07 [6]
$Cu(OH)_2$	4.5	3.8 [6]
Initial concentration of metal ion 0.01 M		
$Cd(OH)_2$	8.2	8.2 [5]
$Ni(OH)_2$	7.7	7.7 [5]
$Fe(OH)_2$	7.5	7.5 [5]
$Mn(OH)_2$	8.66	8.8 [5]
$Pb(OH)_2$	7.47	–
$In(OH)_3$	2.37	–
$Cu(OH)_2$	5.5	–

Equation (4) is only applicable if $m/M \le c_M V$. As follows from Eq. (4), the relative fraction of the metal ion precipitated in the form of a hydroxide depends on kind of a metal ion, initial concentration of the salt in solution, and pH, which was noted in [5].

The figure shows dependences of the relative fraction of the cadmium ion in the form of an insoluble hydroxide (curve *1*) and as an ion in solution (curve *2*) on the solution pH at an initial concentration of cadmium ions in solution equal to 1 M, calculated using Eq. (4) on a computer by a specially developed software. The solubility products of cadmium hydroxide and other hydroxides were taken from the reference book [5].

Similar curves were obtained for other metals that form no hydroxo complexes.

In view of the aforesaid, we presumably can take as pH of the precipitation onset of metal hydroxides the pH value at which a certain fraction of the initial amount of a metal ion, e.g. 10%, has precipitated. The thus defined pH values, calculated by Eq. (4), and the pH values of the precipitation onset of metal hydroxides from [5, 6] are listed in the table.

Comparison of the data presented in the table shows that the pH values of the precipitation onset of hydroxides, calculated by Eq. (4), and those taken from the reference book [5] virtually coincide, but strongly differ from those reported in [6]. The latter is due to the circumstance noted above: uncertainty in the initial concentration of a metal ion in solution.

Thus, the pH values of the precipitation onset of hydroxides, reported in [5], presumably refer to 10% precipitation of metal ions initially present in the solution.

Equation (4) can also be used to roughly determine pH of the precipitation onset of metal hydroxides for metals that form hydroxo complexes, if we assume that virtually no hydroxo complexes are formed at a given pH.

Abstract—The possibility of raising the yield of stabilized polymeric sulfur by rapid cooling of melts in the presence of previously unstudied complex systems including α,α,α,α',α',α'-hexachloro-*p*-xylene was examined.

DOI: 10.1134/S1070427206030347

Polymeric sulfur (PS) is the simplest inorganic polymer of nonbranched chain structure with $M = 10^3$–10^7, which has low thermodynamic stability. Stabilized polymeric sulfur (SPS) can be successfully used as a lightfast agent in vulcanization of butadiene and isoprene rubbers [1, 2]. The steadily increasing number of publication indicates that the problems associated with optimization of the manufacture of SPS are a matter of current interest [3–7].

There exist three main methods for synthesis of SPS: rapid cooling of a sulfur vapor, reaction between SO_2 and H_2S, and rapid cooling of sulfur melts. The latter method has the lowest selectivity with respect to the target product (no more than 50–55%), compared with values as high as 80–90% for the first two. However, this technique involves considerably lower expenditure of materials and energy, compared with the method of vapor cooling, is environmentally safer, and requires simpler apparatus, compared with the method of reaction between SO_2 and H_2S [2]. The aforesaid suggests that the method of rapid cooling of sulfur melts is rather promising for industrial research, in particular, via use of stabilizing additives. Of interest for a study are systems including α,α,α,α',α',α'-hexachloro-*p*-xylene (HCX) [2–4]; however, published evidence about these systems is scarce.

The aim of this study was to improve the procedure for synthesis of SPN by rapid cooling of sulfur systems by using mixtures of HCX with other substances as stabilizing additives.

EXPERIMENTAL

In the first stage of the study, the main task was to select additives that would enhance the stabilizing effect of HCX in the course of formation of polymeric sulfur.

The experiments were carried out as follows: a mixture of crystalline sulfur (90 wt %), HCX (5%), and an additive (5%) was finely ground in a porcelain mortar. The resulting mixture was transferred into a thin-walled porcelain crucible with a cover, a mechanical stirrer, and a thermometer and heated on an oil bath at 210–215°C for 1 h. The resulting melt was rapidly poured into a mixture of water and ice, so that the temperature of the cooling water did not exceed 10°C in the course of quenching. The degree of hardening was assessed from the consistence of the sample: 3–7 days after the quenching, the sample usually could be finely ground in a porcelain mortar. When a satisfactory result was obtained in grinding, the sample was analyzed for the content of a toluene-insoluble residue (150 ml of toluene was taken per 1.5000 ± 0.1000 g of the product). The resulting yields of an insoluble residue, which characterize the possibility of formation of polymeric sulfur in relation to the type of a stabilizing system, are listed in the table.

The choice of inorganic additives was largely determined by the evidence concerning the favorable effect of silicon oxide [3] and aluminum and zinc chlorides [2]. Probably, the stabilizing action is accounted for in

this case by the possibility of formation of polysulfides of the corresponding elements. A study of the influence exerted by hexamethylenetetramine and *p*-chlorobenzenesulfonic acid (*p*-CBSA) seemed to be of interest because representatives of certain classes of organic substances (aliphatic amines, aromatic sulfo acids, chlorine-substituted alkanes, aromatic compounds) favor formation of organic polysulfides [8]. Urea was used mainly because its thermal decomposition yields ammonia capable of blocking the ends of a polymer chain of sulfur.

To study the influence exerted by an additive introduced together with HCX, an experiment with only HCX was also performed (10 wt % HCX and 90% crystalline sulfur were taken) under conditions similar to those described above. Despite the rather high yield of an insoluble residue (68%) for the method of quenching of sulfuric melts as a whole, such a high content of HCX in the fusion cake is economically unfeasible in view of the strongly and steadily increasing price of HCX. The results obtained for two-component stabilizing systems indicate that the organic additives tested either weaken (urea, to a lesser extent) or enhance (*p*-CBSA) the stabilizing effect of HCX in formation of polymeric sulfur, compared with the inorganic materials used. In the latter case, such an effect of the additive can be accounted for by the probable nucleophilic substitution of the chlorine atom in the benzene ring by the polysulfide residue.

Because the experiment with *p*-CBSA yielded the best result, two experiments were also performed, aimed to determine the optimal ratio of the components of the stabilizing mixture. In particular, an experiment with the following composition (wt %): rhombic sulfur 85, HCX 10, *p*-CBSA 5, made it possible to obtain 74% yield of the insoluble residue, and the experiment with (wt %) rhombic sulfur 85, HCX 5, and *p*-CBSA 10 gave 58%. Thus, HCX plays a considerably more important role in the mixture of the stabilizing components.

Because the main goal is the economical feasibility of synthesis of preparations with a high content of sulfur (the price of *p*-CBSA is nearly an order of magnitude higher than that of urea), the formulation with urea was taken as a basis. A number of formulations of the following initial composition were tested (wt %): crystalline sulfur 85, urea 5, HCX 5, and the third stabilizing additive 5. In this case, the synthesis conditions remained the same as those in a study of two-component stabilizing mixtures.

The choice of the third component for a mixture of additives was governed both by data on the possibility of formation of organic and inorganic polysulfides [8, 9] and by the assumption that some compounds and, in particular, triphenylmethyl chloride, which can form stable radicals in decomposition, could interact with the radical ends of the chain of polymeric sulfur.

Effect of a stabilizing system containing HCX (5 wt %) and additives A (5 wt %) and B (5 wt %) on the content of a toluene-insoluble residue in the product

Additive		Residue, wt %
A	B	
SiO_2	–	40
Al_2O_3	–	43
P_2O_5	–	39
$AlCl_3$	–	47
$FeCl_3$	–	41
$CaCl_2$	–	41
$(CH_2)_6N_4$	–	34
$(NH_2)_2CO$	–	56
$4\text{-}ClC_6H_4SO_3H$	–	71
$(NH_2)_2CO$	Al_2O_3	61
$(NH_2)_2CO$	SiO_2	48
$(NH_2)_2CO$	$CaCl_2$	44
$(NH_2)_2CO$	Na_2SiO_3	43
$(NH_2)_2CO$	$Na_2B_4O_7 \cdot 10H_2O$	43
$(NH_2)_2CO$	$B(OH)_3$	58
$(NH_2)_2CO$	H_2NSO_3H	60
$(NH_2)_2CO$	PhOH	82
$(NH_2)_2CO$	$4\text{-}H_2NC_6H_4SO_3H$	52
$(NH_2)_2CO$	$1,3\text{-}(OH)_2C_6H_4$	48
$(NH_2)_2CO$	$2\text{-}HOC_6H_4COOH$	57
$(NH_2)_2CO$	$C_{14}H_{29}C_6H_4SO_3H$	50
$(NH_2)_2CO$	$C_{14}H_{29}C_6H_4SO_3H$ (2.5 wt %), H_2SO_4 (2.5 wt %)	39
$(NH_2)_2CO$	$4\text{-}HO\text{-}3\text{-}HOOCC_6H_3SO_3H$	84
$(NH_2)_2CO$	Cellulose	34
$(NH_2)_2CO$	α-Pinene	26
$(NH_2)_2CO$	Ph_3CCl	38

The results of these experiments (yields of the toluene-insoluble residue) are listed in the table. In particular, it was found that the highest yields of the insoluble residue are obtained with phenol and 4-hydroxy-3-carboxy-1-benzenesulfonic acid (HCBSA) as the third component (82 and 83 wt %, respectively).

To study more thoroughly the effect of phenol and sulfosalicylic acid, experiments with the corresponding two-component stabilizing systems (i.e., those in the presence of HCX) were carried out by the procedure described above. In this case, the yield of the

insoluble residue decreased to 67% for phenol and to 70% for HCBSA. In addition, the viscosity of the reaction mass significantly increased in the course of synthesis itself, which, in turn, complicated the process of rapid cooling of the fusion cake.

Phenol was used to carry out an experiment with the same relative amounts of the components by the general procedure, but with the time of keeping shortened to 40 min, and an experiment without HCX and urea: phenol 10 wt %, crystalline sulfur 89 wt %, and 1 wt % sodium hydroxide as a promoting additive. The yield of the insoluble residue was 67% in the first experiment and 10% in the second. Apparently, the highest efficiency of formation of polymeric sulfur, which is due to the presence of phenol or sulfosalicylic acid in the reaction mass, is only observed when HCX is used together with urea.

Reducing the time of keeping of the reaction mixture is a negative factor in all cases.

Thus, the method of quenching of sulfur melts containing HCX will, in prospect, successfully compete in selectivity and economical parameters with the technique of rapid cooling of a sulfur vapor and with that involving reaction of hydrogen sulfide with sulfur dioxide.

CONCLUSIONS

α,α,α,α',α',α'-Hexachloro-*p*-xylene is effective as a stabilizing additive in synthesis of polymeric sulfur by rapid cooling of sulfur melts in the presence of *p*-chlorobenzenesulfonic acid, urea, phenol, and 4-hydroxy-3-carboxy-1-benzenesulfonic acid (the yield of stabilized polymeric sulfur is as high as 82–83%).

BRIEF COMMUNICATIONS

Thermodynamics of Discharge of the Nickel Oxide Electrode

A. I. Demidov, M. S. Kokhatskaya, and B. V. Chernovets

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received February 15, 2006

Abstract—Standard Gibbs energies and standard potentials of the reactions presumably occurring during discharge of the nickel oxide electrode were calculated.

DOI: 10.1134/S1070427206030359

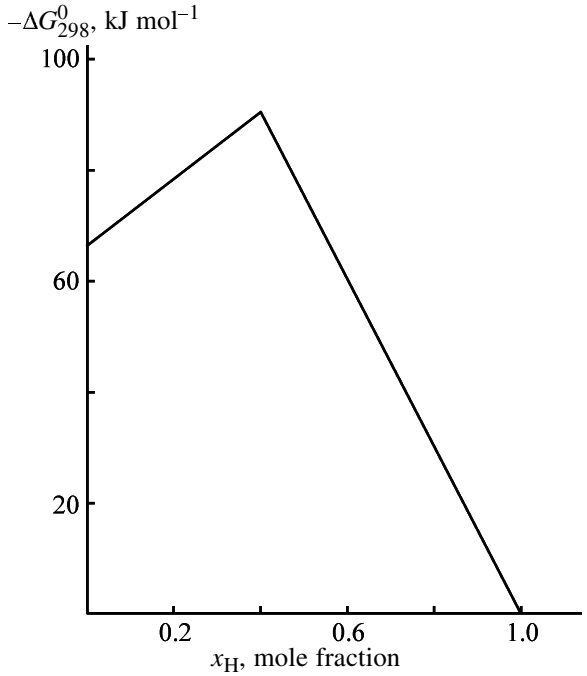
The nickel–iron battery suggested by Edison in the beginning of the past century [1] belongs to alkaline lamellar batteries. The nickel–iron battery is conventionally described as the following electrochemical system [2]:

$$(-)\,\mathrm{Fe}\,|\mathrm{MOH}|\,\mathrm{NiOOH}\,(+),$$

where Fe is a negative electrode based on iron; MOH, an aqueous solution of KOH or NaOH with LiOH added; and NiOOH, a positive nickel oxide electrode.

As for the nickel oxide electrode, this notation is conventional to a certain extent, as the active material of the positive electrode consists of a mixture of nickel(II) metahydroxides having two structural modifications, β and γ, with graphite as a conducting additive [3]. The oxidation state of nickel in β-NiOOH is 3, and in γ-NiOOH it varies within the limits of 3.32–3.7 [4], i.e., nickel in the γ-phase is present in two oxidation states, 3 and 4. Therefore, reaction (1) occurring on the positive electrode at the potentials of the first section of the discharge curve corresponds only to the β-phase, and for the γ-phase it is conventional.

$$\mathrm{NiOOH} + \mathrm{H_2O} + \mathrm{e} \rightarrow \beta\text{-}\mathrm{Ni(OH)_2} + \mathrm{OH^-}. \quad (1)$$



The discharge curve of the nickel oxide electrode contains the second section [3] of an unclear origin. Its potential is lower than the potential of the first section by approximately 0.4 V. Therefore, we decided to calculate the standard Gibbs energies and standard potentials of the reactions presumably occurring during the discharge of the nickel oxide electrode and to compare these values with published data.

In the calculations we used the standard Gibbs energies of formation of $Ni(OH)_2$ and NiO_2 taken from the literature [5] (Table 1). It should be noted that the O : Ni ratio in these compounds is 2, i.e. their compositions lay on the secant of the concentration triangle H–Ni–O drawn from the H vertex to the O–Ni side. The recalculation of the standard Gibbs energies of formation of the compounds per mole of atoms entering into their composition (Table 1) allows us to construct the dependence of the standard Gibbs energy (ΔG^0_{298}) of the quasibinary system $Ni_{0.333}O_{0.66}$–H on the composition x_H (see figure). It should be noted that the standard Gibbs energy found analytically for the compound $Ni_{0.25}O_{0.50}H_{0.25}$ and recalculated to the composition NiOOH agrees well with the value given in [6] for β-NiOOH at the onset of discharge (Table 1). The resulting dependence of the standard Gibbs energy for the quasibinary system $Ni_{0.333}O_{0.66}$–H on the composition allowed us to calculate the standard Gibbs energies of formation of nickel compounds with oxidation states 3.32 ($NiOOH_{0.68}$) and 3.7 ($NiOOH_{0.30}$) (Table 1).

Knowing the standard Gibbs energies of formation of nickel compounds, we have calculated the standard Gibbs energies of reactions (1)–(4) and their standard

Table 1. Standard Gibbs energies of formation of nickel compounds

Compound	ΔG^0_{298}, kJ mol^{-1}	Compound	ΔG^0_{298}, kJ mol^{-1}
NiO_2	–198.7	$Ni_{0.333}O_{0.667}$	–66.2
$NiOOH_{0.30}$	–236.8	$Ni_{0.303}O_{0.606}H_{0.091}$	–71.75
$NiOOH_{0.68}$	–285.1	$Ni_{0.272}O_{0.543}H_{0.185}$	–77.47
NiOOH	–325.8 –325.8 [6]	$Ni_{0.25}O_{0.50}H_{0.25}$	–81.45
$Ni(OH)_2$	–453.1	$Ni_{0.20}O_{0.40}H_{0.40}$	–90.6

Standard Gibbs energy ΔG^0_{298} of the quasibinary system $Ni_{0.333}O_{0.66}$–H as a function of composition x_H.

potentials (Table 2):

$$NiOOH_{0.68} + 1.32H_2O + 1.32e \rightarrow \beta\text{-}Ni(OH)_2 + 1.32OH^-, \quad (2)$$

$$NiOOH_{0.30} + 1.7H_2O + 1.7e \rightarrow \beta\text{-}Ni(OH)_2 + 1.7OH^-, \quad (3)$$

$$NiO_2 + 2H_2O + 2e \rightarrow \beta\text{-}Ni(OH)_2 + 2OH^-. \quad (4)$$

It is seen from Table 2 that the standard potentials of reactions (1)–(4) almost coincide. Thus, our calculations confirm the constancy of the experimental value of the discharge potential of the nickel oxide electrode (the first section of the discharge curve), which is independent of the ratio of β- and γ-phases in its composition [3]. Attempting to understand the origin of the second section of the discharge curve with a constant potential, we assumed that the oxidized and reduced forms of nickel compounds can react with each other, e.g., β-NiOOH can react with β-$Ni(OH)_2$ and NiO_2, with β-$Ni(OH)_2$:

Table 2. Standard Gibbs energies ΔG^0_i and standard potentials E^0_i of reactions (1)–(4)

Reaction	ΔG^0_i, kJ	E^0_i, V
(1)	–47.4	0.491
(2)	–65.5	0.491
(3)	–80.5	0.491
(4)	–94.6	0.490

$$2\beta\text{-}NiOOH + \beta\text{-}Ni(OH)_2 = Ni_3O_4 \cdot 2H_2O, \quad (5)$$

$$NiO_2 + 2\beta\text{-}Ni(OH)_2 = Ni_3O_4 \cdot 2H_2O. \quad (6)$$

The negative values of the standard Gibbs energies of reactions (5) and (6) $\Delta G^0_5 = -81.6$ and $\Delta G^0_6 = -81.4$ kJ indicate that the equilibria of reactions (5) and (6) are shifted toward formation of $Ni_3O_4 \cdot 2H_2O$. In turn, this compound can be reduced during the battery discharge:

$$Ni_3O_4 \cdot 2H_2O + 2H_2O + 2e \rightarrow 3\beta\text{-}Ni(OH)_2 + 2OH^-. \quad (7)$$

The standard potential of reaction (7) describing the second section of the discharge curve with a constant potential is $E^0_7 = 0.068$ V. The difference between the standard potentials of the first and second sections is 0.423 V, which agrees well with the experimental data [3]. Thus, the results of the thermodynamic calculation suggests the possibility of the reaction between the oxidized and reduced forms of nickel compounds and of participation of the reaction product in the electrochemical process.

CONCLUSION

The calculated standard potentials of the reactions presumably occurring during discharge of the nickel oxide electrode are consistent with the experimental constant potentials observed in the discharge curves.

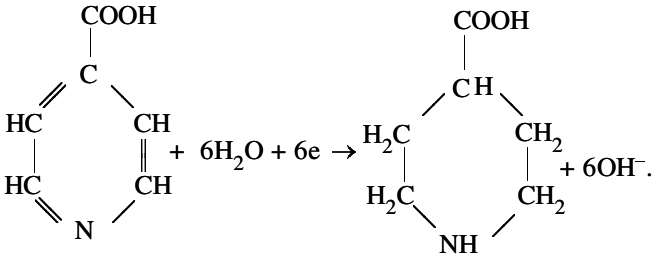
Abstract—An electrocatalytic synthesis of isonipecotic acid was carried out by cathodic reduction of isonicotinic acid in a membrane electrolyzer on a copper cathode activated with Raney nickel in an alkaline medium under mild conditions.

DOI: 10.1134/S1070427206030360

Isonipecotic acid (INPA), 4-piperidinecarboxylic acid, is an important intermediate product in synthesis of biologically active compounds for medicine and veterinary, in particular, it is used for preparing Aceclydine.

It is known [1] that cathodic reduction of heterocyclic compounds, among them pyridine, in an acid medium allows preparation of dihydro derivatives and dimeric products.



It was reported [2] that, in cathodic reduction of isonicotinic acid anilide in alkaline media on a mercury cathode at controllable potential, this substance is quantitatively converted to its dihydro derivative.

In this study we developed a procedure for exhaustive cathodic reduction of isonicotinic acid (INA).

The cathodic reduction of isonicotinic acid was studied in aqueous alkali on a cathode activated with powdered Raney nickel. An electrolyzer of membrane type was equipped with a nickel anode and a flat horizontal copper cathode. The powdered catalyst was fixed on the cathode surface with a permanent magnet.

15–40 wt % aqueous alkalis were used as anolytes, and 3–10 wt % aqueous alkalis as catholytes. The INA concentration was varied within 5–15%. The catholyte and anolyte were stirred with a mechanical stirrer (50–100 rpm). The catalyst amount on the cathode surface was 5–15 g cm^{-2}. In the course of cathodic reduction, the temperature in the electrolyzer was in the range 20–35°C.

We found that the optimal conditions for cathodic reduction of isonicotinic acid were as follows: initial INA concentration 5–10 wt %, initial sodium hydroxide concentration 5–6 wt % in catholyte and 20–25 wt % in anolyte, temperature 20–30°C, and catalyst content on the cathode surface 8–10 g cm^{-2}. Taking into account that INPA is difficultly separated from INA, in our experiments we ensured quantitative cathodic reduction of INA by passing the electricity in the amount exceeding the calculated value (6 F per mol INA) by 65–70%. The maximal current efficiency for INPA was 60%. We established that cathodic reduction of INA proceeds by the following scheme:

The target product was isolated in the form of INPA hydrochloride which was used in further organic syntheses.

EXPERIMENTAL

Isonicotinic acid, sodium hydroxide, and hydrochloric acid were of the reagent grade.

Electrolyses were performed in a glass cylinder with a lid holding a nickel anode incorporated into a ceramic diaphragm. A hollow copper disk connected to a voltage source was used as a cathode. The electrolyzer was equipped also with a mechanical stirrer and a connecting tube for removing gaseous electrolysis products [3].

The cathodic chamber was loaded with 5% aqueous NaOH (170 cm^3), INA (8.5 g), and Raney nickel (2 g), and the anodic chamber, with 40 cm^3 of 20% aqueous NaOH. The electrolysis was carried out with mild stirring (60 rpm) at 25–30 °C at a current strength of 5 A and a cathodic current density of 8.3 A dm^{-3} (per geometric surface area) for 4.1 h up to completion of hydrogen uptake. After completion of the electrolysis, the catholyte was treated with hydrochloric acid to convert INPA to its poorly soluble hydrochloride derivative. The resulting suspension was cooled and filtered, and the white precipitate of the final product was washed with cold water and dried. Yield of INPA hydrochloride 11.3 g.

Found, %: C 42.80, N 8.29, Cl 21.95.
$C_6H_{12}NCl$.
Calculated, %: C 43.77, N 8.50, Cl 21.55.

The amount of electricity passed through the electrolyzer was 20.5 A h, which exceeds the calculated value by a factor of 1.7. The INPA chemical yield and the corresponding current efficiency were 99 and 60%, respectively.

CONCLUSION

An electrocatalytic synthesis of isonipecotic acid was carried by cathodic reduction of isonicotinic acid on a copper cathode activated with Raney nickel in aqueous alkali with quantitative yield and 60% current efficiency.

Abstract—Changes in the nature and concentration of functional groups in the anion exchanger at oxidation of hydrogen sulfide in Fe(II)–ethylenediaminetetraacetate/anion exchanger catalytic system were studied.

DOI: 10.1134/S1070427206030372

As shown previously [1–4], Fe(II)–ethylenediaminetetraacetate (EDTA)/anion exchanger system effectively catalyzes oxidation of hydrogen sulfide with atmospheric oxygen to form H_2O and elemental sulfur. Water formed in the process compensates a decrease in the water content of the catalytic system at its contact with purified air and thus positively affects the process. Sulfur is accumulated in the anion exchanger phase, but its amounts are small, and thus its negative effect on the catalytic system can be decisive only at prolonged operation.

Another factor strongly affects the stability of the system studied. It is known [5, 6] that the oxidation of the reduced chelate containing Fe(II) is accompanied by a side reaction yielding hydrogen peroxide, which, when reacting with $[Fe(II)–EDTA]^{2–}$, generates $OH^•$ radicals:

$$2[Fe(II)–EDTA]^{2–} + O_2 + H_2O \rightarrow 2[Fe(III)–EDTA]^– + H_2O_2 + 2OH^•,$$

$$2[Fe(II)–EDTA]^{2–} + H_2O_2 + H_2O \rightarrow 2[Fe(III)–EDTA]^– + OH^– + OH^•.$$

The $OH^•$ radicals react with the CH_2 group adjacent to the carboxy group in the $EDTA^{4–}$ anion, causing degradation of the complexone in accordance with the following reaction:

$$R'R''NCH_2COO^– + 4OH^• \rightarrow R'R''NH + {}^–OOC–COO^– + 2H_2O + H^+.$$

The methylene groups of the EDTA ethylene bridges can also be oxidized with $OH^•$ radicals.

The possibility of improving the stability of the Fe(II)–EDTA/anion exchanger catalytic system by its modification with anions that exhibit reducing power was studied in [7, 8]. It was found that the strongest stabilization effect is observed when the catalytic system is modified with oxalate ions.

Since organic amines are easily oxidized, it was of particular interest to study the behavior of $OH^•$ radicals with respect to the functional groups of the anion exchanger and to analyze the results of possible oxidative degradation of these functional groups.

EXPERIMENTAL

The catalytic systems were prepared using FIBAN fibrous anion exchangers [9]: FIBAN A-5 weakly basic anion exchanger in the chloride basic form with the exchange capacity (EC) of 4.84 mg-equiv $g^{–1}$ and FIBAN A-6 anion exchanger with strongly and weakly basic amino groups in the chloride basic form (EC_{st} and EC_w 2.19 and 1.18 mg-equiv $g^{–1}$, respectively). A weighed portion of the anion exchanger was kept in a 0.25 M solution of Fe(II)–EDTA (pH 8.0) for 0.5 h. Then the resulting sample was removed from the solution and squeezed with a filter paper.

Hydrogen sulfide was oxidized in a flow tubular reactor at room temperature. A 0.3-g portion of the catalyst (swollen and squeezed) was placed in the reactor and a flow of air containing 0.14 vol % H_2S was passed through the reactor at a rate of

Content and nature of functional groups in the support of Fe(II)–EDTA/anion exchanger catalytic system

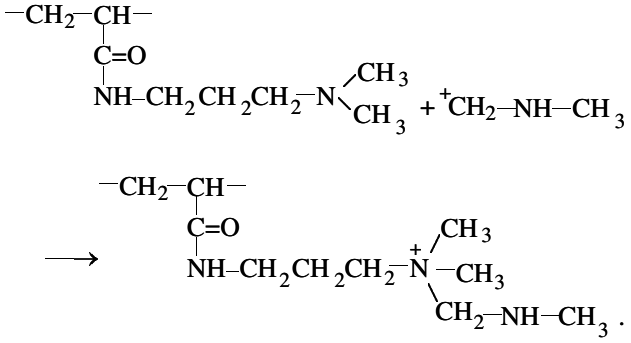
Sample	Exchange capacity for amino groups, mg-equiv g^{-1}			EC_{st}/EC_w
	EC_{tot}	EC_w	EC_{st}	
A-5:				
initial	4.84	4.84	–	–
after treatment	4.16	2.78	1.38	0.5
modified with oxalate ions (after experiment)	4.31	3.05	1.26	0.4
A-6:				
initial	3.37	1.18	2.19	1.86
after treatment	2.75	0.92	1.83	1.99

18 ml min^{-1} for 6 h. After the experiment, the sample was taken out and washed with several portions of 0.1 M HCl to remove the complex. The content of amino groups (strongly and weakly basic) in the support samples was determined by the procedure given in [10, 11]. Mass spectrometric analysis of air after its treatment to remove hydrogen sulfide was performed on an MKh 1320 unit.

As seen from the table, the exchange capacity of the support in the Fe(II)–EDTA/anion exchanger system after the experiment is 14–18% smaller than the initial value, which is probably due to partial oxidative degradation of the functional groups of the anion exchanger in the reaction with $OH^{\bullet}$ radicals. The reaction of the amino groups with $OH^{\bullet}$ radicals is confirmed by mass-spectrometric data on the composition of air after its treatment to remove H_2S in the presence of the Fe(II)–EDTA/anion exchanger catalytic system.

The sample studied contained dimethylamine and excess CO_2 relative to its content in air.

It should be noted that in the spent A-5 material the amount of weakly basic groups strongly decreases, whereas new strongly basic groups appeared. Similar phenomenon is observed for A-6 sample: a decrease in EC is accompanied by an increase in the amount of strongly basic centers. These results suggest that in the course of catalytic oxidation of H_2S weakly basic amino groups are alkylated with reactive fragments formed in reactions with available oxygen. This is confirmed by the fact that modification of Fe(II)–EDTA/anion exchanger catalyst with oxalate anion reduces the degradation of the anion exchanger and thus a smaller amount of strongly basic centers is formed.



For example, alkylation of the tertiary amino group can proceed according to the scheme given below.

(1) The reaction of $OH^{\bullet}$ radical with amine realized by degradation of the amino group, followed by formation of carbocation:

$$CH_3–NH–CH_3 + OH^{\bullet} \rightarrow {}^{\bullet}CH_2–NH–CH_3 + H_2O,$$

$${}^{\bullet}CH_2–NH–CH_3 + [Fe(III)–EDTA]^{-} \rightarrow {}^{\bullet}CH_2–NH–CH_3 + [Fe(II)–EDTA]^{2-}.$$

(2) Formation of tertiary ammonium compound:

CONCLUSIONS

(1) In the course of oxidation of hydrogen sulfide with molecular oxygen on the Fe(II)–ethylenediaminetetraacetate/anion exchanger catalytic system, the exchange capacity of the anion exchanger decreases, which is due to partial degradation of functional groups in the reaction with available oxygen.

(2) Fragments of organic amines formed by oxidative degradation of functional groups of the anion exchanger can alkylate weakly basic functional groups converting them into the strongly basic centers.

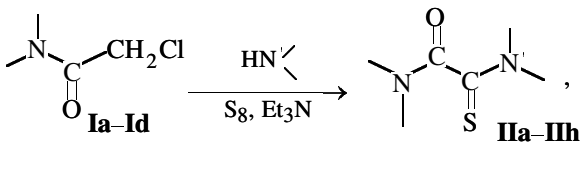
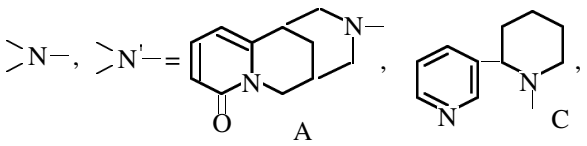
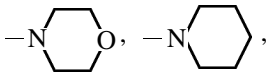
Received December 1, 2005



Abstract—Monothiooxamides were synthesized by the reaction of chloroacetamides with elemental sulfur and cyclic amines in the presence of triethylamine. The compounds were tested for fungicidal and aphicidal activity.



DOI: 10.1134/S1070427206030384



It is known [1] that monothiooxamides contain closely located amide and thioamide groups. Such a combination of the fragments in the structure of derivatives of natural alkaloids can occasionally impart unexpected properties and open new synthetic prospects.

Among the described methods [2, 3], the synthesis of monothiooxamides based on reactions of substituted amides (mainly chloroacetamides) with elemental sulfur and amines is the simplest and most convenient [4]. However, this method (with simultaneous mixing of the reactants) has disadvantages caused by prolonged heating of the reaction mixture; in the process, sulfur reacts with amines to form a complex mixture of products. This substantially complicates preparation and isolation of monothiooxamides.

In order to prepare new potentially bioactive compounds, we synthesized monothiooxamides **IIa**–**IIh** by the reaction of chloroacetamides **Ia**–**Id** with elemental sulfur and amines (cytisine and anabasine) in the presence of triethylamine in dimethylformamide at room temperature (20°C).

where =N– = A (**Ia, IIa, IIe**); C (**Ib, IIb, IIf, IIg**); M (**Ic, IIc**); P (**Id, IId, IIh**); =N'– = A (**IIe**); C (**IIf**); M (**IIa**–**IId**); P (**IIg, IIh**).

A systematic study of S-functionalization of chloroacetamides **Ia**–**Id** showed that the order of mixing the reactants substantially affects the product yields. For instance, preparation of a solution of elemental sulfur in amine beforehand increases the yield of monothiooxamides **IIa**–**IIh** to 64.61%. This is due to the fact that, under the action of amine, eight-membered cyclic molecule of sulfur is cleaved, and polysulfide anions are accumulated in the solution. They substantially facilitate thiolation of the methylene fragment of chloroacetamides **Ia**–**Id**, while in the case of simultaneous introduction of reactants the probability of side reaction of amine alkylation with chloroacetamides **Ia**–**Id** substantially increases.

The physiological properties of the new derivatives synthesized can be of interest. Compounds **IIa**–**IIh** are soluble in many organic solvents.

The structures of compounds **IIa**–**IIh** were determined by IR and ^{1}H NMR spectroscopy, and the composition, by elemental analysis. The IR spectra contain a strong band at 1640 cm^{-1} caused by stretching vibrations of the C=O group and a broad band at 1160 cm^{-1} caused by stretching vibrations of the C=S group.

In the ^{1}H NMR spectra of compounds **IIa**–**IIh**,

* Eluent is EtOAc : hexane = 1 : 1.

the chemical shifts of proton signals of the amine (alkaloid) core have typical values [5].

The physicochemical constants and elemental analyses of compounds **IIa**–**IIh** are listed in the table.

Compounds **IIa**–**IIh** were tested for the fungicidal and aphicidal activity. The fungicidal activity was estimated as the intensity of propagation of microorganisms on a cultural medium in comparison with a control (without introduction of compounds studied). We found that 1,2-dianabasinoethan-1-one-2-thione **IIf** *in vitro* has pronounced fungicidal activity with respect to phytopathogenic fungus *Botrytis cinerea* (64–68% suppression).

The aphicidal activity of compounds **IIa**–**IIh** was estimated in laboratory experiments on cucurbit and peach aphids in comparison with Aktellik reference preparation. Laboratory-vegetation experiments showed that 1-anabasino-2-morpholinoethan-1-one-2-thione **IIb** has pronounced aphicidal activity (77.3% suppression for cucurbit aphids at a substance concentration of 0.01%).

The results obtained were confirmed by protocols of biological tests, and compounds **IIf** and **IIb** were recommended for further detailed studies of their applicability in agriculture as pesticides.

EXPERIMENTAL

The IR spectra were recorded on an Avatar-320 spectrometer in KBr pellets, and ^{1}H NMR spectra, on a Tesla BS-587 spectrometer with an operating frequency of 80 MHz in DMSO-d_6 relative to HMDS. The melting points were determined on a Boetius heating stage. The reaction progress and purity of the products were monitored by TLC on Silufol UV-254 plates with EtOAc–hexane, 1 : 1 (by volume) eluent. Chloroacetamides were synthesized by the method described in [6].

Monothiooxamides IIa–IIh. A solution of appropriate amine (0.005 mol) and sulfur (0.16 g, 0.005 mol) in the presence of triethylamine (0.7 g, 0.005 mol) in 10 ml of DMF was added to chloroacetamide **Ia**–**Id** (1.01 g, 0.005 mol). The reaction mixture was stirred at 20°C for 30 min, and then 25 ml of water was added and the precipitate that formed was filtered off. The product was dissolved in acetone (10 ml), and the solution was filtered. After acetone removal, the substance was recrystallized from 95% EtOH.

CONCLUSIONS

(1) Monothiooxamides derived from some alkaloids and their analogs were prepared by S-functionalization of chloroacetamides.

(2) The pronounced fungicidal and aphicidal activities of monothiooxamides containing anabasine and morpholine fragments were revealed.

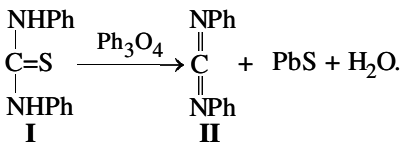
Received July 15, 2005; in final form, January 2006

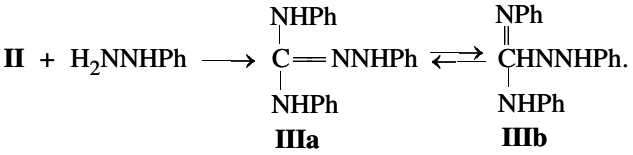
Abstract—1,4-Diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazolium hydroxide (Nitron) is prepared by the reaction of Pb_3O_4 with diphenylthiourea, followed by the reaction of the obtained diphenylcarbodiimide with phenylhydrazine to form triphenylaminoguanidine, whose heterocyclization yields 1,4-diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazole, which is subsequently oxidized.

DOI: 10.1134/S1070427206030396



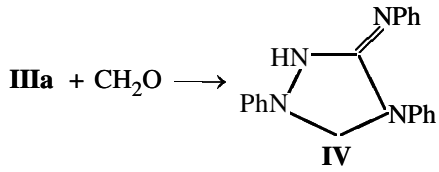
1,4-Diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazolium hydroxide (Nitron) is a well-known reagent for analysis of nitrate, perchlorate, tungstate, rhuthenate, and iodide anions [1], as well as silicon, germanium, arsenic, and phosphorus [2, 3]. Nitron was used for preparing lithium iodide power sources utilized in manufacture of electrocardiostimulators [4].

The published method of preparation of Nitron [5] allows its synthesis in a yield of ≤20% based on diphenylthiourea **I** because of incomplete conversion in the step of the reaction of phenylhydrazine with diphenylcarbodiimide and formation of a tautomer decreasing the yield and purity of the final product.

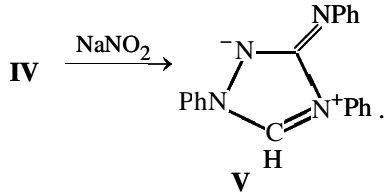


In this study we developed the conditions for synthesis of purer Nitron reagent in higher yields.

EXPERIMENTAL



The synthesis includes four steps. First, thiourea is desulfurized with Pb_3O_4 into *N,N*-diphenylcarbodiimide **II**:



Addition of phenylhydrazine to diimide **II** at 29–31°C yields the desired triphenylaminoguanidine tautomer **IIIa** in 80% yield, which is virtually free of impurity tautomer **IIIb** transforming under the reaction conditions into the ballast "pseudonitron":

Condensation of guanidine **IIIa** with formaldehyde in isopropanol at 55–60°C yields 1,4-diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazole **IV** in 87–89% yield:

This is followed by oxidation of triazole **IV** into Nitron by the reaction with sodium nitrite; the final product is isolated by reprecipitation from a mixture of acetic acid and 25% ammonia solution:

The resulting Nitron **V** is 98 wt % pure, which corresponds to the analytically pure grade.

The yield of Nitron based on diphenylthiourea was 43%, which is virtually 2 times that reported in [5].

The IR spectra were recorded on an FSM-1201 Fourier spectrometer in Nujol, and the ^1H NMR spec-

tra, on a Varian FT 80A (80 MHz) spectrometer in $CDCl_3$ (with TMS as internal reference).

***N,N*-Diphenylcarbodiimide II.** Thiourea **I** (300 g) in 700 ml of benzene was refluxed with vigorous stirring until water ceased to liberate (Dean–Stark trap), and 300 g of Pb_3O_4 was added in portions. Desulfurization was regarded as complete when water ceased to liberate. The sludge was separated, and diphenylcarbodiimide **II** was taken to the next step without isolation.

Ttriphenylaminoguanidine IIIa. To the solution of diimide **II** (see above), cooled to 10°C, 136 ml of phenylhydrazine was added dropwise so that the temperature in the reaction mixture was about 30°C. Then 100 ml of benzene was distilled off at atmospheric pressure; 300 ml of isopropanol was added to the remaining solution, and the resulting mixture was kept at 0°C for 8–10 h. The crystalline reaction product was filtered off and dried in air; yield 350 g (88%), mp 156–158°C.

1,4-Diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazole IV. To 200 g of compound **IIIa**, 200 ml of 40% aqueous solution of formaldehyde and 1.0 l of isopropanol were added. The reaction mixture was heated at 55–60°C for 0.5 h and cooled to 22°C. The reaction product was filtered off, washed with 150 ml of isopropanol, and dried in air, which yielded 184 g (89%) of triazole **IV**; mp 126–128°C.

1,4-Diphenyl-3-phenylimino-1,2-dihydro-1,2,4-triazolium hydroxide V. To a solution of 240 g of triazole **IV** in 1 l of isopropanol, glacial acetic acid was added at 65–67°C until complete dissolution of crystalline substance **IV**, which required 200 ml of the acid. Then a solution of 88 g of sodium nitrite in 200 ml of water was added. The reaction was regarded as complete when the color of the solution changed from light green to red. The reaction mass was cooled to room temperature and poured into a 25% aqueous ammonia solution with ice. The resulting finely divided yellow precipitate of Nitron **V** was filtered off and reprecipitated from a mixture of glacial acetic acid and ammonia solution (1 : 3 by volume). The reaction product was dried in a vacuum oven at 50–60°C and a pressure of 0.2 kg cm^{-2}. The yield of Nitron reagent was 176 g (74%), mp 186–188°C (dec.). Published data: mp 189°C (dec.).

Found (%): C 76.89, H 5.20, N 18.01.
$C_{20}H_{16}N_4$.
Calculated (%): C 76.92, H 5.13, N 17.95.

IR spectrum (cm^{-1}): 3052 [$\nu(CH_{arom})$], 2924 [$\nu(CH)$], 572 [$\delta(CH_{arom})$]. ^1H NMR spectrum ($CDCl_3$), δ (ppm): 6.64–7.64 m (16H, Ph, CH).

CONCLUSION

Conditions were developed for synthesis of high-purity (98 wt %) Nitron reagent in the preparative yield of 43% with the use of Pb_3O_4 instead of lead oxide (PbO_2) and 2-propanol instead of ethanol.

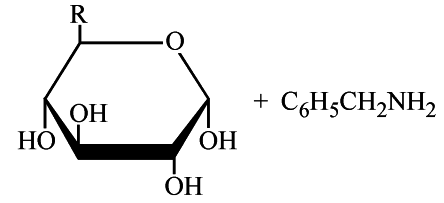
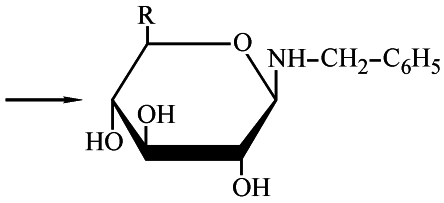
Abstract—*N*-Glycosylamines, triethylammonium salt of xylosyl- and glucosylbenzyldithiocarbamates, and their derivatives containing fragments of alkaloids were synthesized; some of these substances exhibit fungicidal activity.

DOI: 10.1134/S1070427206030402



Among numerous substances comprising the environment, carbohydrates and their derivatives occupy an extremely important place and have enormous significance in technology and everyday human activity. Carbohydrates in the form of various derivatives enter into the cell composition of any living body, playing the role of structural material, energy source, substrates, and regulators of specific and biochemical processes [1].

Modified derivatives of monosaccharides are of great scientific and practical interest, since many of these have pronounced biological activity with a wide spectrum of effect. A number of derivatives of monosaccharides find wide use in medicine, e.g., as effective anticancer and antiviral agents [2]. All this stimulates an interest in synthetic chemistry of modification of monosaccharides.



In recent years, *N*-glycosylamides (*N*-glycosides) find expanding application for synthesis of natural glycopeptides, their analogs, and glycoconjugates used in various biological studies. *N*-Glycosylamines are considered as potential pharmaceuticals, since introduction of carbohydrate group into a molecule not only increases the solubility but in some cases alters the biological effect as well [3].

We obtain a series of new carbohydrate-containing derivatives based on xylose and glucose for subsequent study of their reactivity and biological activity.

Condensation of *D*-xylose (**1**) and *D*-glucose (**2**) with benzylamine was performed in alcoholic solution under heating by the procedure described in [4]:

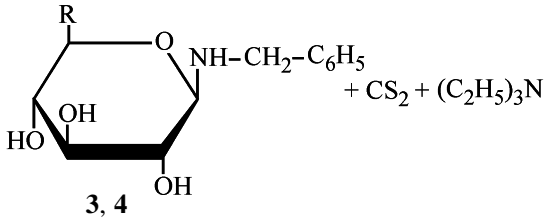
1, **2**

3, **4**

where R is H (**1, 3**), CH_2OH (**2, 4**).

The synthesized xyloxylbenzylamine (**3**) and glucosylbenzylamine (**4**) are hygroscopic white crystalline substances darkening in air. Depending on the synthesis conditions, *N*-glycosides can crystallize with 1 or 0.5 mol of water. When stored in a desiccator over P_2O_5, they become anhydrous.

The IR spectra of the compounds contain an absorption band at 891 ± 7 cm^{-1}, suggesting β-conformation at the anomeric center. Vibrations of the NH group appear in the range 2880–2920 cm^{-1}, and out-of-plane bending modes of the CH group of the aromatic ring, in the ranges 745–755 and 695–705 cm^{-1}. The IR spectra of **3** and **4** show that they contain no C=N bonds, i.e., they are not Schiff bases.



According to published data [5], the absorption in

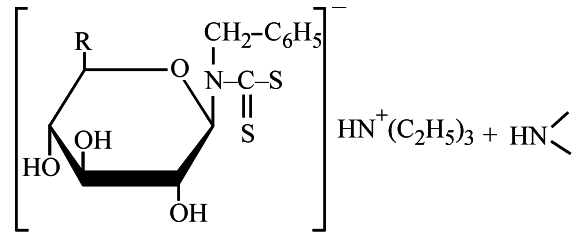
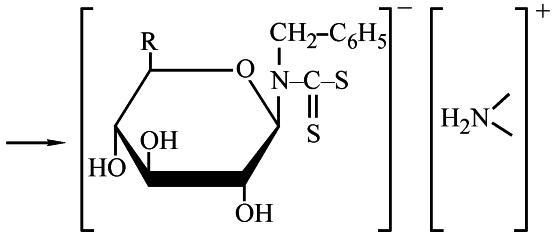
11	41.8	99–100	57.51	6.79	5.88	$C_{23}H_{32}N_2O_5S_2$	57.10	6.63	5.80
12	51.1	73–74	56.57	6.86	5.59	$C_{24}H_{34}N_2O_6S_2$	56.45	6.71	5.49

the range of 1120–1170 cm^{-1} is characteristic of cyclic forms of carbohydrates, since sugar alcohols having the open-chain structure do not absorb in this range, which is in good agreement with the data obtained.

The synthesized xylosylbenzylamine (**3**) and glucosylbenzylamine (**4**) are fairly reactive compounds. Triethylammonium salts of xylosyl- and glucosylbenzyldithiocarbamates (**5, 6**) were synthesized by the reaction of the corresponding *N*-glycosides with carbon disulfide in ethanol in the presence of triethylamine:

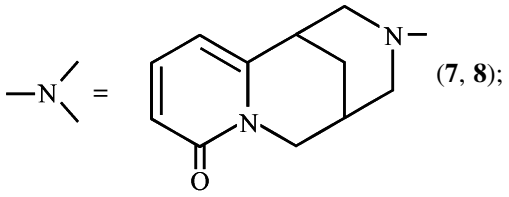


3, **4**

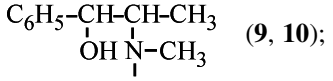


5, **6**

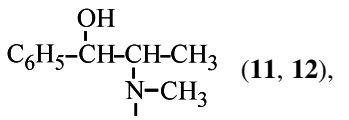
where R is H (**3, 5**), CH_2OH (**4, 6**).



The next stage is substitution of alkaloid fragment for triethylamine by the reaction of triethylammonium xylosyl- and glucosylbenzyldithiocarbamate with alkaloids cytisine, 1-ephedrine, and *d*-pseudoephedrine in alcohol:



5, **6**



7–**12**

(**7**, **8**);

(**9**, **10**);

(**11**, **12**),

where R is H (**5, 7, 9, 11**); CH_2OH (**6, 8, 10, 12**).

Compounds **7**–**12** are white powders readily soluble in water, ethanol, and DMF and insoluble in hydro-

carbons. The composition and structure of **7**–**12** were confirmed by elemental analysis and IR spectroscopy. The IR spectra of **7**–**12** contain no absorption bands at 844 ± 8 cm^{-1}, which suggests β-conformation of pyranose ring of the compounds synthesized. In the range 2900–2930 cm^{-1}, there are stretching vibration bands of the N–H bond; at 1640–1650 cm^{-1}, the >N–C=O bands; and at 1070–1100 cm^{-1}; the thiocarbonyl group (C=S) bands.

There are contradictory opinions on how the important structural feature of carbohydrates, the presence of pyranose or furanose ring, is manifested in the IR spectrum [6]. The presence of several peaks in the range 1010–1090 cm^{-1} suggests the pyranose form of the glycoside fragment.

The characteristics of **3**–**12** are listed in the table. The spectra of all the compounds studied are characterized by broad strong bands in the range 3250–3400 cm^{-1}, caused by stretching vibrations of OH groups.

Two synthesized compounds **7** and **8** were tested for fungicidal activity. Phytopathogenic fungi *Fusarium oxysporum* and *Botrytis cinerea* were used as test cultures. The fungicidal activity was estimated from the intensity of microorganism development in a nutrient medium in comparison with the reference tests without addition of the compounds studied.

We found that cytisine salts of xylosyl- and glucosylbenzyldithiocarbamates tested *in vitro* have pronounced fungicidal activity against phytopathogenic fungi *Fusarium oxysporum* (72–78 and 69–74% suppression of development, respectively).[1]

The results obtained were recorded in a statement of biological tests.

EXPERIMENTAL

The IR spectra were recorded on an Avatar-320 spectrometer in KBr pellets. Melting points were determined on a Boetius device. The reaction course and purity of the resulting compounds were monitored by thin-layer chromatography on Silufol UV-254 plates in the system isopropanol : ammonia : water = 7 : 2 : 1. The plates were developed with iodine vapor.

Xylosyl- and glucosylbenzylamine (3, 4). To a 0.05 M solution of benzylamine and 8 ml of alcohol, 0.05 M of anhydrous finely ground carbohydrate was added. The mixture was heated on a water bath at 60–65°C for 20 min, then 10 ml of alcohol was added, and the solution was left to crystallize in a refrigerator. In a few hours, the substance completely crystallized. The product was washed with anhydrous ethanol and then with ether and dried in a desiccator upon P_2O_5.

Triethylammonium xylosyl- and glucosylbenzyldithiocarbamates (5, 6). To a 0.01 M solution of xylosyl- or glucosylbenzylamine in 5 ml of ethanol, 0.01 M of triethylamine was added with stirring, after which 0.01 M of carbon sulfide in 10 ml of alcohol was slowly added with cooling (3–5°C), and the mixture was stirred for 60 min at room temperature. After slight cooling, a precipitate formed. The precipitate was washed with anhydrous ethanol and then with anhydrous ether and dried in a desiccator upon P_2O_5.

Cytisine xylosyl- and glucosylbenzyldithiocarbamates (7, 8). To a stirred 0.001 M solution of compound **5** or **6** in 3 ml of ethanol, a 0.001 M solution of cytosine in 5 ml of ethanol was added at room temperature, and the mixture was stirred for 60 min. Then the mixture was heated at 55–58°C for 3 h. The solvent was removed on a water bath. The oily product was triturated with petroleum ether. The resulting powder was washed with diethyl ether.

Compounds **9**–**12** were obtained similarly (see table).

CONCLUSIONS

(1) *N*-Glycosylamines based on xylose and glucose were synthesized.

(2) Triethylammonium xylosyl- and glucosylbenzyldithiocarbamates and their derivatives containing fragments of alkaloids cytisine, 1-ephedrine, and *d*-pseudoephedrine were synthesized.

(3) Cytisine xylosyl- and glucosylbenzyldithiocarbamates exhibit pronounced fungicidal activity.

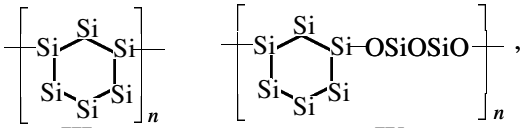
Abstract—Certain deformation–strength properties of vinyl-containing siloxane rubber cured with oligomeric and polymeric compounds containing silicon–silicon bonds and with dicumyl peroxide were studied.

DOI: 10.1134/S1070427206030414



Low mechanical properties are one of disadvantages of organosilicon rubbers exhibiting a wide temperature range of performance. The mechanical properties of organosilicon rubbers can be enchanced by introduction of various modifying additives and crosslinking with various reagents. In particular, dicumyl peroxide is often used to cure siloxane rubbers [1, 2], however, the presence of peroxide initiator or its remainder after vulcanization causes premature aging of the vulcanized composition and impairs its physicomechanical properties.

It was shown that oligoorganosilanes, oligoorganosilane–siloxanes, and polysilane–siloxanes are efficient vulcanizing agents of photolytic curing of siloxane rubbers [3–6]. As a continuation of these studies, we examined photolytic vulcanization of siloxane rubber with oligomeric and polymeric compounds with Si–Si bonds and certain physicomechanical properties of the cured rubber.

EXPERIMENTAL

Liquid siloxane rubber SKTV-0.2MED (synthetic medicinal rubber) containing 0.2% vinyl groups randomly distributed along the chain and terminal hydroxy groups was used to test compounds for the vulcanization power.

Dodecamethylcyclohexasilane $(Me_2Si)_6$ (**I**), low-molecular-weight polydimethylsilane $-(Me_2Si)_n-$ (**II**) (prepared by extraction of high-molecular-weight polydimethylsilane with benzene in a Soxhlet apparatus for 24 h), and two cyclolinear polymers, poly(cyclohexasilane) (**III**) and poly(cyclohexasilane–disiloxane) (**IV**) (methyl groups are not shown)

III **IV**

were used as photoinitiators.

Compounds **I** and **II** were prepared by known methods [7, 8]. Polymers **III** and **IV** were synthesized by a Wurtz-type reaction of 1,3-dichlorodecamethylcyclohexasilane with sodium metal and by its heterofunctional polycondensation with 1,3-dihydroxytetramethyldisiloxane, respectively [9]. Some properties of the polymers prepared are listed in Table 1.

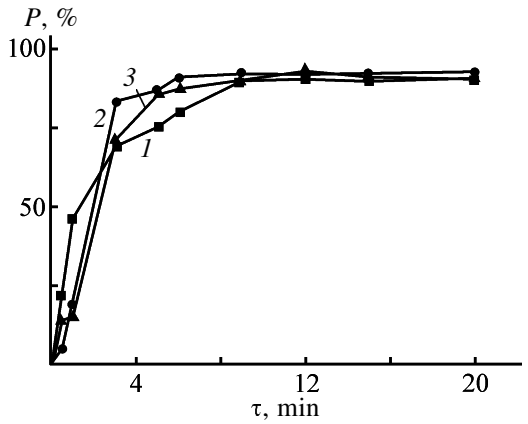
Films 0.5–0.7 mm thick were formed on aluminum foil supports from solutions in toluene and irradiated with light of a DRT-250 high-pressure mercury lamp arranged at a distance of 8 cm. The optimal time of vulcanization was determined from gel fraction content.

Static mechanical properties of the cured films were determined by standard methods on a Autograph AGS-10kNG (Shimadzu) device at room temperature; the sample length was 4 cm, and the extension rate, 4 cm min^{-1}.

Cyclosilane is well compatible with the rubber and forms transparent films. Under UV irradiation, the gel fraction content reaches 92% in 9 min and then changes insignificantly (see figure). Low-molecular-weight polysilane (**II**) gives turbid films, which is apparently caused by microphase segregation of the

Table 1. Yield and molecular-weight* and spectral (UV) characteristics of polymers** **III** and **IV**

Polymer	Yield, %	$M_w \times 10^{-3}$	$M_n \times 10^{-3}$	M_w/M_n	λ_{max}, nm
III	71.2	7.0	2.7	2.59	252, 313
IV	60.5	8.1	4.3	1.88	254



* From data of gel-permeation chromatography.
** 1 wt % of photoinitiator was added.

Table 2. Deformation–strength characteristics of films of cured rubber

Curing agent	Tensile strength, MPa	Modulus of elasticity, MPa	Relative elongation at break, %
I	0.17	0.25	167.0
II	0.20	0.28	168.0
III	0.28	0.37	185.4
IV	0.17	0.26	169.6
Dicumyl peroxide	0.12	0.01	1023.0

components because of their poor compatibility. However, after 3 min of irradiation, the film becomes more transparent, and the gel fraction content sharply increases from 19 to 83%. Polymer **III** gives with rubber very turbid films, which are partially clarified after 7 min of irradiation (the gel fraction content was not determined). Polymer **IV** containing siloxane units is well compatible with the rubber and gives transparent films which are rapidly cured under the action of UV light. Films prepared for studying the static mechanical properties of the compositions were irradiated for 12 min to reach the maximal gel fraction content in the samples with polymeric photoinitiators.

It was found that rubbers cured at room temperature under the action of UV light with oligomeric (**I**, **II**) and polymeric (**III**, **IV**) initiators have better deformation–strength properties as compared to the rubber cured for 6 h at 200°C with dicumyl peroxide (1 wt %) (Table 2). The rubber cured with polymer **III** had the best deformation–strength characteristics: the tensile strength was higher than that of the rubber cured with dicumyl peroxide by a factor of more than 2 and modulus of elasticity, by a factor of more than 35. This is probably caused by the fact that silane photoinitiators provide thicker cross-linking as compared to dicumyl peroxide, which is also confirmed by a decrease in the deformability of the cross-linked rubber when the peroxide is replaced by oligo- and polysilane photoinitiators.

Gel fraction content P in rubber cured with compounds (*1*) **I**, (*2*) **II**, and (*3*) **III** as a function of irradiation time τ.

CONCLUSION

Oligomeric and polymeric compounds with silicon–silicon bond are efficient photoinitiators of curing of vinyl-containing organosilicon rubber: they allow substantial increase in the rubber tensile strength and modulus of elasticity as compared to the rubber cured with dicumyl peroxide by a standard procedure.

The 10th European Conference on Fire Retardant Polymers

DOI: 10.1134/S1070427206030426

The 10th European Conference on Fire Retardant Polymers was held from September 7 to 9, 2005 at the Federal Institute for Materials Research and Testing (BAM) in Berlin, Germany.

The conference participants were 250 scientists from 100 research centers of 23 countries including Austria, Belgium, China, France, Germany, Hungary, Iran, Israel, Italy, Japan, the Netherlands, Norway, Poland, Russia, Spain, South Korea, Sweden, Switzerland, Taiwan, the United Kingdom, and the United States.

The Opening Ceremony included the speeches by Prof. M. Hennecke (President, BAM) and Prof. B. Schartel (Conference Chairman, BAM). In his speech Prof. Hennecke proclaimed the motto of the Federal Institute for Materials Research and Testing: "Safety and reliability in chemical and materials technologies." The participants welcome this motto.

The Conference Program included eleven plenary sessions. In Session I (Fundamental Aspects), Prof. M. Lewin gave an overview lecture "Fire Retardancy: Challenges of the Past, Present, and Future" and Prof. R.E. Lyon (the United States) told about the solid state thermochemistry of flaming combustion.

Sessions II and III were devoted to fire retardancy of polymers. In these sessions the participants considered such topics as intumescence of polymers in burning [S. Duquesne, S. Bourbigot, and R. Delobel (France)], fire retarding mechanisms of red phosphorus in polybutylene terephthalate [U. Braun and B. Schartel (Germany)], thermal stability and fire performance of polypropylene loaded with ammonium phosphate microencapsulated by polyurethane shell [S. Giraud, A. Castrovinci, I. Vroman, and G. Camino (Italy)], flame retardant polymers by preformulation [M. Doering, S. Seibold, U. Armold, et al. (Germany)], optimization of flammability and mechanical performances in flame retardant glass reinforced epoxy composites [B.K. Kandola, P. Myler, A.R. Horrocks, et al. (the United Kingdom)], flame retarded epoxy resin system for liquid composite moulding applications [R. Perez, J.K.W. Sandler, V. Alstadt, et al. (Germany)], thermal behavior of covalently bonded phosphorus flame retardant systems [D. Price, L.R. Cunliffe, K.J. Bulett-Pyrah, et al. (the United Kingdom)], and flame retardance of polyacrylonitriles covalently modified with phosphorus-containing groups [J.R. Ebdon, V.L. Crook, B.J. Hunt, et al. (the United Kingdom)].

Session IV (Industrial Application, Regulation and Standardizations) included four presentations. In the invited lecture M. M. Hirschler (the United States) reported on the experience in full scale fire testing of consumer products. The other lectures gave information on epoxy laminates flame retarded with phosphorus-based curing agent and inorganic fillers [S.V. Levchik, V. Buczek, S. Dashevsky (the United States)], new environmentally friendly phosphorus-based flame retardants [S. Horold, O. Schaker (Germany)], and the use of unique type amorphous silicon dioxide as an additive to improve fire retardancy of thermoplastic compounds (G. Schmauks, B. Friede, A. Soerhuus, and J.O. Roszinski).

Session V (Textiles) covered the topics concerning the challenge of replacing halogen flame retardants in textile applications [A.R. Horrocks, P.J. Davies, and B.K. Kandola (the United Kingdom)], optimization of the structure of a polyurethane/clay nanocomposite used as flame-retardant textile coating [M. Rochery, M. Taktak, S. Giraud, et al. (France)], recent advances in flame retardancy of textiles [S. Bourbigot, S. Duquesne, P. Flambard, et al. (France)], and flammability improvement of technical textiles by spunlacing process [X. Flambard, D. Saihi, M. Pochery, et al. (France)].

Session VI (New Materials and New Methods) included five lectures. In the invited lecture J. Gilman, J. Shields, R. Harrisyr, et al. (the United States) told about modern methods for flammability characterization. In other lectures such problems were discussed as evaluation of the effect of nanoclay and aluminium trihydrate in an intumescent formulation by means of a new cone calorimeter test methodology [A. Castrovinci, R. Lyon, R. Walters, et al. (Italy)], development of new halogen-free flame retardant engineering plastics by application of automated optical investigation methods [J.M. Endtner (Germany)]. New ap-

proaches for assessing the performance of intumescent coatings and new method for imparting efficient antidripping properties in flame retarded thermoplastics were considered in the reports presented by the scientists from Germany, Israel, and the Netherlands (M. Bartholmai, B. Shartel, Y. Bar Yaakov, et al.).

Sessions VII and IX concerned the topic "CO, Smoke, and Environmental Aspects." Four lectures were presented in Session VII: Bench-Scale Assessment of Fire Toxicity [T.R. Hull, K. Lebek, K.T. Paul, and D. Price (the United Kingdom)], Effect of Smoke Suppressants on Flammability of Unsaturated Polyester Resin Nanocomposites [S. Nazare, B.K. Kandola, and A.R. Horrocks (the United Kingdom)], Determination of Combustion Toxicity of Electric Cables as a Function of Equivalence Ratio [K. Lebek, T.R. Hull, and D. Price (the United Kingdom)], and Fire-LCA Model: Furniture Including Polyurethane and Textile as Case Study [L. Tange, D. Buszard, C. Blundell, et al. (the Netherlands)].

Five lectures were presented at Session IX, among them Regulations, Harmonization, and Standardization of Fire Testing in the EU—Overview and Trends (J.H. Troizsch), Relevance of SBI Test Results for Fire Safety of Building Constructions [E. Antonatus (Germany)], Modelling Fire Scenarios in Residential Buildings with Respect to the Benefit of Smoke Detectors and Flame Retardants [A. Hofman (Germany)], and IPN Foams with Improved Fire Behavior [A. Lorenzetti (Italy)].

Sessions VIII and X were devoted to nanocomposites. Particularly, Session VIII covered such topics as fire retardancy mechanisms in polymer nanocomposites [B. Schartel, M. Bartholmai, and U. Knoll (Germany)], thermal degradation and flammability of PMMA containing AlOOH submicron particles, Al_2O_3 nanoparticles, and modified montmorillonite [A. Laachachi, M. Cochez, M. Ferriol, et al. (France)], and kinetics of thermal degradation of polymeric nanocomposites [G.E. Zaikov, S.M. Lomakin, I.L. Dubnikova, et al. (Russia)].

Session X included five presentations. The greatest interest has been expressed by the participants in the results reported by Ch.A. Wilkie (the United States) in his invited lecture entitled Nanocomposite Formation as a Component of a Fire Retardant System and also in data on nanostructured flame retardants [G. Beyer (Belgium)]. Other presentations were devoted to comparison of the flame retardant mechanism of nanocomposites in thermoplastic and thermosetting matrices [A. Toldy, G. Marosi, P. Anna, and N. Toth (Hungary)], preparation and combustion properties of nanocomposites based on epoxy resins and organically modified clays [A. Hartwig and D. Putz (Germany)], and physical and flammability properties of polymer/silica and polymer/alumina nanocomposites [F. Yang, I. Bogdanova, and R. Yngard (the United States)].

The last four reports were presented at Session XI: The Emission of Selected Flame Retardants. A Possible Exposure Route [S. Kemmelein, O. Hahn, and O. Jann (Germany)], The EU Regulation: What is the Status for FR Regulation and How Does Industry Respond to It [D. Buszard (the United Kingdom)], Antimony Trioxide as Flame Retardant: Update on Risk Assessment [J.-P. Gaudel and K. Van de Velde (France, Belgium)], and Fire Retardancy of Composites Reinforced by Lignocellulosic Fibers [R. Kozlowski, M. Wladyka-Pizbylak (Poland)].

The Conference also included the Poster Session at which 38 posters were presented, devoted to various aspects of flame retardancy of polymeric materials.

The next XI Conference will be held at the Research Institute in Bolton (the United Kingdom). The organizers of this event are Prof. D. Price and Prof. C.R. Horrocks, world-famous persons in the area of combustion of polymers.

BOOK REVIEWS

Kazanbaev, L.A., Kozlov, P.A., Kubasov, V.L., and Travkin, V.F., *Indii. Tekhnologiya polucheniya* (Indium: Manufacture Technology)

Moscow: Ruda i Metally, 2004, 168 pp.

DOI: 10.1134/S1070427206030438

A comparatively close attention has been given to the properties, manufacture, and use of indium and its alloys by the domestic monographic literature. In 1987 was published the monograph by S.P. Yatsenko, *Indii. Svoistva i primenenie* (Indium: Properties and Use) (Moscow: Nauka, 1987, 257 pp.), in which particular attention was paid to indium alloys, their phase diagrams, and physicochemical and thermodynamic properties of the alloys in the solid and liquid states. The vast reference material contained in the monograph still remains important. Yatsenko's book luckily supplemented in those years the already available domestic monographs on coordination chemistry of indium compounds and the indium recovery technology.

Later was published the monograph by P.I. Fedorov and R.Kh. Akchurin *Indii* (Indium) (Moscow: Nauka, MAIK Nauka/Interperiodica, 2000, 276 pp.). This exhaustive monograph for the most part systematically describes the chemical properties of widely diverse classes of indium-containing compounds. A comparatively little attention was given in the book to technological issues. Even though the authors note that Russia occupies one of the leading positions in the world in manufacture of indium, the manufacture technology itself is not detailed.

The monograph by L.A. Kazanbaev and co-authors concentrates the whole attention on the technology of indium recovery from domestic raw materials and methods for refining of the metal. The book comprises three chapters, with bibliographic lists given separately for each chapter. Small Chapter 1 (pp. 5–19, 46 references) contains general evidence about indium and sources of indium-containing raw materials. The content of indium in the Earth's crust is estimated at 1.4×10^{-5} wt % (4×10^{-4} to 5.6×10^{-6}); minerals of indium itself are extremely rare and have no industrial importance. In processing of concentrated ores of nonferrous metals (lead, zinc, tin), indium is accumulated in various products and can be recovered from these products in a number of ways.

Chapter 2 (pp. 20–105, 125 references) is devoted to methods for recovery of indium from various indium-containing raw materials and to manufacture of raw indium. Particular attention is given to indium recovery from products formed in processing of zinc concentrates produced by Chelyabinsk zinc plant. Hydrometallurgical methods in manufacture of raw indium, extraction techniques for recovery of indium from indium-containing solutions, removal of impurities, and production of raw indium by cementation are discussed in most detail. Also discussed are methods for production of raw indium from wastes and industrially produced raw materials.

Chapter 3 (pp. 106–164, 77 references) presents a rather detailed description of methods for production of high-purity indium. As is known, the content of the main component in the raw metal commonly does not exceed 99.0 wt %. At the same time, radio electronics, manufacture of semiconducting compounds and special alloys, and some other fields of technology require indium with a total content of impurities of 10^{-2}–10^{-6}%. The authors consider the whole set of methods for purification of raw indium: chemical purification techniques, refining of indium by successive cementation, physical purification methods, electrolytic methods for production of high-purity indium, and vacuum-thermal distillation purification. In particular detail are discussed electrochemical techniques, including use of diaphragm electrolyzers with molten salt electrolytes. Special attention is given to description of an original method for production of high-purity indium powders.

The monograph by Kazanbaev and co-authors is of a clearly pronounced technological nature and significantly differs in this respect from the other two publications mentioned above. The book is primarily intended for technologists directly engaged in processing of indium-containing materials, production and refining of indium, and manufacture of indium powders. The monograph is based on the results of numerous studies by mostly Russian authors. The book is well published and contains a highly illustrative material.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Binding Formulations Based on Thermally Treated Serpentinite and Aqueous Salt Solutions

N. F. Fedorov, M. A. Andreev, and A. A. Khartukova

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received December 12, 2005

Abstract—Binding properties of thermally treated serpentinite combined with aqueous solutions of chlorides, sulfates, phosphates, and nitrates of a number of Group I–III elements were studied. The influence exerted by the nature of an anion and a salt-forming cation on the absolute value of the strength and its buildup was revealed.

DOI: 10.1134/S107042720604001X

Serpentinite has rather long been attracting researchers' attention as a basis for production of binders. More than half a century ago, Mchedlov-Petrosyan developed a binder named "serpentinite cement" [1, 2]. His work consists in that the starting serpentinite is subjected to thermal treatment at temperatures close to the dissociation temperature (~670°C) and then kept during a time in which the residual water content becomes less than 3 wt %. The product of thermal decomposition is ground to a fineness approximately corresponding to the milling fineness of portland cement and mixed with water. According to Mchedlov-Petrosyan's data [2], confirmed by Kaminskas [3], the serpentinite cement is a hydraulic binder that has a pronounced compressive strength (up to 20 MPa) and is distinguished by a $\sigma_{compr}/\delta_{bend}$ ratio markedly exceeding that of portland cement and other building binders. However, serpentinite has found no practical use, presumably because of the lack of calcinating apparatus with a highly strict control over the thermal treatment temperature.

More effective was combination of a very finely ground and thermally treated serpentinite and phosphoric acid [4], i.e., production of serpentinite phosphate cements.

In our opinion, the number of binders based on serpentinite can be considerably increased. This conclusion follows from [5, 6], where theoretical foundations of a purposeful search for new binders were presented. In accordance with the concept of [5, 6], we assume that the hardening effect will be observed for thermally activated serpentinite combined not only with phosphoric acid, but also with other acids, as well as with aqueous solutions of salts that can react with serpentinite by the oxide–salt scheme, if thermally treated serpentinite is regarded as a mixture of silicon and magnesium oxides, or by the salt–salt scheme, if it is considered to be a "methoserpentinite," i.e., a hypothetical magnesium salt of polysilicic acid. The aim of the present study was to verify this assumption.

EXPERIMENTAL

As the starting material served serpentinite[1] of the following chemical composition (wt %) (as determined by atomic-absorption spectroscopy):

Si	Mg	Fe	Al	Cr	Ni	Mn	Ti	Ca	Na
23.00	25.00	5.70	0.41	0.06	0.17	0.07	0.03	0.11	0.02

A crystal-optical analysis revealed that the mineralogical composition of the rock used includes antigorite, a minor amount of chrysotile, and chromite, brucite, and garnet as impurity phases. The starting serpentinite was thermally treated in a muffle furnace at 750°C to complete dehydration, which was reached in 2 h. The product formed in thermal treatment of serpentinite was ground in a grinder to a milling fineness satisfying the requirements of GOST (State Standard) to portland cement.

* Strength of a sample stored in water.

The binding properties of the formulations composed of a thermally treated serpentinite and a salt were studied by the method of "small" samples. As additives served aqueous solutions of salts (50 wt %) of a number alkali, alkaline-earth, and rare-earth elements at a 1 : s ratio of 0.3. Samples prepared from a paste were stored in air, and those for which preliminary tests revealed stability in water were placed in water after three days of hardening in air and, in 28 days, were tested together with the samples stored in air. The results of the tests are listed in the table.

Analysis of the data obtained shows that, as expected, thermally treated serpentinite is a good basis for preparing binding substances with acid–base type of interaction.

Binding properties were observed in all of the formulations studied. Here, it should be noted that the absolute value of the strength and the type of its buildup are strongly affected by the nature of both the cation and the anion. Among the salt types used (chlorides, sulfates, nitrates, phosphates), the highest strength is observed for phosphate formulations, a somewhat lower strength, for nitrate formulations, and still lower, for sulfate and chloride ones. The following tendency is observed within the same family of formulations: the strength of binding formulations obtained with salts of bivalent metals exceeds that with salts of alkali metals. This tendency is the most clearly pronounced for nitrate cements. Among these cements, those obtained using nitrates of rare-earth metals as additives are distinguished by the following: they have a rather high strength and gain strength in hardening in water. This feature of the binding formulations under consideration seems to be rather remarkable: it opens up a new, previously unknown way to production of hydraulic binders. It should be emphasized that the capacity for hydraulic hardening is observed not only for formulations prepared with nitrates of rare-earth elements as additives, but also for all other nitrate formulations.

In the case when salts of phosphoric acid are used as additives, it is noteworthy that the strength properties are strongly affected not only by the nature of a salt-forming cation (potassium salts provide better strength characteristics than sodium salts), but also by the degree of substitution of hydrogen ions in phosphoric acid. The best results are achieved with sodium and potassium dihydrophosphates mixed with serpentinite.

As is known from the chemistry of binders, the reason for manifestation of binding properties is a chemical interaction, under specific conditions, of compounds constituting, e.g., portland cement or alumina cement, with water. This reaction yields new formations, a hydrated phase [5]. In the binding formulations considered in this study, the binding properties also result from a chemical interaction between thermally treated serpentinite and salts used as additives.

The validity of this statement is confirmed by the results of thermographic and X-ray phase analyses. Figure 1 shows thermograms of europium and calcium nitrates and of cements produced using these salts as additives. It can be seen from Fig. 1 that endothermic effects characteristic of the starting nitrates are totally absent in thermograms of hardened samples. These thermograms show only a single low-temperature endothermic effect characteristic of adsorption-bound and zeolite-like water. The thermograms of hardened samples are virtually identical for dif-

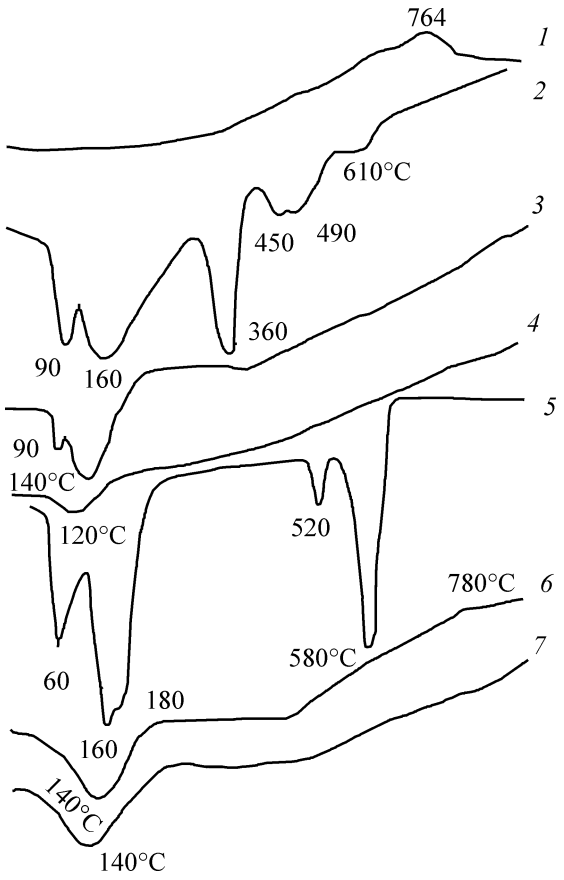

Fig. 1. Thermograms of thermally treated serpentinite, salt additives, and cement stone. Fig. 2. X-ray diffraction patterns of thermally treated serpentinite, salt additives, and cement stone. Interplanar spacings are indicated in Å.

ferent salt additives, which indicates that cementing phases of the same type are formed in hardening for the whole group of serpentinite–nitrate binding formulations.

The occurrence of a chemical interaction between the salt solution and thermally treated serpentinite is also confirmed by the results of an X-ray phase analysis. It can be seen from Fig. 2, in which X-ray diffraction patterns of the starting salt additives $Ca(NO_2)_2$ and $Eu(NO_3)_3$ and hardened samples are shown, that the starting salts completely disappear in the course of hardening: the main reflections of the salts are not seen in the X-ray diffraction patterns of cement stone, which only contain reflections belonging to thermally treated serpentinite: *d*/*n* 2.45, 2.50, 2.26, 2.74 Å, etc. No reflections indicating that new crystalline formations appear in hardening of nitrate binding formulations. This gives reason to believe that the products formed in hardening of these binding compositions are X-ray amorphous.

CONCLUSIONS

(1) All the formulations under study, composed of thermally treated serpentinite and aqueous solutions of chlorides, sulfates, nitrates, and phosphates of uni-, bi-, and trivalent elements, exhibit binding properties.

(2) The strength properties of the formulations studied are determined by the nature of both the salt-forming cation and the anion. The strength is the highest for the phosphate formulations, somewhat lower for the nitrate binders, and the lowest for the chloride and sulfate binding formulations.

(3) Among the nitrate binding formulations, the strength is the higher, the larger the charge of the salt-forming cation. The highest strength is observed for the cement composed of thermally treated serpentinite and rare-earth nitrates. The presence of rare-earth elements with a large thermal-neutron capture cross-section in these cements makes them suitable for protection from hard radiation.

(4) Binding formulations based on thermally treated serpentinite and aqueous solutions of nitrates are hydraulic binders.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Portland Cement Hydration in the Presence of Sodium Hydrosilicates

A. S. Brykov, B. V. Danilov, and A. V. Larichkov

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received June 22, 2005; in final form, December 2005

Abstract—Specific features of hydration of a portland cement with addition of alkaline silicates and the ability of these additives to affect the concentration of hydroxide ions and Ca^{2+} ions in the liquid phase of the cement paste are considered.

DOI: 10.1134/S1070427206040021

The opinion that compounds of alkali metals (sodium and potassium) stimulate the hydration of the main phases of portland cement, at least in early stages of the process, has rather long been established in the literature devoted to cements [1, 2]. There is no common opinion on how their presence affects later stages of hydration, even though most of researchers tend to believe that alkalis adversely affect the final strength and durability of the stone (concrete). In all probability, the aforesaid also refers to alkaline compounds introduced into cement pastes as additives in the form of hydroxides, silicates, and other salts and to alkaline compounds present in the portland cement clinker itself (mostly in the form of sulfates).

Silicates of alkali metals (Na and K), introduced into pastes in the hydrated state, as aqueous solutions, and, more rarely, in the anhydrous state, are well known and find stable use as accelerators of setting and hardening of cement pastes and mortar mixtures [3–5].

The results of previous studies [6, 7] indicate that, depending on the molar ratio SiO_2/M_2O (where M is an alkali metal), alkaline additives introduced into cement pastes in the form of hydrated silicates (HS) differently affect the pH value of the liquid phase, hydration rate of clinker minerals, and morphology of the C–S–H gel formed as a result of hydration.

The aim of the present study was to explain the accelerating effect of HS of alkali metals (K, Na) in early stages of portland cement hydration, using the results of physicochemical studies of the liquid phase of portland cement pastes with addition of sodium silicates with a SiO_2/Na_2O molar ratio of 1 and 2.8.

EXPERIMENTAL

Portland cement of the CEM 1 52.5 NA brand (Aalborg Portland) was used in the study. It had the following mineralogical composition (wt %): C_3S 73, C_2S 16, C_3A 4.5, and C_4AF 1. The parameters of the sodium silicates used (HS1 and HS2) are listed in Table 1.

Table 1. Physicochemical parameters of powdered hydrated sodium silicates*

Parameter	HS1	HS2
SiO_2, wt %	28.5	58.6
Na_2O, wt %	28.7	21.4
Silica ratio	1.0	2.8
H_2O, wt %	42.8	20.0
Particle size, μm	<1600	<250
Dissolution time, min	<5	<5

* HS1, sodium metasilicate pentahydrate $Na_2O \cdot SiO_2 \cdot 5H_2O$ (Akzo PQ Silica Vof, the Netherlands); HS2, $Na_2O \cdot 2.8SiO_2 \cdot 3H_2O$ obtained by microwave dehydration of an aqueous solution of sodium silicate, modified with hydrogen peroxide [8]; white powders.

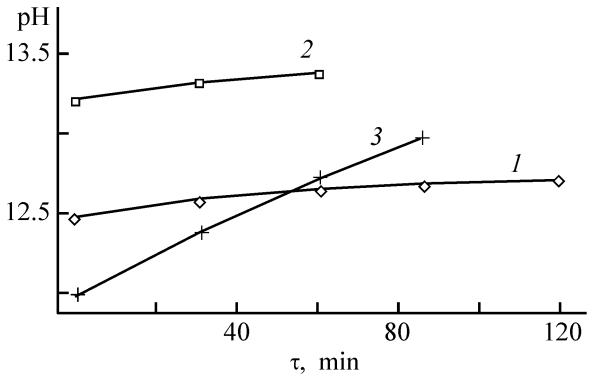

Fig. 1. pH values of pore solutions of cement pastes vs. time τ. Paste: (*1*) control, (*2*) with HS1 additive, and (*3*) with HS2.

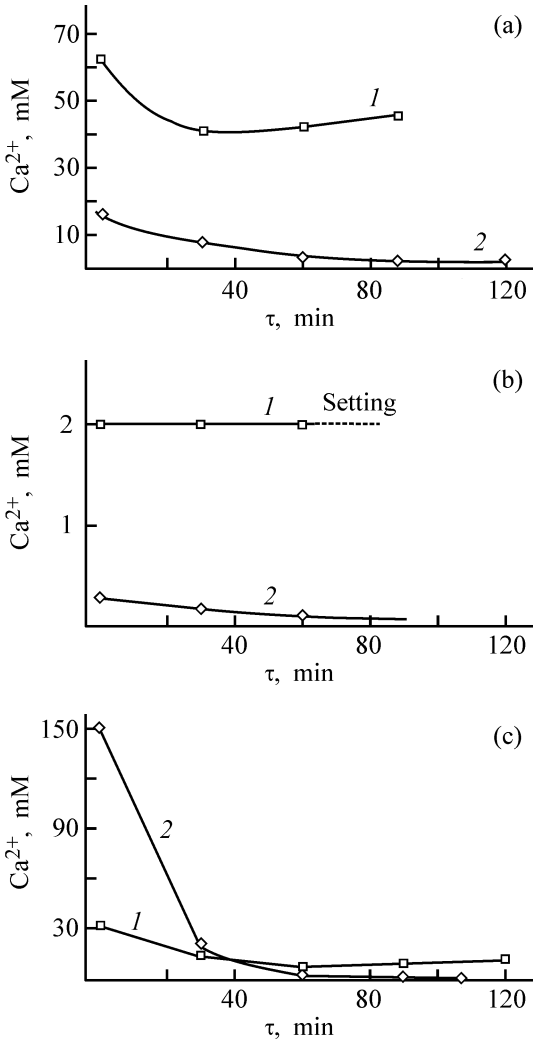

Fig. 2. (*1*) Experimental and (*2*) calculated (equilibrium) Ca^{2+} concentrations in the liquid phase vs. the time τ elapsed from the beginning of cement hydration. Paste: (a) control, (b) with HS1, and (c) with HS2.

To prepare a control (additive-free) paste, cement was mixed with water (w/c = 0.45); in 15 min the paste was sampled and the liquid phase of the sample was separated by centrifugation. Ca(II) was determined in the liquid phase by EDTA titration [9], with subsequent sampling 30, 60, and 90 min after the beginning of hydration.

The HS1 and HS2 additives were calculated in such a way that a constant amount of SiO_2 was introduced into pastes with the additives: 3% relative to the cement mass (which constituted 5 and 10% additives relative to the cement mass, respectively). When preparing the pastes, HS1 and HS2 powders were mixed directly with the cement. The w/c ratio was maintained constant (0.45) for all the formulations. In the case of metasilicate, the water of crystallization contained in its composition was taken into account. The sampling and analysis of the liquid phase were performed as described above.

The pH value of the liquid phase of the cement pastes was measured with a pH-673.M pH-meter.

The equilibrium concentration of Ca^{2+} (M) in a solution saturated with $Ca(OH)_2$ at a steady-state pH value of the paste was calculated using the relation

$$SP_{Ca(OH)_2} = [Ca^{2+}][OH^-]^2 f_{Ca^{2+}} f_{OH^-}^2, \qquad (1)$$

where $SP_{Ca(OH)_2} = 6.5 \times 10^{-6}$ at 20°C [10]; $a_{OH^-} = f_{OH^-}[OH^-] = 10^{-(14-pH)}$ M; and $f_{Ca^{2+}}$, activity coefficient of calcium ions, taken to be 0.44, 0.5, and 0.45 for the control paste and pastes with HS1 and HS2 additives, respectively [10].

The setting times of the pastes under study were determined using the procedure described in [11].

The influence exerted by alkaline silicate additives on the pH value of the liquid phase of the portland cement pastes under study (Fig. 1) is in agreement with the previously obtained results [7].

The calculated equilibrium concentrations of Ca^{2+}, which correspond to a solution saturated with $Ca(OH)_2$ at a steady-state pH value, are presented in Fig. 2. It can be seen from formula (1) and Fig. 2 that the calculated and experimental concentrations of Ca^{2+} are highly sensitive to changes in the pH value.

It should be noted that the highest concentrations of calcium(II) are attained during the first minutes of hydration, after which the content of calcium(II) rather rapidly decreases because of the formation of primary hydrates (Figs. 2a and 2c).

Table 2 lists data on the influence of hydrated sodium silicates on the setting time of cement pastes.

In the pure paste, an induction period begins immediately after a short stage of primary hydration. The duration of this period (up to 1.5–3 h) determines the onset time of setting. A pH value of 12.7 is attained in the system. With the induction period complete and transition to the stage of accelerated hydration, the cement paste loses its plasticity and, after a certain time, acquires initial strength.

An important factor affecting the induction period by supersaturation of the pore solution of the cement paste with calcium ions [with respect to $Ca(OH)_2$] [2, 12]. Immediately after addition of water to the cement, a high concentration of Ca^{2+} and OH^- ions is created in the paste. The supersaturation of the pore solution with calcium ions strongly hinders the dissolution of the clinker phases. In several hours, when the supersaturation reaches values severalfold exceeding the equilibrium concentration of $Ca(OH)_2$, first nuclei of $Ca(OH)_2$ appear. This initiates growth of the C–S–H gel, the supersaturation decreases, and the dissolution of cement particles resumes.

It is of interest, in determining how alkaline silicates affect the hydration of portland cement, to correlate the experimentally determined concentrations of calcium(II) in the pastes with the equilibrium concentrations of calcium(II), which correspond to saturation with $Ca(OH)_2$ at steady-state pH values (Fig. 2).

It can be seen in Fig. 2c that supersaturation is not created originally in a paste with addition of high-silica sodium hydrosilicate HS2: calcium ions that pass into solution are bound by silicate ions of the additive and $[Ca^{2+}]_{exp}$ is considerably lower than the saturation concentration at the corresponding pH value. Further, as the initial pH values of the pastes with addition of water-soluble silicates increase, the equilibrium concentration of Ca^{2+} decreases in accordance with formula (1) and, at a certain stage (at pH 12.5, i.e., approximately 45 min after the instant of mixing of cement with water), the liquid phase in the paste with HS2 will also be a saturated solution. In a pure paste, an induction period begins when the saturation is reached, whereas in a paste with addition of HS2, hydration continues, in all probability, even when the solution becomes supersaturated and the pH value stabilizes at values exceeding that of the pure paste.

While the paste with HS2 is far from supersaturation with Ca^{2+} ions [with respect to $Ca(OH)_2$], the clinker minerals contained in the paste are intensively hydrated and OH^- ions pass into solution to be consumed there for depolymerization and hydrolysis of silicate anions of the additive [6] and for an increase in the pH value of the liquid phase. During this period, hydrated calcium silicates are formed both via precipitation of silicate ions of the additive and via release of silicate and aluminate ions from the clinker. The basicity of the forming calcium silicates continuously varies with the pH value of the liquid phase.

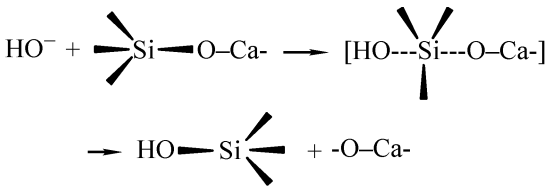

Table 2. Setting time of the cement paste in relation to the type of sodium hydrosilicate added

Sodium hydrosilicate	Setting time, min	
	beginning	end
Without HS (control paste)	95	200
HS1	15	60
HS2	10	45

At a high rate of interaction between hydroxide ions and silicate anions of the additive (e.g., in the case when the HS powder dissolves very rapidly), the period during which a paste has lower pH values than that of the pure paste may be short and virtually unnoticeable.

It is more difficult to understand the acceleration of hydration in a paste with a low-silica (highly alkaline) metasilicate HS1, when pH values exceeding those in an additive-free paste are reached. The concentration of calcium(II) virtually immediately becomes supersaturated [with respect to $Ca(OH)_2$], even though being considerably lower than that in the pure paste (Fig. 2b). The hydration in the pure paste is controlled by crystallization of $Ca(OH)_2$ until the supersaturation is attained. Therefore, it is reasonable to assume that, in the paste with HS1, the onset of intensive hydration is determined by the beginning of crystallization of $Ca(OH)_2$. In this system, the supersaturation of the liquid phase with Ca^{2+} ions [with respect to $Ca(OH)_2$] is so high already in the first minutes of hydration that first nuclei of $Ca(OH)_2$ appear immediately and hydration is initiated. This conclusion is in agreement at least with the known published data according to which additives that make higher the alkalinity of portland cement pastes, including low-silica sodium silicates, accelerate the setting [1, 2, 5], i.e., the concentration of OH^- ions determines the rate of the process. The data in Table 2 also confirm the aforesaid.

It is highly probable that the mechanism by which the main phase of the cement, alite, is hydrated in a strongly alkaline medium includes a primary reaction between the –Si–O–Ca– bond and the hydroxide ion by the type of an S_N2 nucleophilic substitution, with a transition state (bipyramid) formed and the silica tetrahedron inverted [13]:

The rate of this reaction is proportional to the concentration of hydroxide ions.

All the aforesaid is an attempt to explain from a common standpoint the influence exerted by silicates of alkali metals on portland cement pastes during the first hours after the beginning of hydration. Here, account should be taken of the fact that, in later stages, the hydration and fundamental aspects of hardening of pastes with addition of silicates of alkali metals depend on a large number of factors: basicity and morphology of the C–S–H gel being formed and stability of separate hydration products at steady-state pH values.

CONCLUSIONS

(1) The specific features of hydration of a portland cement with addition of silicates of alkali metals are determined in early stages of the process by the ability of these compounds to affect the concentration of hydroxide ions and Ca^{2+} ions in the liquid phase of the cement paste.

(2) Less basic (high-silica) sodium silicates eliminate the supersaturation of the liquid phase with Ca^{2+} [with respect to $Ca(OH)_2$] in the initial stage.

(3) In the presence of highly basic alkaline sodium silicates, the liquid phase becomes supersaturated with Ca^{2+} [with respect to $Ca(OH)_2$] virtually immediately after mixing the cement with water; as a result, hydration is accelerated in both cases, i.e., in the acid and alkaline (with respect to the pure paste) medium.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Interaction of Graphite with Hydroxide–Salt Melts

O. G. Zarubitskii, B. F. Dmitruk, and N. F. Zakharchenko

Received December 8, 2005

Abstract—The mechanism and kinetics of graphite dissolution in melts based on sodium hydroxide were studied. The effect of various salt additives on the intensity of the occurring reactions is considered. A method recommended for removal of graphite in the form of remainders of molds and mold cores from titanium casts is described.

DOI: 10.1134/S1070427206040033

The existing industrial methods for cleaning the surface of machine and equipment parts to remove operational contaminations are imperfect: they are, as a rule, low-intensive, fail to always provide a satisfactory quality of cleaning, involve manual labor, and cannot rule out health hazard and occurrence of dangerous situations, e.g., inflammation [1]. This, in particular, refers to cleaning of titanium alloy casts to remove remainders of graphite molds and mold rods. Commonly, graphite is removed from casts of this kind manually, with auxiliary cutting tools, with these tools frequently broken; this procedure fails to always provide the due quality of surface cleaning and may cause mechanical damage to articles so that they go to scrap.

The aim of this study was to develop a high-temperature procedure for cleaning the surface of titanium alloy casts to remove graphite rods.

There is no published evidence about systematic studies of the interaction between graphite and hydroxide–salt melts. There have only been reports describing the behavior of carbon electrodes and structural elements in electrochemical processes [2].

EXPERIMENTAL

A derivatographic study of processes occurring in binary C–NaOH, C–KOH, C–$NaNO_3$ systems and ternary mixtures C–NaOH–$NaNO_3$ was carried out. The molar ratio of the components was varied from 5 : 1 to 1 : 4 for the first two systems and from 2 : 1 to 15 : 1 for the third. The molar ratios for the ternary system were 5 : 1 : (0.7, 2.5), 1 : (2–4) : 2, 1 : 2 : 1, and 1 : 1 : 0.5. The measurements were performed on an OD-102 derivatograph at a heating rate of 5.1 deg min^{-1}. The weighed portions of the starting substances were in the range from 0.2 to 1.8 g.

An interaction between the components in mixtures of graphite and sodium and potassium hydroxides is observed even at low temperatures. For example, release of a certain amount of heat begins in the C–2NaOH mixture at approximately 160°C. The process is enhanced as the alkali melts. The quantitative characteristics of the effects observed strongly depend on the ratio of the components. It is noteworthy that oxidation of powdered graphite by atmospheric oxygen begins only at temperatures exceeding 400°C. The processes occurring in C–NaOH mixtures are accompanied by slight changes in the sample weight: the weight loss is due to moisture removal, and the weight gain upon melting of the alkali is associated with oxygen absorption. The thermal and gravimetric effects are considerably more pronounced for mixtures of graphite with potassium hydroxide.

In the C–$NaNO_3$ mixtures, the components interact at a temperature markedly exceeding the melting point of the nitrate. Depending on the component ratio, the beginning of a vigorous reaction is observed in derivatograms at 380–420°C. In mixtures with component ratios of 2 : 1 to 10 : 1, the interaction is markedly enhanced on reaching a temperature of 450°C. At large nitrate contents, the reaction proceeds in a moderate mode.

As follows from the experimental data obtained, the interaction of graphite with sodium and potassium hydroxides is considerably weaker than that in mix-

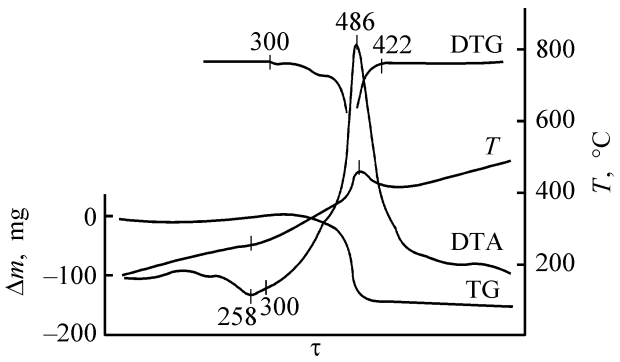

Fig. 1. Derivatogram of the $2NaOH–2NaNO_3$–C mixture. (Δm) Weight loss, (T) temperature, and (τ) time.

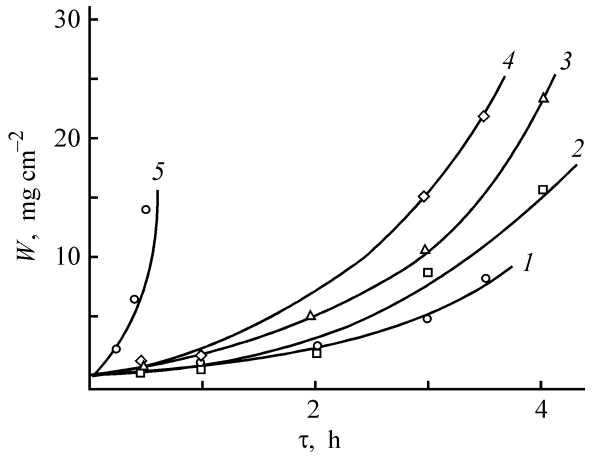

Fig. 2. Amount W of graphite etched away in melts of (*1*) $NaNO_2$, (*2*, *3*) NaOH, and (*4*, *5*) $NaNO_3$. Temperature (°C): (*1*, *2*, *4*) 450 and (*3*, *5*) 500. (τ) Time.

tures of graphite and sodium nitrate. Apparently, atmospheric oxygen is involved in reactions after the melting of the alkali:

$$C + 2MOH + O_2 = M_2CO_3 + H_2O. \quad (1)$$

In the C–NaOH–$NaNO_3$ mixtures, the components intensively interact with carbon at temperatures 80–100°C lower than those in the mixture with sodium nitrate (Fig. 1) and this interaction is accompanied by a considerable weight loss. The values of the weight loss, experimentally determined for the C–2NaOH–$2NaNO_3$ (initial weighed portion of the mixture 1.867 g), correspond to the occurrence of the reaction

$$C + 2NaOH + 2NaNO_3 = Na_2CO_3 + 2NaNO_2 + H_2O. \quad (2)$$

It is noteworthy that the rate of reaction (2) strongly depends on the component ratio. For example, its intensity in the C–4NaOH–$2NaNO_3$ mixture is considerably higher, which can be judged from the abrupt weight loss and a more pronounced rise in temperature.

In addition to carrying out a derivatographic study, the kinetics of graphite etching in molten sodium hydroxide, nitrate, and nitrite and NaOH–$NaNO_3$, NaOH–$NaNO_2$, and KOH–KNO_3 mixtures was examined. The method of isothermal gravimetry of a sample under free-convection conditions was used. Graphite samples (99.9% C) in the form of rods (6–8 cm^2) or plates (10–18 cm^2) were treated in melts at 450 and 500°C. The mass of the melt was 120–140 g. The samples were preliminarily polished to obtain the same surface quality in each case. After treatment in the melt, samples were cooled to room temperature, washed in boiling distilled water for 15–20 min, and calcined at 200°C. In determining the rate of graphite etching in molten NaOH–$NaNO_3$ and NaOH–$NaNO_2$ mixtures, the time of experiment was limited to 20 min and the average value was calculated.

The kinetic curves of graphite etching in the individual melts under study have a shape typical of autocatalytic processes (Fig. 2), which is caused by an increase in the reaction area with time. The kinetic dependences are described by a power equation whose constants are listed in Table 1.

The rate of graphite etching in molten NaOH–$NaNO_3$ and NaOH–$NaNO_2$ mixtures depends to a greater extent on the component ratio. The isotherms of etching rate in these mixtures pass through a maximum (Fig. 3) at a nitrate content of approximately 35% (500°C) and 45% (450°C) in the first system and a nitrite content of 20% at both temperatures in the second system. It is noteworthy that the data for the NaOH–$NaNO_3$ system are in agreement with the results of a derivatographic study of processes in the ternary mixture C–NaOH–$NaNO_3$ in relation to the ratio of the components of the hydroxide–salt phase.

A number of alkaline formulations used to process titanium alloys, namely, to remove scale, are known [3, 4]. However, preliminary experiments demonstrated that formulations of this kind are ineffective or at all unacceptable for removal of graphite present

Table 1. Constants of the power equation $d_0\tau^n$, g cm^{-2} h^{-1}

in the form of remainders of molds and mold rods from titanium casts. It was found experimentally that the intensity of graphite removal in such melts at temperatures lower than 500°C is insufficient, in particular, for long rods. At the same time, treatment at above 500°C may lead to inflammation of articles. For comparison, a melt patented in a number of countries was used [5–7]. The melt contained (wt %): 50–78 sodium hydroxide, 8–20 potassium hydroxide, 9–15 sodium nitrate, and 5–15 sodium chloride. The intensities of graphite (rod) removal and types of corrosion behavior of the titanium alloy were compared for a particular alloy containing the above components in close to the middles of the indicated ranges. The optimal parameters of the process of cast cleaning were found for the VT5 alloy.

The results obtained in the study served as a basis for suggesting a melt containing four components. The melt is based on sodium hydroxide and nitrate. Potassium chloride contained in the melt improves its technological properties and, in addition, serves to prevent inflammation and explosion of potassium nitrate; KCl was introduced in an amount of 4–10 wt %. Making its content higher is undesirable because of a pronounced decrease in the dissolution rate of graphite. New properties are imparted to the melt by sodium orthotitanate. This additive to the alkaline melt exerts the strongest inhibiting influence on the corrosion of titanium. Also, the thermal stability of titanium and its alloys substantially increases. The solubility of sodium orthotitanate in molten sodium hydroxide is limited. For example, it is somewhat higher than 6 wt % at 550°C. The advantage of this salt is that Na_4TiO_4 can be obtained from a titanium waste, and, provided that certain conditions are satisfied, this can be done directly in the alkaline melt.

Comparative experiments demonstrated that the composition containing sodium hydroxide, nitrate, and orthotitanate and potassium chloride has a higher (by a factor of 2.5–10) reactivity toward graphite, and no inflammation is observed at 550°C and a treatment duration providing complete removal of a rod.

The experiments performed suggested as the optimal melt for removal of graphite in the form of remainders of molds and mold rods from titanium casts the following formulations (wt %): sodium nitrate 40–55, potassium chloride 4–10, sodium orthonitrate, 2–6 and sodium hydroxide the rest.

Industrial tests of the technique suggested were carried out at a titanium casting shop of a machine-building plant in an industrial thermal furnace. The melt prepared in a rectangular steel bath had the following composition (wt %): sodium nitrate 48, potassium chloride 5.5, sodium orthotitanate 2.05, and sodium hydroxide the rest.

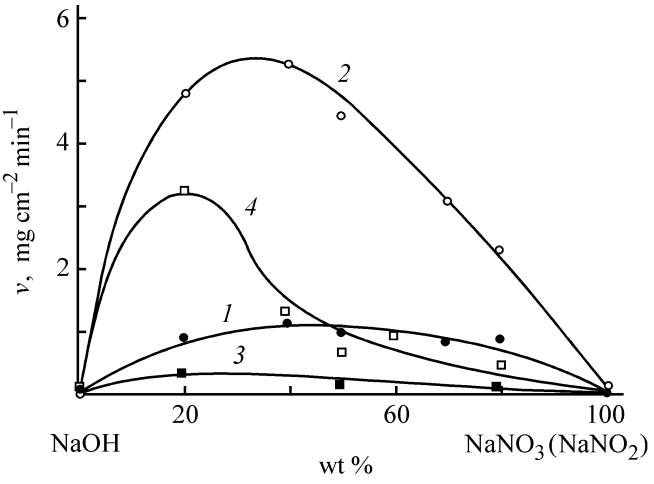

Fig. 3. Isotherms of etching rates v of graphite in molten (*1*, *2*) NaOH–$NaNO_3$ and (*3*, *4*) NaOH–$NaNO_2$. Temperature (°C): (*1*, *3*) 450 and (*2*, *4*) 500.

On melting the mixture and removing moisture at 400–500°C in the course of 1 h, the temperature was elevated to the working point. Casts of a VT5L alloy with remainder of molding sand and graphite rods of variously intricate shapes were cleaned. The removal of rods was periodically monitored in the course of processing. The results of the tests are listed in Table 2. A high rate of rod removal (8–10 mm h^{-1}) was achieved in the tests. A metallographic analysis demonstrated that the surface of the casts remains unchanged, with no corrosion etching occurring, and the mechanical properties of the alloy satisfy the standard requirements.

The advantage of the chemical method for removal of graphite from titanium alloy casts consists in that there is no need for manual labor, the output capacity significantly increases, cutting tools are saved, and the cleaning quality is improved.

CONCLUSIONS

(1) The mechanism and kinetics of graphite dissolution in hydroxide–salt melts and the effect of various salts ($NaNO_3$, $NaNO_2$, KCl, NaCl, Na_4TiO_4, KNO_3) were studied. As a result, an efficient method for removal of graphite in the form of remainder of molds and mold rods from titanium casts was suggested. The optimal melt composition is as follows (wt %): sodium nitrate 40–55, potassium chloride 4–10, sodium orthotitanate 2–6, and sodium hydroxide the rest. The working temperatures of the method are in the range 500–550°C.

(2) The new technique was successfully tested in industry. The tests demonstrated the advantages of the chemical method for removal of graphite from inner hollows of titanium alloy casts.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Glass Formation and Gelation in the System K_2O–SiO_2–H_2O

A. S. Brykov

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received October 24, 2005

Abstract—Systems produced in interaction of colloid SiO_2 particles with potassium hydroxide solutions form, as a result of aging, solid transparent gels and jellies. Depending on the pH value, the systems formed retain the colloid structure or take features of a homogeneous glassy body, with the glass formation possible within a rather large area in the K_2O–SiO_2–H_2O triangle, adjacent to the K_2O–SiO_2 line.

DOI: 10.1134/S1070427206040045

An opinion has strengthened in modern literature that glass formation processes can occur not only in anhydrous silicate systems M_2O–SiO_2 (M = Na, K, Li), but also in ternary systems M_2O–SiO_2–H_2O, with the content of water in these systems varying rather widely [1, 2]. At the same time, when speaking about glass formation, the authors, as a rule, restrict consideration to systems with a molar ratio SiO_2/M_2O (silica ratio) not exceeding 3–4, even though similar processes also occur under certain conditions in higher-silica aqueous silicates and in their solutions with a water content of up to 60–70 wt %. Many of these systems have applied importance as binders (formation of silicate masses, films, and gels).

In the M_2O–SiO_2 system, cooling of melts leads to glass formation at a SiO_2 content exceeding 60% (SiO_2/M_2O molar ratio exceeding 1.5–2) [3]. Aqueous alkaline silicates with a SiO_2/M_2O molar ratio of 2 to 4 (known as liquid glasses) can be obtained by direct dissolution of an alkali silica glass in water, with the subsequent dehydration of the resulting solution to any final content of water. The results of NMR and IR studies of these systems by spectroscopy and other methods underlie the modern concepts of water-containing silicates of alkali metals as systems with an exceedingly complex polymeric structure [4, 5]. At ordinary temperatures, the region in which aqueous sodium silicates with a SiO_2/M_2O molar ratio of about 3 are in a glassy state is limited from above by the water content of 30–40 wt % [2].

In our opinion, glass formation can occur within a rather large region in the ternary system M_2O–SiO_2–H_2O, adjacent to the M_2O–SiO_2 line.

Systems with any value of M_2O/SiO_2, including those exceeding 4–5, can be obtained upon interaction of highly active forms of silica, e.g., SiO_2 particles of colloid size, with solutions of alkalis or silicates of alkali metals (sodium, potassium, or lithium). The content of SiO_2 in the resulting solutions may be 30–50 wt % and more, and the solutions themselves may form, after a certain time, solid or solid-like transparent gels and jellies. Depending on the pH value, the systems being formed retain their colloid structure or acquire features of a homogeneous glassy body. It would be of use to make a general description of these systems and their position in the M_2O–SiO_2–H_2O triangle.

Here we consider systems obtained by mixing of colloid solutions of SiO_2 with potassium hydroxide at SiO_2/K_2O molar ratios in the range from 2 to 100. We restrict our consideration to the most widely occurring commercial stabilized silica sols with a SiO_2 content of 30–50 wt % and a particle size of 7–30 nm.

In contrast to NaOH and LiOH, potassium hydroxide is easily and rapidly assimilated by silica sols in any proportions, which markedly simplifies the preparation of the systems under study.

EXPERIMENTAL

We used in the study commercial monodisperse silica sols with various particles sizes, stabilized with NaOH (Table 1).

Dry KOH was introduced, in an amount necessary to obtain systems with SiO_2/K_2O molar ratios of 2

Table 1. Parameters of silica sols

Silica sol brand, manufacturer	Outward appearance of a silica sol	Particle diameter, nm	Content, wt %		pH
			SiO_2	Na_2O	
Sialit (Silikat ZAO, Russia)	Weakly opalescent	7	29	0.54	10.1
Ludox HS40, Grace Davison, USA	Opalescent	12	40	0.41	9.7
Ludox CL–X, Grace Davison, USA	Strongly opalescent	22	46	0.19	9.1
Levasil 100/45, Bayer, Germany	Milky	30	45	0.23	10.0

to 80–90, into SiO_2 sols under agitation. Accordingly, the K_2O/Na_2O molar ratio in the solution prepared is approximately in the range from 50 to 1 (the lower SiO_2/K_2O, the lesser the extent to which the effect of Na^+ on the properties of the system should be taken into account).

The solutions we prepared were degassed under vacuum for 5 min and stored in hermetically sealed glass ampules for 2–3 months. To accelerate the physicochemical processes occurring in the systems prepared, we stored them at 60°C.

IR spectra of the coagulation structures formed were measured in KBr pellets on a UR-20 spectrophotometer.

The pH values of the solutions prepared were measured with a pH-673M laboratory pH-meter.

Figure 1 show the results of a visual inspection of the state in which systems composed of silica sols and KOH are several months after being prepared.

The IR spectra of the systems under study (the most characteristic band of stretching vibrations of Si–O, peaked at 1000–1150 cm^{-1}) are shown in Fig. 2.

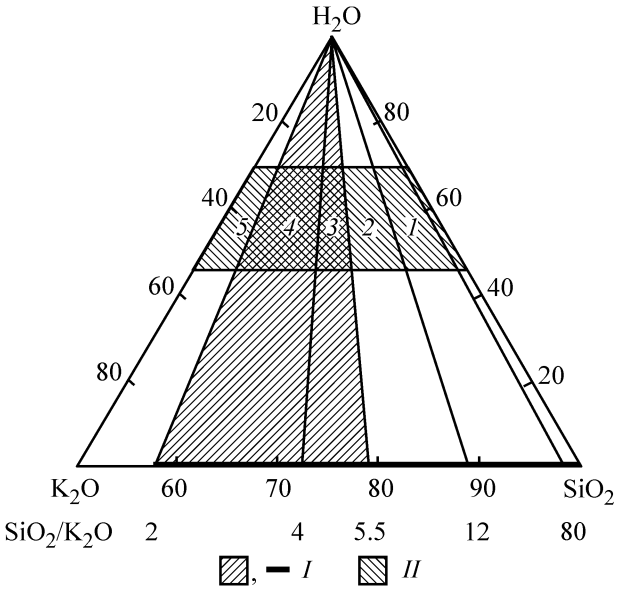

Fig. 1. Structures formed upon interaction of silica sols with KOH: (*1*) brittle gels constituted by SiO_2 colloid particles, (*2*) nontransparent coagulation structures, (*3*) glassy polysilicate jellies, (*4*) viscous liquids (liquid glasses), and (*5*) glassy hydrated silicates. (K_2O, SiO_2) Content (wt %). (*I*) Glass-forming regions in the K_2O–SiO_2 and K_2O–SiO_2–H_2O systems, respectively. (*II*) Range of compositions in the K_2O–SiO_2–H_2O system, produced upon interaction of commercial silica sols with KOH.

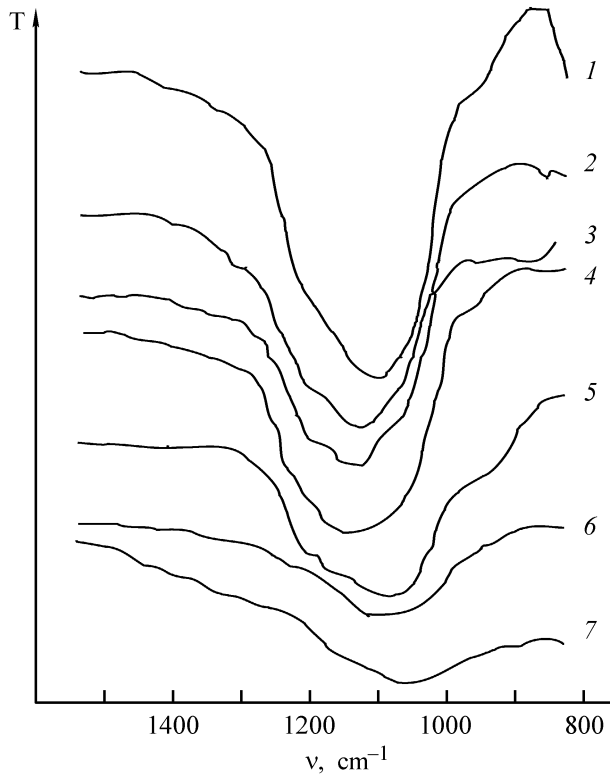

Fig. 2. IR spectra of (*1*) Sialit sol and (*2–7*) gels prepared from this sol. SiO_2/K_2O molar ratio: (*2*) 70, (*3*) 60, (*4*) 25, (*5*) 6, (*6*) 5, and (*7*) 4. (T) Transmission and (ν) wavenumber.

The pH values in these systems in the first day after the preparation (20°C) are listed in Table 2.

As can be seen in Fig. 1, the final states of the systems composed of concentrated silica sols and potassium hydroxide strongly vary with the SiO_2/K_2O ratio. Two regions correspond in this case to a stable state of solid transparent gels.

At small amounts of KOH, for which introduction of potassium hydroxide into a colloid solution of SiO_2 does not lead to an increase in the pH of the whole system to more than 12, brittle (crumbling) gel-like structures are formed. As shown by visual inspection, these structures preserve the optical density of the starting colloid solutions. Gels prepared from sols with particles less than 10 nm in size are transparent, whereas those with coarser particles are slightly turbid or "milky."

Depending on the molar ratio and temperature, the gelation time may be in the range from several hours to several days. The aging of systems of this kind is not accompanied by significant changes in IR absorption spectra (Fig. 2, systems with SiO_2/K_2O = 25, 60, 70) and changes in the pH value. A certain shift of the peak of the absorption band to larger wave numbers points to aggregation of particles and formation of chemical bonds between them.

Apparently, KOH mostly acts in the formation of gels of this type as an electrolyte additive that destabilizes the electrical double layer around silica particles. As a consequence, particles may be fixed with respect to one another at distances sufficient for manifestation of intermolecular attraction forces acting via liquid interlayers and for formation of chemical (siloxane) bonds. When silica sols are mixed with KOH, the system is destabilized and a gel is formed at SiO_2/K_2O molar ratios smaller than 70–90. The stability region of gels of this kind is bounded below by SiO_2/K_2O molar ratios of about 12–25. At a comparatively low content of KOH, conditions are created for slow coagulation, in which new colloid particles are easily attached at ends of chainlike fragments, i.e., at those places where the energy barrier associated with repulsion forces is the lowest. The sol turns into a gel at certain points of contact between particles via formation of an infinite network. Thus, the structure of gels of this type is formed by SiO_2 colloid particles, and, similarly to the starting colloid silica sols, the gels remain heterogeneous, two-phase systems. The same gels are formed upon introduction of electrolytes with pH ≤ 7 into silica sols. The most comprehensive notion of these structures was given by Iler in his monograph [6].

Table 2. Dynamics of variation of the pH value in systems with different SiO_2/K_2O molar ratios

SiO_2/K_2O molar ratio	pH value at indicated time elapsed from the instant of preparation, h		
	first minutes	1	24
5	14.0	12.7	~12.0
12	13.2	12.7	12.2
25	12.9	12.5	12.1
70	11.7	11.6	11.6

As a result of the subsequent processes of shrinking and strain buildup in the silica network, the gels become brittle. In the course of aging of such gels, especially in the case of aging accompanied by dehydration (drying), cracks are formed and split the gel into separate fragments.

Gels of a distinctly different type are formed in aging of systems formed by mixing colloid SiO_2 with potassium hydroxide at SiO_2/K_2O molar ratios ranging from 2–4 to 6. They show a conchoidal fracture characteristic of glasses and, depending on the water content and SiO_2/K_2O ratio, may be more or less hard ?and brittle and are somewhat softened upon moderate heating (up to 60°C). The strength and hardness of the gels formed is the higher, the larger the amount of SiO_2 they contain. In general, these systems have much in common with glasses as regards their physical properties.

High pH values (up to 14) are originally created in systems of this type; subsequently, the alkalinity decreases and stabilizes at pH 11.5–12. In a strongly alkaline aqueous medium (pH > 12), the dissolution of silica particles is accelerated, so that gels become transparent in the course of aging even when prepared from nontransparent or opalescent sols with coarse SiO_2 particles (of the Ludox HS_{40} type).

The IR spectra of these systems significantly differ from the spectra of the starting silica sols and, in the course of time, take the form characteristic of alkali silica systems containing no SiO_2 colloid particles (the high-intensity band of Si–O stretching vibrations at 1125–1150 cm^{-1} is replaced with a broad medium-intensity band peaked at 1050–1100 cm^{-1}).

In our opinion, the dissolution of sol particles is a key process in the formation of gels of the second type. In this case, gelation is a consequence of the formation of a homogeneous spatial structure from residues of silicic acid, which are formed in dissolution of SiO_2 colloid particles under high-alkalinity condi-

tions, are polymerized to a varied extent, and contain various amounts of water. These processes can be considered similar to those occurring in formation and vitrification of silicate melts. At the same time, it is pertinent here to draw analogy with jellification of solutions of some organic polymers, and, therefore, it would be more appropriate to regard gels of this type as jellies.

As is known, the ability of silica-containing melts to form glasses is accounted for by the presence in these melts of 3D silicon–oxygen polymeric structures, whose interaction leads to a considerable increase in the viscosity of the melts in cooling and to their solidification below the glass-transition point, with the disordered structure characteristic of liquids retained.

The of dissolution of compact SiO_2 particles in alkali solutions involves splitting of the siloxane bonds in accordance with the reaction equations

$$\text{Si–O–Si} + \text{OH}^- \rightarrow \text{SiOH} + \text{SiO}^-, \quad (1)$$

$$\text{H}_2\text{O} + \text{SiO}^- \rightarrow \text{Si–OH} + \text{OH}^- \quad (2)$$

and transfer of silica into the liquid phase in the form of ions of silicic acids with various degrees of polymerization. As can be seen from the reaction equations (1) and (2), the polymeric state of the silicon–oxygen structures in the solutions formed depends on the concentration of hydroxide ions and, consequently, on the concentration of the solution and on its silica ratio. The polymeric state of silica becomes more complex as the concentration of SiO_2 and the SiO_2/M_2O molar ratio increase. In higher-silica systems, silica passes into solution in the form of high-polymer ions and whole fragments, which mostly lose the dense amorphous structure of the initial colloid particles [7].

Similarly to glass, the forming polysilicate gel is homogeneous, i.e., is composed, after the dissolution of SiO_2 colloid particles is complete, of a single phase, gelatinized (with an exceedingly high viscosity) lyophilic solution of high-polymer water-containing silica fragments and ions of silica acids.

In an aqueous medium, the extent of destruction of the silicon–oxygen polymeric structure exceeds that in silicate glass-forming melts owing to the high activity of OH^- ions and their permanent regeneration as a result of hydrolysis by Eq. (2). The forming high-polymer ions of silicic acids and cations of alkali metals interact indirectly, via the hydrate sheaths and interlayers of water molecules. This leads to formation of glassy jellies whose state the better corresponds to that of a solid, the lower the content of water they contain. Thus, a high importance is assumed in glass formation in silicate solutions by the nature of the alkali metal cation and its ability to coordinate a certain number of water molecules. It is well known that aqueous solutions of polysilicates of lithium and quaternary ammonium bases exhibit a considerably higher stability against gelation, compared with sodium and potassium polysilicates, in a wide range of silica ratios. Anyway, the boundaries of different regions of state of the $M_2O–SiO_2–H_2O$ system may rather strongly depend on the type of cation.

As the silica ratio increases from 2 to 5–6, i.e., as the polymeric state of silica becomes more complex, the ability of a solution to form glassy structures grows. Systems with a ratio of about 5 readily transform into transparent jellies at a water content of up to 60–70 wt %, whereas systems with a ratio lower than 4, which have a simpler polymeric structure, retain at this concentration the state of a mobile or viscous liquid down to 0°C. Near this temperature the solution crystallizes. Apparently, the glass-formation point of these systems must lie at negative temperatures. At an ordinary temperature, such systems, prepared from commercial silica sols, are to be dehydrated to a water content of 30–40 wt % for transition to the glassy state [2]. Solid transparent glassy films with a SiO_2/K_2O molar ratio of 2 to 5 and water content of about 20 wt % were obtained by dehydration of the corresponding solutions and gels in a closed system over sodium hydroxide. Soluble powders of sodium and potassium silicates, which are glassy hydrates and have a silica ratio of 2 to 3.5 and H_2O content of 15–20 wt %, are industrially manufactured by drying of the corresponding aqueous solutions [1].

Thus, the following pattern is observed for systems with fixed water content and various silica ratios: the larger the silica ratio, the higher the glass-transition point. Raising the content of water at a fixed silica ratio leads to a decrease in the glass-transition point of the system. This pattern is in full agreement with the extent to which the polymeric composition of silicon–oxygen fragments is complex and to which the intermolecular interaction between these fragments in the systems formed is strong.

The jellies and gels formed are thermodynamically unstable nonequilibrium systems. At silica ratio of 3–12, we can only speak about the kinetic stability of these systems, which rapidly decreases as the SiO_2/K_2O molar ratio becomes higher than 5.

The compositions with a SiO_2/K_2O molar ratio of 6 to 11–12 originally form transparent solid gels, which rather rapidly coagulate (especially at elevated temperatures) to give dense nontransparent structures. In some cases, this process is accompanied by syneresis, shrinking of the gel with liberation of a liquid phase. The gels especially readily disintegrate under dehydration or in the presence of mechanical or chemical admixtures. In all probability, certain polymeric varieties of silica appear in this range of silicate ratio, which, in the course of formation, gradually combine into large dense agglomerates or coagulate on incompletely dissolved silica particle, with the result that the system loses transparence. The high alkalinity and, consequently, less complex polymer composition of low-silica aqueous silicates, are the reason for their high stability against coagulation. At silica ratio exceeding 12, i.e., in systems in which the dissolution of colloid particles is slow or virtually does not occur at all, the stability of gels against coagulation also increases.

The above-mentioned boundaries between the gelation regions are rather conventional: transitions from one structure to another are gradual and depend on the temperature and age of a system. The rate of silica dissolution becomes nonzero at pH > 10.7, and the higher the originally created pH values, the faster the dissolution rate of colloid particles [6]. Thus, the only thing to be discussed is what processes predominate in formation of a gel structure. In systems with pH not exceeding 11–11.5, the colloid structure of the solution may be retained for an indefinitely long time. By contrast, SiO_2 particles may dissolve in highly alkaline systems and homogeneous solutions may be formed rather rapidly, depending on the nature and size of colloid particles [7]. In accordance with this circumstance, the systems formed show a gradual transition from solid colloid gels and nontransparent coagulation structures to glassy jellies and viscous liquids.

CONCLUSIONS

(1) In interaction of colloid forms of SiO_2 with KOH solutions, the final state of the systems being formed is determined by whether these systems retain the colloid structure or become homogeneous. Accordingly, a large region in the K_2O–SiO_2–H_2O triangle is occupied by solid gels and glassy jellies.

At small amounts of KOH (an increase in the pH value of the whole system to no more than 12), the structure of gels is constituted by SiO_2 colloid particles and the gels remain heterogeneous, two-phase systems. KOH mostly destabilizes the electrical double layer that envelops silica particles. These particles are fixed with respect to one another by molecular attraction forces acting via liquid interlayers or because of the formation of chemical bonds.

(2) Glassy gels are formed in aging of systems formed by mixing colloid SiO_2 with hydroxides of alkali metals or their aqueous solutions at a SiO_2/K_2O molar ratio of 2 to 6 and initial pH values of about 14. The dissolution of colloid particles, accumulation of silica and silicic acids in forms differing in polymeric state and water content, and predominant involvement of these forms in the formation of the 3D structure distinguishes polysilicate gels from other types of silica hydrogels.

Abstract—Desulfation of lanthanide concentrates recovered from sulfuric acid solutions of phosphohemihydrate leaching as sulfates and double sulfates with sodium was studied.

DOI: 10.1134/S1070427206040057

Lanthanides are precipitated as sulfates [1] or double sulfates with sodium from solutions obtained by sulfuric acid leaching of phosphohemihydrate and containing 20–30 wt % H_2SO_4, 0.45–0.8 g l^{-1} CaO, and 1.7–3 g l^{-1} ΣLn_2O_3. The resulting concentrates mainly consist of lanthanide and calcium compounds and contain 30–35 wt % ΣLn_2O_3, 8–12.8 wt % CaO (mainly as $CaSO_4 \cdot 0.67H_2O$ according to X-ray phase analysis), and 55–59 wt % SO_4^{2-}. They also contain substantial amount of sodium (4.6–6.4 wt % Na_2O).

To separate lanthanides, preliminary elimination of sulfate ion is required.

In this study, we considered three approaches to separation of sulfate from such concentrates, involving their treatment with solutions of calcium nitrate, sodium carbonate, or sodium hydroxide.

EXPERIMENTAL

Before experiments on desulfation, the lanthanide concentrates were dried at 100°C. The concentrates were not washed to remove residual mother liquor and contained 8–10 wt % free H_2SO_4. A sample of lanthanide sulfate concentrate was treated with appropriate reagents for a definite time at room temperature and continuous stirring. The concentration of lanthanide sum in solutions and precipitates was determined by oxalate gravimetric method [2]. Concentrations of individual lanthanides were determined by atomic emission spectrometry with inductively coupled plasma on a Plasma 400 spectrometer (Perkin–Elmer). The sulfate ion content in solutions was determined gravimetrically by barium sulfate precipitation from solutions neutralized with HCl to pH 7.

We suggested occurrence of the following reactions between lanthanide sulfate and calcium nitrate:

$$Ln_2(SO_4)_3 + 3Ca(NO_3)_2 + 6H_2O = 2Ln(NO_3)_3 + 3CaSO_4 \cdot 2H_2O\downarrow, \quad (1)$$

$$H_2SO_4 + Ca(NO_3)_2 + 2H_2O = CaSO_4 \cdot 2H_2O\downarrow + 2HNO_3, \quad (2)$$

$$NaLn(SO_4)_2 \cdot H_2O + 2Ca(NO_3)_2 \cdot 4H_2O = Ln(NO_3)_3 + NaNO_3 + 2CaSO_4 \cdot 2H_2O\downarrow + 5H_2O. \quad (3)$$

The lanthanide sulfate concentrate was precipitated from leaching solutions with the initial concentration of sulfuric acid $c_{H_2SO_4}$ 22 wt %, by increasing $c_{H_2SO_4}$ to 42–44 wt % [1]. This concentrate was treated under continuous stirring at L : S = 10 with a $Ca(NO_3)_2$ solution, whose amount exceeded by 5% the stoichiometry of reactions (1) and (2). After definite time intervals, samples of the solution were taken, and the contents of lanthanides and calcium were determined. The conversion was estimated from the fraction of lanthanides transferred into the solution.

As seen from Table 1, desulfation of the concentrate proceeded readily: upon the treatment for 60 min, 91.7% of the lanthanides passed into the solution. Further increase in the time of treatment to 180 min did not noticeable change the degree of conversion. The resulting solution contained 41.4 g l^{-1} ΣLn_2O_3 and 9.4 g l^{-1} CaO.

Table 1. Concentrations of lanthanides $c_{\Sigma Ln_2O_3}$ and calcium c_{CaO} in the solution at various times of treatment of the lanthanide sulfate concentrate with a $Ca(NO_3)_2$ solution

Time, min	Concentration in solution, g l^{-1}		Recovery of ΣLn_2O_3 into solution, %	Time, min	Concentration in solution, g l^{-1}		Recovery of ΣLn_2O_3 into solution, %

50	41.0	9.5	91.1				

Table 2. Distribution of lanthanides between products of treatment of double lanthanide sulfate concentrate with calcium nitrate solutions

Product	Treatment time, h	$Ca(NO_3)_2$, % of stoichiometry	Recovery of ΣLn_2O_3, %	$c_{\Sigma Ln_2O_3}$ (liquid, g l^{-1}; solid, wt %)
Solution from stage:				
first	1	108.7	22.51	6.10
second	1	108.7	34.23	9.28
third	1	49.5	16.71	8.23
Wash water	–	–	15.75	4.26
$CaSO_4 \cdot xH_2O$	–	–	10.8	2.7
Total	3	267	100	

The elevated content of calcium in the solution containing lanthanides is caused by the higher solubility of calcium sulfate in the nitric acid solution [3] in comparison with its solubility in water and can be decreased by neutralization of free nitric acid formed by reaction (2).

The lanthanide loss is probably caused by isomorphous cocrystallization of double sodium lanthanide sulfates with calcium sulfate [4, 5]. The ΣLn_2O_3 content in $CaSO_4 \cdot 2H_2O$ amounts to no less than 6 wt %. Lanthanides were not leached by treatment of the gypsum formed with sulfuric acid.

To accumulate lanthanides in nitrate solution, we decreased the L : S ratio and used a fresh nitrate solution for conversion of the subsequent portions of lanthanide sulfate concentrate.

Solutions containing 106.5 g l^{-1} ΣLn_2O_3 and 13.9 g l^{-1} CaO were obtained at L : S = 4 in 1 h without decreasing recovery when additional amounts of $Ca(NO_3)_2$ and lanthanide sulfate concentrate were introduced into the solution with $c_{\Sigma Ln_2O_3}$ = 41.4 g l^{-1}. The amount of $Ca(NO_3)_2 \cdot 4H_2O$ added was 2.2–2.3 kg per kilogram of ΣLn_2O_3.

The data on desulfation of the concentrate containing double sodium lanthanide sulfates (55 wt % SO_4^{2-}) are listed in Table 2. The process included three stages. In each stage, after introduction of calcium nitrate solution, the pulp was mixed for 1 h, the solution was separated, and the concentrations of the lanthanide sum and of individual lanthanides were determined. Then, a solution of calcium nitrate was added to the solid phase, and the treatment was continued. The process was performed at V_l : S = 1 : (5–10) with solutions containing 4–5 wt % $Ca(NO_3)_2$. The consumption of $Ca(NO_3)_2$ calculated for reaction (3) was considered as stoichiometric.

As seen, lanthanides pass into the solution from the concentrate containing double sulfates substantially more slowly than from the concentrate prepared by the precipitation from the solution upon addition of sulfuric acid. Although the lanthanide recovery into the solution remained approximately the same (about

Table 3. Ratio of Ln_2O_3 and Ce_2O_3 concentrations in the initial lanthanide concentrate and in nitrate solutions obtained by treatment of the concentrate with calcium nitrate

90%), the required time increased from 1 to 3 h and specific consumption of $Ca(NO_3)_3 \cdot 4H_2O$ increased to 7.27 kg per kilogram of ΣLn_2O_3 (for the sulfate concentrate, 2.2–2.3 kg per kilogram of ΣLn_2O_3). As in the previous case, lanthanides did not pass into the solution after treatment of the calcium sulfate formed with sulfuric acid solution ($c_{H_2SO_4}$ = 26 wt %).

The lower lanthanide recovery in the first stage suggests that the conversion is diffusion-controlled.

On the whole, the slower desulfation of the concentrate based on double sulfates is obviously determined by substantially lower solubility of double sodium lanthanide sulfates as compared to the solubility of lanthanide sulfates.

Table 3 shows that individual lanthanides pass into the nitrate solution in the first two stages virtually in proportion to their content in ΣLn_2O_3. Small deviation in the third stage is of no practical interest for separation.

Thus, by desulfation of lanthanide concentrates with calcium nitrate solutions we can obtain solutions of lanthanide nitrates with fairly high concentration, but the lanthanide loss with calcium sulfate is as high as 10–11%. In addition, the resulting solution contains up to 23 g l^{-1} sulfate ion because of the substantial calcium sulfate solubility (9.4–13.8 g l^{-1} CaO). Thus, more efficient desulfation methods should be searched for.

In the further studies, we used concentrates based on double sulfates (hereinafter, lanthanide concentrates) as the form more convenient for recovery.

We studied the treatment of lanthanide sulfate concentrate with a sodium carbonate solution and further dissolution of the resulting carbonate product in nitric acid. We presumed the occurrence of the following reactions:

$$2NaLn(SO_4)_2 \cdot H_2O + 3Na_2CO_3 + (x - 2)H_2O = Ln_2(CO_3)_3 \cdot xH_2O\downarrow + 4Na_2SO_4,\ x = 5-8, \quad (4)$$

$$CaSO_4 \cdot 0.67H_2O + Na_2CO_3 + 4.33H_2O = CaCO_3 \cdot 5H_2O\downarrow + Na_2SO_4, \quad (5)$$

and

$$Ln_2(CO_3)_3 \cdot xH_2O + 6HNO_3 = 2Ln(NO_3)_3 + (3 + x)H_2O + 3CO_2, \quad (6)$$

$$CaCO_3 \cdot 5H_2O + 2HNO_3 = Ca(NO_3)_2 + 6H_2O + CO_2. \quad (7)$$

The lanthanide concentrate contained (wt %): ΣLn_2O_3 34.26, SO_4^{2-} 51.7, and CaO ~10. The main components of the concentrate were double sodium lanthanide sulfates and bassanite $CaSO_4 \cdot 0.67H_2O$. 57.4% of total SO_4^{2-} is bound with double sodium lanthanide sulfate, and 33.2%, with bassanite. About 10% of the sulfate is in the occluded sulfuric acid mother liquor.

The desulfation efficiency was estimated as the fraction of the sulfate transferred into the solution. The treatment with a sodium carbonate solution was performed under stirring. The initial content of Na_2CO_3 was 6 wt %; it was taken in 105% amount relative to the stoichiometry of reactions (4) and (5); L : S = 10. To study the efficiency and kinetics of desulfation, we took samples of solution every 30 min and determined in them the concentrations of sulfate and unchanged sodium carbonate (by titration). The results listed below showed that desulfation decelerated after 0.5 h and stopped after 3 h, in spite of low degree of desulfation (52.7%) reached. The solution and wash water contained no lanthanides:

Time, h	SO_4^{2-} passed into the solution, %	Time, h	SO_4^{2-} passed into the solution, %
0.5	40.7	2.5	51.1
1.0	42.1	3.0	52.7
1.5	47.9	3.5	52.7
2.0	49.4	4.0	52.7

After treatment with sodium carbonate, the solution was separated, and the residue was washed with water and repeatedly treated with a sodium carbonate solution for 1 h (L : S = 10, sodium carbonate consumption 160% relative to the stoichiometric amount corresponding to the residual SO_4^{2-} content). After these procedures, additional 21.7% of the initial SO_4^{2-} content in the concentrate passed into the solution. Because of high crystallization water content in calcium and lanthanide carbonates, the weight of the product obtained was somewhat larger than that of the initial concentrate.

After treatment of the carbonate–sulfate precipitate with 17.5 wt % HNO_3 taken in an amount of 167% relative to the stoichiometry of reactions (6) and (7), only about 44% of the lanthanides contained in the carbonate precipitate passed into the solution. The complete dissolution of the precipitate was attained only after its repeated treatment with nitric acid with addition of hydrogen peroxide.

The consumption per 1 kg of lanthanide sum was as follows: sodium carbonate 1.3 kg and 65 wt % HNO_3 6.7 kg. The sodium carbonate consumption is close to optimal, while the nitric acid consumption can be substantially lowered by using the counterflow mode and precipitating the main part of calcium from nitric acid solutions with sulfuric acid [2]. We can suggest that it will not be higher than 2 kg per kilogram of ΣLn_2O_3.

Lanthanides should not coprecipitate with the gypsum formed, since the nitric acid solutions are virtually sodium-free.

Thus, preliminary treatment of the concentrate with a sodium carbonate solution in combination with the subsequent leaching of the residue with nitric acid allows transfer of lanthanides into the nitric acid solution without losses. However, nitric acid is consumed for dissolution of not only lanthanides, but also calcium, which increases its consumption. The resulting nitric acid solution contains increased concentrations of sulfate ion and calcium.

We assumed that under the action of sodium hydroxide desulfation proceeds by the reactions

$$NaLn(SO_4)_2 \cdot H_2O + 3NaOH + (x - 1)H_2O = Ln(OH)_3 \cdot xH_2O\downarrow + 2Na_2SO_4, \quad (8)$$

$$CaSO_4 \cdot 0.67H_2O + 2NaOH = Ca(OH)_2\downarrow + Na_2SO_4 + 0.67H_2O. \quad (9)$$

In the experiments on desulfation with a sodium hydroxide solution, the chemical procedures were the same as in desulfation with sodium carbonate solutions. A small difference consisted in a somewhat higher content of SO_4^{2-} in the concentrate (59.5 wt %).

A solution containing 3.25 wt % NaOH was used. At L : S = 10, the NaOH excess over the stoichiometry was 30%. As seen from the data on the kinetics of sulfate transfer into the solution, with sodium hydroxide the desulfation proceeded noticeably faster and more completely than with sodium carbonate.

Time, h	SO_4^{2-} passed into the solution, %	Time, h	SO_4^{2-} passed into the solution, %
0.5	86.9	2.0	90.6
1.0	90.6	3.0	90.6
1.5	90.6	4.0	90.6

After the repeated 1-h treatment of the precipitate with NaOH solution, the residual content of SO_4^{2-} ions in the precipitate was 0.12 wt%. Thus, the degree of two-step desulfation of the lanthanide concentrate with an alkali solution was no less than 99.9% (it was taken into account that in this desulfation procedure the weight of the precipitate decreased almost by half). Incomplete desulfation at one-step treatment with a NaOH solution is caused by reversibility of Eqs. (8) and/or (9) or by a decrease in the chemical activity of sodium hydroxide because of partial conversion into sodium carbonate with atmosoheric carbon dioxide. Such a reaction can be noticeable because of small amount of the solution used in the experiment and long reaction time at vigorous stirring. The contribution of this process should decrease at enlargement of the apparatus and its sealing.

As in the case of desulfation with sodium carbonate, the solutions contained no lanthanides.

Calcium hydroxide can be selectively recovered with aqueous ammonium chloride from the lanthanide concentrate after desulfation [6]. To check this assumption, the precipitate that contained hydroxide and carbonate compounds of lanthanides and calcium was calcined at 900°C to decompose calcium carbonate formed in the reaction of the precipitate with atmospheric carbon dioxide. After treatment of the freshly calcined precipitate with an ammonium chloride solution at room temperature, calcium hydroxide formed completely passed into the solution. From this solution, calcium can be precipitated as carbonate with carbon dioxide [6].

In the process, lanthanides were completely concentrated in the precipitate which readily dissolved in the nitric acid. The selective leaching of calcium oxide with ammonium chloride from the concentrate containing 35 wt % Σ Ln_2O_3 and 10 wt % CaO allows a decrease in the nitric acid consumption by one third and preparation of solutions containing lanthanide nitrates only.

CONCLUSIONS

(1) Removal of sulfate ion from lanthanide concentrates precipitated from sulfuric acid leaching solutions in the form of sulfates and double sulfates with sodium by treatment of these concentrates with dilute solutions of calcium nitrate, sodium carbonate, or sodium hydroxide was studied.

(2) From sulfate concentrates treated with calcium nitrate solutions, lanthanides are leached into the solution faster than from concentrates consisting of double sodium lanthanide sulfates. However, about 10% of lanthanides are lost with the gypsum precipitate formed in the process.

(3) After treatment with sodium carbonate solutions, lanthanides completely pass to the carbonate precipitate, but the degree of desulfation is insufficient (less than 75%).

(4) Desulfation with sodium hydroxide solutions is preferred as compared to the other methods studied. This method ensures efficient separation of sulfate and preparation of the hydroxide concentrate readily soluble in nitric acid. This desulfation method allows separation of calcium from the concentrate and involves virtually no loss of lanthanides.

Abstract—Certain fundamental aspects of leaching-out of nickel with sulfuric acid solutions from spent catalysts for steam conversion of methane under static and dynamic conditions were studied.

DOI: 10.1134/S1070427206040069

At present, a considerable attention is given to the problem of utilization and processing of solid wastes containing nonferrous metals. Wastes of this kind are toxic substances hazardous to the environment, on the one hand, and a valuable chemical raw material, on the other.

A widely occurring type of solid wastes from petrochemical and oil refining industries are spent catalysts, including nickel–alumina catalysts for steam conversion of methane. In the course of operation, the catalysts lose activity as a result of changes in their composition and structure. At high temperatures (600–700°C), the catalyst undergoes sintering and its active surface area decreases.[1] In the course of time, a considerable fraction of nickel cations diffuses from the catalyst surface deep inside alumina, active nickel oxide is converted on alumina into inactive nickel aluminate, and spinel-like compounds, inactive in catalysis, are formed [1, 2].

In some cases, deactivated catalysts are regenerated, but this cannot be done for a large number of catalysts. They are removed from the process and reprocessed.

Commonly, two methods are suggested for recovery of nickel from ores and raw materials of technological origin: pyrometallurgical technique, whose main product is ferronickel obtained at high temperatures, and hydrometallurgical, based on leaching-out of nickel from raw materials with various acids and solutions of ammonia and ammonium salts.

The use of ammonia for leaching-out of nickel relies on the fact that nickel hydroxides readily react with ammonia to give stable complexes of various compositions. This circumstance serves as a basis for recovery of nickel from oxidized ores [3], spent catalysts [4], and worked-out electrodes of nickel–iron batteries [5, 6]:

$$Ni(OH)_2 + 6NH_3 \rightarrow [Ni(NH_3)_6](OH)_2.$$

It was found that addition of ammonium salts to aqueous solutions improves the efficiency of dissolution via the buffer action precluding accumulation of OH^- ions:

$$Ni(OH)_2 + 4NH_3 + 2NH_4Cl \rightarrow [Ni(NH_3)_6]Cl_2 + 2H_2O.$$

It has been suggested to leach-out nickel from oxide raw materials with solutions of $(NH_4)_2SO_4$ and $(NH_4)_2CO_3$ and with mixtures of these at pH 6–8 [7]:

$$NiO + (NH_4)_2SO_4 + 4NH_4OH \rightarrow [Ni(NH_3)_6]SO_4 + 5H_2O.$$

Leaching-out of nickel from ores and raw materials of technological origin with solutions of mineral acids was suggested in [8–12].

However, the leaching methods described in the literature have certain disadvantages. For example, the

[1] The temperature of steam conversion of methane is 800°C.

leaching solutions used are not always harmless: ammonia, which is the most frequently used to leach-out nickel, is a toxic gas. The leaching techniques suggested by certain authors [8, 13] meet technological difficulties. Autoclave leaching requires expensive special apparatus. Use of acid solutions with pH < 1 for leaching-out of nickel complicates the process of selective recovery of nickel from a solid matrix.

Nevertheless, the hydrometallurgical method for nickel recovery, compared with the pyrometallurgical technique, is the most promising because it conforms to the principle of combination of environmental and economical interests (markedly diminishes the number of technological procedures, does not require fuel expenditure for high-temperature processes, minimizes the amount of solid wastes and toxic discharges into the atmosphere). One more advantage of the given technique is that it can recover from leaching solutions, at an appropriate choice of methods used, both metallic nickel (electrolytically) and its salts.

An analysis of published data demonstrated that, despite the wide variety of methods for leaching-out of nickel from raw materials of technological origin, including spent catalysts, the fundamental aspects of nickel recovery by the hydrometallurgical technique are far from being fully understood.

The difficulty encountered in leaching-out of nickel consists in that part of nickel is in the form of compounds that are formed in the course of operation of a catalyst and the composition of these compounds is frequently unknown. Also, a certain part of nickel may be situated deep inside (in pores) catalyst particles, at places inaccessible to the leaching solution. One more difficulty is that, to obtain a product solution enriched with the target component, the leaching solution should be selective with respect to the metal being recovered and should not dissolve the catalyst matrix.

The aim of this study was to examine the fundamental aspects of the process of nickel leaching-out with sulfuric acid from spent nickel–alumina catalysts for methane conversion.

EXPERIMENTAL

In the course of exploitation, a deactivated catalyst is removed from reactors as it loses its activity and is delivered to storage in batches. This gives a mixture of spent catalysts that differ in the content of nickel, degree of coking, porosity, particle shape, and other properties.

As objects of study served spent nickel–alumina catalysts of K-905 and K-87 brands for steam conversion of methane. These catalysts are fabricated by joint precipitation of nickel and aluminum hydroxides, with the subsequent forming and calcination. Therefore, nickel oxide is distributed throughout the catalyst volume.

Grains of K-87 catalyst are gray cylinders about 15 mm in diameter and a height of 14 mm, and those of K-905 catalyst are rings with outer and inner diameters of 15 and 10 mm, respectively, and a height of 14 mm.

An average sample was originally taken from a batch of mixed catalysts. Then the sample was reduced to 100–200 g by the ring-and-cone method [10].

It was noticed that the catalysts differ in outward appearance. It was assumed that the degree of nickel leaching-out from these catalysts will also vary. To elucidate this question, part of catalyst samples were classified into portions: portion 1, dark gray particles of K-905 catalyst; portion 2, gray particles of K-905 catalyst; portion 3, black particles of K-87 particles; and portion 4, gray particles of K-87 catalyst.

The content of nickel in a catalyst was determined by X-ray fluorescence analysis and by complexometric titration.

The X-ray fluorescence analysis was made as follows. A 50-g catalyst sample was calcined in a muffle furnace at 600°C for 2 h and then ground in a ball mill to a dustlike state. The resulting powder was compacted into pellets 10 mm in diameter and 5 mm high.

The catalyst samples were analyzed on a Spectroscan-4 automated X-ray spectrometer (Spektron-OPTEL, St. Petersburg, Russia). The error in nickel determination did not exceed 2.5%.

To determine the content of nickel by complexometric titration, a 150-g catalyst sample was crushed in an agate mortar to a particle size of 2–10 mm, placed in a 500-ml flask, poured over with 300 ml of a 20% sulfuric acid solution, and the mixture was boiled for 20–24 h. Preliminary studies demonstrated that nickel is completely recovered from the catalyst under these conditions.

The thus obtained leaching solution was titrated with Na_2EDTA at pH 9, maintained with an ammonia buffer mixture. Murexide served as indicator.

The content of nickel in the catalyst sample was 7.05% according to the results of complexometric ti-

tration, and 7.04% as indicated by X-ray fluorescence analysis.

Nickel was leached-out from the catalyst under static and dynamic conditions.

Nickel was leached-out under static conditions as follows. The reactor having the form of a cylindrical glass vessel (height 15–25 cm, diameter 3–8 cm, volume 200–1000 ml) with a discharge cock was charged with a weighed portion of a mixture of spent catalysts. Then a prescribed volume of a sulfuric acid solution was poured into the reactor. Every hour, the acid solution was discharged from the reactor, a sample for analysis was taken, and the solution was again poured into the reactor. The experiment was performed until a constant nickel concentration was reached in the leaching solution.

In the case of leaching under dynamic conditions, a weighed portion of a catalyst was placed in a conical vessel, poured over with a prescribed volume of a sulfuric acid solution, and agitated with a mechanical stirrer at a rate of 40–50 rpm. Samples for analysis were taken from the leaching solution at regular intervals of time. As a pH value of 2 was reached in the leaching solution, concentrated sulfuric acid was added to pH 0.7. The experiment was terminated as a constant nickel concentration was reached in the leaching solution at pH 2.

The sulfuric acid solutions were prepared by dilution of concentrated (91–92%) sulfuric acid. The concentration of sulfuric acid in the solutions prepared was determined by acid–base titration.

The influence exerted by the concentration of sulfuric acid on the rate and extent of nickel leaching-out from the catalyst under static conditions was studied. Irrespective of the acid concentration, complete recovery of nickel from the catalyst could not be achieved. Therefore, leaching was performed in several stages in order to obtain the maximum possible degree of nickel recovery. For this purpose, the leaching solution was discharged after a steady state was attained. After that the catalyst was poured over with the same volume of a fresh sulfuric acid and leaching was continued until a new steady state was attained. The results obtained are listed in Table 1.

Table 1. Ni recovery from catalysts with sulfuric acid solutions of various concentrations under static conditions (weight of catalyst sample 50 g)

* Total degree of recovery in the first and second stages.

** Total degree of recovery in the first, second, and third stages.

The studies demonstrated that equilibrium is attained in the second and third stages of leaching at a lower nickel concentration in solution: about 0.13 M in the second stage, and 0.07 M in the third. In all cases, the concentration of sulfuric acid has no effect on the degree of nickel recovery (nickel concentration in leaching solutions). These facts indicate that the attainment of equilibrium by the leaching process is not related to formation of nickel-saturated leaching solutions in the reactor volume. The solubility of nickel sulfate in sulfuric acid solutions was evaluated. It was found that the solubility of nickel sulfate at 25°C is 59 g l^{-1} in a 30% sulfuric acid solution and 103 g l^{-1} in a 5% solution.

It was assumed that the equilibrium position is determined in this process mode by saturation with nickel of leaching solutions that fill pores in catalyst particles and by blocking of these pores by nickel sulfate precipitated from saturated solutions.

To confirm the blocking of pores in catalyst particles by nickel sulfate, an attempt was made to perform a microscopic study of the cross-section of catalyst samples before and after leaching. However, no reliable and unambiguous results confirming that crystalline nickel sulfate is present in the pores of catalyst particles could be obtained. Therefore, to verify the assumption made above and to examine the possibility of preventing the blocking of the pores in the

catalyst by particles of nickel sulfate, leaching under static conditions with a dilute (1%) sulfuric acid solution, strengthened at regular intervals of time, was studied.

The leaching solution was strengthened with a 20% sulfuric acid solution after the solution pH reached values of 2–3. The volume of the 20% sulfuric acid solution added to the leaching solution was chosen so as to restore the initial concentration of sulfuric acid in the leaching solution. The leaching-out of nickel in this mode was also performed until the leaching solution was saturated with nickel ions. The results obtained in these experiments are listed in Table 2. In all cases, leaching solutions with a high concentration of nickel sulfate and greater degree of nickel leaching-out from the catalyst were obtained. The results of these experiments confirmed the validity of the assumption that the catalyst pores are blocked by nickel sulfate when concentrated sulfuric acid solutions are used as a leaching agent.

A study of the leaching process under static conditions demonstrated that its rate is low. The possible reason may be the appearance of an outer-diffusion control over the leaching process. Therefore, leaching was studied under dynamic conditions, because the outer-diffusion limitations are lifted in this mode.

Nickel was leached from four catalyst samples differing in the outward appearance with a 1% sulfuric acid solution at 20–25°C, with permanent strengthening of the leaching solution. The results of these experiments are listed in Table 3. It can be seen that the degree of nickel recovery does rather strongly depend on the type of a sample, but does not exceed 55% at the very best.

As demonstrated by the results of the experiments, the concentration of the sulfuric acid solution has no effect on the extent of nickel leaching-out from catalyst particles. In leaching-out of nickel with both concentrated and dilute sulfuric acid solutions, the degree of nickel recovery is virtually the same (55–60%). The experimental study also revealed that, in leaching-out of nickel with a dilute (1%) sulfuric acid solution under dynamic conditions, the degree of nickel recovery from the catalysts is lower than that in leaching with the same solution under static conditions, with the leaching solution periodically discharged from the reactor and the same solution poured in.

It follows from the experimental results that the leaching-out of nickel from the catalyst is limited by its diffusion from catalyst pores into the bulk of the leaching solution. In those cases when the rate of nickel diffusion from the catalyst pores is lower than the nickel dissolution rate, nickel sulfate is deposited in the catalyst pores, pore mouths are completely blocked by solid products, and leaching terminates. Agitation of the leaching solution (dynamic mode) does not lift the inner-diffusion limitations.

The leaching rate can be markedly raised if the catalyst pores are periodically freed of the leaching solution.

CONCLUSIONS

(1) Nickel recovery from spent alumina–nickel catalysts for methane conversion mainly occurs in the inner-diffusion region and is controlled by the rate of nickel diffusion from catalyst pores into the bulk of the leaching solution.

(2) The maximum possible degree of nickel recovery from catalyst particles (85–90%) and the minimum expenditure of the reagents are achieved in leaching with a dilute (1%) sulfuric acid solution, with permanent strengthening of this solution in the course of leaching and catalyst pores periodically freed of the leaching solution.

Abstract—The effect of alkanotrophic Rhodococcus strain on mechanical and IR spectroscopic characteristics of highly porous quartz glass was studied.

DOI: 10.1134/S1070427206040070

Controllable modification of silica surface with stable nanostuctural units is an urgent problems of modern materials technology. This problem is commonly solved by colloidal-chemical technique. New uncommon approaches to modification of the silica surface were discussed in [1]. Taking into account that specific bacterial strains can excrete colloidal silica [2], one of promising approaches to solution of the above problem can be based on treatment of silica with bacteria. Silicon is one of the most abundant elements in the lithosphere. Its stable (quartz) and metastable (colloidal) forms are widely involved into environmental biogeochemical processes [3].

In this study we examined the effect of the bacterial suspension on the IR spectra and physicochemical characteristics of quartz glass both in the absence and in the presence of a carbon source.

EXPERIMENTAL

Samples of highly porous quartz glass were prepared by replication of a polymeric matrix (Fig. 1) [4]. The cells of network-cellular framework of these samples were, on average, 0.5 mm in diameter. The specific surface area determined by the BET technique was about 0.1 $m^2 g^{-1}$. No less than five samples were tested in each experimental series. The surface area of the tested samples (weight 1–2 g, volume 1–1.5 cm^3) was in the range 0.5–1.0 m^2.

The samples of porous quartz glass were treated with an aqueous suspension of alkanotrophic Rhodococcus strain cells *R. Ruber* IEGM 231 submitted by the Regional Profiled Collection of alkanotrophic microorganisms at the Institute of Genetics and Ecology of Microorganisms (IEGM), Ural Division, Russian Academy of Sciences [5]. The treatment of quartz glass with aqueous bacterial suspension was carried out in the laboratory of alkanotrophic microorganisms at IEGM. Before experiments, all the quartz glass samples were treated in an autoclave with superheated steam at 120°C. To ensure favorable conditions for vital activity of alkanotrophic microorganisms, all the experiments were carried out in aqueous potassium phosphate buffer recommended in [6]. In the reference experiments, quartz glass samples were placed into potassium phosphate buffer solution containing no microorganisms. The Rhodococcus strain content in the test systems was 4.0×10^9 cells per ml. The preliminary immobilization of the bacterial cells on

* Immediately after immobilization in PB.

the quartz glass surface was carried out by two-week keeping of a quartz glass sample in peptone broth (PB). The effect of Rhodococcus strain on quartz glass was studied under following conditions: (1) after preliminary immobilization of microorganisms on the quartz glass surface from peptone broth, (2) without preliminary immobilization, (C) with addition of acrylamide (0.003%) as an accessible carbon source (CS), and (b) without it. The following combinations of these conditions were used in our experiments: 1C (preliminary immobilization + CS), 1b (preliminary immobilization, without CS), 2C (without preliminary immobilization + CS) and 2b (without preliminary immobilization, without CS).

After completion of the experiments, the quartz glass samples were washed, dried, and calcined, and their compression strength was measured on a 2054 R-5 tensile-testing mashine at a loading rate of 2 mm min^{-1}.

We failed to reliably determine the effect of Rhodococcus strain on the quartz glass structure by X-ray phase analysis.

The IR spectra of quartz glass (crushed in an agate mortar, mull in Vaseline oil), were recorded on an IFS-66 Fourier spectrometer (Bruker, Germany) (KBr windows, resolution 1 cm^{-1}, 100 scans). All the IR spectra were reduced to the zero baseline. The resolution of complicated absorption bands was carried out with an OPUS-3 computer program. Taking into account the heterogeneity of crushed quartz, the shape of separate absorption bands was approximated by Gaussian functions. The IR spectra were characterized by the wavenumber ν, half-width, and maximal (D_m) and integral (D_i) optical densities of the individual absorption bands.

Since, in recording the IR spectra, the absorption layer thickness and Vaseline oil amount were not standardized, the intensity of absorption bands of various samples noticeably differs. Therefore, in comparison of intensities of particular absorption bands of various samples, instead of their intensity we used the ratios

$$A_{rel,\,i} = D_i/\Sigma D_i,$$

where $A_{rel,\,i}$ is the relative intensity of ith absorption band; D_i, integral optical density of ith absorption band; and ΣD_i, sum of the integral optical densities of all the absorption bands of the stretching vibrations of the SiO_4 tetrahedra.

Table 1 shows the effect of immobilized Rhodococcus strain on the IR spectra of quartz glass in system 1C.

The characteristic vibration frequences of free and condensed SiO_4 tetrahedral groups are in the ranges 800–1050 and 1000–1250 cm^{-1}, respectively [7, 8]. The ratio A_2/A_1 of the total relative intensity of the absorption bands of condensed SiO_4 groups A_2 (1095–1250 cm^{-1}) to the total relative intensity of the absorp-

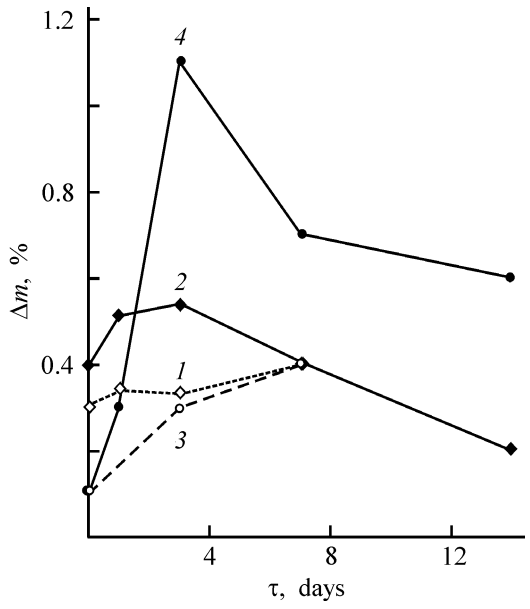

Fig. 2. Weight loss of quartz sample Δm vs. treatment time τ. (*1*, *3*) Reference systems and (*2*, *4*) test systems. Systems: (*1*, *2*) 1C and (*3*, *4*) 1b.

tion bands of free SiO_4 groups A_1 (800–1050 cm^{-1}) characterizes the relative content of condensed SiO_4 tetrahedra in the structure of quartz glass, i.e. the degree of crystallinity of quartz. Table 2 and Fig. 2 show the quartz glass characteristics (weight loss, Δm, %; compression strength, σ_c, MPa; and relative content of condensed SiO_4 groups, A_2/A_1) as influenced by treatment with Rhodococcus strain.

Figure 3 shows the dependence of the compression strength of quartz glass samples on their degree of crystallinity A_2/A_1 for reference (Fig. 3a) and test (Fig. 3b) systems, constructed from the data in Table 2. It should be noted that these plots are identical for systems containing a carbon source and without it.

It is seen that in the reference systems an increase in the degree of crystallinity of quartz glass is accompanied by a decrease in its strength. The similar effect was observed in gradual annealing of highly porous quartz glass and is caused by transformation of quartz into cristobalite [4]. In the test systems, we found no correlation between the degree of crystallinity of quartz glass and its strength.

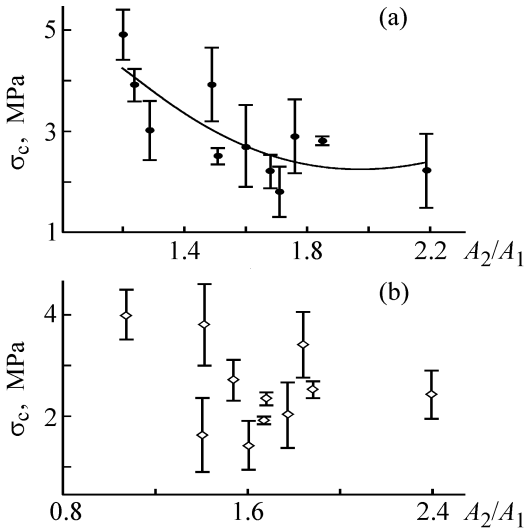

Fig. 3. Compression strength σ_c, vs. degree of crystallinity of quartz glass (A_2/A_1). (a) Reference systems and (b) test systems.

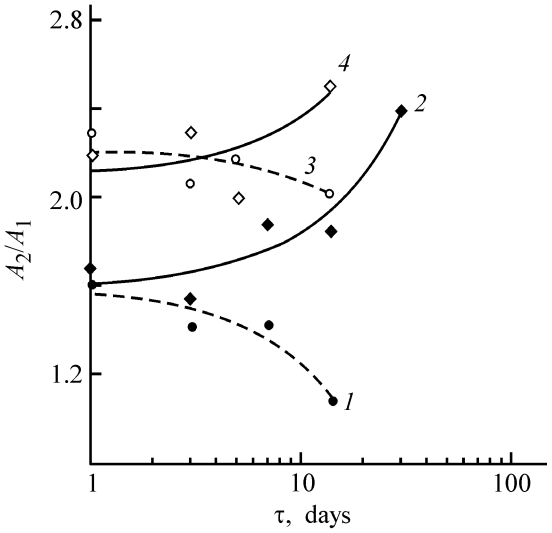

Fig. 4. Degree of crystallinity of quartz glass A_2/A_1 vs. treatment time τ in the systems containing a carbon source and without it. System: (*1*) 1b, (*2*) 1C, (*3*) 2b, and (*4*) 2C.

The time dependence of the effect of Rhodococcus on the degree of crystallinity of quartz glass in the presence and absence of a carbon source is shown in Fig. 4. It seen that in the systems containing no CS the crystallinity decreases with increasing treatment time, i.e., quartz glass becomes more amorphous. Even after 14-day incubation we observed no large-scale death of microorganisms. In the presence of carbon source, the crystallinity of quartz glass increased. After 90-day treatment, it started to decrease, apparently due to both the exhaustion of a carbon source and changes in the system composition. Figure 4 also shows that, irrespective of preliminary immobilization of Rhodococcus strain, the bacterial activity in the absence of CS causes amorphization of quartz glass (decrease in crystallinity), whereas, in the presence of CS, the structure-making effect prevails (increase in crystallinity).

Physicochemical characteristics of amorphous quartz significantly differ from those of crystalline quartz. In the series quartz, cristobalite, quartz glass the entropy of formation in the aqueous solution decreases in the order –41.84, –42.68 and –46.86 J mol^{-1} K^{-1} [9]. It is known that the structural ordering is accompanied by lowering of the entropy, whereas the structural disordering increases the entropy [10]. We believe that, in the absence of a carbon source, the methabolism of Rodhococcus strain is maintained by the energy released in amorphization of quartz glass. On the contrary, in the presence of a carbon source, the energy consumed by Rhodococcus cells from the carbon source can be partly used for increasing the crystallinity of quartz glass with accumulation of the energy for the future.

CONCLUSIONS

(1) In keeping porous quartz glass samples in aqueous potassium phosphate buffer containing no Rhodococcus strain (reference experiment), their crystallinity (relaive content of condensed SiO_4 groups) increases and the strength of quartz glass decreases, irrespective of the presence or absence of a carbon source.

(2) In keeping porous quartz samples in aqueous potassium phosphate buffer (without carbon source) populated with Rhodococcus strain, the crystallinity of quartz (relative content of condensed SiO_4 tetrahedra) decreases. In the presence of a carbon source, the crystallinity of quartz increases. In the reference systems these structural effects are absent.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Comparative Analysis of Solubility in CuCl–MCl–H_2O Systems at 25°C (M^+ = Li^+, Cs^+, NH_4^+)

Abstract—Solubility in the ternary system CuCl–NH_4Cl–H_2O at 25°C was determined by the method of isothermal lifting of oversaturation. A comparative analysis of solubility in this system and the previously studied systems CuCl–MCl–H_2O (M^+ = Li^+, Na^+, K^+, Cs^+) was made. The results obtained were interpreted in terms of competition between hydration, association, and complexation processes in water–salt systems.

DOI: 10.1134/S1070427206040082

We have been systematically studying the solubility in multicomponent halide water–salt systems for years. It has been shown that the solubility, as well as other physical and chemical macroscopic properties, should be considered as a result of the combination of all competitive interactions occurring in solutions: association of ions, their hydration, and complexation. In this study, such an approach was applied to analysis of solution–solid equilibria in ternary systems containing copper monochloride.

Multicomponent systems containing copper monohalides are of great interest from the practical point of view. For example, CuCl admixtures strongly affect the photochromic properties of silver halide glasses by sharply reducing the rate of relaxation of the photoinduced form into the initial form, which expands potentialities of practical use of these glasses [1]. The development of copper halide photochromic glasses in the 1970s initiated a study of chloride-containing sodium and potassium borosilicate glasses [2–4], whose optical characteristics are determined by the mutual solubility of the components. In the process, a pronounced analogy between the equilibrium diagrams of salt melts and those of the corresponding aqueous solutions was revealed [5]. Aqueous-alcoholic solutions containing copper monochloride and magnesium chloride or lithium chloride and hydrochloric acid are used to extract ethylene from cryogenically inseparable exhaust gases [6, 7] and also serve as sorbents for carbon monoxide [8].

The ability of copper(I) to form complexes with organic compounds predetermines its high catalytic activity in a number of organic reactions, such as decomposition of diazo compounds, double carbonylation, dimerization of acetylene, etc. [9–15]. The catalytic activity, in turn, can be strongly modified by introduction of halides of other elements, including alkali metals. Thus, the results obtained in studying copper(I) complexation in multicomponent water–salt systems can be used to optimize the existing processes and develop new ones.

We have studied previously the solubility in ternary systems constituted by copper(I) halide, alkali metal halide, and water (M^+ = Li^+, Cs^+) [16–18]. The phase equilibria in such a technologically important system as CuCl–NH_4Cl–H_2O (it is the main component of the industrial contact solution for dimerization of acetylene into vinylacetylene [11]) were studied in [19]. Unfortunately, the results obtained were only represented as a schematic diagram, with no numerical data given. The difference between the CuCl–NH_4Cl–H_2O system and its analogs, clearly seen even in such a schematic representation, and its practical importance stimulated a study of solution–solid equilibria in this system.

We studied the solubility by the method of isothermal lifting of oversaturation, because application of the method of isothermal saturation gives poorly reproducible results for systems containing copper monochloride. Heterogeneous samples were heated to

complete dissolution of the solid phase, and then thermostated at 25 ± 0.1°C for three days with continuous stirring. To prevent the photoinitiated disproportionation of copper(I), the experiment was carried out in the dark. To reveal the possible oxidation of copper(I), we carried out, on completion of the experiment, an iodometric titration of copper(II): the content of copper(II) did not exceed 0.2% of the total copper (i.e., it was within the experimental error), which does not affect significantly the solubility.

The samples being analyzed were treated with nitric acid to oxidize copper(I) to copper(II) and then the copper(II) concentration was determined by EDTA titration, and that of chloride anions, by the mercurimetric titration. The accuracy of analysis was ±0.5%. The concentration of ammonium chloride was calculated from the difference. The composition of the solid phase was found by the Schreinemakers method of wet residues and additionally confirmed by X-ray phase analysis. The results obtained are listed in Table 1.

The data obtained enabled a comparative analysis of solubility in all the $CuCl–MCl–H_2O$ systems (M^+ = Li^+, Cs^+, NH_4^+) at 25°C. It was demonstrated the domination of the Cu(I) complexation ($\beta_2 = 3.47 \times 10^5$ [20]) predetermines the qualitative similarity of systems containing copper monohalides.

(1) The solubility of CuCl in ternary solutions, s_{eut}, is higher than the solubility s_0 in binary solutions:

MCl	LiCl	NaCl	KCl	CsCl	NH_4Cl
s_{eut}/s_0	6360	5020	4070	600	9770

(2) Salting-in of an alkali metal chloride is observed in all the systems (only in the system CuCl–LiCl–H_2O, the crystallization branch of $LiCl \cdot H_2O$ is a salting-out–salting-in branch).

Undoubtedly, both these effects are accounted for by strong complexation of copper(I), which is known to increase the solubility [21].

(3) Complex salts crystallize in all the systems except CuCl–NaCl–H_2O.

At the same time, there is a significant quantitative difference in solubility, depending on the nature of an alkali metal ion M^+, which, in our opinion, is determined by two main factors: action of M^+ ions on the structure of water and solutions and association of MCl.

As a quantitative measure of the effect of M^+ on the solubility we used the quantity dm_1/dm_2, which characterizes the intensity of salting-in (salting-out) of salt components. The variation of this parameter along the crystallization branches of copper monochloride and alkali metal chlorides is shown in Fig. 1.

The data obtained indicate that the intensity of CuCl salting-in at low MCl concentrations (approximately up to 0.5 *m*) grows in the order: LiCl < NaCl < KCl < CsCl < NH_4Cl, i.e., it changes in parallel with the structure-breaking effect of the M^+ cation. At high concentrations (>0.8 *m*) the order of variation of the salting-in intensities changes: LiCl < CsCl < NaCl < KCl < NH_4Cl.

The specific position of CsCl in the last series is caused by the ability of Cs(I) to form contact ion pairs, in contrast to the other ions, which form non-contact ion pairs. As a result, association of CsCl

$$Cs^+ + Cl^- \rightleftarrows Cs^+Cl^-$$

competes with the complexation Cu^+–Cl and, accordingly, shifts to the left the equilibrium

$$CuCl + xCl^- \rightleftarrows Cu^+Cl^{x-}_{x+1}$$

and this is the reason why the solubility decreases.

As for the intensity of MCl salting-in, the order of its variation remains the same within the entire range of concentrations. It is similar to the series of CuCl salting-in intensity at high concentrations: LiCl < NH_4Cl < NaCl < KC1, i.e., to the series of the structure-breaking effect of the M^+ cation (LiCl < NaCl < KCl).

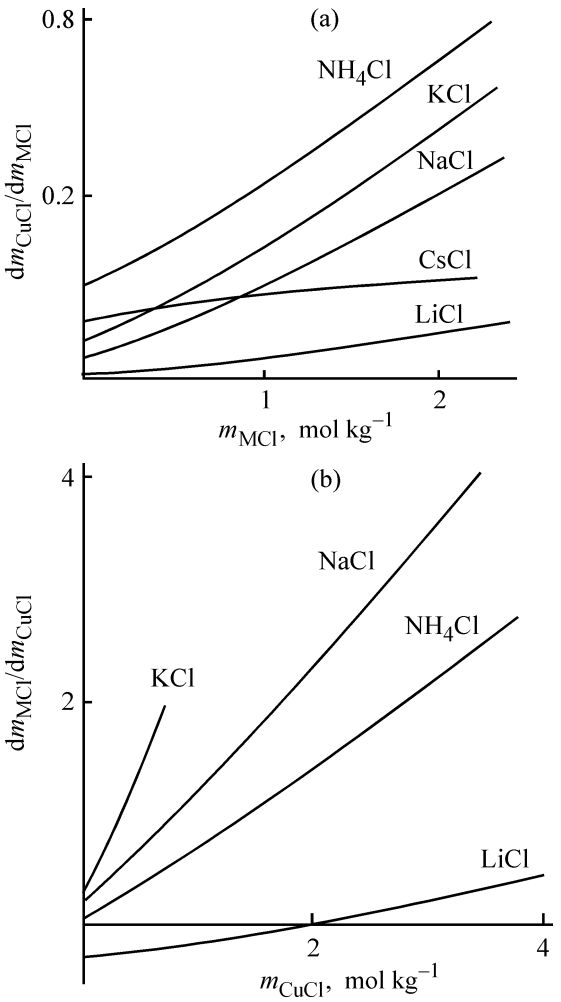

Fig. 1. Salting-in intensity of a salt, dm_1/dm_2, vs. the concentration *m* of a component being added for the crystallization branches of (a) CuCl and (b) MCl.

The acido complexation and association should also significantly affect the length of the branches of copper chloride crystallization. The necessity for structural rearrangements in solution before the onset of crystallization of complex compounds {transition from linear $CuCl_2$ anions to tetrahedral mono- and polynuclear acido-complexes $CuCl_3(H_2O)^{2-}$, $CuCl_4^{3-}$, $Cu_2Cl_5^{3-}$, and $Cu_2Cl_6^{4-}$ [22]} and the high stability of the zinc-blende-type CuCl lattice predetermine the considerable length of CuCl crystallization branches. The specificity of the alkali metal cation markedly affects in this case the competition for the chloride ion in formation of polynuclear acido complexes of copper and association of the alkali metal chloride. Noteworthy is the clearly pronounced correlation between the concentrations at which the crystallization of CuCl and MCl terminates, on the one hand, and the concentrations at which the ion–ion association

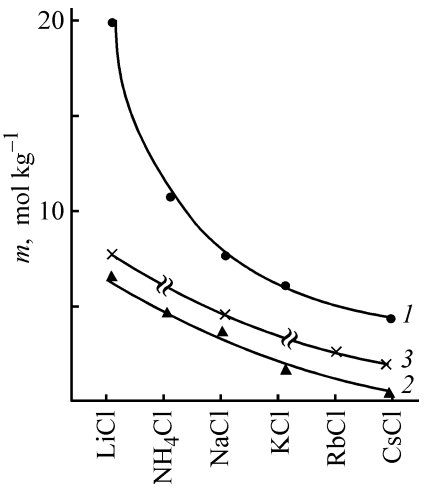

Fig. 2. Correlations between the positions of the eutonic points of (*1*) CuCl/complex compound and (*2*) MCl/complex compound, on the one hand, and (*3*) concentrations *m* of the onset of domination of associative processes in binary MCl solutions, on the other.

starts to dominate in binary MCl solutions [23], on the other (Fig. 2).

The correlation between the concentrations of completion of the crystallization of CuCl, $m^{eut}_{MCl}(CuCl)$, and MCl, $m^{eut}_{CuCl}(MCl)$ and the concentrations $m_a(MCl)$ of the onset of domination of association processes in binary MCl solutions is as follows:

Table 2. Bond length *r* and frequency ν of Cu–Cl stretching vibrations in copper(I) compounds

Compound	r_{M-Cl}, Å		r_{Cu-Cl}, Å	ν_{M-Cl}, cm^{-1}	Reference
	Compound	MCl			
CuCl			2.46	225, 246	
Li_2CuCl_3				220, 242	
$NH_4Cu_2Cl_3$	3.34	3.24	2.34	228, 246	[26]
$(NH_4)_3Cu_2Cl_5$				227, 247	
K_2CuCl_3	3.27	3.15	2.31	229, 249	[27]
$Cs_3Cu_2Cl_5$	3.69	3.56	2.28	243, 252	[28, 29]
$Cs_3CuCl_4 \cdot H_2O$				242, 251	

m, mol kg^{-1} H_2O:	LiCl	NH_4Cl	NaCl	KCl	CsCl
$m^{eut}_{MCl}(CuCl)$	22.01	11.14	8.4	6.35	4.08
$m^{eut}_{CuCl}(MCl)$	6.89	5.06	4.16	0.3	0.05
$m_a(MCl)$	7.4	4.5	2.3		

These data clearly demonstrate that MCl association strongly affects the length of branches of copper monochloride crystallization.

The system CuCl–NH_4Cl–H_2O also occupies a special position both in the salting-in intensity and in the length of branches of CuCl and MCl crystallization (Fig. 1). We calculated the distribution of complex species in this system, which indicated that the formation of copper(I) chloride ($K_{st} = 10^6$) and ammonia complexes ($K_{st} = 10^{14}$) occurs in parallel. Ammonia is formed in hydrolysis of ammonium ions, $NH_4^+ + H_2O = NH_3 \cdot H_2O + H^+$, with the complexation strongly shifting the hydrolytic equilibrium to the right. It is the joint action of both the parallel processes that determines the maximal intensity of CuCl salting-in in the system CuCl–NH_4Cl–H_2O. The values of $m^{eut}_{CuCl}(NH_4Cl)$ and $m^{eut}_{NH_4Cl}(CuCl)$ fall within the range between those for the least associated lithium and sodium, although, taking into account the hydration energy of ammonium ions and their action on the water structure, we could expect that the concentrations of completion of crystallization of binary components would be intermediate between the corresponding characteristics of the systems with sodium and potassium salts. The reason is that NH_4Cl is not associated up to very high concentrations. The "concentration-induced" formation of ion pairs is only observed when the amount of water in solution is insufficient for complete hydration of ions.

As mentioned above, the formation of copper(I) acido complexes is the predominant type of interaction in all the systems under consideration, which predetermines the similarity in form, composition, and structures between the crystallizing solid compounds. In this case, we can expect that the complex salts formed in this systems will be of the same type, i.e., products of the acido complex formation of chloride ions with Cu^+ cations. In salts of this kind, cations occupy voids in the forming structure [23]. As demonstrated previously [24, 25], elongation of M–Cl bonds and shortening of the bonds between the central atom and ligands, compared with the corresponding binary compounds, are characteristic of compounds of this type. The available published data on the structure of potassium, ammonium, and cesium chlorocuprates(I) support our assumption concerning the type of crystallizing compounds (Table 2). The formation of stronger copper–chlorine bonds, compared with

those in copper monochloride, is also confirmed by the shift of the frequency of stretching vibrations to higher frequencies.[1] In this case, the Cu–Cl bond in copper(I) compounds should be the stronger, the weaker the polarizing action of the outer-sphere cation M^+ ($Li^+ > NH_4^+ > K^+ > Cs^+$), and this is confirmed experimentally.

CONCLUSIONS

(1) A study of the systems CuCl–MCl–H_2O (M^+ = Li^+, Na^+, K^+, Cs^+, NH_4^+) revealed that the predominance of Cu(I) acido-complex formation predetermines the qualitative similarity of the systems under consideration.

(2) At low MCl concentrations, the intensity of salting-in of copper monochloride ($Cs^+ > K^+ > Na^+ > Li^+$) is determined by the action of a singly charged cation on the solution structure and varies in the opposite direction with the hydration energy of cations. The length of the crystallization branches of copper monochloride is determined by competitive processes of copper complexation and association of an alkali metal chloride. A stronger MCl association results in a decrease in the length of the crystallization branches of copper monochloride.

(3) The particular position of the system CuCl–NH_4Cl–H_2O is caused by specificity of the ammonium cation and by the fact that ammonia formed in its hydrolysis can form complexes with copper; the parallel occurrence of ammonia- and acido complex formation results in the highest salting-in intensity and the longest branches of CuCl and NH_4Cl crystallization.

(4) The predominance of copper acido complex formation in all the systems results in that the type of crystallizing solid compounds is the same. The different polarizing effects of alkali metal cations lead to only slight changes in the strength of Cu–Cl bonds.

SORPTION AND ION-EXCHANGE PROCESSES

Porosity and Sorption Properties of Activated Carbons Prepared from Anthracite by Steam–Air Activation

Received August 9, 2005; in final form, December 2005

Abstract—Fundamental aspects of the steam–air activation of anthracite from Donets coal fields were studied. The effect of the flow rate of moistened air on the development of a porous structure and the sorption properties of the adsorbents obtained were examined.

DOI: 10.1134/S1070427206040094

The intense development of sorption technologies imposes increasingly stringent requirements to such properties of adsorbents as high sorption capacity determined by the pore structure, presence of surface functional groups, and service characteristics associated with purity, abrasion resistance, and cost.

Fossil coals used as one of the main raw materials for manufacturing carbon adsorbents for various purposes largely satisfy these requirements [1, 2].

Among these coals, anthracite is one of the most attractive raw materials owing to the high content of carbon and low ash content, as well as to the high mechanical strength of the final product, activated carbon.

At the same time, activation of anthracite to obtain an adsorbing material encounters the problem of its low reactivity in a high-temperature contact with the conventionally used activating gases. This is due to the high degree of metamorphism of this kind of fossil coals (a strong change in the texture, structure, and mineral composition under the action of temperature, pressure, and chemical activity of stratal solutions). It is for this reason that an adsorbent with a polymodal pore structure frequently cannot be produced by steam activation [3–5].

Of high importance in the technology of sorption purification of liquids to remove inorganic and organic contaminations, recovery of precious metals from solutions, and accumulation of process gases is the possibility of controlling the pore structure.

In manufacture of activated carbons, the pore structure and properties are controlled by selecting the activation method and the activating agent and by varying the process duration and conditions.

The porous structure is rather frequently developed by chemical activation [6–12], which consists in that coal is treated with carbonates, sulfates, hydroxides, sulfuric and phosphoric acids, and zinc chloride, which release an activating gas (e.g., CO_2, O_2) at high temperatures.

As a rule, chemical activation gives an adsorbent with a sufficiently developed surface and comparatively wide micropores. However, it is contaminated with inorganic admixtures. Moreover, such a catalytic activation impairs the mechanical strength of the final product. Thus, the chemical activation is a technologically unjustified procedure: it complicates the process of manufacture of activated coals because the process is corrosive and it is necessary to wash carbon.

The authors made an attempt, as an alternative procedure for production of activated coals with a developed porous structure, to use activation with a combined activating gas, humidified air.

The aim of the study was to examine kinetic aspects of the anthracite activation with a steam–air mixture, specific features of the process of formation

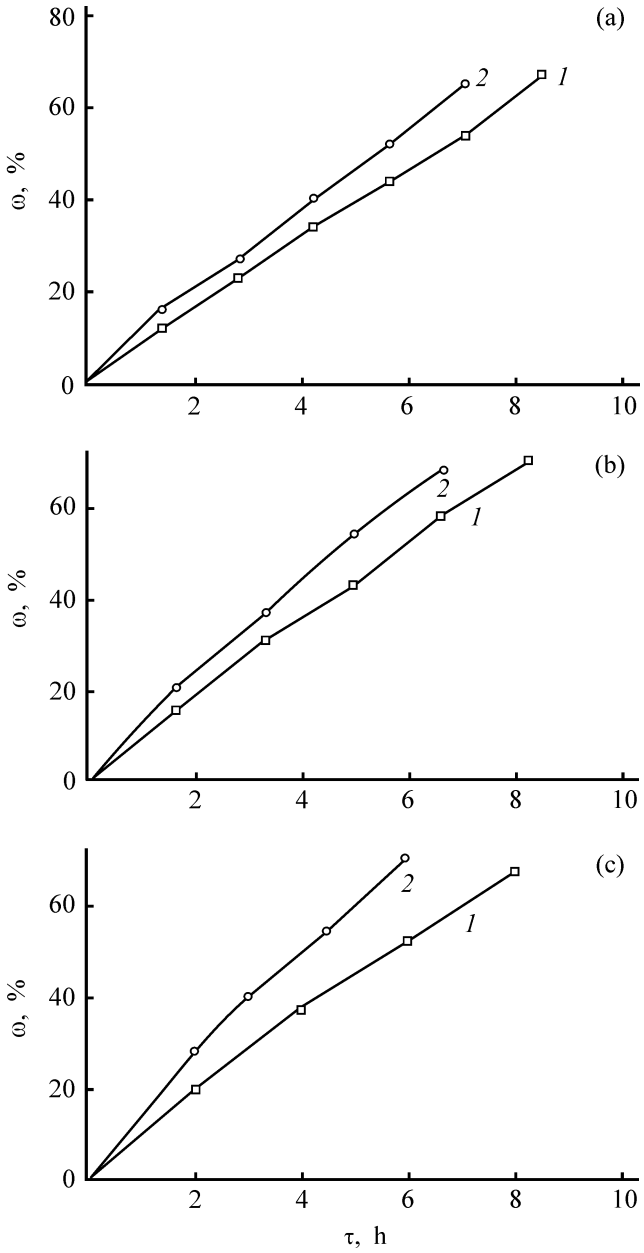

Fig. 1. Kinetics of anthracite activation with (*1*) steam and (*2*) steam–air activating mixture (air flow rate 100 ml min^{-1}) at different temperatures. Temperature (°C): (a) 800, (b) 850, and (c) 900. (ω) Combustion loss and (τ) time.

of a porous structure, and sorption parameters of the activated carbons obtained in various temperature modes.

EXPERIMENTAL

Anthracite of A brand from the Donets coal field (Sverdlovsk, Lugansk oblast, Ukraine) served as the starting material. The chemical composition of the main components of the raw material was as follows: A_c = 4–5%, V_{daf} = 6–7%, C_{daf} = 95%. Size of anthracite particles 0.5–2.0 mm, initial volume of sorption pores for benzene <0.01 $cm^3\ g^{-1}$, bulk density 0.94 $g\ cm^{-3}$.

The activation was performed in a SUOL-044/12-M2-U42 laboratory furnace [GOST (State Standard) 13474–79]. Anthracite samples were placed in a 500 × 45-mm cylindrical quartz reactor. The study was carried out in the static mode with intermittent rotation of the reactor in the furnace. The temperature was monitored with a built-in platinum–platinum-rhodium thermocouple and controlled with the control unit (GOST 9736–68) supplied with the SUOL furnace.

The activation process included supply of steam preliminarily mixed with a flow of air. The flow rate of steam was 0.28×10^{-7} $m^3\ s^{-1}$, and that of air passing across a layer of hot (boiling) water, 0.33×10^{-6} and 1.67×10^{-6} $m^3\ s^{-1}$.

To reveal the influence of atmospheric oxygen in steam–air activation, the initial sample was also directly activated with pure steam at the same temperature and flow rate of steam.

In all stages of the study, the samples were subjected to porometric analysis by measuring the sorption pore volume V_s for benzene [13]. In the course of activation, the sample yields by mass and volume (R_m and R_v) were recorded and the bulk density Δ and combustion loss ω were determined.

To evaluate the sorption properties of the activated carbons obtained, the sorption capacity for Methylene Blue and the sorption activity for iodine were determined.

Of particular importance for understanding of the fundamental aspects of steam–air activation of anthracite is a study of the process kinetics. Figures 1a–1c show the kinetics of the combustion loss of anthracite in various modes of activation with pure steam and steam with addition of atmospheric oxygen bubbled across a hot water layer. It follows from the data presented that use of steam mixed with atmospheric oxygen as an activating agent starts to take effect even at 800–850°C, which is manifested in a change in the activation rate (Figs. 1a and 1b). At 900°C, the acceleration of the process becomes more considerable (Fig. 1c). For example, the combustion losses of 40–60% are reached in 3 to 5 h in the first case, and in 4–6 h in activation with pure steam.

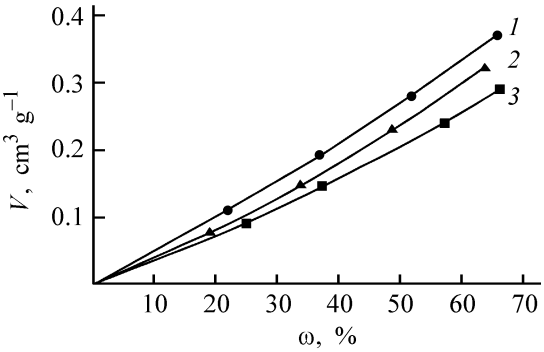

Fig. 2. Effect of the flow rate of humidified air on the development of the sorption pore volume V for benzene. (*1*) Activation with H_2O, (*2*) activation with H_2O + humidified air (flow rate 0.33×10^{-6} m^3 s^{-1}), and (*3*) activation with H_2O + humidified air (flow rate 1.67×10^{-6} m^3 s^{-1}). (ω) Combustion loss; the same for Fig. 3.

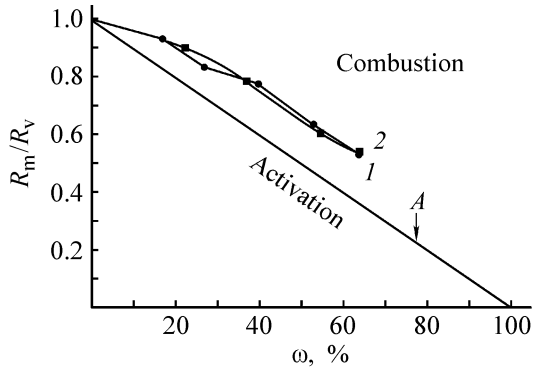

Fig. 3. Variation of the activation index in activation of anthracite with (*1*) steam and (*2*) steam–air mixture (air flow rate 1.67×10^{-6} m^3 s^{-1}) at 900°C.

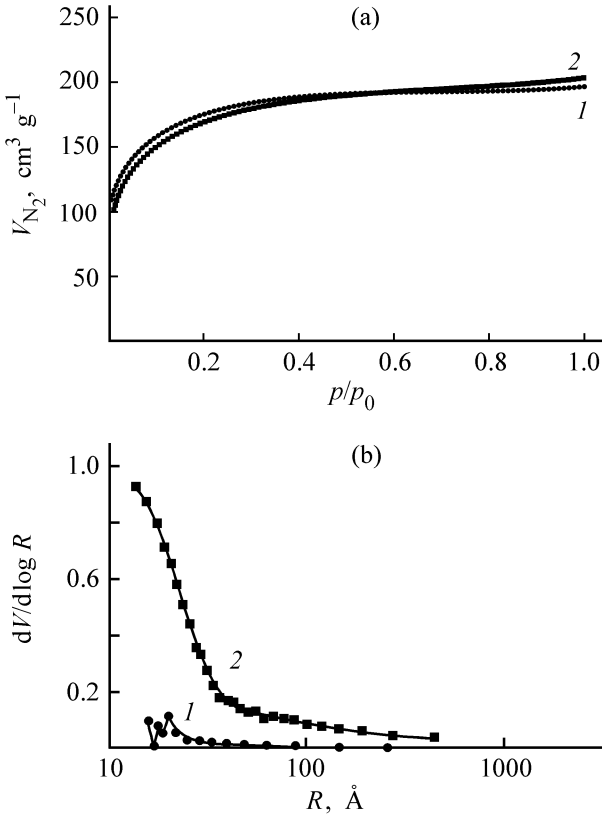

Fig. 4. (a) Isotherms of nitrogen adsorption for anthracite samples activated with (*1*) combined steam–air activating agent and (*2*) steam and (b) their differential curves of pore volume distribution with respect to pore radii. (V_{N_2}) Volume of absorbed nitrogen, (p/p_0) relative pressure, and (R) pore radius.

At the same time, the sorption pore volumes for benzene (Fig. 2) slightly decrease upon application of the combined activating agent, which may point to redistribution of pore sizes at the surface of the carbon matrix.

In this case, an increase in the concentration of oxygen in the air–steam flow also leads to a decrease in the sorption pore volume for benzene that can be obtained upon the activation.

The activation index, defined as the ratio of the product yield by mass to that by volume, characterizes the activation efficiency. Figure 3 shows that, in the case of both direct activation (curve *1*) and activation in the steam–air system (curve *2*), the activation index varies similarly and is close to that characteristic of pure pore formation (line *A*).

The virtually coincident runs of the curves in Fig. 3 verify the assumption that the change in the porometric characteristics is in all probability due to redistribution of the pore structure, rather than to the possible enhancement of combustion, accompanied by formation of the gaseous oxides CO and CO_2, for which carbon may be expended. Presumably, atmospheric oxygen introduced into the flow of the activating gas exerts a milder effect because of its humidification in bubbling across a water layer.

One more evidence in favor of modification of the pore structure is the difference between the specific surface areas for nitrogen of samples subjected to direct activation and activation with a steam–air mixture (900°C) to a combustion loss of 65% (Figs. 4a and 4b). The specific surface area is 800 m^2 g^{-1} in the first case, and 680 m^2 g^{-1} in the second (Fig. 4a), whereas the volume of nitrogen absorbed at $p/p_0 \approx 1.0$ is the same and equal to 200 cm^3 g^{-1} in both cases. The decrease in the specific surface area of samples activated to the same combustion loss is presumably due to an increase in the meso component of the pore structure.

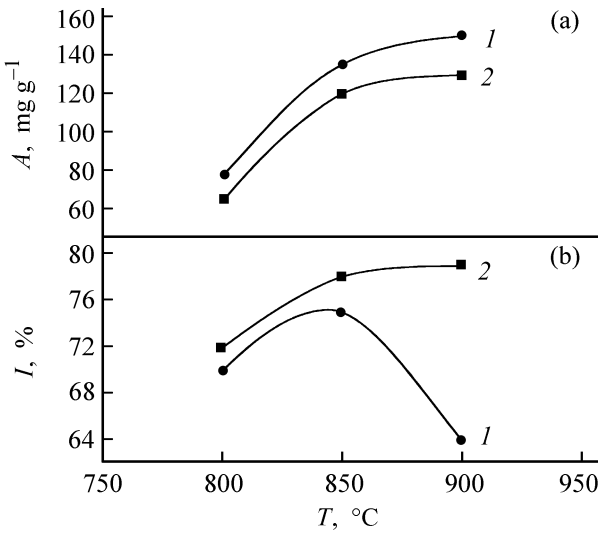

Fig. 5. Temperature dependences of (a) absorption capacity for MB and (b) sorption activity with respect to I_2 in activation of anthracite samples with (*1*) combined steam–air activating agent (air flow rate 1.67×10^{-6} $m^3 s^{-1}$) and (*2*) steam. (*A*) Absorption capacity for MB, (*I*) sorption activity with respect to I_2, and (*T*) temperature.

It is of interest that the differential curves of pore volume distribution with respect to pore radii (Fig. 4b) also show significant changes. The intensity of peaks corresponding to the effective pore radii dramatically falls when the combined steam–air activating agent is used, which points to a decrease in the microporosity of the samples studied.

Figures 5a and 5b show temperature dependences of the adsorption of Methylene Blue (MB) and iodine for anthracite samples activated with steam (curve *2*) and combined (curve *1*) activating agent. It can be seen that the sorption capacity for MB is higher upon steam–air activation, whereas the sorption activity with respect to iodine is markedly lower.

In this case, the activation temperature strongly affects the development of the surface porous structure in activation with both steam and combined activating agent. As temperature is raised, the sorption capacity of the activated carbons obtained for MB grows. This fact clearly confirms the change in the absorption capacity for MB for anthracite samples treated to a combustion loss of 65% at 800, 850, and 900°C (Fig. 5a).

The variation of the absorption capacity for I_2 indicates that the volume of micropores changes as the activation temperature is raised (Fig. 5b). In the case of steam–air activation, the sorption activity with respect to I_2 reaches a maximum at 850°C and then falls dramatically at 900°C, whereas in the case of steam activation, the maximum activity is observed at 850°C. This indicates that the number of micropores increases at high activation temperatures, whereas the number of mesopores increases, which confirms that the sorption capacity for MB grows.

CONCLUSIONS

(1) The results obtained in a study of the steam–air activation of anthracite from Donets coal fields demonstrate that it is possible to obtain highly porous activated carbons with a specific surface area for N_2 of up to 680 $m^2 g^{-1}$ and pore volume for benzene of up to 0.32 $cm^3 g^{-1}$ at a product yield of 35%.

(2) Activation with a steam–air mixture depends on temperature and flow rate of air in the flow of the activating gas.

(3) Comparison of the porometric and sorption characteristics of adsorbents produced by activation with steam and steam–air mixture indicates that the volumes of micro- and mesopores are redistributed in favor of the latter if humidified air is used as an activating gas.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Palladium(II) Chloride Complexes by Nitrogen-containing Modified Shungites

A. M. Akimbaeva

Bekturov Institute of Chemical Sciences, Ministry of Education and Science of the Republic of Kazakhstan, Almaty, Kazakhstan

Received June 3, 2005; in final form, November 2005

Abstract—The sorption properties of anion exchangers based on modified shungites with respect to palladium(II) ions from chloride solutions were studied. The effect of sorbent nature, pH of a solution, and process duration on the degree of their recovery was considered.

DOI: 10.1134/S1070427206040100

Sorbents based on organic polymers, chemically modified silicas, and fibrous and carbon materials have been suggested for selective sorption and recovery of platinum metals from solutions [1–8]. Particular attention is paid in concentration of platinum metal ions to nitrogen-containing sorbents, which are the most effective [9] because of having the highest capacity for complexation with platinum-group metals. However, the complex ion exchangers recommended for selective recovery of platinum metals are difficultly accessible and rather expensive. A promising way to obtain such ion exchangers is to modify the surface of natural sorbents to improve their capacity and kinetic characteristics. Carbon-containing materials are insufficiently widely used as a matrix for production of modified sorbents. Of particular interest among carbon-containing materials is shungite rock, whose main components are carbon and silicon dioxide, which constitute a common composite system. Materials of this kind are particularly promising for recovery of platinum metals [10] and, in particular, palladium ions.

The aim of this study was to examine recovery of palladium(II) ions from chloride solutions with modified nitrogen-containing shungites.

EXPERIMENTAL

A shungite-based ion exchangers (Sh) was produced by chemical modification of a natural sample containing 20% carbon with polyethylen imine (PEI) with the subsequent cross-linking with glycidyl methacrylate (GMA) [11]. Shungite containing grafted groups of polymethylvinylpyridine (PMVP) was synthesized by polymerization of 2-methyl-5-vinylpyridine in grains of a shungite concentrate containing 80% carbon [12].

Sorption of palladium(II) ions was studied under static conditions at room temperature. The starting solution was prepared by dissolving the metal in a mixture of nitric and hydrochloric acids. The concentration of Pd(II) ions in the working solution was 11 mg l^{-1} at pH 1.3. To study the process kinetics, a 0.5-g portion of the sorbent was brought in contact with 50 ml of a Pd(II) solution ($c_{Pd^{2+}}$ = 11 mg l^{-1}) and agitated with a magnetic stirrer at the 400–500 rpm. The necessary pH values were adjusted with HCl and KOH solutions and monitored with an EV-74 pH-meter equipped with an ESL-43-07 glass electrode. The amount of sorbed Pd(II) ions was calculated from the difference of the Pd content in the solution before and after sorption. Atomic-absorption measurements were performed on a Carl Zeiss Jena AAS-1 spectrophotometer with an acetylene–air flame atomizer. The atomic absorption was recorded at 247.6 nm and monochromator slit width of 0.2 mm.

The capacity characteristics of sorbents depend on the content of functional groups, nature of an ion being recovered, and recovery conditions and may vary widely.

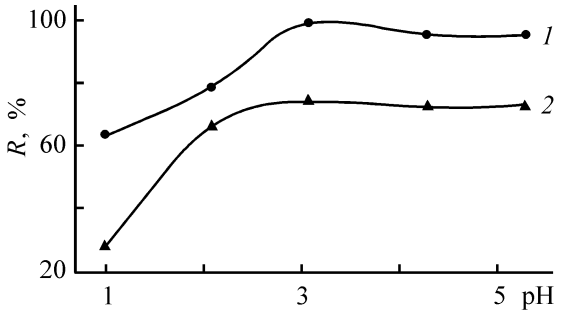
According to the results obtained in a study of the sorption of palladium(II) chloride complexes at a liquid-to-solid phase ratio (l : s) of 100–1000 [Pd(II) concentration 11 mg l^{-1}], the degree of recovery (R, %)

Table 1. Sorption of palladium(II) chloride complexes in relation to the phase ratio ($c_{Pd^{2+}}$ = 11 mg l^{-1}, 24 h)

Anion exchanger	l : s	*R*(Pd), %
Sh : PMVP	100	99
	200	61
	1000	26
Sh : PEI : GMA	100	70
	200	50
	1000	15

markedly decreases as the solution volume becomes larger (Table 1). For example, upon a tenfold increase in l : s, the sorption value decreases for anion exchangers based on Sh : PMVP and Sh : PEI : GMA by a factor of 3.8 and 4.6, respectively.

The pH value of the medium largely determines the relative amounts of various palladium(II) and makes it possible to vary the acid–base properties of the anion exchanger. Most of schemes used to determine palladium in geological and technological objects include decomposition of samples and use of chloride media, in which Pd(II) ions are present in the form of labile complex ($PdCl_4^{2-}$) and some polynuclear species. They readily interact both with various reagents in solution and with functional groups of sorbents, e.g., with nitrogen-containing groups. It has been noted [13] that stable complexes with a palladium(II)–nitrogen coordination bond are mostly formed in weakly acidic solutions. For the anion exchangers under study, the degree of recovery increases with decreasing acidity in the range pH 1–3 (Fig. 1). Presumably, this is due to Pd(II) sorption not only via anionic exchange, but also via complexation. As the pH value increases, amino groups in sorbents with ethylenediamine groups undergo deprotonation, and



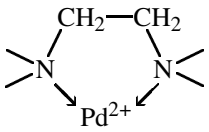


Fig. 1. Effect of the acidity of the aqueous phase on the degree of recovery of palladium(II) chloride complexes, *R*, with the anion exchangers. $c_{Pd^{2+}}$ = 11 mg l^{-1}, V_{el} = 10 ml, m_s = 0.1 g, 24 h, 0.5 M HCl, 20°C. Anion exchanger: (*1*) Sh : PMVP and (*2*) Sh : PEI : GMA; the same for Fig. 3.

the recovery will presumably occur mostly via coordination of the functional groups to metal ions. The anion exchangers mentioned above can absorb palladium(I) ions to give a chelate complex
