The easily performed basic experiment consists in that a set of kinetic curves of adsorption of an impurity is measured under static conditions. For this purpose, a number of weighed portions of the sorbent are brought in contact with portions of the feed with different concentrations of an impurity being extracted, the systems constituted by the adsorbent and the feed are kept for a necessary time, and then the samples are analyzed and the excess (Gibbs) adsorption of the impurity by the adsorbent is determined. The kinetic curves are used to plot the Gibbs adsorption isotherm.

The experience of kinetic studies of the sorption of various hydrocarbons shows that, to form the necessary minimum data file on the adsorption statics, it suffices to plot kinetic curves at two contents c_0 of the component being adsorbed, low (c_{0l}, 1–4%) and high (c_{0h}, 50–80%), with the corresponding equilibrium of adsorption values, a_l and a_h, determined. Processing of these data makes it possible to calculate the maximum adsorption value, a_{max}, at c_0 = 100%, with account of the adsorption gradient da/dc_0, and the coefficients A and B in the equation of Langmuir (full) adsorption isotherm

$$a_L = ABc_0(1 + Bc_0), \quad (1)$$

which characterizes the equilibrium adsorption of the impurity by the adsorbent. The relationship between the excess (Gibbs) adsorption a_G and full (Langmuir) adsorption is taken into account by the equation of the Gibbs adsorption isotherm in the form

$$a_G = a_L - (da/dc_0)c_0 = ABc_0/(1 + Bc_0) - (a_{max}/100)c_0. \quad (2)$$

A study of the kinetics of liquid-phase adsorption of aromatic hydrocarbons by NaX zeolites demonstrated [11] that the classical equation of adsorption kinetics [12]

$$da/d\tau = \beta(a_\infty - a). \quad (3)$$

where a_∞ is the equilibrium activity of the adsorbent; β, mass-transfer coefficient; and a, running value of the adsorbent activity after a time τ from the beginning of sorption, can be interpreted as the equation for the function of the response of a hydrodynamic model of the adsorption cell to a pulsed perturbation in the form of introduction of a portion of the feed into the cell. In this situation, the numerical value of β can be calculated as a reciprocal of the first static moment of the kinetic curve by the equation

$$\beta = 1/\int_0^\tau \tau(1 - a/a_\infty)d\tau. \quad (4)$$

In this case, β can be regarded in the conditions of liquid-phase sorption as the overall effective volume mass-transfer coefficient taking into account the diffusion resistance in macro- and micropores of the adsorbent.

Processing of kinetic curves of adsorption of certain aromatic hydrocarbons from solutions in *n*-heptane demonstrated that the thus determined value of β depends only on the physicochemical properties of the adsorbent and adsorbate, with the concentration of the component being adsorbed in the feed having virtually no effect on β (Fig. 1). This made it possible to calculate, with a minimum amount of input information, the Langmuir coefficients A and B (Table 1) and the Gibbs adsorption isotherm (Fig. 2) for the aromatic hydrocarbons studied.

To evaluate the diffusion resistance in the course of adsorption, the effective diffusion coefficient D of aromatic hydrocarbons within pores of the zeolite grains was calculated by the equation of diffusion in a finely crystalline adsorbent [14]

$$D_e = (\pi\gamma^2/4\tau)(V/S)^2. \quad (5)$$

where V and S are the volume of a zeolite grain (cm^3)

Table 1. Characteristic parameters of the adsorption kinetics

Adsorbate	Maximum activity, g g^{-1}		β, min^{-1}	Diffusion coefficient $D \times 10^8$, cm^2 s^{-1}			Constants of the Langmuir equation	
	by Gibbs	total		effective within pores		in solution		
				D_{max}	D_{min}		A, wt %	B, vol %
Benzene	0.14	0.17	0.031	281.5	31.9	4196.3	17.5	0.364
Toluene	0.25	0.285	0.029	228.9	31.9	3460.1	30.0	0.196
p-Xylene	0.196	0.225	0.025	224.5	28.4	2731.8	24.0	0.150
Isopropylbenzene	0.125	0.162	0.028	217.6	31.9	2228.9	27.0	0.586
Naphthalene	0.12	0.13	0.025	193.1	31.9	2714.5	13.2	0.774

and its outer surface area (cm^2); γ, relative adsorption found from the kinetic curve at instant of time τ (min). The diffusion coefficient D_s of aromatic hydrocarbons in a solution in *n*-heptane was calculated by the Wilke–Chang equation modified by Scheibel [15]

$$D_s = 8.2 \times 10^{-8}[1 + (3V_2/V_1)^{2/3}]T/(\mu_2 V_1^{1/3}), \quad (6)$$

where μ is the viscosity of *n*-heptane (cP): T, adsorption temperature (K); and V, molar volume of a diffusing aromatic hydrocarbon (cm^3 mol^{-1}).

The results of a calculation of the diffusion coefficients demonstrated that the dependence of the effective diffusion coefficient of aromatic hydrocarbons in zeolite grains on the adsorption time passes through a maximum in a wide range of concentrations of the aromatic hydrocarbons in the feed and durations of the adsorption process. Lower values of the diffusion coefficient D_e and, accordingly, a higher diffusion resistance in grains are reached in the final stage of the sorption process (Fig. 3). For example, the diffusion coefficient of benzene in a solution in *n*-heptane, D_s, is 42×10^{-6} cm^2 s^{-1}, i.e., is 14 times the maximum observed value of D_e, equal to 3×10^{-6} cm^2 s^{-1}, and 140 times the asymptotic values of D_e, equal to about 0.3×10^{-6} cm^2 s^{-1}. This makes it possible to consider quite correct the previous assumption that the limiting diffusion resistance is concentrated in the microporous space of sorbent grains, rather than in the flow of the feed between the grains, and to disregard diffusion phenomena in the intergrain space of the sorbent bed when developing the model of sorption dynamics.

The information basis considered enables simulation of the adsorption dynamics in a fixed sorbent bed with the use of material balance equations solved by numerical integration.

The sorption dynamics in separation of a binary mixture of, e.g., hydrocarbons with zeolites in a sorption column of height h (cm) and diameter D (cm) with an adsorbent charge G (g) at flow rate V (cm^3 min^{-1}) of the feed containing c_0 (vol %) of the adsorpate was

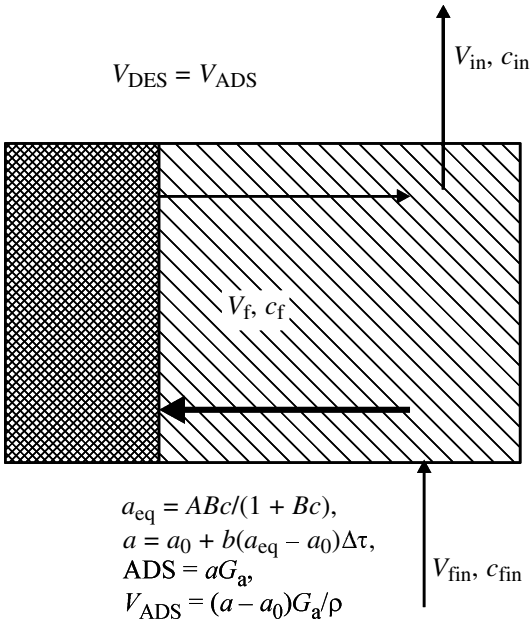

Fig. 4. Model of the adsorption cell.

calculated. As input data for the calculation served the following parameters: coefficients A (wt %) and B (vol %) of the Langmuir equation, mass-transfer coefficient β (min^{-1}), fraction of the free space in the sorbent bed with account of its porosity and specific volume of transport pores and micropores in the grains, and flow velocity w (cm min^{-1}) per total cross-section area of the column.

At the beginning of a calculation, the sorbent bed is divided along its height into N elementary cells of thickness Δh (Fig. 4). For each cell, the work of the corresponding part of the bed during a prescribed duration τ (min) of the sorption process is calculated in short intervals of time $\Delta\tau = \Delta h/w$. In view of the discrete nature of the calculation, Δh is 1 cm (several sorbent grain diameters). Commonly, the corresponding $\Delta\tau$ is in this case 0.5–2 min, which constitutes 0.2–0.5% of the time interval under study and provides that no less than 200–500 integration steps are made in calculation of each adsorption cell. The motion of the flow being purified along the column as a whole occurs in the ideal displacement mode, and that within a single cell, in the ideal mixing mode.

In the course of calculation of the adsorption process in ith cell during a time $\Delta\tau$, the following quantities are determined: (1) amount V_j of the feed that passed across the cell,

$$V_j = V_{in,j}\Delta\tau + V_f; \quad (7)$$

(2) content c_{feed} of the impurity in the feed, with account of the liquid present in the cell space free of the adsorbent, at the beginning of an adsorption event

$$c_{feed} = (V_{in,j}c_{in,j}\Delta\tau + V_f c_f)/V_j, \quad (8)$$

(3) equilibrium content a_{eq} of the adsorbed impurity in the adsorbent (equilibrium activity) by the Langmuir equation, and the running content a of the adsorbed impurity in the adsorbent (running activity), which enable calculation of the driving force of adsorption,

$$a_{eq} = ABc_0/(1 + Bc_0), \quad (9)$$

$$a = a_0 + \beta(a_{eq} - a_0)\Delta\tau, \quad (10)$$

[a_0, running content of the adsorbed impurity in the adsorbent (running activity) in the cell (wt %) at the preceding time step $\Delta\tau$ of the calculation], with the integral amount ADS of the adsorbed substance and its differential volume V_{ADS} calculated as

$$ADS = aG_a, \quad (11)$$

$$V_{ADS} = (a - a_0)G_a/\rho, \quad (12)$$

[G_a, mass of the adsorbent in the cell (g); ρ, adsorbate density (g cm^{-3})] and the gain in the sorbent activity in the cell during a time $\Delta\tau$ via transition of a part of the adsorbate from the bulk of the feed to the adsorbed state, equal to $a - a_0$; (4) content of the impurity in the feed with account of the liquid present in the cell space free of the adsorbent at the end of a sorption event

$$c_{fin,j} = (V_{in,j}c_{in,j}\Delta\tau + V_f c_f - 100V_{ADS})/V_j, \quad (13)$$

[$V_{in,j}$, $c_{in,j}$, the flow rate of the feed (cm^3 min^{-1}) and the content of the impurity in the feed (vol %) at the inlet into the cell being calculated; V_f, c_f, volume of the liquid filling the cell (cm^3) and content of the impurity in the liquid (vol %), $c_f = c_{fin,j}$ obtained in the preceding stage of cell calculation]; and (5) amount of liquid leaving the cell during the time $\Delta\tau$.

The calculation of the ith sorption cell during the whole time τ of the sorption process yields an array of the final amounts of the liquid and the contents of the impurity in the liquid at the cell outlet at small intervals of time, $\Delta\tau$. The subsequent readdress of the array of the final values of the parameters of the ith cell (flow rate of the liquid and the content of the component being adsorbed in the liquid) to the array of initial values of the corresponding parameters of $(i + 1)$st cell, which are distributed over the process duration τ, enables a calculation by the above al-

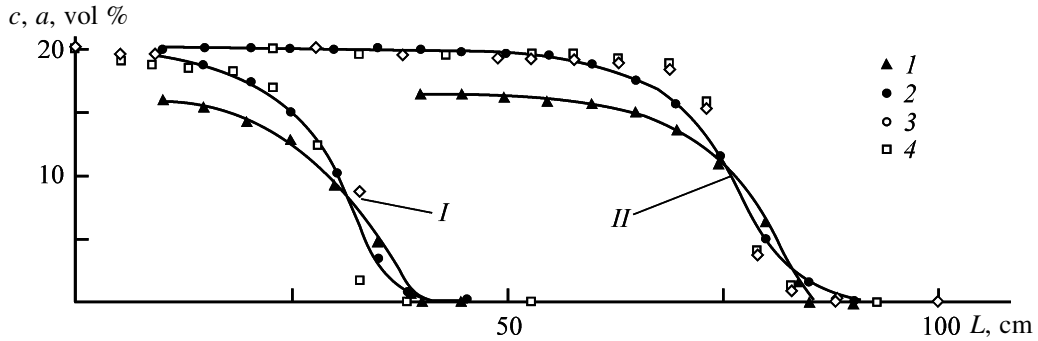

Fig. 5. Variation of the benzene content c of the flow and of the adsorbent activity a along the height L of the NaX zeolite bed, with the adsorption front recorded at (*I*) 61 and (*II*) 164 min in separation of a mixture of benzene and *n*-heptane. gorithm for the $(i + 1)$st cell. Calculations for all the cells of the adsorption column are performed similarly.

In the calculation of the sorption dynamics, three problems are successively solved for each cell in the course of the contact between the feed and the adsorbent, in addition to the calculation of the sorption: (1) filling of a cell with the feed (in the middle and end parts of the bed, cells are filled with the product purified to remove the impurity in the preceding cells); (2) exit of the first portion of the product being purified from a completely filled cell; and (3) steady flow out of the cell of the product being purified, considered on the assumption that the volume of the impurity adsorbed during time $\Delta\tau$ is equal to that of the purified product desorbed from the adsorbent, which is displaced from the adsorbent in an adsorption event and previously filled vacant places at adsorbate-free active centers of the zeolite.

The model developed forms the breakthrough curve of the adsorption process, adsorption isoplane, which is used to calculate the dynamic activity of the adsorbent to a conditional breakthrough into the raffinate of the impurity being extracted and the total dynamic activity of the adsorbent. The model also gives the concentration profile of the impurity being extracted and the curve of variation of the adsorbent activity across the adsorbent bed (along its height) for any process duration.

The obtained information about the concentration profile of the impurity being recovered along the height of the adsorbent bed makes it also possible to calculate the height of the working bed of the adsorbent (length of the mass-transfer zone) in processes with a moving adsorbent bed.

Owing to the simplicity of the model of adsorption dynamics, developed in this study, the problem can be solved with a computer to a full extent in only 2–3 min, despite the large number of the adsorption cells studied.

Thus, the model developed enables calculation of all the necessary characteristics of the adsorption dynamics.

In the experimental part of the study, dynamic characteristics of the liquid-phase adsorption of benzene with NaX zeolites from solutions in *n*-heptane were obtained in addition to the experiments on adsorption kinetics, considered above, and then the experimental data were compared with the results of calculations of the adsorption dynamics in terms of the model.

The adsorption of benzene under dynamic conditions was studied on a laboratory column of diameter 28 mm and zeolite bed height of 1010 mm (adsorbent charge ~420 g), in which it was possible, in addition to raffinate discharge from the upper level of the zeolite bed, to sample the liquid along the adsorbent bed height. This made it possible to determine, from the results obtained in analysis of the samples, how the content of benzene varies along the height of the adsorbent bed and find experimentally the length of the mass-transfer zone. The sampling system comprised 19 syringes mounted at intervals of 4–5 cm along the zeolite bed height and made it possible to take (virtually simultaneously, in the course of 15–20 s) 1 cm^3 samples from the axial zone of the column. The calculated length L_0 of the mass-transfer zone was found using the equation [16]

$$L_0 = L\frac{a_E - a_B}{a_E - (1 - f)a_B}, \qquad (14)$$

where a_E and a_B are, respectively, the total dynamic activity of the adsorbent and the dynamic activity of the adsorbent till conditional breakthrough of benzene

into the raffinate (wt %); L, length of the adsorbent bed (cm); and f, symmetry factor of the breakthrough curve (adsorption isoplane).

The mass-transfer coefficient β and the constants A and B of the Langmuir equation, which are necessary for simulation of the process, were obtained in a study of the adsorption kinetics with ~2-g weighed portions of the zeolite, which were brought in contact with 10 cm^3 of the feed for 2–240 min (Table 1).

The results obtained in simulation of the adsorption of benzene from a solution in *n*-heptane demonstrated that the method for calculation of the sorption dynamics, developed in this study, makes it possibly to satisfactorily determine, both qualitatively and quantitatively, the position of the adsorption front in the adsorbent bed (Fig. 5) and the breakthrough curve (Fig. 6), as well as the basic characteristics of the adsorption process: activity of the adsorbent till conditional breakthrough of benzene into the raffinate, total dynamic activity of the adsorbent, and the length of the mass-transfer zone (Table 2). The inevitable minor discrepancies between the calculated and experimental data are due, in the case in question, to the neglect of the effect of the discrete sample volumes on the overall characteristics of the process, perturbation of the operation mode in the regeneration and adsorption stages of the process, errors of analysis, and a number of other factors.

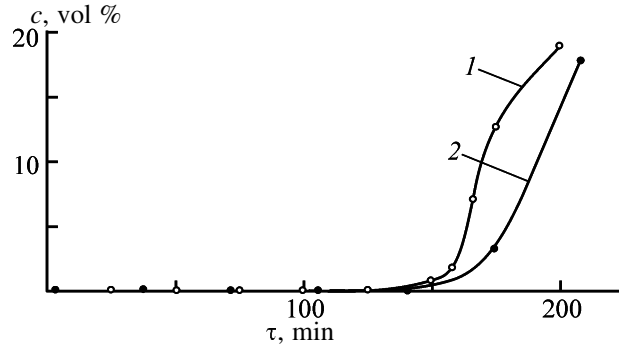

Fig. 6. Benzene content c of the raffinate vs. the elution duration τ at a feed flow velocity of 0.286 cm min^{-1} in separation of the benzene–*n*-heptane mixture with NaX zeolites. Zeolite activation temperature 300°C, zeolite bed height 1010 mm. (*1*) Experiment [19] and (*2*) calculation in terms of the model.

The adequacy of solution of the problem in hand in terms of the model developed was objectively assessed using the Fisher test [17]

$$F = S_{res}^2/S_r^2 = \frac{[\sum_M (y_{exp} - y_{calc})^2]/M}{[\sum_N (y_{exp} - y_{av})^2]/(N - 1)}, \qquad (15)$$

where S_{res}^2 and S_r^2 are, respectively the residual variance and variance of reproducibility; M and N, the number of parallel and independent experiments, respectively; and y_{exp}, y_{av}, and y_{calc}, the values of the parameters tested for adequacy: experimental, average over a set of parallel experiments, and calculated in terms of the model.

As follows from the results of adequacy assessment, calculation by the suggested mathematical

model of the adsorbent activity a_B till conditional breakthrough of benzene into the raffinate, total dynamic activity a_E of the adsorbent, and length L_0 of the mass-transfer zone is adequate with the probability of erroneously taking the hypothesis that the model is adequate equal to 0.05. The tabulated value of the Fisher test, equal to 234 [18], markedly exceeds the calculated values of the test for the parameters a_E, a_B, and L_0, which are 4.67, 166.6, and 13.8, respectively.

CONCLUSIONS

(1) A method for calculation of the dynamics of adsorption of hydrocarbons from solutions with zeolites was developed on the basis of a minimum amount of experimental data on the adsorption kinetics.

(2) An algorithm of simulation of the adsorption dynamics in a fixed sorbent bed was implemented on the basis of material balance equations solved by numerical integration.

(3) The model developed forms the output curve of the adsorption process, adsorption isoplane, which makes it possible to calculate the dynamic activity of the adsorbent till conditional breakthrough into the raffinate of the impurity being extracted, total dynamic activity of the adsorbent, and length of the mass-transfer zone.

(4) The adequacy of the results of calculations in terms of the model developed to the data obtained in control experiments on the dynamics of liquid-phase adsorption was confirmed.

(5) The method suggested for calculation of the adsorption dynamics is acceptable for rough prediction of the parameters of sorption dynamics.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Improved Synthesis of 2-Amino-1,2,4-triazolo[1,5-*a*]pyrimidines

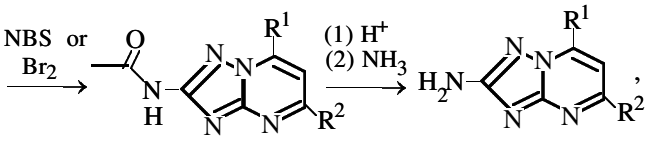
Abstract—An improved procedure is suggested for preparing 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines from 3,5-diamino-1,2,4-triazole and unsaturated aromatic ketones, with acetyl protection of the amino group in the step of oxidation of 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines.



DOI: 10.1134/S1070427206070172

2-Amino-1,2,4-triazolo[1,5-*a*]pyrimidines exhibit a broad spectrum of biological activity and can be used as analgetics [1], blood pressure regulators [2], antibacterial agents [3], and herbicides [4, 5]. The presence of a reactive amino group makes these compounds valuable building blocks in syntheses of biologically active compounds [6, 7].

One of the most convenient routes to 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines is the cyclocondensation of 3,5-diamino-1,2,4-triazole **I** with α,β-unsaturated ketones [1, 7–11] followed by heteroaromatization of the resulting 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines with bromine or *N*-bromosuccinimide (NBS) [11, 12]. An advantage of this route, compared to other methods for forming triazolopyrimidine core, is high regioselectivity and availability of the starting compounds [8, 9]. However, an experimental check showed that the oxidation of the dihydro derivatives is accompanied by formation of a large amount of impurities (presumably azo derivatives), probably because of side oxidation of the amino group. Separation of these impurities involves major loss of the desired 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines, so that their yield does not exceed 25–30%. We believe that this procedure can be improved by acetyl protection of the amino group in the oxidation step. This possibility was examined in the present study with a series of 2-amino-1,2,4-triazolo[1,5-*a*]-pyrimidines:

I **II–VIII**

IX–XV **XVI–XXII**

where R^1 = Ph, R^2 = Me (**II**, **IX**, **XVI**); R^1 = *p*-Cl·C_6H_4, R^2 = Ph (**III**, **X**, **XVII**); R^1 = Ph, R^2 = *p*-Cl·C_6H_4 (**IV**, **XI**, **XVIII**); R^1 = *p*-MeC_6H_4, R^2 = Ph (**V**, **XII**, **XIX**); R^1 = Ph, R^2 = *p*-MeC_6H_4 (**VI**, **XIII**, **XX**); R^1 = *p*-$MeOC_6H_4$, R^2 = Ph (**VII**, **XIV**, **XXI**); R^1 = R^2 = *p*-MeC_6H_4 (**VIII**, **XV**, **XXII**).

The first step of the suggested scheme involves the condensation of diamine **I** with unsaturated ketones to obtain 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]-pyrimidines. Since it was difficult to isolate and purify the majority of the dihydro derivatives because of their high solubility, acetyl derivatives **II**–**VIII** were prepared by adding acetic anhydride to the reaction mixture after the condensation completion. The yield of **II**–**VIII** in the one-pot process was 52–90% (see table). These compounds were not described previously and were identified by elemental analysis, ^{1}H NMR spectroscopy, and mass spectrometry.

2-Acetylamino-1,2,4-triazolo[1,5-*a*]pyrimidines **IX**–**XV** were obtained in 84–95% yields (see table) by oxidation of **II**–**VIII** with *N*-bromosuccinimide in ethanol at 50–60°C or with bromine in acetic acid at 15–20°C. In this step, it is very important to maintain the required temperature and reactant ratio. Performing the oxidation at higher temperatures or with excess oxidant results in formation of difficult-to-separate impurities identified by mass spectrometry as brominated derivatives of **IX**–**XV**. Acid hydrolysis of acetyl derivatives **IX**–**XV** gave the desired 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines **XVI**–**XXII** in almost quan-

titative yield (see table). The overall yield of **XVI**–**XXII** based on **I** was 40–70%. Compounds **IX**–**XXII** were identified by elemental analysis, ^{1}H NMR spectroscopy, and mass spectrometry (see table).

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Varian Unity-300 spectrometer (300 MHz, DMSO-d_6, internal reference TMS). The mass spectra were taken on a Finnigan LCQ Deca XP MAX device in the electrospray mode with positive polarization at direct inlet of 0.5 mg ml^{-1} solutions of the compounds in acetonitrile. Elemental analysis was performed with a Perkin–Elmer 2400 analyzer. The melting points were determined by the capillary method with a PTP device.

2-Acetylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]-pyrimidines II–VIII. A mixture of 1 g (0.01 mol) of **I**, 0.01 mol of appropriate unsaturated ketone, and 4 ml of anhydrous DMF was refluxed for 20 min, after which 1.39 g (0.0136 mol) of Ac_2O was added, and the mixture was refluxed for an additional 3 min. Then the mixture was cooled, 4 ml of acetonitrile was added, and the precipitate of the target product was filtered off and washed with 20 ml of acetone. Compounds **II**–**VIII** were purified by twofold refluxing with 5 ml of acetonitrile.

2-Acetylamino-1,2,4-triazolo[1,5-*a*]pyrimidines IX–XV. (a) To a stirred mixture of 0.003 mol of acetyl derivative **III**–**VIII** and 0.27 g (0.0044 mol) of sodium acetate in 20 ml of ethanol, 0.52 g (0.003 mol) of *N*-bromosuccinimide was added in 0.1-g portions over a period of 10 min at 50–60°C. Then the mixture was refluxed for 15 min and diluted with 15–20 ml of water; the precipitate was filtered off, washed with 20 ml of water, and crystallized from DMF–ethanol (1 : 3).

(b) To a solution of 0.003 mol of **II**, **IV**, **VII**, or **VIII** and 0.27 g (0.0044 mol) of sodium acetate in 10–15 ml of acetic acid, 0.48 g (0.003 mol) of Br_2 was added dropwise over a period of 5 min at 15–20°C. The solution was stirred for 30 min and diluted with 15–20 ml of water. The precipitate was filtered off, washed with water (20 ml), and crystallized from DMF–ethanol (1 : 3).

2-Amino-1,2,4-triazolo[1,5-*a*]pyrimidines XVI–XXII. Concentrated HCl (1 ml) was added to a suspension of 0.0014 mol of **IX**–**XV** in 10 ml of ethanol; the mixture was refluxed for 40 min, the solvent was distilled off, and the residue was neutralized with aqueous NH_3 to pH 6–8. The precipitate was filtered off and crystallized from DMF–ethanol, 1 : 3.

CONCLUSIONS

(1) Successive reactions of 3,5-diamino-1.2.4-triazole with α,β-unsaturated aromatic ketones and acetic anhydride allow one-pot synthesis of 2-acetylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines in 52–90% yield.

(2) The acetyl protection of the amino group in 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines in the step of their oxidation with *N*-bromosuccinimide or bromine prevents oxidation of the amino group and allows the overall yield of 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines to be increased to 40–70% based on 3,5-diamino-1,2,4-triazole.

Abstract—The melting points of the polyethylene glycol–$NaBPh_4$ system synthesized in ethanol were determined by optical microscopy. The influence of the molecular weight of polyethylene glycol on the phase formation in the system was studied.

DOI: 10.1134/S1070427206070184

Molecular complexes of alkali and alkaline-earth metal salts with nonionic polymers containing heteroatoms are known to be ion-conducting materials [1, 2].

A wide variety of problems concerning the influence of various factors, such as flexibility of macromolecules, nature of heteroatoms in polymers, and type of cations and ions constituting the low-molecular-weight salts, on the ionic conductivity and structure of the complexes was considered previously [3]. At the same time, the effect exerted by the nature of the medium on the composition, morphology, and structure of complexes is as yet insufficiently studied.

In the previous studies, the possibility of formation of various complexes was demonstrated for the system polyethylene glycol (PEG)–sodium tetraphenylborate in organic solvents. The composition and structure of solid complexes formed in the solvent and their change upon solvent removal remain unclear.

At the same time, a study of the composition and structure of solid complexes and the features of their formation in organic solvents of different nature is of great significance for the development of processes for preparation of individual complexes or their mixtures.

In this connection, the features of formation of polyethylene glycol complexes in protonic solvents of linear and branched structure were studied previously by optical microscopy and X-ray diffraction analysis. The results obtained confirmed the formation of several complexes in the above media [4, 5]. It was established in these studies that the number of the formed complexes decreases as the structure of alcohol becomes more complex, i.e., in going from linear to branched alcohols. However, the effect exerted by the molecular weight of the polymer on the structure of complexes composed of polyethylene glycol and sodium tetraphenylborate was not considered.

In this study we examined how the length of the PEG macromolecule chain affects the composition and structure of the PEG–sodium teraphenylborate complexes formed in ethanol. Taking the PEG–$NaBPh_4$ system as example, we studied the features of the interaction of alkali metal salts with the polyether of a varied molecular weight (MW).

EXPERIMENTAL

Sodium tetraphenylborate $NaB(C_6H_5)_4$ (analytically pure grade) was used in the study after additional drying. Polyehtylene glycols with molecular weights (MWs) of 2000, 4000, 15000, 40000, and 100000 (Schuchardt, Germany) were used after drying in a rough vacuum. Ethanol was purified by the method described in [6].

The complexes were synthesized by mixing solutions of individual components under the standard conditions. The solvent was evaporated in a vacuum

at room temperature. Then, samples were kept in a vacuum at 30–35°C for several days to remove the residual solvent (to constant weight).

The melting points of the starting components and their molecular complexes were determined on a Boëtius optical microscope (Rapido, Germany) at ×16 magnification.

It was found previously that complexes constituted by PEG and alkali metal salt, synthesized in different media, have essentially different properties [4]. To ascertain the influence of the molecular weight of polyethylene glycol on the morphology and structure of the solid complexes, we continued a study of the PEG–salt system.

In this study we considered the phase state of the products formed by the interaction of PEG (MW 2000, 4000, 15000, 40000, and 100000) with $NaB(C_6H_5)_4$.

The phase diagram constructed from data on the melting points of the PEG (MW = 2000)–$NaBPh_4$ complexes is shown in Fig. 1. The melting points, T_m, of the formed molecular complexes strongly differ from those of the starting components, which confirms formation of new complex compounds. The constructed phase diagram has three distectic points at ratios of 6 : 1 (T_m = 513 K), 3 : 1 (T_m = 473 K), and 1 : 3 (T_m = 423 K) and two peritectic points at ratios of 15 : 1 (T_m = 323 K) and 8 : 1 (T_m = 396 K). The eutectic points are identified at ratios of 30 : 1 (T_m = 318 K), 4 : 1 (T_m = 423 K), 1 : 2 (T_m = 418 K), and 1 : 5 (T_m = 403 K). The liquidus curves and the solidus lines divide the phase diagram into 14 regions. The melting point of PEG is 326 K.

The first eutectic E_1 with a melting point of 318 K was observed in the PEG–$NaBPh_4$ system at a ratio of 30 : 1, i.e., in the region of high polymer : salt ratios. Region *1* above the liquidus curve corresponds to a liquid phase, i.e., a melt. The melting point of the solid complexes increases from the point E_1 to the peritectic point P_1, at which the complex of composition 15 : 1 melts incongruently. At a ratio of 10 : 1, the melting point increases along the liquidus curve, and the second peritectic point P_2 with T_m = 396 K is identified at a ratio of 8 : 1. Crystals of the molecular complex of the composition 15 : 1 are separated from P_1 to P_2. At ratios of 7 : 1 to 1 : 1, a part of the product in the PEG–$NaBPh_4$ system melts, whereas another its part starts melting at a higher temperature. In this case, two distectic points are observed: M_1 is observed at a ratio of 6 : 1 (T_m = 513 K) and M_2, at 3 : 1 (T_m = 473 K). The points below the main liquidus curve correspond to the melting point of a molecular complex

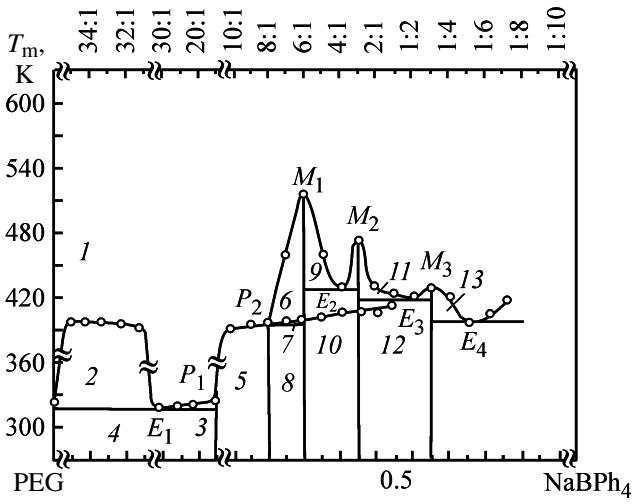

Fig. 1. Phase diagram of the system PEG (MW 2000)–$NaBPh_4$ prepared in ethanol. (T_m) Melting point; the same for Figs. 2–5. Points: (M_1, M_2, M_3) distectic, (P_1, P_2) peritectic, and (E_1, E_2, E_3, E_4) eutectic. The component ratio is indicated along the upper abscissa. Italic figures denote regions of the phase diagram; the same for Figs. 2–5.

of the composition 8 : 1. In this region (*4*), the liquid coexists with crystals of the molecular complex MC_1. The second melting points are observed above the indicated melting points. This confirms two morphologies of one newly formed complex. In region *6* below the $P_2M_1E_2$ curve, the liquid phase coexists with MC_1 crystals.

The crystals of MC_1 are separated along the M_1E_2 curve at the point E_2 at which three phases, liquid + crystals of MC_1 complex + crystals of MC_2 complex, coexist. At point M_2, the complex MC_2 melts. Region *12* below the solidus line constructed through the point E_3 includes two solid phases, which are crystals of MC_2 and MC_3 complexes.

At the 1 : 3 composition (T_m = 423 K), the third distectic point is identified. The liquid phase coexists with the crystalline phase of the MC_3 complex below the M_3E_4 curve. The obtained distectic points show that three stable complexes are formed in the PEG (MW 2000)–$NaBPh_4$ system: MC_1 complex with the 6 : 1 composition (T_m = 513 K), MC_2 complex with the 3 : 1 composition (T_m = 473 K), and MC_3 complex with the 1 : 3 composition (T_m = 423 K). Starting with the 1 : 8 composition, the interaction product does not transform into the liquid state, i.e., it does not melt. At higher temperatures, the complexes obtained become dark. This means that the molecular complexes formed in this region are carbonized. The high melting points of the solid complexes belong to the continuous highly ordered double-helix regions,

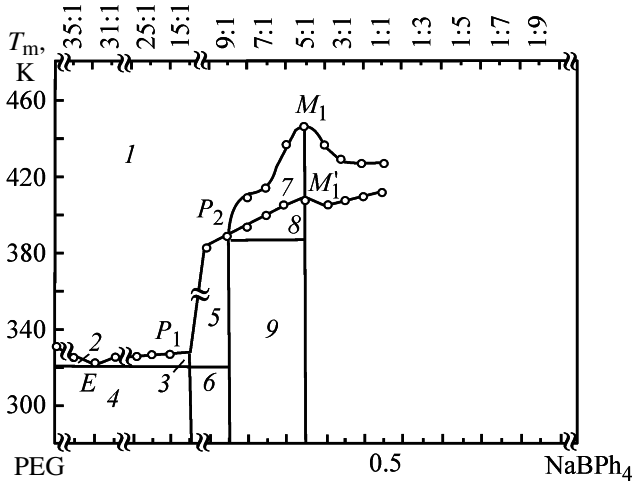

Fig. 2. Phase diagram of the PEG (MW 4000)–$NaBPh_4$ system. Points: (M_1, M_2) distectic, (P_1, P_2) peritectic, and (E) eutectic.

whereas their low values, to a defective disordered structure [3].

The results of this study show that the 6 : 1, 3 : 1, and 1 : 3 complexes are formed in the PEG (MW 2000)–$NaBPh_4$ system in ethanol.

For further studies we synthesized solid complexes in the PEG (MW 4000)–$NaBPh_4$ system. The phase diagram has one eutectic point, two peritectic points, and two distectic points (Fig. 2). The peritectic point P_1 (T_m = 328 K) is observed at a component ratio of 15 : 1 and the peritectic point P_2 (T_m = 388 K), at 9 : 1. The distectic points M_1 (T_m = 443 K) and M'_1 (T_m = 408 K) are identified at a ratio of 5 : 1. At a ratio of 33 : 1, the eutectic point E (T_m = 323 K) is observed.

The complexes formed by PEG with MW = 15000 have 2 : 1 and 7 : 1 compositions (Fig. 3). The phase diagram has two distectic points, M_1 (T_m = 533 K) and M'_1 (T_m = 473 K), at the same molar ratio of 2 : 1, two peritectic points at ratios of 15 : 1 (T_m = 323 K) and 7 : 1 (T_m = 413 K), and two eutectic points at ratios of 20 : 1 (T_m = 318 K) and 1 : 10 (T_m = 508 K).

In the phase diagram of the PEG (MW 40000)–$NaBPh_4$ system prepared in ethanol, the complexes of compositions 9 : 1, 8 : 1, and 2 : 1 were identified (Fig. 4). The peritectic points exist at component ratios of 9 : 1 (T_m = 368 K) and 8 : 1 (T_m = 453 K), the distectic points, at 2 : 1 (T_m = 468 and 558 K), and the eutectic points, at 30 : 1 (T_m = 321 K) and 1 : 2 (T_m = 543 K).

The existence of the distectic points M_1 and M'_1 at the same initial molar ratios (Figs. 2–4) shows that structures formed in these systems are polymorphous, i.e., they have the different morphologies at the same initial ratios of the interacting components.

According to the phase diagram (Fig. 5), the molecular complexes formed in the systems composed of polyethylene glycol with MW 100000 have 8 : 1 and 2 : 1 compositions.

The eutectic points are observed at ratios of 35 : 1 (T_m = 318 K) and 7 : 1 (T_m = 473 K); the distectic points, at 2 : 1 (T_m = 498 K) and 8 : 1 (T_m = 493 K), and the peritectic point, at 15 : 1 (T_m = 383 K).

The complexation involving PEG with MW 100000 differs from that involving polyethers of other

MWs in that no polymorphism is observed.

The eutectic, peritectic, and distectic points for complexes involving polyethylene glycol of varied molecular weight and sodium tetraphenylborate are given in the table.

The eutectic points E_1 are identified from 318 to 323 K, and points E_2 are identified at various compositions with T_m from 423 to 508 K. At the same time, for complexes with MW 4000 this eutectic point was not revealed. The points E_3 and E_4 were determined for the complex with MW 2000 at T_m 418 and 403 K, respectively, whereas in the other cases these points do not exist.

For complexes composed of PEG with MW 2000, 4000, 15000, and 100000, the peritectic points P_1 are identified at a ratio of 15 : 1, and for those composed of PEG with MW 40000, at 9 : 1. The melting points of the complexes lie from 323 to 383 K, with the melting point of the PEG (MW 100000) complex being the highest (T_m = 383 K).

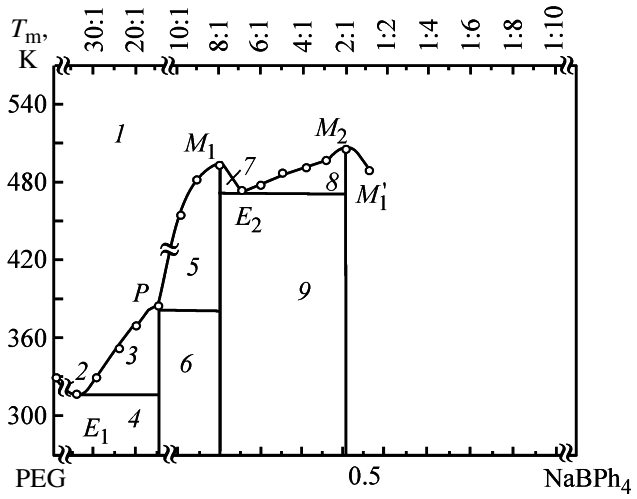

Fig. 5. Phase diagram of the PEG (MW 100000)–$NaBPh_4$ system. Points: (M_1, M_2) distectic, (P) peritectic, and (E_1, E_2) eutectic.

For complexes with MW 2000, 4000, 15000, and 40000, the peritectic points P_2 are identified at T_m 396, 388, 413, and 453 K, respectively, whereas for complexes with MW 100000 the point P_2 was not identified.

The distectic points M_1 for PEG complexes differing in the MW are observed at T_m from 443 to 513 K. The points M'_1 are found for the PEG systems (MW 4000, 15000, and 40000) at T_m 408, 473, and 468 K, respectively. For complexes with MW 2000 and 100000, the points M_2 were determined at T_m 473 and 498 K. The point M_3 is identified only for complexes with MW 2000 at T_m = 423 K. In the remaining cases, it is not identified. This shows that, as the MW of the polymer decreases, the number of molecular complexes increases. Probably, the different compositions and melting points of the complexes are due to the change in the polymer molecular weight and transformation of the structure of the complex.

CONCLUSIONS

(1) The phase diagrams of the systems consisting of polyethylene glycol of varied molecular weight and sodium tetraphenylborate, prepared in ethyl alcohol, differ considerably in eutectic, peritectic, and distectic points.

(2) Results obtained in studying the polyethylene glycol–$NaBPh_4$ complexes synthesized using polyethylene glycol with a varied length of macromole-

cules show that the molecular weight of the polymer affects the formation of new complex compounds significantly differing in the structure, composition, and morphology.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Modified *N*-Vinylpyrrolidone–Crotonic Acid–*p*-Nitrophenyl Crotonate Terpolymer

M. V. Solovskii

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received March 2, 2006

Abstract—Aminolysis of *N*-vinylpyrrolidone–crotonic acid–*p*-nitrophenyl crotonate terpolymers with 2-hydroxyethylamine and 3-hydroxypropylamine in dimethyl sulfoxide at 25°C was studied by UV spectroscopy. The factors affecting the aminolysis kinetics were determined. Preparative synthesis of the aminolysis products in dimethyl sulfoxide was performed and the composition of the aminolysis products was determined.

DOI: 10.1134/S1070427206070196

Previously [1], we prepared by reactions in the polymeric chains a reactive terpolymer of *N*-vinylpyrrolidone VP, an unsaturated carboxylic acid (acrylic, methacrylic, crotonic), and its *N*-nitrophenyl ester. The kinetics of aminolysis of these terpolymers with *n*-butylamine and *tert*-butylamine was studied. It was found that these terpolymers react with organic compounds containing sterically unhindered primary aliphatic amino group.

Proceeding with these studies, I examined aminolysis of VP–crotonic acid (CA)–*p*-nitrophenyl crotonate (NPC) terpolymers (**I**) with 2-hydroxyethylamine (HEA) and 3-hydroxypropylamine (HPA) with the aim to prepare VP copolymers containing reactive carboxy and primary hydroxy groups. These copolymers can be used to modify some biologically active compounds (BACs) and to prepare hydrophilic polymers with polyfunctional biological activity.

The choice of copolymers **I** is caused by the fact that they are prepared from water-soluble nontoxic *N*-vinylpyrrolidone–crotonic acid copolymers which have low molecular weight and narrow MWD and do not contain blocks of the reactive units [2]. These physicochemical and biological properties are required for a hydrophilic synthetic bionondegradable polymer to be used as a BAC carrier.

Copolymers **Ia**–**Ie** were prepared by condensation of BP–CA copolymers with pnitrophenol (NP) in DMF in the presence of *N,N'*-dicyclohexylcarbodiimide as a dehydrating agent. The composition of copolymers **I** was determined by UV spectroscopy in DMSO using the absorption band of bound *p*-NP at 274 nm (ε = 9500 l mol^{-1}, calibrated against *p*-nitrophenyl acetate). The UV spectra were recorded on an SF-46 spectrometer in a 1-cm cell. The IR spectra of the target terpolymers **II** were recorded in KBr pellets on a Bruker JFS spectrometer.

The kinetics of aminolysis of terpolymers **I** with amino alcohols in DMSO was studied by UV spectroscopy in 0.2-cm cells temperature-controlled at 25°C. The time dependence of the relative decrease in the intensity of the absorption band at 274 nm was determined [3]. The initial concentration of the *p*-nitrophenoxy groups (ONP) in the solution was constant (9.2×10^{-4} M) in all the experimnets. The ($-NH_2$) : (–ONP) molar ratio *n* was varied in a wide range. After reaction completion, concentrated ammonium hydroxide solution (20 μl) was added into the cell and the optical density corresponding to 100% aminolysis was measured in 24 h. The average half-conversion time $\tau_{1/2}$ in the examined reaction was determined from the results of 2–3 experiments. The determination error of $\tau_{1/2}$ was no higher than 5%.

Preparative synthesis of copolymers **II** was performed in DMSO at room temperature, initial concentration of terpolymer **I** of 0.85 M, and *n* = 20 or 40 for 6 h. Terpolymers **II** were isolated by precipitation with diethyl ether and purified by dialysis against water. In the course of dialysis, the unchanged –ONP groups of terpolymers **I** were hydrolyzed to carboxylate groups. To convert the carboxylate groups of copolymers **II** into the carboxy groups, aqueous solutions of terpolymers **II** were passed through a column packed with KU-2 cation exchnager in the H^+ form. The composition of terpolymers **II** was calculated from the content of their OH groups, determined by

** Q is the degree of substitution of –ONP groups of terpolymers **I** by –NH–$(CH_2)_x$–OH groups.

acetylation [4]. The amino alcohols were purified by vacuum distillation, and DMF and DMSO, by the standard procedures [5].

The respesentative curves of aminolysis of terpolymers **I** with amino alcohols are shown in Fig. 1. As seen from Fig. 1, aminolysis of VP–CA–NPC terpolymer at n = 50 and 25°C is fast. The aminolysis rate estimated from the half-conversion time $\tau_{1/2}$ appreciably increases in going from 2-HEA ($\tau_{1/2}$ = 6.2± 0.2 min) to more nucleophilic 3-HPA ($\tau_{1/2}$ = 3.3± 0.1 min). As the molar ratio of the reacting groups increases, the half-conversion time in the examined reaction decreases (the aminolysis rate increases) in proportion to n (Fig. 2). Based on the kinetic data, we suggest that the examined reaction can be described by the following scheme:

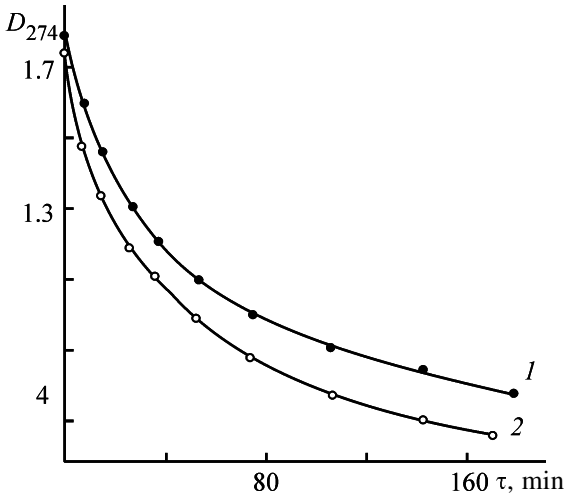

Fig. 1. Aminolysis of VP–CA–NPC terpolymer **Ic** with (*1*) 3-hydroxypropylamine and (*2*) 2-hydroxyethylamine in DMSO at 25°C and n = 50. (D_{274}) Optical density of the terpolymer solution at 274 nm and (τ) reaction time.

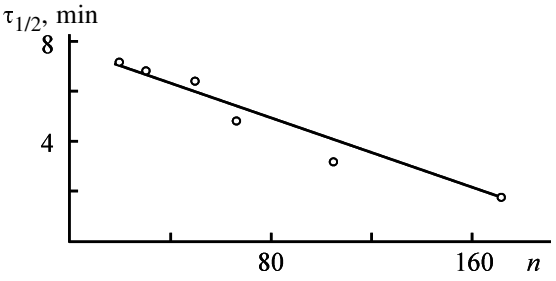

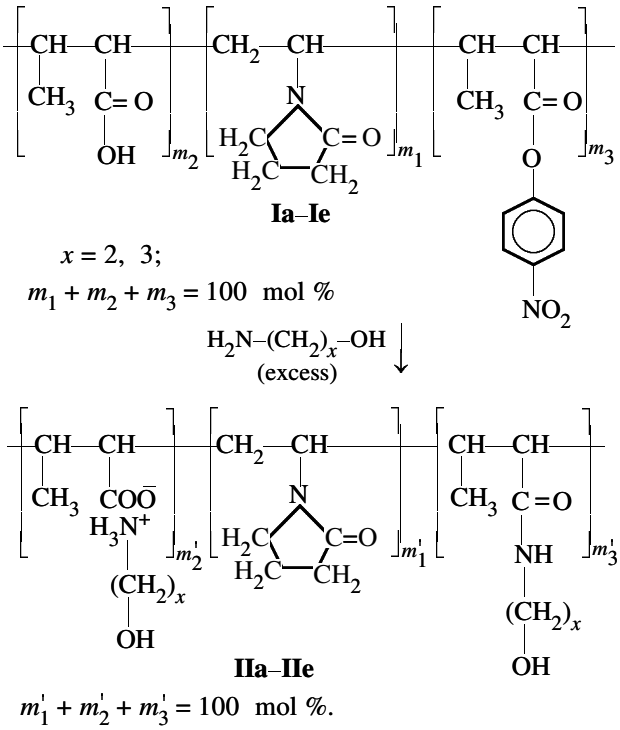

Fig. 2. Half-conversion time $\tau_{1/2}$ in aminolysis of terpolymer **Ic** with 2-hydroxyethylamine as a function of the molar ratio of the reacting groups n.

The results of the preparative synthesis of terpolymers **Ia**–**Ie** are presented in the table. As seen from the table, the degree of substitution Q of recative –ONP groups of terpolymers **I** with –NH–$(CH_2)_x$–OH groups under the examined conditions is as high as 90.6–94.3%. The content of hydroxy and carboxy

groups in the resulting water-soluble terpolymers **II** is up to 21.5 and 29.0 mol %. The IR spectra of terpolymers **II** contain the bands of stretching vibrations of the hydroxy group at 3430 cm^{-1}, which is absent in the IR spectra of the initial copolymers **I**. The strong band of bound *p*-NP at 274 nm, present in the UV spectra of terpolymers **I**, is absent in the UV spectra of the aminolysis products **II** in DMSO.

CONCLUSIONS

(1) The rate of aminolysis of *N*-vinylpyrrolidone–crotonic acid–*p*-nitrophenyl crotonate terpolymers in dimethyl sulfoxide depends on the chemical nature of the amino alcohol (the rate for 3-hydroxypropylamine is higher than that for 2-hydroxyethylamine) and increases with increasing the $[-NH_2] : [-ONP]$ molar ratio in the solution.

(2) The conditions of preparative synthesis of low-molecular-weight *N*-vinylpyrrolidone terpolymers containing 12.2–21.5 mol % hydroxy and 9.4–29.0 mol % carboxy groups were determined. These terpolymers can be used as supports for some biologically active compounds.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Kinetics of Flocculation and Thickening of Precipitates of Bentonitic Clay Suspension in the Presence of Acrylamide Copolymers in Aqueous Salt Solutions

V. E. Proskurina, M. N. Akopyan, and V. A. Myagchenkov

Received February 1, 2006

Abstract—The kinetics of hindered sedimentation and thickening of the sediments of a real disperse system (bentonitic clay suspension) was studied. The flocculation parameters of acrylamide copolymers in aqueous and aqueous salt solutions were evaluated in relation to the chemical nature and concentration of flocculants and electrolytes.

DOI: 10.1134/S1070427206070202

The question of how to enhance efficiency of polymeric flocculants was analyzed in many studies dealing with the flocculation mechanism or with application of flocculants to solution of various technological problems such as intensification of sedimentation, filtration, and dehydration of sludge in coal-preparation and ore-dressing, selective separation of mineral components, treatment of natural and waste waters to remove dispersed pollutants, and concentration and recovery of biomass [1]. Domestic industry produces rather broad assortment of water-soluble polymeric flocculants, among which polyacrylamide flocculants (PAAFs) occupy the key position as regards both the application area and production volume. It should be noted that the flocculation power of PAAFs depends on various factors: chemical nature of alternating units and composition of copolymer macromolecules, flocculant concentration, and combination of chemical, physicochemical, and physical properties of the disperse phase particles (such as specific surface area, concentration of localized adsorption centers, lyophilic properties of the surface) and dispersion medium (pH, nature and concentration of electrolytes, surfactants, etc.). Main theoretical concepts and technological principles of flocculation for predominantly model disperse systems (DSs) are summarized in reviews [1–4].

Proceeding with systematic studies aimed to enhance the effectiveness of water-soluble ionic and nonionic PAAFs, we quantitatively evaluated the effect of the ionic strength and nature of three inorganic electrolytes on the sedimentation kinetics and flocculation parameters of acrylamide copolymers in the mode of hindered sedimentation and thickening of the precipitates of a real DS (bentonitic clay suspension). It should be noted that the kinetic data on the relationship between flocculation and thickening of the precipitates are scarce.

EXPERIMENTAL

We used a multicomponent real DS (Bentokam bentonitic clay suspension [TU (Technical Specifications) 39-0147001-105–93]) with an average particle radius $\bar{R} = 7.28 \times 10^{-6}$ m and density $\rho = 2.63 \times 10^3$ kg m^{-3}. As water-soluble PAAFs we used samples of nonionic polyacrylamide (N) and anionic (A1, A2) and cationic (C) acrylamide copolymers with various content of the ionic groups α. For comparison, polyoxyethylene (POE) and sodium salt of carboxymethyl cellulose (Na-CMC) were also studied. The main properties of the above polymers are listed in Table 1. Our preliminary experiments showed that the most reliable data on the sedimentation kinetics of bentonitic clay suspension in the mode of hindered sedimentation are obtained at the content of the dispersed phase (DP) $c_d = 4\%$. Below this optimal concentration, the phase boundary becomes very diffuse, whereas above it the working clarified area of the cylinder decreases. The kinetics of flocculation and thickening of the bentonitic clay suspension was studied in 100- and 2000-ml cylinders by the shift of the boundary between the clarified and unclarified

fractions of the suspension. For more correct determination of the phase boundary, the bottom part of the 2000-ml cylinder was equipped with an additional vertical (millimeter) scale.

To obtain the quantitative characteristics of the flocculation kinetics, we calculated the flocculation effect D [1]:

$$D = v/v_0 - 1 = t_0/t_i - 1, \quad (1)$$

where v and v_0, and t_i and t_0 are the rates and times of sedimentation of the bentonitic clay suspension to the degree of clarification $Q = 0.3$ in the presence of polymeric flocculant with concentration c_i and without it, respectively.

The flocculation activity, characterizing the relative change in the sedimentation rate due to the unit dose of the polymeric additive, was evaluated from the kinetic curves using the following equation:

$$\lambda = (v/v_0 - 1)/c_i. \quad (2)$$

The viscosities of the PAAF and POE solutions were measured on an Ostwald viscometer with a capillary diameter of 0.54×10^{-3} m. The correction for the kinetic energy of the liquid flow was smaller than 1.5% and was not taken into account in the calculations of the specific viscosity:

$$\eta_{sp} = (\tau - \tau_0)/\tau_0, \quad (3)$$

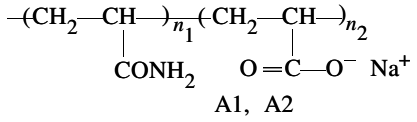
where τ and τ_0 are the times of outflow of the aqueous solutions of copolymers and solvent (water).

The electrokinetic potential ζ of the bentonitic clay suspension in aqueous and aqueous salt solutions was determined by macroelectrophoresis [5], by measuring the shift of the phase boundary between the clay suspension (DS) and electrolyte (0.003 M KCl) in the electrical field (potential $E = 127$ V, distance between the electrodes $I = 42.5$ cm). The shift of the phase boundary was controlled simultaneously in two elbows of the electrophoretic cell. The electrokinetic potential of the DP particles was calculated from the Smoluchowski equation [6].

$$\zeta = \frac{4\pi\eta u \times 300^2}{\varepsilon E l^{-1}}, \quad (4)$$

The electrophoretic rate u was calculated as the difference between the rates of movement of the DP particles in two cell elbows [5]. The factor 300^2 converts the electrokinetic potential ζ values to common volts; η and ε are the viscosity and dielectric permittivity of the bentonitic clay suspension, respectively. The viscosity η of the bentonitic clay suspension was calculated using the Einstein expression:

$$\eta = \eta_0(1 + 2.5\varphi) = \eta_0(1 + 2.5c/\rho), \quad (5)$$



where ψ and c are the volume and weight fraction of the DP particles in the suspension, and $\eta_0 = 0.01$ P is the viscosity of the dispersion medium (water).

First we studied the flocculation kinetics of the bentonitic clay suspension in aqueous solutions of the polymeric flocculants given in Table 1. The effect

of the copolymer concentration is illustrated by the flocculation kinetic curves obtained at various concentration of copolymer A1 (Fig. 1) and generalized data for all the six copolymer samples (Table 2). As seen from Fig. 1, even small flocculant additions ($c = 5 \times 10^{-6}$ wt %) strongly accelerate sedimentation of the bentonitic clay suspension, and with increasing polymer concentration this effect regularly increases. To compare the flocculation parameters of the copolymer samples in question, it is advisable to use the dependences of the flocculation activity on the flocculant concentration, i.e., $\lambda = f(c)$ (Fig. 2). As seen, the parameter λ decreases with increasing flocculant concentration for all the six copolymers studied. This phenomenon can be explained by the fact that the probability of formation of the bridging bond (γ_b) by a given macromolecule, providing formation of the floccules and their further growth, decreases with increasing flocculant concentration. With decreasing γ_b, the probability of formation of the anchor bond (γ_a) by a given macromolecule, when the macromolecule

is either adsorbed on the DP particle or on the globule, obviously increases. The reason is that in the case of adsorption of a given macromolecule $\gamma_b + \gamma_a = 1$, and hence $\gamma_a = 1 - \gamma_b$. Certain increase in λ with increasing c at small flocculant concentrations is probably due to the formation of superfloccules in the disperse system [7]. As seen from Table 2 and Fig. 2, anionic (A1, A2) and nonionic (N) PAAFs are the most efficient water-soluble flocculants studied, which is confirmed by their maximal parameters D and λ. For cationic PAAF (C) , POE, and Na-CMC, these parameters are somewhat smaller. The flocculation activities of various polymeric flocculants were compared at fixed copolymer concentrations c.

The flocculation characteristics of the water-soluble polymers studied are affected by certain active parameters determining the interaction of adsorbed copolymer macromolecules with localized or nonlocalized adsorption centers on the surface of the DP particles. These active parameters include the presence of defective elements (such as hollows, irregularities, crystal edges, foreign inclusions, etc.) in the near-surface layer of the DP particles, nature and concentration of the localized (formed predominantly by ions and charged functional groups) and nonlocalized adsorption centers on the DP particle surface, effective size and flexibility of the macromolecule globules, and actual ratio of the probabilities of formation of the bridging γ_b and anchor γ_a bonds between the PAAF macromolecules and DP particles [1, 7–9].

Before the analysis of the adsorption of separate ionic and nonionic (acrylamide) fragments of the copolymer macromolecules A1, A2, and C on the charged and neutral sections of the phase boundary surface, we should distinguish the "effective" macromolecules participating in bridging between two and more DP particles and the macromolecules that, being adsorbed through the anchor bond on the surface of a single DP particle, do not participate in the formation of floccules [1, 7]. To explain a sharp difference in the flocculation parameters of copolymers A1, A2, and C, we should take into account that γ_b(A1 or A2) $\gg \gamma_b$(C) and γ_a(A1 or A2) $\ll \gamma_a$(C). These ratios show that, for anionic copolymers A1 and A2, the fraction of the bridging contacts is significantly greater than that for copolymer C. To explain the above ratios, we should take into account the charges of the ionic acrylamide copolymer macromolecules and DP particles (namely, negative for anions A1 and A2 and for DP particles and positive for cation C). This difference in the charges of the ionic PAAFs promotes formation of predominantly bridging contacts between the DP particles and anions A1 and A2 and of predominantly anchor bonds (through the neutralization mechanism) for cation C, i.e., γ_b(A1 or A2) $\gg \gamma_b$(C). Moreover, the sediment density ρ_s (Table 2) and, thus, its permeability strongly depend on the polymeric additive. This fact should be taken into account in processing and utilization of the precipitates [10].

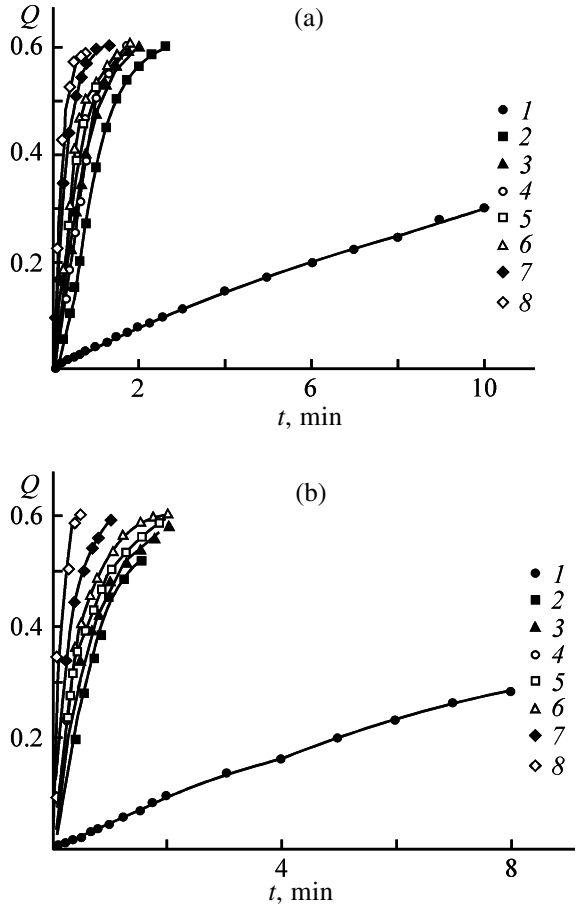

Fig. 3. Sedimentation kinetic curves of the bentonitic clay suspension in aqueous salt solution ($I = 1.8 \times 10^{-2}$ N) in the presence of ionic PAAF (A1) and (a) NaCl and (b) $FeCl_3$ electrolytes. Concentration of A1, $c \times 10^4$, wt %: (*1*) 0, (*2*) 0.5, (*3*) 1, (*4*) 2, (*5*) 5, (*6*) 10, (*7*) 20, and (*8*) 35.

Since in the oil production a bentonitic clay suspension is added to multicomponent aqueous solutions containing various salt additives, it was advisable to evaluate the effect of the ionic strength of solutions on the sedimentation kinetics of real DCs. The flocculation kinetic curves of the bentonitic clay suspension in the aqueous salt solution ($I = 1.8 \times 10^{-2}$ N) in the presence of anionic (A1) PAAF and NaCl and $FeCl_3$ coagulants are show in Fig. 3. As seen, with increasing PAAF concentration in the aqueous salt solution, the sedimentation rate of the

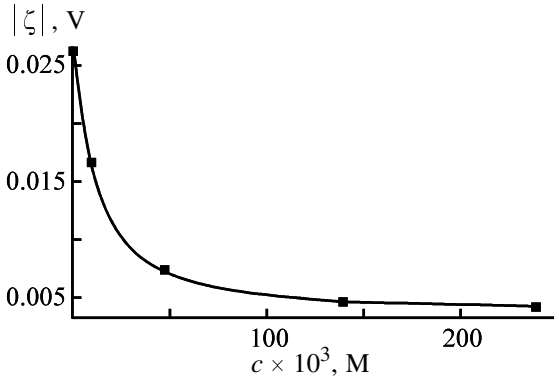

Fig. 5. Electrokinetic potential ζ as a function of the electrolyte (NaCl) concentration c.

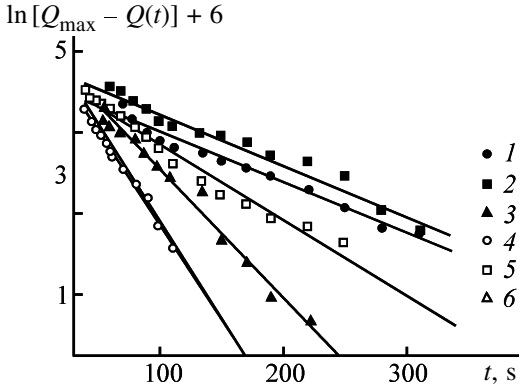

Fig. 6. Kinetic curves of thickening of the bentonitic clay suspension in the presence of copolymer A1 (1×10^{-4} wt %) and electrolyte NaCl ($I = 1.8 \times 10^{-2}$ N) in the $\log[Q_{max} - Q(t)] + 6 = f(t)$ coordinates: (*1*) without A1 and NaCl, (*2*) with NaCl only, and (*3*) with A1 only; the mode of adding A1 and NaCl: (*4*) first, (*5*) second, and (*6*) third.

bentonitic clay suspension also regularly increases, and the flocculation effect D changes simultaneously. It should be noted that addition of electrolytes to the bentonitic clay suspension primarily affects (1) the conformation state of macromolecules of the flocculant and especially ionic PAAFs and (2) the parameters of the electrical double layer of the DP particle, and hence the aggregation and sedimentation stability of the disperse system.

The first effect of the electrolyte is illustrated by Fig. 4. As seen, on adding NaCl, $FeCl_3$, and $K_4[Fe(CN)_6]$ electrolytes, the specific viscosity η_{sp} of the aqueous solution of copolymer A1 gradually decreases. The most pronounced decrease in η_{sp}, which corresponds to changes in the effective size of macromolecules [11], is observed with $FeCl_3$ (Fig. 4, curve *4*).

As for the second effect, with increasing electrolyte concentration the electrical double layer contracts [6, 12], which should be accompanied by a decrease in the electrokinetic potential ζ of the bentonitic clay suspension. This is confirmed by direct experiments on the macroelectrophoresis of the bentonitic clay suspension in aqueous salt (NaCl) solutions (Fig. 5). With increasing NaCl concentration, the ζ potential decreases, i.e., the aggregation (and sedimentation) stability of the DP particles decreases also. It is obvious that the electrolyte ions, along with the two above-mentioned factors, affect the physicochemical parameters of the localized and nonlocalized adsorption centers and, thus, the intensity of electrostatic interactions of PAAF ions with localized charges on the DP particle surface [9], and also the hydrophilic–hydrophobic balance at the phase boundary.

Studies on the flocculation in model dispersion systems [9, 13] revealed the dependence of the sedimentation stability on the process factors, in particular, on the mode of addition of the active flocculants into the system. At the same time, the effects of the process factors on the precipitate thickening are still poorly understood. In the second stage of our study, we analyzed the kinetics of flocculation and precipitate thickening at three modes of addition of the active components: (1) flocculant is added after electrolyte, (2) electrolyte is added after flocculant, and (3) aqueous solution containing both electrolyte and flocculant is added to the bentonitic clay suspension. It should be noted that in all three cases the overall compositions of the suspensions containing flocculant A1 and electrolytes were similar.

Figure 6 shows how the order of addition of the active components affects the precipitate thickening,

Table 3. Flocculation and thickening of the sediment of the bentonitic clay suspension in aqueous salt solutions at three addition modes of the active components (A1 and NaCl). Concentration: 1×10^{-4} wt % A1 and 1.8×10^{-2} M NaCl

System	$\lambda \times 10^{-3}$, $m^3\ kg^{-1}$	Q_{max}	$\rho_s \times 10^{-3}$, $kg\ m^{-3}$	$\gamma \times 10^4$, s^{-1}
BCS* ($I = 0$)	–	0.828	1.144	1.36
BCS + A1 ($I = 0$)	16.2	0.807	1.128	5.40
BCS + NaCl ($I = 1.8 \times 10^{-2}$ N)	4.16	0.827	1.143	1.37
First mode, BCS + (NaCl + A1) ($I = 1.8 \times 10^{-2}$ N)	8.00	0.803	1.126	3.60
Second mode, BCS + (A1 + NaCl) ($I = 1.8 \times 10^{-2}$ N)	3.00	0.803	1.126	2.06
Third mode, BCS + (NaCl + A1)	4.90	0.813	1.132	5.45

* BCS is 4% bentonitic clay suspension.

with a combination of copolymer A1 and NaCl ($I = 1.8 \times 10^{-2}$ N) as example. The kinetics of the precipitate thickening was studied at high degrees of clarification ($Q > 0.6$, 2000-ml cylinders). At the exposure time ≥800 min, all the kinetic curves recorded (in the presence of PAAF and without it) reach the constant degrees of clarification $Q = Q_{max} = \text{const}$. The experimental data (Fig. 6) were treated in the $\log[Q_{max} - Q(t)] = f(t)$ coordinates, which allowed us to calculate the constants of precipitate thickening θ from the curve slopes using the following expression [14]:

$$\ln[Q_{max} - Q(t)] = -\gamma t. \quad (6)$$

This procedure of evaluation of the precipitate thickening kinetics allows additional determination of two important characteristics for highly concentrated bentonitic clay suspension: minimal sediment volume V_s and sediment density ρ_s:

$$V_s = (1 - Q_{max})V_0, \quad (7)$$

$$\rho_s = m + (V_s - m/\rho)\rho_0 V_s^{-1}, \quad (8)$$

where V_0 is the volume of the bentonitic clay suspension in the cylinder, ρ and ρ_0 are the densities of the bentonitic clay ($\rho = 2.63 \times 10^3\ kg\ m^{-3}$) and water ($\rho_0 = 1.0 \times 10^3\ kg\ m^{-3}$), respectively, and m is the weight of the bentonitic clay sample ($m = 80$ g).

Data on the flocculation of the bentonitic clay suspension and sediment thickening in aqueous salt (NaCl) solutions ($I = 1.8 \times 10^{-2}$ N) in the presence of anionic PAAF (A1) at all the three addition modes of the active components are summarized in Table 3. The effect of the addition mode can be explained by the fact that, in the three-component system of the bentonitic clay suspension (BCS + electrolyte + A1), preliminarily addition of the salt provides formation of primary aggregates of the DP particles, which are suitable precursors to form secondary structural elements involving, along with DP particles and electrolyte, the PAAF macromolecules (A1), i.e. floccules. At the second addition mode (BCS + A1 + electrolyte), formation of the floccules is affected, in particular, by irreversible adsorption of macromolecules on the DP surface [7, 8]. At the third addition mode, changes in the flocculation of the bentonitic clay suspension and sediment thickening and in the structure of the resulting floccules are due to strong changes in the size of macromolecule floccules on preliminarily addition of the electrolyte to A1 solution.

As seen from Table 3, the mode of the active component addition strongly affects important macroscopic parameters of the dispersion system such as λ, ρ_s, and γ. The highest ρ_s and minimal γ are observed for the dispersion systems in the absence of PAAF (A1) (Fig. 6, curves *1, 2*). Significant differences in ρ_s and γ (Table 3) suggest certain differences in the sediment structure, i.e., the loosest sediment is formed in the bentonitic clay suspension with the systems containing both NaCl electrolyte and anionic PAAF (A1), i.e., when voluminous floccules in which the DP particles are packed more randomly are formed (including the $Q \sim Q_{max}$ areas). It should be noted that the above dependences of the flocculation and thickening of the bentonitic clay suspension on the addition modes become of particular importance in the development of promising processes for the control of the aggregation and sedimentation stability of real disperse systems at combined use of flocculants and electrolytes.

CONCLUSIONS

(1) The kinetics of flocculation and thickening of the sediment of a real disperse system (bentonitic clay suspension) in the mode of hindered sedimentation in the presence of water-soluble copolymers of various

nature in aqueous salt (NaCl, $FeCl_3$, $K_4[Fe(CN)_6]$) solutions with varied ionic strength was studied. The highest flocculation parameters are observed with nonionic and anionic acrylamide copolymers.

(2) The kinetic analysis reveals a strong dependence of the sedimentation stability of the bentonitic clay suspension on the chemical nature, concentration, and addition mode of the active components (flocculant and electrolyte) in the disperse system. The correlation between the flocculation characteristics and parameters of the sediment thickening (thickening constants and sediment density) of the bentonitic clay suspension in aqueous salt solutions was determined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electret Properties of Blends of High-Density Polyethylene and Polystyrene

M. F. Galikhanov and T. A. Luchikhina

Kazan State Technological University, Kazan, Tatarstan, Russia

Received February 13, 2006

Abstract—Corona-electrets based on heterogeneous blends of high-density polyethylene and polystyrene were studied. The observed double-maximum composition dependence of the electret properties of polymer blends was explained in terms of the concept of their colloid structure and electrical conductivity.

DOI: 10.1134/S1070427206070214

On the background of the increasing amount of studies in the field of electret materials science, the area associated with analysis of composite polymer electrets stands out [1]. As a basis for development of electrets serve polymer formulation composed of a polymer binder and dispersed fillers, plasticizers, and other additives, as well as gas-filled polymers and polymer blends [2–15]. A distinctive feature of the electret state of heterogeneous systems is the important role of the Maxwell–Wagner polarization caused by the difference in the electrical conductivities of the coexisting phases. In the overwhelming majority of composite materials studied, the electrical conductivities of their components differ rather strongly. A question arises concerning the polarization in composites with approximately the same electrical properties. This condition is satisfied by blends of nonpolar polymers. However, the reports that consider the charge state of formulations of this kind are few in number [10–15].

In [10, 11], a mixture of low-density polyethylene (LDPE) with 10 wt % ethylene–propylene copolymer (EPC) was considered. It was noted that the polymer blend possesses increased activation energy of charge traps, compared to polyethylene. The data of [13] demonstrated that, for blends of LDPE and EPC, the composition dependence of the electret properties has two maxima, with enhanced electret properties characteristic of blends with predominant content of one of the polymers.

Improved electret properties, compared to polypropylene (PP), have been observed for its blends with a cycloolefin copolymer (COC) [12]. A blend of COC with 10% PP has higher charge stability than blends with 25 and 40% polypropylene. Of interest are the data obtained in [15], whence follows that a blend of PP with a terpolymer of ethylene, propylene, and butadiene (EPBT) has good electret properties, whereas that of PP with polytetrafluoroethylene (PTFE) may, by contrast, be an antistatic at certain polymer ratios.

It was found in [14] that the dependence of the surface density and lifetime of electret charges in blends of PP and high-density polyethylene (HDPE) on the content of polyethylene shows a maximum.

In view of the incompleteness of data obtained in studies of the electret effect in blends of nonpolar polymers, it is of interest to examine the electret properties of blends of this kind in the entire range of ratios of their polymer components.

EXPERIMENTAL

We chose as objects of study HDPE of 276–73 brand [GOST (State Standard) 16338–85] (density 0.96 g cm^{-3}, weight-average molecular weight 27×10^4, volume resistivity 1.7×10^{14} Ω m) and polystyrene (PS) of PSM 115 brand (GOST 20282–86E) (density 1.06 g cm^{-3}, viscosity-average molecular weight 3×10^5, volume resistivity 9×10^{13} Ω m).

The polymers were mixed with laboratory microrolls at 175 ± 5°C and mixing time of 3 min. Plates of thickness 1.1–1.2 mm were produced by pressing in accordance with GOST 12019–66 at 180 ± 5°C and time of keeping under pressure equal to 5 min. The polymer plates were polarized in the field of a corona discharge with an electrode comprising 196 pointed

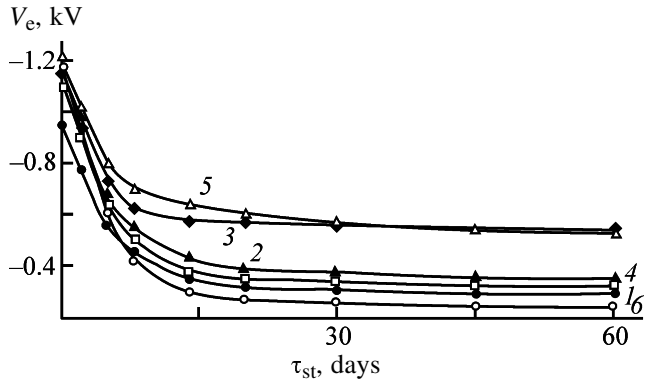

Fig. 1. Surface potential V_e of corona-electrets based on (*1*) polyethylene, (*6*) polystyrene, and blends of these in ratios of (*2*) 80 : 20, (*3*) 70 : 30, (*4*) 50 : 50, and (*5*) 20 : 80 vs. storage time τ_{st}.

needles uniformly distributed over a square of area 49 cm^2. The distance between the plates and the electrode was 20 mm, the polarization voltage was 35 kV, and the polarization time, 60 s. Before being polarized, the plates were kept in an oven at 90°C for 10 min.

We measured the electret potential difference U_{EPD} every 24 h during 150 days by the method of a vibrating electrode (noncontact induction method) in accordance with GOST 25209–82 (measurement error 0.15%). The time elapsed from the polarization of a plate till the first measurement of its surface potential was 1 h. The electrets were stored in an unshorted state in paper envelopes. The surface charge density σ_{eff} was calculated by the formula

$$\sigma_{eff} = U_c \varepsilon\varepsilon_0/\delta,$$

where U_c is the compensating voltage (U_{EPD}) (V); ε, dielectric constant of a formulation; ε_0, permittivity of free space, equal to 8.854×10^{-12} F m^{-1}; and δ, electret thickness (m) [16].

We measured the electric field strength *E* and surface potential V_e daily with an IPEP-1 meter whose operation principle is based on the method of periodic screening of the pick-up electrode situated at a certain distance from the electret surface. The measurement error of the electret characteristics did not exceed 3%.

To determine the phase structure of the polymer blend, we placed 15 × 15 mm plates in dimethylformamide (at a formulation : solvent ratio of 1 : 20) and kept them there with intermittent shaking for 21 days. The undissolved part of the formulations was dried in a vacuum oven and weighed.

We determined the volume resistivity of the polymer blend in accordance with GOST 6433.2–71 with an E6-13 teraohmmeter on samples having the form of 60 × 60 mm plates.

Of the several existing methods for fabrication of electrets based on polymeric materials, wide acceptance has been gained by the method of polarization in a corona discharge, whose advantages are the simplicity of the apparatus use and rather high speed. In charging of this kind, charge carriers (electrons, ions) are injected into the polymer and captured by energy traps of varied nature to give a homocharge.

Corona-electrets based on polymer insulators are described by the curve of charge relaxation in the course of time. One of parameters characterizing the electret state is the surface potential. The curve describing the dependence of the surface potential of the polyethylene-based corona-electret on the storage time consists of two portions (Fig. 1, curve *1*). The initial, steeper, portion is associated with release of injected charge carriers from shallow surface energy traps, whose role is played by chemically active impurities, specific surface defects produced by oxidation processes, adsorbed molecules, and disruptions in the short-range order of molecule arrangement on the surface and in the bulk. This process occurs during the first 24 h of storage of corona-electrets. The second portion is associated with release of charge carriers from deep traps, whose role is played by impurity ions, free volume of the polymer, defects of monomer units, chain irregularities and crystal imperfections, phase boundaries, etc. It is this portion that determines the stability of a corona-electret: a more gradually sloping curve corresponds to a high stability of an electret and, consequently, to a longer lifetime. A similar appearance is characteristic of the dependence of the surface potential of a polystyrene-based corona-electret on the storage time (Fig. 1, curve *6*). Other characteristics of polymer electrets (e.g., effective surface charge density) vary in storage in a similar way.

A study of the polarization of heterogeneous mixtures of polyethylene with a copolymer of ethylene and propylene of various compositions in the field of a corona discharge yielded the following data (see table; Figs. 1, 2).

It can be seen that, for mixtures of HDPE and PS stored for 45 days, the composition dependence of the surface potential has an unusual appearance: the curve has two peaks exceeding in intensity the additive values (theoretically calculated from the properties of individual polymers of the blend) (Fig. 2). In

Electret properties of polyethylene–polystyrene blends by 45th day of storage

Blend composition, vol %		V_e, kV	E, kV m^{-1}	$\lvert U_{EPD} \rvert$, kV	$\lvert \sigma_{eff} \rvert$, μC m^{-2}

10	90	–0.50	–35.3	0.54	9.97
0	100	–0.25	–22.7	0.53	9.38

this case, enhanced electret properties are characteristic of polyethylene–polystyrene blends with predominant content of one of the polymers. The rest of the electret properties of the polymer blend (field strength, electret potential difference, and effective surface charge density) vary in a similar way (see table).

Taking into account that polyethylene and polystyrene have comparable electret characteristics, we can suggest that the key role in the manner in which the electret properties of their blends vary is played by the phase boundary. In this case, the stronger the structural heterogeneity of the blend [and this heterogeneity gives rise to polarization at the interface between the polymer phases (Maxwell–Wagner effect)], the higher should be the values of V_e, E, U_{EPD}, and σ_{eff} of corona-electrets. If this assumption were correct, the optimal polymer blend for preparing an electret would be that with a 1 : 1 volume ratio of the components. It can be seen, however, that, contrariwise, the electret properties of an HDPE–PS blend of this composition exhibit a clearly pronounced minimum (see table, Fig. 2).

Another factor determining the electret characteristics of polymer blends may be discontinuity of the phase boundary. In other words, the colloid structure of a polymer blend can exert key influence on its polarizability. A blend with a predominant content of polyethylene should be a common dispersion in which polystyrene is the dispersed phase, and polyethylene, dispersion medium. In the case of a predominant content of PS in a polymer blend, HDPE forms the dispersed phase. In the middle of the composition range, the blend has two continuous phases and forms a matrix structure. The discontinuity of the phase boundary in one case and its continuity in another may affect the electret properties exhibited by the blends.

We studied the colloid structure of the blend by the selective dissolution technique. Samples of formulations with various ratios of the polymer components were placed in dimethylformamide, in which polystyrene dissolves completely, and polyethylene swells to a limited extent (to 1–2 wt %). Then the undissolved part of the formulation was dried and weighed. The results obtained in extraction of polystyrene were used to judge the colloid structure of the polymer blend (Fig. 3, curve *1*). It should be noted that plates of formulations containing up to 30 vol % polystyrene remained virtually intact after the dissolution, those with 30–80 vol % PS became a continuous porous film, and those with 90 vol % polystyrene disintegrated into particles of a highly dispersed powder and formed a precipitate in the solvent. This means that HDPE–PS blends with component ratios in the range from 60 : 40 to 20 : 80 have

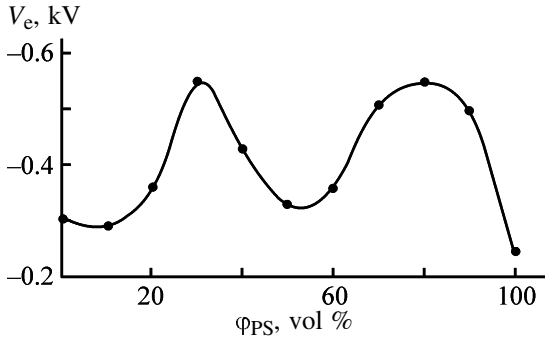

Fig. 2. Surface potential V_e of corona-electrets based on polyethylene–polystyrene blends vs. the volume content of polystyrene φ_{PS}. Electret storage time 45 days.

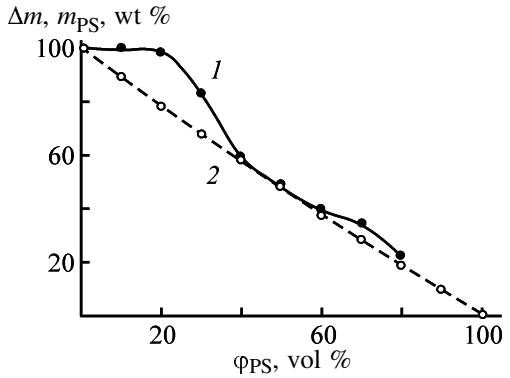

Fig. 3. (*1*) Change in the weight, Δm, of polyethylene–polystyrene blends after the extraction of polystyrene with dimethylformamide and (*2*) calculated weight fraction of polyethylene, m_{PS}, in polymer blends with varied volume fraction of polystyrene, φ_{PS}.

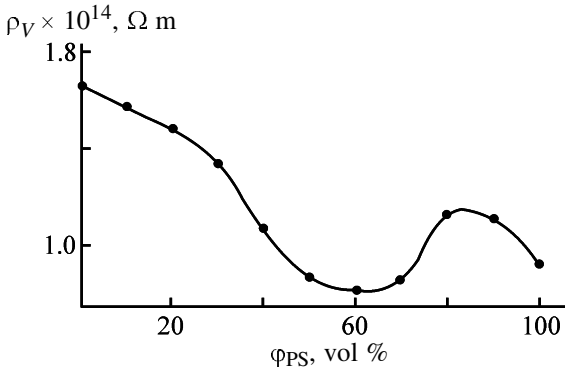

Fig. 4. Volume electrical resistivity ρ_V of a corona-electret based on polyethylene–polystyrene blends vs. the volume content of polystyrene, φ_{PS}.

a matrix structure, and the others are common dispersions. The shift of the phase inversion regions (transition from one colloid structure to another) toward predominance of polystyrene is due to the difference in viscosity between polyethylene and polystyrene.

Comparison of the data obtained in a study of the colloid structure of HDPE–PS blends with their electret characteristics suggests that, while one of polymers forms a continuous phase, values of V_e, E, U_{EPD}, and σ_{eff} increase with the content of the dispersed phase. This is due to an increase in the area of the phase boundary serving as the main source of traps for injected carriers in heterogeneous composite materials. However, as soon as the phase boundary becomes continuous, the electret properties of the blends are strongly impaired. This can be understood as resulting from the existence of the phase boundary as an interphase region with its own structure and properties, which governs the electret properties of the blend as a whole. It was noted in [17] that the interphase region in polymer blends is loose, i.e., it can have an increased electrical conductivity because of the higher mobility of macromolecules in it. A study of the volume electrical resistivity confirmed this assumption (Fig. 4). Consequently, charge carriers localized in polarization in a corona discharge at the phase boundary are released from traps in the course of time and "move" in the process of recapture within the interphase region with a higher conductivity, rather than within the phases of the polymeric blend components.

Using the results of this study, we can generalize the available published experimental data for electrets based on blends of various nonpolar polymers [10–16]. Addition to polyethylene of 10 wt % ethylene–propylene copolymer gives rise to a new type of traps at the polymer phase boundary, which is confirmed by the increased activation energies of charge traps in the blend, compared to polyethylene. This results in that the electret properties of LDPE are improved upon addition of EPC [10, 11]. The same phenomenon was observed in a study of a blend of polypropylene and terpolymer of ethylene, propylene, and butadiene [15].

The existence of a phase boundary can also be responsible for the improved electret properties of blends of a cycloolefin copolymer with propylene, compared to individual PP (unfortunately, the electret properties of COC were not reported) [12]. We can attribute the poorer stability of charge in blends with the PP content increased from 10 to 25 and 40% to a transition of the colloid structure from the dispersed to the matrix state, which is accompanied by formation of a continuous phase boundary with its own electrical conductivity. In the same way, we can explain the extremal behavior of the dependence of the surface density and lifetime of electret charges in blends of polypropylene and high-density polyethylene on the HDPE content [14].

We can suggest with high confidence that the electrical conductivity of the phase boundary between polypropylene and polytetrafluoroethylene exceeds the electrical conductivities of the individual components to such a great extent that blends of PP and PTFE with approximately equal contents of the polymers are not electrified [15].

CONCLUSIONS

(1) The composition dependence of the electret parameters of blends of high-density polyethylene and polystyrene has two maxima, with enhanced electret properties characteristic of blends with predominant content of one of the polymers.

(2) The polarizability of a polymer blend is governed by its colloid structure and, as a consequence, by the discontinuity of the phase boundary. While one of the polymers forms a continuous phase, the electret parameters increase with the content of the dispersed phase. This is due to an increase in the area of the phase boundary, which serves as the main source of traps for injected carriers in heterogeneous composite materials. If, however, the colloid structure of a blended formulation is of the matrix type and the phase boundary is continuous, the electret properties of the polymer blend are unsatisfactory. This is due to the fact that the phase boundary is an interphase region with increased electrical conductivity and the carrier transport to the surface of the electret and its depolarization both occur in this region.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Heterocoagulation of Anionic and Cationic Latexes with Particles Bearing Intrinsic Charge

V. N. Verezhnikov and I. N. Pshenichnaya

Voronezh State University, Voronezh, Russia

Received January 16, 2006

Abstract—Kinetics of coagulation of dilute latexes of styrene copolymers with methacrylic acid and *N*-dimethylaminoethyl methacrylate is studied turbidimetrically. The pH dependence of the limiting turbidity of the coagulating dispersion, characterizing the heterocoagulation efficiency, is examined.

DOI: 10.1134/S1070427206070226

Heterocoagulation represents the most common case of interparticle interaction in both the nature and technology. The use of polymer dispersions (latexes) is practically always accompanied by interaction of polymer globules with foreign particles or macroscopic surfaces (heteroadagulation), e.g., in impregnation and sizing of dispersed and fibrous materials, in combination of latexes with mineral fillers and binders, in production of nonwoven fabrics, in coating processes, etc. [1]. Of great interest are the cases of interaction of latex particles with oppositely charges substrates, e.g., in modification of cellulose fibers of pulp [2, 3] or natural and synthetic fibers [4, 5] with cationic latexes. It is known from the technological practice that anionic and cationic latexes are incompatible because of mutual coagulation of particles stabilized by the adsorption layers of, respectively, anionic and cationic surfactants. In this case, the specific character of heterocoagulation is lost to a considerable extent, since the mechanism of destabilization of a mixture of such latexes is restricted to only chemical interaction of anionic and cationic emulsifiers with formation of insoluble ion–salt complexes, which deprives the particles of the protective adsorption shell. Additionally, of a considerable interest is the interaction between anionic and cationic latexes stabilized by only their own charges, which could be imparted to them in the course of synthesis through the use of the respective ionic surface-active comonomers. In addition to purely theoretical interest, mutual coagulation of such latexes is worth noting as a possible route to preparation of polymeric composites free from inorganic salts, which is impracticable in the case of ordinary electrolyte-induced coagulation.

In this study we examined the interaction between two latexes obtained by copolymerization of the ionic monomers, *N*-dimethylaminoethyl methacrylate (DMAEM) and methacrylic acid (MAA), with styrene, which are composed by, respectively, positively and negatively charged particles. Our goal was to elucidate the pH effect on the heterocoagulation efficiency of the latexes (taking into account considerable difference in the acid–base characteristics of the charge-forming functional groups of the comonomers) and also the effects of the nature and concentration of inorganic salts.

EXPERIMENTAL

In synthesis of latexes we used freshly distilled styrene (n_D^{20} = 1.545) and methacrylic acid (n_D^{20} = 1.430), and DMAEM from Aldrich (n_D^{20} = 1.440). *N*-Dodecylpyridinium bromide (DDPB) and azobis(isobutyronitrile) (AIBN) were recrystallized twice from alcohol, and potassium persulfate (PPS), from water. The anionic emulsifiers, alkyl sulfonate (commercial product used in synthetic rubber production) and bis(2-ethylhexyl) sulfosuccinate sodium salt (SUS-875), were used without additional purification. The formulations used in synthesis of the latexes are given in Table 1.

In synthesis of the cationic latex, the aqueous phase (solution of sulfuric acid and the emulsifier) was heated to 50°C, and styrene was added. Ten minutes after, a solution of the initiator in a small volume of styrene was added stepwise. After 2 h, the reaction mixture was heated to 60°C. Two hours prior completion of the polymerization, the cationic monomer

(DMAEM) was added. The total process time was 7 h. The anionic latex was obtained as follows. The aqueous phase (solution of the sulfonate and succinate) was heated to 60°C, and styrene and partly MAA (0.5 wt % relative to styrene) were added. After 10 min, a solution of the initiator (PPS) in a small volume of the aqueous phase was added dropwise. The mixture was heated to 80°C. After 1 h, the rest amount of MAA (1.5 wt % relative to styrene) was added, and the polymerization was carried out for 2 h.

The resulting latexes were dialyzed for two weeks through a collodion membrane and then electrodialyzed with surface tension monitoring. Concentrations of the anionic and cationic functional groups in the dialyzed latexes were determined by conductometric back-titration [6] and coagulation titration (with sodium tetradecyl sulfate) [7], respectively.

The surface tension was measured by the ring detachment (Du Nouy) method [6]; the turbidity, on an NMF nephelometer calibrated by the standard sample; pH, on an EV-74 ion meter; and conductivity, on an N5701 conductometer (Poland).

Characteristics of the initial and dialyzed latexes are summarized in Table 2.

Table 2 shows that, as a result of dialysis, the polymer content in the latexes and conductivity decreased, and the surface tension σ considerably increased (to the values close to the surface tension of water) by virtue of removal of the emulsifiers. From the surface tension isotherms obtained for the emulsifiers used we found that the σ values of the dialyzed latexes correspond to the surfactant concentration below 10^{-4} M, i.e., the emulsifiers were virtually fully removed from the latexes. The mean particle size r remained practically unchanged, suggesting sufficiently high aggregative stability of the latexes, which can be attributed to the intrinsic charge of the particles. This charge is controlled by the pH-dependent degree of ionization of the functional groups (–COOH and –N=C) in the polymers. Therefore, it may be expected that pH has a considerable effect on the heterocoagulation.

The elucidate the pH effect, we performed a turbidimetric study of the kinetics of heterocoagulation of dilute latexes at various pHs [6]. An estimated volume of the cationic latex (m = 2.9 wt %) was introduced into a volumetric flask, and the volume was brought to the mark with a solution of H_2SO_4 or KOH. Then the anionic latex (m = 1.1 wt %) was added. The final concentration of the disperse phase was 1.8×10^{-3} wt %. The turbidity τ was measured as a function of the coagulation time t. Typical τ–t curves are given in Fig. 1. In all cases, regardless of pH, we observed an abrupt increase in τ in the first 1–1.5 min, followed by saturation at a level corresponding to the limiting turbidity τ_{lim}. Thus, the heterocoagulation

kinetics of cationically and anionically charged latexes differs considerably from the case of coagulation of latexes (stabilized with ionic emulsifiers) under the action of electrolytes [8]. In the latter case, as known, the duration of the initial agglomeration stage regularly depends on such factors as the electrolyte nature and concentration, degree of adsorption saturation of the particle surface with an emulsifier, etc., including pH [9]. Interpretation of this difference requires a special study.

Figure 1 shows that τ_{lim} characterizing the mean size of the aggregates formed strongly depends on pH. Therefore, τ_{lim} was chosen as a measure of the heterocoagulation efficiency. In the subsequent experiments, this parameter was determined as the turbidity at t = 5 min.

The pH dependence of τ_{lim} over a wide pH range is given in Fig. 2. The curve was obtained by subtracting the turbidity of the initial mixture of two latexes from the measured current turbidity. As seen, the τ_{lim}–pH curve is very complex in shape. In moderately acidic media (pH ~3–6), the heterocoagulation is insignificant. At pH < 3, τ_{lim} passes through a maximum, and in the alkaline range, it regularly increases with increasing pH. To interpret this result, let us consider the interparticle interaction as a sequence of two events: approach under the effect of electrostatic attraction force between the diffuse clouds of the counterions and fixation through chemical interaction between functional groups of the polymer chains on the particle surface. This interaction is essentially a process similar to ionic reactions between macromolecules of oppositely charged polyelectrolytes [10]. Evidently, at pH 3–6, the latex particles are weakly ionized, so that the mutual electrostatic attraction between them is only slightly pronounced, and the presence of the solvate shells blocks the coagulation. On passing to the strongly acidic range, the protonation of the nitrogen atom of the surface amino groups become more pronounced, promoting their interaction with anionic species. As a result, τ_{lim} increases with decreasing pH. The possibility of such interaction between the ionized amino groups (=NH^+–) and the carboxy groups at low pH is probably caused by the cooperative nature of the reactions between macromolecules of anionic and cationic polyelectrolytes, which are characterized by a significant shift of the equilibrium to the right, as compared to similar reactions between low-molecular-weight analogs. In this case, a weak polymeric acid may effectively replace a strong one from its salt with a polymeric base [10]. At pH < 1, as a result of increasing ionic strength, the screening of the particle charge by the counterions increases, thus suppressing the coagulation.

On the contrary, in the alkaline range, with increasing pH, the ionization of the carboxy groups of the anionic latex increases, thus enhancing the heterocoagulation efficiency.

To characterize the effect of the nature and charge of the coagulating ions on heterocoagulation, we studied the electrolyte effect on τ_{lim}. As electrolytes we used potassium halides, to eliminate the neutralization factor, which could be pronounced in the presence of multivalent cations, as a result of their interaction with the carboxy groups. A fixed volume of the anionic latex ($m = 1.1 \times 10^{-2}$ wt %) was introduced into a volumetric flask, and the volume was adjusted to the mark with a KOH solution containing the desired amount of the salt. Then the cationic latex ($m = 2.9 \times 10^{-2}$ wt %) was added, and τ_{lim} was measured. The solution pH was 8.1–8.2. The results are shown in Fig. 3.

In all cases, τ_{lim} decreased with increasing electrolyte concentration, i.e., the heterocoagulation effici-

ency decreased, which can be attributed to weakening electrostatic attraction as a result of compaction of the oppositely charged diffuse clouds of the counterions. The significant role of this factor is supported by the observed effect of the nature (size) of the halide ion: the effect of decreasing τ_{lim} increases with an increase in the ionic radius and, therefore, in the adsorbability in the series $F^- < Cl^- < Br^- < I^-$, i.e., on passing from fluoride to iodide, the suppression of the heterocoagulation becomes more pronounced (naturally, these considerations refer to the cationic component of the latex mixture, for which counterions are anions). The stronger the ability of the counterions to compact the diffuse part of the electrical double layer, the more efficiently they block the aggregation, which can be considered as the inversion of the Schulze–Hardy rule. Previously this effect was observed in studying the heterocoagulation in mixtures of certain inorganic colloids with oppositely charged species, such as aqueous sols of gold and iron(III) hydroxides [11], sols and suspensions of silica and Fe_2O_3 [12], and also in the AgI–$Pb(OH)_2$ system [13].

The inversion of the Schulze–Hardy rule is supported also by comparison of the effects of singly and doubly charged counterions (Fig. 3): In the presence of K_2SO_4, the decrease in τ_{lim} is considerably more pronounced as compared to the halides, as a result of stronger capacity of the sulfate for compaction of the electrical double layer.

CONCLUSIONS

(1) Heterocoagulation of anionic and cationic latexes with particles bearing intrinsic charge (due to acidic or basic functional groups) is strongly pH-dependent.

(2) The heterocoagulation efficiency is maximal in strongly acidic and strongly alkaline media.

(3) Introduction of electrolytes suppresses the heterocoagulation, the effect being more pronounced with increasing size and charge of the coagulating ions, i.e., inversion of the Schulze–Hardy rule is observed.

Abstract—Depolymerization of chitin and chitosan in the course of deacetylation in an alkaline medium was studied, and the influence exerted on the process by the nature and concentration of the alkali (NaOH, KOH) and salts (NaCl, NaI, KI) was examined.

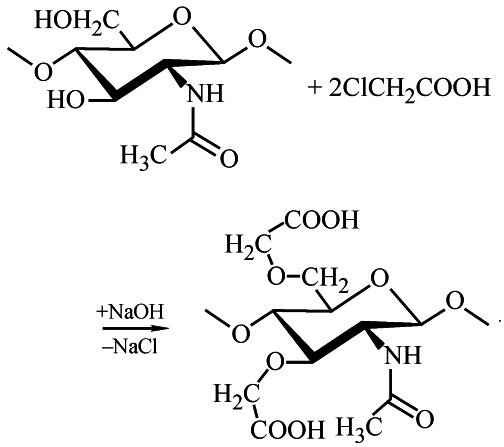
DOI: 10.1134/S1070427206070238

Base hydrolysis of chitin (CTN) and chitosan (CTS) is one of the main chemical methods for modification of these natural polysaccharides; it mainly involves cleavage of the acetamide bonds resulting in deacetylation [1, 2].

Depolymerization of the macromolecules in alkaline solution is considerably slower than the deacetylation and, as believed by many researchers, is due to oxidative degradation of glycoside units rather than to hydrolysis of glycoside bonds [3, 4].

This study was aimed to refine the factors affecting the depolymerization of chitin and chitosan in the course of their base deacetylation.

EXPERIMENTAL



Chitin was recovered from Kamchatka crab shells by the standard procedure [5, 6]. Chitosan was prepared by deacetylation of chitin with 50% aqueous NaOH.

The extent of saturation of the examined solutions with oxygen or nitrogen was recorded with an Anion 4151 ion meter (Infraspak-Analit, Russia) equipped with an ammetric sensor of the oxygen partial pressure.

It is known that solutions of chitosans with the degree of deacetylation exceeding 85% are virtually transparent in the UV and visible range. At a degree of deacetylation less than 55%, chitosan and chitin are insoluble in weakly acidic aqueous solutions; therefore, chromatographic analysis of such samples requires special choice of suitable solvents and eluents. The conditions of chromatographic analysis of chitin and chitosan were close to those used for solutions of chitosan in HCl.

For this purpose, we modified the procedure for preparing carboxymethylated derivatives of chitins (CMCTN) [7] with the aim to use them for determining the molecular weight and molecular-weight distribution by exclusion chromatography.

Samples of chitins and chitosans with various degrees of deacetylation were acetylated with a 20% solution of acetic anhydride in ethanol at 4°C for 24 h. Similar procedure for pretreatment of chitooligosaccharide samples was used, e.g., in mass spectrometry of chitin hydrolyzates [3, 8]. The products of exhaustive acetylation were treated with monochloroacetic acid in alkaline solution [7] to obtain CMCTN:

Carboxymethylation was performed in isopropyl alcohol at 4°C for 3 days. After the reaction comple-

tion, the samples were washed with two portions of ethanol and one portion of acetone and dried at 60°C. The resulting chitin derivatives are readily soluble in water and have high extinction coefficients in the UV range (205–210 nm) due to acetyl groups. The monomeric units in these samples have virtually the same composition, which allows comparison of their chromatograms.

For chromatographic measurements, we prepared 0.1% solutions of carboxymethyl chitin in the eluent, 0.3 M NaCl, at pH 6.5–7.5. The chromatography of chitin samples with a high degree of deacetylation was performed in the eluent containing 0.3 M NaCl at pH 3.0. Chromatographic experiments were performed with an LC-10A_{VP} HPLC system (Shimadzu, Japan). Exclusion chromatography was performed with TSK-gel Alpha-4000 columns (30 × 0.78 cm) and a TSK-guardcolumn Alpha precolumn (6 × 0.4 cm) (TOSOH, Japan). The eluted fractions were monitored by the optical absorption of hydrolysis products using a SPD-10A_{VP} UV spectrophotometric detector or an SPD-M10A_{VL} diode matrix at wavelengths of 205 and 210 nm.

The column was calibrated using chitosan samples of known viscosity-average molecular weights (MW) determined from the intrinsic viscosity by the Mark–Kuhn–Houwink equation

$$[\eta] = K(\mathrm{MW})^{\alpha},$$

where $[\eta]$ is the intrinsic viscosity of chitosan in the system containing 0.334 M CH_3COOH and 0.3 M NaCl (dl g^{-1}); the coefficients K and α (based on data from [9]) are 3.41×10^{-3} and 1.02, respectively.

The viscometric method allows calculation of the viscosity-average molecular weight, which is close to the weight-average molecular weight [10, 11].

Calculation of MW from HPLC data was made using the calibration curve (Fig. 1) constructed from data for chitosan samples of known viscosity-average molecular weight:

$$\log \mathrm{MW} = -0.275V + 6.856,$$

where MW is the mean molecular weight (Da); V, eluent volume corresponding to the maximum of the chromatographic peak of the polymer (ml).

It is known that heterogeneous deacetylation of chitin in an alkaline medium is accompanied by depolymerization of the macromolecules; as a result, the molecular weight of chitosan and the viscosity of its solutions decrease [12].

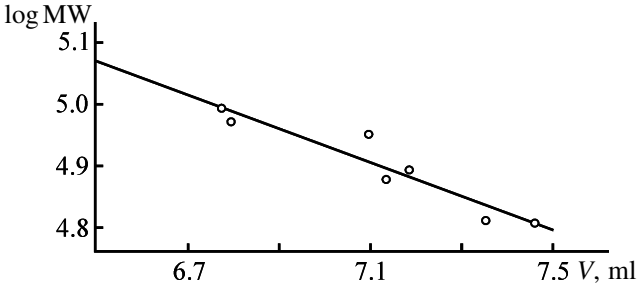


Fig. 1. Plot of log MW vs, eluent volume V corresponding to the maximum of the chromatographic peak of chitosan.

Although it was stated that the molecular weight of chitin and chitosan decreases in the course of base deacetylation, the mechanism of the cleavage of the glycoside bond leading to the depolymerization was not discussed.

The depolymerization of the polysaccharides under consideration in alkaline media, though being less pronounced than upon acid treatment, depends on the deacetylation conditions. The extent of the depolymerization increases with temperature and time [6, 13]. Nud'ga et al. [4, 14] observed degradation of chitin macromolecules in the presence of atmospheric oxygen when the deacetylation was performed under nitrogen at 140°C. They concluded that a combination of a low temperature with an oxygen-free atmosphere is required to prepare high-viscosity (high-molecular-weight) chitosans.

As for the effect of base hydrolysis conditions (concentration and nature of alkali, mutual arrangement of acetylated and deacetylated groups, presence of oxidants), there are different opinions in the literature.

Most attention was given to the dependence of the degree of deacetylation on the alkali concentration [15]. Virtually no attention was given to the effect exerted on the depolymerization of the polysaccharides by the nature of the alkali and its concentration.

It should be expected that an increase in the alkali concentration should promote the depolymerization. However, it was reported in some papers that the alkali concentration has no effect on MW of chitosans, in particular, of those prepared from β-chitin [16].

Smidsrod et al. [17, 18] showed that the mutual arrangement of the acetylated and deacetylated units exerts no effect on the redox and enzymatic cleavage of glycoside bonds in chitosan macromolecules.

It is believed [19, 20] that one of possible causes of the depolymerization of chitin and chitosan in alkaline solutions is oxidative degradation of glycoside bonds under the action of atmospheric oxygen. The deacetylation in that studies was performed in an inert atmos-

phere or in a vacuum. To suppress oxidative degradation of the polymeric chain, Domard and Rinaudo [19] used thiophenol as antioxidant.

We believe that the oxidative degradation exerts an ambiguous effect on the depolymerization. Bough et al. [12] studied the effect of oxygen on the molecular weight of the polymers evaluated from their intrinsic viscosities. They concluded that the dynamic viscosity of chitosan solutions and hence its molecular weight drastically decrease in the presence of atmospheric oxygen. The characteristics of chitosan samples prepared in [12] are given in Table 1.

From the data given in Table 1, we calculated the degree of deacetylation (DD) and plotted MW vs. DD (Fig. 2). It is seen that the points corresponding to the experimental data on the deacetylation in the presence

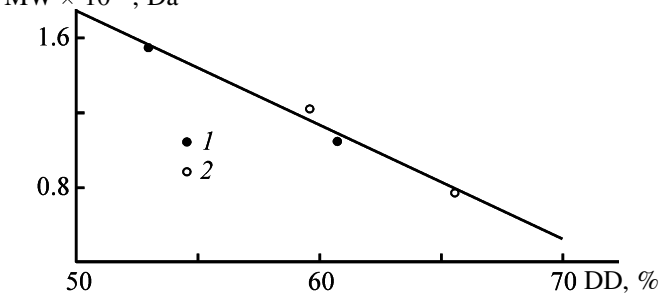

Fig. 2. Molecular weight MW of chitosan vs. degree of deacetylation DD (calculated using data from [12]). Deacetylation: (*1*) under nitrogen and (*2*) in air.

and in the absence of atmospheric oxygen fall on the same straight line. Thus, a decrease in MW is apparently associated with the variation of DD. With an increase in DD, the solubility of chitosan increased and hence the viscosity of its solutions decreased. In this case, MW correlates with DD, because MW is calculated from the solution viscosities.

The effect of oxygen on the decrease in the MW was noted by Focher et al. [21] who performed the deacetylation of chitosans at 140–150°C in a vacuum and obtained the same intrinsic viscosities as in common deacetylation in air at 80–100°C. They believe that this fact confirms the participation of oxygen in the degradation of chitosan in alkaline solutions.

However, experiments on base deacetylation made by Tolaimate et al. [20] showed that the use of the nitrogen atmosphere does not affect the molecular weight of the product. This fact is consistent with the assumption that cleavage of glycoside bonds in base hydrolysis is not an oxidative process.

In this study we made an attempt to estimate the contribution of oxidative and base-induced thermal depolymerization to the degradation of chitin and chitosan macromolecules.

The absence of noticeable depolymerization of chitin in the course of base deacetylation was confirmed by the example of samples that were preliminarily subjected to degradation in HCl (Table 2, sample nos.

2–5). Chitin samples were treated with HCl (0.5 and 5.0 M) at 50°C for 30 min. Then chitin sample nos. 2 and 4 and chitosan sample nos. 3 and 5 were exhaustively acetylated and converted to carboxymethyl chitins by the procedure described above. As seen from Table 2, the mean molecular weights of CMCTN samples prepared from the same chitin samples (sample nos. 2 and 3, 4 and 5) coincide and are appreciably lower than the molecular weight of CMCTN prepared from the initial chitin (sample no. 1). The molecular weights of CMCTN were determined by HPLC.

CMCTN sample nos. 2 and 3, and also 4 and 5 have the same molecular weight, and this fact confirms the absence of depolymerization in the course of base deacetylation.

It is known that hemiacetal bonds (including glycoside bonds) are hydrolyzed in the presence of dilute mineral acids. In alkaline and neutral solutions, these bonds are stable [22, 23].

By the analogy with the hydrolysis of an ether bond, the hydrolysis of a glycoside bond starts with an electrophilic attack (protonation) of the oxygen atom with the formation of an oxonium ion, followed by a nucleophilic attack of the C atom adjacent to oxygen, with the cleavage of the C–O bond.

To elucidate the role of nucleophilic agents in the cleavage of the glycoside bond, we examined the effect of alkalis (NaOH, KOH of different concentrations) and salts (NaCl, NaI, KI).

Depending on the substitution mechanism, the effect of the nature of the nucleophile can be the following.

If the S_N2 mechanism, in which the limiting step is the attack by the nucleophilic agent, is realized, an increase in the nucleophilicity of the attacking agent should facilitate the cleavage of the C–O bond.

In the case of the S_N1 mechanism, the rate is independent of the nature of the nucleophile, because it is not involved in the limiting step [24].

Table 3 shows how the conditions of chitin treatment affect the mean molecular weight of the resulting CMCTN samples. The initial chitin was treated for 2 and 3 days at 95°C with water, 25% NaCl solution, and 50% solutions of NaOH, KOH, NaI, and KI in air, under O_2, and under N_2.

Table 3 shows that the nucleophiles (OH^-, Cl^-, I^-) exert virtually no effect on the rate of cleavage of glycoside bonds. Oxidative degradation does not occur either, because the MW/MW_0 ratio for the samples prepared in air, under N_2, and under O_2 is essentially the same.

Since in all the experiments the deacetylation was performed in aqueous solutions (concentrations of salt and alkali solutions 25 and 50%), the cleavage of glycoside bonds could be effected by water. The hydrogen ion formed by the ionization of water could act as an electrophile. This assumption is apparently confirmed by the MW/MW_0 values for sample nos. 6–8: with an increase in the water content in the system, MW/MW_0 decreases.

Presumably, the glycoside bond in alkaline solution is cleaved by the same mechanism as in acidic solutions (S_N1). Apparently, even trace concentrations of H^+ ions in alkaline solutions lead to the formation of a carbenium ion. This reaction is fast, and it occurs even at low concentrations of hydrogen ions. Virtually equal rate of the reaction in water and in 50% NaOH confirms the possibility of occurrence of the reaction by the S_N1 mechanism.

CONCLUSIONS

(1) In base hydrolysis of chitin and chitosan, oxygen and hydroxide ions do not initiate cleavage of the glycoside bond. Apparently, this role is played by water, which is present in excess in all the examined systems.

(2) Trends in variation of the molecular weight of chitin in the course of its hydrolysis in solutions of NaOH, KOH, NaCl, NaI, and KI, and also in air, under O_2, and under N_2 are essentially similar.

Abstract—Carbon-chain polymers with 1,3,4-oxadiazole rings were prepared by radical polymerization and polymer-analogous transformations. The kinetic relationships of the polymerization of vinyl-1,3,4-oxadiazole monomers and some properties of the resulting polymers were studied. The thermodynamics of interaction of poly-2-vinyl-5-methyl-1,3,4-oxadiazole, a nonionic water-soluble polymer, with water was examined.

DOI: 10.1134/S107042720607024X

Macromolecular compounds containing 1,3,4-oxadiazole rings in the backbone are widely used as chemically stable and heat-resistant, semiconducting, fiber-forming, and gas-separating materials [1, 2]. The main routes to these polymers, including commercial procedures, involve polycondensation of bifunctional heterocyclic compounds or formation of the 1,3,4-oxadiazole ring in a macromolecule of a polymeric precursor. At the same time, available data on vinyl derivatives of oxadiazoles, on their polymerization, and on the properties of carbon-chain polymers with pendant 1,3,4-oxadiazole rings are scarce and concern the synthesis of vinyl-1,3,4- and vinyl-1,2,4-oxadiazoles, and also the use of polyvinyl-1,2,4-oxadiazoles for preparing heat-resistant fibers [1, 3–5]. Recently we studied the polymerization of vinyl monomers with 1,3,4-oxadiazole rings [6].

This paper deals with the synthesis of poly-2-vinyl-5-R-1,3,4-oxadiazoles

[R = CH_3 (**I**), Ph (**II**), CF_3 (**III**), C_9H_{19} (**IV**)] by radical polymerization of the corresponding vinyl monomers and by polymer-analogous transformations of the macromolecular precursor, poly-5-vinyltetrazole (PVT), and with the properties of the resulting carbon-chain polymers containing pendant 1,3,4-oxadiazole rings.

EXPERIMENTAL

2-Vinyl-5-methyl-1,3,4-oxadiazole was prepared in one step from 5-vinyltetrazole as described in [4]; yield ~80%. 2-Vinyl-5-phenyl-1,3,4-oxadiazole was prepared in two steps. First 5-vinyltetrazole was acylated with benzoyl chloride in the water–toluene system at room temperature in the presence of a phase-transfer catalyst. Then the organic phase was separated and heated to 368–373 K to decompose the benzoyl derivative of vinyltetrazole. After the gas evolution ceased, the solvent was removed and the residue was subjected to fractional distillation. Yield of the target product ~70%. 2-Vinyl-5-trifluoromethyl-1,3,4-oxadiazole was prepared by mixing equimolar amounts of 5-vinyltetrazole and trifluoroacetic anhydride in methylene chloride at room temperature. After the reaction completion, the solvent was removed and the product was isolated by vacuum distillation (yield ~95%). The constants of the synthesized vinyl monomers purified by column chromatography on alumina are given in Table 1. The purity of the compounds was checked by NMR, IR, and UV spectroscopy. The kinetic relationships of the polymerization of the vinyl monomers were studied by the procedure described in [6].

The synthesis of poly-2-vinyl-5-R-1,3,4-oxadiazoles **I**–**IV** by polymer-analogous transformations

Table 1. Characteristics of 2-vinyl-5-R-1,3,4-oxadiazoles

R	bp, K (*P*, kPa)	n_D^{20}	*d*, g cm^{-3}
CH_3	314 (1.33)	1.4905	1.12
CF_3	313 (20.0)	1.3945	1.32
Ph	395 (1.33)	1.5885	1.17

involved the reaction of PVT with acetic anhydride, trifluoroacetic anhydride, benzoyl chloride, and decanoyl chloride, respectively, in pyridine or dimethylformamide (DMF) on heating. As in the case of the monomers, the reaction completion was judged from the cessation of evolution of gaseous nitrogen from the reaction mixture. The resulting polyvinyloxadiazoles were precipitated with diethyl ether, washed with the precipitant, and vacuum-dried to constant weight. The degree of conversion of the tetrazole fragments into oxadiazole fragments was calculated from elemental analysis data (Table 2).

The reaction of polyvinyloxadiazole **I** with formamide was performed by heating a solution of the polymer in excess formamide at 348 K in an argon flow for 5 h with continuous stirring. The resulting poly-3-vinyl-5-methyl-1,2,4-triazole was precipitated by pouring the reaction mixture into a mixture of acetone and diethyl ether, washed with the precipitant, and vacuum-dried to constant weight. The degree of conversion of the oxadiazole fragments into triazole fragments was about 97% according to ^{13}C NMR and elemental analysis of the resulting polymer.

The reaction of **I** with aniline was performed in polyphosphoric acid at 358–363 K in an argon flow for 7–8 h with continuous stirring. The resulting poly-3-vinyl-4-phenyl-5-methyl-1,2,4-triazole was precipitated by pouring the reaction mixture into water, reprecipitated from DMF into diethyl ether, and vacuum-dried to constant weight. The degree of conversion of oxadiazole fragments into triazole fragments was 95% according to ^{13}C NMR and elemental analysis of the resulting polymer.

Complexes of polyvinyloxadiazole **I** with metal salts were prepared by combining the solutions of the polymer and salt in appropriate solvent at room temperature with stirring. The precipitates of the metal complexes were washed with water, filtered off, and vacuum-dried to constant weight. The compositions of the products were determined by elemental analysis.

For thermodynamic studies of the interaction with water, we used nonfractionated, thoroughly dried in a vacuum, samples of polymer **I** prepared both by radical polymerization ($M = 6 \times 10^5$) and by polymer-analogous transformations ($M = 1.7 \times 10^5$). The isothermal sorption of water vapor with the polymer samples at 298 K was studied gravimetrically using highly sensitive quartz spirals [7]. The sorption isotherms were expressed in the coordinates $x/m = f(p/p_s)$, where x is the amount of water vapor absorbed by the polymer sample of weight m, and p/p_s is the relative water pressure. The Gibbs energies of mixing Δg_m were calculated from the sorption isotherms of water vapor [8]. The integral heat of solution of the polymers in water and the integral heat of dilution of polymer solutions of given concentration in a large amount of the solvent were determined with a DAK-1-1-A microcalorimeter. The mean specific enthalpies of mixing Δh_m and the mean entropies of mixing Δs_m were calculated by the procedure suggested in [9].

The ^{1}H and ^{13}C NMR spectra were recorded on a Varian VXR-500 spectrometer, and the IR spectra, on a Specord M80 spectrometer. The molecular weights of the polymer samples were determined by small-angle light scattering with an FSR laser photometer (Russia). The thermograms of the polymers were recorded on an MOM derivatograph (Hungary) in the dynamic mode at a heating rate of 5 deg min^{-1}. The

viscosities of polymer solutions were measured with an Ubbelohde viscometer at 273 K.

The synthesis of the monomeric and polymeric compounds containing 1,3,4-oxadiazole rings is based on the recyclization at elevated temperatures of unstable acylated derivatives of tetrazole into the oxadiazole ring with the release of gaseous nitrogen:

where R = CH_2=CH–, –(CH_2–CH–)$_n$–; X = Cl, O(O)CR'.

The starting compound can be 5-vinyltetrazole or its polymer. In the first case, the reaction yields monomeric vinyl derivatives of substituted 1,3,4-oxadiazoles, and in the second case, carbon-chain polymers with pendant 1,3,4-oxadiazole rings. A distinctive feature of the reaction with trifluoroacetic anhydride as acylating agent is that the transformation of the tetrazole ring into the 1,3,4-oxadiazole ring occurs virtually quantitatively at room temperature in the case of the synthesis of the vinyl monomer and at 313–318 K in the case of the modification of the polymeric precursor. In all the other cases, the similar transformation of the azole ring requires heating to 373–393 K.

As shown in [6], vinyl derivatives of 1,3,4-oxadiazole are very active in radical polymerization and form polymeric products of high molecular weights in high yields. The kinetic relationships of the radical polymerization of 2-vinyl-5-methyl-, 2-vinyl-5-phenyl-, and 2-vinyl-5-trifluoromethyl-1,3,4-oxadiazoles do not differ from those found previously for vinyl derivatives of azoles containing only nitrogen heteroatoms in the ring [10–13]. In the polymerization of all the three monomers in acetonitrile under the action of AIBN, the reaction order with respect to the initiator concentration is 0.5, and with respect to the monomer concentration, 1.0. As expected, the highest activity in the radical polymerization is exhibited by the monomer containing in the 1,3,4-oxadiazole ring an acceptor trifluoromethyl group. For 2-vinyl-5-trifluoromethyl-1,3,4-oxadiazole, the parameter $k_p/k_0^{0.5}$ used as a criterion of the monomer activity in radical polymerization is by a factor of 3 higher than for 2-vinyl-5-methyl-1,3,4-oxadiazole (Table 3). In turn, the latter monomer is by an order of magnitude more active than the vinyloxadiazole with the phenyl substituent in the ring. The energy consumption in the chain propagation step (the quantity $E_p - 0.5E_0$) regularly increases with a decrease in the monomer activity parameter. The fact that 2-vinyl-5-trifluoromethyl-1,3,4-oxadiazole is the most active in the polymerization among the compounds studied is well consistent with the typical trend noted previously for vinylazoles [14]: an increase in the activity of monomers in radical polymerization with an increease in the electron-withdrawing power of the heterocyclic substituent at the vinyl group.

The lower reactivity in polymerization of phenyl-substituted vinyloxadiazole compared to the methyl-substituted monomer is attributable to the steric effect of the bulky phenyl substituent or to the lower reactivity of the radical center due to additional delocalization of the unpaired electron. Comparison of the kinetic parameters of the polymerization of vinyl 1,3,4-oxadiazole derivatives (Table 3) with those reported for another *C*-vinylazole, 2-methyl-5-vinyltetrazole ($k_p/k_0^{0.5}$ = 0.31 $l^{0.5}$ mol$^{-0.5}$ s$^{-0.5}$ [14]), shows that the oxadiazole monomers are less reactive in the polymerization, which is consistent with the stronger electron-withdrawing power of the tetrazolyl substituent compared to the oxadiazolyl substituent. 2-Vinyl-5-methyl-1,3,4-oxadiazole is a water-soluble monomer, and water exerts a strong accelerating effect on its polymerization. In aqueous solution, the activity parameter of the monomer increases by a factor of 18 ($k_p/k_0^{0.5}$ = 1.24 $l^{0.5}$ mol$^{-0.5}$ s$^{-0.5}$ [6]) compared to the polymerization in acetonitrile (Table 3), and the

Table 4. Solubiity and decomposition points of polyvinyloxadiazoles

Polymer	Solvent	Softening point, K	Decomposition onset point, K
I	DMF, DMSO, acetone, acetonitrile, ethanol, acetic acid, 1,2-dichloroethane, water	478	622
II	DMF, DMSO, CH_2Cl_2	483	603
III	DMF, DMSO, acetonitrile, acetic acid	460	585
IV	1,2-Dichloroethane, benzene, dioxane	–	579

molecular weights of the resulting polymers increase. Whereas the molecular weight of samples of polyvinyloxadiazole **I** prepared in acetonitrile is within $(1–7) \times 10^5$, in an aqueous solution it is possible to prepare polymer samples with M as high as 4×10^6.

Spectroscopic studies of the polymers show that the polymer backbone is formed exclusively by opening of the vinyl double bonds, without involvement of the heterocyclic fragments. Polyvinyloxadiazoles **I**–**V** prepared by the polymer-analogous transformation from PVT have a similar structure. The absorption bands of the 1,3,4-oxadiazole ring at 1250, 1350, 1530, and 1580 cm^{-1} remain unchanged in the spectrum of the polymers prepared by various procedures. A minor distinctive feature of the spectra of the polymers prepared by the modification to a conversion less than 95% is the presence of a broad absorption band at 2250–3700 cm^{-1} corresponding to the vibrations of the residual N–H groups in the unsubstituted tetrazole rings [15]. The ^1H NMR spectra of polyvinyloxadiazoles **I** and **II** prepared by various procedures are similar in the shape and position of signals of the methyl (δ 2.4 ppm) and phenyl (δ 7.2–7.6 ppm) groups. Protons of the nonyl substituent in the spectra of **IV** give four signals at δ 0.9 (CH_3), 1.32, 2.02, and 3.25 ppm (CH_2). The CF_3 groups in the ^{13}C NMR spectra of samples of **III** prepared by different procedures give a quartet at 113.0–119.5 ppm.

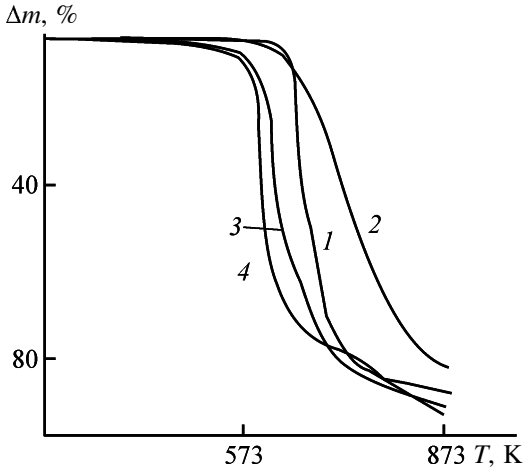

Fig. 1. Dynamic thermogravimetric analysis of polyvinyloxadiazoles (*1*) **I**, (*2*) **II**, (*3*) **III**, and (*4*) **IV**. (Δ*m*) Weight loss and (*T*) temperature.

Polyvinyloxadiazoles **I**–**III**, irrespective of the synthesis procedure, are amorphous colorless powders (polymer **IV** is rubber-like) with the softening and decomposition points depending on the substituent in the heteroring (Table 4, Fig. 1). On the whole, carbon-chain polyvinyloxadiazoles can be regarded as relatively heat-resistant polymers, despite the fact that they are inferior to the known heterochain oxadiazole-containing polymers by approximately 100°C [2].

The solubility of polyvinyloxadiazoles is characterized by the same trends as the solubility of vinylazole polymers containing only the nitrogen heteroatoms in the heterorings [16]. Polyvinyloxadiazole **I** whose heterocyclic fragments contain a small alkyl substituent, CH_3 group (Table 4), dissolve in the widest set of solvents. An increase in the size of the alkyl group (passing to nonyl-substituted polyvinyloxadiazole **IV**) results in the loss of the solubility in polar solvents, but makes the polymer more readily soluble in low-polarity liquids such as benzene and dioxane. Polyvinyloxadiazoles are not polyelectrolytes; therefore, solutions of polymers prepared by polymerization show a linear concentration dependence of the reduced viscosity (Fig. 2). However, the polymers prepared by the modification and containing residual N–H-unsubstituted tetrazole fragments (>5 mol %) behave in solutions as typical polyelectrolytes: Their reduced viscosity increases with the dilution.

In contrast to hydrophobized polyvinyloxadiazoles with phenyl, nonyl, and trifluoromethyl substituents, polymer **I**, similarly to polymers with the 1,2,4-triazole ring, is a nonionic water-soluble macromolecular compound. Comparison of 1,2,4-oxadiazole- and 1,2,4-triazole-containing polymers is interesting from the viewpoint of the effect of the ring-forming heteroatoms (at their equal number) on the compatibility with water. However, it was noted previously [16] that polyvinylazoles containing sequences of two and

more nitrogen atoms in the ring are insoluble in water (e.g., poly-1-vinyl-1,2,3-triazole, poly-1-vinyl-1,3,4-triazole, poly-1-vinyltetrazole). Polyvinylazoles containing an isolated "pyridine" nirogen atom in the heteroring are water-soluble (poly-1-vinylimidazole, poly-1-vinyl-1,2,4-triazole). In the structure of the 1,3,4-oxadiazole ring, there are two vicinal "pyridine" nitrogen atoms which, by analogy with poly-1-vinyl-1,3,4-triazole, is unfavorable for the affinity of the polymer for water, and an isolated oxygen atom of the furan ring. Apparently, this oxygen atom is responsible for the solubility of **I** in water.

The thermodynamic parameters of the interaction with water of polymer **I** prepared by polymerization and modification were estimated from the sorption and calorimetric data. For both samples of **I**, the isotherms of water vapor sorption asymptotically increase at $p/p_s \to 1$ (Fig. 3), which is typical of polymers infinitely miscible with water. The concentration dependences of the Gibbs energy of mixing (Δg_m) of the polymers with water, calculated from the sorption isotherms, are negative, and the second derivative $\partial^2 \Delta g_m / \partial W_2^2 > 0$, i.e., the systems are thermodynamically stable in the entire composition range. Polyvinyloxadiazole **I** prepared by the modification exhibits somewhat lower affinity for water because of the presence of residual tetrazole fragments. Comparison with the Δg_m values obtained for mixing of poly-1-vinyl-1,2,4-triazole with water shows that the oxadiazolyl substituent is substantially less hydrophilic than the triazolyl substituent. This fact cannot be attributed to the presence of the methyl substituent in the heteroring of **I**, since the previous studies showed that electron-donor methyl substituents in azolyl fragments of polyvinylazoles, as a rule, enhance the affinity of the polymer for water [16].

The weaker, compared to the 1,2,4-triazole-containing polymer, interaction of polyvinyloxadiazole **I** with water also follows from the substantially smaller negative enthalpies of mixing (Δh_m) of **I** with water (Fig. 4b). The stronger exothermic effect of the donor–acceptor interaction with water and the shape of the dependence $\Delta h_m = f(W_2)$ for the sample of **I** prepared by the polymer-analogous transformation are attributable to the presence of the residual monomeric units with N–H-unsubstituted tetrazole rings [17].

The difference in the water affinity of oxadiazole- and triazole-containing polymers is also manifested in variation of the entropy parameters at formation of the aqueous systems. Dissolution of oxadiazole polymers is characterized by substantially smaller negative entropies of mixing $T\Delta s$ (Fig. 4c), which indicates that these polymers show a weaker tendency to form joint ordered polymer–water structures, compared to the triazole-containing polymer. Thus, the difference between the triazole and oxadiazole derivatives in the kind of one of the three heteroatoms does not result in the loss of the capability of the polymer with the 1,3,4-oxadiazole pendant group to dissolve in water but appreciably decreases its thermodynamic affinity for water.

As noted above, poly-2-vinyl-1,3,4-oxadiazoles can be prepared by modification of PVT. In turn, oxadiazole polymers can act as precursors for preparing

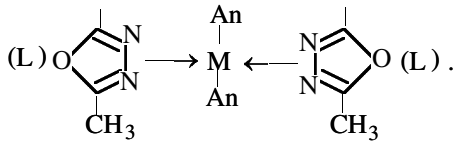
macromolecular compounds with other heterocyclic fragments. Similarly to the known transformations of heterochain polymers containing the 1,3,4-oxadiazole ring into those containing the 1,2,4-triazole ring [2], polyviyloxadiazole **I** reacts with formamide or aniline to form the corresponding poly-*C*-vinyl-1,2,4-triazoles, which are extremely difficult to prepare by polymerization:

The reaction with formamide gave poly-3-vinyl-5-methyl-1,2,4-triazole with a high conversion (up to 97%); this was confirmed by the ^{13}C NMR spectrum of the final product. The ^{13}C NMR spectrum of the starting polymer **I** consists of the following signals (ppm): 11.7 (–CH_3), 32.3–39.5 (–CH–CH_2– of polymer chain), 167.5 (C^2 of ring), and 169.5 (C^5 of ring). The chemical shifts in the spectrum of the triazole-containing polymer are somewhat different (ppm): 12.9 (–CH_3), 35.4–44.7 (–CH–CH_2– of polymer chain), 158.2 (C^3 of ring), and 172.7 (C^5 of ring). Assignment of the latter two signals to the triazole ring was based on the NMR data for model 3,5-disubstituted 1,2,4-triazoles. In contrast to the starting polyvinyloxadiazole, the triazole-containing polymer is insoluble in organic solvents but remains soluble in water. Because of weak acid properties of the 1,2,4-triazole ring, poly-3-vinyl-5-methyl-1,2,4-triazole in aqueous solutions exhibits no polyelectrolyte properties (linear concentration dependence of the reduced viscosity, Table 2), in contrast to tetrazole-containing polymeric NH acids [17].



The reaction of polyvinyloxadiazole **I** with aniline in polyphosphoric acid yields poly-3-vinyl-4-phenyl-5-methyl-1,2,4-triazole with a high degree of conversion (up to 95%). The ^{13}C NMR data confirm that the final product contains the phenyl fragment (a set of signals in the range 126.1–130.8 ppm). The resulting triazole-containing polymer is soluble in DMF and DMSO but, in contrast to the starting polymer, insoluble in water.

Similarly to other known polyvinylazoles [18], polyvinyloxazole **I** forms complexes with metal ions. Complexes with Cu^{2+}, Ni^{2+}, Pd^{2+}, and Ag^+ salts are formed just when solutions of the polymer and salt are mixed at room temperature. The resulting complexes of the composition $L : MAn_n = 2 : 1$ (Table 5) are soluble neither in organic solvents nor in water and separate out from the reaction mixtures as finely dispersed precipitates. In the IR spectra of the reaction products, the absorption bands of the bending vibra-

Table 5. Complexation of poly-2-vinyl-5-methyl-1,3,4-oxadiazole with metal salts MAn_n. L : MA_n = 2 : 1 (base mole : g-equiv)

MAn_n	Solvent	Yield, %	Found, %		
			C	N	Cl
$CuCl_2$	Ethanol	80	32.6	14.5	15.9
$NiCl_2$	"	73	27.5	11.8	16.0

$Pd(CH_3COO)_2$	DMF	55	27.4	11.4	

tions of the heteroring are shifted toward higher frequencies by approximately 10–20 cm^{-1}. In accordance with the generally accepted views on the structure of metal azole complexes, it can be suggested that the complexation with polyvinyloxadiazole is due to the donor–acceptor interaction of the ring nitrogen atoms with the metal ion:

Participation of the oxygen atom in the coordination is not confirmed.

CONCLUSION

Previously unknown carbon-chain polymers with pendant 1,3,4-oxadiazole fragments can be successfully prepared from low- and high-molecular-weight precursors. The synthesized vinyl-1,3,4-oxadiazole monomers are somewhat less active in radical polymerization than vinylazoles containing only nitrogen heteroatoms in the ring. Polyvinyl-1,3,4-oxadiazoles are nonionic, relatively heat-resistant polymers and can act as starting compounds for further chemical modification.

Abstract—The kinetics of degradation of cellulose nitrates in low-water organic solvents in the presence of various catalysts was examined.

DOI: 10.1134/S1070427206070251

Low-viscosity colloxylins, a commercial brand of cellulose nitrates (CNs), which are used for production of a broad spectrum of paint and varnish materials, are in a high consumers' demand. The molecular weight of CNs (typically characterized by the viscosity of their solutions in acetone) is the limiting indicator of the duration of the stabilization phase and of the process of production of commercial low-viscosity cellulose nitrates as a whole, which is eventually responsible for the performance of the product.

In practice, to decrease the viscosity of CNs, they are subjected to degradation in an aqueous medium at a pressure of 0.5–0.7 MPa and temperature of about 140°C. Long time of the operation and high power consumption in high-temperature treatment of a CN suspension necessitate the search for alternative ways of controlling the molecular weight of CNs. This is especially urgent in preparation of low-viscosity lacquer colloxylins, when the use of batch autoclaves gives rise to certain process problems.

All these facts necessitate the search for methods to change to "milder" temperature regimes of treatment compared to those currently used, as well as to ambient-pressure reduction of viscosity so as to produce CNs with a higher quality at considerably lower costs. The relationships in hydrolysis of CNs in aqueous media were described in sufficient detail [1–3], whereas there are only limited data on degradation of CNs in low-water organic solvents [4].

In this study we examined the relationships in controlling the molecular weight of CNs by catalytic degradation in organic solvents in the presence of various catalysts.

EXPERIMENTAL

As the initial substance served CNs with the nitrogen content of 11.9–12.5% and intrinsic viscosity in acetone at 25°C $[\eta] = (1.23–3.00) \times 10^2$ cm^3 g^{-1}. Degradation was carried out in a three-necked flask equipped with a jacket for heating, a mechanical stirrer with a hydroseal, a thermometer, and a reflux condenser. The required temperature was maintained with a temperature-control device using a water thermostat. The CN : solvent ratio was 1 g : 10 cm^3. After the catalyst was introduced, samples were taken at regular intervals, precipitated into water, thoroughly washed with distilled water to neutral pH of the wash water, crushed, and dried. The change of the viscosity was estimated by determining the intrinsic viscosity of a series of acetone solutions of CNs at 25°C [5, 6].

In the initial stage, the catalytic performance of compounds of different nature (H_2O_2, NH_4OH, H_2SO_4, H_3PO_4, $HClO_4$, and HNO_3) was estimated in hydrolysis of CNs in a homogeneous medium. Table 1 presents the conditions and experimental degrees of hydrolytic degradation of cellulose nitrates.

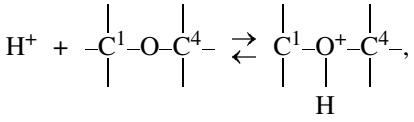

Table 1 shows that dissolution of CNs decreases the intensity of intermolecular interaction and the role of the diffusion component of the process, thereby substantially accelerating hydrolytic degradation of CNs. In a homogeneous medium, both hydrolysis of CNs (1) at the C^1–O–C^4 glycoside bond and hydrolysis of the –C–O–NO_2 moieties (2) (denitration of CNs) are accelerated. This is consistent with the conventional views on faster hydrolysis of cellulose and its derivatives in homogeneous media:

$$HA \rightleftarrows H^+ + A^-,$$

The nature of the catalyst strongly affects the degree of degradation and the rates of the constituent reactions. Hydrogen peroxide is the least active in the series of the substances examined; however, it significantly decreases the contribution of CN saponification. The catalytic activity of acids decreases in the series mentioned and qualitatively correlates with their dissociation constants, pK_a [$HClO_4$ ~–8.00, HNO_3 ~–1.64, H_3PO_4 (1) ~2.12]. The hydrolytic degradation of CNs is substantially accelerated with increasing content of the catalyst in the system. For example, an increase in the content of perchloric acid from 1 to 2% of the weight of CNs causes the viscosity to decrease almost by half, all other factors being the same. Rising the reaction temperature also promotes the hydrolysis. For example, rising the temperature from 60 to 70°C decreases the viscosity of CNs by a factor of 1.5–2.0, and that from 50 to 60°C, by a factor of almost 8.

As known [3], cleavage of the glycoside bond at C^1 under excess of water is described by a first-order equation; in the initial stages of the process, when the degrees of polymerization are high,

$$1/p_t - 1/p_0 \approx k_1 t, \quad (6)$$

holds, where p_0 is the number-average degree of polymerization of the initial sample; p_t, degree of polymerization after the hydrolysis time t; and k_1, rate constant of the reaction.

Taking into account the known constants $k = 5 \times 10^{-1}$ cm^3 g^{-1} and $\alpha = 1.0$ in the Mark–Houwink equation $[\eta] = kp^{\alpha}$ for the CN solutions in acetone [3], the relationship (1) can be represented as

$$1/[\eta] - 1/[\eta_0] \approx k_{app} t, \quad (7)$$

where k_{app} is the apparent constant taking into account k_1 and the degree of polydispersity of the CN sample.

Table 2 presents the conditions and experimental data for the hydrolytic degradation of CNs dissolved in ethyl acetate and, for comparison, the data on hydrolysis of CNs in an aqueous medium.

Data in Table 2 were used for calculating the $1/[\eta] - 1/[\eta_0]$ parameters and plotting their depen-

dences on the hydrolysis time. Figure 1a shows that, irrespective of the reaction conditions, the experimental data are adequately described by relationship (7).

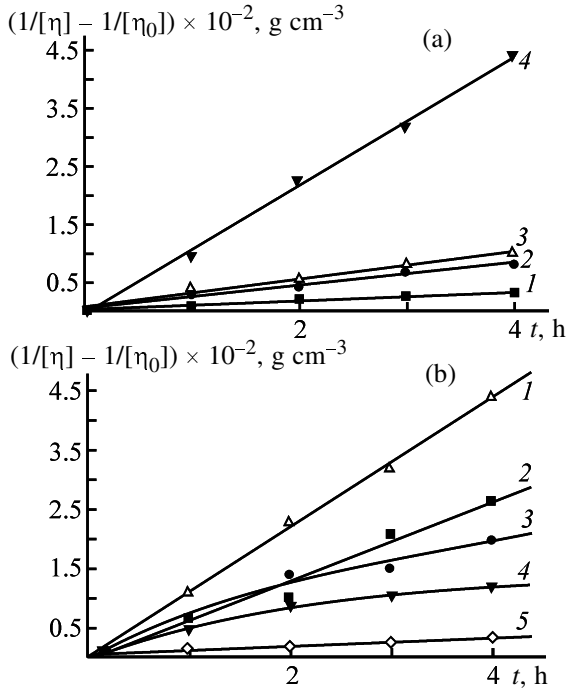

Fig. 1. Variation of $1/[\eta] - 1/[\eta_0]$ with the hydrolysis time t in various media (a) Figures at straight lines correspond to run nos. in Table 2; (b) (*1*) ethyl acetate, (*2*) toluene, (*3*) benzene, (*4*) methylene chloride, and (*5*) water.

Catalytic degradation is the most intense in ethyl acetate in the presence of $HClO_4$ as the catalyst, and in an aqueous medium the viscosity decreases most slowly. This agrees well with the published data on acceleration of saponification and hydrolysis in the presence of substances that cause swelling and dissolution of CNs [6, 7]. It should be noted that the reaction is accelerated with decreasing water content in the system. This is most likely due to increased role of the competing reaction of the acid with water, yielding hydroxonium cation (3), and the ensuing decrease in the concentration of the intermediate oxonium ion [reaction (1)].

It is also seen that the nature of the acid strongly affects the hydrolysis rate. For example, acetic acid with a lower catalytic power causes the viscosity of CNs to decrease in hydrolytic degradation to a lesser extent than does perchloric acid.

Table 3 presents the kinetic data on hydrolysis of CNs under heterogeneous conditions in nondissolving media.

Despite the heterogeneity of the process and fairly mild reaction conditions, in all the experiments the viscosity of CNs significantly decreases with increasing hydrolysis time, most rapidly in benzene. Thus, hydrochloric acid is close to perchloric acid in the catalytic power, and nitric acid has the lowest catalytic power.

Table 4. Conditions and selected results of hydrolysis of VNV colloxylin in various media at 70°C*

Medium	H_2O content, M	Intrinsic viscosity of CNs $[\eta] \times 10^{-2}$, $cm^3\ g^{-1}$, at indicated hydrolysis time, h				
		0.0	1.0	2.0	3.5	5.0
H_2O	55.578	3.00	2.77	2.33	2.23	1.97
Methanol**	–	3.00	1.91	1.71	1.56	1.36
Ethanol	2.244	3.00	1.87	1.70	1.70	1.44
Isopropanol	–	3.00	2.13	1.92	1.79	1.54
Butanol	0.028	3.00	2.76	2.00	2.00	1.66

* Content of the catalyst $HClO_4$ in the system 0.006 M (1 wt % of CNs).
** Hydrolysis was carried out at 60°C.

It should be noted that, in a homogeneous process, the kinetic plots are linear (in our case, this concerns the hydrolysis in ethyl acetate, i.e., the relationships in the reaction correspond to those in first-order reactions). In the case of heterogeneous hydrolysis, linear sections are observed in the initial stage only (1–2 h). At longer hydrolysis, the linearity is violated, due probably to enhanced role of the diffusion processes.

Our data show that, despite milder temperature conditions of hydrolysis in a heterogeneous medium, the reaction rate remains fairly high. As a result, the viscosity can be reduced to the level corresponding to that of the NV brand of lacquer CNs, $[\eta] = 0.66 \times 10^2\ cm^3\ g^{-1}$.

Table 4 shows how the intrinsic viscosity of the sample of preliminarily stabilized commercial CNs of VNV brand decreases upon hydrolysis in various alcohols and, for comparison, in water.

We found that, in all the experiments, the viscosity tends to decrease with increasing hydrolysis time.

The hydrolysis is the most intensive in methanol, and the least intensive, in an aqueous medium; it is naturally decelerated with increasing molecular weight of the alcohol. In the case of methanol and ethanol, the viscosity sharply decreases in the first 2 h, and in the case of isopropanol and butanol, it uniformly decreases throughout the hydrolysis time.

It is seen that, at the hydrolysis time of 5 h, the rates of hydrolysis of CNs in different alcohols become close, but the viscosities are lower than those of commercial samples of lacquer CNs. Minor changes in the rate of the catalytic degradation in alcohols compared to an aqueous medium are probably due to enhancement of the role of the competing reaction of the acid with the alcohol, yielding alkoxonium cation (5), and to the ensuing decreases in the concentration of the intermediate oxonium ion [reaction (1)] and in the rate of the main reaction of cleavage of the 1,4-β-glycoside bond.

CONCLUSIONS

(1) The catalytic degradation of cellulose nitrates in low-water organic solvents, catalyzed by $HClO_4$, goes at a high rate both in homogeneous (dissolving) and heterogeneous (nondissolving) media, and it is governed by the balance of the acid-base interaction of all the components of the system.

(2) The inhibiting action of water and alcohols can be due to the competing reactions yielding hydroxonium and alkoxonium cations, respectively.

(3) These relationships are used in the development of a power-saving process for production of paint and varnish materials based on low-viscosity cellulose nitrates.

Abstract—Changes in the supramolecular structure of heat-resistant fibers based on polyimide PM were studied by X-ray diffraction analysis and NMR spectroscopy.

DOI: 10.1134/S1070427206070263

It is well known that carbon fibers can be prepared from various macromolecular compounds whose properties determine the conditions of the preparation of these polymeric fibers and their subsequent carbonization. As seen from published data, heat-resistant fibers based on polyimides are widely used for this purpose, which is due to the absence of toxic gaseous carbonization products, thermal stability and high coke residue, and possibility of low-temperature carbonization without cracking and pore formation [1]. It should be noted that the majority of studies dealing with the behavior of polyimides under heat treatment with the aim to prepare carbon fibers predominantly concerned the role of the chemical structure of polyimides [2–4]. The studies of carbonization of polyamides [5] revealed the effect of the unit structure and macromolecule flexibility on the course of the polyimide pyrolysis. It was found that the three-dimensional cross-linked structure of polyimide affects the fiber carbonization and that polyimide and its derivatives can be used to initiate carbonization of the entire class of polyheteroarylenes (especially nitrogen-containing analogs).

Although pyrolysis and carbonization of polyheteroarylenes and, in particular, polyimides was concerned in numerous papers, there are virtually no data on changes in the supramolecular structure of these oriented polymers in the course of pyrolysis and on how these changes affect the formation of the turbostratic structure of carbon.

In this study we examined changes in the supramolecular structure of the fibers in the course of thermal treatment using one of the most stable aromatic polyimides, PI PM, prepared from pyromellitic dianhydride and diaminodiphenyl oxide.

EXPERIMENTAL

The arimide fibers were prepared from solutions of PM polyamido acid (PAA) in a coagulating bath: 20–25% DMA, 45% water, and 30–35% sodium thiocyanate.

The X-ray diffraction (XRD) patterns were recorded on DRON-1.5 and KRM-1 devices (Kratky collimation, CuK_α radiation). The high-resolution solid-state (HRSS) ^{13}C NMR spectra at room temperature were recorded on a CXP-100 (Bruker) spectrometer using the procedures of magic angle spinning (MAS) and cross-polarization (CP).

Changes in the polyimide structure at its thermal treatment were studied using a combination of the large- and small-angle XRD and HRSS ^{13}C NMR spectroscopy. The pyrolysis and carbonization of the fibers were carried out in a laboratory unit in a nitrogen flow (under the condition of unhindered shrinkage) at a heating rate of 20 deg min^{-1} (dynamic heating mode).

The XRD patterns (equatorial and meridional scattering) of the initial samples and those treated in the dynamic mode at 500–800°C are shown in Fig. 1. As seen, the XRD patterns of the fibers pyrolyzed at 500–575°C are virtually identical. Certain changes in the XRD patterns (namely, strong decrease in the peak intensity at $2\theta = 5.5°$ and disappearance of higher-order reflections) are observed in the samples pyro-

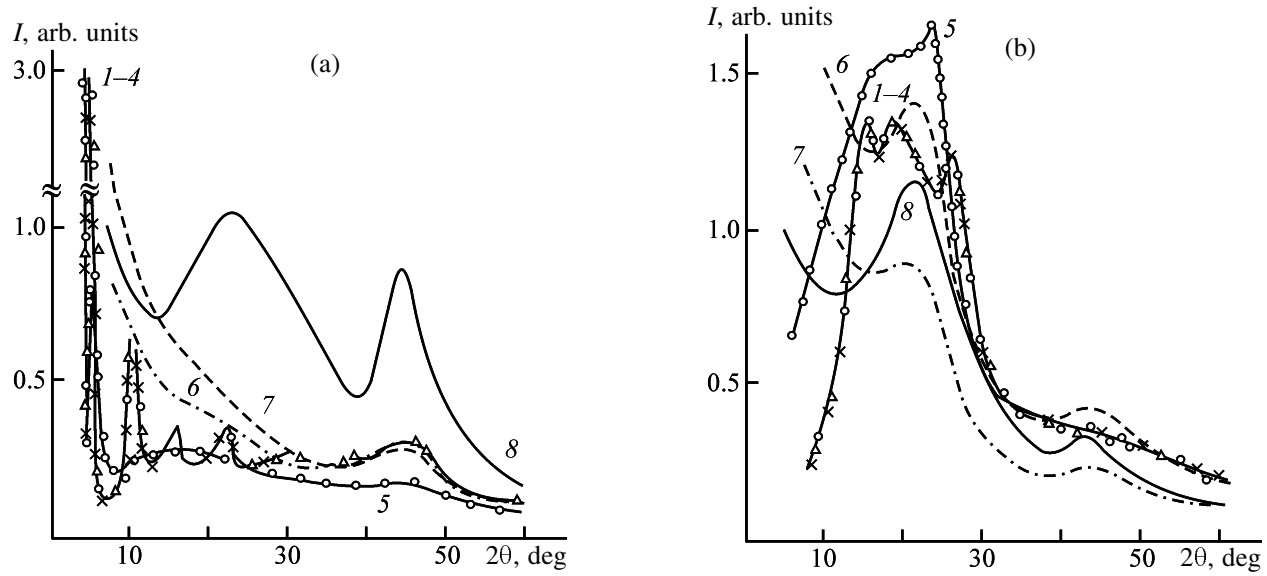

Fig. 1. Large-angle XRD patterns of the (*1*) initial polyimide fiber and fibers pyrolyzed at (*2*) 500, (*3*) 550, (*4*) 575, (*5*) 600, (*6*) 700, (*7*) 800, and (*8*) 900°C. (*I*) Intensity and (2θ) Bragg angle; the same for Fig. 2. (a) Meridional and (b) equatorial scattering.

lyzed at 600°C. However, the peak typical for the PI PM structure is retained up to 600°C, which suggests extremely high heat resistance of the PI PM crystallites. The HRSS ^{13}C NMR spectra showed that the typical peaks corresponding to the polymer chain only slightly change up to 600°C, which indicates that the polymer chain structure is preserved. Appearance of the carbon reflection (002) in the XRD patterns of the fibers pyrolyzed at 600°C suggests formation of turbostratic carbon (Fig. 1). With increasing temperature to 700–800°C, the reflections of the initial polyimide disappear and the intensity of reflections (002) and (110) belonging to carbon increases, which confirms intense carbonization of the fiber. In the NMR spectra, the half-width of the peak at 125 ppm corresponding to the polyaromatic structure increases.

Carbonization of the PI PM fibers at 900°C (Fig. 1, curve *8*) increases the reflections (110) and (002) belonging to carbon, which suggests formation of stacks of turbostratic carbon. The differences in the meridional and equatorial scattering, in particular, higher intensity of reflection (002) at equatorial scattering and its smaller intensity at meridional scattering, indicate that planes (002) are arranged in parallel to the fiber axes.

The small-angle XRD patterns (Fig. 2) showed that in the course of pyrolysis the density heterogeneity of the PI PM structure remains almost constant up to 550°C. This is confirmed by similar intensities of the reflections recorded at both equatorial and meridional scattering. On pyrolysis of the fibers at 575°C, the intensity of small-angle reflections increases. Exactly at this temperature the reflection (002) appears in the large-angle patterns (Fig. 1), indicating formation of turbostratic carbon. Further pyrolysis and carbonization at 700–800°C increases the heterogeneity of the carbon structure; as a result, the intensity of the small-angle scattering also increases. This structure contains the areas of turbostratic carbon, less ordered areas of amorphous carbon, and significant number of pores and cracks of various size and shape.

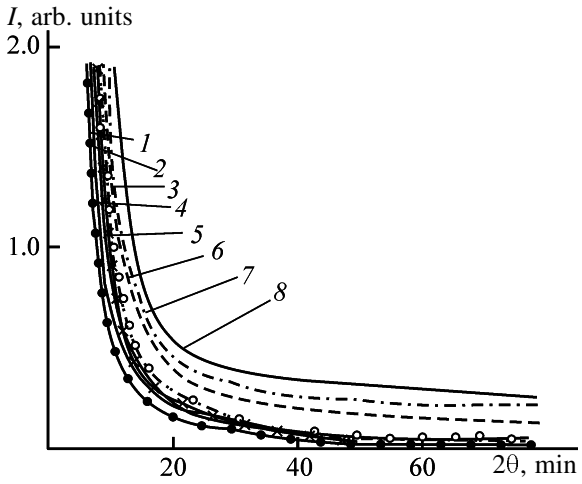

Fig. 2. Small-angle XRD patterns of the (*1*) initial polyimide fiber and fibers pyrolyzed at (*2*) 500, (*3*) 550, (*4*) 575, (*5*) 600, (*6*) 700, (*7*) 800, and (*8*) 900°C; meridional scattering.

Formation of the stacks of turbostratic carbons begins at 490–500°C in the less ordered regions of the polymer, where the pyrolysis proceeds at a higher rate. Degradation of polyimide crystallites occurs at temperatures significantly higher than 575°C, which would affect the kinetics of chemical degradation of the polymers and cause a local decrease in the coke residue. The deficit of carbon atoms should lead to the formation of a less ordered amorphous structure and appearance of pores.

This conclusion is confirmed by the fact that the carbon fibers formed from polyimide PM at 900°C exhibit low strength (σ = 560 MPa) and low elastic modulus (E = 34 GPa).

CONCLUSIONS

(1) Thermal degradation of polyimide PM and formation of the turbostratic carbon structure occur virtually simultaneously.

(2) The crystalline structure of the polyimide PM fibers exhibits high thermal stability, and its elements are retained up to 600°C.

(3) Low strength and elastic characteristics of carbon fibers prepared by carbonization of polyimide PM fibers at 900°C are associated with the high thermal stability of the crystallites.

Abstract—The structure and properties of castable polyurethanes with different content of the aluminum oxide filler were studied by X-ray diffraction, electron microscopy, and determination of the apparent cross-link density.

DOI: 10.1134/S1070427206070275

Previously [1] we developed SKU-OM castable polyurethanes (PUs) with high content of aluminum oxide (AO), filler which is a waste from petrochemical industry. The relative elongation and elasticity of PUs do not decrease, and their elastic modulus and especially hardness increase after introduction of AO, unlike the use of conventional fillers. The increase in the hardness with preservation of the strength suggests that AO is a reinforcing filler for PUs.

To determine the mechanism of this influence of AO filler on PUs, we studied the structure of PUs filled with AO by X-ray diffraction and electron microscopy and determined the apparent cross-link density of PUs in a wide temperature range.

EXPERIMNETAL

We studied monolithic SKU-OM castable PUs prepared from oligoethylene glycol adipate (OEA) with $M \sim 2 \times 10^3$ and a mixture of 2,4- and 2,6-toluene diisocyanate (TDI) taken in an 80 : 20 molar ratio (OEA : TDI molar ratio 1.0 : 1.6) [2]. Active AO with the particle size of 5–20 μm (substandard desiccant) was used as the filler.

X-ray diffraction analysis of PUs was performed on a DRON-2.0 automated diffractometer (CuK_α radiation with λ = 1.54178 Å) in the Bragg–Brentano symmetrical recording mode [3].

The morphology of the initial and filled PUs was studied by high-resolution transmission electron microscopy using self-shadow-cast replicas. To determine the structural relief, the samples were etched in a high-frequency electrodeless discharge plasma [4, 5].

The apparent cross-link density was determined by the Clough–Gladding procedure on an axial compression relaxometer [6]. 5 × 6-mm cylindrical samples were tested in the range 25–170°C. The apparent cross-link density ν_a/V (mol m^{-3}) was calculated by the equation

$$\nu_a/V = A/RTS,$$

where A is the slope of the linear portion of the F vs. $(h/h_0)^2 - (h_0/h)^2$ dependence; F is the loading (N); h_0 is the initial sample height (m); h is the equilibrium height of the deformed sample after a 15-s exposure (m); R is the universal gas constant (8.314 J mol^{-1} K^{-1}); T is the temperature (K); and S is the initial cross-section area of the sample (m^2).

The X-ray pattern of PU is typical for an amorphous polymer (Fig. 1, curve *1*).

The interplanar spacing of the amorphous sample (4.371 Å) is not a characteristic value but lies in the range typical for amorphous rubbers [7]. In addition, as we showed previously [2], PUs prepared at NCO : OH ≥ 1.6 do not crystallize.

As determined by X-ray analysis, two AO samples differ not only in the water content but also in the crystal structure (Fig. 2). This unexpected result is caused by preparation of these desiccants and is

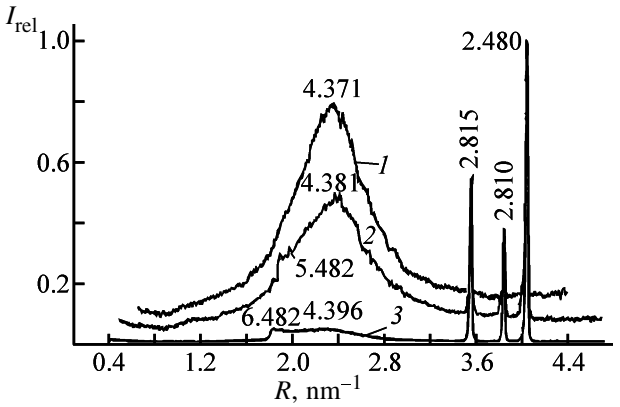

Fig. 1. X-ray pattern of PU containing (*1*) 0, (*2*) 5, (*3*) 50 wt % AO. (I_{rel}) relative intensity I/I_0 and (R) reciprocal interplanar spacing; the same for Fig. 2.

studied in detail in [8]. It is known that active aluminum oxide widely used as a sorbent in many processes of organic synthesis and oil refining is prepared from aluminum hydroxide having the undeveloped surface. Aluminum oxide with the required pore diameter is prepared by hydrothermal or thermal treatment.

The first step of hydrothermal treatment involves rehydration of active AO to form metahydroxide with the pseudoboehmite structure. Then the methahydroxide is converted into boehmite (Fig. 2, curve *2*) with coarse pores. After calcination at 550°C for 2 h, boehmite is converted into AO with the same pore structure (Fig. 2, curve *1*). The pore diameter of this product is 150–170 Å [9].

The reflections corresponding to interplanar spacings of 6.127, 3.149, and 2.345 Å (Fig. 2, curve *2*) are assigned to boehmite (γ-AlOOH) [7]. The other reflections are due to the presence of residual hydroxides.

The X-ray pattern of boehmite sharply ascends at small angles (Fig. 2, curve *2*). Since the X-ray pattern was recorded in the wide-angle range, the small-angle range was recorded incompletely. However, this shape of the X-ray pattern suggests that a second amorphous (disordered) phase with different density is present in the system [10]. In our case, this can be only due to the porous structure with a random pore arrangement. In the subsequent experiments, we used as a filler AO containing 1 wt % water.

No chemical reactions were observed after introduction of the filler into PU. The phase compositions of the polymer and filler also do not change, and the system is described by the additivity rule [3]. The X-ray pattern of the filled sample is a superposition of those of amorphous PU and crystalline AO. The fraction of the amorphous phase regularly decreases and that of the crystalline phase increases with increasing the filler content. However, an additional reflection with d 5.482 Å appears in the pattern of the PU phase (Fig. 1, curve *2*) after introduction of the filler. This suggests appearance of new phases.

These data agree well with the morphology of these samples studied by electron microscopy. The appearance of an additional reflection in the X-ray pattern is most likely due to formation of a dense physical network by the porous filler in the polymer matrix.

As seen from the electron micrograph (Fig. 3a), the globular structures are uniformly distributed in the initial PU. Rhombic-parallelepiped structures combined in chains are formed after introduction of the filler (Fig. 3b). Probably, these structures are AO particles coated with the adsorbed polymer. Apparently, in the course of PU synthesis, OEA molecules are adsorbed as a monolayer on the surface of AO particles, thus becoming more accessible for the reaction with TDI. This uniform distribution of the polyester and the filler favors formation of a regular polymer structure, which, in turn, affects the physicomechanical properties of PU (see table).

At an AO concentration of 30 wt % and more, the chain structures form a continuous phase in the area of the solid phase of the polymer (Fig. 3c). At a 50% filler content (Fig. 3d), a uniform network structure is formed. The composite consists of filler particles reinforcing the PU matrix. A polymer layer is adsorbed on the highly developed surface of these particles. This type of the three-dimensional network of a polymer is typical for composites with reinforcing fillers. The chain structures of the filler bind separate aggregates of rigid PU blocks and fill the whole volume. In addition, areas with globular structure of PU uniformly distributed between the chain structures formed by the filler are observed in the

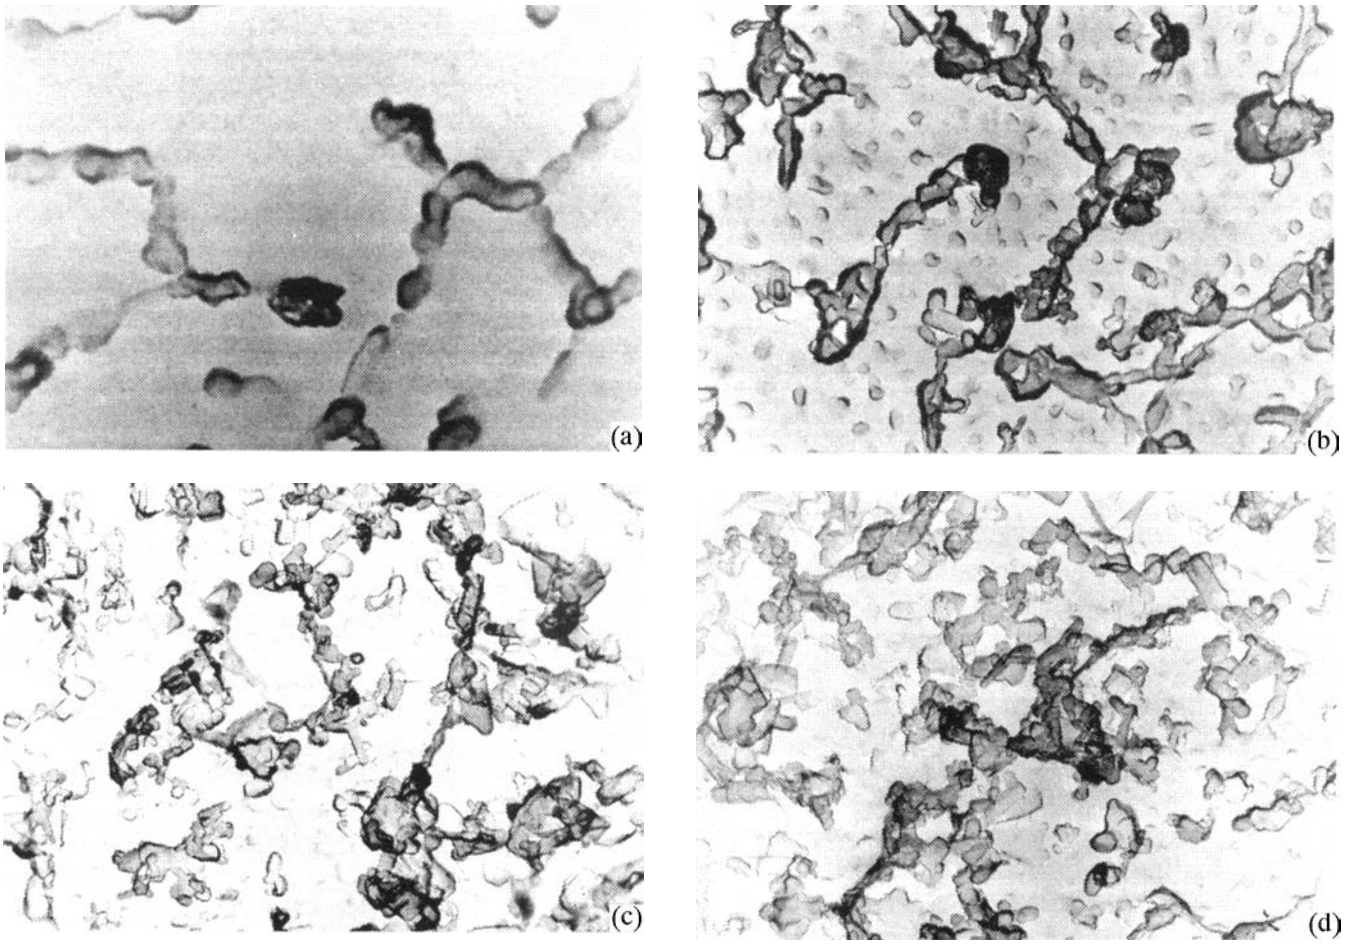

Fig. 3. Electron micrographs of (a) unfilled PU 10 and PU containing (b) 10, (c) 30, and (d) 50% AO. Magnification: (a) 14000 and (b–d) 10000.

electron micrographs. This structural arrangement enhances the physicomechanical properties of PU.

Hence, two reflections (d = 4.4 and 5.5 Å) in the X-ray patterns are assigned to the areas with globular PU structure observed in the micrographs. These structures are randomly distributed between the chain structures formed by the active filler.

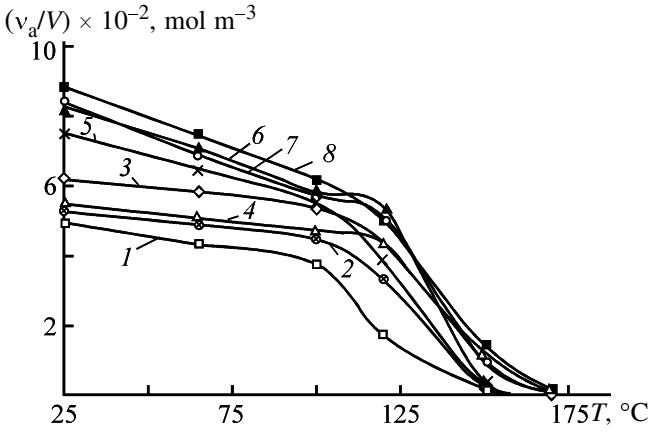

Fig. 4. Apparent cross-link density ν_a/V of PU containing (*1*) 0, (*2*) 3, (*3*) 5, (*4*) 10, (*5*) 20, (*6*) 30, (*7*) 40, and (*8*) 50 wt % AO as a function of temperature T.

PUs revealed the presence of a physical network produced by AO (Fig. 4.). Three temperature ranges 25–100, 100–150, and >150°C can be distinguished in these dependences. We suggest that the physical polymeric network degrades in the first temperature range. The second range is characterized by rupture of relatively weak chemical bonds. Heat-resistant bonds are ruptured on heating above 150°C.

The decrease in the cross-link density of the unfilled polymer in the first range is due to rupture of physical bonds. The decrease in the density in the second temperature range can be assigned to degradation of allophanic groups. In the third range, the urethane groups start do degrade. The isocyanurate units remain unchanged [11].

The shape of the temperature dependence of the cross-link density of PUs filled with AO is determined by the filler content. Generally, the higher the filler content, the higher is ν_a/V at a definite temperature (Fig. 4). The run of the initial portion of the curve becomes steeper with increasing filler content. In the range from 100–110 to 140–150°C, the curves sharply drop and flatten out above 150°C. The cross-link density in all cases is as low as 10–20 mol m^{-3}.

The features of the temperature dependence of the apparent cross-link density are caused by the presence of an additional physical network in the polymers filled with AO. The higher the filler content, the higher ν_a/V. The physical network formed by the filler degrades in the second temperature range. Since the contribution of the physical interactions to the total apparent cross-link density increases with increasing filler content, the descent of the temperature dependence of ν_a/V becomes steeper.

It should be noted that the temperature dependence of the apparent cross-link density of the composites containing more than 30 wt % filler flatten out in the range 100–120°C. As shown by electron microscopy and X-ray diffraction (Fig. 4, curves *6*–*8*), this is due to formation of a continuous phase of the filler in the polymeric matrix, which is stable under the experimental conditions.

However, at 140–150°C, all physical and weak chemical (allophanate and partially urethane) bonds are cleaved and the ν_a/V value reflects the presence of sufficiently heat-resistant triisocyanurate units in PU [11].

The high apparent cross-link density (870 mol m^{-3}) of the examined PU composites is due to a large number of physical interactions of AO. At the same time, PUs filled with AO remain highly elastic, whereas their hardness increases (see table).

CONCLUSION

The structural study of the filled polyurethanes showed that the presence of aluminum oxides with highly developed sorption surface in the system results in redistribution of intra- and intermolecular interactions, which favors formation of additional physical network in the polymer, preservation of high mechanical properties, and an increase in the elastic modulus and hardness.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Control of the Molecular Characteristics of Cationic Oligopiperylene Using Isomeric Methylbutenes

V. A. Rozentsvet, V. G. Kozlov, and A. S. Khachaturov

Institute of Ecology of Volga Basin, Russian Academy of Sciences, Togliatti, Samara oblast, Russia

Received January 24, 2006

Abstract—Additions of 2-methyl-1-butene or 2-methyl-2-butene to a monomer mixture with piperylene were tested as means for controlling the molecular parameters of cationic oligopiperylene prepared with the $TiCl_4$–H_2O catalytic system.

DOI: 10.1134/S1070427206070287

The process for commercial production of SKOP rubber (synthetic oligopiperylene rubber) is based on the cationic oligomerization of piperylene (1,3-pentadiene) in the presence of the $TiCl_4$–H_2O catalytic system [1]. It was found previously that the resulting cationic oligopiperylene can have either mono- or bimodal molecular-weight distribution depending on the oligomerization conditions [2, 3]. In the course of the oligomerization, the high-molecular-weight fraction of bimodal oligopiperylene can be cross-linked to form an insoluble gel fraction, which substantially impairs the consumer properties of the finished product [3, 4].

It is known that addition of certain olefins to the reaction mixture of cationic polymerization of dienes allows efficient control of the molecular weight of the resulting polymer [5].

In this study we examined how additions of isomeric methylbutenes (2-methyl-1-butene, 2M1B; 2-methyl-2-butene, 2M2B; 3-methyl-1-butene, 3M1B) affect the cationic oligomerization of piperylene on the $TiCl_4$–H_2O catalytic system and the molecular parameters of the resulting oligomer. From the practical viewpoint, search for an efficient agent for controlling the molecular weight is necessary for preparing cationic oligopiperylene containing no insoluble gel fraction.

EXPERIMENTAL

Piperylene was purchased from Sterlitamak Synthetic Rubber Joint-Stock Company; it contained (wt %) *trans*-piperylene 61.9, *cis*-piperylene 34.5, cyclopentene 1.6, isoprene 0.3, 2M2B 0.3, cyclopentadiene 0.1, and saturated hydrocarbons 1.3.

2-Methyl-2-butene (99 wt %, Aldrich), 2-methyl-1-butene (98 wt %, Fluka), and 3-methyl-1-butene (96 wt %, Aldrich) were used without additional purification.

Oligomerization was performed in heat-treated glass ampules in an atmosphere of purified Ar. The experimental details and procedures for purifying the solvent and catalyst components are described elsewhere [1–4]. The content of the gel fraction (GF) in the oligomer was determined by extraction with toluene in a Soxhlet apparatus for 24 h. The soluble (sol) fraction was separated from GF on a centrifuge from a solution of the oligomer in hexane.

The molecular paameters of the sol fraction were determined with a Waters-Alliance GPCV-2000 liquid chromatograph equipped with three Styrogel columns HR-2, HR-4, and HR-6. Eluent toluene; elution rate 1 ml min^{-1}.

The microstructure of the oligomers was analyzed by high-resolution ^{13}C NMR spectroscopy with a Bruker AM-500 spectrometer (operating frequency for ^{13}C 125 MHz). The spectra were recorded at room temperature with accumulation of 4000–6000 scans in the DEPT-135° mode, with the subsequent Fourier transform.

Figure 1 shows the dependence of the total yield of the oligomer on the concentration of methylbutenes in the starting mixture with piperylene. With 2M1B and

Table 1. Influence of th 2M2B concentration in the monomer mixture on the molecular parameters of the resulting oligomer. Oligomerization conditions: 50°C; 120 min; toluene; $[C_5H_8]$ = 9.0, $[TiCl_4] = 3.5 \times 10^{-2}$, $[H_2O] = 1 \times 10^{-2}$ M

2M2B content in monomer, mol %	GF content in oligomer, wt %	LMWF/HMWF ratio in sol fraction	LMWF parameters		HMWF parameters	
			$M_w \times 10^{-3}$	$M_n \times 10^{-3}$	$M_w \times 10^{-3}$	$M_n \times 10^{-3}$
0.3	18.2	85/15	9.5	3.7	201.0	154.0
5.0	3.0	87/13	6.8	2.4	187.0	151.0
12.0	1.0	90/10	6.2	2.0	143.0	115.0
22.0	0	95/5	3.9	1.1	82.0	71.0
26.0	0	100/0	3.2	0.7	–	–
40.0	0	100/0	2.2	0.5	–	–
50.0	0	100/0	1.0	0.2	–	–

2M2B, these dependences pass through a maximum at a methylbutene content in the starting monomer of 12–15 mol % (Fig. 1, curves *1*, *2*). In this point, the total yield of the oligomer increases from 66 (without methylbutenes added) to 80–83%. In contrast to 2M1B and 2M2B, addition of 3M1B to piperylene leads to a gradual decrease in the yield throughout the examined concentration range (Fig. 1, curve *3*).

Addition of methylbutenes to the piperylene significantly affects the molecular parameters of the oligomers formed. Figure 2 shows the molecular-weight distribution (MWD) curves for the sol fraction of the oligomers prepared at various contents of 2M2B in a mixture with piperylene. If no 2M2B was added to piperylene, the MWD curve showed two distinct maxima (Fig. 2, curve *1*). The left maximum describes the MWD of the high-molecular-weight fraction (HMWF), and the right maximum, the MWD of the low-molecular-weight fraction (LMWF) of the oligomer. As the 2M2B content in the monomer is increased to 12 mol %, the HMWF content in the oligomer decreases (Fig. 2, curve *2*), and at a 2M2B content of 26 mol % the HMWF fully disappears, and the MWD of the oligomer becomes unimodal (Fig. 2, curve *3*).

Table 1 shows the molecular-weight parameters of the oligomers in relation to the 2M2B content in the monomer mixture. With an increase in the 2M2B content, the number-average (M_n) and weight-average (M_w) molecular weights of both LMWF and HMWF of the oligomer decrease, apparently due to the transfer of the propagating chain to the olefin [5].

Additions of 2M1B exert a similar effect on the molecular parameters (Table 2). Addition of 15 mol % 2M1B fully suppresses the formation of the insoluble GF, and addition of 20 mol % 2M1B suppresses the formation of HMWF. As in the case with 2M2B, with an increase in the 2M1B content in the monomer mixture the molecular weights of the LMWF of the oligomer decrease and the polydispersity M_w/M_n increases.

3M1B is considerably less effective as an agent

50.0	1.0	90/10	6.1	2.4	2.5

controlling the molecular parameters of the oligomer (Table 2, Fig. 3). Addition of 30 mol % 3M1B to the monomer mixture does not fully suppress the formation of the insoluble GF; its content in the oligomer remains as high as 5.0 wt %. The LMWF/HMWF ratio changes insignificantly even on adding 50 mol % 3M1B to the monomer. The weight-average molecular weight of the LMWF of the oligomer prepared at both 50 and 100°C somewhat decreases on adding 3M1B (Fig. 3, curves *1*, *2*). For comparison, Fig. 3 shows how the weight-average molecular weight of the LMWF of the oligomer decreases in the presence of 2M2B, at the same polymerization temperatures (curves *3*, *4*).

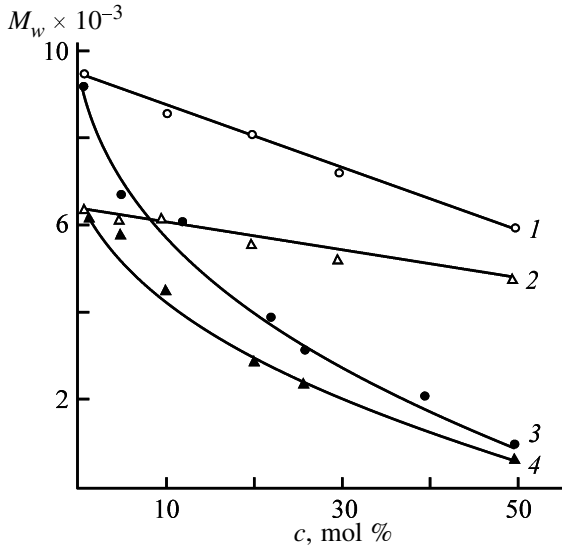

Fig. 3. Weight-average molecular weight M_w of the LMWF of the oligomer as a function of the concentration c of (*1*, *2*) 3M1B and (*3*, *4*) 2M2B in the mixture with piperylene. Oligomerization temperature, °C: (*1*, *3*) 50 and (*2*, *4*) 100.

A GLC analysis of the monomer mixtures before and after the oligomerization showed that during the process a part of 2M1B isomerizes into 2M2B (Table 3). In particular, upon oligomerization of a mixture of 50 mol % 2M1B + 50 mol % piperylene, the 2M2B concentration in the unchanged monomer increases by more than an order of magnitude relative to its initial content (from 0.24 to 2.81 mol %). For comparison, Table 3 shows changes in the concentrations of saturated hydrocarbons (2-methylbutane, *n*-pentane), which may play the role of "internal reference" in analysis of the monomer mixtures. At other contents of 2M1B in its mixture with piperylene, the 2M2B concentration also increases by more than an order of magnitude.

Table 3. Results of analysis of the monomer mixture before and after oligomerization

Components of monomer mixture	Content, mol %	
	before reaction	after reaction
trans-Piperylene	30.95	22.15
cis-Piperylene	17.25	15.13
2-Methyl-1-butene	49.05	56.60
2-Methyl-2-butene	0.24	2.81
2-Methylbutane	0.10	0.15
n-Pentane	0.10	0.14

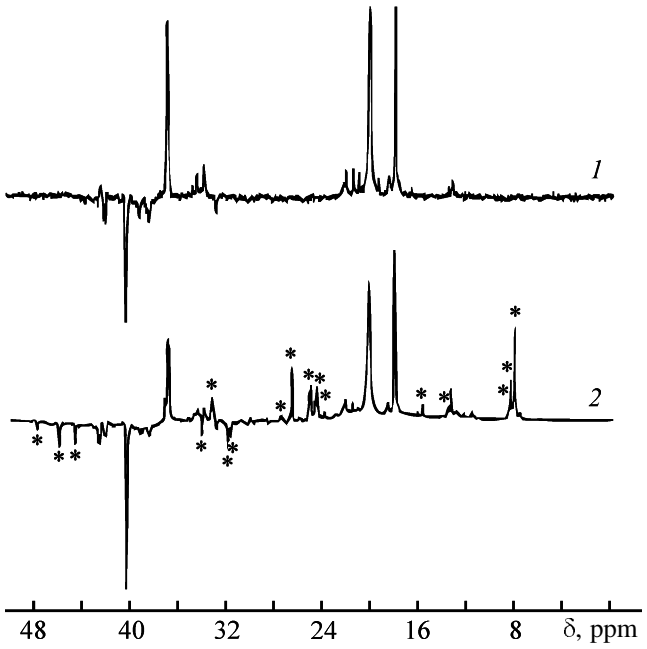

Fig. 4. ^{13}C NMR spectra of oligomers prepared from (*1*) 100 mol % piperylene and (*2*) 80 mol % piperylene + 20 mol % 3M1B. (δ) Chemical shift; the same for Fig. 5.

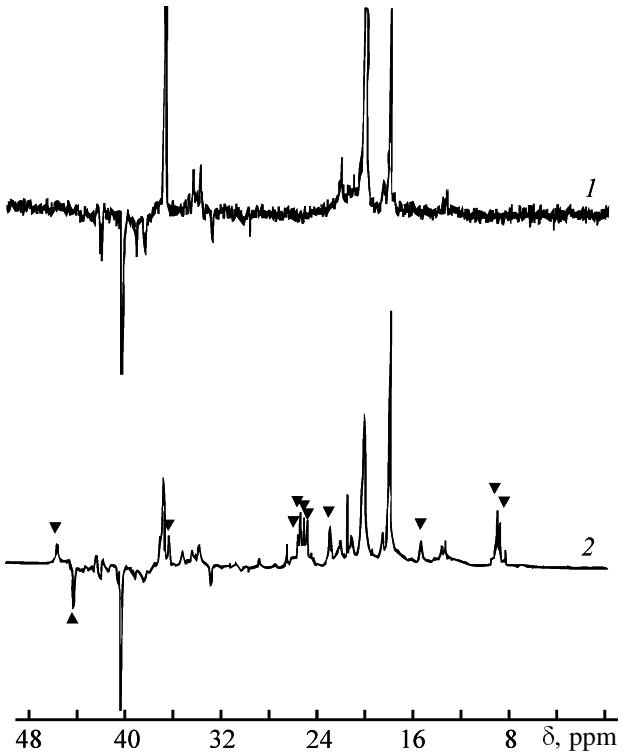

Fig. 5. ^{13}C NMR spectra of oligomers prepared from 80 mol % piperylene + 20 mol % methylbutene [(*1*) 3M1B and (*2*) 2M2B].

Therefore, we suggested that, under the conditions of the cationic oligomerization, 2M1B first fully or partially isomerizes into 2M2B and then cooligomerizes with piperylene.

To check this assumption, we studied the structures of the cooligomers of piperylene with methylbutenes by high-resolution ^{13}C NMR.

Figures 4 and 5 show the aliphatic portions of the ^{13}C NMR spectra of the piperylene homooligomer and its cooligomers with 2M1B, 2M2B, and 3M1B. The cooligomers of 2M1B and 2M2B with piperylene exhibit new well-defined signals corresponding to the olefinic structures in the oligopiperylene chain (asterisks and triangles, respectively, in Fig. 4, spectrum *2* and Fig. 5, spectrum *2*). The new signals in the spectrum of the piperylene–2M1B cooligomer (8.01, 8.33, 8.47, 13.46, 15.60, 23.75, 24.40, 24.88, 26.47, 27.43, 31.50, 31.92, 33.19, 34.02, 44.71, 45.92, 47.85 ppm) do not coincide in the position with those in the spectrum of the piperylene–2M2B cooligomer (8.83, 9.06, 15.26, 22.85, 24.77, 25.06, 25.34, 25.54, 36.39, 44.40, 45.74 ppm).

The observed difference in the structure of the cooligomers indicates that, although partial isomerization of 2M1B into 2M2B does occur in the course of the cooligomerization of 2M1B with piperylene, this process is not prevalent.

The ^{13}C NMR spectrum of the oligomer prepared by cooligomerization of piperylene wth 3M1B (Fig. 5, spectrum *1*) is essentially similar to the spectrum of the piperylene homooligomer (Fig. 4, spectrum *1*), which is indicative of a weak reactivity of 3M1B in the cationic cooligomerization with piperylene.

CONCLUSIONS

(1) Additions of 2-methyl-1-butene and 2-methyl-2-butene to piperylene allow efficient control of the molecular parameters of the cationic piperylene oligomer prepared on the $TiCl_4$–H_2O catalytic system: 12–15 mol % additions of 2-methyl-1-butene or 2-methyl-2-butene to the monomer fully suppress the formation of the insoluble gel fraction, and 20–25 mol % additions suppress the formation of the high-molecular-weight fraction in the resulting oligomer.

(2) 3-Methyl-1-butene added to the monomer is inefficient as an agent controlling the molecular parameters of cationic oligopiperylene.

(3) Recommendations on optimization of the composition of the piperylene fraction fed to the cationic

oligomerization unit were formulated and industrially implemented, which allowed preparation of SKOP rubber containing no high-molecular-weight and insoluble gel fractions and thus improvement of the product quality.

CHEMISTRY OF FOSSIL FUEL

Revealing the Common Sources of Commercial Explosive-Containing Articles

Abstract—A method for identification of explosive-containing commercial articles is suggested. The method is based on chromatographic analysis of petroleum products present in the articles as process admixtures and structural components.

DOI: 10.1134/S1070427206070299

Articles containing explosives (TNT blasting cartridges of various types, ammonite cartridges, cumulative perforating charges with retarded hexogen and octogen) have industrial marking with information about manufacturer, production batch, etc. In the case of illegal use of explosives, however, the industrial marking is eliminated and special expertise is necessary for identifying the supply sources of explosive articles.

As objects of expertise can serve both the main material of an article (explosives proper) and microscopic process impurities contained in it, as well as other structural elements of the article, package materials, waterproofing coatings, etc. At present, comparative studies of high explosives are performed by analyzing the composition of impurities contained in explosives by a set of chromatographic methods (gas and liquid chromatography combined with various detecting systems). This makes it possible to reveal specific features of the production process and to obtain indirect information about the manufacturer and production and storage condition of an explosive. For example, in the case of TNT, it is possible not only to identify the manufacturer, but also to reveal the source of raw material (toluene) and methods used to obtain (nitration) and purify the product [1, 2]. However, obtaining so detailed data requires, in addition to appropriate analytical equipment, samples for comparison and access to information about the technology employed by the manufacturer of an explosive. This approach is justified in the case of identification of explosive themselves, but seems to be inefficient for comparative studies of explosives in the form of charges and commercial articles.

Thus, analysis of the composition of an explosive proper is, in most cases, poorly informative for expertise purposes because the number of manufactures of explosives is limited and the basic composition of explosives of the same type and even that of process microimpurities they contain varies very narrowly. As a result, it is highly probable that studies of finished articles would reveal, in articles of different types (e.g., in 200- and 400-g TNT blasting cartridges) or in those of the same type, but produced by different manufacturers, explosives (e.g., technical-grade TNT) that are produced at the same plant or even belong to the same production batch.

A more detailed and reliable, as regards identification purposes, information about finished articles can be obtained by analysis of specific features that appear in final stages of article fabrication from raw materials.

Products of oil refining constitute a material that is the most widely used in final stages of fabrication of commercial articles and can contain identifying information. For example, blasting cartridges have waterproofing coatings composed of paraffin, petrolatum, and mixtures of these. Octogen and hexogen are virtually not used at all in pure form, and explosives based on these compounds are products of their retardation with paraffin-like materials. A similar situation takes place for blended explosives based on ammonium nitrate. In addition, ammonite cartridges have a multilayer sheath of waxed paper. Thus, virtually all explosive-containing commercial articles include heavy petroleum products or mixtures of these.

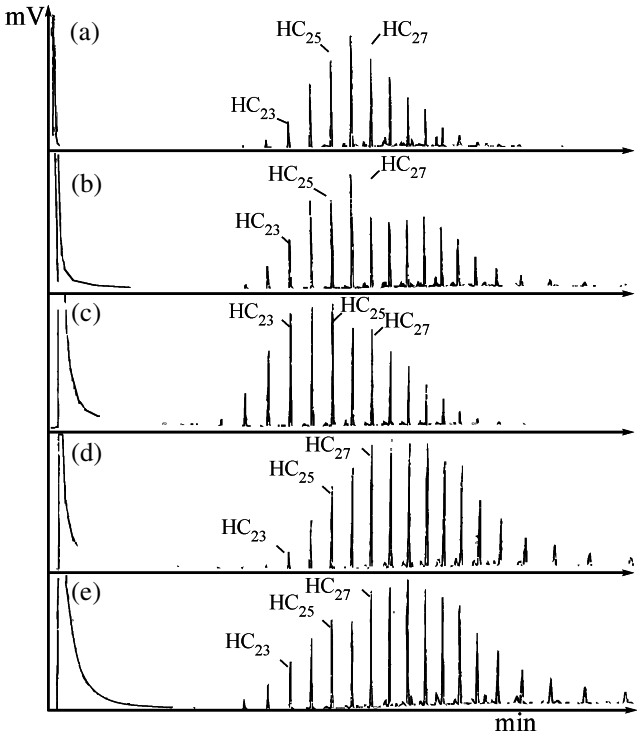

Fig. 1. Typical chromatograms of hydrocarbons extracted from structural elements of explosive-containing articles. Sample: (a) hexane solution of the waterproofing coating of a 200-g TNT blasting cartridge, (b) hexane solution of the waterproofing coating of a 400-g TNT blasting cartridge, (c) hexane extract of N 6ZhV ammonite, (d) hexane extract of retarded hexogen from a cumulative perforating charge of the ZPRK42S type, and (e) hexane extract of retarded octogen from a cumulative perforating charge of the ZPK105S type.

The petroleum products used in this case are multicomponent mixtures of individual hydrocarbons, and these mixtures are artificially produced from mixtures of natural origin, i.e., from oil. In the case of high-purity paraffin, the number of individual hydrocarbons in its composition rarely exceeds 25–30, whereas for petrolatum this number is several times larger. Hence follows that the quantitative and, to a certain extent, qualitative hydrocarbon composition of the starting petroleum products, and the more so that of the finished mixtures on their base, is accidental and may vary rather widely from one production batch to another (and even more so, from one manufacturer to another). For example, the compositions of waterproofing coatings of TNT blasting charges, prepared from different petroleum components or from starting components from the same batches, but taken in different ratios, will differ from one another in the quantitative composition of individual hydrocarbons in the mixtures and in the distribution of their relative contents. Because waterproofing coating of TNT blasting cartridges is the final stage of the production process, the composition of the waterproofing layer should provide information about a production batch in a narrower range, compared with the composition of process impurities in the technical-grade TNT.

It seems that the most efficient method for a comparative study of the qualitative and quantitative composition of petroleum products used in commercial high explosives and as structural elements of explosive-containing articles is gas–liquid chromatography.

EXPERIMENTAL

A FISONS-GC 8000 laboratory gas chromatograph was used in the study. The conditions of chromatographic analysis were as follows: flame-ionization detector; HP-Ultra-1 capillary column of length 12.5 and diameter 0.2 mm, with a thickness of the fixed phase of 0.33 μm; carrier gas helium; injector with a 1 : 20 flow division; flow velocity of carrier gas 1 ml min^{-1}; sample volume 1 μl; injector temperature 280°C; detector temperature 310°C; temperature schedule of the thermostat, 1-min isotherm at 100°C, heating at a rate of 10 deg min^{-1} to 300°C, and isothermal keeping at this temperature for 15 min.

Figure 1 shows typical chromatograms of petroleum products used in commercial high explosives and contained in structural elements of explosive-containing articles. Homologs of normal saturated hydrocarbons with 20 to 38 carbon atoms are readily identified in the chromatograms, and the chromatograms themselves differ in the quantitative ratios between the peaks of individual substances and in their relative distributions.

The results obtained demonstrated that the following general approach can be used for identification of various explosives and articles on their base: revealing the structural elements and comparing their quantitative hydrocarbon composition by gas chromatography. The modern level of development of the computing technology makes it possible to substantially facilitate comparison of quantitative characteristics and to create special databases for automated identification of a manufacturer and a production batch of articles.

To demonstrate the potential of the method for identification of explosives and articles on their base, we made a comparative study of the waterproofing coating of blasting cartridges of the TP-200G-K type

from five different batches manufactured in 1998–1999.

Waterproofed compacted TNT blasting charges of the TP-200GK type are commercially manufactured and intended to be used as explosives in seismic prospecting on the ground surface in all climatic zones of CIS countries at temperatures of –50 to +50°C. The TP-200G-K blasting charges comprise compacted TNT and a paper sheath and have a cylindrical shape with a pocket for a blasting cap or electric detonator. The weight of a blasting cartridge was 200 g. The surface of the blasting cartridges (except that of the pocket) is covered with a continuous thin waterproofing layer of a paraffin–petrolatum mixture [3].

The paraffin–petrolatum mixture used in waterproofing coatings of blasting cartridges is prepared by mixing petrolatum and paraffin in a melt to obtain a homogeneous mixture with a prescribed dropping point.

Now, the starting components of the waterproofing mixture will be analyzed in more detail. As is known, paraffin is a mixture of normal hydrocarbons of the methane series (*n*-paraffins) with 18–40 carbon atoms in a molecule. In addition, paraffin contains a certain amount of hydrocarbons with an aromatic or naphthene ring in the molecule. Technical-grade paraffin is a white crystalline substance with a melting point of 50–55°C and average molecular weight of 300–450. Paraffins are industrially produced in dewaxing of oil distillates [4].

Petrolatum is a light brown substance with a dropping point not lower than 55°C. It is a mixture of paraffin, ceresin, and oil, produced in dewaxing of oils obtained by sulfuric acid or selective purification [4].

In this study, ten blasting cartridges were randomly selected from each batch, and three 10-mg samples of the waterproofing coating were taken from different parts of the surface of each blasting cartridge. Each of the samples was dissolved in 1 ml of hexane and studied by gas–liquid chromatography under the conditions described above.

Examples of chromatograms of the waterproofing coatings of TNT blasting cartridges from five different production batches are shown in Fig. 2.

For a more detailed comparison of the quantitative hydrocarbon compositions of the coatings, it is suggested to use both the relative contents of *n*-paraffins and those (both total and individual) of the hydrocarbons eluted in chromatographic analysis between the

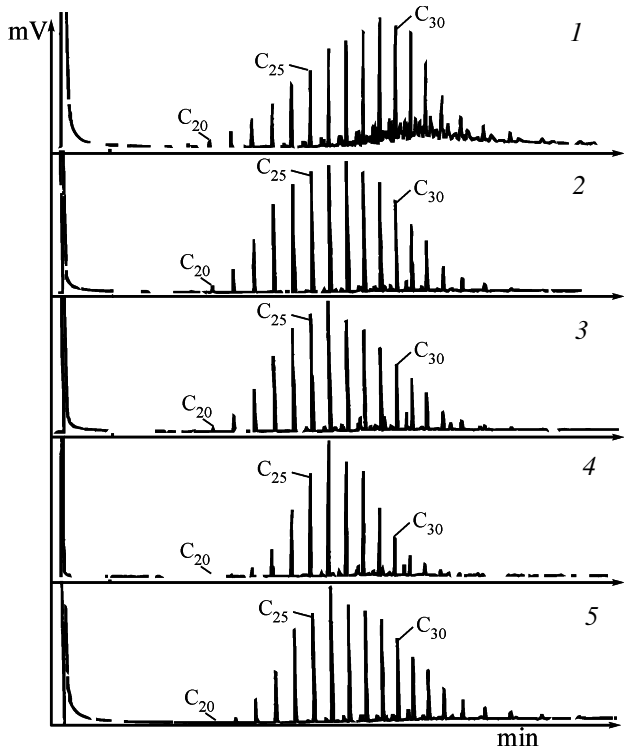

Fig. 2. Chromatograms of hydrocarbons from waterproofing coatings of TP-200G-K TNT blasting charges from five different production batches. Digits *1–5* denote batch numbers; the same for Figs. 3 and 4.

peaks of *n*-paraffins. These relative contents were found by the following normalization procedure:

$$X_i = \frac{100S_i}{\sum_{i=1}^{i=n} S_i},$$

where X_i is the relative content of *i*th component (%); S_i, area of the peak (group of peaks) of *i*th component (arb. units); $\sum_{i=1}^{i=n} S_i$, sum of areas of the component peaks (arb. units); and *n*, number of the components.

The results of parallel analyses were used to determine the average values of the quantities obtained and calculate the confidence intervals, after which the results obtained were compared. The relative contents of the normal saturated hydrocarbons and of the sum of hydrocarbon eluted between the peaks of the normal saturated hydrocarbons in samples of the objects being compared were considered the same if the confidence intervals of the average values of the

Total content of *n*-paraffins and other hydrocarbons of the article batches studied

Sample no.	Total content, %	
	n-paraffins	other hydrocarbons
1	54.8	45.2
2	89.6	10.4
3	79.8	20.2
4	80.6	19.4
5	85.0	15.0

corresponding quantities overlapped. In addition, we compared the relative contents of individual hydrocarbons in groups eluted between the peaks of normal saturated hydrocarbons.

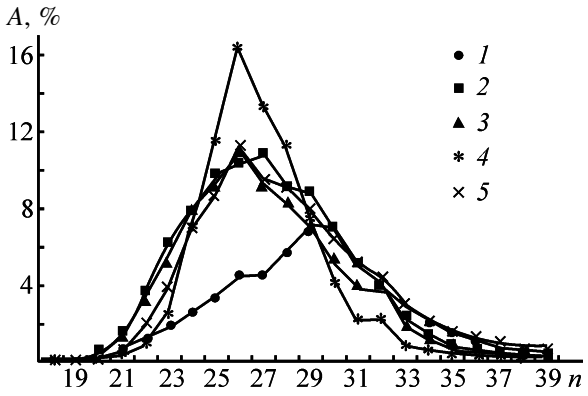

Fig. 3. Relative content *A* of *n*-paraffins in the waterproofing coatings of TNT blasting cartridges of the TP-200G-K type from five different production batches. (*n*) Number of carbon atoms in the molecule of a hydrocarbon.

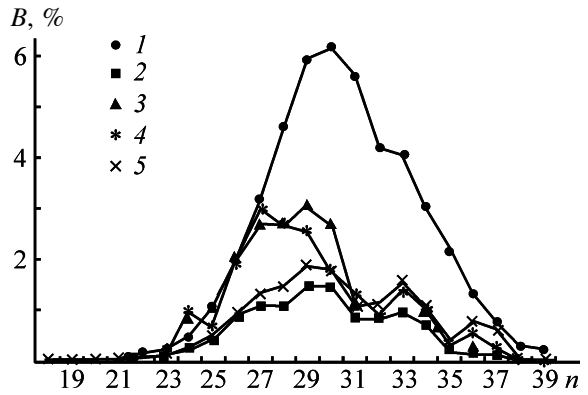

Fig. 4. Relative content *B* of sums of hydrocarbons eluted between the peaks of *n*-paraffins in waterproofing coatings of TNT blasting cartridges of the TP-200G-K type from five different production batches. (*n*) Number of carbon atoms in the molecule of a hydrocarbon after which this group is eluted.

The group contents of the normal saturated hydrocarbons and sums of hydrocarbons eluted between the peaks of *n*-paraffins are listed in the table.

As follows from the table, even the total contents of *n*-paraffins and other hydrocarbons can be used to differentiate most of the samples. However, the integral characteristics coincide within the determination error for sample nos. 3 and 4.

In this case, it is necessary to use data on the content of individual hydrocarbons to differentiate between samples with close integral characteristics. To ensure better clarity and easier perception, these data are presented in the graphic form in Figs. 3 and 4. For this purpose, the average relative percentage content was plotted against the number of carbon atoms in the molecule of the given *n*-paraffin (for *n*-paraffins) or of the *n*-paraffin whose peak precedes the peaks of the given hydrocarbons (for the sum of hydrocarbons).

The set of the chromatographic analyses performed revealed that the quantitative hydrocarbon composition of the waterproofing coatings of TNT blasting cartridges is the same within a production batch stored for a year in a dry reinforced-concrete warehouse without heating.

Clearly pronounced differences were revealed between blasting cartridges from different production batches both in the relative contents of *n*-paraffins (Fig. 3) and in total contents of hydrocarbons eluted between the peaks of normal saturated hydrocarbons (Fig. 4). The differences in the composition of waterproofing coatings in different batches are well identified even by the peaks of *n*-paraffins, and comparison of the contents of hydrocarbons eluted between the chromatographic peaks of normal hydrocarbons can be regarded as additional evidence confirming these differences.

CONCLUSIONS

The possibility of identifying classification of various commercial explosive-containing articles by the quantitative hydrocarbon content of admixtures of petroleum products in their structural elements was demonstrated. The identification features obtained in chromatographic analyses make it possible to differentiate articles of the same type but belonging to different production batches. The composition of hydrocarbons in the structural elements of the articles, by which they are classified, remains unchanged during a year of storage under warehouse conditions.

BRIEF COMMUNICATIONS

Extraction of Th(IV) with Tributyl Phosphate from Aqueous HCl Solutions Containing Sodium, Calcium, or Aluminum Chloride

V. G. Maiorov and A. I. Nikolaev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 1, 2006

Abstract—Extraction of thorium(IV) from 0.1–3 M aqueous hydrochloric acid solutions containing NaCl, $CaCl_2$, or $AlCl_3$ was studied. The experimental results are discussed.

DOI: 10.1134/S1070427206070305

Published data on the extraction of thorium(IV) from aqueous chloride solutions are scarce and contradictory [1–3]. The diversity of thorium(IV) speciation in aqueous chloride solutions is caused by its strong tendency to hydrolysis and complexation depending on the acidity and kind of anions. These factors affect also the chemical composition of Th-containing extractable complexes. It was reported [2, 4] that neutral organic solvents predominantly extract Th(IV) from moderately acidic solutions in the form of $ThCl_4$, and, to a lesser extent, of $ThOHCl_3$. In extraction from concentrated aqueous HCl, Th(IV) passes to the organic phase in the form of a complex acid $HThCl_5$. Currently the hydrochloric acid processing of rare-metal raw materials is being actively developed [5–7]. Therefore, the study of extraction of Th from hydrochloric acid solutions, especially from those containing large amount of metal salts, is an urgent problem.

In this study we examined the influence of sodium, calcium, and aluminum chlorides on the extraction of thorium from aqueous HCl solutions. It is known that these impurity metals significantly affect the distribution of thorium. The Na(I) and Ca(II) cations are common impurities in rare-earth titanoniobates loparite and perovskite. Al(III) was chosen as a typical trivalent element. Tributyl phosphate (TBP) was used as the most available and widely applied extractant. Aqueous solutions intended for extraction were prepared by mixing concentrated aqueous Th(IV), Ca(II), and Al(III) chlorides with aqueous HCl. The resulting solutions were kept before use for no less than 5 days. TBP and other chemicals were of pure grade. The extraction was carried out at the organic to aqueous phase volume ratio $V_o : V_{aq} = 1 : 1$ at room temperature (18 ± 2°C). The contact time was 15 min. To determine the Th(IV) content in the organic extract, it was backwashed with water. The backwash was acidified with HCl and Th was determined photometrically. The procedure was described in detail in [7].

Figure 1 shows how the degree of extraction of Th with TBP from 1 M aqueous HCl depends on the concentration of $CaCl_2$ or $AlCl_3$. On replacement of $CaCl_2$ or $AlCl_3$ by NaCl (up to 4 M), the degree of recovery of Th(IV) becomes less than 0.5%. It is known [2] that, on the addition of nonextractable electrolytes to the extraction system containing HCl in

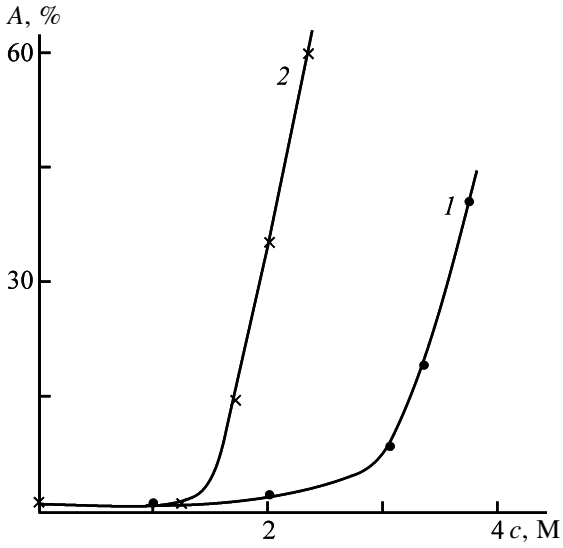

Fig. 1. Extraction of Th(IV) from 1 M HCl containing (*1*) $CaCl_2$ and (*2*) $AlCl_3$. (*A*) Degree of recovery of Th; (*c*) $CaCl_2$ or $AlCl_3$ concentration. Initial Th concentration (recalculated to ThO_2) 0.72 g l^{-1}.

the aqueous phase, the activity of water decreases and, as a result, the transfer of the extractable metal to the organic phase increases. This salting-out effect increases in the order $NH_4Cl < NaCl < CaCl_2 < MgCl_2 < AlCl_3$, i.e., with an increase in the cationic charge and a decrease in the cationic radius. In our study we observed the similar order of influence of foreign electrolytes on the extraction of Th ($NaCl < CaCl_2 < AlCl_3$). The plot of the degree of the Th extraction vs. $CaCl_2$ or $AlCl_3$ concentration shows that these salts do not affect the extraction of Th(IV) at their content less than 2 and 1.3 M, respectively, but with a further increase in their concentration, the extraction of Th(IV) sharply increases. It should be noted that, if the results are plotted as the degree of Th extraction vs. concentraiton of chloride anion supplied into the solution with $CaCl_2$ or $AlCl_3$, both extraction curves approach each other, and a sharp increase in the extraction of Th starts at a chloride content of about 4 M. These changes apparently show that the salting-out effect of the impurity metal chlorides under consideration includes both the cationic [Ca(II), Al(III)] and anionic (Cl^-) contributions.

The similar relationships were observed in the extraction of Mn(II) and Co(II) with TBP in the presence of $CaCl_2$ [8]. It was found that these nonferrous metals are poorly extracted at [$CaCl_2$] below 2–3 M, but their extraction sharply increases at higher $CaCl_2$ concentration. For example, at [$CaCl_2$] 4.9–5.8 M the distribution ratios were as follows: Ca 0.2, Mn(II) 20, and Co(II) 140. Jezowska-Trzebiatowska et al. believe [8] that this effect is specific for the extraction with TBP only. In the extraction of the above-mentioned nonferrous metals with alcohols, their distribution ratios are only about 0.1–0.5 at [$CaCl_2$] ~4.5 M. To elucidate how Th(IV) is extracted from concentrated solutions of chlorides of calcium and other metals, further studies are required.

Our results show that extraction of thorium and its separation from concomitant metals are strongly influenced by the salt content in the aqueous phase. Taking into account the divesity of thorium-containing raw materials, numerous extraction experiments should be carried out to comprehensively elucidate the influence of foreign metals on the extraction of Th(IV). It should be noted that the technologically acceptable efficiency of extraction of Th(IV) with TBP is reached only in the presence of large amounts of $CaCl_2$ (4 M) or $AlCl_3$ (2 M) in the aqueous phase. Under these conditions, at $V_o : V_{aq} = 1 : 1$, the degree of extraction of Th(IV) in one extraction step exceeds 50%, and Th can be quantitatively recovered from the aqueous phase by multistep countercurrent extraction with TBP.

Influence of the HCl concentration on the extraction of Th(IV) from its solution in HCl containing 2 M NaCl, $CaCl_2$, or $AlCl_3$

HCl, M	Recovery of Th(IV), %		
	NaCl	$CaCl_2$	$AlCl_3$
0.1	–	~1	17
1	<0.5	~2	36
3	~0.5	~3	59

We found that the extraction of Th(IV) increases not only with increasing salting-out agent concentration, but also, although to a smaller extent, with increasing HCl concentration. Whereas at metal chloride concentrations below 1 M the increase in the HCl concentration from 1 to 3 M insignificantly affects the degree of recovery of Th(IV), the similar change in the HCl content in a 2 M solution of the metal chlorides leads to a severalfold increase in the Th recovery (see table). This table also shows once again that the salting-out efficiency with respect to Th significantly increases in the order $NaCl < CaCl_2 < AlCl_3$.

Figure 2 shows the log–log plot of D vs. [Cl^-] at constant [H^+] = [HCl], where [Cl^-] is the total chloride amount introduced into solution with both HCl and $CaCl_2$ (or $AlCl_3$). Figure 3 shows the log–log plot of D vs. [H^+] at constant [Cl^-]. It is known [2] that

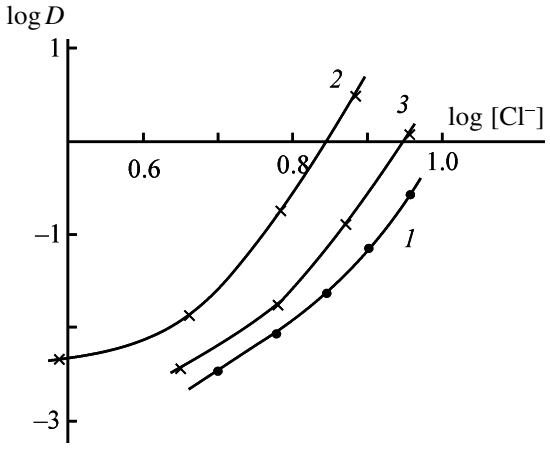

Fig. 2. Distribution ratio of Th(IV) vs. chloride ion concentration [Cl^-] in the aqueous phase in the extraction of Th(IV) from aqueous HCl solutions containing (*1*) $CaCl_2$ and (*2, 3*) $AlCl_3$ at constant [H^+] = [HCl], equal to (*2*) 0.1 and (*1, 3*) 3 M. (*D*) Distribution ratio of Th(IV); the same for Fig. 3. Initial Th concentration in the aqueous phase (recalculated to ThO_2) 0.72 g l^{-1}.

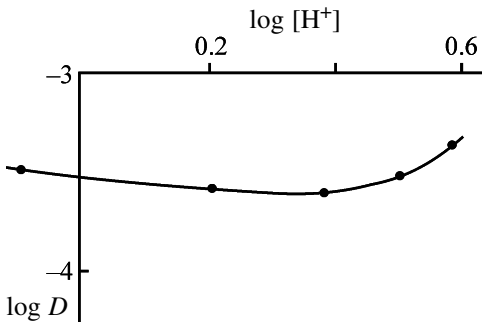

Fig. 3. Distribution ratio of Th(IV) vs. $[H^+]$ in the extraction of Th(IV) from HCl solutions containing NaCl. Initial Th concentration (recalculated to ThO_2) 10 g l^{-1}, $[Cl^-]$ 3.84 M.

the slope of these log–log plots is equal to the amount of Cl^- (Fig. 2) or H^+ (Fig. 3) entering the composition of the extractable complex. This technique for the determination of the composition of the extractable complex has several drawbacks. In particular, this method does not take into account the variations in the activity coefficients. Therefore, with this technique only approximate stoichiometry of the extractable complex can be obtained.

Figure 2 shows how the chloride anion concentration affects the distribution of Th. The nonlinearity of the distribution curves does not allow the determination of the number of chloride anions coordinated with thorium in the extractable complex. However, since these curves have a similar shape, we can suggest that the extraction of Th(IV) from all the solutions occurs by a similar mechanism. As seen from Fig. 2, the extraction of Th in the presence of $AlCl_3$ decreases with increasing HCl concentration. At first glance, these results contradict those listed in the table. However, this contradiction is only apparent, because the increase in the HCl concentration in a solution of $AlCl_3$ in HCl at constant $[Cl^-]$ means that the actual $AlCl_3$ content decreases and, as a result, its salting-out effect with respect to Th(IV) becomes weaker.

Figure 3 shows how the acidity of the aqueous phase $[H^+]$ affects the extraction of Th(IV) from an HCl solution containing NaCl at a constant chloride concentration $[Cl^-]$ 3.84 M. The use of NaCl as salting-out agent was found to be the most suitable for studying the dependence of the distribution ratio of Th(IV) on the acidity [2]. As seen from Fig. 3, the acidity virtually does not affect the Th(IV) recovery within the entire $[H^+]$ concentration range. This means that H^+ does not enter the composition of the extractable complex and Th(IV) is mainly extracted as $ThCl_4$. A small minimum present in this extraction curve is apparently caused by a decrease in the NaCl salting-out effect at partial replacement of NaCl with HCl. Further increase in $[H^+]$ is accompanied by an increase in the extraction of Th(IV) due to formation of an extractable complex acid $HThCl_5$. Taking into account that the extraction of Th(IV) is virtually independent of $[H^+]$ within the thorium concentration range studied, we can suggest that an increase in the extraction of thorium with increasing HCl concentration in the presence of $AlCl_3$ (see table) is caused by an increase in the total chloride concentration $[Cl^-]$ in the aqueous phase rather than an increase in the acidity.

CONCLUSIONS

(1) Thorium(IV) is not extracted with TBP from aqueous hydrochloric acid solutions containing $CaCl_2$ or $AlCl_3$ in the amount below 2 and 1.3 M, respectively. At higher concentration of these salts, the extraction of thorium strongly increases and the degree of its recovery exceeds 50% at $CaCl_2$ and $AlCl_3$ concentration exceeding 4 and 2 M, respectively. On replacement of $CaCl_2$ or $AlCl_3$ by NaCl, the degree of thorium(IV) recovery is smaller than 0.5% up to the NaCl concentration of 4 M.

(2) The plot of $\log D$ vs. $\log[H^+]$ shows that, in extraction of thorium(IV) with TBP from aqueous HCl containing $CaCl_2$ or $AlCl_3$, the extractable complex contains no protons. Under these conditions, thorium is apparently extracted in the form of $ThCl_4$ solvate with TBP.

Abstract—Electrodeposition of bismuth from acid lactate electrolyte was studied.

DOI: 10.1134/S1070427206070317

Bismuth and its alloys are widely used in industry as antifriction and corrosion-resisting coatings, as electrical contacts to semiconductors, including rectifying and ohmic contacts formed by them on silicon and germanium, and as coatings for soldering [1].

Presently, perchlorate, fluoroborate, phenolsulfonic, fluosilicate, sulfate, EDTA, pyrophosphate, and other electrolytes are used for the electrodeposition of bismuth and bismuth-containing alloys [1].

Though ensuring deposition of high-quality coatings at high cathodic current efficiency and possessing a high throwing power, the above electrolytes contain, apart from bismuth ions, toxic anions, which makes them more environmentally hazardous.

Much attention is given today to replacement of toxic anions in electroplating solutions by less toxic anions [2]. Lactic acid is abundant in nature and is an intermediate product of metabolism in biological tissues. The acid is readily biodegradable and, therefore, environmentally safe. In this respect, the development of a lactate bismuth-plating electrolyte is of certain theoretical and practical significance.

The effect of the electrolysis mode and electrolyte composition was studied at 20°C and a cathodic current density of 0.3 A dm^{-2} in the solution containing 80% lactic acid [GOST (State Standard) 490–79] 100 ml l^{-1}, bismuth nitrate (in terms of metal) 10 g l^{-1}, sodium sulfate 20 g l^{-1}, and 65% nitric acid (GOST 4461–77) 50 ml l^{-1}.

With an increase in the concentration of bismuth ions in the electrolyte from 10 to 20 g l^{-1}, the cathodic current efficiency decreases from 97.5 to 91.7%, with the coating quality improved. Raising the bismuth concentration further results in a drastic deterioration of the coating quality and a decrease in the cathodic current efficiency.

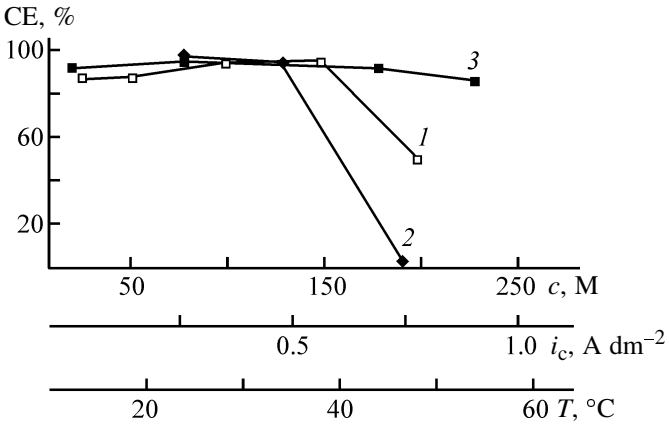

Fig. 1. Cathodic current efficiency (CE) by bismuth vs. (*1*) concentration of lactic acid *c* in the electrolyte, (*2*) cathodic current density i_c and (*3*) solution temperature.

As the concentration of lactic acid in the electrolyte is increased from 25 to 150 ml l^{-1}, the cathodic current efficiency by bismuth increases from 90.4 to 98.7%. In this case, light gray, good-quality coatings are deposited. Raising the concentration of lactic acid to 200 ml l^{-1} leads to a decrease in the cathodic current efficiency by bismuth to 55.1%, with the coating quality deteriorated (Fig. 1, curve *1*).

The further study was carried out in the electrolyte containing lactic acid 150 ml l^{-1}, bismuth nitrate (in terms of metal) 10 g l^{-1}, sodium sulfate 20 g l^{-1}, and 65% nitric acid (GOST 4461–77) 50 ml l^{-1}.

Increasing the cathodic current density within 0.3–0.75 A dm^{-2} leads to deterioration of the coating quality and a sharp decrease in the cathodic current efficiency by bismuth from 97 to 4.87%, which is due to intensification of hydrogen evolution (Fig. 1, curve *2*).

With an increase in temperature from 12 to 24°C, the cathodic current efficiency by bismuth increases

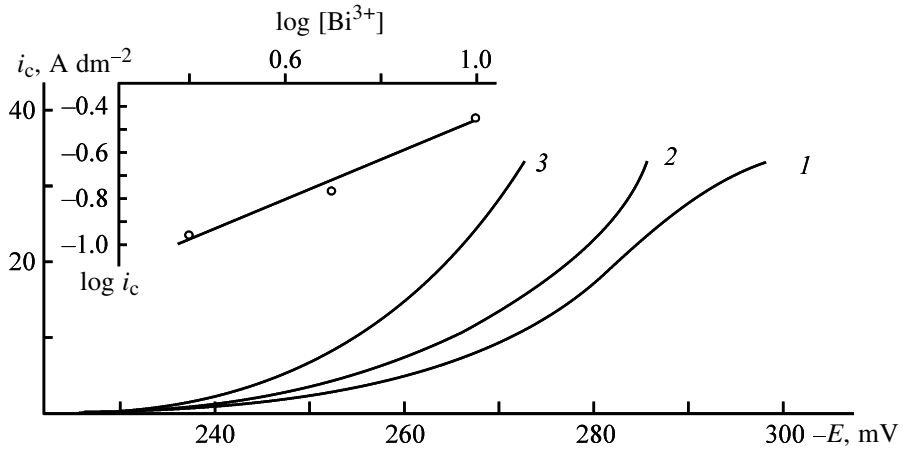

Fig. 2. Cathodic potentiodynamic curves taken in the course of bismuth deposition at different concentrations of bismuth ions in the solution. (*E*) Potential and (i_c) current density. Bi^{3+} concentration, g l^{-1}: (*1*) 2.5, (*2*) 5, and (*3*) 10. Insert: $\log i_c$ vs. $\log [Bi^{3+}]$ dependence at a cathode potential of –260 mV.

from 93 to 97%. At higher temperatures, the cathodic current efficiency by bismuth decreases to 88%, which may be accounted for by acceleration of chemical dissolution of the coating or by intensification of hydrogen evolution (Fig. 1, curve *3*).

Stirring of the solution results in drastic deterioration of the coating quality and a decrease in the cathodic current efficiency by bismuth.

The potentiodynamic curves taken at a potential sweep rate of 4 mV s^{-1} (Fig. 2) show that, with decreasing bismuth concentration, the polarization curves shift toward more negative potentials. For example, at the cathodic current density of 0.3 A dm^{-2} the cathode potentials (relative to SHE) in the solution containing 10, 5, and 2.5 g l^{-1} bismuth ions are 262, 274, and 278 mV, respectively (Fig. 2).

The log–log dependence of the cathodic current density on the bismuth concentration in the electrolyte is linear (Fig. 2, insert at the top). The slope of this straight line is 1.3, which shows that the discharge of bismuth ions occurs in steps [3].

The study of the processes occurring at the anode showed that, as the anodic current density increases from 0.1 to 0.5 A dm^{-2}, the anodic current efficiency by bismuth (in terms of Bi^{3+}) decreases from 141 to 102%. This high value of the current efficiency is likely due to the fact that the electrochemical dissolution is accompanied by the chemical dissolution of the anodes.

CONCLUSIONS

A process for the electrodeposition of high-quality bismuth coatings was developed, and a less toxic electrolyte containing 80% lactic acid (GOST 490–79) 150 ml l^{-1}, bismuth nitrate (in terms of metal) 10 g l^{-1}, sodium sulfate 20 g l^{-1}, and 65% nitric acid (GOST 4461–77) 50 ml l^{-1} was suggested. At a cathodic current density of 0.3 A dm^{-2} and 20–25°C, the cathodic current efficiency is 95–98%. The deposition rate of the bismuth coatings at these electrolysis conditions is 7.6 μm h^{-1}.

Abstract—The kinetic dependences of the relative weight loss of the solvent from dilute solutions of fullerene C_{60} in toluene under ambient conditions were determined. Evaporation of the pure solvent is slower than that of the same solvent from dilute solutions (≤0.01%).

DOI: 10.1134/S1070427206070329

Previously the supramolecular structure of fullerene C_{60} solutions in aromatic solvents, *p*-xylene and toluene, was studied by the small-angle X-ray diffraction [1–3] and densitometry [4]. From the data obtained, it was concluded that addition of fullerene to the above solvents results in nonmonotonic variations in the structure. Formation of solvophobic shells with decreased solvent density around fullerene molecules predominates at low concentrations of fullerene (≤0.01%), and structuring and ordering of the solvent accompanied by an increase in its density and the overall solution density prevail at higher concentrations. The observed increase in the density is in good agreement with the heat release in dissolution of fullerene in toluene [5]. It is evident that the features of variation of the supramolecular structure of fullerene C_{60} solutions, formation of solvophobic shells and structuring of the solvent, should affect various characteristics of solutions. This study deals with the kinetics of solvent evaporation from solutions of fullerene C_{60} in toluene.

To prepare the solutions, we used 99.7% pure fullerene C_{60} synthesized by the Huffman–Krätschmer procedure [6] and toluene of chemically pure grade after its twofold distillation.

The solution of fullerene C_{60} in toluene (0.01%) was prepared by weight using an analytical balance. To accelerate dissolution, the suspension of fullerene in toluene was treated with ultrasound for 10 min (an UZV-1/100-TN device, power 95 W, frequency 22–44 KHz). The solutions with concentrations of 0.005 and 0.001% were prepared by dilution of the 0.01% solution.

For measurements we used two types of equipment and, correspondingly two approaches. First, we used a C derivatograph equipped with a microprocessor (MOM, Hungary). Heating in the device was switched off, and for solutions with various initial concentrations the weight loss due to free evaporation of the solvent from an open corundum crucible with the solution (initial weighed portion 100 mg) was measured over the course of 100 min (Fig. 1). It should be noted that even at the lowest concentrations of fullerene the rate of solvent evaporation from the solution

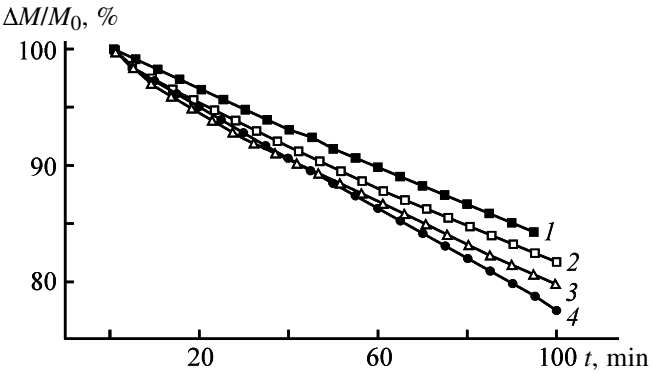

Fig. 1. Relative weight loss of fullerene C_{60} solutions $\Delta M/M_0$ as a function of time t at 25°C. Initial concentration, wt %: (*1*) 0 (pure solvent), (*2*) 0.005, (*3*) 0.01, and (*4*) 0.1.

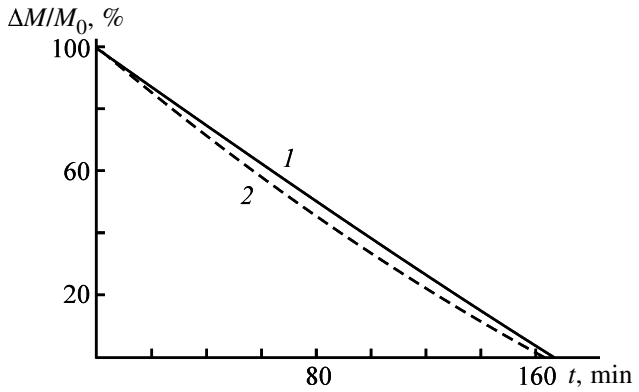

Fig. 2. Relative weight loss of fullerene C_{60} solutions $\Delta M/M_0$ as a function of time t at 30°C. Netzsch thermal analyzer, argon flow rate 50 ml min^{-1}. Initial concentration, wt %: (*1*) 0 (pure solvent) and (*2*) 0.01.

is higher than that from the pure solvent. This fact can be explained by formation of solvophobic shells of the solvent (with decreased density) around fullerene molecules. The higher the initial concentration of fullerene C_{60}, the higher the rate of weight variation and, correspondingly, the larger the total weight loss. Within 100 min, the weight loss reaches 22–23%.

The other series of the measurements was performed on a Netzsch thermal analyzer (Germany) at a constant temperature of 30°C. A solution sample (weighed portion 16–17 mg) was placed into a crucible. When the crucible was open, evaporation was so fast that at a high sensitivity of the device it was impossible to fix the initial concentration of the solution from which the experiment started. Therefore, the crucible filled with the solution was covered with a lid with a small orifice limiting the evaporation. The air space upon the crucible was purged with a weak argon flow (50 ml min^{-1}). The measurements were performed until complete evaporation of the solvent.

The results of measurements for the pure solvent (curve *1*) and 0.01% C_{60} solution (curve *2*) are presented in Fig. 2. Since the solution concentration increases as the solvent is evaporated, the evaporation rate is scanned along the run of curve *2*: the slope of curve *2* in each point characterizes the evaporation rate at the corresponding concentration. The run of curve *2* shows that initially (in the first 50 min) the evaporation rate is higher than that of the pure solvent, and then it decreases and becomes lower than the evaporation rate of the pure solvent. This transition occurs approximately 80 min after the beginning of the evaporation, when approximately 50% of the solvent is evaporated, i.e., the solution concentration reaches approximately 0.02%. This is in good agreement with the densitometry data [4] and data of small-angle X-ray diffraction [1–3] according to which in the above concentration range the run of the concentration dependences of the solution density and intensity of small-angle X-ray scattering becomes opposite. Thus, the increased rate of solvent evaporation from the solution is in good agreement with formation of solvophobic shells and the decreased rate, with structuring of the solvent.

Micelle Formation in Aqueous Dodecylpyridinium Chloride

O. P. Korotkikh and N. N. Kochurova

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received December 12, 2005; in final form, April 2006

Abstract—Micelle formation in aqueous dodecylpyridinium chloride is studied at 20, 25, 30, 35, and 40°C using the surface tension and conductivity methods.

DOI: 10.1134/S1070427206070330

Physicochemical studies of surfactants are important in view of great importance of these substances for private life, agriculture, medicine, and a variety of industrial processes [1].

In this study we examined micelle formation in aqueous solutions of a cationic surfactant, dodecylpyridinium chloride ($C_{12}H_{25}NC_5H_5Cl$) (DPC), using the surface tension and conductivity methods.

The quality of DPC used was confirmed by the lack of a minimum in the surface tension isotherm near the critical micelle concentration (CMC), and also by the spectroscopic and HPLC tests. Aqueous DPC solutions were prepared using double-distilled water.

The surface tension was measured by the ring detachment method [2] on a digital instrument (Markada, St. Petersburg) [3].

The instrument was calibrated by measuring the surface tension of hexane, isopropanol, benzene, ethylene glycol, and double-distilled water. The calibration curve was linear, allowing easy recalculation of the readings to the surface tension. The error of determination was within 0.5 mN m^{-1}.

The measurements were carried out at 20°C. The DPC concentration was varied from 5.5×10^{-4} to 3.1×10^{-2} M. Figure 1 show that the surface tension decreases with increasing DPC concentration, which is typical of the surfactant solutions [1, 4]. The CMC was determined to be 1.78×10^{-2} M by crossing two straight lines obtained using the least-squares method (Fig. 1).

The conductometric measurements were carried out on a V3-60 ac bridge at 2500 Hz, to eliminate polarization. The cell was calibrated with 0.01 N KCl. The temperature was maintained constant to within 0.05°C. The error of the conductivity determination was within 2%.

The conductivity was measured after establishment of the temperature and concentration equilibria. Solution preparation and all the measurements were carried out in a temperature-controlled glass cell taking into account the recommendations made in [5–7].

Figures 2a–2e shows the concentration dependences of the equivalent conductivity $\lambda = f(c^{1/2})$ for aqueous DPC of solutions at 20, 25, 35, and 40°C and concentrations $(1–4) \times 10^{-2}$ M. The curves follow the general trend, i.e., the equivalent conductivity decreases with increasing concentration [7, 8]. There are maxima and minima in the curves, like those reported in [7]. The first maximum corresponds to CMC_1 determined from the dependence of the specific conductivity æ on the DPC concentration, as the

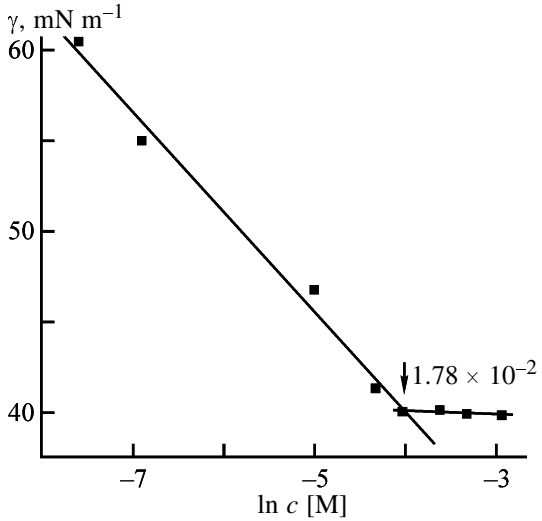

Fig. 1. Surface tension of DPC γ at 20°C as a function of ln *c*. (*c*) DPC concentration; the same for Fig. 2.

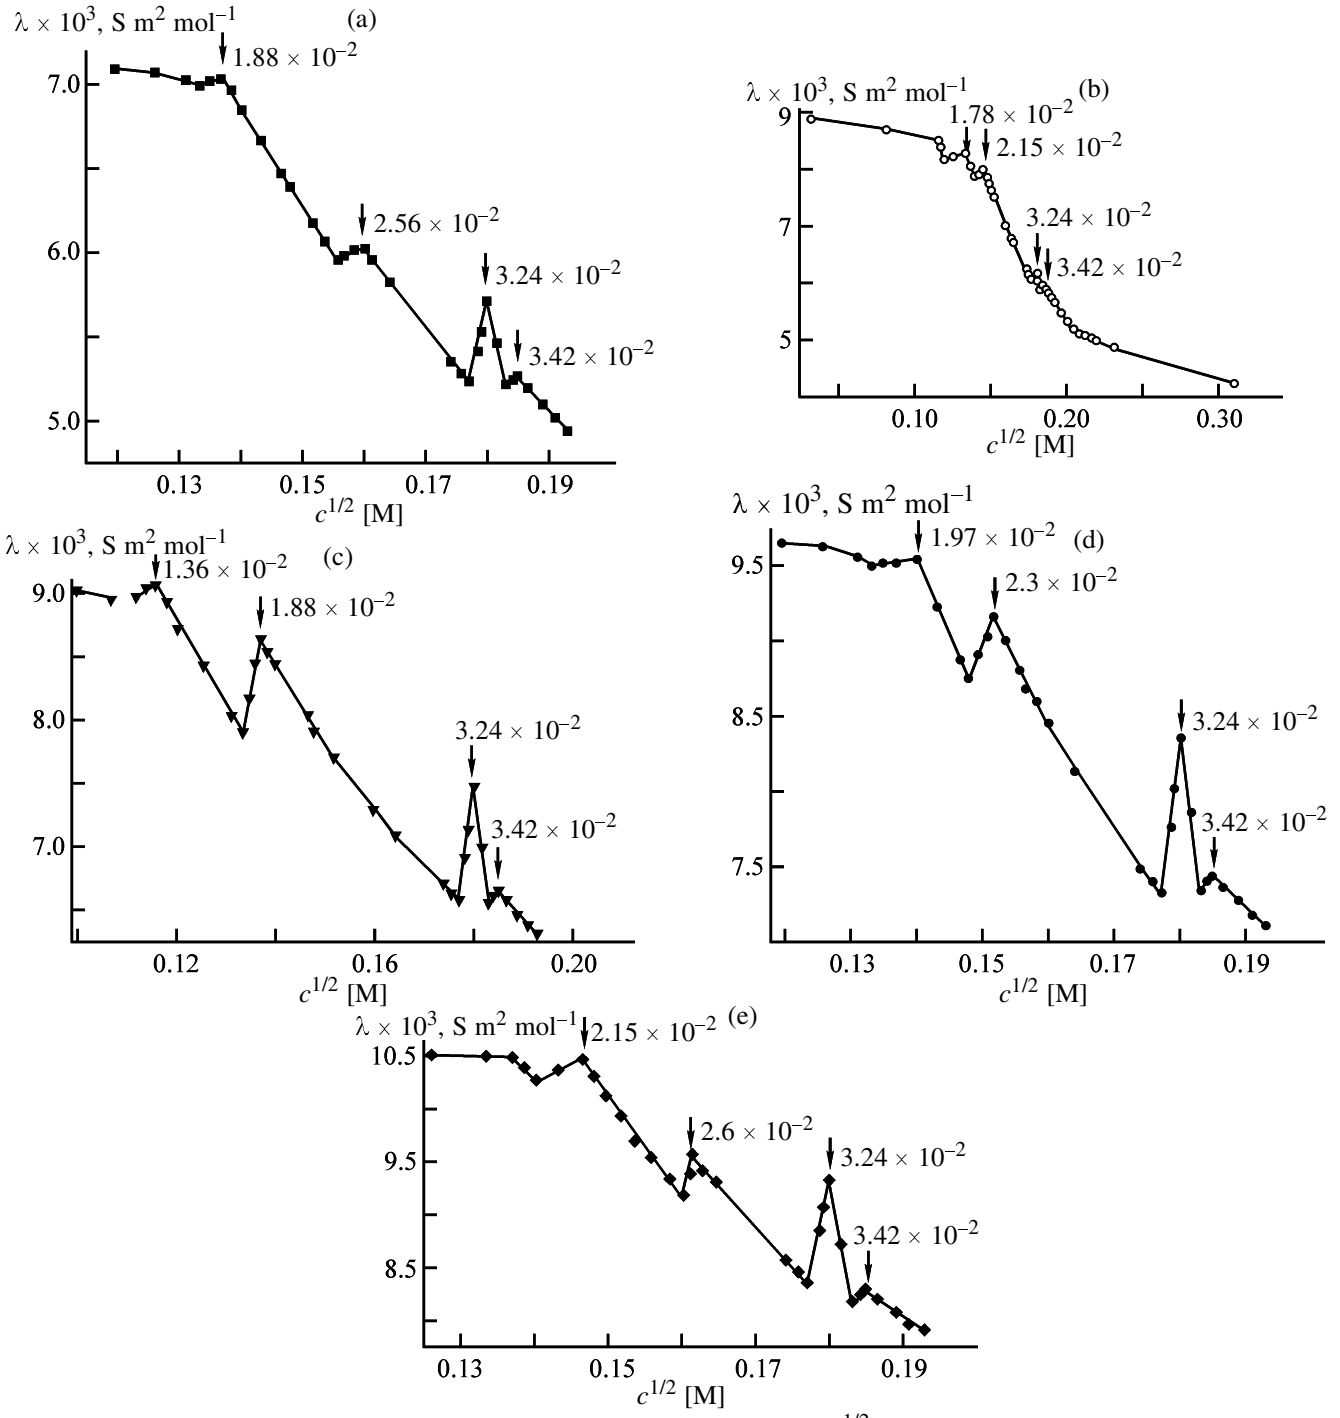

Fig. 2. Equivalent conductivity λ in aqueous DPC solutions as a function of $c^{1/2}$. Temperature (°C): (a) 20, (b) 25, (c) 30, (d) 35, and (e) 40.

intersection of two straight lines drawn using the least-squares method.

The table summarizes data on CMC_1 from various sources [4, 9] for the investigated surfactant at various temperatures. As seen, CMC_1 corresponding to the maximum in the curve $\lambda = f(c^{1/2})$ is in satisfactory agreement with the values determined by other methods.

There are three more features in the λ–$c^{1/2}$ curve above CMC_1 for which, as for CMC_1, each maximum follows a minimum [10], i.e., the conductivity abruptly changes in extremely narrow concentration ranges.

* (ST) Surface tension and (EC) conductivity.

In this case, the maxima in the λ–$c^{1/2}$ curve correspond to the breaks in the æ–c curve at the respective concentration. Analyzing the behavior of the equivalent conductivity in micellar solutions, Rusanov has demonstrated [10] that the changes in the aggregation numbers, degree of aggregation, and degree of association with counterions in the course of micelle formation can be responsible for the appearance of extrema in the λ–$c^{1/2}$ curve.

In the range near 30°C, we found two maxima corresponding to CMC_1 and CMC_2. Similar temperature dependences of CMC were also observed for other surfactants [4, 11]. Such a behavior can be attributed to the structural transformations in water and to the change in the mode of hydration of the surface-active ions near 30°C [12].

At this temperature, the interaction mode of the cation with water changes. At lower temperatures, addition of ions decreases the activation energy of translational motion of the water molecules adjacent to the ion (negative hydration by Samoilov [13]), loosening the structure of water. Above 30°C, addition of ions increases the activation energy (positive hydration), thus structuring water. Therefore, there is a temperature (near 30°C) corresponding to the minimal CMC. At higher and lower temperatures, a higher surfactant concentration is required to form micelles.

No distinct temperature dependences were found for CMC_3 and CMC_4 (they are practically temperature-independent).

CONCLUSION

The experimental surface tension and conductance data show that the investigated surfactant is characterized by a series of CMC values (CMC_1–CMC_4). CMC_1 is consistent with the value obtained from the surface tension and calorimetric data. CMC_1 and CMC_2 are temperature-dependent, passing through a minimum at about 30°C, which is probably due to changing structure of water and hydration mode of the surfactant at this temperature. CMC_3 and CMC_4 are temperature-independent.

The study was performed under the Grants of the President of the Russian Federation for Support of Scientific Schools nos. NSh-789.2003.3 and NSh-4241.2006.3.

Abstract—Changes in the morphology and surface energy of polytetrafluoroethylene coatings in the course of their growth and after annealing were determined.

DOI: 10.1134/S1070427206070342

Physicochemical processes occurring in the course of adsorption and nucleation of particles and in the initial steps of thin polymeric film growth from the active gas phase affect the structure of the resulting coatings and their properties [1, 2]. Previously we showed that the first deposition steps of polymer coatings from volatile products of electron-beam dispersion of the initial polymer, unlike adsorption and nucleation of, e.g., metallic phase, are obviously nonequilibrium [3, 4]. The parameters of the surface distribution of the polymer particles and the kinetics of the change in their density in the course of the deposition depend on the support and the degree of its activation [4]. We also found [5] that the volatile products of electron-beam dispersion are highly reactive and can react with the support during their adsorption. This feature, the long-range influence of the support surface, and selective desorption from the surface determine the physicochemical properties of the coatings and the structural nonuniformity of the boundary layers [6].

In the course of formation of thin polymer coatings from volatile dispersion products, the growth of the macromolecular chains and the films as a whole, as well as their structure and properties are determined by the mobility of the kinetic elements and by the intermolecular interactions [2]. Therefore, all external actions (heat treatment, irradiation, surface and bulk modification, etc.) affecting the synthesis and conformations of the macromolecules can be used to effectively control the deposition with the aim to change the structure and properties of the coatings.

In this study we examined the kinetic features of the first steps of deposition of polytetrafluoroethylene (PTFE) coatings and the influence of heat treatment on their morphology and surface properties.

EXPERIMENTAL

The coatings were prepared by electron-beam dispersion of PTFE by the procedure described in [3]. The coatings with the required properties were deposited using a special device with a controlled damper. The growth rate and the effective thickness of the coatings were measured with a quartz thickness gage (QTG). Polished silicon single-crystal wafers pretreated with R-646 organic solvent were used as the supports.

We studied the morphological changes and the adsorption properties of PTFE coatings in the course of their growth and vacuum annealing. The coatings were annealed in a vacuum at 455 K for 20 min with the aid of a resistive heater and then were cooled at a rate of 8–12 K min^{-1}. The morphology of the as-grown or annealed coatings was studied by atomic force microscopy (AFM) using a NANOTOP-2003 measuring setup. The scanning was performed in the tapping mode. To analyze the cluster formation, additional mathematical treatment was performed. The surface cluster distribution was constructed by the horizontal cross-section procedure with marking of the clusters. The cross sections with the minimal cluster content were analyzed [7]. The minimal considered surface area of the cluster (0.03 μm^2) did not exceed the microscope resolution. The maximal considered surface area of the cluster was 0.42 μm^2.

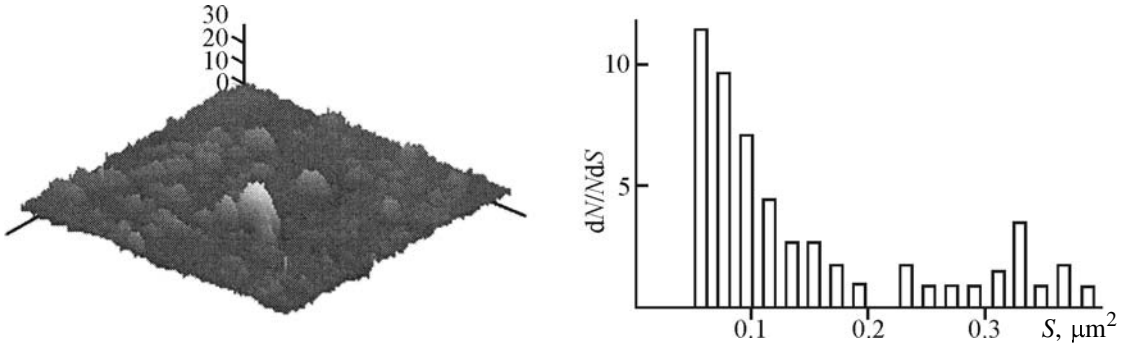

Fig. 1. AFM image of PTFE coating with the effective thickness of 9.1 nm and the particle distribution d*N*/*N*d*S* with respect to the surface area of their base *S*. Scanning area 13.5 × 13.5 μm.

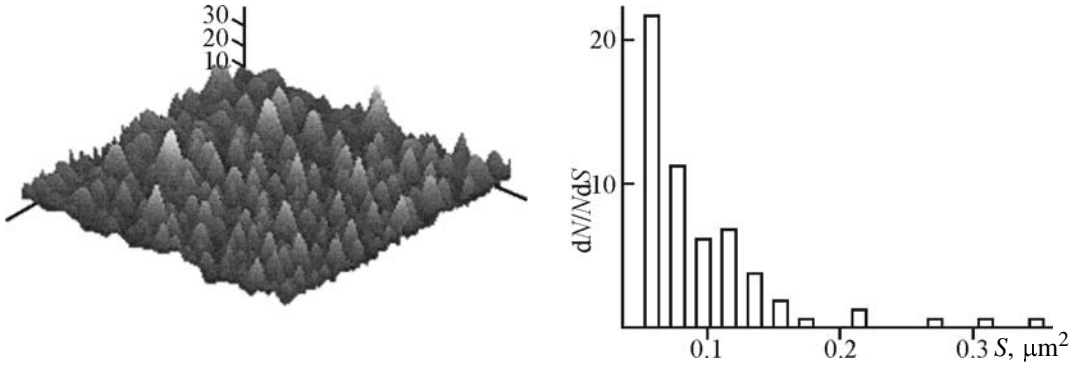

Fig. 2. AFM image of annealed PTFE coating with the effective thickness of 4.5 nm and the corresponding particle distribution d*N*/*N*d*S* with respect to the surface are of their base *S*. Scanning area 7.4 × 7.4 μm.

To study the surface properties of the coatings, the limiting wetting angles of their surface with distilled water and glycerol were measured. The polar and dispersion components of the surface energy were determined by the Fowkes procedure [8].

The shape of PTFE microparticles and their distribution over the surfcae of a silicon crystal in the initial deposition steps are determined by high adsorption nonuniformity of the support. The polymer microparticles grow on the active sites of the support, whose density is relatively low. This is consistent with our previous results [4]. The particle distribution with respect to the surface area of their base is complex (Fig. 1) and can be considered a superposition of the exponential distribution (in the range of low particle areas) and distribution with a maximum which is shifted to the larger particle size with increasing film thickness.

The density and height of polymer microparticles increase and the average surface area of their base decreases after annealing of the dispersed polymeric coating. The cluster density increases by a factor of 3.5, the weighted-average area decreases by a factor of 1.8, and the average cluster height increases form 7.6 to 12.2 nm after heat treatment of a PTFE coating with the effective thickness of 4.5 nm. When thicker coatings (e.g., with the effective thickness of 9.1 nm) are heated, the average height of their microparticles increases from 11.4 to 27.1 nm. To understand this experimental result, it should be taken into account that the adsorption layer of dispersed particles involved in polymerization is formed on the support surface in the first deposition steps [3, 4]. On heating of the coating above the glass-transition point, the macromolecules become more mobile and hence their agglomeration intensifies. The temperature effect on the density of polymeric particles sorbed from solutions is similar [9]. The parameters of particle distribution in annealed coatings of different thickness were determined. We expected that, as in the case of the unannealed samples, larger polymer microparticles are formed with increasing coating thickness. However, our experimental results showed that in the annealed samples the weighted-average particle surface area (0.12 μm^2) did not noticeably change and the particle density decreased from 2.28×10^{12} to 1.12×10^{12} m^{-2}. The distribution of the microiparticles with respect to the surface area of their base is close to exponential (Fig. 2). This is probably due to the fact that the adsorption phase of the 4–10-nm coatings is

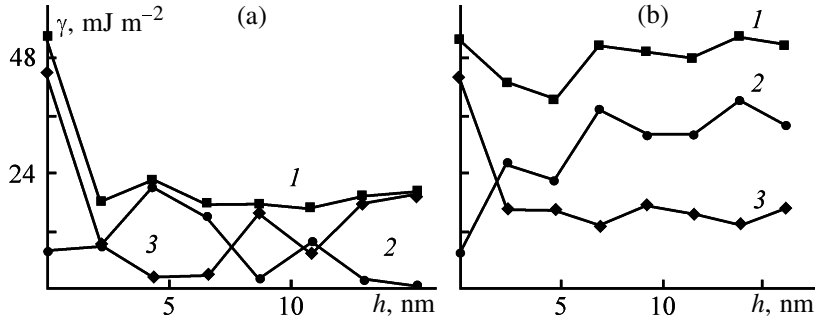

Fig. 3. (*1*) Total surface energy γ of PTFE coating and its (*2*) dispersion and (*3*) polar constituents as functions of the thickness *h*. (a) Before and (b) after annealing.

sufficiently continuous (the monolayer thickness is from 1 to 2 nm [10]) and the adlayer containing mobile particles is structured on heating. The increase in the average height of microparticles in the annealed samples can be due, on the one hand, to thermal desorption of low-molecular-weight fragments (decrease in the effective thickness of continuous adlayer) and, on the other hand, to thermal activation of structuring processes in the bulk.

It was found that the dependence of the surface properties of annealed and unannealed samples on the effective thickness of a polymer layer is complex. The surface energy of the coating increases by a factor of almost 2 after the heat treatment (Fig. 3).

As we expected, in both cases, the polar constituent of the surface energy substantially decreases in the course of monolayer deposition. This is caused by the features of adsorption interaction and appearance of more active sites of the macromolecules at the interface. The change in the dispersion and polar constituents of the surface energy is caused by this structuring.

The variation of the dispersion constituent of the surface energy correlates with that of the polar constituent. It should be noted that the run of the kinetic curves of the surface energy is similar to that of the fractal dimension determined in our previous study [4]. In both cases, the examined parameters are determined by the number of deposited monolayers, a change in the deposition conditions, and the transformation of the two-dimensional growth of the associates into the three-dimensional growth.

CONCLUSIONS

(1) The particle density and particle height of the polymer coatings increase and the average surface area of the particle base decreases after annealing of the coating.

(2) The surface energy of the annealed coating increases *S* by a factor of almost 2. The change in the dispersion constituent correlates with that of the polar constituent.

Abstract—Features of complexation of chitosan with Cefotaxime antibiotic were examined. Optimal conditions for preparing the complexes were found, and their chemical composition and physicochemical properties were studied.

DOI: 10.1134/S1070427206070354

Recent studies show that chitosan (CTS) is promising as a carrier of pharmacological molecules and ions for biologically active preparations of prolonged effect [1–4]. For this application, such properties of the polysaccharide are important as its capability for fiber and film formation, ion exchange, and complexation. Complexation of CTS with metal ions was examined in numerous studies [5–7], but interactions of the polysaccharide with low-molecular-weight drugs are less understood [8–10].

In this study we examined the interaction of chitosan with an antimicrobial drug, Cefotaxime (CFT) [11].

EXPERIMENTAL

CTS was recovered from Far-Eastern crab shells and had the following characteristics: initial number-average degree of polymerization P_n = 860, degree of deacetylation 70–75%, and moisture content 4.5%. CFT (pharmaceutical preparation) was used without additional purification.

The IR spectra were recorded on a Specord M-80 spectrophotometer (KBr pellets or thin films). The ^{1}H NMR spectra were taken on a Bruker AM 300 spectrometer from samples dissolved in a solution of HCl in D_2O. The UV spectra of all the samples in 1% acetic acid were recorded on a Specord M-40 spectrophotometer in 1-cm quartz cells relative to water. The pH values of solutions were measured with an Anion 4100 pH meter. The specific rotation was measured with a Perkin–Elmer (model 141) polarimeter.

The complexes prepared were separated from unchanged CFT by double reprecipitation, which was performed by adding a solution of the complex into isopropyl alcohol (volume ratio of the reaction mixture and isopropyl alcohol 1 : 5); in so doing, the free antibiotic remained in the solution. The precipitate formed was washed with isopropyl alcohol and vacuum-dried to constant weight.

Cefotaxime is a β-lactam compound based on 7-aminocephalosporic acid. The presence of the carboxy group in CFT makes possible its complexation with amino groups of CTS. The electronic absorption spectrum of CFT at its concentration in 1% aqueous acetic acid (pH 4.2) of 1×10^{-5} M has a single maximum at 261 nm. On adding increasing amounts of chitosan, the intensity of the CFT absorption band increases, and the absorption maximum shifts toward shorter wavelengths by 22 nm. Chitosan has no absorption in this range. The spectral changes are indicative of a strong effect exerted by chitosan on the electronic system of CFT and of the formation of a complex. The band shift may be caused not only by complexation, but also by changes in the solution pH. However, variation of pH in the range 2–6 only slightly affects the intensity of the CFT absorption band and has no effect on its position. By the method of isomolar series [12] we showed that the stoichiometry of the CTS–CFT complex is 1 : 1 (Fig. 1). The complexation constants were calculated by the method of molar ratios [12]. At a constant concentration of CFT,

in the presence of a variable excess of chitosan, the spectral changes in CTS solutions are described by the equation [12]

$$[CTS]_0/(A - A_0) = 1/(\varepsilon - \varepsilon_0) + 1/\{(\varepsilon - \varepsilon_0)K[CFT]\},$$

where A and A_0 are the optical densities of the solutions in the presence and in the absence of CTS, respectively; [CTS], initial CTS concentration; ε and ε_0, molar extinction coefficients of the 1 : 1 complex and CFT, respectively; K, stability constant (β_c); and [CFT], CFT concentration.

From the slope of the plot of $[CTS]_0(A - A_0)$ vs. 1/[CFT] (Fig. 2), we determined by the least-squares method the stability constant of the complex, $\beta_c = (2.2 \pm 0.7) \times 10^5$ l mol^{-1}.

Complexes of CTS with CFT were isolated, purified, and characterized by IR, UV, and ^{1}H NMR spectroscopy and by elemental analysis (Table 1).

The electronic absorption spectra of the complexes are characterized by a hypsochromic shift of the absorption maximum of the modified chitosan molecule (λ_{max} = 253–258 nm; for free CFT, λ_{max} = 261 nm). Chitosan shows no absorption in this range. A new band at 1752 cm^{-1}, characteristic of the stretching vibrations of the carbonyl group in CFT, appears in the IR spectra of the complexes. In addition, the absorption maxima of the OH (3350–3250 cm^{-1}) and C–O (1200–1000 cm^{-1}) groups of the glycoside in the IR spectra of the complexes are shifted to lower frequencies by 30–50 and 10–15 cm^{-1}, respectively, suggesting formation of intermolecular hydrogen bonds between the CFT and CTS molecules. Comparison of the ^{1}H NMR spectra of CTS, CFT, and their complex shows that the proton signals of the complex (δ_H 3.20 ppm) are shifted downfield relative to free CTS (3.01 ppm). The electron density redistribution due to the complexation causes a downfield shift of the H^2 signal. As in the case of the complexation of dextrins with low-molecular-weight organic compounds [15], analysis of the chemical shifts in the ^{1}H NMR spectra of the CTS–CFT complex shows that the interaction of CTS with CFT is appreciable. The physicochemical properties of the CTS–CFT complex are given in Table 1.

Elemental analysis shows that approximately every fifth chitosan unit, on the average, participates in the complexation with CFT. Apparently, in a 2% CTS solution not all the polysaccharide units are accessible for the interaction with CFT. This is indicated by data on the influence exerted by the CTS : CFT ratio at

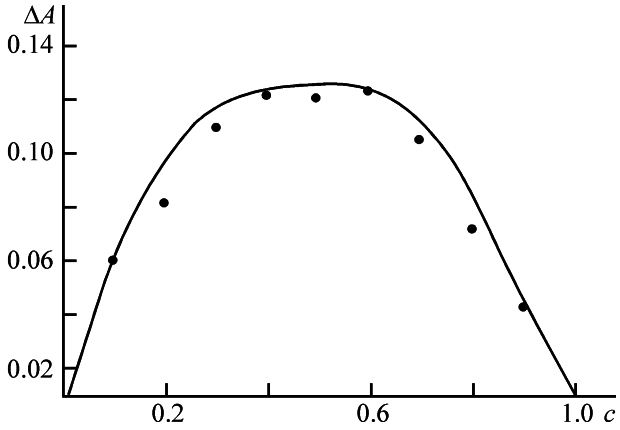

Fig. 1. Isomolar diagram. [CTS] + [CFT] = 5 × 10^{-4} M; pH 4.2; l 1 cm. (A) Optical density and (c) concentration ratio $c_{CFT}/(c_{CFT} + c_{CTS})$.

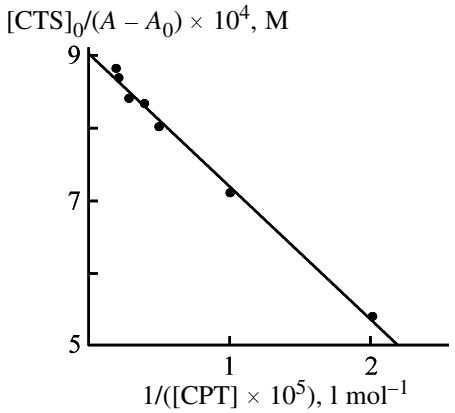

Fig. 2. Plot of $[CTS]_0/(A - A_0)$ vs. 1/[CFT] for the complex of chitosan with Cefotaxime.

[CTS] = 2 wt % on the CFT content in the complex (Table 2).

As the molar ratio of the components is changed from 1 : 0.25 to 1 : 3, the CFT content in the reaction product increases; the temperature and time of the

complexation reaction do not appreciably affect the drug content.

Examination of the influence exerted by the chitosan concentration on the CFT content in the complex leads to interesting conclusions. Table 2 shows that the CFT content in the complex prepared from more concentrated solutions is higher than in the complex prepared from the dilute chitosan solution. Also, an increase in the concentration of acetic acid in solution, i.e., a decrease in pH of the medium, is accompanied by a considerable decrease in the CFT content in the reaction product (Table 2). These facts can be explained only taking into account the degree of protonation of chitosan amino groups. The lower the CTS concentration in solution and the higher the solution acidity, the higher the degree of protonation of the amino grops. Therefore, under these conditions the incorporation of CFT in the complex is insignificant. The lower the degree of protonation, the higher the probability of the complexation. Thus, by varying the reaction conditions, it is possible to prepare complexes based on chitosan with a CFT content from 3.4 to 33.5%.

CONCLUSIONS

(1) Examination of the complexation of chitosan with Cefotaxime revealed the formation of the stoichiometric complexes.

(2) Optimal conditions for preparing the complexes were found. Complexes containing from 3.4 to 33.5% drug were prepared depending on the complexation conditions.

ACKNOWLEDGMENTS

The study was financially supported in part by the Foundation for Support of Leading Scientific Schools (grant NSh 728.2003.3.), by project UR.05.01.008 within the framework of the scientific program of the Federal Education Agency "Development of the Scientific Potential of Higher School," and by the State Scientific and Technical Program of the Bashkortostan Republic for the years 2005–2007 (contract 419-Kh).

BOOK REVIEWS

Poole, C.P., Jr. and Owens, F.J., *Introduction to Nanotechnology*

New York: Wiley–Interscience, 2003

Translated under the title *Nanotekhnologiya*

Moscow: Tekhnosfera, 2004, 328 pp.

DOI: 10.1134/S1070427206070366

Among quite a number of monographs, textbooks, and popular-science editions published in recent years and devoted to nanomaterials and nanotechnologies, the book by C.P. Poole and F.J. Owens is one of the best in its scientific level, manner of presentation, and number of materials covered. The book is recommended by the Institute of Chemical Physics, Russian Academy of Sciences, as a textbook for students specializing in nanotechnology.

The book includes the authors' preface and that by the editor of the Russian translation (Prof. Yu.I. Golovin), thirteen chapters, two appendices, and a supplement. A brief list of the recommended literature is given at the end of each chapter.

The authors' preface (pp. 12, 13) notes that the interest in nanotechnologies originated in the United States in 1996–1998, when a government commission, aided by the World Technology Evaluation Center (WTEC) and financed by the National Science Foundation and other federal agencies, started to analyze the world's R&D experience in nanotechnology in order to assess its technological innovation potentialities. In the years that followed, a very large amount of funds was assigned to the development of nanoscience and nanotechnologies and interdisciplinary research covered a wide area at the frontline of physics, chemistry, biology, and technical sciences.

The preface of the editor of the Russian translation (pp. 14–16) discusses the advantages and certain disadvantages of the book by Poole and Owens and presents a list of domestic and foreign books on nanomaterials and nanotechnologies, published in 2001–2004. Chapter 1 (pp. 17–22) serves as introduction. The authors give a general historical notion of nanoparticles and specially emphasize at the conclusion of the introduction the interdisciplinary nature of work in the field of nanomaterials and nanotechnologies and the related difficulties and specific circumstances, which, in particular, affected the structure of the book. The authors admit that the field of nanotechnology is too wide, involves a too large number of disciplines, and too rapidly develops for an exhaustive book on the subject to be written. Chapter 2 (pp. 23–46) presents several concepts of solid state physics, which bear direct relation to understanding of nanostructures (atomic structure, energy band structure, localized particles, and quasi-particles).

The considerable recent progress in the development of nanotechnologies is, in particular, associated with improvement of the already existing instrumental means for determining the parameters of nanostructures and appearance of new ones. The operation principles of some of the devices and research techniques are considered and their opportunities are assessed in Chapter 3 (pp. 47–78). Chapter 4 (pp. 79–102) describes the properties of individual nanoparticles. It discusses metallic nanoclusters, semiconducting nanoparticles, clusters of inert gases, molecular clusters, and various methods for synthesis of nanoparticles. The authors demonstrate with a large number of specific examples that the physical, chemical, and electronic properties of nanoparticles strongly depend on the number and type of the constituent atoms. The authors emphasize that nanosize materials can serve as a basis for a whole new class of atomically engineered materials.

Chapter 5 of the book (pp. 103–126) is exclusively devoted to analysis of a wide variety of carbon nanostructures, and carbon nanotubes in the first place, methods of their fabrication, structure, various properties, and application fields. Chapter 6 (pp. 126–152) describes bulk nanostructured materials: disordered solid-state structures and nanostructured crystals.

Chapter 7 (pp. 153–174) contains evidence concerning ferromagnetism in nanostructures. It presents the basic concepts of ferromagnetism, effect of nanostructuring of a bulk material on its magnetic properties, deposition of films composed of nanosize mag-

netic particles, and development of materials by filling of pores with magnetic nanoparticles. The chapter also discusses nanocarbon ferromagnetic materials and ferromagnetic fluids.

Various kinds of spectroscopy are among the main methods used to study nanoparticles. Chapter 8 (pp. 175–198) discusses, together with optical spectroscopy in the visible and UV ranges, methods for analysis of nanomaterials by IR and Raman spectroscopy. Special attention is given to methods for obtaining additional information about nanostructures, such as photoluminescence, fluorescence, and thermoluminescence.

As the size of sample decreases from macroscopic to very small, its properties first remain unchanged and then start to be gradually modified, with fundamental changes observed at a size less than 100 nm. If a sample has size in the nanometer range in one dimension and is large in the other two, such a structure is named a quantum well. If a sample is small in two dimensions and is large in the third, such an object is named a quantum wire. The limiting case, when the sizes in three dimensions lie in the lower part of the nanometer range, is that of a quantum dot. The epithet "quantum" used for these three types of structures is due to the quantum-mechanical change in properties. The specific type of behavior of samples with one, two, or three dimensions lying in the nanometer range are the subject of Chapter 9 of the book (pp. 199–224).

Chapter 10 (pp. 225–244) is named "Self-Assembly and Catalysis." By self-assembly is understood spontaneous organization of small molecules into large, strictly defined, stable molecular complexes or aggregates and deposition of atoms or molecules onto a substrate with subsequent self-ordering into nanostructures suitable for various applications. The catalysis in nanoscience can play two basic roles. On the one hand, catalysts can be used in various methods for synthesis of quantum dots, nanotubes, and many other nanostructures. On the other, certain nanostructures can themselves serve as catalysts for particular chemical reactions.

Chapter 11 (pp. 245–270) is devoted to nanoparticles of organic origin. These nanoparticles can be obtained from large organic molecules of various types and from polymers composed of organic building blocks. Chapter 12 (pp. 271–290) is devoted to nanostructures in biology. The final Chapter 13 (pp. 291–310) describes nanomachines and nanodevices: micro- and nanoelectromechanical systems, molecular and supramolecular switches. Appendix *A* (pp. 311, 312) contains a number of mathematical expressions related to delocalization or partial localization of conduction electrons in nanostructures. Appendix *B* (pp. 313–318) includes evidence concerning the crystallographic, thermodynamic, and some other properties of III–V and II–VI semiconducting compounds in the bulk state.

The supplement to the Russian edition (pp. 319–327) is devoted to the technology of micromodification of composites with fulleroid nanomaterials.

The book by Poole and Owens is very well written and intended for a wide audience of specialists with moderate physicochemical background. The large number of clear illustrations favors better understanding of the material.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Heterogeneous Reduction of Potassium Heptafluorotantalate

V. M. Orlov, M. N. Miroshnichenko, and V. V. Sukhorukov

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received October 25, 2005; in final form, April 2006

Abstract—The results obtained in the study of the influence of heterogeneous reduction conditions on the characteristics of the tantalum powder obtained are presented. A new technique for heterogeneous reduction of potassium heptafluorotantalate with sodium is described. The technique allows production of powders with characteristics corresponding to those obtained in a large-scale experiment, with small amounts of reactants.

DOI: 10.1134/S1070427206080015

The main method for production of metallic tantalum is its reduction with sodium from potassium heptafluorotantalate (PFT) by reaction (1) to give a tantalum powder.

$$K_2TaF_7 + 5Na = Ta + 2KF + 5NaF. \quad (1)$$

The reaction involves a significant heat release and proceeds spontaneously in a mixture of the reagents upon local heating to 450–500°C [1]. The resulting powder has a highly developed surface of particles. Up to 60% of the world's output of tantalum is used for fabrication of anodes of volume-porous tantalum capacitors. Therefore, the specific surface area of the powder is of great importance, because it predetermines the possibility of raising the specific charge of the capacitors and their miniaturization.

In practice, the reduction process is used in several variations. These may be reduction of PFT in a melt of salts, with liquid sodium delivered to the melt surface ("liquid-phase reduction") [2]. In another variant, the reaction is initiated in a mixture of solid PFT and sodium by heating the stock to the reaction onset temperature. This temperature is higher than the melting point of sodium and considerably lower than the melting point of PFT, and the reaction zone moves in the bulk as the heat front propagates. Therefore, the process should be considered "heterogeneous," because substances in different states (liquid and solid phases) enter into the reaction.

The aim of this study was to examine specific features of the reaction of potassium heptafluorotantalate with sodium, using both a premixed homogeneous stock and reagents loaded in layers, and also to analyze characteristics of the resulting tantalum powders.

EXPERIMENTAL

The reduction process is accompanied by heat release into the environment, whose share depends on the weight (volume) of the reactants. Preliminary studies demonstrated that, in experiments carried out with a small mass of reagents by the conventional technique in a steel retort heated by a resistance furnace, most part of the tantalum powder obtained significantly differs in granulometric characteristics from that formed in a large-scale experiment because of the considerable temperature differences in the volume of the stock. To obtain sufficiently reliable data in laboratory conditions, we developed a procedure that could eliminate this disadvantage to a considerable extent.

The reactor (Fig. 1) has the form of a quartz ampule *1* with an airtight cover *2* equipped with pipes *3* for evacuation and delivery of an inert gas, admission openings for the stirrer *4*, thermoelectric couple *5*, and holder *6* of a steel vessel *7* with a diameter of 6 cm and 8 cm high, filled with the stock. Ampule *8* with a weighed portion of an alkali metal was suspended

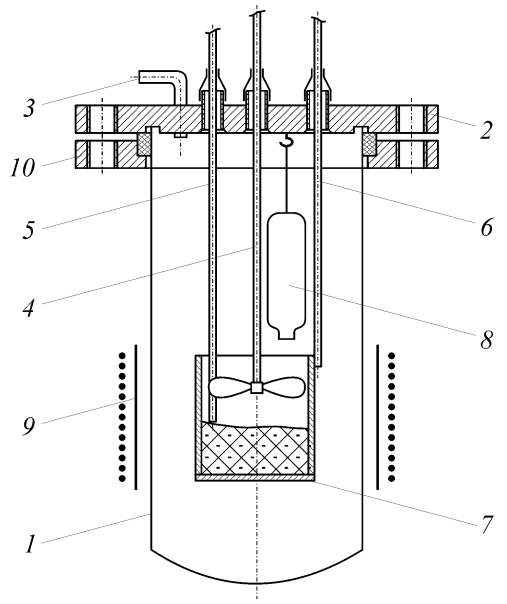

Fig. 1. Schematic of the reactor: (*1*) Quartz ampule, (*2*) airtight cover, (*3*) pipe for evacuation and delivery of an inert gas, (*4*) stirrer, (*5*) thermocouple, (*6*) holder of the steel vessel, (*7*) steel vessel, (*8*) ampule with a reducing metal, (*9*) resistance furnace, (*10*) flange.

from a hook on the inner side of the cover. The heating prior to an experiment was carried out with a resistance furnace *9*. To compensate for the pressure buildup in the course of reaction, a rubber tube (not shown in Fig. 1) was connected to the retort.

We used in the study high-purity potassium heptafluorotantalate with various granulometric compositions: original, with particle size of 5 to 50 μm; recrystallized, with particle size exceeding 250 μm; and recrystallized and thermally treated. The content of metallic impurities in the reagent did not exceed 0.001% for each impurity. The heat treatment of K_2TaF_7 consisted in twofold heating in a vacuum to 250°C with an intermediate cooling to 100°C. In the process, the size of crystals decreased to 300 μm and less (main fraction 40–140 μm) as a result of the polymorphic transformation at 203°C [3]. Chemically pure KCl, NaCl, KF, and NaF, used as fluxing additives, were preliminarily calcined at 650°C.

To obtain a homogeneous stock, a mixture of K_2TaF_7 (65 g) and a necessary amount of a flux were charged into the steel vessel and placed in the reactor, and an opened ampule with sodium (20 g) was suspended from the reactor cover. The reactor was evacuated, and the vessel with the salts was heated at 150°C for 1 h for additional dehydration. Then the furnace was shifted to the zone with the ampule, and sodium was melted and discharged. The reactor was filled with argon, and the stock was cooled to 100°C and thoroughly agitated to a homogeneous state. Then the reactor was cooled to room temperature, placed in an inductor of a VCHI-10/0.44 high-frequency generator, and the vessel was heated with a high-frequency current to initiate a reaction. This heating technique allowed high-rate heating, with the wall temperature of the reaction vessel maintained close to that of the reaction mass, which largely compensated the loss of heat into the environment. Owing to the low temperature of walls, the quartz retort was not destroyed by the sodium vapor and could be repeatedly used. The transparency of its walls allowed us to visually inspect the quality of mixing of the reactants and monitor the reaction course. The temperature was recorded with a measuring-computing complex comprising an analog-to-digital converter and a computer, with chromel–alumel thermocouples used as sensors.

In another variant, a mixture of the salts and sodium was charged layer by layer into the reaction vessel. The stock was covered with a NaCl layer serving as a heat shield, which, in addition, diminished the evaporation loss of the reducing agent. The vessel was placed in the reactor, which was evacuated and filled with argon. The reaction was also initiated by high-frequency heating.

After the process was complete and the reactor was cooled, it was opened, the remaining sodium was eliminated, reaction products were withdrawn, and the powder was washed to remove the salts [4]. After the powder was dried, its granulometric characteristics were determined: bulk weight γ, in conformity with GOST (State Standard) 19440 in a cell of volume 5.5 cm^3; and the specific surface area *S*, by the method of gas permeability in a vacuum with a UGP-2 instrument. The anodes were fabricated, and their characteristics, measured, using the standard technique [5].

Our study demonstrated that halides of alkali metals introduced into the stock are necessary not only as a thermal ballast controlling the maximum temperature reached in the reaction, but also as a condition for obtaining a homogeneous stock. Because PFT is not wetted by sodium at 100°C, preparation of a homogeneous mass without flux additives was virtually impossible. The introduction of KCl and KF into the stock considerably simplified the mixing. The mixture looked like a shining homogeneous paste. We may assume that the substitution reaction

$$KCl\,(KF) + Na = K + NaCl\,(NaF) \qquad (2)$$

yields a certain amount of metallic potassium, which improves the wetting. The occurrence of reaction (2) was indicated by the presence of a liquid alkali metal on the stock surface in a number of experiments at temperatures below the melting point of potassium. This could only be a low-melting alloy of sodium with potassium. However, the use of KF as a flux led to severe difficulties because the reaction frequently started spontaneously when mixing the stock. It is probable that sodium reacted with water, whose certain amount could be present despite all the precautions because of the high hygroscopicity of the salt. As a result, there occurred a local heating sufficient for the reaction to be initiated. With NaCl and NaF used as a flux, the stock had, after mixing with sodium, the form of a loose homogeneous black mass. The wetting of these salts by sodium favored formation of a homogeneous stock in this case.

The temperature variation during the reduction was monitored at two points: on the inner wall of the reaction vessel and in the central part of the stock. A typical temperature variation with time is shown in Fig. 2. The bend in curve *2* (point *a*) at 130°C corresponds to the onset temperature T_{on} of the reduction reaction. It varies rather widely, in the range 120–250°C. Noteworthy is the fact that the reaction begins at a temperature considerably lower than that (450–500°C) reported in [1]. It is seen from Fig. 2 (curve *2*) that the temperature first slowly increases to the inflection point, owing to the propagation of the heat front, and then a sharp rise in temperature is observed, which points to the onset of the reaction. Although the reaction itself occurs at a high rate, its propagation is limited by the motion rate of the temperature front. Measurements carried out with a high-frequency heating of the mixture of the flux with sodium demonstrated that the rate of the temperature front propagation is about 2 deg s^{-1} at a temperature of the mixture lower than the melting point of sodium, and 8 deg s^{-1} at a temperature higher than the melting point of sodium. Despite the excess pressure of argon, a significant amount of sodium vapor was observed at the instant when the reaction occurred. This suggests that the local temperature at the points of interaction of the reactants is higher than the average temperature of the stock, measured with a thermocouple, and exceeds the boiling point of sodium (883°C). No ejection of the stock, caused by pressure buildup, occurred. As can be seen from the plots, the temperature in the central part of the reaction mass is higher than the wall temperature of the reaction vessel, but this difference is insignificant. The temperature of the outer wall is maintained constant by the high-frequency heating, which minimizes the loss into the environment.

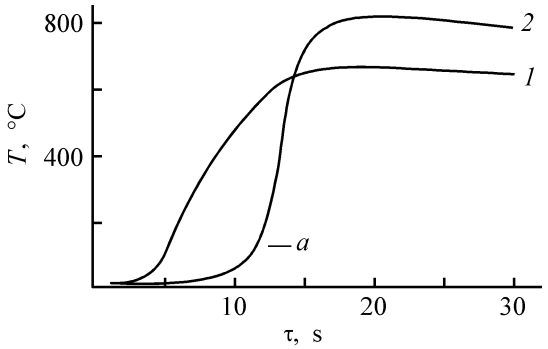

Fig. 2. Typical temperature variation in the course of the reaction. (*T*) Temperature and (τ) time. (*1*) Inner wall of the reaction vessel, (*2*) central part of the reaction mass.

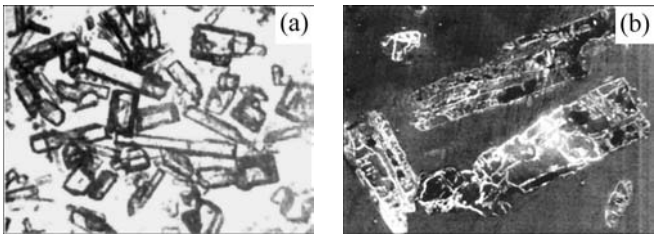

Fig. 3. Microstructure of (a) K_2TaF_7 crystals and (b) tantalum powder particles.

We can distinguish three regions in the reaction mass formed. In some cases, a loose layer composed of a mixture of salts and an alkali metal was observed on the surface. The probable reason is that the temperature in this zone is low because the heat released in reaction (1) is absorbed by the excess sodium displaced from pores onto the surface of the stock. This layer was removed by scraping. The main part of the reaction products was a light poorly sintered mass. The powder obtained from this part was composed of platelet particles with a metallic luster. The thin layer adjacent to the walls of the reaction vessel had the form of a black fusion cake of salts. The powder was finer, dark, and its coarse particles readily disintegrated under a mechanical action. The weight of this layer did not exceed 10%, whereas in the case of reduction of the same amount of the stock in a retort heated by a resistance furnace, its amount was no less than 60% of the total mass.

A microscopic study demonstrated that many particles, both light and dark, reproduce the shape of fluorotantalate particles (Fig. 3). We can assume that, at a close contact between K_2TaF_7 particles and a reducing agent, the heat released upon the reaction onset

Table 1. Parameters of the powder at various contents of a fluxing additive in the stock (temperature of anode sintering 1550°C)

Flux	K_2TaF_7 : flux (mole ratio)	T_{max}, °C	γ, g cm^{-3}	S, cm^2 g^{-1}	Q, μC l^{-1}

	0.3	880	0.7	8400	22 600

is sufficient for melting of the remaining part of a salt particle, and the reaction further occurs between liquid heptafluorotantalate and liquid or even vaporous sodium. As a result, a metallic cocoon reproducing the shape of a K_2TaF_7 crystal is formed. Further growth of the particle occurs due to the reaction of the reducing agent penetrating through fractures with the remaining part of the PFT melt. The thickness of the metallic particle formed correlates with the size of a salt crystal. This model is confirmed by the dependence of the granulometric composition of the resulting powder on that of the starting heptafluorotantalate. In reduction of PFT with crystal sizes less than 300 μm, the amount of the fraction with a crystal size less than 44 μm in the tantalum powder was up to 35%. If a recrystallized salt with crystals larger than 250 μm was used, the amount of particles smaller than 44 μm in the powder did not exceed 15%.

The experiments showed that another factor affecting granulometric characteristics of the powder is the amount of a neutral salt in the stock. As the content of a fluxing additive decreases (Table 1), the maximum temperature reached in the bulk of the stock, the surface area of the powder and, accordingly, the specific charge of the anodes increase. The low bulk weight of the powders is accounted for by the specific features of their morphology [6]. Unfortunately, it is technically hardly possible to obtain powders with a larger surface area in such a process because of the decrease in sizes of K_2TaF_7 particles. When primary PFT with particle size less than 50 μm was used, its high reactivity resulted in that a spontaneous reaction, as a rule, commenced even under stirring at temperatures not higher than 100°C.

The use of finely dispersed PFT as a raw material for the heterogeneous reduction did not cause any complications in the case of the layer-by-layer charging of reagents. However, powders had in this process mode a smaller specific surface area and a considerably greater bulk weight (Table 2). The reduction itself started at a higher temperature (480–560°C). The addition of a flux (NaCl) to the stock had virtually no effect on the onset temperature of the process, but noticeably lowered the maximum temperature, which affected the parameters of the powder and anodes. A similar dependence of the onset temperature of the reduction on the state of the stock was also observed in the case of a sodium-reduction of zirconium from K_2ZrF_6 [7].

We can explain this phenomenon as follows: in the case of a layer-by-layer loading of the reactants, they are separated by the oxide layer present on the surface of the reducing agent and the reaction

Table 2. Comparative parameters of powders obtained in reduction of a homogeneous stock and that loaded in layers (mole ratio K_2TaF_7 : flux = 2)

Stock	K_2TaF_7	Flux	T_{on}, °C	T_{max}, °C	γ, g cm^{-3}	S, cm^2 g^{-1}	$\Delta d/d$, %	Q, μC l^{-1}
Homogeneous	Primary	NaCl	140	835	0.7	6300	8.5	21 600
	Heat-treated	NaCl	140	960	1.0	5700	6.4	18 300
		KCl	125	840	0.9	5700	4.8	17 700
		NaF	120	920	1.1	3200	2.7	14 400
Layered	Primary	No	485	890	1.8	3400	4.1	14 100
		NaCl	510	770	1.4	4400	5.8	15 000
	Heat-treated	No	530	960	1.7	3200	3.7	14 500
		NaCl	510	770	1.4	3800	4.4	15 100

begins only after this layer disintegrates, which occurs at a sufficiently high temperature. In the case of a homogeneous stock obtained by mixing of the reactants, there is no oxide film at the place of contact, and the main part of salt crystals are in a direct contact with the reducing agent, owing to which the reaction begins at a lower temperature. Varying the reduction conditions strongly affected the morphology of the powders. In the case of a layered stock, most part of the powder is represented by equiaxial particles with a developed surface, and only an insignificant amount of the particles have a shape corresponding to that of K_2TaF_7 crystals. The reason is that, initially, the main part of the salt has no direct contact with the reducing agent. The majority of particles of the tantalum powder are formed either as a result of the reaction of sodium vapor with K_2TaF_7 crystallites that had not enough time to melt, or as a result of coagulation and caking of finer primary powder particles.

The characteristics of the anodes sintered from powders of both types at 1550°C are listed in Table 2. Noteworthy is the fact that, at a large difference in surface area between the powders obtained by reduction of homogeneous and layered stocks, the specific charges of anodes made from these powders differ to a lesser extent. This means that a significant part of the surface of planar particles is constituted by microscopic irregularities smoothed-out in sintering of the anodes and in growth of the anodic oxide, making no contribution to the actual surface area of the powder.

CONCLUSIONS

(1) The conditions of heterogeneous reduction affect the characteristics of the tantalum powder obtained. In the case of reduction in a homogeneous mixture of K_2TaF_7 and sodium, a powder with platelet particles corresponding in size to K_2TaF_7 particles is formed. In the case of a layer-by-layer loading of the reactants, equiaxial particles with a developed surface constitute the main part of the powder.

(2) The onset temperature of the reduction reaction in a homogeneous mixture is 200–400°C lower than that for the layerwise loading of the reactants. Mechanisms responsible for the dependences of the parameters of K_2TaF_7 reduction by sodium and the characteristics of the resulting powder on the mode of the heterogeneous process were suggested.

(3) The onset temperature of the reduction reaction and the morphology of the powder are determined by the extent of contact between potassium heptafluorotantalate and sodium.

(4) The technique developed for studying the heterogeneous sodium-reduction makes it possible to obtain reliable results with small amounts of reactants.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

On Stabilization of Anatase with the Fluoride Ion

Abstract—Introduction of fluoride ions into titanium oxo hydroxide causes calcination to result in the anatase modification of titanium dioxide, which is stable up to temperature of no less than 900°C and retains a high specific free surface area on heating.

DOI: 10.1134/S1070427206080027

For destruction of organic contaminants present in aqueous solutions, methods for their photocatalytic decomposition with anatase nanoparticles as a photocatalyst are being intensively studied [1–3]. These processes are especially promising for purification of wastewater containing nonbiodecomposable contaminants [3]. Methods based on hydrolysis of organometallic titanium compounds have been for the most part developed for synthesis of anatase nanopowders [4–6].

Moreover, a highly dispersed anatase retaining a high specific surface area on heating to a temperature of no less than 500°C is required as catalyst and catalyst support for a number of processes of organic synthesis [7]. The thermal stability is necessary for regeneration of the catalyst by high-temperature burning-out of tarry products accumulated in the catalyst in the course of its operation [7].

It has been suggested to obtain materials of this kind by hydrolysis of organic compounds of titanium (ethylate, propylate, butylate, and methyl cellosolvate) in the presence of stabilizers (hydrochloric or nitric acid) with subsequent drying at 120°C to constant mass and calcination at 500°C (calcination time not reported). In some cases (not specified in the study), samples with a specific surface area of up to 105 $m^2 g^{-1}$ have been obtained [7].

Titanium alkoxides are expensive and chemically active, which requires that special intricate equipment should be developed to enable their use in large-scale production. In addition, the formation of Ti^{3+} upon calcination of a xerogel has been revealed by EPR [8]. Therefore, it was of interest to obtain thermally stable anatase nanopowders from inorganic precursors. The most interesting among them are sulfate, chloride, and nitrate compounds of titanium, which can be obtained by various methods from mineral raw materials.

Titanium dioxide nanopowders obtained by plasmochemical synthesis initiated by a pulsed electron beam are a mixture of anatase and rutile. Their ratio in a mixture could be controlled by varying the synthesis conditions [9].

Data on the structure of phases formed in hydrolysis of sulfate, chloride, and nitrate solutions of titanium are contradictory [10]. It has been shown, however, that the crystal structure of the phases formed and its subsequent change upon heating depend on the composition of a starting titanium compound and of the impurities contained in solution. Metatitanic acid produced by thermal hydrolysis from sulfuric acid solutions contains about 7 wt % SO_4^{2-}. Its heating to about 850°C gives anatase, which is transformed into rutile only at 850–950°C [11]. At higher calcination temperatures, micrometer-size powders of titanium dioxide are formed.

Metatitanic acid produced by thermal hydrolysis from nitrate or chloride solutions is transformed into rutile below 500°C [10].

The phase composition and coarseness of titanium dioxide particles depend on the temperature (150–250°C interval was studied) and time (10 min–6 h) of the hydrothermal treatment [12]. Nanocrystalline anatase powders (crystallite size 10–30 nm) were obtained by hydrothermal treatment of the sulfate $TiOSO_4$,

nitrate $TiO(NO_3)_2$, a complex acid $H_2TiO(C_2O_4)_2$, and amorphous titanium hydroxide gel $TiO_2 \cdot nH_2O$, which was synthesized by precipitation from a H_2TiCl_6 solution with an excess amount of aqueous ammonia. Extending the time of hydrothermal treatment to 6 h revealed significant differences in the behavior of the systems studied. In the case of oxo titanium sulfate solutions and an amorphous titanium hydroxide gel, the nanocrystalline anatase was retained, whereas for other solutions, anatase was recrystallized into the rutile, with the crystallites coarsened to 50–100 nm [12]. These were oxo titanium nitrate solutions, a 0.07 M $H_2TiO(C_2O_4)_2$ solution (incomplete recrystallization at 150°C, and complete at 250°C), and 0.28 M $H_2TiO(C_2O_4)_2$ solution (complete recrystallization at 150°C).

Rutile nanopowders have been obtained by thermal hydrolysis of a $TiCl_4$ aqueous solution [13]. At the same time, it has been reported that nanocrystalline anatase with a minor content of brookite was precipitated in the presence of a $TiCl_4$ precursor [14]. As the pH of hydrolytic precipitation increased, the crystal lattice constants of the anatase became larger. The content of brookite in the mixture decreased with the pH value. As the volume fraction of brookite increased, the temperatures of the beginning and end of the anatase–rutile transformation decreased.

Thus, methods for synthesis from inorganic precursors of a highly dispersed anatase, which retains a high specific surface area upon being heated to 500°C or more, have not been developed so far.

It has been found that the insoluble titanium–silica residue formed in nitric [15] and sulfuric acid leaching-out of calcium from sphene concentrate contains a mixture of anatase and rutile and the relative fraction of rutile increases as the process temperature is elevated. When fluorinecontaining compounds (HF or H_2SiF_6) are introduced in an amount of 0.25–0.3 mol F^-/mol TiO_2 into nitric or hydrochloric acid, the whole amount of titanium dioxide is present in the titanium–silica residue in the form of anatase.

The goal of this study was to examine the effect of fluoride ions on the synthesis of anatase from inorganic precursors and on its thermal stability.

EXPERIMENTAL

Anatase doped with fluoride ions was synthesized by sintering a weighed portion of a pure-grade titanium dioxide of the rutile modification with ammonium hydrofluoride at 160 °C for 3 h. Ammonium hexafluorotitanate(IV) obtained by the reaction

$$TiO_2 + 3NH_4F \cdot HF \rightarrow (NH_4)_2TiF_6 + NH_3 + 2H_2O \quad (1)$$

was treated with ammonia water (or ammonium hydroxide) to obtain titanium hydroxide:

$$(NH_4)_2TiF_6 + (4 - x)NH_4OH \rightarrow TiO(OH)_{2-x}F_x + (6 - x)NH_4F + H_2O. \quad (2)$$

In an excess of ammonia, the following reaction proceeds [16]:

$$TiO(OH)_{2-x}F_x + (2 - x)NH_4OH \rightarrow TiO(ONH_4)_{2-x}F_x + (2 - x)H_2O. \quad (3)$$

The precipitate separated from the solution by filtration was washed by repulpation in water at a $V_1 : S$ ratio of 10 or 20.

In this case, the following reactions may occur in washing, depending on the equilibrium pH value [17]:

$$TiO(ONH_4)_{2-x}F_x + H_2O \rightarrow TiO(OH)(ONH_4)_{1-x}F_x + NH_4OH, \quad (4)$$

$$TiO(OH)(ONH_4)_{1-x}F_x + (1 - x)H_2O \rightarrow TiO(OH)_{2-x}F_x + (1 - x)NH_4OH. \quad (5)$$

Partial transfer of fluoride ions into solution also seems to be probable. In this case, the processes that occur in washing can be described by the reaction:

$$TiO(ONH_4)_{2-x}F_x + (2 - x)H_2O \rightarrow TiO(OH)_{2-y}F_y + (x - y)NH_4F + (2 - 2x + y)NH_4OH. \quad (6)$$

Raising the $V_1 : S$ ratio favors an increase in the extent of hydrolysis of ammonium titanates.

The precipitates obtained were thermally treated at 100–900°C, with the calcination loss determined for selected samples. The structure of the heat-treated powders was identified by X-ray phase analysis (DRON-3 diffractometer, Cu_{K_α}-radiation) and their specific surface area was found from the low-temperature adsorption of nitrogen (BET method, FlowSorb II 2300 apparatus). The powders were also ana-

* Not determined.

lyzed for the content of TiO_2 and F. The results obtained are listed in the table.

As can be seen from the data in the table, the samples obtained by washing with water at $V_l : S = 10$ have a higher content of bound fluorine and a larger calcination loss than samples washed with water at $V_l : S = 20$. This is probably due to the higher content of ammonium ions in titanium hydroxide.

The powders obtained at treatment temperatures below 300°C were amorphous. They contained no less than 6 wt % water (as determined by comparison with the calcination loss of the sample obtained at $V_l : S = 20$ and calcined at 900°C). Heating in this temperature interval mostly leads to evaporation of water, with the bound fluorine remaining in the product.

The anatase structure starts to be formed at higher temperatures, and, according to XPA, the oxide treated even at 350°C contains the anatase TiO_2 phase, along with the amorphous phase, with the calcination loss increasing. The precipitates treated within the range 400–900°C, contain only the anatase modification of TiO_2.

As the calcination temperature is raised, the content of fluorine in the products and their specific surface areas decrease. For example, the specific surface area of the products treated at 100°C, which contain up to 3 wt % F, is as large as 227 m^2 g^{-1}. As the calcination temperature is elevated, the content of bound fluorine gradually decreases, to reach a value of 0.13–0.19 wt % at 900°C. In the process, the specific surface area of the powders decreases to 54–68 m^2 g^{-1}, but remains rather high. On elevating the heat treatment temperature to $T \geq 1000$°C, the content of fluorine and the specific surface area further decreased, with rutile appearing in the product. Rutile was predominant in the product calcined at 1100°C, and no anatase was found in that obtained at 1200°C.

It should be noted that powders obtained from more thoroughly washed precipitates ($V_l : S = 20$) have a more developed surface. This contradicts the tendency common to the experimental results obtained: direct relationship between the content of bound fluorine and the specific surface area of the precipitate, which invites an additional study.

Three crystalline modifications: anatase, brookite, and rutile, are known for titanium dioxide. Rutile and anatase belong to the tetragonal crystal system and are, in structural regard, alternative forms with a 6 : 3 coordination. In their structure, each titanium atom is surrounded by six oxygen atoms, and each oxygen atom, by three titanium atoms [17].

However, the anatase density (3.84 g cm^{-3}) is 9% lower than the rutile density (4.26 g cm^{-3}), i.e., atoms in the anatase lattice are less densely packed, compared with rutile.

It was assumed that formation of the thermodynamically most stable rutile modification in synthesis and the subsequent high-temperature treatment can be, in particular, hindered by anionic impurities forming chemically stable complexes with titanium. In the course of heat treatment, these impurities come to dislocation growth steps and block the recrystallization of anatase, thereby precluding formation of the rutile crystal lattice of titanium dioxide. In this case, anatase should be regarded as a solid solution that is based on titanium dioxide and contains microimpurities (in particular, OH^-, SO_4^{2-}, F^-, etc.), rather than a stoichiometric titanium dioxide.

It is known that the capacity of Ti(IV) for complexation increases in the order $NO_3^- < Cl^- < SO_4^{2-} < F^-$. This predetermines the higher content of SO_4^{2-} and F^- ions upon hydrolysis of the corresponding titanium compounds. It may be suggested that it is the high content of SO_4^{2-} ions (about 7 wt % [10, 11]), which cannot be washed out with water, that hinders direct crystallization of anatase or rutile in thermal hydrolytic precipitation of titanium from sulfate solutions.

Formation of anatase in thermal treatment of metatitanic acid precipitated from titanium-containing sulfate solutions is also hindered by the high concentration in the acid of difficultly removable sulfate ions and proceeds at a temperature of about 850°C, at which sulfur oxides start to be removed to a noticeable extent. However, there simultaneously occurs intense sintering of particles of the forming anatase, which results in that powders with a small specific surface area are formed.

Fluoride ions, which form rather strong complexes with titanium, must hinder rutile formation. The presence of minor concentrations of fluoride ions in the hydrolysis products should lead not only to formation of the thermally stable anatase modification of titanium dioxide, but also to the related preservation of its large specific surface area. Indeed, the bonding energy of titanium with fluorine is considerably higher than that with chlorine or oxygen, and the ionic radii of fluorine and oxygen are rather close (1.40 and 1.36 Å, respectively) [16].

Consequently, F^- can replace, for stereometric and thermodynamic reasons, oxygen in titanium–oxygen octahedra, which are structural elements of the crystal lattices of both rutile and anatase, but the charge of the titanium cation is not completely neutralized upon this substitution. It is this fact that probably leads to the formation of a less dense anatase structure.

The bound fluorine remains in a sufficient amount even upon heating to 900°C, and this is a probable reason why the anatase structure and rather large free specific surface area are retained at elevated temperatures. With the heat-treatment temperature raised further, the content of F^- decreases to 0.0021 wt % and less, the rutile phase appears, and the specific surface area rapidly decreases.

In conclusion, we note that anatase obtained by calcination at 850°C of metatitanic acid precipitated by thermal hydrolysis from sulfate solutions contained 0.15 wt % SO_4^{2-}, which corresponds to the S/Ti = 0.001 atomic ratio. In anatase calcined at 900°C, the F/Ti atomic ratio was found to be 0.0055–0.008. The higher relative concentration of fluoride ions is the probable reason for the enhanced thermal stability of anatase.

Abstract—Ferrites with the composition $GdM^{II}Fe_2O_{5.5}$ (M^{II} = Mg, Ca, Sr) were synthesized from the corresponding oxides by the solid-phase method. The temperature dependence of the specific heat was studied by dynamic calorimetry in the temperature range 298.15–673 K. Equations describing this temperature dependence were derived. The temperature dependences of the thermodynamic functions were calculated.

DOI: 10.1134/S1070427206080039

Ferrites are compounds of iron(III) oxide with oxides of other metals, which show a unique combination of magnetic, electrical, and other properties. They are interesting objects for study of the internal energy by methods of true specific heat. In many ferrites, processes of magnetic ordering are combined with polymorphic transformations and ion ordering.

In recent years, the creation of the magnetic bioceramic as an effective means of control over bone tissue cancer has been deserving particular attention. A glassy ceramic of this kind is formed via filling of an Al_2O_3–SiO_2–P_2O_5 glassy matrix with microscopic magnetic particles of lithium ferrite $LiFe_5O_8$ or hematite α-Fe_2O_3 [1].

The aim of the present study was to examine the thermodynamic properties of ferrites $GdM^{II}Fe_2O_{5.5}$ (M^{II} = Mg, Ca, Sr). The isobaric specific heat of the ferrites was studied on an IT-S-400 calorimeter under monotonic, nearly linear heating of a sample at an average rate of about 0.1 deg s^{-1} at temperature differences of 3–30 K. The temperature dependence of the parameter under study was measured in a single run. The measuring circuit of the instrument provided determination of the temperature at fixed points in the lower and upper parts of the working cell at intervals of 25 K with a built-in dc potentiometer and a switch. The working mode (temperature differences on a sample and nonlinearity of heating) was chosen in such a way that corrections for changes in the thermal properties and for the heating rate did not exceed 1–2% under normal conditions and could be neglected in calculations. The time in which measurements were performed in the whole temperature range, and the experimental data obtained were processed, did not exceed 2.5 h. The rated measurement error of the IT-S-400 instrument is ±10% [2].

At each temperature, chosen at 25-K intervals, five parallel runs were made and the data on the delay time of the heat meter were averaged and processed using method of mathematical statistics. Root-mean-square deviations $\bar{\delta}$ were calculated for the average values of specific heats at each temperature, and the random component of the error, $\mathring{\Delta}$, for the averaged values of the molar specific heat [3]. The random component of the error, $\mathring{\Delta}$, is expressed in J mol^{-1} K^{-1}, and the root-mean-square deviation $\bar{\delta}$, in J g^{-1} K^{-1}.

The operation of the instrument was tested by determining the specific heat of α-Al_2O_3. The resulting value of C_p^0 (298.15) for Al_2O_3 (76.0 J mol^{-1} K^{-1}) is in a satisfactory agreement with reference data (79.0 J mol^{-1} K^{-1}) [4].

Figure 1 and Table 1 present the results of a calorimetric determination of the specific heats of the ferrites under study.

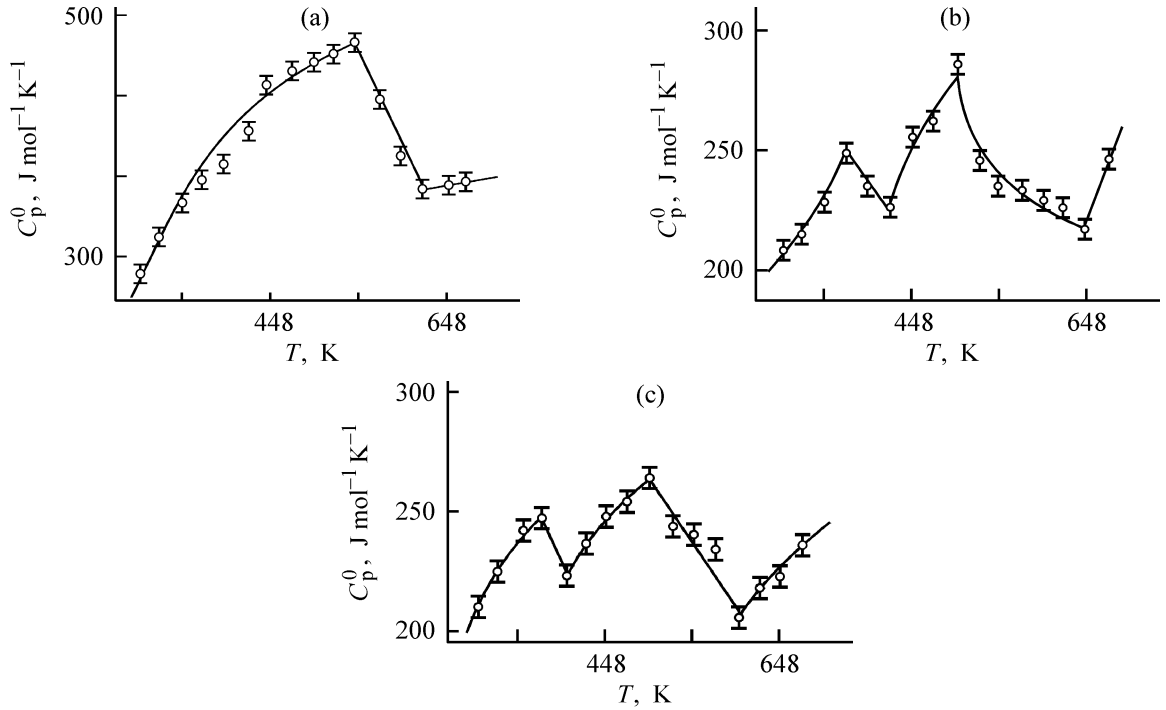

Fig. 1. Specific heat C_p^0 of the ferrites $GdM^{II}Fe_2O_{5.5}$ (M^{II} = Mg, Ca, Sr) vs. temperature T. (a) $GdMgFe_2O_{5.5}$, (b) $GdCaFe_2O_{5.5}$, and (c) $GdSrFe_2O_{5.5}$.

The experimental data were used to derive equations for the temperature dependence of the specific heats of the ferrites (Table 2).

As can be seen from Table 2 and Figs. 1a–1c, the ferrites under study show in the $C_p^0(T)$ curves a lambda-shaped behavior characteristic of second-order phase transitions: $GdMgFe_2O_{5.5}$ at 548 K, $GdCaFe_2O_{5.5}$ at 373 and 498 K, and $GdSrFe_2O_{5.5}$ at 373 and 498 K. These phase transitions are due to electronic transitions or Schottky effects. It should be noted that similar effects have been observed in studies of the specific heat of many oxides of 4*f*-elements. The reason for the splitting of the electron levels of paramagnetic rare-earth ions is the effect of the field of ligands-anions surrounding a cation [5].

Because the technical parameters of the IT-S-400 calorimeter give no way of calculating the entropy from experimental data, the standard entropies of the compounds were evaluated using the system of ionic entropy increments [6]. The temperature dependences of the functions $C_p^0(T)$, $S^0(T)$, $H^0(T) - H^0(298.15)$, and $\Phi^{**}(T)$ of the ferrites were calculated using the known relations in the temperature range 298.15–673 K (see Table 3) from the experimen-

tal dependence $C_p^0(T)$ and calculated values of $S^0(298.15)$.

The inaccuracy of the temperature dependences of the thermodynamic functions was calculated with account of the average errors in determining the specific heat and calculating the entropy (3.0%).

CONCLUSIONS

(1) The isobaric specific heats of the ferrites $GdMgFe_2O_{5.5}$, $GdCaFe_2O_{5.5}$, and $GdSrFe_2O_{5.5}$ were studied for the first time in the temperature range 298.15–673 K, and equations describing the dependence $C_p^0(T)$ were derived.

(2) The standard entropies of the ferrites were calculated by the method of ionic increments, and the functions $H^0(T) - H^0(298.15)$ and $\Phi^{**}(T)$ were found from the experimental data on $C_p^0(T)$ and calculated values of $S^0(T)$.

(3) Lambda-shaped peaks associated with second-order phase transitions were found in the dependences

$C_p^0(T)$ for all of the ferrites studied ($GdMgFe_2O_{5.5}$ at 548 K, $GdCaFe_2O_{5.5}$ at 373 and 498 K, and $GdSrFe_2O_{5.5}$ at 373 and 498 K).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Evaporation of Substances under Kinetic or Diffusion Control in Sublimation in a Vacuum

I. G. Martinson

Mendeleev Institute of Metrology, St. Petersburg, Russia

Received December 16, 2004; in final form, April 2006

Abstract—A diffusion–kinetic model of sublimation of substances in a vacuum is presented. The model defines two regions of the evaporation process depending on temperature: evaporation in the kinetic and diffusion control. The model was verified in experiments with benzoic acid and naphthalene by calculation of the sublimation rate of Zn, Co, V, and W, and by the known values of α.

DOI: 10.1134/S1070427206080040

Previously, an equation for the sublimation rate has been derived in terms of the diffusion model [1–3]. The sublimation rate of benzoic acid and naphthalene has been measured experimentally. The strongest disagreement between the experiment and calculation was about 10%. Substances purified by zone melting and by growth of single crystals from the melt were used in the experiments [4, 5]. A sublimation rate of the same order of magnitude was obtained in sublimation purification of diphenyl and benzophenone (~10^{-3} mol m^{-2} s^{-1}).

Kinetic sublimation model. The kinetic and diffusion modes are distinguished in the kinetics of physicochemical processes. The kinetic sublimation rate, i.e., the rate of transfer of molecules from the solid phase into a vapor, commonly is calculated by the Hertz–Knudsen equation

$$I = \alpha \frac{p}{(1\pi MRT)^{1/2}}, \quad (1)$$

where I is the sublimation rate (mol m^{-2} s^{-1}; p, saturated vapor pressure (N m^{-2}); M, molecular weight (kg mol^{-1}); R = 8.3144 (J mol^{-1} K^{-1}); T, temperature (K); and α, evaporation coefficient.

The Hertz–Knudsen equation was derived in [6, 7]. In the reference book [8], data obtained during the period of time from 1910 to 1968 were generalized: α = 1 for refractory metals (Ti, V, Cr, Co, Ir, etc.); α = 1 for salts (LiF_3, PrF_3, ZnSe, CdSe, etc.); α < 1 for certain metals and organic substances (camphor 0.18, thymol 0.14, benzoic acid 0.1, Sb_2S_3 0.1–0.4, α increases as temperature is lowered); α = 1 for some organic substances (naphthalene at –22…+15°C, anthracene at 49°C, etc.). More recent data were published in the review [9]. The values of the evaporation coefficient were found using different methods. Apparently, this is the reason for the diversity of the results. A value α = 1 was obtained for chromium in three studies, and α = 1.5–2.0, in one study under the same conditions. The coefficient α was defined in [8] by the equation

$$\alpha = I_{exp}/I_G,$$

where

$$I_G = p/(2\pi MRT)^{1/2}, \quad (2)$$

is the original Hertz equation.

In [10], the evaporation coefficient was defined as the ratio of the evaporation rate in the effusion Knudsen method to that in the Langmuir method, which is determined from the loss of mass by a pellet of the substance evaporating in a vacuum, and it was shown that the Hertz equation gives the maximum possible evaporation rate. It is commonly believed that α ≈ 1 in the Langmuir method and α < 1 in the Knudsen method because of the resistance of the effusion opening to the outflow of the saturated vapor. At the same time, it has been found experimentally that, at the same membrane thickness, the rates of evaporation through openings with d 0.832 and 0.258 mm differ by only several percent [11, 12]. In the monograph [13], the Hertz–Knudsen equation is represented as

$$dG/d\tau = F^+(M/2\pi RT)^{1/2}p, \quad (3)$$

where G is the mass of the substance (kg); F^+, evaporation area occupied by active molecules (m^2); and τ, time (s).

In this case, the evaporation coefficient

$$\alpha = F^+/F,$$

where F is the total surface area of the solid phase (m^2).

The coefficient α was also regarded in [13] as a function of the activation energy; in [14], this function was represented as the fraction of molecules having a velocity (kinetic energy) exceeding a certain required value.

When studying the evaporation, Knudsen obtained evaporation rates lower than that given by the Hertz equation, attributed this fact to surface contamination of substances, and supplemented the Hertz equation with a coefficient $\alpha < 1$ [15].

Thus, the evaporation coefficient in the kinetic Hertz–Knudsen equation (1) is regarded as the rate coefficient of the interphase reaction.

Diffusion sublimation model. In sublimation into air or an inert gas, the process rate is determined by the diffusion rate of the substance molecules in the medium. In the case of a forced convection of the medium, the diffusion equation can be used in the following form [7]

$$I = D\frac{\Delta c}{\delta}, \tag{4}$$

where D is the diffusion coefficient ($m^2\ s^{-1}$); Δc, difference of the concentrations in the diffusion layer (mol m^{-3}); and δ, thickness of the boundary diffusion layer (m) [16].

Because calculation of the diffusion sublimation rate in a medium gives coincidence with the experiment, the diffusion sublimation rate in the absence of a medium, in a vacuum, was considered [2].

The diffusion model of the sublimation process comprises the diffusion equation for the substance being evaporated, heat conduction equation, and gas-state equation. The equations contain the diffusion coefficient [17, 18] and the heat conductivity coefficient, which was taken to be constant. A solution of the system of these equations gave an equation for the substance evaporation rate (mol $m^{-2}\ s^{-1}$)

$$I_v = D_v\frac{c_v}{2L}\frac{T_v - T_c}{(T_v^{1/2} - T_c^{1/2})T_v^{1/2}}\log\frac{c_v}{c_c} \tag{5}$$

and that for the condensation rate

$$I_c = D_c\frac{c_c}{2L}\frac{T_v - T_c}{(T_v^{1/2} - T_c^{1/2})T_v^{1/2}}\log\frac{c_v}{c_c}, \tag{6}$$

where c_v and c_c are the concentrations of molecules in the saturated vapor near the evaporation and condensation surfaces (mol m^{-3}); T_v and T_c, temperatures of these surfaces (K); and L, distance between the surfaces (m).

The variation of the substance concentration in the vapor along the distance from the evaporation surface to the condensation surface is described by

$$\log c = \log c_v + \frac{[T_v - (T_v - T_c)x/L]^{1/2} - T_v^{1/2}}{T_v^{1/2} - T_c^{1/2}}\log\frac{c_v}{c_c}, \tag{7}$$

and the corresponding variation of temperature, by

$$T = T_v - (T_v - T_c)\frac{x}{L}, \tag{8}$$

where $x = 0$ at the evaporation surface and $x = L$ at the condensation surface.

Equations (7), (8) and the gas-state equation make it possible to determine how the pressure varies from $x = 0$ to $x = L$.

Thus, the sublimation process may occur under kinetic or diffusion control. Let us denote the kinetic sublimation rate by I_G (Hertz rate) and the diffusion rate by I_D. At high temperatures the process occurs in the diffusion region and the evaporation coefficient is given by

$$\alpha = I_D/I_G. \tag{9}$$

As the temperature of the evaporation surface is lowered, these rates become equal at a certain T_α and the evaporation coefficient $\alpha = 1$. As the evaporation temperature is lowered further, $I_G < I_D$, and the process occurs under kinetic control, in which the evaporation coefficient remains constant and equal to unity, because the evaporation rate is equal the Hertz rate. This is the general scheme of evaporation in a vacuum.

Equations (5), (6) contain the diffusion coefficient calculated as follows. Under atmospheric pressure at 273 K in the SI system

$$D_0 = \frac{0.02662\times10^{-20}}{\sigma^2\Omega p_0}\left(\frac{T_0^3}{M}\right)^{1/2}, \tag{10}$$

where σ is the gas-dynamic diameter of molecules, (m) and Ω, a tabulated function [17].

343	5.026	6.087	4.537	5.509
348	5.323	6.541	4.808	5.919

The diffusion coefficient at the temperature of the experiments was calculated by the equation

$$D = D_0 \frac{p_0}{p}\left(\frac{T}{T_0}\right)^{1/2}. \quad (11)$$

For naphthalene, two equations describing the temperature dependence of the saturated vapor pressure were reported in [11]

$$\log p = 11.70 - 3798/T, \quad (12)$$

$$\log p = 10.52 - 3444/T. \quad (13)$$

We use designations $I_v(1)$ and $I_c(1)$ when applying Eq. (12), and $I_v(2)$ and $I_c(2)$ for Eq. (13). For naphthalene, we have from Eqs. (10), (11)

$$D_0 = \frac{0.02662 \times 10^{-20}}{34.669 \times 10^{-20} \times 2.377 \times 10\,1325}\left(\frac{273^3}{128.18}\right)^{1/2} = 1.270 \times 10^{-6}.$$

The input data for calculating the sublimation rate of naphthalene are listed in Table 1, and the results of calculation of the sublimation rate by Eqs. (12) and (13), in Table 2.

It was taken in the calculations that λ = const. The kinetic theory of gases [17–19] gives for the ideal gas the following heat conduction equation:

$$\lambda = \frac{1}{3}\rho C_Y v l = \rho C_V D = aT^{1/2}, \quad (14)$$

where ρ is the gas density; C_V, specific heat at constant volume; v, mean motion velocity of molecules; l, mean free path of molecules; and a, constant.

Using the dependence $\lambda = aT^{1/2}$ in the initial system of equations gives the following equations for the evaporation and condensation rates:

$$I_v = D_v \frac{2c_v}{3L}\frac{T_v^{3/2} - T_c^{3/2}}{(T_v - T_c)T^{1/2}} \log\frac{c_v}{c_c}, \quad (15)$$

$$I_c = D_c \frac{2c_v}{3L}\frac{T_v^{3/2} - T_c^{3/2}}{(T_v - T_c)T^{1/2}} \log\frac{c_v}{c_c}. \quad (16)$$

Calculation of I_v and I_c by these equations and Eqs. (5), (6) gives coinciding values of the sublimation rate, with a discrepancy of less than 1%.

It follows from Eq. (14) in accordance with Eq. (10) that

$$D = a\frac{1}{\Omega p}T^{1/2},$$

where a is a constant, and p, saturated vapor pressure. Then

$$\lambda = \frac{a}{\Omega T^{1/2}}.$$

The tabulated function can be approximated at its values in the range 1.88–2.66 by the dependence

$$\Omega = 4.837(T^*)^{-0.496} = 4.837(T^*)^{-1/2},$$

where $T^* = T/1.39 \times T_b$.

We obtain that the heat conductivity of the gas

$$\lambda = 0.287aT_b = \text{const}$$

is independent of pressure and temperature if the heat conductivity can be taken constant.

One more phenomenon is observed: pressure and temperature drops arise across phase boundaries in the course of sublimation and condensation, and these drops can be calculated [20, 21]. In sublimation of naphthalene at 348 K,

$$\Delta p = I_v(2\pi MRT)^{1/2} = 5.231 \times 10^{-3} \times 48.261 = 0.253 \text{ Pa},$$

$$\Delta T = 0.35 \text{ K}.$$

When testing the model of the process, with a calculation error of up to 10%, the pressure and temperature drops were disregarded.

EXPERIMENTAL

The substance fluxes in sublimation of naphthalene were measured on a modification of the installation used in [1]. A glass tube (sublimator proper) was placed in a hermetical steel container, which could be evacuated to a residual pressure of 0.1 Pa. A steel condenser was mounted in the upper part of this tube, and an evaporator, in its lower part. The surface area of the condenser was equal to that of the evaporator, i.e., the surface of naphthalene being sublimed in a steel vessel with an inner diameter of 24 mm and height of 16 mm. The condenser was in the form of a hollow flat cylinder cooled with water to 10°C. The glass with the substance was in thermal contact with the evaporator whose temperature was maintained constant by a temperature control unit. Five measurements were made at each temperature, with the successively longer durations of the experiments. The vessel was filled with molten naphthalene and weighed on a VLR-200 analytical balance. Prior to an experiment, the container was evacuated and kept in this state for 30–40 min. The instants when the heater was switched on and off were taken as the beginning and end of a run. The amount of sublimed naphthalene was found from the decrease in the weight of the vessel with the substance. Each run was performed with a new sample.

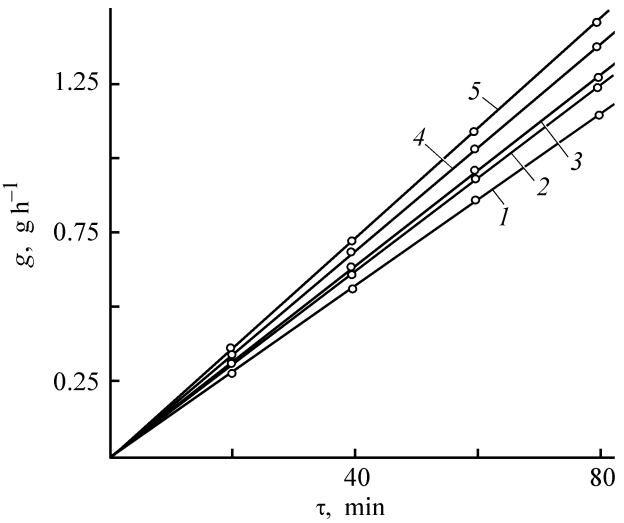

Fig. 1. Amount g of sublimed naphthalene vs. time τ. Temperature (K): (*1*) 331, (*2*) 335, (*3*) 339, (*4*) 343, and (*5*) 348.

The dependence of the amount g (g h^{-1}) of sublimed naphthalene on the experiment duration is shown in Fig. 1. All the dependences are plotted as straight lines, and, consequently, the saturated vapor pressure is attained near the evaporation surface considerably faster than substance is transferred from the evaporator to the condenser. Table 3 lists the results of the experiments.

The sublimation of naphthalene has been previously studied to give $\alpha = 0.85–0.95$ at –19…+5°C and $\alpha = 1$ at –22…+15°C. Because α increases for all substances as the temperature is lowered, the sublimation rate of naphthalene was calculated by Eqs. (2), (5). In doing so, the condenser temperature was taken to be $T_c = 250$ K; the evaporation temperature was 260, 270, 283, and 300 K; and $2L = 0.1$ m. The re-

sulting temperature dependences of the sublimation rate are shown in Fig. 2. It can be seen from the dependences for I_G and I_D that the kinetic sublimation rate is lower than the diffusion sublimation rate below 285.5 K, and, consequently, the former is the process-rate-determining factor, $\alpha = 1$. At $T > 288.5$ K the kinetic rate by Hertz rapidly increases and starts to exceed the diffusion rate of the naphthalene vapor, so that the latter becomes the rate-determining factor,

$$\alpha = \frac{I_D}{I_G} < 1,$$

and decreases as temperature grows.

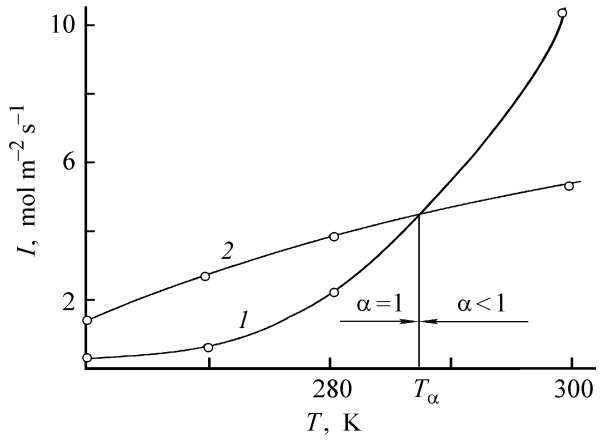

Fig. 2. Sublimation rate I of naphthalene at low temperatures T; T_c = 250 K, $2L$ = 0.1 m. (*1*) Kinetic rate by Hertz and (*2*) rate of vapor diffusion; the same for Fig. 3.

It should be noted that the transition from the kinetic to diffusion control occurs at 288.5 K under the experimental conditions we used, and this temperature will be different in some other conditions.

It was of interest to verify the diffusion-kinetic model of the sublimation process on substances having higher melting points. In monograph [22], the evaporation coefficient was considered in relation to crystal defects and association of atoms in vapor molecules, relevant publications were reviewed, and the following conclusion was made: "As regards the evaporation kinetics of magnetic substances and metallic alloys, the theory is in the initial stage of its development." In [23], a decrease in the evaporation coefficient (I_{exp}/I_G) from 0.48 to 0.13 was observed in the temperature range 1870–2200 K and the temperature dependence was represented as

$$\log\alpha = -3.71 + 0.63 \times 10^{-4}/T,$$

i.e., the evaporation coefficient grows as the evaporation temperature is lowered.

The diffusion sublimation rate of metals (Zn, Co, V, W) was calculated using the known temperature dependences of the saturated vapor pressure (Table 4) and Eqs. (1), (2), (5), (6), and (10). The temperature dependences of the sublimation rate for Zn, Co, and V are presented in Fig. 3, and that for W, in Table 5. As

standard experimental conditions were taken those for naphthalene, T_v and T_c were taken in accordance with the melting points of the metals.

In sublimation of zinc, the kinetic sublimation rate is lower than the diffusion sublimation rate nearly up to the melting point of zinc. At temperatures of up to 418.5°C, sublimation occurs in the kinetic mode, with $\alpha = 1$. At temperatures above 418.5°C, the process passes to the diffusion mode and α decreases as temperature becomes higher, which is also valid in the case of evaporation of the melt.

In sublimation of cobalt, $\alpha = 1$ up to 1387°C (kinetic control of the evaporation process). At higher temperatures (diffusion control), $\alpha < 1$ up to the melting point of cobalt (1494°C) and further, over the melt.

In sublimation of vanadium over solid vanadium, $\alpha = 1$ up to the melting point of 1920°C (kinetic control); as temperature is raised further, molten vanadium also evaporates under kinetic control up to approximately 2000°C, after which the process becomes diffusion controlled, with $\alpha < 1$.

In sublimation of tungsten, the diffusion sublimation rate substantially exceeds the kinetic rate in the temperature range from 2727°C to the melting point of 3380°C and above: the process occurs in the kinetic control, with $\alpha = 1$. The values of the process rates, obtained in the study, are listed in Table 5.

The diffusion-kinetic model of the sublimation process, represented by the scheme in Fig. 1, was confirmed by the available published data and verified by experiments with benzoic acid and naphthalene and by calculations of the evaporation rate of metals with high melting points. The sublimation process is commonly performed at temperatures close to the melting points of the substances involved, in order to raise the process rate. The following conclusions can be made on the basis of the results obtained.

(1) Sublimation of substances with melting points of up to approximately 200°C occurs under diffusion control; the sublimation rate of such substances is the rate of diffusion of the saturated vapor from the evaporation surface to the condensation surface. Sublimation of high-melting substances with melting points of about 1800°C and higher occurs under kinetic control; the sublimation rate of such substances, which is the kinetic rate of the phase transition of a substance from the solid phase to a vapor, is given by the Hertz equation.

For substances with melting points in the range 200–1800°C, the kinetic region lies at low tempera-

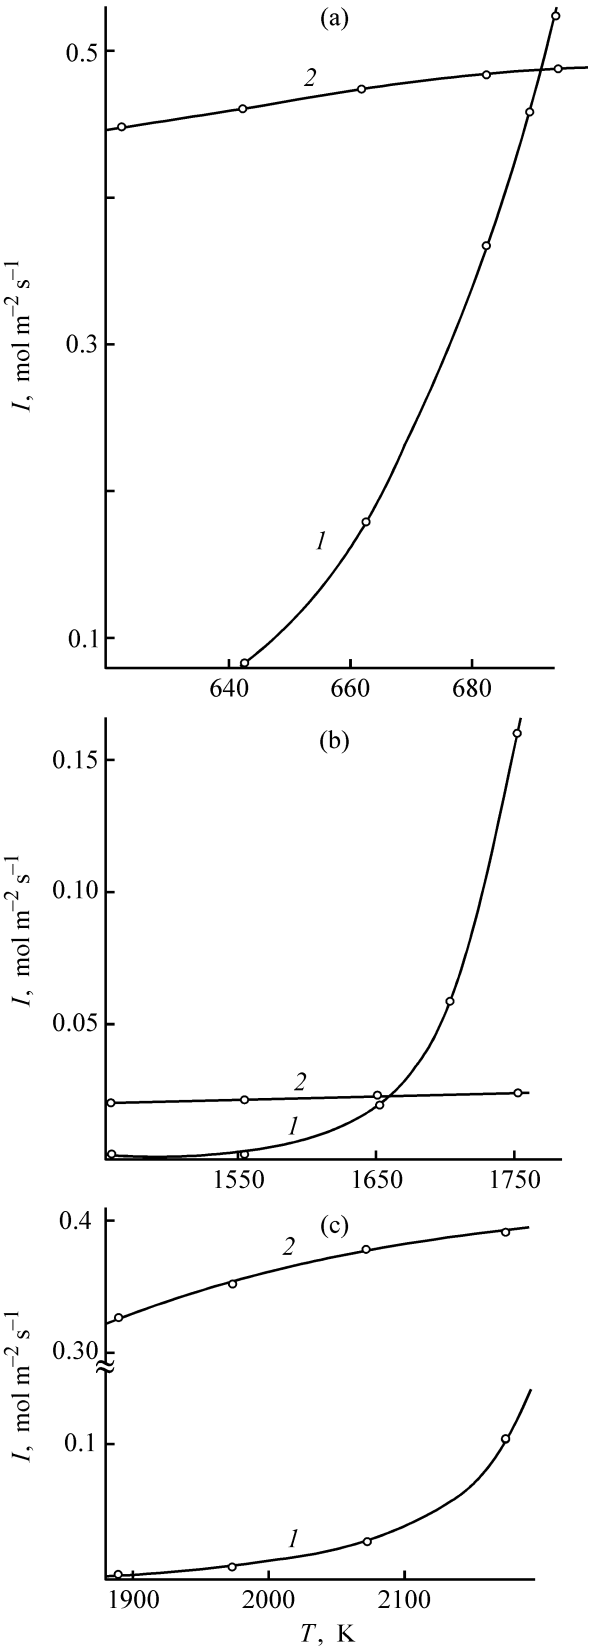

Fig. 3. Sublimation rate I of (a) zinc, (b) cobalt, and (c) vanadium vs. temperature T.

tures, and the diffusion region, at high temperatures. Depending on the objective to be achieved, the process can be performed in an appropriate region.

(2) The conditions of the adopted standard of the process, Eqs. (5) and (6) at $2L = 0.1$ m, as well as the ratios of T_v to T_c and c_v to c_c, will be different in other experiments (studies). If, for example, the sublimation of zinc is carried out in the evaporator–condenser system at $2L > 0.1$ m, the temperature dependence of the diffusion sublimation rate will be shifted downwards, the temperature range of the kinetic control will be shifted to low temperatures. In the experimental conditions corresponding to $2L < 0.1$ m, the temperature dependence of the diffusion sublimation rate will be shifted upwards and the region of the kinetic control over sublimation will extend to molten zinc. The rate of the diffusion process can also be raised by lowering the temperature of the condenser.

(3) It was found in experiments with benzoic acid and naphthalene that the evaporation rate is equal to the condensation rate. A calculation yielded that the latter somewhat exceeds the former. This circumstance can be attributed to inaccuracy of the equations describing the dependence of the saturated vapor pressure on temperature and that of the diffusion coefficient on temperature and pressure. Therefore, it is better to take the evaporation rate I_v as the process rate. It also follows that the evaporator–condenser method can be used to refine the equation $\log p = A - B/T$.

(4) A large number of substances with high melting points have an evaporation coefficient $\alpha = 1$ and there are no kinetic hindrances in evaporation of substances of this kind. However, it is not improbable that such hindrances may exist in condensation, when only part of molecules reaching the crystalline phase, rather than all of them, are involved in the crystallization process. In this case, the pressure and temperature drops Δp and ΔT at phase boundaries are related to the activation energy ΔG.

CONCLUSIONS

(1) The diffusion-kinetic model of sublimation, considered in the study, establishes two modes of the evaporation process: (i) with kinetic control at low temperatures, in which the evaporation rate is equal to the Hertz rate and the evaporation coefficient $\alpha = 1$ up to a temperature T_α, and (ii) with diffusion control at high temperatures, in which the evaporation rate is given by the diffusion equation and α rapidly decreases from unity to very small values.

(2) The model makes it possible to define the evaporation coefficient in the case of the diffusion control as a ratio of the diffusion rate of the process to the kinetic rate by Hertz and to calculate the evaporation rate with an error of up to 10% in the case of the diffusion control and, probably, with a very small error in that of the kinetic control.

(3) The model explains why small (down to 10^{-10}) values of the evaporation coefficient α are obtained for low-melting substances and $\alpha = 1$ for substances with high melting points.

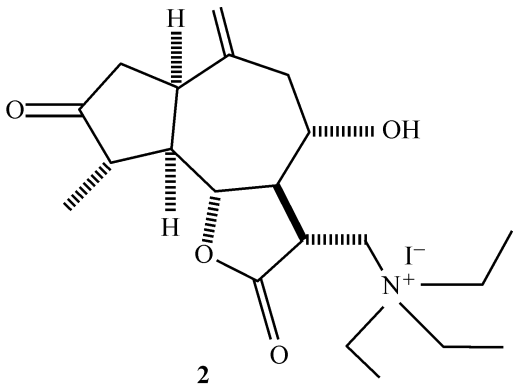
Received April 16, 2005; in final form, April 2006

Abstract—The method of isothermal calorimetry at dilutions (moles salt/moles water) of 1 : 9000, 1 : 18 000, and 1 : 36000 was applied to study the heats of solution of methyl iodides of dimethyl- and diethylamino grosshemin. The data obtained were used to calculate the standard enthalpies of solution of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ in an infinitely diluted (standard) aqueous solution. The heats of combustion and melting of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ were estimated. The experimental and calculational techniques were combined to calculate the standard heats of formation of methyl iodides of dimethyl- and diethylamino grosshemin and their 66 analogues.



DOI: 10.1134/S1070427206080052

A study of thermochemical and thermodynamic properties of natural compounds and their derivatives is of certain theoretical and practical interest for directed synthesis and standardization of samples of medicinal substances based on these compounds [1, 2]. To biologically active compounds of this kind belongs a sesquiterpene lactone grosshemin, extracted from vegetable raw materials [3].

It should be noted that the thermochemical and thermodynamic properties of this theoretically and practically important sesquiterpene lactone and its derivatives have not been studied so far. Therefore, an experimental study of the thermochemical properties of methyl iodides of dimethyl- and diethylamino grosshemin was carried out and the data obtained were used to find by a combination of calculational techniques the standard enthalpies of formation of $C_{18}H_{28}O_4NI$ (**1**), $C_{20}H_{32}O_4NI$ (**2**), and their analogues:

EXPERIMENTAL

The calorimetric study of the enthalpy of solution of methyl iodides of dimethyl- and diethylamino grosshemin was performed on a DAK-I-IA calorimeter under isothermal conditions at different dilutions of 1 : 9000, 1 : 18000, and 1 : 36000 (moles salt/moles water). The theory of the calorimetric study and the procedure used were described in detail in [4–7]. The operation principle of the calorimeter is based on measurements of the integral heat flux from the calorimetric cartridge, with a substance being dissolved, through the differentially connected thermopiles and bulky central unit of the microcalorimeter. The rated determination accuracy of heat effects by the calorimeter is ±2.0%.

Five parallel runs were carried out for the compounds under study at each dilution. The results obtained were averaged and processed using methods of mathematical statistics [8]. The root-mean-square deviation $S(y_i)$ was calculated for the averaged values of the enthalpy of solution at each dilution and the random error ε_{rand} was determined using the Student coefficient $t_{1-\alpha}(n-1)$ [8]. The value $\alpha = 0.95$ was chosen as the optimal confidence probability.

The uniformity of variance $s^2(y_i)$ of the quantities $y_i = \log \Delta H_i^m$ was evaluated using the Cochran criterion [8] because the number of measurements of ordinates y_i for different x_i is the same ($n_1 = n_2 = n_3 = n_4 = n_5 = n$). The hypothesis of uniformity of the variances of reproducibility of the ordinates $y_i = \log \Delta H_i^m$ was taken with a 5% significance level.

Parameters of the regression line were determined: $a_0(\mathrm{I}) = 1.495$, $a_0(\mathrm{II}) = 1.073$, $b_0(\mathrm{I}) = -25.41$, $b_0(\mathrm{II}) = -63.54$, $a(\mathrm{I}) = 1.584$, $a(\mathrm{II}) = 1.298$. These parameters were used to derive the sought-for regression equation for models (I) and (II):

$$Y(\mathrm{I}) = 1.584 - 25.41x, \quad (1)$$

$$Y(\mathrm{II}) = 1.298 - 63.54x. \quad (2)$$

The linearity hypothesis is satisfied by the inequalities $F_{exp} = 36.67 < 243.9$ for model (I) and $F_{exp} = 2.552 < 243.9$ for model (II). Hence follows that the linearity hypothesis should be taken with a 5% significance level.

The enthalpies of combustion of methyl iodides of dimethyl- and diethylamino grosshemin were calculated by the Karas and Frost methods [9], and the enthalpies of melting, by the empirical equation recommended in [10].

A calculation of $\Delta_f H^0(298.15)$ for analogues of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ was performed using the system of enthalpy increments of anions [11, 12].

The grosshemin derivatives, methyl iodide of dimethylamino grosshemin $C_{18}H_{28}O_4NI$ (**1**) and methyl iodide of diethylamino grosshemin $C_{20}H_{32}O_4NI$ (**2**) were obtained in high yields by reacting amino derivatives of grosshemin with methyl iodide.[1] The structure of the substances was determined by with the use of IR, UV, and ^{1}H NMR spectroscopies and X-ray diffraction analysis. The purity of the substances was better than 99.0%. The melting points of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ are 217–218 and 107–108°C, respectively [13].

The calorimetric determination of the enthalpy of solution of the compounds under study in water was carried out in the mode of automatic heat compensation. The heat effects were recorded with a KSP-4 self-recorder and, in parallel, by an IP-4 precision integrator. A substance was placed in a metallic ampule, which was inserted into a metallic cartridge with the solvent. The time of preliminary thermostating of the solvent and substance was 2 h. The zero drift of the integrator did not exceed three units of the last digit in 100 s. The substance studied dissolved as the ampule was immersed in the solvent.

The operation of the instrument was tested by measuring the heat of solution of a thrice recrystallized KCl at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (moles salt/moles water). The resulting average value of the heat of KCl solution in water at 25°C, equal to 17860 ± 283 J mol^{-1}, is in a satisfactory agreement with the reference values of 17577 ± 34 J mol^{-1} [14] and 17489 ± 371 J mol^{-1} [15] at the same temperature with an accuracy of 1.6 and 2.0%.

Table 1 lists the enthalpies of solution of methyl iodides of dimethyl- and diethylamino grosshemin at various dilutions.

The calorimetrically obtained enthalpies of solution of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ at various dilu-

[1] Methyl iodides were obtained at the laboratory of chemistry of terpenoids, Institute of Phytochemistry, Ministry of Education and Science of the Republic of Kazakhstan.

tions were used to calculate their ΔH^0 of solution at the infinite (standard) dilution. The dependences of the enthalpy of solution of the compounds, ΔH^m_{sol} (kJ mol^{-1}), on the molal concentration ($\sqrt{m}$) are described by the equations [16]

$$\Delta H^m_{sol}(C_{18}H_{28}O_4NI) = (44.1 \pm 0.6) - (218.4 \pm 3.0)\sqrt{m}, \quad (3)$$

$$\Delta H^m_{sol}(C_{20}H_{32}O_4NI) = (23.8 \pm 0.3) - (198.8 \pm 2.5)\sqrt{m}. \quad (4)$$

Equations (3) and (4) were used to calculate the standard enthalpies of solution of the methyl iodides in the infinitely diluted aqueous solution, equal to 44.1 ± 0.6 and 23.8 ± 0.3 kJ mol^{-1}, respectively. These values were further used to calculate the standard heats of formation of various derivatives of grosshemin.

The standard heats of combustion, $\Delta_f H^0(298.15)$, of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ were evaluated by the Karas and Frost methods [9], which are the best suitable for taking into account the contributions of various groups to the heat of combustion. The averaged values of the heats of combustion of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ are 10 697 ± 257 and 12 005 ± 257 kJ mol^{-1}, respectively. The reaction equations

$$2C_{18}H_{28}O_4NI_{(l)} + 46O_{2(g)} = 36CO_{2(g)} + 28H_2O_{(l)} + N_{2(g)} + I_{2(g)} - \Delta H^0_{comb}, \quad (5)$$

$$2C_{20}H_{32}O_4NI_{(l)} + 52O_{2(g)} = 40CO_{2(g)} + 32H_2O_{(l)} + N_{2(g)} + I_{2(g)} - \Delta H^0_{comb} \quad (6)$$

were used to calculate the standard enthalpies of formation of liquid $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$, equal to –395.5 and –447.2 kJ mol^{-1}, respectively. With the exception of ΔH^0 of combustion, the data necessary for calculation of $\Delta_f H^0(298.15)_{(l)}$ by schemes (5) and (6) were taken from the reference book [17].

Because the given grosshemin derivatives are in the crystalline state at 298.15 K, their $\Delta_f H^0(298.15)$ in the solid state were determined. For this purpose, ΔH_{melt} of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ was evaluated in accordance with the empirical equation [10]

$$\Delta H_{melt} = 44.4T_{melt} - 4400, \quad (7)$$

commonly used for strongly polar halide compounds. The values of ΔH_{melt}, found for $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ by Eq. (7), are 17.4 and 12.5 kJ mol^{-1}, respectively. The equations

$$\Delta_f H^0(C_{18}H_{28}O_4NI_{(s)}, 298.15) = \Delta_f H^0(C_{18}H_{28}O_4NI_{(l)}, 298.15) - \Delta H_{melt}, \quad (8)$$

$$\Delta_f H^0(C_{20}H_{32}O_4NI_{(s)}, 298.15) = \Delta_f H^0(C_{20}H_{32}O_4NI_{(l)}, 298.15) - \Delta H_{melt} \quad (9)$$

were used to calculate the standard enthalpies of formation of methyl iodides of dimethyl- and diethylamino grosshemin in the crystalline state, equal to –412.9 and –459.7 kJ mol^{-1}.

The values of ΔH^0 of solution of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ at the infinite dilutions, were used to calculate by the equations

$$\Delta_f H^0(298.15)\,C_{18}H_{28}O_4NI\,(solution, H_2O, st. state) = \Delta_f H^0(298.15)\,C_{18}H_{28}O_4NI_{(s)} + \Delta H^0_{(solution)}, \quad (10)$$

$$\Delta_f H^0(298.15)\,C_{20}H_{32}O_4NI\,(solution, H_2O, st. state) = \Delta_f H^0(298.15)\,C_{20}H_{32}O_4NI_{(s)} + \Delta H^0_{(solution)} \quad (11)$$

$\Delta_f H^0(298.15)$ for $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ in the standard aqueous solution (–368.8 and –435.9 kJ mol^{-1}). The relations

$$[\Delta_f H^0(298.15)\,C_{18}H_{28}O_4N^+(solution, H_2O, st. state)] = [\Delta_f H^0(298.15)\,C_{18}H_{28}O_4NI\,(solution, H_2O, st. state)] - [\Delta_f H^0(298.15)I^-(solution, H_2O, st. state)], \quad (12)$$

$$[\Delta_f H^0(298.15)\,C_{20}H_{32}O_4N^+(solution, H_2O, st. state)] = [\Delta_f H^0(298.15)\,C_{20}H_{32}O_4NI\,(solution, H_2O, st. state)] - [\Delta_f H^0(298.15)I^-(solution, H_2O, st. state)] \quad (13)$$

served to calculate, using the data obtained and the reference value $[\Delta_f H^0(298.15)I^-$ (solution, H_2O, st. state)], $\Delta_f H^0(298.15)$ of formation of $C_{18}H_{28}O_4N^+$ and $C_{20}H_{32}O_4N_+$ ions in the standard aqueous solution, equal to –313.5 and –380.6 kJ mol^{-1}, respectively.

Further, the standard enthalpies of formation of $C_{18}H_{28}O_4N^+$ and $C_{20}H_{32}O_4N^+$ ions in the standard aqueous solution were used to calculate $\Delta_f H^0(298.15)$ for other grosshemin derivatives. In [11, 12], a system of thermochemical enthalpy increments was developed for calculating the standard enthalpies of formation of compounds in the crystalline state by the equation

$$\Delta_f H^0(298.15)Me_m(X_\alpha O_\beta)_n = [m\,\Delta_f H^0(298.15, Me^{n+}, solution, H_2O, st. state)]K + n\,\Delta_f H^j(298.15)X_\alpha O_\beta^{m-}, \quad (14)$$

where $\Delta_f H^j(298.15)$ is the enthalpy increment of the anion, and K, proportionality factor.

To calculate $\Delta_f H^0(298.15)$ of compounds by Eq. (14), it suffices to know $\Delta_f H^0(298.15$, solution, H_2O, st. state) of the cation, whereas the coefficients K and values of $\Delta_f H^i(298.15)$ of anions are tabulated [11, 12]; the accuracy of this calculation is ±5.0%. For two grosshemin derivatives ($C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$), Eq. (14) can be represented as

$$\Delta_f H^0(C_{18}H_{28}O_4NI_{(s)}, 298.15) = \Delta_f H^0(C_{18}H_{28}O_4N^+, solution, H_2O, st. state, 298.15)K + \Delta_f H^i(I^-, 298.15), \quad (15)$$

$$\Delta_f H^0(C_{20}H_{32}O_4NI_{(s)}, 298.15) = \Delta_f H^0(C_{20}H_{32}O_4N^+, solution, H_2O, st. state, 298.15)K + \Delta_f H^i(I^-, 298.15). \quad (16)$$

Table 2 lists the values of $\Delta_f H^0(298.15)$ for 66 derivatives of these compounds, calculated by Eqs. (15), (16).

CONCLUSIONS

(1) The enthalpies of solution of methyl iodides of dimethyl- and diethylamino grosshemin in water were determined for the first time by isothermal calorimetry.

(2) The enthalpies of combustion and melting of these compounds were calculated, a combination of calculated data and experimental values of the enthalpy of solution of the methyl iodides in a standard aqueous solution was used to find the standard heats of formation of $C_{18}H_{28}O_4N^+$ and $C_{20}H_{32}O_4N^+$ ions in the aqueous solution.

(3) The method of enthalpy increments was employed to calculate the standard heats of formation of $C_{18}H_{28}O_4NI$ and $C_{20}H_{32}O_4NI$ and their 66 analogues.

(4) The results of the study are of certain interest for thermochemistry of aqueous solutions of biologically active substances and for directed synthesis of derivatives of natural compounds. These results can serve as input data arrays to be loaded into fundamental databases and included in reference books with thermodynamic constants.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of Distribution Coefficients of Volatile Sulfur-containing Compounds among Aqueous Solutions and Gas Phase by Continuous Gas Extraction

Yu. G. Dobryakov and A. G. Vitenberg

St. Petersburg State University, St. Petersburg, Russia

Received March 1, 2006

Abstract—The method of continuous gas extraction at 10–40°C was used to measure the distribution coefficients of hydrogen sulfide, methyl mercaptan, ethyl mercaptan, dimethyl sulfide, and dimethyl disulfide between the gas phase and buffer aqueous solutions with a constant pH value.

DOI: 10.1134/S1070427206080064

The problem of determining trace and microscopic concentrations of volatile sulfur-containing substances: hydrogen sulfide, alkyl mercaptans, sulfides, and disulfides, in air, aqueous, and hydrocarbon media remains topical because the existing methods, including those officially accepted, fail to satisfy in the overwhelming majority of cases the modern requirements to sensitivity, selectivity, and accuracy of analysis. A rather promising way to solve numerous problems encountered in the development of techniques for monitoring of volatile sulfur-containing impurities in particular liquid or gaseous objects consists in use, improvement, and development of the existing methods and procedures of gas-chromatographic vapor-phase analysis (VPA) [1, 2]. This technique is based on principles of gas extraction [3], i.e., on the distribution of a substance in the liquid–gas system. Therefore, a key parameter determining the reliability of data obtained in measurements of microscopic concentrations of volatile sulfur-containing substances is the distribution coefficient, which is the ratio of the equilibrium mass concentrations of a substance in the liquid (c_L) and gas (c_G) phases

$$K = c_L/c_G. \quad (1)$$

A group of the most important objects in which the content of volatile sulfur-containing substance is to be measured is constituted by aqueous solutions. Microscopic concentrations of hydrogen sulfide, volatile mercaptans, sulfides, and disulfides are to be monitored not only in wastewater and natural water, industrial discharges, and in the air of the working zone at pulp-and-paper and petrochemical plants, but also in various natural objects.

Data on the numerical values of the distribution coefficients of hydrogen sulfide, methyl mercaptans (MM), ethyl mercaptans (EM), dimethyl sulfide (DMS), and dimethyl disulfide (DMDS) among water or aqueous solutions of mineral substances and the gas phase can be found in two reports [3, 4], which, however, show strong discrepancies, as large as several tens of percent for some components. These discrepancies presumably result from use of different variants of static VPA to measure K. The fundamental difference between these variants consists in that different gas extraction procedures are employed. In [3], double extraction was used and the phase distribution constant was calculated from relative areas under peaks in chromatograms. In the later publication [4], a single-stage gas extraction was used and K was calculated from the absolute values of the substance concentrations in the liquid and gas phases.

The aim of this study was to refine the available published data and obtain reliable information about phase distribution constants among water or aqueous solutions and the gas phase for volatile sulfur-containing substances of priority importance in sanitary-chemical and ecological regards.

To improve the accuracy and eliminate the possible systematic errors inherent in the static VPA (especially in analysis of the unstable mercaptans), the numer-

ical values of K were measured by the dynamic VPA method based on continuous gas extraction (CGE). As a gas flow is passed through a solution that contains volatile components, the solutes are gradually recovered (extracted) from the liquid into the gas phase in accordance with the distribution law (1). The method requires a comparatively simple apparatus and can be used to measure distribution coefficients in a wide range, from small ($K < 10$) to large ($K > 10^3$). A very important advantage of the technique is that, when necessary, the CGE process can be performed in the absence of even trace amounts of oxygen, which is particularly important for the readily oxidized and unstable hydrogen sulfide and mercaptans. In addition, numerical values of K are calculated in the case of CGE from relative areas under the peaks of target components in chromatograms. This technique rules out any errors associated with calibration of chromatographic detectors for measurement of the absolute concentrations of substances in each of the two phases of a heterogeneous system.

The dynamic VPA diminishes the sorption effects in the gas circuit of the installation, which introduce significant errors into the results of analysis. Previously, this method has been used to measure large $K > 10^3$. The calculation of the numerical value was based on the approximate equation [1]:

$$c_L = c_L^0 \exp\left(-\frac{V_g}{KV_L}\right), \quad (2)$$

which describes how the concentration of the target substance in a solution of a virtually nonvolatile solvent varies from the initial value c_L^0 to the running value c_L corresponding to the volume V_g of the extracting gas passed through a solution volume V_L. However, Eq. (2) disregards the spreading of the substance concentration in the gas volume V_G of the extraction vessel, which has virtually no effect on the result in measurement of large K.

In this study, the dynamic VPA is applied for the first time to systems with small $K < 20$. In systems of this kind, the gas volume V_G can strongly affect the absolute concentrations of the substance in the gas phase, and this influence is accounted for by the equation suggested by Novak [5]:

$$c_G = c_G^0 \exp\left(-\frac{V_g}{KV_L + V_G}\right). \quad (3)$$

Equation (3) describes the CGE of volatile substances from a solution in a vessel with gas volume V_G and relates the initial concentration c_G^0 of the substance in the gas phase over the solution at $V_g = 0$ to its running value c_g in the gas flow at the outlet from the extraction vessel, which corresponds to the volume V_g of the gas passed.

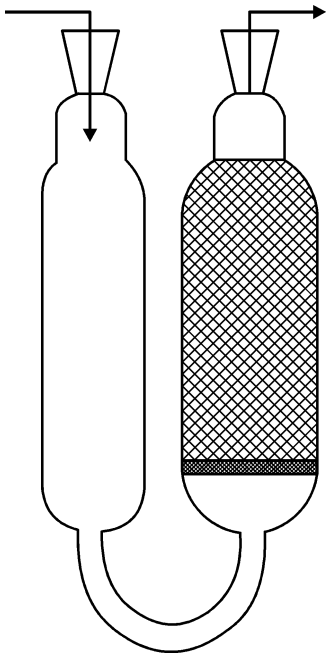

Fig. 1. Saturator for continuous gas extraction.

EXPERIMENTAL

The measurements were made on a Tsvet-500 chromatograph with a Khromdet-1020 photoionization detector. The use of the photoionization detector was due to its high sensitivity and selectivity toward sulfur-containing substances and low sensitivity to water. The recording and processing of chromatograms were done with a MultiKhrom computer complex (v. 1.5). The chromatographic separation and analysis of components were carried out on a 50 m × 0.53 mm quartz capillary column with an SE-30 immobile phase of thickness 3 μm. Gaseous samples were introduced into the column with a six-way two-position gas cock with a 0.5-cm^3 batching loop from the BDG-178 standard pneumatic unit of the Tsvet-500 chromatograph, supplemented with an electronic timer for automated batching. The CGE cell (Fig. 1), the saturator, comprises two cylindrical glass vessels of different diameters (40 and 30 mm), connected by a U-shaped tube. The larger vessel has a sealed-in disc of finely porous glass (porosity 3) and is used for bubbling of the extracting gas through the liquid. The smaller vessel acts as receiver for the gas. The saturator was placed in a U-10 liquid thermostat, which maintained a prescribed temperature with an accuracy not worse than ±0.1°C. The gas flow rate through the saturator

was set and monitored with an IRG-100 gas flow controller (Tsvet OAO). The flow rate of the extracting gas was maintained in the range 15–25 ml min^{-1} with an accuracy not worse than 0.05 ml min^{-1}. The volume of the aqueous buffer solutions was 100 ± 0.5 ml at a height of the liquid layer of 100 mm. The saturator was connected directly to the gas cock via a heated capillary, whose temperature was maintained constant at about 50°C.

Prior to an experiment, the buffer solution was thermostated and saturated with the vapors of the substance under study. As sources of hydrogen sulfide, methyl mercaptan, and ethyl mercaptan served cylinders with reference gas mixtures, purchased from Monitoring OOO. The gas mixture of three components, each with a concentration of 200 ppm, in nitrogen was bubbled through an aqueous solution till its saturation, and then the saturator was connected to IRG-100 to begin the gas extraction. In this way, the distribution coefficients were simultaneously measured for hydrogen sulfide, MM, and EM. Diffusion microflow sources (Monitoring OOO) served to supply the vapor of DMS. Dimethyl sulfide (Acros, USA) was metered directly as a liquid in amounts of 0.5 μl, using a microsyringe.

The aqueous buffer solutions were prepared from a mixture of acid salts KH_2PO_4 and Na_2HPO_4, pH 4.8 [6]; also, a 7% solution of sodium hydrosulfate $KHSO_4$, pH 0.9, was produced.

For sufficiently diluted solutions, the ratio of the concentrations of the volatile substance in the gas phase, c_G and c_G^0, can be replaced, within the linearity range of the chromatographic detector and in accordance with a value of the distribution coefficient (1), with the corresponding ratio of peak areas in the chromatograms, A_G and A_G^0. Then, the results of a chromatographic analysis of the flow of the extracting gas passed through a solution under study can be used to calculate, in accordance with Eq. (3), the numerical value of the distribution coefficient by the equation

$$K = \frac{V_g/V_L}{\ln(A_G^0/A_G)} - \frac{V_G}{V_L}. \quad (4)$$

The specificity of application of CGE for measuring the distribution coefficients consists in that the accuracy of the results obtained strongly depends on the ratio between the volumes of the solution and the extracting gas passed through it, or, in other words, on the fraction δ_g of the component being determined, recovered from the solution:

$$\delta_g = 1 - \exp\left(-\frac{V_g}{KV_L + V_G}\right) = 1 - \frac{A_G}{A_G^0}. \quad (5)$$

The error in measuring the volumes V_G and V_L is negligible as compared with the error in measuring the concentrations c_G and c_G^0 as the areas under the peaks in the chromatogram, A_G and A_G^0. In such cases, the relative error in determining the distribution coefficient ($\Delta K/K$) is related to the CGE conditions and to the fraction of the substance recovered from solution by the expressions

$$\frac{\Delta K}{K} = \left(\frac{\Delta A_G^0}{A_G^0} + \frac{\Delta A_G}{A_G}\right)\left[\ln\left(\frac{1}{1-\delta_g}\right)\right]^{-1}$$
$$= \left(\frac{\Delta A_G^0}{A_G^0} + \frac{\Delta A_G}{A_G}\right)\left[\ln\left(\frac{A_G^0}{A_G}\right)\right]^{-1}, \quad (6)$$

derived from Eq. (3). It is quite clear that the relative error in measurement of K by the CGE method decreases as the volume of the extracting gas passed through the solution increases, and it will not exceed the total error in measuring the peak areas in the chromatogram if the fraction of the substance recovered into the gas phase is no less than 63% and the ratio $(A_G^0/A_G) \geq e$ (e is the base of the natural logarithm).

The values of K were calculated in the CGE method in two ways. In the first of these, the calculation was done by EQ. (4) for two peak areas measured in the chromatogram: initial A_G^0 at $V_g = 0$ and A_G corresponding to a volume V_g of gas passed through a solution of volume V_L. Successive measurement of peak areas for different volumes of passed gas makes it possible to calculate K for the whole range of substance concentrations measured in the system. The error of the thus calculated distribution coefficient is found as the deviation from the average value of K.

Another, graphical, technique makes it possible to calculate the distribution coefficient from a set of values of the chromatographic signal A_G, which exponentially decrease with time [7]. At a constant flow rate w_g of the extracting gas, the volume V_g of the gas passed through the solution is proportional to the time t elapsed from the beginning of extraction till sampling ($V_g = w_g t$). In accordance with the procedure used, samples were periodically taken in the automatic mode at strictly equal intervals of time from the flow of a gas that was in equilibrium with the solution under study. Therefore, the time τ of appearance of a given component in the chromatogram was used as

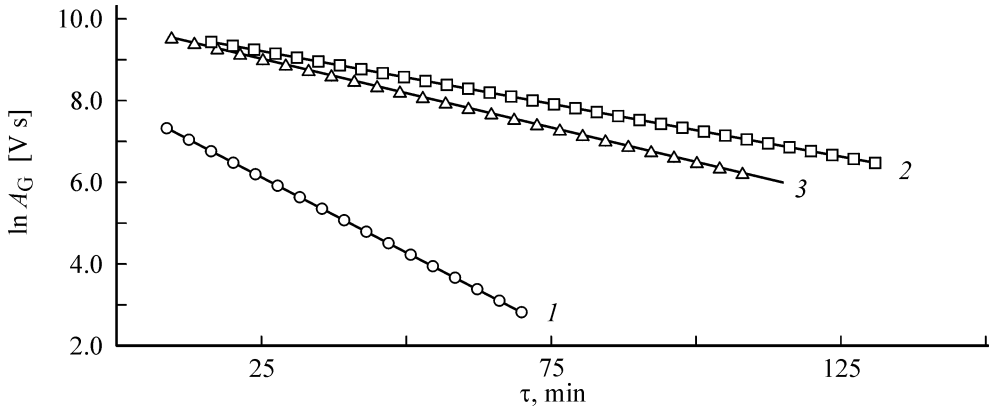

Fig. 2. Graphical method for determining the distribution coefficients. (*1*) Hydrogen sulfide, (*2*) methyl mercaptan, and (*3*) ethyl mercaptan. R^2: (*1, 2*) 0.9996 and (*3*) 0.9989. ($\ln A_G$) Logarithm of the peak area and (τ) time.

independent variable. To calculate K, the dependence $\ln A_G = f(\tau)$ was plotted (see for hydrogen sulfide, MM, and EM in Fig. 2). As a rule, this is a linear dependence (correlation factor $R^2 \geq 0.999$) and the slope α of the straight line is given by

$$\alpha = -w_g/(KV_L + V_G).$$

If the flow rate w_g of the carrier gas and the volume of the coexisting liquid and gas phases are known, the distribution coefficient can be easily calculated. In this method of processing of the measurement results, the experimental error was determined by the measurement accuracy of the volumes ΔV_L and ΔV_g of the liquid and the extracting gas passed through the liquid. For all of the systems studied, the error in measuring the distribution coefficients did not exceed 4%. The calculations of the distribution coefficients of DMDS for the phosphate buffer solution (pH 4.8) at 15°C by the two methods described above give close results (Table 1). The differences are in this case considerably smaller than the measurement error of K.

For components that dissociate in water, the solution acidity may affect the content (fraction) of their molecular form in the aqueous medium. In the case in question, these are hydrogen sulfide and mercaptans. The partial pressure of vapors of these substances over a solution and, consequently, their concentrations in the gas phase are proportional to the undissociated part of the substance in the system. As a result, the numerical values of the distribution coefficients of hydrogen sulfide and mercaptans strongly depend on the degree of their dissociation in solution. The pH value at which the dissociation equilibrium is virtually completely shifted to the left should satisfy the inequality [1, 8] pH $\leq$ pK_a – 2. At 25°C, hydrogen sulfide has $pK_a^{H_2S} = 7.2$, and methyl and ethyl mercaptans, $pK_A^{MM} = 10.33$ and $pK_a^{EM} = 10.61$ [9], and, therefore, the solution acidity has no effect on the distribution coefficients at pH $\leq$ 5 for hydrogen sulfide and at pH $\leq$ 8 for mercaptans. Therefore, an aqueous buffer solution wit pH 4.8 was chosen as

MM	6.2	5.8	7.9
EM	4.7	4.4	6.1

the liquid phase for measuring the distribution coefficients (temperature variations of the pH value in the phosphate buffer solutions used were disregarded because of being insignificant, several percent [10]). The data obtained (Table 2) confirm the conclusion that, at pH < 5 and 10–40°C, the solution acidity has virtually no effect on the numerical values of the distribution coefficients for all of the volatile sulfur-containing substances studied, including hydrogen sulfide and mercaptans. As the acidity of a solution decreases to the point of its becoming neutral, the distribution coefficients increase manyfold for hydrogen sulfide and change only slightly for mercaptans. In distilled water (Table 3), a significant part of hydrogen sulfide molecules are in the hydrated, bound state, with the fraction of molecular forms markedly decreasing. For mercaptans, the neutral medium is still sufficiently acidic for the numerical values of the distribution coefficients to be affected. Certain discrepancies between the experimental data for mercaptans in distilled water and in buffer solutions are, in all probability, due to the salt background of the buffer solutions.

Presence of mineral substances in a solution causes a "salting-out" effect, which affects the substance distribution among the aqueous and gas phases and the numerical values of the distribution coefficients. Presence of inorganic salts in the liquid phase, as a rule, leads to a decrease in *K*. The extent of this influence depends on the ionic strength of a solution, i.e., on the type, size, and charge of the ions present, as well as on the salt concentrations. For example, data on the distribution coefficients of certain mercaptans and organic sulfides at 25, 35, 45, and 75°C, obtained for distilled water with an ionic strength $I = 0$ and seawater ($I \approx 0.7$), and also for aqueous sodium sulfate solutions with varied salt concentration and ionic strength ($I = 1$–4), were reported in [14]. In this series, a clearly pronounced decrease in *K* is observed as the ionic strength of the solution increases. For example, the distribution coefficient of DMS at 25°C decreases from 13.42 in distilled water to 4.45 ($I = 4$), and that of DMDS, from 24.66 to 8.83. In this case, the data obtained for seawater somewhat "drop out" from the general pattern, which, in all probability, means that seawater has a more

complex composition than aqueous sodium sulfate solutions with about the same ionic strength.

The temperature dependence of the distribution coefficients characterizes the thermodynamic properties of the system and enables calculation of certain important parameters of diluted solutions, such as the limiting activity coefficients [11, 12], Henry constant, excess Gibbs energy and enthalpy [13], and the solvation energy of solutes [14]. A comprehensive study of these thermodynamic quantities makes it possible not only to obtain parameters for mathematical models that can predict the properties of systems of this kind in a wide range of temperatures and pressures, but also to elucidate the nature of intermolecular interactions in solution and assess the influence and role of hydrogen bonds.

The temperature at which the phase equilibrium is attained in the liquid–gas system is of interest for analytical purposes as regards its stability for providing an acceptable accuracy of analysis and the extent to which the distribution coefficient decreases as temperature is raised, for improving the sensitivity of VPA.

Commonly, a linear dependence on inverse temperature is observed in the range 20–30°C at temperatures close to room temperature. In the case in question, such dependences are observed at 10–40°C (Fig. 3). The sufficiently simple behavior of the dependence of the distribution coefficient on inverse temperature can be used to assess the temperature dependence in a certain range of extrapolation of the experimental data.

The results obtained when measuring the distribution coefficients of volatile sulfur-containing substances among aqueous solutions and the gas phase are in a rather good agreement with published values of K [2], measured by the static method. As can be seen in Fig. 4, the same behavior of the temperature dependence of the distribution coefficients is observed in both cases. The discrepancies are systematic, fall within the range 10–50% for different components, and are presumably associated with the chemical composition of the buffer solutions used.

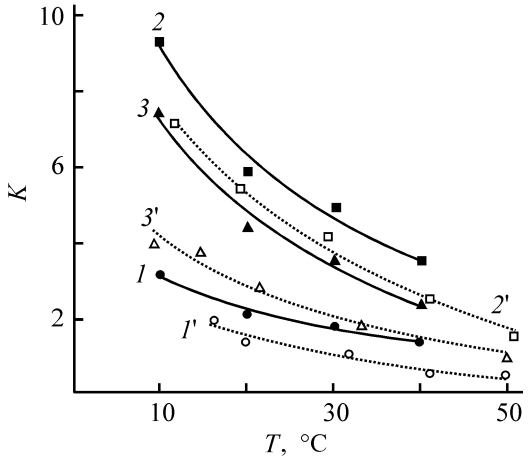

Fig. 4. Comparison of (*1–3*) experimental values of the distribution coefficients K with (*1'–3'*) published data [2]. (*1*, *1'*) Hydrogen sulfide, (*2*, *2'*) methyl mercaptan, and (*3*, *3'*) ethyl mercaptan. (*T*) Temperature.

CONCLUSIONS

(1) The method of continuous gas extraction was used to measure the distribution coefficients of hydrogen sulfide, methyl and ethyl mercaptans, dimethyl sulfide, and dimethyl disulfide among aqueous buffer solutions and the gas phase at different solution temperatures and acidities.

(2) It was shown that the phase behavior of easily volatile sulfur-containing substances in aqueous salt solutions is rather complicated and depends on factors that govern the ionic strength of the solutions, which should be taken into account in studies of natural objects without a prior knowledge of the composition and concentrations of solutes. Use of buffer solutions makes it possible to level the effect of the medium (supporting electrolyte) of the object being analyzed, and the numerical values of the distribution coefficients for buffer solutions of this kind can be used for analytical purposes in a quantitative analysis of solutes by the vapor-phase method.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Properties of Adamantane Derivatives

K. K. Konstantinova and S. V. Kurbatova

Samara State University, Samara, Russia

Received February 6, 2006

Abstract—The chromatographic behavior of adamantane derivatives as sorbates and sorbents was studied. The retention characteristics of adamantane derivatives and some organic compounds on an adamantylsilicone stationary phase were determined. The effect of various substituents on the chromatographic behavior of the compounds was examined. Correlations between the sorption and structural characteristics of adamantane derivatives were found.

DOI: 10.1134/S1070427206080076

Framework hydrocarbons have been attracting steady researchers' interest for many decades owing to the structural diversity of these compounds, their specific physicochemical properties, and biological activity. Various adamantane derivatives or compounds containing an adamantane core have been isolated from natural sources or synthesized, and the number of these compounds steadily grows [1]. Today more than 20000 structures belonging to the so-called diamondoid type are known, including derivatives of adamantane, diamantane, triamantane ($C_{18}H_{24}$), and even tetramantane ($C_{22}H_{28}$); pentamantanes ($C_{26}H_{32}$) and hexamantanes ($C_{30}H_{36}$) occur in the nature [2–4].

Other adamantane homologues have also been prepared. As far back as 1957, P. Schleyer prepared congressane, a hydrocarbon consisting of two fused adamantane molecules. Very numerous are heteroadamantanes containing in the framework the O, N, P, or S atoms, e.g., derivatives of 1,3,5,7-tetrasilaadamantane, 1,3,5,7-tetraazaadamantane (hexamethylenetetramine), 2,4,6,8,9,10-hexamethyl-2,4,6,8,10-hexaboraadamantane, etc. [5–7].

Diamondoids are classed with organic nanostructures; therefore, adamantane derivatives have become particularly popular with the development of nanotechnologies. The applications of adamantane derivatives are diverse: from antiviral drugs to nanorobots and molecular machines [8–10]. Crown ethers derived from adamantane and capable of complexation with metal ions and of their extraction have been studied [2]. Adamantane-containing films exhibiting specific properties and capable of acting as building blocks in the development of various nanomaterials have been prepared [9].

The structure and physicochemical properties of new adamantane derivatives have been studied by various methods. In particular, RHF calculations revealed the possibility of the overlap of the C^1–C^3–C^5–C^7 hybrid atomic orbitals in adamantane derivatives, giving rise to certain electron density inside the framework; the hybridization of carbon atoms that are not bonded to H atoms approaches sp^2 [11]. The thermochemical parameters (enthalpy of formation, bond dissociation energies, enthalpy of vaporization, etc.) have been determined by precision calorimetry for oxygen-containing, nitro, and nitrato derivatives of adamantane [8]. The structures of crystalline adamantane, diamantane [4], and 1,3-diphenyladamantane [12] have been studied by laser Raman spectroscopy; the luminescence of pyrene adamantane derivatives has been examined [10].

Particular attention is given to the chromatographic behavior of adamantane derivatives, because various chromatographic methods allow not only separation of multicomponent mixtures of isomers and structurally related framework hydrocarbons and their derivatives, but also qualitative and quantitative analysis of these mixtures [12]. For example, the relationships in the gas-chromatographic retention of hydrocarbons, ketones, and halo derivatives of the adamantane series on packed columns with stationary phases of different polarity have been revealed. It was shown that the retention of adamantane derivatives is determined by their electronic and steric structure; the major contribution to the retention is made by the bulky adamantyl fragment [13, 14].

We believe that the unusual structure of the adamantane core should also be manifested in the properties of stationary phases or sorbents derived from adamantane. There are indications in the literature that introduction of an adamantane fragment into the structure of the stationary phase should enhance its selectivity, at least toward polynuclear aromatic hydrocarbonds [15]. In this context, our goal was to study the sorption properties of adamantane derivatives as sorbates and sorbents, and also to examine the relationship between the physicochemical properties and chromatographic behavior of adamantanes.

EXPERIMENTAL

Experiments were performed on an M-3700 gas chromatograph equipped with a flame ionization detector in the mode of capillary chromatography with flow splitting. A 22000 × 0.22-mm column with grafted adamantylsilicone was used (film thickness d_f = 0.2 μm). As carrier gas we used helium. Solid substances were introduced into the chromatograph as solutions in acetone or hexane (sample volume 1 μl).

In the determination of the retention indices (RIs), the measurements were performed at a column temperature of 200°C and a vaporizer temperature of 230°C. The retention indices were calculated by the Kovats formula [16]. Their reproducibility was 1–2 units. The contributions of substituents and functional groups (δI_R) were determined from the experimental values of the retention indices of the substituted (I_{AdR}) and unsubstituted (I_{Ad}) compounds:

$$\delta I_R = I_{AdR} - I_{Ad}.$$

The differential molar free energy of sorption ΔG was calculated by the formula [17]

$$\Delta G = -RT \ln k\beta,$$

where k is the retention factor, $k = (t_x - t_m)/t_m$, t_x is the retention time of the substance being tested, and t_m is the retention time of a nonsorbable component (dead time).

The phase ratio β was calculated from the geometric parameters of the chromatographic column using the model of two coaxial cylinders [17]:

$$\beta = (d_c - 2d_f)^2/4(d_c d_f - d_f^2),$$

where d_c is the inside diameter of the capillary column and d_f is the thickness of the stationary phase film on the column walls.

Let us assign subscripts 0 and s to the gas and liquid, respectively. Then

$$V_0 = 1/4\pi L(d_c - 2d_f)^2,$$

$$V_s = V - V_0,$$

where $V = 1/4\pi L d_c^2$ is the volume of the empty capillary at a column length L.

The experimental values of the indices, averaged over 7–10 determinations, and the ΔG values are listed in Table 1.

The specific retention volumes V_v^T and V_s^T were calculated by the formulas

$$V_v^T = \frac{V_R' j_3^2}{V_s},$$

$$V_s^T = \frac{V_R' j_3^2}{A_s},$$

$$j_3^2 = \frac{3}{2}\frac{(P_i/P_0)^2 - 1}{(P_i/P_0)^3 - 1},$$

where V_s is the stationary phase volume; A_s, adsorbent surface area; and j_3^2, James–Martin coefficient [18].

Quantum-chemical calculations were performed with QSAR HyperChem software package (version 7.0) by the AM1 semiempirical method with full optimization of the molecular geometry. The calculated van der Waals volumes (V_{vdW}), molecular refractions (MR), distribution ratios in the *n*-octanol–water system (log P), polarizabilities α, and dipole moments μ of the compounds are listed in Table 2. The van der Waals volumes of the molecules were also calculated by the Bondi method [19] (Table 2).

The topological characteristics of the compounds (Wiener indices) were calculated as described previously [20].

The framework structure of adamantane and its derivatives is responsible for their specific physical and chemical properties. The three-dimensional model of the adamantane molecule is a highly symmetrical structure with a low surface area and weak intermolecular interactions in the crystal lattice. On introducing various substituents, the molecular symmetry becomes lower and the physicochemical characteristics of the compounds, including their retention indices, change.

It is known [12] that the C–H bond involving the tertiary carbon atom in the adamantane molecule is appreciably polarized under the action of strong polarizing agents. As a result, effective charges arise on the atoms of this bond. The adamantane core can accept an appreciable fraction of the electron density from the carbon atom and thus decrease its effective charge. A decrease in the charge on the carbon atom favors further polarization of the C–H bond under the action of polarizing agents (e.g., polar fragments of stationary phases in gas chromatography). It is assumed that the uptake of the electron density by the adamantane core is due to the overlap of the "rear" sides of the orbitals of the bridgehead carbon atoms, resulting in a direct contact of atoms that are not linked by a valence bond. This effect has been termed the cage effect [12]. Thus, the substituent effects can be transferred in the adamantane framework both through C–C bonds (*I* effect) and through the field (*F* effect) [21].

Previously we have examined the chromatographic retention of eight adamantane derivatives on a capillary column with cross-linked adamantylsilicone as a stationary phase (SP) [22]. In this study, we extended the range of adamantane derivatives and used silicone modified by grafting of the adamantyl radical to the base silicone matrix as a stationary phase. Despite that there is as yet no common opinion in the literature on the differences between cross-linked and grafted stationary phases, it is usually believed that cross-linking results in binding of particular groups of the polymer phase with each other to give a more stable macromolecular film, whereas grafting is chemical fixation of a stationary phase on the surface of a quartz capillary [23]. Thus, a grafted layer is a set of functional groups, grafted molecules, or substances covalently fixed on the surface. Its constituent elements are grafted molecules themselves, a part of the support base, and residual structural groups of the surface [24].

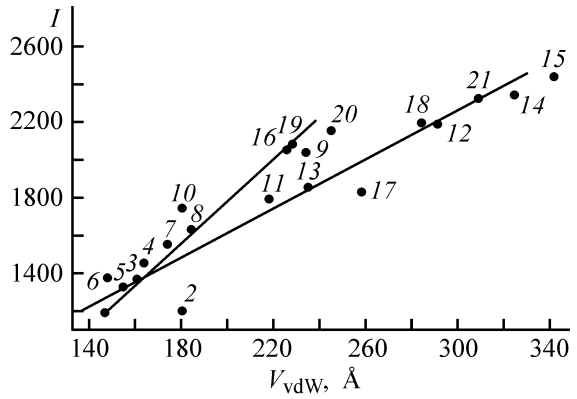

Fig. 1. Correlation between the van der Waals volumes of molecules, V_{vdW}, calculated by the Bondi method, and retention indices I of adamantane derivatives on adamantylsilicone. *Figures at points* are compound nos. in Table 1; the same for Figs. 2 and 3.

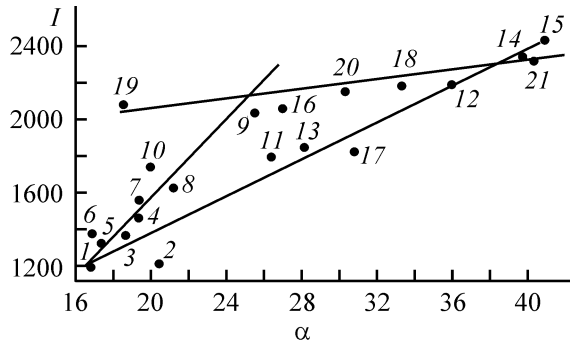

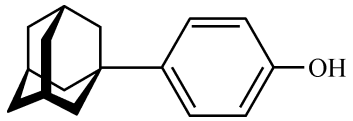

Fig. 2. Correlation between the molecular polarizabilities of adamantane derivatives, α, and their retention indices on adamantylsilicone I.

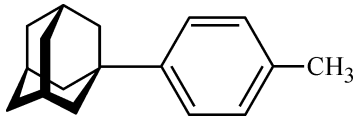
It has been shown previously [25] that, irrespective of the modification procedure, columns with adamantylsilicone stationary phases are weakly polar, but the polarity factors (especially those characterizing polar interactions) are somewhat higher for grafted adamantylsilicone.



It is known that, in the case of nonpolar or weakly polar stationary phases, the chromatographic retention of sorbates is determined by dispersion forces; therefore, the relationship between the structure of compounds and their retention is based on the assumption that the free energies of sorption are additive and can be calculated by summation of the structural increments. Furthermore, the sorbates are, as a rule, eluted in such systems in the order of increasing molecular size; thus, the retention characteristics appreciably depend on the deformability of molecules and hence on their volume and polarizability.

The retention of adamantane and its derivatives is primarily determined by the presence of a bulky adamantane framework, by the nature and position of substituents (both directly participating in the retention and affecting the redistribution of the electron density within the adamantane core), and by the steric factor [14]. In the chromatographic system used, the adamantane fragments are present not only in sorbate molecules, but also in the structure of the stationary phase; therefore, the steric factor acquires a particular importance. Also, up to 50% of free silanol groups, accessible to molecules of different volumes, remain on the surface after the immobilization of the silicone SPs with any modifier [23]. Furthermore, the larger the grafted fragments (radicals or functional groups), the lower the grafting density. Therefore, residual silanol groups are apparently present in a certain amount in adamantylsilicone; these groups are capable of hydrogen bonding with the corresponding sorbates [25].

This assumption is confirmed by Table 1, which shown that substances capable of hydrogen bonding (hydroxy and carboxy derivatives of adamantane) have considerably higher RIs I than compounds capable of only dispersion interactions with the stationary phase (aryl and alkyl derivatives), at similar molecular volumes:

I = 2061, V = 227

I = 1855, V = 236

Furthermore, for adamantylsilicone, the contributions to the retention made by functional groups capable of hydrogen bonding are appreciably larger than those for Apiezon L. For example, the contributions of the OH group of 1-adamantanol are 135 and 117 units, respectively; for 4-(1-adamantyl)phenol, the contribution of the OH group on adamantylsilicone increases considerably, reaching 265 units.

Similar factors are apparently responsible for the increased contribution of the carboxy group on adamantylsilicone compared to Apiezon L: 365 and 297 units for adamantanecarboxylic acid, and 438 and 282 units for adamantylacetic acid, respectively, and also for the increased retention of haloadamantanes.

Figures 1 and 2 show that, on the whole, the retention indices of the adamantane derivatives vary in the same direction with the volume and polarizability of

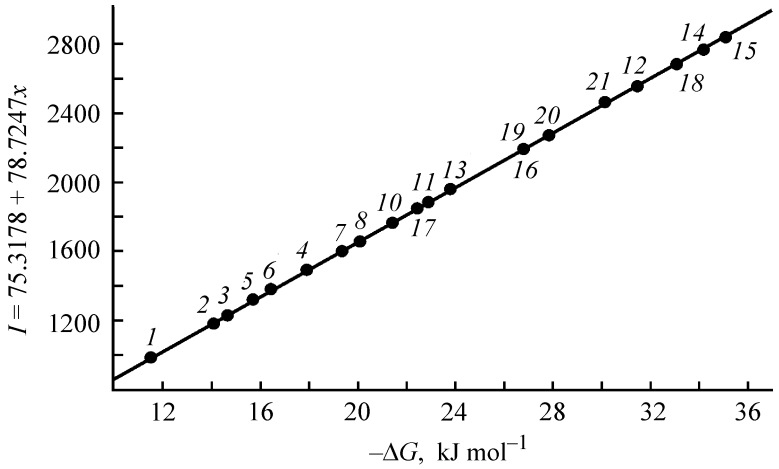


Fig. 3. Correlation between the retention indices I and differential molar free energy of sorption, ΔG, on adamantylsilicone (r = 1.0000, p = 0.0000).

the molecules. However, there is no common correlation, and the compounds are subdivided into several correlation groups consisting of adamantane derivatives that are retained by the stationary phase mainly through hydrogen bonding with residual silanol groups or dispersion interactions. A similar pattern was observed with cross-linked adamantylsilicone [22]; with the grafted SP, however, the correlation groups are manifested more clearly.

The adamantane fragments in the stationary phase considerably enhance the retention of the aromatic derivatives. As already noted, such a behavior is characteristic of systems in which the intermolecular interactions of the sorbate with the stationary phase are governed by the dispersion forces, which are determined by the volume and polarizability of the molecules.

The applicability of the linear free energy relationship to the retention characteristics of adamantane derivatives on adamantylsilicone is illustrated by the plot of the Kovats retention indices I vs. the differential Gibbs energy ΔG (Fig. 3).

The quantity ΔG characterizes the structural and sorption properties of a substance and the energy of its interaction with the stationary phase at a given temperature; therefore, the temperature is an important factor affecting the GLC retention. It is known that the energy of polar interactions considerably decreases with increasing temperature [21]. Despite that the retention with low-polarity adamantylsilicone is mainly governed by the dispersion interactions, free silanol groups in the starionary phase also play, as already noted, a certain role in the retention of polar molecules. The occurrence of specific interactions with the stationary phase results in a considerable decrease in the retention volume of polar sorbates with increasing temperature. The parameters of the equation describing the dependence of the retention volume on the reciprocal temperature (Table 3) show that the slope of the straight line [coefficient a in the equation $\log V_g^T = a(1000/T) - b$] for the hydroxy and carboxy derivatives of adamantane is somewhat larger than that for the other derivatives.

Also, it is known that the retention on nonpolar stationary phases can be characterized by a compensation effect, namely, by a linear correlation between

Table 3. Parameters of the equation $\log V_g^T = a(1000/T) - b$ for adamantane derivatives

ΔH^0 and ΔS^0, suggesting the similarity of the physicochemical processes in the series of the compounds under consideration [25]. Figure 4 shows that the dependences of log V_v^T on $1/T$ are linear for all the sorbates studied in the temperature range examined. These straight lines, when extrapolated, should intersect at a point corresponding to the compensation temperature. It follows from the compensation relationships that the retention parameters of sorbates of various structures should approach each other with increasing column temperature, which should make lower the separation selectivity.

The correlations between the structural characteristics and chromatographic parameters determined by the type of intermolecular interactions in a chromatographic column are also examples of the linear free energy relationship as applied to adamantane derivatives. The coefficients of the correlation equations describing the relationships between the physicochemical and chromatographic characteristics of adamantane derivatives are listed in Table 4.

Such correlations can be used for predicting the chromatographic retention of substances and the properties of hypothetical molecules, for identifying compounds without references, for choosing a selective chromatographic system, etc.

CONCLUSIONS

(1) The chromatographic retention of polar compounds on adamantylsilicone is provided by the dispersion interaction with bulky adamantane fragments of the stationary phase and by specific interactions with the residual silanol groups of the base silicone matrix.

(2) The chromatographic behavior of functional derivatives of adamantane is determined by the linear free energy relationship and is characterized by a compensation effect.

ACKNOWLEDGMENTS

SORPTION AND ION-EXCHANGE PROCESSES

Optimization of the Conditions of Sorption Recovery and Concentration of Noble Metals on Anion Exchangers and Their Subsequent Determination in Geochemical Objects by Atomic-Emission Spectroscopy

Received March 7, 2006

Abstract—Sorption of Au(III), Pt(IV), Pd(II), and Rh(III) ions on ANS-80, AN-108-4 macrocellular anion exchangers and on AV-17-10P macroporous anion exchanger from hydrogen chloride media was studied in relation to HCl concentration and time. The residual concentration of matrix elements in analytical concentrates of a real object was determined and their influence on the delivery of vapors of noble metals into the cloud of the arc discharge and on their excitation in the discharge was revealed. The conditions of recovery, concentration, and atomic-emission determination of noble metals were examined. The effect of matrix elements, combined with a number of supports (NaCl, CdO, TeO_3, Sb_2O_3), on the amplitude of analytical signals was evaluated.

DOI: 10.1134/S1070427206080088

When determining noble metals in geochemical and industrial objects with complex multicomponent composition, there is, as a rule, no way of obviating the stage of separation of matrix elements (ME) even in the case of high-sensitivity analytical methods (neutron-activation, mass-spectral, etc.). High sensitivity and determination accuracy can be achieved by rational combination of separation and concentration techniques with the potentialities and specific features of more accessible instrumental analytical procedures. In the authors' opinion, the optimal combination is that of atomic-emission spectroscopy with preliminary sorption recovery and concentration of microelements. Their detection limits can be lowered by choosing those conditions of spectral analysis of the concentrate which favor enrichment of the plasma of the light source with the elements being determined.

Earlier studies of application of sorption methods for recovery and concentration of noble metals were based on the ability of their chloro complexes to be firmly fixed by strongly basic anion exchangers [1]. However, chelate-forming ion exchangers containing electron-donor atoms of nitrogen or sulfur are more promising for selective recovery of noble metals [2–5].

The present study is concerned with weakly basic ANS-80 and AN-108-4 S- and N-containing macrocellular anion exchangers obtained by amination with ethylenediamine of copolymers of methyl acrylate with a long-chain cross-linking agent (divinyl sulfide and divinyl ether of diethylene glycol, respectively) and AV-17-10P macroporous ion exchanger. The physicochemical properties of the sorbents have been studied previously [6].

Upon sorption concentration of noble metals, base elements of natural objects were found in the ion-exchange concentrate. These elements can strongly affect the conditions of sample heating in the electrode crater, delivery of vaporized noble metals into the arc discharge cloud, and excitation in the cloud. In the study, the effect of matrix elements was examined in order to formulate recommendations concerning their content, and the joint effect of a number of supports and the residual amount of matrix elements was analyzed in order to achieve lower determination limits of noble metals.

EXPERIMENTAL

To chose the optimal conditions of quantitative recovery of noble metals (Au, Pt, Pd, Rh) with the aim of their concentration and separation from the base elements of the rock (Ca, Mg, Fe, Al, Na), their sorption from hydrochloric acid solutions was studied in the acidity range from 2 M to pH 3. This range of

HCl concentrations is due to existence in solutions of this kind of stable chloro complexes of noble metals and an insignificant fraction of anionic forms of macrocomponents, and primarily Fe(III). Experiments were carried out in the static mode. Weighed portions of a sorbent (0.1 g) were poured over with 10 ml of a solution containing $n \times 10^{-4}$ M of a noble metal ion and a certain concentration of HCl. The necessary pH value was created by adding NaOH or HCl solutions, with monitoring with a pH meter. The solutions with the sorbent were kept until equilibrium was attained. The concentrations of Pd(II), Pt(IV), and Rh(III) ions in the equilibrium solution were determined by spectrophotometry with $SnCl_2$ [1], and that of Au(III), by anodic inversion voltammetry with a graphite electrode on the background of 1 M HCl. The loss of concentration was used to calculate the degree of recovery of noble metals, R (%).

The sorption of noble metal ions in the course of time was studied by a similar method without agitation of the solution and under agitation with a magnetic rabble. After a certain period of time, the sorbent was separated from the solution and the residual amount of a metal ion in the solution was determined. Then the degree of approach to equilibrium, $F = Q_\tau/Q_\infty$ was calculated, where Q_τ is the amount of metal ions absorbed by instant of time τ (mmol) and Q_∞ is the amount of metal ions absorbed by the instant of attainment of equilibrium (mmol).

The degree of sorption of the matrix elements of the rock was determined by atomic-emission spectroscopy in the analytical concentrate of a real object. A weighed portion of the rock (10 g) was ground in a ball mill, placed in a glassy-carbon pan, and calcined in a muffle furnace at 500°C for 3 h. Then 20 ml of H_2SO_4 (1 : 1) and the same amount of HF_{conc} were introduced into the sample and the mixture was evaporated to humid salts and cooled. The treatment with a mixture of acids was repeated without calcination. Further, 30 ml of aqua regia was added in portions. After evaporation, the residue was twice treated with 10 ml of HCl_{conc}. To a dry residue was added 40 ml of 6 M (50 ml 0.5 M) HCl and the mixture was heated to dissolution of the salts. The content of the glassy-carbon pan was transferred into a chemical vessel with distilled water, with the volume of water brought to 240 (250) ml. After all the dilutions, the concentration of HCl should be 1 M (0.1 M). A part of unremoved silicon compounds remained in the solution in the form of a precipitate. In 24 h, the solution was separated from the precipitation by decantation, 100 mg of an ion exchanger was introduced, and sorption was performed under agitation for 10 min on AN-108-4 (or for 2 h on AV-17-10P). Further, the ionite was separated from the solution by filtration and washed with an HCl solution of an appropriate concentration. The filter with the sorbent was placed in a quartz dish and acid ashing was performed first on a hot plate, with H_2SO_{4conc} added dropwise, and then in a muffle furnace at 500°C in the course of 1 h.

The content of matrix elements in the resulting analytical concentrate was determined by atomic-emission spectroscopy after its successive dilutions with a buffer suspension composed of a graphite powder and 3 wt % Na in the form of NaCl, with state standard samples SOG-21 [7]. Spectra were recorded on an ISP-30 spectrograph with a dc arc (12 A) as excitation source. Electrodes of common shape with crater dimensions of 4.5 × 3.6 mm were used. The electrode with a sample served as anode, the weighed portion of a substance was 15 mg. The content of sodium was determined in a solution of the ash residue on a PAZh-1 flame photometer.

To assess the influence exerted by the residual amount of the matrix elements (individual or combined with that of supports) on the atomic-emission determination of noble metals, curves of their evaporation were obtained by recording spectra on a moving photographic plate. The evaporation constants A of noble metals (g s^{-1}), proportional to the rate constants of their vaporization were calculated (Table 1)

Table 2. Effect of supports on the amplification coefficients of the spectral lines of noble metals $K = I_{(S+ME)}/I_{GP}$ ($n = 6$, $P = 0.95$)

Support	Ionization potential, eV	Melting point, °C	Boiling point, °C	Amplification coefficient Γ

CdO	8.99	900 (decomp.)	–	0.9	1.3	1.2	1.4

using the quantitative interpretation of the evaporation curves, suggested by Raikhbaum [8]. The ratio of the intensities of two atomic lines of zinc (I_1-ZnI 307.6 and I_2-ZnI 328.2) was used to calculate by the formula $T = 18\,850/[\log(I_1/I_2) + 3.258]$ the effective temperature T (K) of the arc plasma. The electron concentration n_e in the plasma was found from the ratio of intensities of the ionic and atomic lines of magnesium (I_3-MgII 279.6 and I_4-MgI 278.0) by the formula $\log n_e = -\log(I_3/I_4) - 7.72(5040/T) + 3/2\log T + 15.754$ [9]. The thus found temperature and electron concentration were $T \pm 200$ K and $n_e \pm 0.2 \times 10^{15}$ cm^{-3} ($P = 0.95$). The influence exerted by the matrix elements and supports on the amplitude of the analytical signal from noble metals was studied on model samples prepared by introduction of oxides of base elements noble metals into the graphite powder in accordance with their content in the concentrates, and 3 wt % support in terms of the metal. For comparison purposes, samples without matrix elements and supports were used. The blackening density of the analytical lines of noble metals, whose parameters are listed in Table 2 [10], and of the nearby background were recalculated into intensities with the use of characteristic curves plotted with a nine-grade attenuator.

It was found that a high degree of recovery of noble metals by the sorbents studied is observed in the virtually entire range of acidities (Fig. 1). A certain decrease in the sorption of Rh(III) ions on the ANS-80 anion exchanger (Fig. 1a) and of Pt(IV) ions on the AV-17-10P resin (Fig. 1c) in a strongly acidic medium is, in all probability, due to the competing sorption of Cl^- ions. The reason for the lower absorption of Rh(III) by the AN-108-4 anion exchanger (Fig. 1b) and of Pt(IV) by AV-17-10P at pH 2–3 (Fig. 1c) is their hydrolysis leading to the formation of aqua chloro complexes with a lower effective charge. The high degree of recovery of Rh(III) ions by the ANS-80 anion exchanger under these conditions may be due to involvement of a sulfur atom in complexation with a noble metal ion. This assumption agrees with the results of [5]. It is advisable to use for quantitative recovery of noble metals in analysis of real objects the AN-108-4 macrocellular anion exchanger in a strongly acidic medium and AV-17-10P macroporous sorbent in 0.1 M HCl.

Figure 2 shows kinetic curves of sorption of noble metals under the optimal conditions of their quantitative recovery with and without solution agitation. The rate of sorption processes depends on the structure of ion exchangers. The time in which equilibrium is attained in Pt(IV) sorption by the AV-17-10P mac-

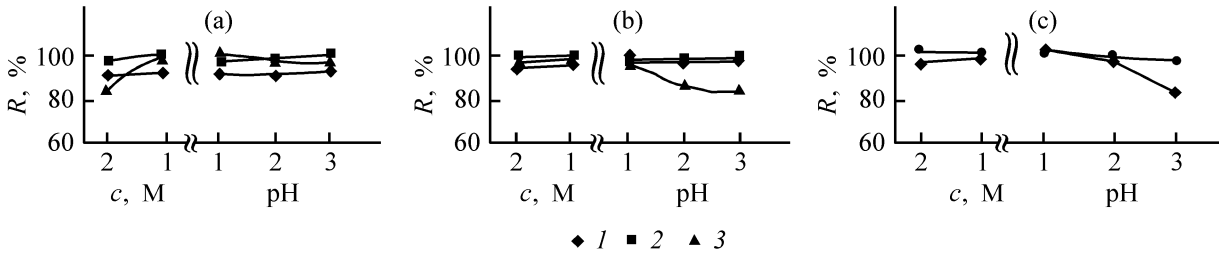

Fig. 1. Degree R of recovery of noble metals by (a) ANS-80, (b) AN-108-4, and (c) AV-17-10P ion exchangers from hydrochloric acid media vs. the acid concentration c and solution pH. $C_M = n \times 10^{-4}$ M, $m_{i.e} = 0.1$ g, $V = 10$ ml; the same for Fig. 2. (*1*) Pt, (*2*) Pd, and (*3*) Rh.

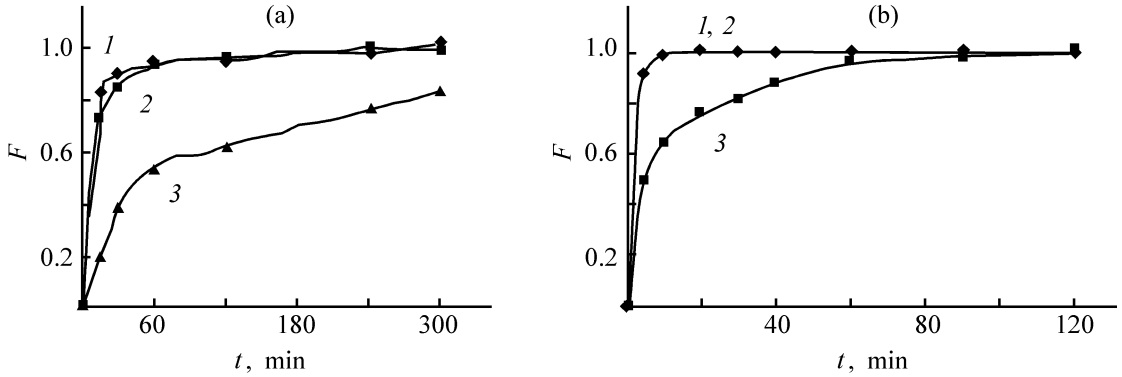

Fig. 2. Kinetic curves of sorption of (*1*) Pd(II) and (*2*, *3*) Pt(IV) by (*1*, *2*) AN-108-4 and (*3*) AV-17-10P ion exchangers (a) without solution agitation and (b) with agitation. (*F*) Degree of recovery and (*t*) time.

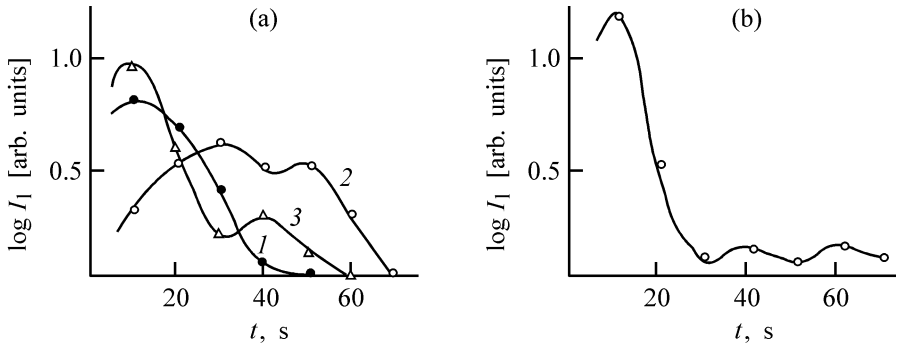

Fig. 3. Evaporation curves of (a) Pt on a support of (*1*) pure graphite powder, (*2*) graphite powder with a residual amount of matrix elements, and (*3*) graphite powder with matrix elements and TeO_3 support and (b) Te on a support of graphite powder with a residual amount of matrix elements. (I_l) Line intensity and (*t*) time.

roporous anion exchanger is 15 h, and decreases to 2 h under agitation (Fig. 2b). Macrocellular sorbents have improved kinetic properties because of the presence of long-chain cross-linking agents in their polymeric chain. Without solution agitation, a 90% absorption of Pt(IV) and Pd(II) ions is observed on the AN-108-4 anion exchanger already in 20 min. The sorption equilibrium is attained in 5 h. Sorption of noble metals in a hydrochloric medium on chelate-forming anion exchangers occurs in two stages [11]: first, the interaction occurs by the ion-exchange mechanism (functional groups are protonated under sorption conditions, pK_a 7.9–8.0), and then there occurs a rearrangement with incorporation of an amine group into the inner coordination sphere of the chloride complex of Pd(II) or Pt(IV), similarly the Andersen rearrangement. If the solution is agitated, the time of quantitative recovery of Pd(II) decreases to 10 min.

The support-collector of noble metals may contain, depending on the conditions of their concentration, various residual amounts of the matrix elements. When the AV-17-10P macroporous ion exchanger is used as a sorbent, the concentrate contains (wt %): 15–20 Ca, 5–15 Si and Al, 1–10 Na, Fe, and Mg, and also minor amounts (<1 wt %) of Mn and Ti. As the time in which equilibrium is attained in sorption of noble metals becomes longer, the residual content of the matrix elements grows and the interval of their variation, which also depends on the nature of an object being analyzed, is extended. Therefore, the sorption conditions should be chosen taking into account the effect of matrix elements on the impurities being controlled. It was found that presence of the residual amount of matrix elements, specified above, leads to a decrease in the arc temperature from 6370 to 5450 K and to an increase in the electron concentration in the plasma from 0.4×10^{15} to 5×10^{15} cm^{-3}. This is accounted for by the predominance in the concentrate of elements with low ionization potentials (Ca, Al, Na). The high values of the electron concentration diminish the ionization, which should lead to an increase in the intensity of the atomic lines of noble metals [9]. However, the results obtained in the study demonstrate that, in the presence of a considerable amount of matrix elements, low plasma temperatures are less favorable for atomization and excitation of noble metals. This is manifested in a change of the shape of the evaporation curves of noble metals in the presence of base elements (Fig. 3a, curves *1*, *2*). Their

maximum intensity decreases and shifts to longer exposures, and the time of total evaporation becomes longer. As a result, the evaporation rate of the elements being controlled falls and the analytical signals decrease by a factor of 1.5–2 for Pt, Pd, and Rh, and by a factor of 3.8 for Au, which has the highest ionization potential (Table 1). Therefore, it is preferable to perform the sorption concentration of noble metals on the AN-108-4 macrocellular anion exchanger, with the solution agitated and heated. This makes it possible to reduce the time in which equilibrium is attained to 10 min and to lower the content of matrix elements in the analytical concentrate by approximately a factor of 10. Under these conditions, the content of Ca, Al, and Si does not exceed 3–5 wt %, and that of Na, Mg, and Fe is not higher than 0.5–1.0 wt %.

The detection limits of noble metals in geochemical materials can be additionally lowered by introduction of supports into samples. A versatile support NaCl and oxides of readily vaporizable elements (Sb, Cd, Te) having low boiling points and high ionization potentials were studied (Table 2). Their choice was due to the presence in the concentrate of readily ionizable matrix elements (Ca, Al, Na), which affect, as shown previously, the excitation conditions. Compounds of some of these elements have been studied as collectors-coprecipitators of the elements to be determined, including noble metals, in analysis of pure substances [12].

The efficiency of the action of the supports and the residual amount of the matrix elements (Table 2) was evaluated by comparing the amplification coefficients K, which are numerically equal to the ratio of the intensities of the lines related to noble metals in the presence of matrix elements and supports to the intensity of similar lines of noble metals on a substrate of graphite powder ($K = I_{ME + S}/I_{GP}$). It was found that, in the presence of a minor residual amount of readily ionizable matrix elements (Na, Al, Ca), the intensity of lines of noble metals having lower ionization potentials (Rh, Pd) becomes higher owing to an increase in the electron concentration. Additional introduction of a readily ionizable NaCl support makes the spectral lines of noble metals weaker ($K < 1$). An effect of this kind, resulting from a decrease in the temperature of the arc plasma, has been observed previously in the case of an excess amount of matrix elements. In the presence of highly volatile elements, the amplification coefficients of the lines of Pt, Pd, and Rh exceed unity. However, the highest amplification coefficients are obtained in the presence of TeO_3. The nature of the experimentally observed amplification of the spectral lines of noble metals is not related in this case to changes in the parameters of the arc discharge plasma, because changes in T and n_e are insignificant in the presence of TeO_3. Highly volatile elements affect transport processes in the arc source. For example, tellurium evaporates at the first instants of arc burning and favors an increase in the height of primary peaks in the evaporation curves of noble metals, which points to their enhanced supply from the electrode rater into the discharge (Fig. 3a, curve *3*). Reactions in which volatile compounds are formed by noble metals are unlikely in the given case. Therefore, delivery of tellurium into the discharge zone leads, in all probability, to a strong change of the gas dynamic conditions in the electrode channel, and the TeO_3 vapor carries along vapors of noble metal admixtures. In the case of Au, which has the lowest melting and boiling points among all the noble metals (Table 1), rates of its evaporation in the presence of highly volatile supports are probably very high, which does not always lead to an increase in the intensity of spectral lines, because diffusion and convective processes become more important.

The results of the study were used to suggest a scheme for analysis of geological materials for the content of noble metals by atomic-emission spectroscopy, with their preliminary ion-exchange recovery and concentration. The detection limits calculated using the 3σ criterion fall in the range 2×10^{-7}–10^{-6} %, with S_r not exceeding 20%.

CONCLUSIONS

(1) It was found that quantitative concentration of noble metals and their most complete separation from matrix elements occurs on the AN-108-4 macrocellular anion exchanger from 1 M HCl solutions in the course of 10 min.

(2) It was demonstrated that matrix elements affect the intensity of the spectral lines of noble metals in atomic-emission spectroscopy: an increase in the content of matrix elements in the ion-exchange concentrate impairs the sensitivity of their determination. To make lower the detection limit of noble metals, it is suggested to use joint effective action of the residual amount of the matrix elements in the ash residue and of the TeO_3 support.

Abstract—Extraction of Th(IV), La(III), and Y(III) from aqueous solutions containing 0–4 M sodium nitrate with a composite solid extractant based on a polymeric support impregnated with trialkylamine (Alamine-336) was studied. The extraction isotherms were analyzed assuming that lanthanides and thorium are extracted with the solid extractant in the form of complexes $(R_3HN)_3[Ln(NO_3)_5]$ and $(R_3HN)_2[Th(NO_3)_6]$, respectively. The extraction constants were calculated. The joint extraction of Th(IV) and La(III) [Y(III)] with the solid extractant from aqueous salt solutions was studied.

DOI: 10.1134/S107042720608009X

Russian loparite, orthite, and monazite, along with rare-earth metals, usually also contain thorium and uranium as natural radioactive impurity metals. Therefore, the separation of thorium and uranium from rare-earth metals is a topical technological problem. This problem is usually solved by solvent extraction [1]. Another approach to solution of this problem is the use of composite solid extractants based on a porous support impregnated with a liquid extractant. This technique eliminates certain drawbacks characteristic of common solvent extraction procedures.

The extraction of rare-earth metals(III) [REM(III)] from aqueous solutions containing sodium nitrate (1–5 M) with a composite solid extractant (SE) based on a polymeric support impregnated with trialkylamine (Alamine-336) was studied in [1]. The extraction isotherms were processed assuming that the extractable complex $(R_3HN)_3[Ln(NO_3)_5]$ is formed in the solid extractant. No data have been reported on the joint extraction of La^{3+}, Th^{4+}, and Y^{3+} from aqueous solutions with the composite solid extractant. Since extraction of these metals with solid extractants is important from both scientific and practical viewpoints, we tried to fill this gap in this study.

We used a granulated composite solid extractant (Purolite Company) based on super cross-linked, poly(styrene–divinylbenzene) matrix impregnated with trialkylamine [TAA, (Alamine-336), general formula $(C_7H_{17}–C_9H_{19})_3N$]. Its specific volume was 2.50 ± 0.02 mol dm^{-3}. The Alamine-336 concentration in the composite solid extractant was 0.97 ± 0.01 mol dm^{-3}. The REM(III) concentration in the solid extractant and aqueous phase was determined by a technique similar to that reported in [2–4]. The metal nitrate concentration in SE (mol kg^{-1}) was recalculated to mol dm^{-3}, taking into account the density of the composite solid extractant.

The relative errors were within ± 0.5 % in preparing the solutions, and $\pm$ (1–3) and $\pm$ (1–5) rel. %, respectively, in determining REM(III) [Th(IV)] concentration in the liquid phase and SE. As a rule, each final result was the average of the results of no less than three experiments. The errors in parameter determination are given as standard deviations.

Figure 1 shows the extraction isotherm of nitric acid from aqueous solutions with SE at 298.15 K.

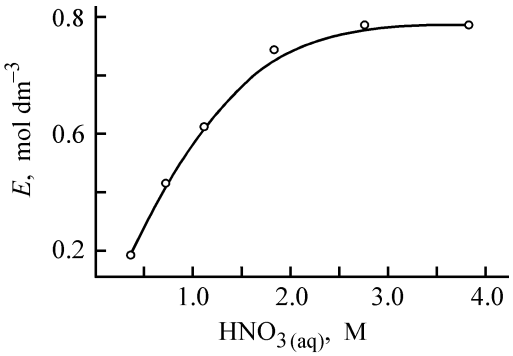

Fig. 1. Extraction isotherm of nitric acid with SE(TAA). (E) HNO_3 content in SE.

This isotherm flattens out due to saturation of the solid extractant with nitric acid. The limiting HNO_3 content in SE was 0.97 mol dm^{-3}, which corresponds to formation of stoichiometric TAA nitrate by the reaction

$$R_3N_{(o)} + HNO_{3(aq)} \rightleftarrows R_3NHNO_{3(o)}. \quad (1)$$

Before use for the extraction of Th(IV) and Ln(III) from aqueous solutions, the initial SE(TAA) was treated with 4 M HNO_3 to convert SE(TAA) into the salt form SE(TAA nitrate) and then was washed with water.

Figure 2a shows the extraction isotherms of Th(IV) from aqueous solutions containing $NaNO_3$ (0–4 M) with SE(TAA nitrate) at pH 1 and 298.15 K. As the $NaNO_3$ concentration in the aqueous phase increases, the Th(IV) concentration in SE grows and becomes close to $c_s/2$, where c_s is the TAA concentration in SE (0.97 ± 0.01 mol dm^{-3}). This fact suggests that, in saturation of SE(TAA nitrate) with thorium(IV) nitrate, the compound $(R_3NH)_2[Th(NO_3)_6]$ is formed.

The extraction of Th(IV) nitrate with TAA nitrate can be described by the equation of the following heterogeneous reaction:

$$Th^{4+}_{(aq)} + 4NO^-_{3(aq)} + 2R_3NHNO_{3(o)} \rightleftarrows (R_3NH)_2[Th(NO_3)_6]_{(o)}, \quad (2)$$

(aq) and (o) refer to aqueous and organic phases, respectively.

The extraction constant of Th with TAA can be calculated by the equation

$$K^{2,0}_{ex} = \frac{\{(R_3NH)_2[Th(NO_3)_6]\}_{(o)}}{\{Th^{4+}\}_{(aq)}\{NO^-_3\}^4_{(aq)} y^5_{\pm}\{R_3NHNO_3\}^2_{(o)}}, \quad (3)$$

where $\{...\}_0$ and $\{...\}_{(aq)}$ are the equilibrium concentrations of the components in the SE and aqueous phase, respectively, and $y_{\pm}$ is the mean ionic molar activity coefficient of Th(IV) nitrate in the aqueous phase.

The equilibrium Th concentrations in SE, calculated assuming the occurrence of reaction (2), (3) are listed in the table. The $y_{\pm}$ values used in these calculations were taken from [2]. The table shows that the calculated Th(IV) concentrations in the solid extractant agree with the experiment to within 1–2 rel.%. Thus, our model adequately describes the extraction of thorium(IV) nitrate from aqueous solutions with the solid extractant in the systems widely differing in the $Th(NO_3)_4$ concentration in both aqueous and solid extractant phases, with $\log K^{2,0}_{ex} = 4.30 \pm 0.05$.

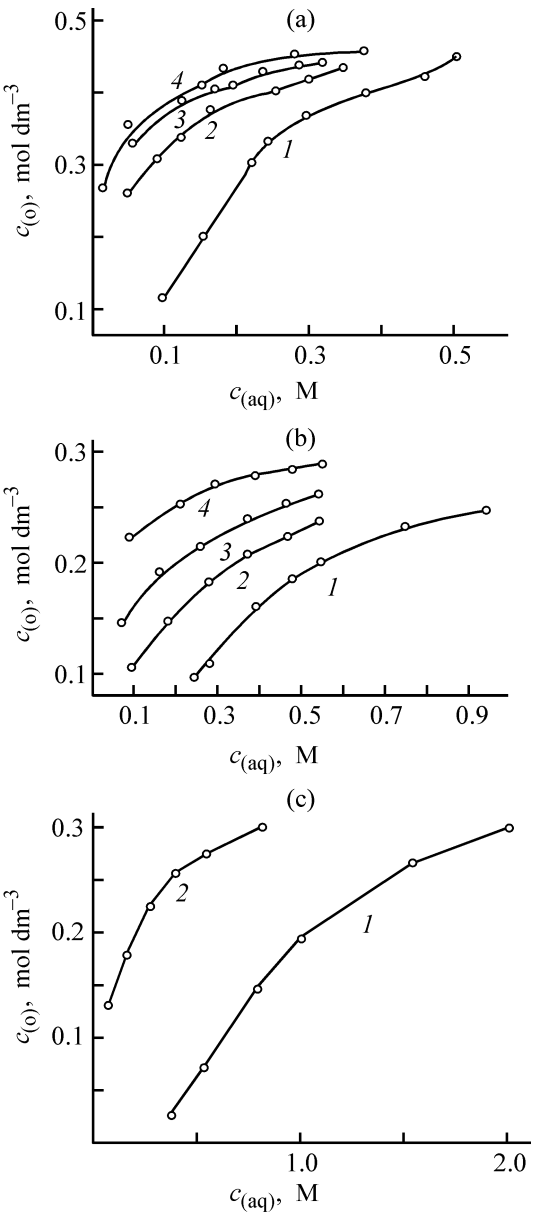

Fig. 2. Extraction isotherms of (a) thorium(IV), (b) lanthanum(III), and (c) yttrium(III) nitrates with SE from aqueous solutions in the absence and in the presence of sodium nitrate. ($c_{(aq)}$) thorium(IV), lantanum(III), or yttrium(III) nitrate concentration in the aqueous phase; ($c_{(o)}$) thorium(IV), lanthanum(III) or yttrium(III) nitrate concentration in SE. Sodium nitrate concentration in the aqueous phase, M: (a, b) (*1*) 0, (*2*) 1.0, (*3*) 2.0, and (*4*) 4.0; (*c*) (*1*) 0 and (*2*) 4.0.

The influence of the ionic strength of the aqueous phase ($I^{\Sigma} = 0.5\Sigma c_i Z_i^2$) on the concentration extraction constants K^2_{ex} can be estimated by the equation [1]

$$\log K^2_{ex}(I^{\Sigma}) = \log K^{2,0} + \Delta Z^2 F_{ex}(I^{\Sigma}) + 10\theta_1\{Th^{4+}\}_{(aq)} + \theta_2 c_{NaNO_3(aq)}, \quad (4)$$

Data on the extraction of thorium(IV), lanthanum(III) and yttrium(III) nitrates from aqueous solutions with SE(TAA) at T = 298.15 K, processed assuming the occurrence of reaction (2)*

* $c_{(aq)}$ is the equilibrium thorium(IV), lanthanum(III), or yttrium(III) nitrate concentration in the aqueous phase; $c_{(o)}$, equilibrium thorium(IV), lanthanum(III), and yttrium(III) nitrate concentration in the organic phase; $c_{(o)}$(calc), the calculated equilibrium thorium(IV), lanthanum(III), and yttrium(III) nitrate concentration in the organic phase; deviation, means the deviation of the calculated values from the experimental data; $[R_3NHNO_3]_{(o)}$, equilibrium extractant concentration; D_{ex}, distribution ratio; and $\gamma_{\pm}$, mean ionic molar activity coefficients of thorium(IV), lantanum(III), or yttrium(III) nitrate in the aqueous phase.

where ΔZ^2 is the algebraic sum of the squared charge numbers of the ionic species participating the extraction equilibrium. For the extraction of Th(IV), $\Delta Z^2 = -20$; $F(I^{\Sigma})$ is a function of the ionic strength, e.g., $F(I^{\Sigma}) = -\alpha(I^{\Sigma})^{1/3}$; θ_1 and θ_2 are empirical parameters; $[Th^{4+}]_{(aq)}$ and c_{NaNO_3} are the equilibrium concentrations of Th(IV) and sodium nitrates in the aqueous phase.

The mathematical processing of the extraction isotherms of thorium(IV) nitrate was carried out with an algorithm reported in [2], taking into account the material balance equations and effect of the ionic strength on the extraction constant. The parameter a in the function $F(I^{\Sigma})$ was 0.155 ± 0.005 at $\{Th^{4+}\} < 0.7$ M and 0.139 ± 0.005 at $\{Th^{4+}\} > 0.7$ M. The other parameters were as follows: θ_1, 0.345 ± 0.005 at $\{Th^{4+}\} < 0.7$ and 0.258 ± 0.006 at $\{Th^{4+}\} > 0.7$; θ_2, 0 ± 0.005; and $\log K_{ex}^{2,0} = 4.30 \pm 0.06$.

Figures 2b, 2c show the extraction isotherms of La(III) and Y(III) nitrates from their solutions both in water and in aqueous sodium nitrate (0–4 M). Similarly to the case of Th(IV), the La(III) and Y(III) nitrate content in SE increases with the sodium nitrate concentration. The limiting La(III) and Y(III) nitrate concentration in SE is close to $c_s/3$. Therefore, we can suggest that the SE extracts REM nitrate in the form

of the $(R_3H)_3[Ln(NO_3)_6]$. Comparison of curves *1* in Figs. 2b and 2c shows that Ln(III) nitrate is better extracted with SE than Y(III) nitrate. The extraction of Y with SE in the absence of sodium nitrate occurs only at yttrium nitrate concentrations higher than 0.3 M (Fig. 2c). The extraction of REM(III) nitrates with TAA nitrate can be described by the equation of the following heterogeneous reaction:

$$Ln^{3+}_{(aq)} + 3NO^-_{3(aq)} + 3R_3NHNO_{3(o)} \rightleftarrows (R_3NH)_3[Ln(NO_3)_6]_{(o)}. \quad (5)$$

The extraction constant can be calculated by equation

$$K^{3,0}_{ex} = \frac{\{(R_3NH)_3[Ln(NO_3)_6]\}_{(o)}}{\{Ln^{3+}\}_{(aq)}\{NO^-_3\}^3_{(aq)}y^4_{\pm}\{R_3NHNO_3\}^3_{(o)}}. \quad (6)$$

The La(III) and Y(III) equilibrium concentrations in SE, calculated assuming the occurrence of reaction (5), are listed in the table. The $y_{\pm}$ values used in these calculations were published in [2, 3]. The table shows that the calculated La(III) and Y(III) concentrations in the solid extractant agree with the experiment to within 1–3 rel. %. Thus, our model adequately describes the extraction of La(III) and Y(III) nitrates from aqueous solutions with the solid extractant in the systems with widely different metal concentration in both aqueous and solid extractant phases. The values of $\log K^{3,0}_{ex}$ for La(III) and Y(III) were found to be 2.95 ± 0.05 and 1.20 ± 0.05, respectively.

The effect of the solution ionic strength on the concentration extraction constants K^3_{ex} of La(III) and Y(III) nitrates can be estimated by the equation

$$\log K^3_{ex}(I^{\Sigma}) = \log K^{0,3} + \Delta Z^2 F_{ex}(I^{\Sigma}) + 6\theta_1\{Ln^{3+}\}_{(aq)} + \theta_2 c_{NaNO_3(aq)}, \quad (7)$$

where $\Delta Z^2 = -12$, $a = 0.238 \pm 0.005$, θ_1 is equal to 0.451 ± 0.005 and 0.579 ± 0.006 for La and Y, respectively; θ_2 is equal to 0.400 ± 0.005 and 0.602 ± 0.005 for La and Y, respectively; $\log K^{3,0}_{ex}$ is 2.95 ± 0.05 and 1.20 ± 0.05 for La and Y, respectively.

We also studied the extraction of Th(IV) with SE in the presence of varied amounts of La(III) or Y(III) nitrates in the aqueous phase (Fig. 3a, 3b). It was found that, within the entire La(III) and Y(III) concentration range, these metals are not noticeably transferred into SE [(La(III) and Y(III) concentrations in the SE were lower than 0.01 mol dm^{-3}]. At the same time, similarly to extraction of Th(IV) in the presence of sodium nitrate (Fig. 2a), the Th(IV) concentration in SE increases with the La(III) and Y(III) nitrate concentration in the aqueous phase and becomes close to $c_s/2$.

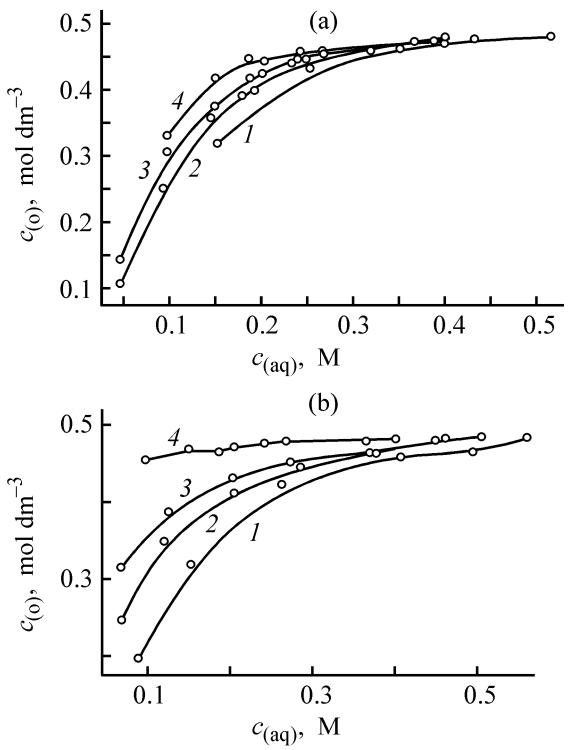

Fig. 3. Extraction of Th(IV) nitrate with SE ($c_{(o)}$) vs. equilibrium Th(IV) nitrate concentration ($c_{(aq)}$) in the aqueous phase containing (a) yttrium nitrate and (b) lanthanum nitrate. Y(III) and La(III) nitrate concentration in the initial aqueous solutions, M: (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, and (*4*) 1.0.

The effect of varied ionic strength of the aqueous phase on the concentration extraction constants K^2_{ex} of Th(IV) nitrate from aqueous solutions containing La(III) or Y(III) nitrates was estimated by the equation

$$\log K^2_{ex}(I^{\Sigma}) = \log K^{0,2} + \Delta Z^2 F_{ex}(I^{\Sigma}) + 10\theta_1\{Th^{4+}\}_{(aq)} + 6\theta_2\{Ln^{3+}\}_{(aq)}, \quad (8)$$

where for $\Delta Z^2 = -20$, $a = 0.139 \pm 0.005$; for Y, $\theta_1 = 0.420 \pm 0.005$ and $\theta_2 = 0.315 \pm 0.005$; for La(III), $\theta_1 = 0.690 \pm 0.005$ and $\theta_2 = 0.300 \pm 0.005$ ($I^{\Sigma} < 7$) and $\theta_1 = 0.400 \pm 0.005$ and $\theta_2 = 0.265 \pm 0.005$ ($I^{\Sigma} > 7$); $\log K^{2,0}_{ex} = 4.30 \pm 0.06$.

Thus, our results show that treatment of concentrated aqueous solutions of REM(III) nitrates with a composite solid extractant based on a polymeric support impregnated with neat trialkylamine allows

their extractive purification to remove Th(IV) impuruties.

CONCLUSIONS

(1) In extraction of nitric acid from aqueous solution with a composite solid extractant based on a polymeric support impregnated with neat trialkylamine (SE), the limiting HNO_3 concentration in SE is 0.97 mol dm^{-3}, which corresponds to the formation of stoichiometric TAA nitrate.

(2) The extraction isotherms were analyzed assuming that lanthanides(III) and thorium(IV) are extracted with the solid extractant in the form of complexes $(R_3HN)_3[Ln(NO_3)_5]$ and $(R_3HN)_2[Th(NO_3)_6]$. The extraction constants were calculated; they decrease in the order Th(IV) > La(III) > Y(III).

(3) In joint extraction of Th(IV) nitrate and La(III) or Y(III) nitrate, La(III) and Y(III) are not noticeably transferred into the SE phase but the extraction of Th(IV) increases with the La(III) and Y(III) nitrate concentrations in the aqueous phase.

(4) The treatment of concentrated aqueous solutions of REM(III) nitrates with a composite solid extractant allows their purification to remove Th(IV) impuruties.

Abstract—The catalytic properties of nanosize catalysts derived from $Pd(acac)_2$ and triethylaluminum in hydrogenation of organic substrates were studied, and the optimal conditions for the catalyst preparation were found. The maximum observed on the plot of the catalyst specific activity vs. Al/Pd ratio was explained by experiments.

DOI: 10.1134/S1070427206080106

Transition metals and their complexes catalyze hydrogenation of unsaturated organic compounds with gaseous hydrogen; the process has numerous industrial applications [1, 2]. A particular place is occupied by palladium catalysts, whose properties significantly differ from those of catalysts containing Rh, Pt, Ru, Ni, or Cu [2]. Palladium is one of the most active metals in the hydrogenation of double bonds conjufated with an aromatic ring, such as Ar–C=C, Ar–C=O, or Ar–C=NR. Furthermore, Pd is one of the most selective metal catalysts in the hydrogenation of triple and conjugated double bonds and the most active metal in hydrogenolysis, i.e., reductive cleavage of C–X bonds. However, at low temperatures Pd is virtually inactive in the hydrogenation of the majority of aromatic rings and shows low activity in the hydrogenation of aliphatic ketones and aldehydes [2]. These characteristics determine the applications of palladium-based catalysts in chemo- and stereo-selective hydrogenation, hydrogenolysis, and dehydrogenation of various organic compounds.

Along with heterogeneous catalysts, hydrogenation catalysts based on transition metal complexes has attracted growing researchers' attention since the second half of the XXth century with the development of coordination catalysis. A particular place among such catalysts is occupied by Ziegler-type catalytic systems [3]. The majority of studies in this field concerned the nature and properties of hydrogenation catalysts based on β-diketonate, carboxylate, and cyclopentadienyl complexes of transition metals of the first row [4–10], and also the synthesis of metal nanoparticles by treatment with organoaluminum compounds [11–16].

The problems of the formation mechanism, phase state, and nature of hydrogenation-active species in Ziegler-type catalytic systems based on Pd(II) complexes and the properties of these systems have been studied to a lesser extent [17, 18] and are the subject of this paper.

EXPERIMENTAL

Solvents (toluene, benzene, hexane) were purified by standard procedures required for manipulations with organometallic compounds [19]. For more exhaustive drying, the solvents were additionally distilled from $LiAlH_4$ on a distillation column and were stored under Ar in sealed ampules over 4 Å molecular sieves.

Palladium bis(acetylacetonate) $Pd(acac)_2$ was prepared according to [20]. ^{1}H NMR, δ, ppm: 5.04 s (2H, CH), 1.76 s (12H, CH_3).

Commercial-grade triethylaluminum $AlEt_3$ was distilled in a vacuum; the fraction boiling at 48–49°C (1 mm Hg) was collected. ^{1}H NMR, δ, ppm: 1.22 t (9H, CH_3, ^3J = 8.24 Hz), 0.45 q (6H, ^3J = 8.24 Hz). The samples were stored in a glass ampule under Ar. Solutions of triethylaluminum in hexane were prepared in a Schlenk vessel under Ar.

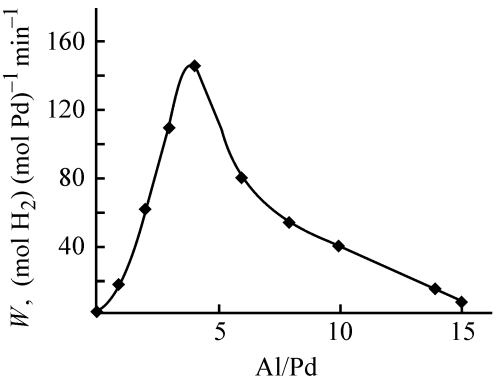

Fig. 1. Hydrogenation of styrene in the presence of the catalytic system $Pd(acac)_2$–$n AlEt_3$. $c_{Pd} = 5 \times 10^{-3}$ M, $n_{styrene}$ = 9 mmol, T = 30°C, P_{H_2} = 1 atm, solvent toluene; the same for Fig. 3. (W) Specific activity of the system.

The hydrogenation of the substrates was performed in a temperature-controlled glass vessel at 30°C and initial hydrogen pressure of 1 atm in the presence of the catalytic system formed in situ. To a solution of 0.01522 g (5×10^{-5} mol) of $Pd(acac)_2$ in toluene, placed in a temperature-controlled duck-shaped vessel, we added dropwise in a hydrogen flow a solution of $AlEt_3$ in hexane from a Schlenk vessel; the mixture was stirred for 5 min. The molar ratio $AlEt_3/Pd(acac)_2$ was varied from 2 to 16. The total solution volume was 10 ml. To the resulting brown-black mixture, we added a substrate whose hydrogenation was performed with vigorous stirring at the initial hydrogen pressure of 1 atm. The reaction progress was monitored volumetrically and by GLC. Experiments involving modification of the catalyst with triphenylphosphine and ethanol were performed similarly.

The NMR spectra were recorded on a Varian VXR-500S pulse spectrometer. The ^{31}P chemical shifts are given relative to 85% H_3PO_4.

A TEM examination of the samples was performed with a BS-300 microscope (Czechia). A drop of a solution was applied onto a supporting grid coated with a carbon film and was dried in an argon atmosphere. The recording conditions excluded melting and decomposition of the samples under electron beam.

The IR spectra of the precipitates were recorded on a Specord 75-IR spectrometer in the range 4000–400 cm^{-1} using KBr windows. Samples for recording the IR spectra were prepared in a box with an inert atmosphere as mulls in mineral oil preliminarily heat-treated to remove traces of moisture.

The catalytic properties of the Ziegler-type systems based on $Pd(acac)_2$ and $AlEt_3$ in the hydrogenation depend on numerous factors, in particular, on the Al/Pd molar ratio. The dependence of the specific activity in the hydrogenation of alkenes on the component ratio passes through a maximum at Al/Pd = 4 (Fig. 1).

A high activity of the $Pd(acac)_2$–$AlEt_3$ system at Al/Pd = 4 was also observed in the hydrogenation of other organic substrates: α-alkenes, alkynes, nitro and carbonyl compounds (Table 1). In particular, the specific activity W in hydrogenation of 1-hexene was 112 (mol H_2) (mol Pd)$^{-1}$ min^{-1}. The hydrogenation was accompanied by isomerization of 1-hexene into 2-hexene (*cis* + *trans*). At 99% conversion of 1-hexene, the reaction system contained 59% hexane, 33% *trans*-2-hexene, and 7% *cis*-2-hexene. The rates of hydrogenation of the terminal and internal double bonds differed by an order of magnitude; however, even under these conditions, 2-hexene fairly rapidly and quantitatively transformed into hexane under mild conditions (30°C, P_{H_2} = 1 atm). The high rate of the positional isomerization of the double bond was observed in the hydrogenation of 1,5-hexadiene whose

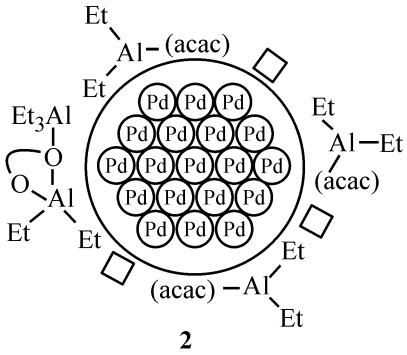
reduction is usually regarded as a model reaction of the hydrogenation of polyene compounds.

The hydrogenation of phenylacetylene in the presence of the catalytic system $Pd(acac)_2$–$AlEt_3$ occurs not only at a high rate, but also with a fairly high selectivity: 97% with respect to styrene at 96% conversion of phenylacetylene. No side reaction of di- and oligomerization of phenylacetylene was observed. The high selectivity of palladium catalysts in the hydrogenation of α-alkynes is due to a thermodynamic factor: considerably higher equilibrium constant of the coordination of α-alkyne, compared to alkene [21], with the active center. The $Pd(acac)_2$–$4AlEt_3$ system also shows high selectivity in the hydrogenation of benzaldehyde to benzyl alcohol, which is usually followed by hydrogenolysis of the $C_6H_5CH_2$–OH bond.



The observed dependence of the specific activity on the Al/Pd ratio is caused by several factors. Previously, when studying the reaction of $Pd(acac)_2$ with $AlEt_3$ in an inert atmosphere by ^1H NMR spectroscopy and electron microscopy, we have revealed three major facts [22]. First, the reduction of $Pd(acac)_2$ with triethylaluminum is quantitative at the ratio Al/Pd ≥ 3.5, rather than at Al/Pd = 2 as could be expected from the stoichiometric equation

$$Pd(acac)_2 + 2AlEt_3 = 1/xPd(O)_x + 2Al(acac)Et_2 + C_2H_4 + C_2H_6.$$

This is apparently due to side catalytic decomposition of triethylaluminum in the presence of Pd(0) nanoparticles. At Al/Pd ≥ 3.5, unchanged triethylaluminum remains in the reaction system. Second, the reduction of $Pd(acac)_2$ yields Pd(0) nanoparticles stabilized with $AlEt_2(acac)$ (**1**) and/or with adduct of $AlEt_2(acac)$ with $AlEt_3$ at Al/Pd ≥ 3.5 (**2**):

1

2

Third, the mean size of the Pd(0) nanoparticles depends on the Al/Pd ratio and decreases with an increase in the triethylaluminum concentration from 4.5 (Al/Pd = 4) to 1–2 nm at Al/Pd ≥ 8.

Thus, the rise in the specific activity of the $Pd(acac)_2$–$AlEt_3$ system in the initial portion of the curve (Fig. 1) is caused by an increase in the fraction of reduced palladium and in the dispersity of the microheterogeneous system. The nonlinear dependence of the styrene hydrogenation rate on the palladium concentration and a decrease in the reaction rate at Pd concentrations exceeding 10 mM suggest association of the active particles into less active aggregates and confirm the microheterogeneous nature of the catalyst (Fig. 2).

The hydrogenation of alkenes is a structure-insensitive reaction [23, 24]. Therefore, a decrease in the catalytic activity with a decrease in the size of Pd nanoparticles (Al/Pd > 4) suggests the appearance of a catalytic poison in the system. Unchanged $AlEt_3$ can act as such a poison. To confirm the inhibiting effect of $AlEt_3$ at high Al/Pd ratios, we studied the effect of

various modifying additives capable of binding $AlEt_3$ (Table 2).

It is known that organoaluminum compounds form stable 1 : 1 adducts with Lewis bases (e.g., ethers, amines) and react, with release of hydrocarbons, with water, alcohols, acids, and other proton-donor compounds. Therefore, we tested as modifiers the substances that should, on the one hand, bind excess triethylaluminum and, on the other hand, be relatively inert toward palladium. Among such compounds are alcohols and triphenylphosphine oxide $OPPh_3$. The ^{31}P NMR spectrum of the mixture from the reaction of equimolar amounts of $OPPh_3$ and $AlEt_3$ does not contain the signal from $OPPh_3$ ($\delta_P = 25$ ppm), but contains a signal at $\delta_P = 39$ ppm, which can be assigned to the adduct $Ph_3PO \cdot AlEt_3$ formed by the donor–acceptor interaction.

As follows from Table 2, addition of ethanol or triphenylphoshine oxide to the $Pd(acac)_2$–$AlEt_3$ catalytic system prepared in advance makes higher the hydrogenation rate. In particular, in the presence of $OPPh_3$ the rate of styrene hydrogenation increases by a factor of approximately 10. With additions of ethanol, even the performance of the most active catalytic system (Al/Pd = 4) is surpassed. Hence, the role of triethylaluminum is not restricted to the reduction of Pd(II) compounds. When in excess, $AlEt_3$ acts as a catalytic poison. The poisoning effect of $AlEt_3$ on the catalyst may be due to formation of surface compounds by the reaction of $AlEt_3$ with hydride **3** or alkyl **4** intermediates of the catalytic cycle:

3 **4**

As noted above, the donor power of α-alkynes is higher than that of alkenes. Therefore, the poisoning effect of triethylaluminum in the hydrogenation of phenylacetylene was observed at higher Al/Pd ratios (Table 3). However, the hydrogenation of α-alkynes is, in contrast to that of alkenes, a structure-sensitive reaction [24], and a question naturally arises: Can the observed drastic decrease in the rate of phenylacetylene hydrogenation at Al/Pd > 10 be attributed to the too strong adsorption of the substrate on small palladium particles? Addition of ethanol to the $Pd(acac)_2$–$15AlEt_3$ catalytic system prepared in advance led to an increase in the specific activity in the hydrogenation of phenylacetylene by a factor of 5. Hence, as in the case of alkenes, the major factor responsible for the decrease in the catalytic activity of the $Pd(acac)_2$–$AlEt_3$ system in the hydrogenation of phenylacetylene at high Al/Pd ratios is the inhibiting effect of triethylaluminum.

An opposite pattern was observed when ethanol was added to the $Pd(acac)_2$–$4AlEt_3$ system, which is the most active in the hydrogenation of styrene: The specific activity decreased with an increase in the alcohol concentration (Table 2). On adding ethanol, the system became aggregation-unstable, and a black precipitate formed. This fact indicates that the compounds $Al(OEt)_2(acac)$ and/or $Al(OEt)Et(acac)$ formed by the reaction of $AlEt_2(acac)$ with ethanol exhibit weaker

stabilizing power than does $AlEt_2(acac)$, which results in the aggregation of the palladium nanoparticles.

Taking into account the microheterogeneous nature of the catalyst based on $Pd(acac)_2$ and $AlEt_3$, one of the ways to enhance the catalytic activity is to decrease the palladium particle size. However, increasing the dispersity by adding more $AlEt_3$ leads to an opposite result because of the poisoning effect of excess triethylaluminum. The dispersity can be increased not only by taking the reductant in a higher concentration, but also by performing the catalyst synthesis by chemical condensation in the presence of a stabilizer; as stabilizer we used triphenylphosphine.

It is known that the complexation of triphenylphosphine with an equimolar amount of $Pd(acac)_2$ leads to the transformation of one of the acetylacetonate ligands from the O,O-chelate to the C^3-bound form, with the formation of the complex $Pd(acac)_2PPh_3$ [25]. At P/Pd < 1, the reaction mixture contains two complexes, $Pd(acac)_2$ and $Pd(acac)_2PPh_3$, and at P/Pd > 1, $Pd(acac)_2PPh_3$ and free triphenylphosphine.

Addition of triphenylphosphine to the $Pd(acac)_2$–$4AlEt_3$ before adding triethylaluminnum affects in a complex fashion the catalytic properties in hydrogenation. In particular, in the hydrogenation of styrene, as the P/Pd ratio is raised, the specific activity first increases (P/Pd = 0.25) relative to the unmodified catalyst, reaches a maximum at P/Pd = 1, and decreases to zero at P/Pd = 2 (Fig. 3). The catalyst prepared at P/Pd = 1 [i.e., by the reduction of $Pd(acac)_2 \cdot PPh_3$ with $AlEt_3$] is the most active; therefore, we studied in more detail the catalyst based on $Pd(acac)_2 \cdot PPh_3$–$AlEt_3$.

The ^{31}P NMR spectrum of the $Pd(acac)_2PPh_3$–$4AlEt_3$ system prepared in an inert atmosphere contains broadened signals from free triphenylphosphine ($\delta_P = -6$ ppm) and from PPh_3 coordinated to Pd in lower oxidation states (δ_P = 22, 16.4 ppm). A TEM examination of the reaction mixture revealed the presence of high-contrast palladium particles, among which particles 2.5 nm in diameter prevail (Fig. 4). The IR spectrum of the brown powder isolated from the reaction mixture contains bands of $AlEt_2(acac)$ [ν(C=O) + ν(C=C) 1585 and 1525 cm^{-1}; ν(C=C) + ν(C–CH_3) 1284, 1218 cm^{-1}; δ(Al–C–H) + ν(C–CH_3) 1187, 1104, 1047, 1010 cm^{-1}] and bands characteristic of out-of-plane bending vibrations of the C–H and C–C bonds in the monosubstituted benzene ring (706, 676, 450 cm^{-1}); this pattern indicates that both triphenylphosphine and diethyl(acetylacetonato)aluminum molecules act as stabilizers of palladium nanoparticles.

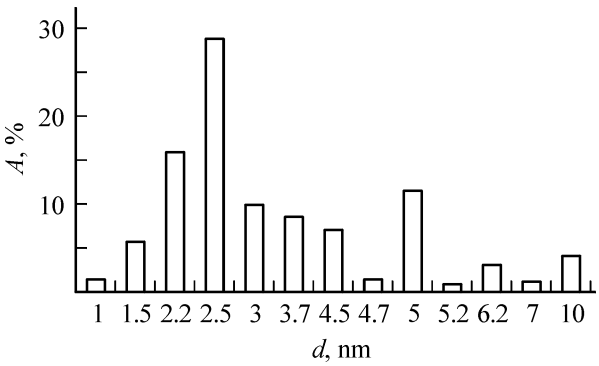

Fig. 4. Electron micrograph of the $Pd(acac)_2PPh_3$–$4AlEt_3$ system and particle size distribution (inert atmosphere). (*A*) Fraction of particles and (*d*) particle size; the same for Fig. 5.

The reaction of $Pd(acac)_2PPh_3$ with $AlEt_3$ in a hydrogen atmosphere yields benzene along with the above-mentioned products. This fact indicates that the catalyst formation is accompanied not only by the reduction of Pd(II) to Pd(0), but also by decomposition of the phosphine ligands. At P/Pd = 1, about half

of the phenyl groups of triphenylphosphine transformed into benzene (Table 4). The detection of broadened signals with δ_P = 22 and 16.4 ppm, which were observed when the reaction was performed in an inert atmosphere and were assigned to PPh_3 coordinated with Pd, indicates that a part of triphenylphosphine remained intact. The PPh_2 and PPh fragments formed by dephenylation of the phosphine ligands readily undergo further degradation, ultimately yielding palladium phosphides of various compositions.

It should be noted that the amount of benzene formed per mole of triphenylphosphine in the course of preparation of the $Pd(acac)_2$–$n PPh_3$–$4AlEt_3$ catalyst in hydrogen increased with a decrease in the P/Pd ratio (Table 4). A similar trend has been observed previously in reduction of $Pd(acac)_2$ in the presence of tertiary and primary phosphines [26, 27]. At P/Pd 0.25 or 0.5, triphenylphosphine decomposes virtually completely, i.e., palladium phosphides are formed, and the majority of Pd(0) passes into the form inactive in the hydrogenation.

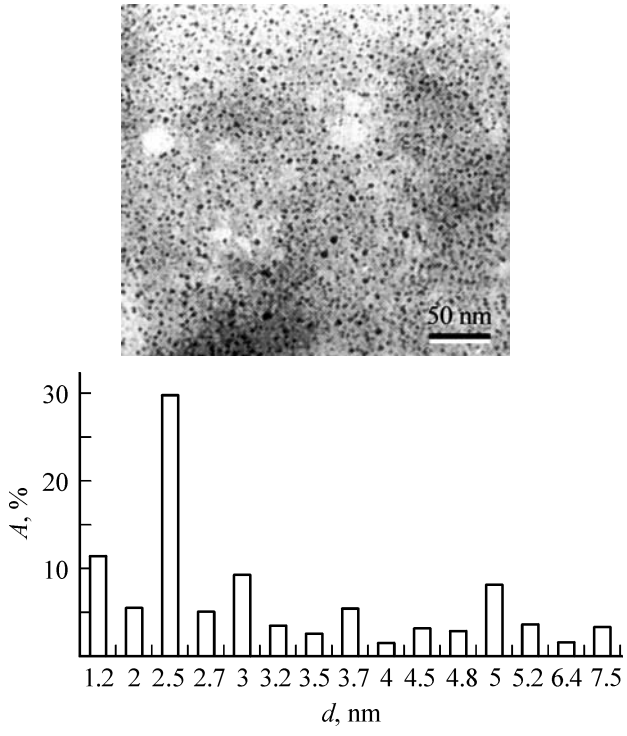

Fig. 5. Electron micrograph of the $Pd(acac)_2PPh_3$–$4AlEt_3$ system and particle size distribution (hydrogen atmosphere).

According to electron microscopic examination, the reaction of $Pd(acac)_2PPh_3$ with $AlEt_3$ (Al/Pd = 4) in a hydrogen atmosphere yields a polydisperse microheterogeneous system in which particles 2.5 nm in diameter prevail; the relative content of 1.2-nm particles increases (Fig. 5). Thus, on the one hand, modification of the catalytic system with phosphine in a hydrogen atmosphere leads to partial transformation of Pd into an inactive form as a result of decomposition of the phosphine ligands; on the other hand, addition of phosphine favors formation of smaller Pd(0) particles. A decrease in the palladium particle size is one of the factors responsible for the promoting effect of triphenylphosphine at P/Pd = 1.

Previously,we have put forward a hydrolysis, according to which palladium phosphides show no catalytic activity in the hydrogenation but act as a matrix for Pd(0) clusters which are actual hydrogenation catalysts [26]. To confirm this hypothesis, we performed additional experiments on modification of the catalytic system $Pd(acac)_2$–$4AlEt_3$ with elemental phosphorus. Irrespective of the order of phosphorus addition (before or after adding triethylaluminum), we observed at P/Pd ≥ 0.5 a decrease in the catalytic activity with an increase in the concentration of elemental phosphorus (Table 5). A slight increase in the specific activity at small additions of P may be due to changes in the catalyst dispersity.

CONCLUSIONS

(1) Examination of the conditions for preparing a Ziegler-type catalyst derived from palladium bis(acetylacetonate) and triethylaluminum and active in hydrogenation of unsaturated compounds and carbonyl and nitro groups showed that the role of triethylaluminum is not limited to the reduction of Pd(II). The complex $AlEt_2(acac)$ formed by the reaction of $AlEt_3$ with $Pd(acac)_2$ is a stabilizer of palladium nanoparticles. At high Al/Pd ratios, triethylaluminum acts as a catalytic poison.

(2) It was found that the modifying effect of ethanol depends on the Al/Pd ratio. At Al/Pd $\leq$ 4, ethanol makes the catalytic activity lower as a result of binding of the stabilizer and, as a consequence, of aggregation of nanoparticles. At high Al/Pd ratios, the promoting effect of ethanol is due to the adduct formation with the catalytic poison, $AlEt_3$.

(3) The nature of the modifying effect of triphenylphosphine on the catalytic properties of the Ziegler-type system $Pd(acac)_2$–$AlEt_3$ was examined. The formation of the hydrogenation catalyst in a hydrogen atmosphere is accompanied by decomposition of the phosphine ligands; the extent of this process increases with a decrease in the P/Pd ratio. The inhibiting or promoting effect of phosphine at P/Pd $\leq$ 1 depends on the ratio of two factors exerting opposite effects on the catalyst activity: transformation of palladium particles into an inactive form as a result of decomposition of phosphine ligands and decrease in the size of Pd(0) particles upon stabilization with phosphine.

Abstract—Gas-phase pyrolytic synthesis of carbon to give multilayer carbon nanotubes on Ni catalysts supported by NaCl and K_2SO_4 mineral water-soluble substrates was studied. The morphology of the nanotubes synthesized was examined.

DOI: 10.1134/S1070427206080118

The method of synthesis of carbon nanotubes (CNT) by chemical vapor deposition of carbon in a comparatively high yield is highly promising for introduction into large-tonnage industrial manufacture. The process of catalytic pyrolysis of carbon-containing reagents is affected by the choice of a catalyst, source of carbon, temperature, partial pressure of synthesis components, and nature of a catalyst support [1]. The key importance of the catalyst support consists in that nanosize particles of metals that belong to the iron subgroup can be formed on its surface, which is a necessary condition for growth of nanosize fibrous carbon structures (fibers, tubes). Use of silicon oxide (primarily that with a developed surface, of the MCM-41 type), silica gels, and zeolites as supports has been found effective for synthesis of CNT [2, 3]. According to the results of [4, 5], aluminum oxide has an advantage over the supports mentioned above, which is manifested in an increase in the yield of CNT. It is assumed that aluminum oxide exhibits catalytic activity in pyrolysis of hydrocarbons and thereby diminishes the formation of pyrolytic carbon on its surface. Syntheses of nanotubes with other catalyst supports carbon and magnesium oxide, have been described. Emphasis should be placed on the study [6], in which CNT was obtained with high selectivity and purity, with calcium carbonate used as support. The technique makes it possible to separate CNT from a catalyst on a support with diluted nitric acid in a single stage and to perform, as it was done in [7], partial purification of nanotubes to remove other forms of carbon.

To disadvantages of the catalyst supports described in the literature can be attributed the fact that their separation from the carbon fraction requires use of corrosive media (HF, HNO_3, HCl, H_2SO_4, $HClO_4$, and alkalis). These media react not only with the substrate and catalyst, but also with carbon nanotubes and the modifying components they contain, which makes lower their amount. Replacement of the conventional supports with novel ones of some other chemical nature will extend the existing synthetic potentialities of the method.

The aim of this study was to find conditions in which CNT can be synthesized with water-soluble catalyst supports, sodium chloride and potassium sulfate.

EXPERIMENTAL

We synthesized CNT using water-soluble substrates: salts of alkali metals, such as sodium chloride and potassium sulfate. A quartz boat was placed in a quartz horizontal flow-through reactor 42 mm in diameter. A layer of nickel(II) acetylacetonate [$Ni(acac)_2$] was deposited onto one half of the boat, and that of a thoroughly ground catalyst support, onto the other. In the inert atmosphere of argon, which served as transport gas, the temperature was gradually raised to 250–300°C and nickel(II) acetylacetonate (sublimation temperature 132°C) passed into the gaseous state. Its subsequent thermal decomposition resulted in that metal nanoparticles appeared on the whole surface of the water-soluble substrate and a carbon-containing gaseous component was formed in the volume of the reactor. After 0.5 h, a mixture of argon with acetylene (C_2H_2) was fed into the system in order to make higher the content of carbon in the reaction mixture, with the temperature raised to 600°C. After pyrolysis of acetylene continued for 20–30 min, the reactor was cooled to room temperature. The resulting carbon-containing composite, in

which black pyrolysis products, catalyst, and support were present, was treated under agitation with warm distilled water to remove the substrate, water-soluble salts. The carbon fraction was separated from the solution by centrifugation and used in further studies. Nanotubes were identified with a JEMOOCX-II transmission electron microscope.

There exist a rather large number of methods for production of catalysts for gas-phase pyrolytic synthesis of carbon nanotubes, and these methods rely on a variety of approaches. One of these is based on codeposition by hydrolysis of a mixture of precursors containing the active component and the component of a support: compounds of metals of the iron subgroup and silicon, aluminum, and magnesium, followed by reduction of the active component to give catalysts on the substrate surface. The support prevents aggregation of nanoparticles of the active metal and favors their more uniform distribution. A distinctive feature of another approach is that oxides with a large specific surface area, impregnated with solutions of metal salts, are used as substrates. The initial substrate has a prescribed structure and porosity, which allows control over the catalyst preparation procedure in the impregnation and reduction stages, with the catalyst formed on the matrix surface. Use of volatile catalyst precursors (e.g., organometallic compounds) enables synthesis of catalytically active substances by pyrolysis directly in the reaction zone and makes it possible to exclude any liquid medium from the process, i.e., synthesis of CNT is performed in the gas phase in all stages. Destruction of these precursors occurs at high temperatures (above 500°C) in an inert atmosphere to give catalyst nanoparticles on the substrate [8].

A most important stage of CNT synthesis is separation of the carbon fraction composed of CNT and other forms of carbon from the substrate with catalyst and further purification of the carbon fraction to remove admixtures of amorphous carbon and carbon nanoparticles. Acids commonly serve to dissolve the conventionally used catalyst supports. For example, the matrix, porous aluminum oxide, was dissolved in HF for 24 h in [9, 10] (in our opinion, full dissolution of such a substrate requires no less than 6 h). Further chemical purification of a CNT sample is based on the fact that the oxidation rate of nanotubes differs from that of more active admixtures of amorphous carbon and other forms of carbon. Thermal treatment of a carbon sample in air at 530°C results in that the loss of mass by the sample exceeds 60% and the content of CNT in the sample increases to 90%. Another purification method is based on treatment of a carbon-containing sample with a 30% HNO_3 solution. As a result, the $CaCO_3$ support and the Fe(II), Co(II) catalyst dissolve and carbon partly oxidizes. The treatment of a carbon sample with HNO_3 can be regarded as the most efficient method of CNT purification because of the high reactivity of pyrolytic carbon toward oxidation, compared with CNT, which enables deep purification of nanotubes.

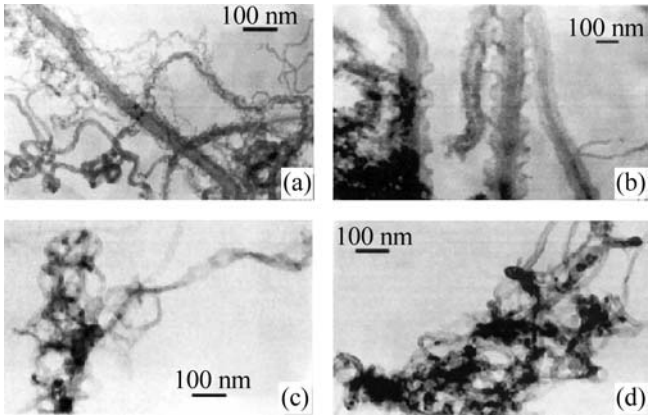

Fig. 1. (a–d) Electron micrographs of CNT with different diameters. Diameter (nm): (a) outer 5–28 and (b) inner 1–15.

Pyrolysis of various sources of carbon in an inert gas yields CNT at high temperatures, as a rule at 500–800°C. Therefore, a necessary requirement to supports of catalysts used in synthesis of CNT is their thermal stability up to temperatures exceeding the synthesis temperature. Thus, we chose salts with high melting points, NaCl (mp 801°C) and K_2SO_4 (mp 1076°C) as model water-soluble catalyst supports. The property of the substrates to dissolve in water imposed limitations on the choice of a source and method of catalyst deposition. The available acetylacetonates of metals of the iron subgroup, with sublimation points in the range 97–132°C and decomposition points of 150–400°C are convenient sources of catalysts and carbon, and the catalysts can be deposited from the gas phase without any aqueous medium. The use of acetylene in CNT synthesis made it possible to preclude a deficiency of carbon in the reaction mixture. Metal nanoparticles are probably formed in decomposition of acetylacetonate at 300°C, or there may occur a redox reaction between Ni(II) and C_2H_2 to give metallic nickel at higher temperatures (up to 600°C).

Figs. 1a–1d show typical electron micrographs of the CNT synthesized: fibers of various diameters. The distribution of CNT over outer diameters exhibits a clearly pronounced peak corresponding to nanotubes

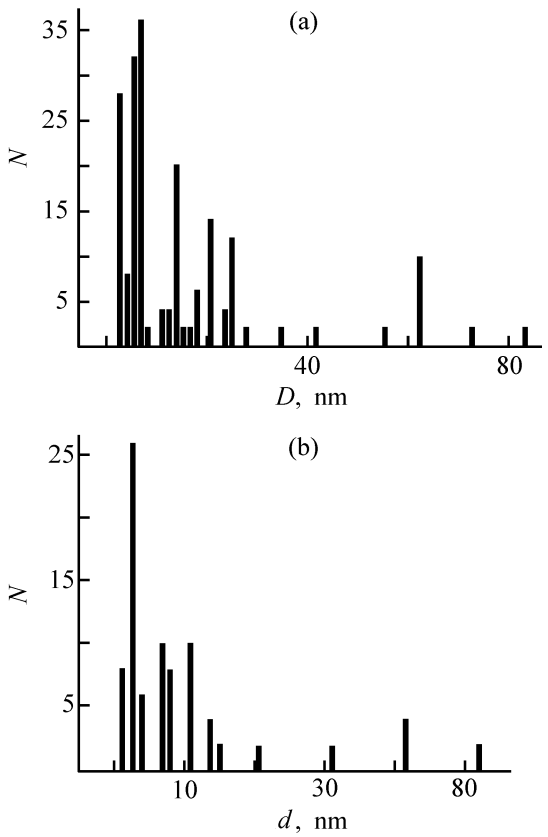

Fig. 2. Distribution of CNT over (a) outer (*D*) and (b) inner (*d*) diameters. (*N*) Number of nanotubes.

with a diameter of about 7 nm. Most of the nanotubes have diameters in the range 5–28 nm, which constitutes 89% of the total amount of the CNT synthesized (Fig. 2a). The diagram of the CNT distribution over inner diameters shows a peak corresponding to nanotubes with an inner diameter of 3 nm. Most of the nanotubes have diameters in the range from 1 to 15 nm, which constitutes 86% of the total amount of nanotubes (Fig. 2b). The minimum outer and inner diameters of the nanotubes are 3 and 1 nm, respectively, and the maximum diameters, 125 and 52 nm.

We may assume that the significant scatter of the diameters of carbon nanotubes, observed in this study, can be accounted for by the mechanism of formation of catalyst nanoparticles of different sizes and shapes on flat undeveloped surfaces of salt crystals. The mechanisms may strongly differ, depending on a technique used to synthesize a catalyst and on the nature of its support. Use of silicas as supports gives a narrower diameter distribution of nanotubes [2]. CNT with diameters of 10–35 nm could be synthesized with a Ni-catalyst supported by silica of the MCM-41 type, and those with diameters in the range 35–52 nm, with a Co-catalyst on the same support. The authors of [2] attributed this behavior to the uniform deposition of the catalysts on the surface of silicon oxide, which is achieved by the application of a method that consists in chemisorption of metal complex compounds, and by the ordered structure of MCM-41 with uniform pores.

The potential advantages of the method of synthesis of carbon nanotubes with water-soluble substrates consist in that the adverse influence exerted by corrosive media in the stage of support separation on the modifying component of nanotubes is eliminated. For example, dissolution of aluminum oxide, on which boron-containing CNT are synthesized, with hydrofluoric acid may lead to a chemical reaction with release of BF_3 and HBF_4 because of the formation of the energetically more favorable B–F bond. Consequently, the content of boron in CNT will decrease under these synthesis conditions, which is undesirable if, e.g., carbon nanotubes are used in lithium capacitors as an active filler. In [11], when creating a nanocomposite material in the form of CNT bimodified with nitrogen and nickel, we separated nanotubes from Al_2O_3 with NaOH under hydrothermal conditions, which was due to the solubility of nickel in acids. According to XPS data, a treatment of a sample with an alkali failed to completely dissolve the matrix and led to the formation of a $NiAl_2O_4$ admixture on the outer surface of CNT. A tendency in the industrial development is application of waste-free technologies. In synthesis of CNT with water-soluble catalyst supports, this goal is achieved by their repeated use in the chemical cycle upon recovery from solution.

CONCLUSION

A method for synthesis of carbon nanotubes with water-soluble catalyst supports was developed. The method allows regeneration of the catalyst supports via their recrystallization from aqueous solutions.

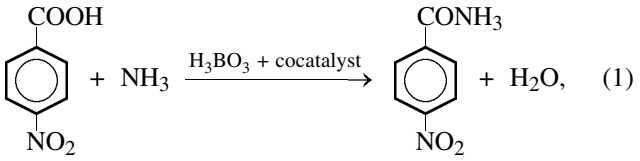
Received March 1, 2006

Abstract—The effect of cocatalysts on the reaction of 4-nitrobenzoic acid with ammonia catalyzed by boric acid was studied.



DOI: 10.1134/S107042720608012X

We have shown previously [1] that the system constituted by boric acid and PEG-400 (polyethylene glycol) efficiently catalyzes the formation of 4-nitrobenzamide in the reaction of 4-nitrobenzoic acid with ammonia. The reaction has been studied in various media, and it was suggested that PEG-400 acts as a cocatalyst, forming with boric acid a complex exhibiting enhanced acidity [2].

Since the acidity of boric acid is also enhanced in its interaction with other alcohols [3], it was of interest to examine their effect on the reaction in question.

This study deals with the effect of various cocatalysts on the activity of boric acid in the catalysis of the formation of 4-nitrobenzamide.

As cocatalysts we tested various polyhydric alcohols and polyethylene glycols (PEGs):

where cocatalyst is PEG-400, PEG-13, PEG-1000, PEG-2000, PEG-115, dibenzo-18-crown-6, ethylene glycol, diethylene glycol, triethylene glycol, or glycerol.

The reaction was performed in 1,2,4-trichlorobenzene, which proved to be one of the most convenient solvents ensuring high yield of 4-nitrobenzamide [2]. The cocatalyst performance was judged from the yield of 4-nitrobenzamide under equal other conditions. The results are listed in the table.

As can be seen from the table, not only PEG-400 (run no. 1) but also other PEGs (run nos. 2–7) are effective as cocatalysts. The PEG size affects their performance insignificantly. For example, the molecular weights of the PEGs used vary by more than

Yield of 4-nitrobenzamide in the presence of boric acid and various cocatalysts [solvent 1,2,4-trichlorobenzene, 170–175°C, reaction time 6 h (12 h), molar ratio 4-nitrobenzoic acid : boric acid : cocatalyst 1 : 0.02 : 0.009]

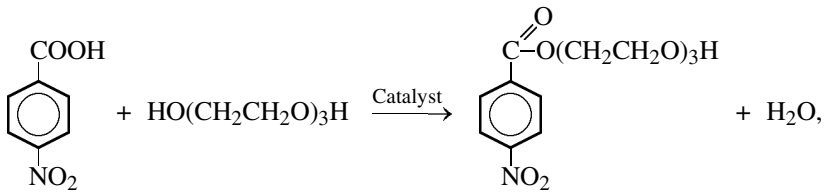
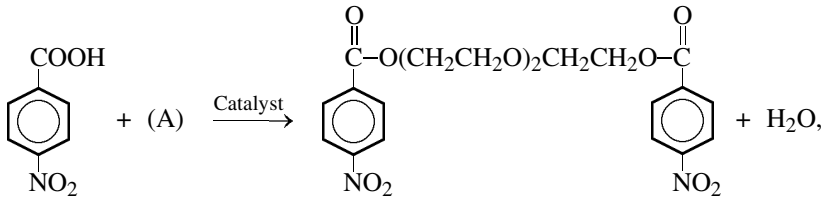
* In run nos. 3, 7, 12, and 14, we took 15 mol % cocatalyst and 33 mol % boric acid.

** Total yield of 4-nitropbenzamide and 4-nitrobenzoic acid esters, calculated from the amount of unchanged 4-nitrobenzoic acid. In parentheses are the yields of 4-nitrobenzamide at a reaction time of 12 h.



an order of magnitude, whereas the highest and the lowest yields of 4-nitrobenzamide differ by a factor of only 1.6. At the reaction time increased from 6 to 12 h, the yield of 4-nitrobenzamide becomes almost quantitative. The amounts of boric acid and cocatalysts, required to attain a high yield of 4-nitrobenzamide, may vary in a wide range (run nos. 2 and 3 with PEG-13, nos. 6 and 7 with PEG-115).

All the cocatalysts that proved to be effective well solubilize boric acid and are known as phase-transfer catalysts [4]. At the same time, dibenzo-18-crown-6 widely used in phase-transfer catalysis does not ensure formation of 4-nitrobenzamide (run no. 8).



Systems constituted by boric acid and polyhydric alcohols (run nos. 9–11, 13) do not catalyze the reaction either. We, however, did obtain 4-nitrobenzamide with triethylene glycol and boric acid taken in a larger amount (run no. 14). However, one more compound is formed in this case along with the target product (TLC data: 4-nitrobenzoic acid, R_f = 0.54; 4-nitrobenzamide, R_f = 0.18; unknown compound, R_f = 0.82). This mixture melts at a lower temperature (150–170°C) than does 4-nitrobenzamide (mp 196–197°C [5]). The IR spectrum of this mixture contains, along with the 4-nitrobenzamide bands (1660, 3400, 3500 cm^{-1}), also bands at about 1720 and 1280 cm^{-1}, characteristic of esters [6]. Apparently, the product is a mixture of 4-nitrobenzamide and an ester formed from 4-nitrobenzoic acid and triethylene glycol.

It is not improbable that 4-nitrobenzamide is formed by aminolysis of such esters. To verify this assumption, we studied the esterification of 4-nitrobenzoic acid with triethylene glycol in the presence of various esterification catalysts. As solvent we used 1,2,4-trichlorobenzene, with *o*-xylene added to provide removal of the released water by azeotropic distillation. The reaction was performed to complete conversion of 4-nitrobenzoic acid (TLC monitoring); sulfuric acid and tetrabutoxytitanium, previously used for preparing 4-nitrobenzamide [1], were taken as catalysts.

We found that sulfuric acid and, to a lesser extent, tetrabutoxytitanium catalyze the esterification. A TLC analysis showed that, in the presence of sulfuric acid, the spot corresponding to 4-nitrobenzoic acid disappears after the 3-h reaction, and two new spots with R_f = 0.34 and 0.82 appear. In the presence of tetrabutoxytitanium, the reaction is slower; the product with R_f = 0.82 is formed first, and the spot of the starting 4-nitrobenzoic acid disappears only in 7 h, with the appearance of a spot with R_f = 0.34. The bottoms formed on distilling off the solvent contain products with the same R_f values. These products were identified by the IR spectrum as esters. Apparently, 4-nitrobenzoic acid reacts with both hydroxy groups of triethylene glycol to form mono- and diesters:

(2)

(3)

where the catalyst is H_2SO_4 or $Ti(OBu)_4$.

However, bubbling of ammonia for 4 h through the reaction mixture containing 4-nitrobenzoic acid esters did not give 4-nitrobenzamide (TLC analysis). Apparently, catalysis by the system constituted by boric acid and triethylene glycol is weak, and 4-nitrobenzamide is formed directly by the reaction of ammonia with 4-nitrobenzoic acid, rather than with its triethylene glycol esters.

The low performance of polyols as cocatalysts suggests that the formation of an acidic complex from

boric acid and an alcohol is not the decisive factor of the catalysis in contrast to what has been assumed previously [2].

It is known [3] that alcohols reacting with boric acid favor its extraction from aqueous solutions into low-polarity organic phases, such as toluene, decane, and *o*-xylene. Low-molecular-weight polyols, which are readily soluble in water, hardly promote the transfer of boric acid into low-polarity solvents. It is not improbable that, in the synthesis of 4-nitrobenzamide too, polyols, in contrast to PEGs, solubilize boric acid in 1,2,4-trichlorobenzene only weakly, and the catalysis becomes inefficient.

The amidation actually occurs in a multiphase system consisting of gaseous ammonia, a low-polarity solvent, and 4-nitrobenzoic and boric acids, which are poorly soluble in this solvent. Apparently, the added PEG initially forms an ester with boric acid, which is more soluble in the low-polarity medium and is the true amidation catalyst:

$$\rangle B{-}OH + H(OCH_2CH_2)_nOH \rightarrow \rangle B{-}O(CH_2CH_2O)_nH + H_2O. \quad (4)$$

At the same time, the role of PEG is hardly restricted to the solubilization of boric acid. We have shown previously [1] that tetrabutoxytitanium, which is readily soluble in nonpolar solvents, also catalyzes the synthesis of 4-nitrobenzamide only in the presence of PEG-400.

The boric acid ester formed can solubilize other molecules (ammonia, 4-nitrobenzoic acid, its ammonium salt) and play the role of a microreactor of a sort, forming a microphase with a high concentration of the reactants adsorbed on the PEG chain [7]. Boric acid can act as a center binding both the reactants and PEG molecules [8].

It is not improbable that other active catalysts of 4-nitrobenzamide synthesis (tetrabutoxytitanium, dimethyl hydrogen phosphite, phosphoric and phosphorous acids [1]) also form esters with PEG, which are subsequently involved in the catalysis.

The absence of free hydroxy groups capable of the reaction with boric acid and the high selectivity to the size of the transferred particles [9] can be responsible for the low catalytic activity of dibenzo-18-crown-6 in the synthesis of 4-nitrobenzamide.

EXPERIMENTAL

4-Nitrobenzoic and boric acids, *o*-xylene, 1,2,4-trichlorobenzene, ethylene glycol, diethylene glycol, triethylene glycol, tetrabutoxytitanium, ammonia, and PEG-400 were purified and used as described in [1, 2]. The other PEGs, dibenzo-18-crown-6, and sulfuric acid (technical and pure grade) were used without additional purification. Glycerol was dried over sodium sulfate and vacuum-distilled.

A chromatographic analysis of the mixtures and evaluation of the product purity were performed on Silufol UV-254 plates, eluents acetone–hexane and acetone–chloroform, development in the UV light. The IR spectra were recorded on a UR-20 spectrometer (KBr pellets). The procedures for the synthesis of 4-nitrobenzamide, analysis of the mixtures, and evaluation of the product purity were the same as in [1]; an additional amount of the target product was isolated from the reaction mixture by distilling off the solvent in a vacuum. Unchanged 4-nitrobenzoic acid was isolated by evaporation of the ammonia mother liquor to 10 ml, acidification with concentrated HCl to pH 1, filtration, and washing of the precipitate with 10 ml of water.

The esterification was performed in the amidation installation as follows. 4-Nitrobenzoic acid (2.0 g, 12.0 mmol), triethylene glycol (1.9 g, 12.7 mmol), and sulfuric acid (0.03 g, 0.3 mmol) or tetrabutoxytitanium (0.1 g, 0.3 mmol) were heated to 160–165°C in 30 ml of trichlorobenzene containing *o*-xylene; the *o*-xylene–water azeotrope was distilled off using a Dean–Stark trap. The reaction was performed until 4-nitrobenzoic acid was fully consumed (TLC monitoring). After that, the temperature was elevated to 170–175°C, and ammonia was bubbled for 4 h.

CONCLUSIONS

(1) The system constituted by boric acid and polyethylene glycol (PEG-400, PEG-13, PEG-115, PEG-1000, PEG-2000) is an effective catalytic system for synthesis of 4-nitrobenzamide by the reaction of 4-nitrobenzoic acid with ammonia.

(2) The effect of polyethylene glycols as cocatalysts is specific. Lower polyols and dibenzo-18-crown-6 used instead do not ensure formation of 4-nitrobenzamide.

(3) Triethylene glycol esters of 4-nitrobenzoic acid do not transform into 4-nitrobenzamide under the reaction conditions.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Model of Heterogeneous Hydrodynamic Coagulation of Microdrops

V. V. Tarasov, N. F. Kovalenko, N. E. Kruchinina, and S. A. Shilin

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received October 5, 2005; in final form, January 2006

Abstract—The Eley–Rideal and Langmuir concepts of surface reactions were used to develop a model of heterogeneous hydrodynamic coagulation of diluted "oil-in-water" emulsions (0.1–2.0 vol %). The mathematical model was verified, and factors that govern the coagulation rate were revealed.

DOI: 10.1134/S1070427206080131

Coagulation and flocculation [1] are widely used in practice for purification of wastewater to remove dispersed particles. Recently, the method of heterogeneous hydrodynamic coagulation (HHC) has been receiving a large development effort because its use can markedly raise the drop size in emulsions stable against sedimentation and accelerate their separation by a factor of 100–200. The HHC procedure and the apparatus used were described in [2, 3]. The same publications described a method for preparation of emulsions comparatively stable against sedimentation, whose light absorption decreased by no more than 10–15% per day. In [2], basic kinetic data, used in the present study to verify the model developed, were obtained.

The HHC mechanism is based on the Deryagin–Landau–Verwey–Overbeek (DLVO) theory [4]. The kinetic energy of correctly organized emulsion flows favors overcoming of potential barriers in the DLVO curve [4], which accelerates the coagulation process. Adsorption of droplets on the apparatus walls probably leads to formation of large droplet aggregates (clusters). A part of a cluster grown is split-off under the action of incident vortices (pulsations). In our opinion, the maternal part of the cluster is smaller in size than the split-off daughter part. Having become not attached to wall, the latter comes under the influence of the Archimedes force and ascends into the comparatively "quiet" part of the fluid in the apparatus. As a result, a certain part of coarsened clusters is removed from the HHC process in the form of transparent (in the case of coalescence) or nontransparent (in the absence of coalescence) drops. The walls and other immobile parts of the apparatus "work" as size converters: small drops arrive to leave coarse.

The aim of our study was to develop a mathematical model of HHC and verify its validity.

EXPERIMENTAL

We used as fluids being dispersed Midel 7131 transformer oil, I-40 machine oil, olive oil, and decane [5].

It is reasonable to assume that the stage of adsorption of microdrops on a solid surface is a necessary stage of HHC. Coagulation becomes a rather probable process because flows of droplets attack at a high velocity the surface of a solid, especially in the case when they have a considerable affinity to this surface. Presence of coarse drops of a second organic solvent facilitates coagulation. Coarse drops can even lead to disappearance of the latent period frequently accompanying the development of HHC. In this study, we considered the process of surface coagulation without any additional solvent. In our opinion, the mechanism suggested includes the following stages [2]: formation of guiding (nucleating) centers from microdrops, surface coagulation of fine drops with the guiding centers, interaction of the guiding centers with coarse drops (coalescence) or with pulsations of the moving fluid, detachment of coarsened drops or drop clusters from the solid surface, and secondary disintegration of coarsened drops or decomposition of drop clusters. The last of the processed listed above is undesirable and should be minimized.

Figure 1 shows how guiding centers are formed and "grown" coarse drops are detached from these centers under attack by other drops or fluid pulsations. The interaction of an adsorbed drop with a drop that attacks the former from the bulk is the basis for further consideration or the so-called Eley–Rideal process.

Formation of clusters from a set of droplets is an energetically favorable process because the droplets associate to form contacts with one another. This leads to a decrease in the free surface energy. Let us use the Eley–Rideal concepts based on the Langmuir theory, which have already been successfully used in description of the kinetics of surface reactions [6, 7]. We mean the so-called SV mechanism: the interaction between a droplet (molecule) in the adsorbed state and a droplet (molecule) incident from the bulk [6, 7]:

$$r = \mathrm{d}x/\mathrm{d}t = -kax\theta = -kaxx/(x + b) = -kax^2/(x + b). \quad (1)$$

Let us consider the irreversible process. The mass rate of the process, r, has dimensionality of grams per square centimeter per second. We assume that the rate at which the drop concentration x decreases is proportional to the concentration itself, to the fraction θ of the surface of walls of flown-around solid bodies (dimensionless), occupied by adsorbed drops, and to the specific surface area a of contact between the phases (cm^{-1}). The rate constant k has dimensionality of the mass-transfer coefficient ($cm\ s^{-1}$).

The quantity k is constant only in the particular case of the kinetic mode. In the transition and diffusion modes, the rate coefficient k is not a constant, being a function of the hydrodynamic conditions, $k = f(\mathrm{Re}, \mathrm{Sc})$. The dimensionless quantity θ is calculated by the Langmuir isotherm equation.

Let us consider the first case, when the adsorption of drops on the solid surface is strong. In this case, $b \ll x$ (b is a coefficient having dimensionality of the mass concentration of drops, $g\ cm^{-3}$). Then, $r = \mathrm{d}x/\mathrm{d}t = -kax$. Integrating over the interval from x_0 to x, we obtain

$$-\ln(x/x_0) = kat \quad \text{or} \quad \ln(x_0/x) = kat. \quad (2)$$

In the second case of $b \gg x$ at any t, when the adsorption of droplets is very weak,

$$r = \mathrm{d}x/\mathrm{d}t = -kax\theta = -kab^{-1}x^2, \quad (3)$$

$$(x^{-1} - x_0^{-1}) = kab^{-1}. \quad (4)$$

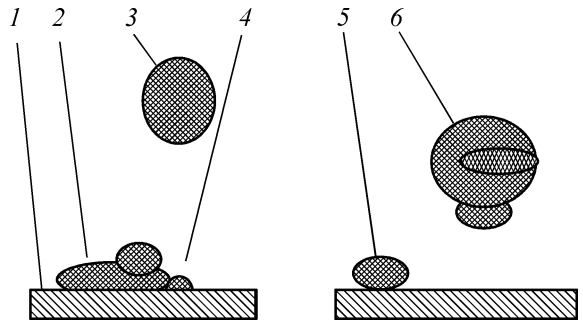

Fig. 1. Schematic of the attack on a guiding center of coagulation by a coarse drop: (*1*) Solid, (*2*) guiding center (drop or droplet cluster), (*3*) attacking drop of an organic substance, (*4*) microscopic droplet, (*5*) residue of the guiding center, and (*6*) detached coagulate (cluster).

At a direct proportionality between x and A we have

$$(A^{-1} - A_0^{-1}) = ka\alpha^{-1}b^{-1}t, \quad (5)$$

where A and A_0 are the colorimetrically measured light absorptions.

In this case, both parts of the equality are dimensionless. It is the dimensionless equation of this kind that is convenient for use. The coefficient α has a dimensionality inverse to that of b.

In the third case of the same model, when none of the terms of the Langmuir denominator can be neglected (which frequently occurs in experiments), we have the equation

$$\ln(A_0/A) + \alpha b(A^{-1} - A_0^{-1}) = kat. \quad (6)$$

The quantity ka has dimensionality of inverse time (s^{-1}). All the terms of Eq. (6) are also dimensionless.

The linearity in the coordinates $\ln(A_0/A) + \alpha b(A^{-1} - A_0^{-1}) = f(t)$ indicates that, on the one hand, the HHC mechanism is valid, and, on the other, αb is close to unity. It is known that, in a homogeneous process, the coagulation rate constant is independent of the hydrodynamics and the equation has a simple form [8]:

$$c^{-1} - c_0^{-1} = -(K_0/2)t, \quad (7)$$

where $c^{-1} - c_0^{-1}$ is the difference of the inverse running and initial concentrations.

In this case, the coagulation rate constant is well described by the dependence $K_0 = 8k_BTc_c/3\mu$ [8],

where k_B is the Boltzmann constant; T, absolute temperature; and $c_c \approx 1$, effective concentration. Thus, the equations of heterogeneous hydrodynamic coagulation, (4) and (5), and the equation of homogeneous coagulation, (7), are identical in form, but have coefficients with different physical meanings.

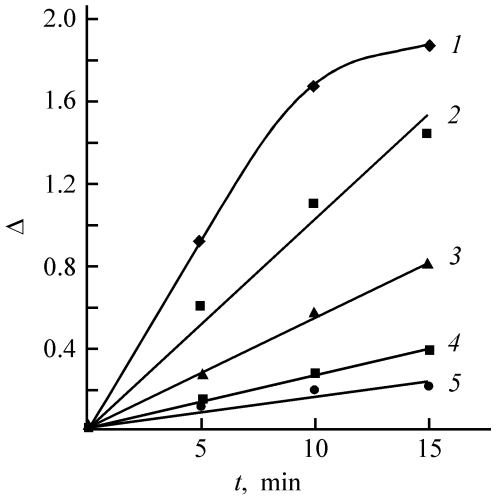

Fig. 2. Dependence $\Delta = f(t)$ in the case of coagulation of a microscopic emulsion of Midel 7131 fluid. (t) Coagulation time. Rotation speed of discs (rpm): (*1*) 2200, (*2*) 1100, (*3*) 700, (*4*) 500, and (*5*) 400.

Verification of the SV model. The relative root-mean-square deviation of the results obtained (Δ) was 12%, which points to a sufficiently good reproducibility. The basic model is verified using the data of [2]. Equations (4) and (5) make it possible to check the simplest coordinate metrics, which will be further named the plot of the Δ–t function. If the HHC concepts developed are correct, the kinetic curves will be straight lines in the coordinates $\Delta = (A^{-1} - A_0^{-1}) = (\alpha^{-1}b^{-1}ka)t$. It is important that there should not occur any repeated disintegration of drops. Such a situation is possible at degrees of purification of about 70–75%.

Let us use Table 1, which was compiled using the data of [2]. Table 1 lists all the quantities necessary for verifying the model. In addition, it contains the quantity n, rotation speed of a rotor with discs (rpm). The data of Table 1 are represented by the linear plots $\Delta = (A^{-1} - A_0^{-1}) = (\alpha^{-1}b^{-1}ka)t$, which indicates that the model is correct and the SV mechanism is valid [Eqs. (4), (5)].

In Fig. 2, the functions $\Delta = f(t)$ are plotted for the Midel 7131 fluid at all disc rotation speeds listed in Table 1.

Table 2. Cumulative data on the kinetics of HHC of various emulsions in relation to the rotor rotation speed n

n, rpm	Equation for the HHC rate			
	olive oil	I-40 oil	Midel 7131	Decane
400	$\Delta = 0.0038t$, $R^2 = 0.956$	$\Delta = 0.0077t$, $R^2 = 0.979$	$\Delta = 0.0184t$, $R^2 = 0.997$	$\Delta = 0.0262t$, $R^2 = 0.996$
500	$\Delta = 0.0088t$, $R^2 = 0.996$	$\Delta = 0.0107t$, $R^2 = 0.998$	$\Delta = 0.0248t$, $R^2 = 0.995$	$\Delta = 0.0622t$, $R^2 = 0.994$
700	$\Delta = 0.0198t$, $R^2 = 0.995$	$\Delta = 0.0185t$, $R^2 = 0.983$	$\Delta = 0.0531t$, $R^2 = 0.997$	$\Delta = 0.1106t$, $R^2 = 0.988$
1100	$\Delta = 0.0309t$, $R^2 = 0.996$	$\Delta = 0.0340t$, $R^2 = 0.991$	$\Delta = 0.0962t$, $R^2 = 0.987$	Nonlinear
2200	$\Delta = 0.0793t$, $R^2 = 0.994$	$\Delta = 0.044t$, $R^2 = 0.983$	Nonlinear	"

As expected, we have for olive oil and I-40 oil straight lines that pass through the origin of coordinates in the whole interval of t, whereas in the case of decane, such a linearity is only observed up to $A < 1.5$ (not shown in Fig. 2). This can be attributed to reversibility of the process and to secondary disintegration. It is noteworthy that, while the value of Δ is lower than 1.4–1.6, the $\Delta = f(t)$ plots are linear. This fact is particularly clearly manifested for the emulsion of Midel 7131 fluid (Fig. 2) and in the case of the decane–water system. In the case of Midel 7131, only a single line, and specifically the steepest, is abruptly curved after $\Delta = 1.6$, which corresponds to a degree of purification to remove drops as high as 70%. The confidence factors of the approximation of plots like those shown in Fig. 2 are very close to unity, which points to a good adequacy of the SV model.

The slope of the $\Delta = f(t)$ plots is the HHC rate coefficient. This slope depends on the disc rotation rate, which points to the diffusion and transition modes.

Table 2 lists the results of processing of kinetic curves by Eq. (5) for all the four fluids. The aim of this processing is to find a full set of equations for the HHC rate. The confidence factors of the approximation lie in the interval $R^2 = 0.994 - 0.956$. It is clear from the data obtained that there is a linear relationship between the HHC rate coefficient and the disc rotation speed (Fig. 3).

We obtained, instead of straight lines in log–log coordinates (observed in the case of mass-transfer processes), straight lines in the natural coordinates φ–n, where n is the disc rotation speed, and φ, the slope of the $\Delta = f(t)$ plot. The HHC rate coefficients were too strongly dependent on the rotor rotation speed. Presumably, the HHC rate coefficients reflect, in contrast to the rate constants of homogeneous coagulation, not only the physical properties of fluids, but also the inertia properties of elements of the fluids, including "oil" drops. This is the principal distinctive feature of the concepts of the HHC kinetics, we developed, from those described by Fuks and Reist [8] and recommended for consideration of the kinetics of homogeneous coagulation.

If we use the known criterial equations that relate the Sherwood numbers to the Reynolds and Schmidt numbers, in an attempt to find the parametric sensitivity p in the equation $\mathrm{Sh} = \mathrm{const}\,\mathrm{Re}^p\mathrm{Sc}^q$, then we obtain too high values of p, up to 2.90 in the case of I-40 oil. Generally speaking, we never obtained p values lower than 1.05. Such a behavior is not characteristic of "purely diffusion" processes, for which p is in the range 0.5–0.8. Consequently, the HHC rate coefficients should be regarded as integrated factors reflecting both the physicochemical (molecular) and hydrodynamic (inertia) properties of the systems.

Thus, we obtained a definite proof that the SV model is valid. Its natural limitation is that it disregards the reversibility of the process, manifested in the repeated disintegration of drops. This disintegration can be accounted for by an additional term in the differential equation (1); however, this complicates the simple form of the analytical equation.

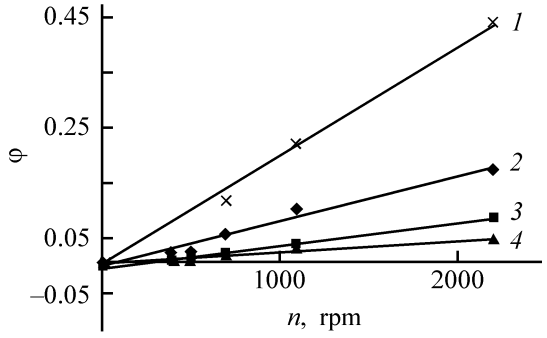

Fig. 3. Slope φ of the functions $\Delta = f(t)$ vs. the disc rotation speed n. Type of emulsion: (*1*) decane, (*2*) Midel 7131, (*3*) I-40 oil, (*4*) olive oil.

CONCLUSIONS

(1) A mathematical model of the kinetics of heterogeneous hydrodynamic coagulation of emulsions with particle size of 1–5 μm and concentration of 0.1–2.0 vol % was developed.

(2) The mathematical model of the kinetics of heterogeneous hydrodynamic coagulation was constructed on the basis of Eley–Rideal equations which coincide in form with the kinetic equations of homogeneous coagulation, but have coefficients with a different physical meaning.

(3) A strong, untypical of mass-transfer processes, dependence of the kinetics of heterogeneous hydrodynamic coagulation on the flow velocities of the emulsions being separated relative to the apparatus walls was found.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Study of the Relationship between the Thermodynamic Quality of Mobile Phases and Their Strength for the Critical Conditions of Liquid Chromatography of Polystyrenes

L. S. Litvinova and N. G. Bel'nikevich

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received March 9, 2006

Abstract—The relationship between the thermodynamic quality of mobile phases and their strength ε was studied for the critical conditions of liquid chromatography. The chromatography of reference polystyrene samples was carried out in the adsorption and exclusion modes, and also under critical conditions, with binary mobile phases and a silica gel column used. The thermodynamic quality of solvent mixtures with respect to one another was evaluated by the intrinsic viscosity [η].

DOI: 10.1134/S1070427206080143

Liquid chromatography under critical conditions (LCCC) is a promising method for analysis of polymers with various types of molecular polydispersity. A common LCCC strategy is to suppress the separation selectivity for one of molecular characteristics (usually, molecular weight), which provides separation by another parameter [1–11].

An important specific feature of LCCC is the necessity for fine adjustment of interactions within the system. This is achieved by careful selection of both mobile and immobile phases for the polymer systems studied and by varying the temperature of the experiment. Another distinctive feature of LCCC is that mixed solvents are used as mobile phases. As a rule, this is a mixture of adsorption-active and adsorption-inactive solvents. Thus, ternary polymer systems (a polymer in a binary solvent) are widely used in LCCC.

In liquid chromatography, the distribution coefficient K_d is related to a change in the Gibbs energy ($-\Delta G$) for polymer–solvent–adsorbent systems [1, 12]:

$$-\Delta G = RT \ln K_d = -\Delta H + T\Delta S, \qquad (1)$$

where $-\Delta H$ is a change in the enthalpy; ΔS, change in entropy upon transition of a macromolecule from the interparticle (free) volume into the immobile phase; T, temperature (K); and R, gas constant.

It follows from Eq. (1) that $\Delta H = T\Delta S$ for $K_d = 1$. Consequently, the change in the entropy at the critical point, when a macromolecule passes from solution into the adsorbent, is compensated for by a change in the enthalpy corresponding to the interaction between the macromolecule and active centers of the adsorbent.

It is important that the critical conditions can be created for the same polymer–adsorbent combination in mixtures of different solvents.

Because a macromolecule competes with solvent molecules for the active centers of the adsorbent, changes in the macromolecule–adsorbent interactions are due to a change in the interaction between the mobile phase and the adsorbent, provided that the system is in equilibrium. The interaction of the mobile phase with the adsorbent and the polarity of the former can be evaluated using Snyder's parameters: solvent strength ε^0 [13] and polarity index P' [14].

A specific feature of polymers is that the molecular conformation (i.e., intramolecular interactions determining the coil size in solution) depends on properties of a solvent, specifically, on its thermodynamic quality. It can be assumed that the conformational changes in solution, which can be evaluated by the intrinsic viscosity [η] [15], may be a reason for changes in the chromatographic behavior of macromolecules.

Table 1. Mark–Kuhn–Hauwink parameters K and α, Snyder's parameters P' and ε^0, and values of the Flory–Huggins constant χ and of the second virial coefficient A_2 for individual solvents

Solvent	α [16]	$K \times 10^3$, ml g^{-1}, [16]	T, °C	P' [14]	$\varepsilon^{0*}_{SiO_2}$ [13]	χ [16]	$A_2 \times 10^4$, mol cm^3 g^{-2} [16]
MEK	0.64	17.1	35	4.7	0.39	0.491	1.00
	0.635	19.5	25

	0.5	76	35				

* $\varepsilon^0_{SiO_2} = 0.77\varepsilon^0_{Al_2O_3}$.

Thus, the chromatographic system is sufficiently fully described in analysis of polymers by three parameters: K_d, [η], and ε (where ε is the strength of a mixture of solvent), which are accessible both to evaluation or measurement and to study of their mutual influence. The critical conditions with constant K_d are ideally suitable for analysis of the mutual influence of the parameters ε and [η]. The best suitable object for a study of this kind is a model polymer, polystyrene (PS), for which the thermodynamic quality of individual solvents has been long and thoroughly studied [16] (Table 1).

It should be noted that, recently, there have been reports in which different concepts concerning the relationship between the thermodynamic quality of a mixed solvent and its strength under dynamic conditions were presented. For example, it has been shown previously that, in LCCC, the polarity of binary mobile phases, necessary for reaching the point of enthalpy-entropy compensation, increases as the thermodynamic quality of such mobile phases is improved [17–19]. In these studies, the thermodynamic quality of a solvent was evaluated by the intrinsic viscosity, with the polarity of solvent mixtures described by Snyder's polarity index P' [14].

When studying the chromatographic behavior of PS on silica gel in mixed mobile phases composed of a solvent and a precipitating agent (hexane), the authors of [20, 21] came to a conclusion that the critical conditions cannot be related to the thermodynamic property of mobile phases, specifically, to values of the Mark–Kuhn–Hauwink parameter α. They also compared the solution strengths ε, calculated for critical formulations by an empirical formula [21], with the hydrodynamic radii of the molecules. When analyzing the results mentioned above, Macko and Hunkeler also noted that the critical conditions are independent of the thermodynamic quality of a solvent.

Thus, in view of the wide variety of opinions concerning the influence of the thermodynamic quality of a solvent on the energy characteristics of the polymer–adsorbent interaction in LCCC conditions, we found it appropriate to carry out an additional study.

EXPERIMENTAL

We used reference PS samples (Waters Co,) with molecular weights M of 1.4 to 2600 kg mol^{-1} ($M_w/M_n \le 1.1$, where M_w is the mass-average molecular weight, and M_n, number-average molecular weight) and PS samples with M of 120 and 460 kg mol^{-1} ($M_w/M_n \le 1.15$).

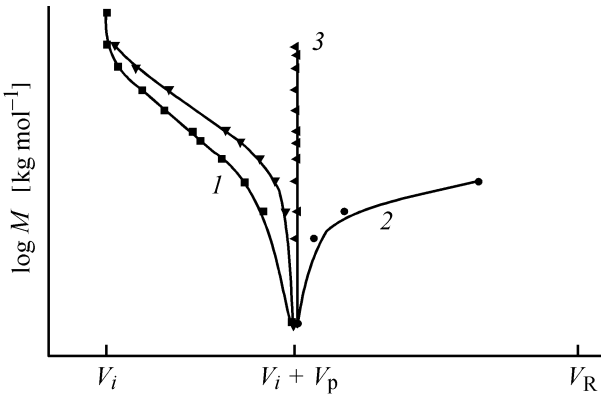
As reference samples in thin layer chromatography (TLC) served polynuclear aromatic hydrocarbons: benzo[α]pyrene (98%, Fluka Chemie, Switzerland), chemically pure scintillation naphthalene (Reakhim), and coronene (99%, Aldrich).

As solvents were used cyclohexane ("for spectroscopy" grade, Merck, Darmschtadt, Germany), pure carbon tetrachloride, analytically pure toluene, and pure methyl ethyl ketone (MEK) (Reaktiv, St. Petersburg, Russia), all of which were additionally purified by distillation. Tetrahydrofuran (Reaktiv) was distilled over KOH immediately prior to use.

Liquid chromatography was performed on a KhZh-1309 microcolumn chromatograph equipped with refractometric and photometric detectors. The results of analysis were recorded and processed using the Mul'tikhrom software (Ampersend, Russia). Mixed mobile phases were prepared by weighing components with an accuracy of no less than 0.1%.

Table 2. Chromatographic data for PS with M = 1.6–2600 kg mol^{-1}, Snyder's parameters for solvent mixtures, and viscometric data for PS with M = 120 and 460 kg mol^{-1}

Solvent mixture	Composition of the mobile phase at the critical point	Snyder parameters		[η], dl g^{-1}, for PS with indicated M, kg mol^{-1}	
		P'	ε	460 (25°C)	120 (35°C)
Toluene/CCl_4	39.89/60.11	2.04	0.220	1.15	0.48
Cyclohexane/Toluene	21.02/78.98	1.89	0.215	1.14	0.48
CCl_4/MEK	99.70/0.30	1.60	0.141	1.15	0.48
Cyclohexane/MEK	89.76/10.24	0.65	0.082	0.66	0.35
Cyclohexane/THF	88.58/11.42	0.58	0.091	0.71	0.35



A 0.5 × 300 mm fluoroplastic column packed with Biospher psi 300 spherical silica gel with a particle size of 5 μm (Labio, Prague, Czechia) was equipped with a water jacket. The column temperature was maintained at 35 ± 0.05°C with a water thermostat. The concentration of PS samples dissolved in the corresponding mobile phase and introduced into the column was 1 mg ml^{-1}; sample volume, 0.1 μl, flow rate of the mobile phase, 4 μl min^{-1}.

The thin layer chromatography was performed on 10 × 10 cm Sorbfil and PTSKh-AF-V-UF (Sorbpolimer, Krasnodar, Russia) plates. After the plates were activated at 105°C for 45 min, solutions of the test compounds in hexane (1 mg ml^{-1}) were deposited with a calibrated capillary (1 μl) (Camag, Switzerland) at a distance of 1 cm from the plate edge. The chromatography was performed in a saturated or unsaturated N-chamber containing 10 ml of a mobile phase (hexane or mixed solvents of composition listed in Table 2). UV_{254} and UV_{366} lamps were used detect the chromatographic zones of polynuclear hydrocarbons. The error of R_F determination (relative standard deviation) did not exceed 5% at n = 3 repetitions.

The intrinsic viscosity [η] of PS solutions in mixed solvents (including the LCCC compositions) was measured by the standard method [22] in a capillary Ubellohde viscometer at 25 ± 0.05 and 35 ± 0.05°C. The outflow time of the solvent was no less than 100 s. PS samples were dissolved in solvent mixtures obtained by mixing the starting components in various volume ratios.

We used five different solvents for PS. Their ability to enhance or hinder PS adsorption was determined in a set of preliminary experiments by TLC. Cyclohexane and CCl_4 were chosen as solvents that favor PS adsorption, whereas THF, MEK, and toluene were used to suppress PS adsorption. Tetrahydrofuran, CCl_4, and toluene are good solvents for PS [16]. The quality of MEK is somewhat poorer [16], and cyclohexane is a theta-solvent at 35°C. Some parameters of the solvents used in the study are listed in Table 1.

We obtained dependences in the log M–V_R (V_R is the retained volume) for the cases of adsorption, exclusion, and critical conditions for various compositions of binary mobile phases. The calibration dependences for the three modes of liquid chromatography are shown schematically in the figure. The critical conditions were determined for five different mobile phases: toluene/CCl_4, cyclohexane/toluene, cyclohexane/THF, cyclohexane/MEK, and CCl_4/MEK. Mixtures composed of a solvent and a precipitating agent were not used in order to prevent occurrence of the precipitation chromatographic mode, because ambiguous results would be obtained otherwise. In all cases, the fact that the critical composition was reached was confirmed graphically by the point of

Schematic of calibration dependences in the log M–V_R coordinates for three modes of liquid chromatography: (*1*) exclusion, (*2*) adsorption, and (*3*) critical. (V_i) Interparticle (or dead) volume, (V_p) pore volume, and (V_R) retained volume.

intersection of the dependences of the retained volume on the composition of the mobile phase [23].

It should be particularly emphasized that the attainment of critical conditions itself is presumably determined by the thermodynamic property of the solvent: the higher the quality of a solvent, the more difficult task is obtaining a calibration plot corresponding to critical conditions. In other words, the width of the critical region depends on the thermodynamic quality of the solvent. In the case in question, it was particularly difficult to determine the critical conditions for the CCl_4/MEK mixture; A 1% change in the composition of the mobile phase resulted in that the chromatographic mode changed from adsorption to exclusion. Snyder's parameters were calculated for the critical compositions of the mobile phases, solvent strengths ε were measured, and the intrinsic viscosities were determined for PS with $M = 120$ and 460 kg mol^{-1} at 35 and 25°C, respectively.

As already noted, some authors [10, 20, 21] give preference, when comparing solvent–polymer interactions, to the exponent α. In the present study, the intrinsic viscosities were used to characterize the thermodynamic quality of solvent mixtures. The choice of this parameter was due to the ease of its experimental determination, as well as to its accuracy and sensitivity. It can be readily shown that the error in determining the intrinsic viscosity is an order of magnitude smaller than that in determining the exponent α, because at least two methods are to be used in the latter case. Making and substantiating the choice of the parameter responsible for the thermodynamic quality of solvent mixtures used in chromatographic conditions were described in more detail in [15].

To evaluate solvent properties, Snyder introduced two parameters: polarity index P' [14] and solvent strength ε^0 [13]. The polarity index P' reflects the ability of a solvent to interact with certain polar test compounds. This index is independent of the properties of the adsorbent, but allows a comparative estimate of solvent polarities. The parameter ε^0 is the relative energy of interaction of solvent molecules with the surface of the adsorbent [13]. The parameters P' and ε^0 are known for most of individual solvents [13, 14, 24]. Moreover, it was shown in [25] that these parameters correlate with each other for pure solvents and such adsorbents as silica gel and aluminum oxide. The correlation is only violated for alcohols and acids, which tend to form hydrogen bonds.

The polarity indices are commonly calculated for solvent mixtures by the additive formula $P' = \Sigma P_i \varphi_i$, where P_i are Snyder's polarity indices for pure components, and φ_i, their volume fractions in the mixture [26]. A more complicated task is calculation of the solvent strength ε for mixtures [13, 24, 27–29]. The reason is that the concentrations of mixture components in the solution bulk and on the surface of the adsorbent do not coincide, with the experimental determination of the latter under dynamic adsorption conditions remaining an unsolved problem.

Calculated values of the solvent strength ε for some mixtures can be found in the literature. Certain experimental data are used to calculate ε [13]. One of the most important parameters is the adsorbent activity. Apparently, the activities may be different even for adsorbents of the same chemical nature. A certain, the most probable in the opinion of those performing a calculation, value of the activity is, as a rule, used in calculations: 1 [21], 0.57 [26], or 0.83–0.66 [13]. Even this simple example shows that the strengths ε calculated by different authors will not coincide.

A more reliable way to determine ε for mixtures is the experimental technique, also developed by Snyder. In our study, values of ε for mixed solvents were calculated from retention factors R_F for polynuclear hydrocarbons, with R_F found using TLC.

Data on the critical compositions of the mobile phases, values of the parameters P' and ε, and intrinsic viscosities for PS are listed in Table 2. The following tendency can be seen: thermodynamically good solvents have high P' and ε; in other words, the better the thermodynamic quality of a mobile phase, the higher P' and ε for compositions corresponding to the critical conditions of liquid chromatography.

It is known that, in solvents of good thermodynamic quality, the temperature dependence of the viscosity is very weak [22, 30]. When the solvent quality deteriorates, the dependence becomes more pronounced. However, differences in intrinsic viscosity remain insignificant in a narrow temperature range. The data obtained confirm this conclusion. It was demonstrated in [19] for a mixture of poor thermodynamic quality, cyclohexane/MEK, that [η] weakly depends on temperature in the range from 25 to 35°C. This solvent mixture is the worst in thermodynamic regard. Consequently, it is admissible to compare results of chromatographic experiments at 5°C with viscometric data obtained at 35 and 25°C.

As can be seen in Table 2, a correlation between P' and ε is also observed for mixed solvents. In ad-

dition, mixtures with high thermodynamic quality have high Snyder's parameters and solvent strengths. Consequently, the same tendency as that in TLC is preserved in the column chromatography [17–19].

Let us consider the reasons why the results of the present study disagree with the conclusions made in [20, 21]. We chose for consideration the results of these authors because just their data were processed and discussed by Macko and Hunleker [10]. As already noted, Baran et al. [21] reported that the critical conditions are in no way related to the thermodynamic quality of a solvent. Possibly, such a conclusion resulted, in part, from an unsuccessful choice of binary mobile phases. First, the precipitation mechanism cannot be completely ruled out for such mixed mobile phases as hexane/MEK and hexane/ethyl acetate because the exponent α is lower than 0.5 for critical compositions [20]. Therefore, the authors of [21] took into account only three of the five mobile phases represented in their study. Second, mixtures with very close properties were studied. At least Snyder's parameters are very close for the critical compositions of these mixtures [1.9, 1.7, 1.7 [21]). In addition, the adsorbent activity was taken to be unity ($\alpha = 1$) when calculating the solvent strength. However, Baran et al. [21] found that the hydrodynamic radii of macromolecules are unequal under critical conditions reached in different mixtures. This points to the corresponding difference in the conformations of macromolecules. The authors of [10] calculated ε for the same mixtures by a simplified method [26] and came to the conclusions coinciding with those in [21].

Let us consider specific features of the behavior of the macromolecule–adsorbent interactions in the case when the solvent quality is improved. For small molecules in the absence of specific interactions, an increase in the solvent strength commonly leads to a decrease in retention. For polymers, however, K_d may remain unchanged as the adsorption activity of the solvent increases. This phenomenon can be attributed to unfolding of the chain and to an increase in the number of contacts of a macromolecule with the adsorbent surface. As the solvent quality is improved, intramolecular interactions become weaker and hinder to a lesser extent the unfolding of the polymer chain on the adsorbent surface. As a result, the number of contacts of the macromolecule with the adsorbent grows. The rise in the number of contact, in turn, leads to preservation of the values of K_α.

CONCLUSIONS

(1) The calibration dependences of V_R on $\log M$ were used to find the compositions of binary solvent mixtures that correspond to the critical conditions of liquid chromatography of polystyrene on a silicate adsorbent.

(2) Snyder's polarity indices P' were calculated, solvent strengths ε were experimentally determined by thin-layer chromatography, and intrinsic viscosities were measured for polystyrene with M_w = 120 and 460 kg mol^{-1}.

(3) The thermodynamic quality of the solvent, evaluated by the intrinsic viscosity for polystyrene, was correlated with Snyder's parameters P' and ε and a conclusion was made that, in chromatography of polystyrene on a silicate adsorbent, the strength of the mobile phase and its polarity are the higher, the better the thermodynamic quality of a binary mixture.

Abstract—Highly permeable aminovinylpyridine ion-exchange resins are synthesized by the reaction of epoxy/polyvinylpyridine prepolymers with aliphatic amines. Synthetic conditions are optimized and physicochemical and sorption characteristics of the resulting polyelectrolytes are examined.

DOI: 10.1134/S1070427206080155

Development of advanced ion-exchange processes stimulates research in the area of synthesis of pyridine-containing polycondensation polymers with desired physicochemical and adsorption properties.

In this context, simple routes to ion-exchange resins of the Ional series have been developed, based on condensation of allyl glycidyl ether with polyethylenimine and poly(2-methyl-5-vinylpyridine) [1] or of aliphatic amines and 2-methyl-5-vinylpyridine with epichlorhydrin [2], and their sorption characteristics with respect to noble and polyvalent metals have been reported [3, 4].

In this study, we synthesized aminovinylpyridine ion-exchange resins by condensation of prepolymers based on various epoxy compounds and poly(2-methyl-5-vinylpyridine) with aliphatic di- and polyamines and characterized the physicochemical and sorption properties of the products.

EXPERIMENTAL

Di- and polyamines (DPA) were purified as follows. Hexamethylenediamine (HMDA) was vacuum-distilled under Ar at 100°C and 2 mm Hg (mp 41–42°C); polyethylenepolyamine (PEPA) (MW 285, c_N 23%) and polyethylenimine (PEI) (MW 10×10^3, c_N 32%) were allowed to stand over granulated NaOH for six days. Poly(2-methyl-5-vinylpyridine) (PMVP) (MW 30×10^3) was prepared by radical polymerization of 2-methyl-5-vinylpyridine [5].

Di-, tri-, and tetraglycidyl epoxy derivatives of aniline, resorcinol, and ethylene glycol (DGA, DGER, DGEE), *m*- and *p*-aminophenols (T*m*-AP, T*p*-AP), *p*-phenylenediamine (TGE*p*-PDA), diaminodiphenylmethane (TGEM), diaminodiphenyl oxide (TGEO), and benzidine (TGEB) were prepared as in [6].

The ion-exchange resins were synthesized by polycondensation of 15% PMVP in ethanol with an epoxy compound (EC) at 50–70°C for 3–5 h (until the epoxy group content decreased by half). Then an aliphatic DPA was added and the mixture was allowed to stand for 2 h. The reaction mixture was poured on a tray and the solvent was removed. The resulting gel was cured at 80–100°C for 3–5 h, crushed, and screened to obtain the 0.25-mm fraction. Prior to addition of an aliphatic DPA, the residual epoxy groups were determined by argentometric back-titration according to GOST (State Standard) 12497–78.

The physicochemical characteristics of the resins were studied using the standard procedures [7, 8]. The IR spectra of the starting reagents, intermediates, and final products were recorded on a Specord M80 spectrophotometer (Carl Zeiss, Germany) using the KBr technique or with samples placed between KRS-5 glasses. The electronic absorption spectra were recorded on a Jasco instrument, model 7850 (Japan).

Sorption of V, Mo, and W was carried out from solutions of sodium metavanadate, molybdate, and tungstate in the static and dynamic modes. The speciation of the adsorbed metals was determined by IR spectroscopy.

The model reaction between EC and PMVP was studied IR- and UV-spectroscopically with an equimolar mixture of DGEE and 4-ethylpyridine (4EP) [9]. After 1 h of heating at 70°C, the initially trans-

TGEO	8.80	5.5	9.00	6.3	9.30	6.5

parent liquid turned to yellow, and the IR intensities of the out-of-plane vibrations of C–H bonds (822 cm^{-1}) in 4EP and of the bands of the epoxy ring in DGE (920 cm^{-1}) decreased by half, which was accompanied by the appearance of new bands of 4-ethylpyridinium at 1560 and 1640 cm^{-1}, whose intensity increased during heating. The UV spectrum of the prepolymers formed by the condensation of DGE with 4EP shows a strong absorption of the pyridinium salt near 254 nm.

To optimize the synthesis of the ion exchangers, we studied under similar conditions the effects of the reagent ratio, temperature mode, and time of curing of PMVP/EC prepolymers with aliphatic DPA on the static exchange capacity (SEC) and swellability V_{sp} of the resulting resins.

As in the case of the reaction between 4EP and DGEE, the condensation of PMVP with DGA or TGEM was performed in isopropanol at 70°C for 3 h to 50% consumption of the epoxy groups. Further curing of the prepolymer in the presence of PEI at 80°C for 5 h produced ion-exchange resins demonstrating simultaneously the properties of aliphatic and heterocyclic polyamines with SEC (0.1 N NaCl) ranging from 0.5 to 1.2 mg-equiv g^{-1}. In the case TGEM, at the reagent ratio of (1–3) : 1 : (3–1), the resulting resins demonstrate a limited swellability (3.0–4.5 ml g^{-1}) (Table 1).

Tables 2 and 3 show that 80°C and 5 h are the optimal temperature and time for the reaction of PMVP/TGEB prepolymers with PEPA. Further increase in temperature and time resulted in the SEC loss

Table 4. Heat resistance of resins in hot water (48-h treatment)

Anion exchanger	SEC (0.1 HCl), mg-equiv g^{-1}				SEC loss, %, at indicated temperature, °C		
	initial	after treatment at indicated temperature, °C					
		80	100	120	60	100	120
PMVP : DGA : PEI = 3 : 1 : 1	5.8	5.7	5.6	5.6	1.7	4.5	4.5

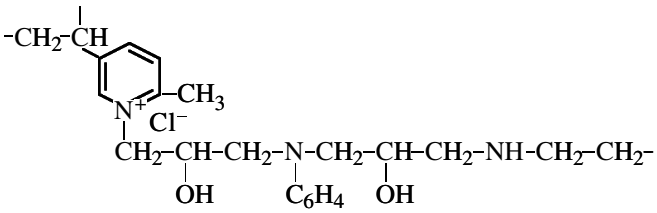
PMVP : TGEO : PEI = 2 : 1 : 2	6.5	6.5	6.4	6.3	0	1.5	3.0

in the final product. The yield of the PEPA-based products is above 80%, and, in the case of PEPA, 95%. Among the di- and polyamines used, PEI appeared to be the most efficient aminating agent, which can be attributed to its branched structure and higher nitrogen content. Raising the curing temperature from 60 to 100°C and the curing time to 5 h favored an increase in SEC. The minimal capacity of the resins was attained in 5–7 h at 80°C.



Therefore, it follows from our results that the optimal conditions for synthesis of aminovinylpyridine ion exchangers based on PMVP, aromatic EC, and DPA are as follows: temperature of synthesis of PMVP/EC prepolymers 70°C (3 h); curing in the presence of aliphatic DPA at 80°C for 5 h; and PMVP : EC : DPA molar ratio (1–3) : 1 : (2–3), depending on the nature of the starting reagents. Further increase in the amount of aliphatic polyamines promoted the formation of weakly cross-linked polyelectrolytes. Among the aliphatic DPA, PEI is the most efficient aminating agent because of the branched structure and high nitrogen content.

Generally, thermal degradation of anion-exchange resins first involves aliphatic NH groups, which is reflected primarily in SEC loss. Therefore, the heat resistance was determined in hot water from the SEC loss after 48-h treatment at 80, 100, and 120°C. The SEC loss in these experiments was within 5% (Table 4).

The IR spectra of the resulting polyelectrolytes show the characteristic bands of the pyridine and benzene rings and the bands due to stretching and bending vibrations of the NH groups of the aliphatic amines at 1460, 1500–1560, 1472–1530, 1600–1640, and 3472 cm^{-1}, but no characteristic bands of the epoxy ring at 760 and 848 cm^{-1}. Also we found the bands due to asymmetric (2940 cm^{-1}) and symmetric (2840 cm^{-1}) vibrations of the CH_2 groups. The appearance of the pyridinium absorption band at 1532 cm^{-1} is consistent with the published IR data on strongly basic commercial anion exchangers VP-1Ap and VP-100 [10].

The polyelectrolytes obtained in this study demonstrate a high chemical resistance. Thus, the SEC_{HCl} loss after treatment of the PMVP : TGEB : PEPA and PMVP : TGEB : PEI resins with 5 N H_2SO_4 and NaOH for 30 min at 100°C was within 5%, and that after treatment with 10% H_2O_2 for 24 h at 25°C, within 10–15%.

Our results suggest the following structure for the resulting polyelectrolytes:

It is known that the aminovinylpyridine ion exchangers are characterized by higher sorption capacity as compared to the commercial vinylpyridine sorbents based on divinylbenzene [4, 11]. Therefore, it was interesting to study the sorption of vanadium, molybdenum, and tungsten polyanions. In our experiments, the sorption efficiency with PMVP : TGEB : PEI = 2 : 1 : 3 increased in acidic and weakly acidic solutions. The maximal SEC was observed at pH 1.0–2.4 (1650 mg V_2O_5/g), 1.6–2.5 (1500 mg Mo/g), and 2.0–3.5 (1340 mg W/g). Under optimal conditions, the V, Mo, and W ions were completely recovered in 15, 45, and 72 h, respectively. The IR spectra of the resins after sorption contain new bands assigned to the polyanions: $Mo_7O_{24}^{6-}$ (860, 895–900, 930 cm^{-1}),

$H_2V_{10}O_{28}^{4-}$ (960 cm^{-1}), and $W_{12}O_{41}^{2-}$ (broadening of the adsorption bands at 770–800, 895–900, and 950–1000 cm^{-1}).

In studying the Mo sorption isotherms, the maximal SEC (1780 mg Mo/g) was observed at a metal concentration of 5 g l^{-1}. Under similar conditions, the maximal SEC of commercial anion-exchange resin VP-1Ap was reported to be only 700 mg Mo/g [11].

In passing a model solution containing 1.5 g Mo/l (pH 2.0) through a column with a diameter to height ratio of 1 : 15, the breakthrough of the Mo ions was observed after passing 75 volumes of the eluate per unit volume of the resin. In this case, the dynamic exchange capacity is 1000 mg Mo/g. The degree of Mo desorption with 12% ammonia amounts to 98%. The desorption efficiency loss in the sorption/desorption cycles was within 0.5–1.0% only after the third cycle.

To conclude, successive reactions of di-, tri-, and tetraglycidyl compounds with PMVP and PEI allow preparation of ion-exchange resins bearing the amino, pyridine, and pyridinium groups. The products demonstrate such useful properties as high heat resistance and resistance to oxidizing agents and concentrated acids. The presence of the aliphatic amino groups improves the flexibility and complexing power of the polyelectrolytes. In this case, the use of epoxy compounds of various structures allows effective control over the size of the channels in the polymer network and its permeability for V, Mo, and W ions [1, 11].

CONCLUSIONS

(1) Aminovinylpyridine ion-exchange resins are synthesized by polycondensation of epoxy compounds with poly(2-methyl-5-vinylpyridine) at 70°C (3 h) followed by curing of the resulting prepolymer in the presence of aliphatic di- and polyamines for 5 h at 80°C at a reagent ratio of (1–3) : 1 : (2–3), depending on the starting components.

(2) The loss in the static exchange capacity (0.1 N HCl) after treatment with 5 N H_2SO_4 and NaOH and hot water, characterizing the chemical and heat resistance of the resulting resins, is within 5%.

(3) The UV and IR spectra of the model compounds and final products suggest the formation of heterolytic pyridine, pyridinium, and aliphatic amino groups in successive reactions of the epoxy compounds with poly(2-methyl-5-vinylpyridine) and di- and polyamines.

(4) The ion-exchangers obtained demonstrate high permeability for vanadium, molybdenum, and tungsten polyanions from solutions at pH 1.5–3.5. In this case, the dynamic exchange capacity of the resin based on PMVP : TGEB : PEI is 1000 mg Mo/g, and the degree of Mo desorption with 12% ammonia is 98%.

Abstract—New sulfonic cation exchangers based on immobilized calix[4]resorcinolarenes were prepared. Their ion-exchange properties toward Na^+, Cu^{2+}, $[Pd(NH_3)_4]^{2+}$, In^{3+}, and Sn^{4+} ions were studied in a wide pH range, and their chemical stability was examined.

DOI: 10.1134/S1070427206080167

Previously, we have prepared new network polymers containing immobilized calix[4]resorcinolarenes [1–5]. These polymers can act as biomimetics [1, 2], nanoreactors for catalytic hydrogenation processes [6, 7], solid polyelectrolytes [8], and weakly acidic cation exchangers [1, 2, 9]. The ion-exchange and ionophore properties of network polymers based on immobilized calix[4]resorcinolarenes are due to the presence of phenolic (resorcinol) OH groups capable of ionization in alkaline solutions (pH > 7). The selectivity of the cation exchange can be enhanced by introducing carboxy [9], phosphate [10], or furyl(hydroxy)methyl [4] functional groups into the monomeric units of immobilized calixarenes.

In this study, we prepared novel bifunctional cation exchangers **I** and **II** by sulfonation of network polymers based on immobilized calix[4]resorcinolarenes. The monomeric units of **I** and **II** contain macrorings of two kinds:

where R = CH_3, R' = SO_3H (**I**); R = Ph–SO_3H, R' = H (**II**).

One of the macrorings is incorporated in the chain via two bridging CH_2 groups, and the other macroring, via three bridging CH_2 groups, forming a network structure. Cation exchangers **I** and **II** contain strongly acidic SO_3H groups dissociating with the release of protons in a wide pH range (pH 0–14) and weakly acidic phenolic OH groups.

The goal of this study was to prepare cation exchangers **I** and **II** and determine of their main ion-exchange characteristics (cation-exchange capacity, potentiometric titration curves).

EXPERIMENTAL

Calix[4]resorcinolarenes immobilized in the phase of network polymers (polytetramethylcalix[4]resor-

cinolarene or polytetraphenylcalix[4]resorcinolarene) were prepared by resol polycondensation of *cis*-tetramethylcalix[4]resorcinolarene or *cis*-tetraphenylcalix[4]resorcinolarene with formaldehyde, as described in [4].

Cation exchanger **I** was prepared by two-step sulfonation of a network polymer, polytetramethylcalix[4]resorcinolarene. Polytetramethylcalix[4]resorcinolarene (4 g, 5 mmol) was kept for 24 h in 20 ml of dichloroethane, after which 25 ml of concentrated (98%) sulfuric acid was added, and the mixture was heated for 5 h at 98°C, with the evaporation of the released water. The sulfonated product was dried in air. Then repeated sulfonation with a 3 : 2 (*v*/*v*) mixture of 98% sulfuric acid and oleum (25% free SO_3 in 98% sulfuric acid) at 98°C was performed. Dry cation exchanger **I** in the H form was thus obtained in the form of dark brown granules of irregular shape; yield 3.4 g (85%).

Cation exchanger **II** was prepared by two-step sulfonation of polytetraphenylcalix[4]resorcinolarene. The polymer (6 g, 5 mmol) in the form of spherical granules 0.05–0.5 mm in diameter was kept for 24 h in 30 ml of dichloroethane, after which 30 ml of 90% sulfuric acid was added, and the mixture was heated for 5 h at 90°C, with the evaporation of the released water. The sulfonated product was dried in air. Then repeated sulfonation with a mixture of concentrated sulfuric acid and oleum at 90°C was performed. Dry cation exchanger **II** in the H form was thus obtained in the form of spherical granules 0.05–0.5 mm in diameter; yield 3.8 g (63%).

* $\Delta_f H^0_{298}(H_2SO_4) = -787.1$, $\Delta_f H^0_{298}(H_2O) = -223.6$ kJ mol^{-1}.

Cation exchangers **I** and **II** were conditioned by the standard procedure [11]. The FTIR and DRIFT spectra were recorded on a Tensor-27 Fourier transform IR spectrometer (Bruker Optics). The FTIR spectra were measured with polymer samples pelletized with KBr, and the DRIFT spectra, with preliminarily ground samples, using a diffuse reflection unit. The procedures for determination of the dynamic ion-exchange capacity and for potentiometric titration of the resins were described in [1, 2, 5].

The sulfur content of the cation exchanger samples was determined according to [12]. Quantum-chemical calculations were performed by the MNDO semiempirical method with PM3 parametrization of the Hamiltonian, using MOPAC 2000 program included in the Chem 3D Ultra 9.0 software package (CambridgeSoft Corporation).

Let us consider the thermodynamic probability (and site) of the electrophilic attack by a sulfonated agent of *cis-meta*-cyclophanoctols **III** and **IV** modeling the monomeric units of the polymers, polytetramethylcalix[4]resorcinolarene or polytetraphenylcalix[4]resorcinolarene, respectively.

III **IV**

Assume that the sulfonation of **III** and **IV** occurs by a reversible reaction

$$LH_4 + nH_2SO_4 \rightleftarrows LH_{4-n}(SO_3H)_n + nH_2O, \quad (1)$$

where LH_4 is **III** or **IV**.

A quantum-chemical calculation showed that the most favorable sulfonation site in **III** is position 4 in each aromatic ring of the tetraresorcinol belt of the meta-cyclophanoctol. Monosulfo derivatives of **IV** can contain a sulfo group in the *p*- or *m*-position of the pendant benzene rings, because sulfonation of the resorcinol rings is less energetically favorable. The incorporation of a SO_3H group into each pendant benzene ring of **IV** is the most probable.

The minimal calculated enthalpies of formation $\Delta_f H^0_{298}$ of **III** and **IV** and of their sulfonation products, and also the enthalpies of reaction (1) are listed in Table 1.

Table 1 shows that sulfonation reaction (1) should be endothermic, with ΔH 97–105 kJ per mole SO_3H in sulfonation of **III** at the tetraresorcinol belt and 49–63 kJ per mole SO_3H in the sulfonation of **IV** at the pendant phenyl groups. Naturally, elevated temperatures are required to promote the reaction. The thermodynamic probability of reaction (1) decreases with an increase in the number of SO_3H groups in the reaction products. In going to cation exchangers **I** and **II**, the pattern changes: In the tetraresorcinol fragmnent, only one or two SO_3H groups can be introduced per macroring, because the other positions favorable for the electrophilic attack (4-positions in **III** and **IV**) are already occupied by the bridging CH_2 groups of the polymeric chains. Based on the analysis of model reaction (1), we developed procedures for preparing sulfonic cation exchangers **I** and **II**.

The FTIR spectra of the polymers are shown in Fig. 1. In the transmission spectra of the samples, there are broad bands at about 3400 cm^{-1}, corresponding to intramolecular hydrogen bonds in diols. The band at 2850 and the doublet at 2940 and 2920 cm^{-1} are due to the C–H vibrations in aliphatic hydrocarbons. The band at 1600 cm^{-1} belongs to stretching vibrations in the benzene ring. Sulfonated polymers **I** and **II** additionally contain bands at 1196, 1145, and 1000 cm^{-1} (stretching vibrations of the sulfo group) and long-wave bands at 570 cm^{-1} in the sulfonated polymer derived from **III** (*o*-substitution [13]) and at 590 and 540 cm^{-1} in the sulfonated polymer derived from **IV** (vibrations of the C–S bond between the sulfo group and benzene ring). The vibration band of the benzene ring is broadened (doublet at 1591 and 1610 cm^{-1} in the spectrum of the sulfonated polymer derived from **IV**).

The bands observed for **I** and **II** in the FTIR and DRIFT spectra are similar.

The potentiometric titration curves of **I** and **II** (Fig. 2) have a stepped shape due to the presence in the monomeric units of both strongly acidic sulfo groups fully dissociating even in acid solutions and phenolic OH groups dissociating at pH > 7. Thus, compounds **I** and **II** are bifunctional cation exchangers.

Analysis of the material balance shows that protons of all the sulfo groups and four of eight OH groups (one OH group per resorcinol fragment) in the monomeric units of **I** and **II** are involved in the ion exchange. The latter fact is associated with a large difference between the ionization constants of resorcinol (pK_{a1} = 9.15, pK_{a2} = 11.33 [14]).

Table 2. Characteristics of sulfonic cation exchangers based on immobilized *cis*-calix[4]resorcinolarenes

Cation exchanger	Sulfur content of polymer, %		Total dynamic cation-exchange capacity, mg-equiv g^{-1} resin in H form					
	elemental analysis	in SO_3H groups	0.1 N NaOH	0.01 N NaCl	0.01 N $CuCl_2$	0.01 N $InCl_3$	0.01 N $SnCl_4$	0.01 N $[Pd(NH_3)_4]Cl_2$
I	8.1 ± 0.2	5.9 ± 0.2	6.47 ± 0.10	1.85 ± 0.05	1.86 ± 0.05	1.85 ± 0.05	1.85 ± 0.05	–
II	7.7 ± 0.2	7.8 ± 0.2	5.65 ± 0.10	2.45 ± 0.05	2.45 ± 0.05	2.45 ± 0.05	2.45 ± 0.05	2.45 ± 0.05

The characteristics of the sulfonic cation exchangers based on immobilized *cis*-calix[4]resorcinolarenes are given in Table 2. Table 2 shows that the sulfonation of network polymers based on calix[4]resorcinolarenes yields sulfonic cation exchangers **I** and **II** containing strongly acidic SO_3H groups. The total ion-exchange capacity of **I** and **II** (for 0.1 N NaOH) is 6.47 and 5.65 mg-equiv g^{-1} dry polymer in the H form, respectively, which considerably exceeds the cation-exchange capacity of the nonsulfonated polymers, polytetramethylcalix[4]resorcinolarene and polytetraphenylcalix[4]resorcinolarene (5.0 and 3.8 mg-equiv g^{-1} [4]).

The sorption capacities for chlorides of alkali, rare, and nonferrous metals and tetraamminepalladium in neutral and acidic solutions correspond to the content of sulfo groups in **I** and **II**. Under these conditions, the sorption capacity of the corresponding nonsulfonated polymers [1, 2] is zero. The working range of **I** and **II** is $0 < pH < 14$.

The sulfur content in **I**, according to elemental analysis, exceeds the calculated value corresponding to the content of SO_3H groups in the polymer. Since the sulfonation of polytetramethylcalix[4]resorcinolarene occurs under more severe conditions (which may lead to formation of sulfones [15]), a part of S atoms in **I** may be incorporated in bridging SO_2 groups. The SO_3H groups in **I** are, apparently, in the 4-position (between two OH groups of the resorcinol fragment), because the band at 570 cm^{-1} in the FTIR spectrum of **I**, according to [13], corresponds to the *o*-substitution in the sulfonation of aromatic rings. The dynamic ion-exchange capacity shows that resin **I** contains no more than two SO_3H groups per macroring, and the content of SO_3H groups following from the potentiometric titration curve (Fig. 2a) is 1.6 per macroring.

The sulfur content of **II** and its capacity for strongly acidic groups show that the whole amount of sulfur in **II** is in the form of four sulfo groups at the pendant phenyl rings (approximately one sulfo group per phenyl ring).

Sulfonic cation exchangers **I** and **II** have important service characteristics. Resins **I** and **II** exhibit the dynamic ion-exchange capacity for strongly acidic SO_3H groups in a wide pH range in sorption of both Na^+ cations and multicharged cations of Cu^{2+}, $[Pd(NH_3)_4]^{2+}$, In^{3+}, and Sn^{4+}. The capacity for cation exchange with phenolic OH groups is fully preserved in both resins. Apparently, the functional groups (OH, SO_3H) belonging to the same macroring of the monomeric unit of **I** and **II** preserve in the polymeric phase the well-known capacity of calixarenes [16] for complementary stereoelectronic interactions with substrate molecules (metal cations in our case). In this context, we expect that sulfonic cation exchangers **I** and **II** can show high selectivity due to formation of ensembles of multicharged cations and ionic groups belonging to the same macroring.

Cation exchangers **I** and **II** are chemically stable in the range $0 < pH < 14$. Comparison of the FTIR and DRIFT spectra of **I** and **II** shows that their surface is resistant to oxidation in air. The chemical resistance of cation exchangers **I** and **II** to alkalis, acids, and oxidants and their high dynamic ion-exchange capacity in a wide pH range determine the possibility of using these resins in various branches of industry for separation of electrolyte mixtures, recovery of nonferrous and rare metals from multicomponent systems, and exhaustive demineralization of water, and also as catalyst supports.

CONCLUSIONS

(1) Novel sulfonic cation exchangers were prepared by sulfonation of network polymers derived from *cis*-tetramethylcalix[4]resorcinolarene or *cis*-tetraphenylcalix[4]resorcinolarene.

(2) The IR spectra, elemental analysis, potentiometric titration curves, and sorption characteristics of these cation exchangers confirm the presence of strongly acidic sulfo groups and weakly acidic phenolic hydroxy groups. Each macroring of the monomeric

unit of the polymer contains one to four SO_3H groups and eight OH groups. The total dynamic cation-exchange capacity (mg-equiv g^{-1}) of the sulfonic cation exchangers based on *cis*-calix[4]resorcinolarenes **I** and **II** is, respectively, 6.47 and 5.65 for 0.1 N NaOH, and 1.85 and 2.45 for 0.01 N NaCl, $CuCl_2$, $InCl_3$, $SnCl_4$, and $[Pd(NH_3)_4]Cl_2$.

(3) The high ion-exchange capacity for multicharged ions and the chemical stability in a wide pH range make the sulfonic cation exchangers based on immobilized *cis*-calix[4]resorcinolarenes suitable for separation of multicomponent electrolyte mixtures, for exhaustive demineralization of water, and for use as catalyst supports.

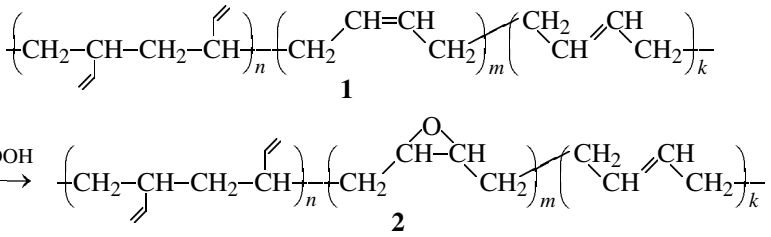
Abstract—Samples of modified 1,2-polybutadiene were prepared by the reaction of the polymer with peracetic acid or *tert*-butyl hydroperoxide in the presence of a catalyst, hexacarbonylmolybdenum. The hydrodynamic characteristics of dilute solutions and the rheological properties of concentrated solutions of the starting and epoxidized polydiene in hydrocarbon solvents were studied. The Huggins constant K_χ, second virial coefficient A_2, root-mean-square size of macromolecular coils $(\overline{R^2})^{1/2}$, and the enthalpy, entropy, and Gibbs energy of activation of the viscous flow of solutions of the starting and modified polydiene were estimated.

DOI: 10.1134/S1070427206080179

According to published data, addition to polymeric formulations of polydienes, including 1,2-polybutadiene (1,2-PB), that contain a small amount of epoxy units in the backbone and pendant chains improves the properties of the compounds and expands the field of their application [1–6]. In particular, 1,2-PB containing 5–8% oxirane oxygen is used for preparing compounds with enhanced flame resistance and improved sealing properties [7] and as a component of paint-and-varnish materials [8] and of compounds whose rigidity does not change with time and the elasticity and high adhesive power are preserved under moist conditions [9].

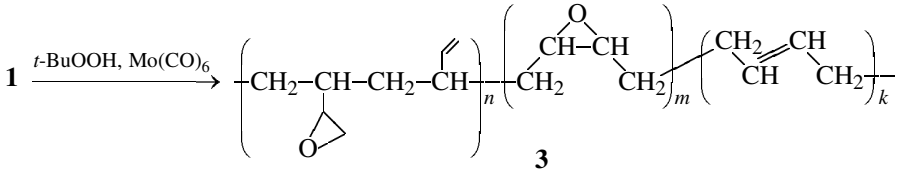
Here we suggest a new approach to the synthesis of epoxy derivatives of syndiotactic 1,2-PB, allowing introduction of a prescribed amount of epoxy groups into the polydiene macromolecules.



As starting polymer we chose syndiotactic 1,2-PB with a Mooney viscosity of 30. The polymer had the following characteristics: flow point T_f = 105°C, glass transition point T_g = –15°C, $M_n = 71.6 \times 10^3$, M_w/M_n = 1.8 (M_n and M_w/M_n were determined by GPC), degree of crystallinity 30%, content of 1,2 and 1,4 units 84 and 16%, respectively.

Epoxidation of syndiotactic 1,2-PB was performed in benzene; the epoxidizing agent was peracetic acid prepared in situ by the treatment of solution acetic acid with a concentrated H_2O_2. The thus synthesized epoxy derivatives of syndiotactic 1,2-PB were characterized by ^{1}H (300 MHz) and ^{13}C (75.47 MHz) NMR spectroscopy. The degree of modification of 1,2-polydiene was determined by comparing its NMR spectra with those of the starting polymer [10]. The signals were assigned using the COSY H–H and COSY C–H 2*D* correlation spectroscopy.

The formation of epoxy groups in the macromolecules of syndiotactic 1,2-PB was confirmed by the presence of weak doublets at 55.89 and 55.65 ppm in the ^{13}C spectra and of an unresolved group of signals at 2.7–2.9 ppm in the ^{1}H spectra, with the chemical shifts typical of epoxy groups [11]. Simultaneously the ^{13}C triplets at 27.57, 27.43, and 27.35 ppm and doublets at 127.8–130.3 ppm, corresponding to the C atoms in the *cis* units formed by 1,4 polymerization, decreased in intensity relative to the starting polydiene.



The experimental results show that the epoxidation of syndiotactic 1,2-PB with peracetic acid mainly involves the >C=C< double bonds in the 1,4-*cis* units of the backbone. This is apparently due to a higher nucleophilicity of these bonds compared to those in the 1,2 units [12]. The NMR spectra of modified syndiotactic 1,2-PB are consistent with the relatively low degree of epoxidation of the polymer upon its treat-

ment with peroxyacetic acid: With this agent, only up to 4–5% of the double bonds in the macromolecule of syndiotactic 1,2-PB are converted into epoxy groups (Table 1). Thus, the formation of oxirane groups in macromolecules of syndiotactic 1,2-PB in its epoxidation with peracetic acid follows the scheme

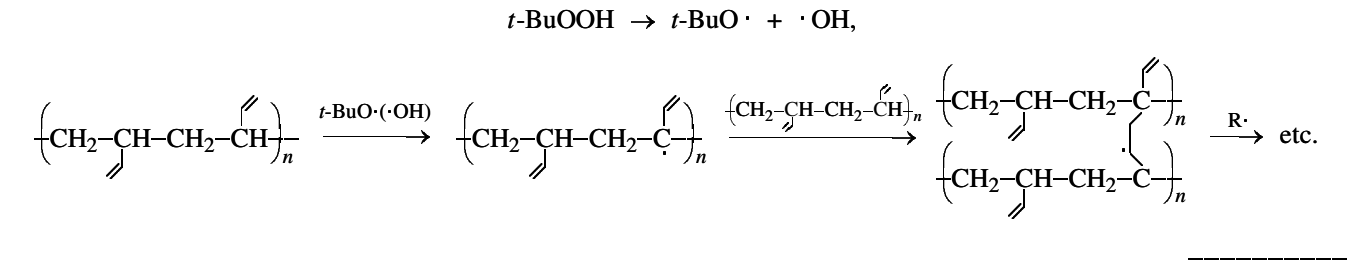
Epoxidation of syndiotactic 1,2-PB with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$ [13] showed an essentially different pattern. In this case, the pendant vinyl groups of the polydiene macromolecules were epoxidized too. The modification was performed in benzene at 20°C. The degree of functionalization was controlled by the amount of the epoxidizing agent added (up to a twofold excess relative to the content of the >C=C< bonds in the macrochains). We prepared epoxy derivatives of syndiotactic 1,2-PB containing up to 9% epoxy groups (Table 1).

The ^{13}C NMR spectra of the polymer modified by treatment with *tert*-butyl hydroperoxide contain, along with the signals from the C atoms of the epoxy groups in the backbone, also stronger signals: a triplet at 57.9 ppm and doublets at 56.36 and 56.88 ppm, with large coupling constants $^1J(^{13}C–^1H)$ 172, 174, and 168 Hz. This fact unambiguously indicates that the vinyl >C=C< bonds are also converted into epoxy groups. The presence in the COSY C–H spectra of the cross peaks of these signals with the proton signals at 2.6–3.0 ppm additionally confirms that the vinyl groups in the macromolecules of syndiotactic 1,2-PB are involved in the epoxidation:

Thus, the course of epoxidation of syndiotactic 1,2-PB strongly depends on the epoxidizing agent. Peracetic acid is insufficiently reactive for the epoxidation of the nonactivated pendant vinyl group. As a result, only the >C=C< bonds of the backbone, and only those with the *cis* configuration, are involved in the epoxidation with this agent. In the epoxidation of 1,2-PB with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$, the epoxy groups are formed both from pendant vinyl groups and from the >C=C< bonds in the backbone. The optimal degree of functionalization can be attained by varying the reaction conditions.

We studied the physicochemical properties of syndiotactic 1,2-PB epoxidized with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$. We examined how the content of epoxy groups in the 1,2-polydiene macromolecules affects the intrinsic viscosity [η] of the modified polymer in CCl_4. From the concentration dependence of the reduced viscosity η_r, we calculated [14] the Huggins constants K_χ.

Table 1. Epoxidation of syndiotactic 1,2-PB with peracetic acid and *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$ in benzene at 20°C



Degree of functionalization of >C=C< bonds,* %		Calculated degree of functionalization of >C=C< bonds in 1,2-PB, %
peracetic acid	*tert*-butyl hydroperoxide	
–	1.5	2.5
1.7	2.3	5.0
2.3	6.0	12.5
3.8	7.4	15.0
4.6	8.9	17.5

* Determined by elemental analysis and functional analysis for epoxy groups.

Table 2 shows that an increase in the degree of epoxidation of syndiotyactic 1,2-PB results in that the intrinsic viscosity of the polymer grows and K_χ decreases. The observed effect is apparently caused by an increase in the mean molecular weight of 1,2-PB (M_w was determined from the light scattering) upon its modification and by a change in the thermodynamic affinity of the polymer for the solvent upon introduction of polar groups into the macromolecules.

We calculated A_2 and $(\overline{R^2})^{1/2}$ for the starting and modified polydiene. We found that an increase in the degree of epoxidation of 1,2-PB results in an increase in [η] and M_w and a decrease in A_2 (Table 2). As a rule, a decrease in A_2 leads to a regular decrease in $(R^2)^{1/2}$ [15]. In the epoxidation of syndiotactic 1,2-PB with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$, $(\overline{R^2})^{1/2}$ decreases only at a relatively low degree of functionalization of the polymer (up to ~1.5%), which is apparently due to worse, compared to the starting polymer, thermodynamic affinity of the modified polymer for the solvent and, as a result, to the more compact conformation of the modified macromolecules. However, when the content of the epoxy fragments in the 1,2-PB macromolecules exceeds 2%, a decrease in A_2 is accompanied, by contrast, by an increase in $(\overline{R^2})^{1/2}$ (Table 2).

The observed contradiction is only apparent and is caused by side reactions involving the macromolecules, such as formation of branchings and interchain cross-links by the reactions with peroxy radicals formed in the reaction mixture in the course of epoxidation of the polydiene with *tert*-butyl hydroperoxide:

The formation of structures of this kind in the polymer causes an increase in its mean molecular weight, which leads to an increase in the root-mean-square radius of its coils $(R^2)^{1/2}$ with simultaneous worsening of the thermodynamic affinity for the solvent. Thus, two trends compete: a decrease in the size of the macromolecular coil due to a decrease in the thermodynamic affinity of the macromolecules for the solvent upon an increase in the content of epoxy groups, on the one hand, and an increase in the coil size due to side reactions leading to the formation of branchings and occurring in the epoxidation of 1,2-PB with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$, on the other hand.

Table 2. Hydrodynamic and molecular characteristics of syndiotactic 1,2-PB, starting and epoxidized with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$ (CCl_4, 20°C)

Degree of epoxidation, %	K_χ	[η], dl g^{-1}	$M_w \times 10^{-5}$	$A_2 \times 10^4$	$(\overline{R^2})^{1/2} \times 10^{-3}$
0	0.98	1.48	3.4	0.80	0.9
1.5	0.94	1.47	4.5	0.50	0.7
3.7	0.91	1.52	8.0	0.30	0.8
6.1	0.89	1.57	8.6	0.20	1.0
8.9	0.68	1.59	13.0	0.15	1.8

With an increase in the polymer concentration in the solution, the mean distance between the macromolecules decreases. As a result, the probability of collision of the macrochains in the course of their random motion and of formation of associates and molecular networks increases. The strength and ordering of the fluctuation structures in polymer solutions can be evaluated from the properties of concentrated solutions, in particular, from the solution viscosity under a shear stress [16].

The rheological properties of solutions of syndiotactic 1,2-PB and its modified derivatives were studied with a Reotest-2M rotary viscometer. We determined how the viscosity η of concentrated (1–10 g dl^{-1}) toluene solutions of syndiotactic 1,2-PB and its epoxy derivatives depends on the shear rate. These data furnish information on the conformation and intermolec-

ular interaction of the macrochains. For modified syndiotactic 1,2-PB containing 2.3 and 8.9% epoxy fragments, we obtained the log–log plots of the viscosity vs. the shear stress (Fig. 1). The curves obtained consist of two portions corresponding to the highest Newtonian (η_0) and effective (η_{eff}) viscosities (regions *A* and *B*, respectively); this pattern is characteristic of non-Newtonian fluids. The lack of the third portion corresponding to the region of the lowest Newtonian viscosity is typical of solutions of flexible-chain polymers [16].

Processing of the experimental results with Frenkel–Eyring's equation (1) allows determination of the activation parameters of the viscous flow, which furnish information on the strength and ordering of molecular structures present in the solution:

$$\eta_0 = A \exp(\Delta G_{vf}/RT), \quad (1)$$

where η_0 is the highest Newtonian viscosity; ΔG_{vf}, activation free energy of the viscous flow; R, gas constant; T, temperature; and A, a coefficient.

If we assume $A = 10^{-4}$ Pa s [15], the calculation of the activation parameters is simplified, and Eq. (1) takes the form

$$\Delta G_{vf} = 2.303RT \log(\eta_0/10^{-4}). \quad (2)$$

The difference between the activation enthalpy of viscous flow, ΔH_{vf}, characterizing the strength of structural bonds and the activation Gibbs energy ΔG_{vf} is the activation entropy of viscous flow (multiplied by temperature) [17]:

$$T\Delta S_{vf} = \Delta H_{vf} - \Delta G_{vf}; \quad (3)$$

then

$$\log \eta_0 = \log 10^{-4} - \Delta S_{vf}/(2.303R) + \Delta H_{vf}/(2.303RT), \quad (4)$$

where ΔS_{vf} is the activation entropy of viscous flow, associated with the ordering of the structure.

From Eq. (2) we can calculate the potential ΔG_{vf}, and from the dependence of $\log \eta_0$ on $1/T$, the activation enthalpy of viscous flow, ΔH_{vf}. The quantities ΔG_{vf} and ΔH_{vf}, calculated from the experimental data for solutions of syndiotactic 1,2-PB and its epoxy derivatives (Fig. 2), are relatively low and, on the whole, typical of flexible-chain polymers [15]; they show that the strength of structural bonds in the derivatives of syndiotactic 1,2-PB is rather low.

The concentration dependences of the activation enthalpy of viscous flow, ΔH_{vf}, of toluene solutions

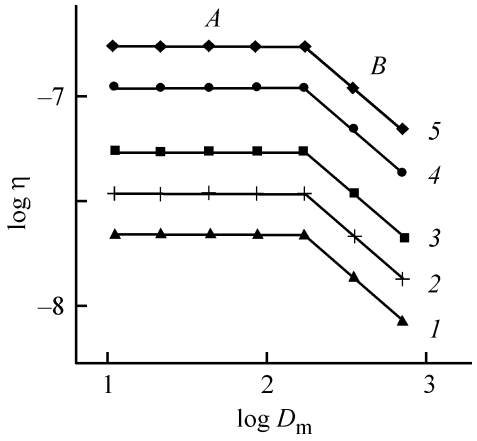


Fig. 1. Viscosity η vs. the shear stress D_m (log–log plot) for a toluene solution of syndiotactic 1,2-PB containing 8.9% epoxy groups (20°C). Polymer concentration, g dl^{-1}: (*1*) 2.0, (*2*) 4.0, (*3*) 6.0, (*4*) 8.0, and (*5*) 10.0. (*A*) Region of the highest viscosity and (*B*) region of effective viscosity.

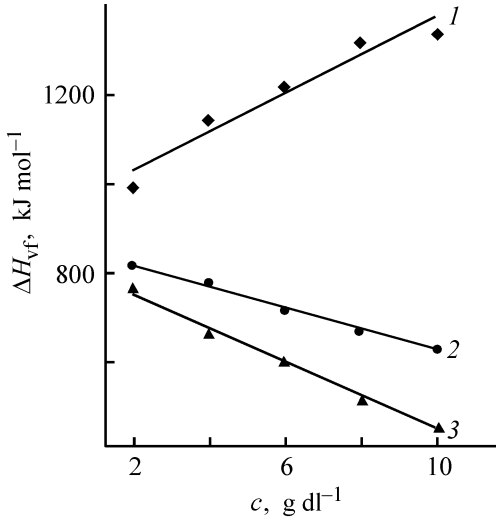

Fig. 2. Activation enthalpy of viscous flow ΔH_{vf} vs. the concentration c of toluene solutions of syndiotactic 1,2-PB and its epoxidized derivatives. Content of epoxy groups in the modified polydiene, %: (*1*) 0, (*2*) 2.3, and (*3*) 8.9; the same for Figs. 3 and 4.

of syndiotactic 1,2-PB and its epoxy derivatives show that ΔH_{vf} decreases upon introduction of epoxy groups to the greater extent, the higher the content of oxirane rings in the macromolecules (Fig. 2). For the modified 1,2-PB, ΔH_{vf} decreases with an increase in the polymer concentration in the solution, whereas for the starting polymer the trend is the opposite. This fact indicates that the bonding strength in associates of the macromolecules containing oxirane groups is lower, compared to the starting polydiene. A decrease in the activation enthalpy of viscous flow with an in-

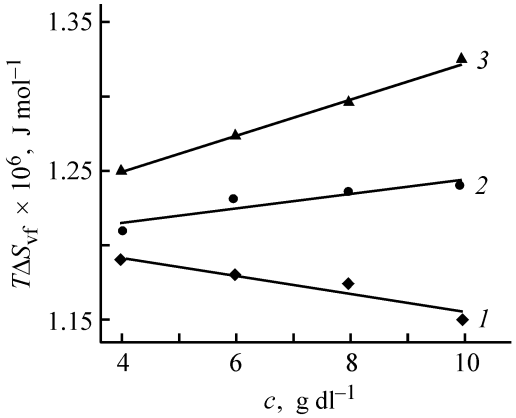

Fig. 3. Activation entropy of viscous flow $T\Delta S_{vf}$ of toluene solutions of syndiotactic 1,2-PB and its epoxy derivatives vs. the polymer concentration c.

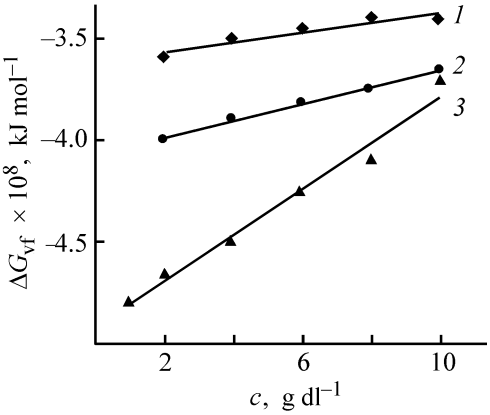

Fig. 4. Activation Gibbs energy of viscous flow ΔG_{vf} of toluene solutions of syndiotactic 1,2-PB and its epoxy derivatives vs. the polymer concentration c.

crease in the content of epoxy groups in the modified syndiotactic 1,2-PB should be attributed to worsening of the affinity of the polymer for the solvent with an increase in the content of epoxy fragments in the macrochains and formation of branched structures.

When a shear stress is applied to solutions of syndiotactic 1,2-PB and its epoxy derivatives, the unrolling of macromolecular coils and molecular orientation prevail, and the system becomes more ordered in the flow. For the starting polydiene, the activation entropy of viscous flow, $T\Delta S_{vf}$, steadily decreases with an increase in the polymer concentration (Fig. 3). For solutions of epoxidized 1,2-PB, the trend is the opposite (Fig. 3) and is caused by hindered unrolling and orientation of macromolecular coils under shear stress, due to the appearance of branched structures upon epoxidation.

The activation Gibbs energy of viscous flow, ΔG_{vf}, increases with the concentration of the starting 1,2-PB (Fig. 4), which is caused by an increase in ΔH_{vf} and a decrease in ΔS_{vf}. This trend should be attributed to profound structurization of the solution at relatively high concentrations of the polymer. Introduction of epoxy groups leads to a decrease in ΔG_{vf} relative to the starting 1,2-PB (Fig. 4), which indicates that the bonding strength in associates of the macromolecules containing oxirane groups is lower, compared to the macrochains of the starting syndiotactic 1,2-PB and hence is more favorable for formation of uniform polymer compositions.

CONCLUSIONS

(1) Syndiotactic 1,2-polybutadiene can be subjected to chemical modification by epoxidation with peracetic acid or with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$. Treatment of the polymer with peracetic acid results in epoxidation of the >C=C< bonds in the *cis* units of the backbone only, whereas treatment with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$ results also in epoxidation of pendant vinyl groups and thus ensures a higher degree of modification of the polymer.

(2) Epoxidation of syndiotactic 1,2-polybutadiene with *tert*-butyl hydroperoxide in the presence of $Mo(CO)_6$ is accompanied by an increase in the mean molecular weight of the polymer due to formation of branchings and cross-links in the reactions with peroxy radicals.

(3) The activation enthalpies ΔH_{vf} and Gibbs energies ΔG_{vf} of viscous flow of solutions of syndiotactic 1,2-polybutadiene and its epoxy derivatives show that the strength of structural bonds in associates of the macromolecules in concentrated solutions is relatively low.

Abstract—Variation of the supramolecular structure of heat-resistant polyimide films in the course of high-temperature treatment was studied by X-ray diffraction analysis and NMR spectroscopy in solids.

DOI: 10.1134/S1070427206080180

A wide range of practical applications of polyimide (PI) films in various branches of industry arouses unremitting scientific interest in carbonization of polyimides. It was shown [1] that high-temperature treatment of polyimides yields crosslinked carbo- and heterocyclic structures. These chemical transformations of macromolecules favor formation of structures having a series of new characteristics and also leads to a high carbon residue in carbonization (up to 50–70%). Subsequent publications have shown [2–4] that the characteristics of carbonized polyimides depend on the chemical structure of the initial polymer, its supramolecular structure, conditions of thermal treatment, and other process parameters. A study of variations of the supramolecular structure of polyimide films in the course of their thermal treatment can give additional data both on thermochemical processes and on expected properties of composite materials based on these films.

In this study, we examined variations of the supramolecular structure of heat-resistant films based on polyimide PM during thermal treatment and the influence of the chemical structure of the polyimide on the type of these variations.

EXPERIMENTAL

The PI PM films were prepared from a solution of polyacrylic acid (PAA), with the subsequent thermal imidization. The film thickness was 20 μm. Pyrolysis was performed in the dynamic mode in an inert medium; the heating rate was 20 deg min^{-1}.

The studies by scanning electron microscopy were performed on a Tesla BS-350 electron microscope; X-ray diffraction measurements, on a DRON-1.5 and KRM devices (Kratky collimation; Cu_{K_α} radiation). The ^{13}C NMR spectra in solids were recorded at room temperature on a Bruker CXP-100 spectrometer using the magic angle spinning (MAS) and cross-polarization (CP) techniques.

The pyrolysis kinetics of the PI PM films was studied at 500°C and keeping time of 1 and 6 h.

The large-angle X-ray diffraction patterns of the initial PI PM films and films pyrolyzed at various temperatures are shown in Fig. 1. The broadening of

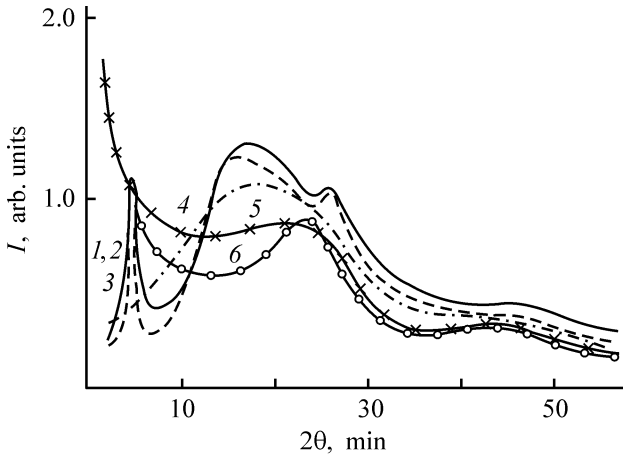

Fig. 1. Large-angle X-ray diffraction patterns of PI PM films: (*1*) initial and (2–6) pyrolyzed at various temperatures. Heat treatment temperature, °C: (*2*) 500, (*3*) 550, (*4*) 600, (*5*) 750, and (*6*) 850. (*I*) Intensity and (2θ) angle.

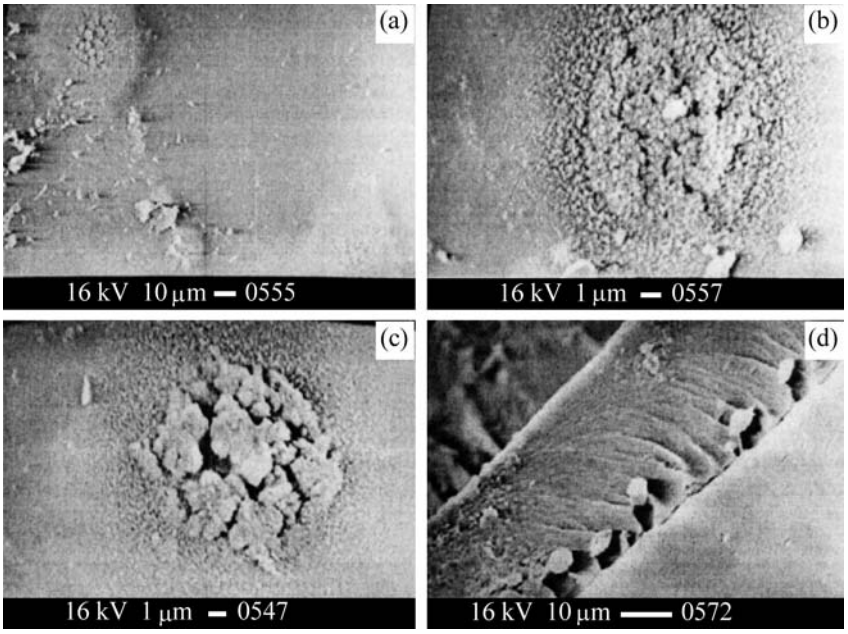

Fig. 2. Photomicrographs of a PI PM film pyrolyzed at 600°C: (a–c) surface and (d) chip in liquid nitrogen.

the reflections in both radial and azimuthal directions in the powder patterns of the initial films suggests the absence of orientation of macromolecules in the film samples and low ordering of the crystallites. A similar structure of crystallites is retained up to 550°C, which follows from the shapes of the X-ray diffraction patterns of the heat treated films.

The main signals in the ^{13}C NMR spectrum of the solid polymer undergo no significant changes up to 550°C, which confirms the constancy of the macromolecule structure. In addition, data of X-ray photoelectron spectroscopy indicate that the main degradation processes in the film studied develop above 550°C [5]. At a pyrolysis temperature of 600°C, the reflections typical of PI PM disappear in the X-ray powder patterns of the films and the carbon reflection (002) appears (Fig. 1, curve *4*). Heating is favorable for formation of turbostratic carbon stacks and, as a consequence, for an increase in the intensity of reflection (002) and decrease in its half-width (curves *5*, *6*). The ^{13}C NMR spectra of pyrolyzed PM samples suggest that heating of the polymer to 600°C causes significant transformation of the polymer chain and strongly alters its structure. At 900°C, the spectrum transforms into a singlet at 123 ppm, corresponding to a polyaromatic turbostratic carbon structure.

The variation of the density heterogeneity of the PI PM films was estimated by the small-angle X-ray scattering. Analysis of the small-angle scattering curves of the initial and pyrolyzed PI PM films shows that the initial films have a weak, virtually degenerated small-angle reflection, which is also preserved after pyrolysis at 550°C. The intensive development of the carbonization process results in disappearance of this reflection (at 600°C) and significant increase in the diffuse scattering above 700°C. This suggests a strong density heterogeneity in the film, caused by the presence of elements of the turbostratic structure, and also the presence of pores with a size of several nanometers to tens of nanometers.

A comparison of the results of large- and small-angle X-ray diffraction analyses suggests that thermal degradation of polyimide PM films begins in less ordered amorphous areas, similarly to the development of pyrolysis of hydrated cellulose fibers and thermal oxidation of polyacrylonitrile fibers [6, 7].

Scanning electron microscopy gives interesting information on the development of the pyrolysis of the PI PM film samples at the micrometer level. The photomicrographs of PI PM films imidized at 400°C, which were used as starting samples for the subsequent pyrolysis and carbonization, are smooth and flat both on the support side and on the free surface. A cleavage made in liquid nitrogen shows the presence of a dense surface layer and a more friable core subjected to scores and exfoliations in little failure at low temperatures. This pattern is in good agreement with numerous published data, in particular [6, 8], for polyimide films and fibers.

The nonuniformity of pyrolysis development at the microlevel is seen in the photomicrographs of the surface of films pyrolyzed at 600°C (Fig. 2).

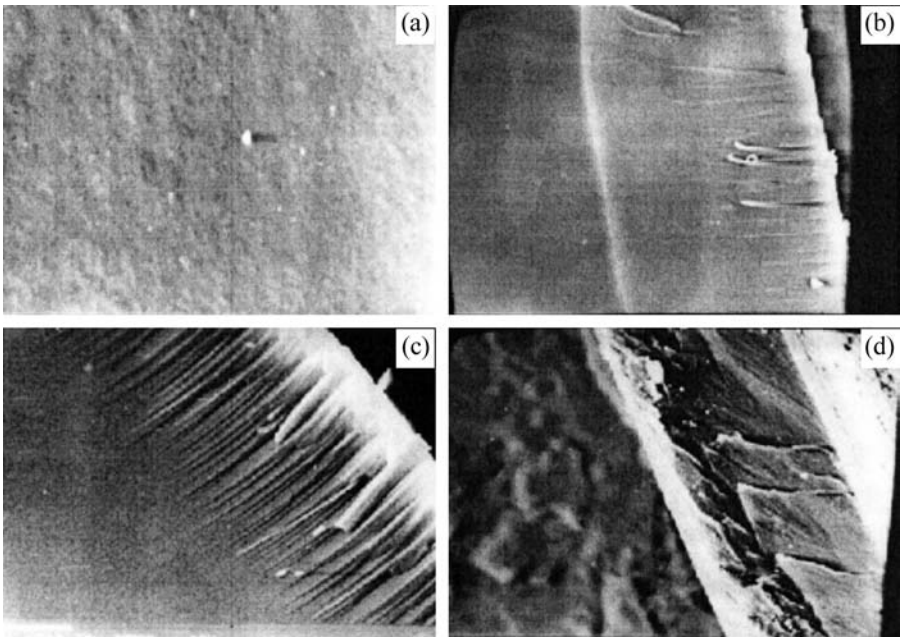

Fig. 3. Photomicrographs of a PI PM film pyrolyzed at 800°C. (a) Surface and (b)–(d) cleavage in liquid nitrogen.

The nucleation sites of the new carbon structure are several micrometers in size and, in turn, consist of finer formations with a size of 1–0.1 μm. The volatile products of polymer decomposition leave the reaction area through the channels clearly visible on the cleaved surfase of the film sample pyrolyzed at 600°C (Fig. 2d).

In carbonization at 700–800°C, the sample is compacted and micropores and cracks are healed, which follows from the photomicrographs of the surface of the PI PM film carbonized at 800°C. This surface is flat and uniform and does not contain no so coarse (of micrometers size) pores and cracks (Fig. 3). It is well known that, in the course of carbonization, the initial sample is subjected to shrinkage, which can reach from 5 to 15–25%.

A large number of parallel cracking strips is seen on the cleaved surface of the carbonized film (Fig. 3). This suggests a layered structure of carbon films based on PI PM.

The carbonized film samples were very little, which did not allow determination of their physicomechanical characteristics.

The heterogeneity of development of the thermal degradation of polyimide films was confirmed in a study of their isothermal pyrolysis.

The large-angle X-ray diffraction patterns of the films pyrolyzed at 500°C in the isothermal mode show that variation of the heating time in a wide range (up to 6 h) does not noticeably affect the shape of the X-ray diffraction patterns. This suggests a high thermal stability of the crystal structure of the PI PM films. At the same time, the intensity of small-angle X-ray scattering increases with the pyrolysis time. The presence of a small-angle X-ray reflection suggests the regular alternation of areas with different densities (large periods) with a size of $c \approx 15.0$–17.0 nm.

In the NMR spectra, the amorphous areas contribute to the signals as broadened pedestals, which is caused by the heterogeneity of the local surrounding of the carbon atoms. In thermal treatment of the PI PM samples, the lines corresponding to the diphenyl oxide fragment are narrowed. This is caused by the conformation ordering of the benzene cores of the macromolecules in the most ordered crystalline areas. In the amorphous areas, where mutual disordering of the chains hampers these processes, thermal degradation with release of thermolysis products is possible. This gives the heterogeneous structure detected by small-angle X-ray scattering.

The increase in the intensity of the small-angle scattering suggests that the density heterogeneity of the structure becomes more pronounced. Since the crystal structure remains unchanged in this process, it can be concluded that thermal degradation of the polymer is localized in intercrystallite amorphous areas, with their density decreasing.

To estimate the influence of phenylene rings in polyimide macromolecule on the structural features of carbonized films, the films based on PI PP were subjected to pyrolysis and carbonization. This polymer contains one phenylene ring in the macromolecule unit, while the PI PM macromolecule contains two phenylene rings.

The large-angle X-ray diffraction patterns of the PI PP films pyrolyzed at 500°C under isothermal conditions show that, as in the case of pyrolysis of PI PM films, the diffraction pattern does not change at this temperature. This fact suggests that the crystal structure of PI PP film does not change during isothermal pyrolysis for various periods (up to 6 h).

As follows from the results of small-angle X-ray diffraction measurements, the intensity of small-angle X-ray scattering significantly decreases as the heating time increases to 6 h, which suggests an equalization of the densities of various structural elements with sizes of 1–5 nm. Therefore, it can be concluded that, in contrast to the PI PM film, the supramolecular structure becomes more compact in pyrolysis of a film based on PI PP.

Comparison of small-angle scattering data for PI PM and PI PP films shows that PI PP films have a significantly higher density heterogeneity of supramolecular structure, compared to PI PM. This is evidently caused by the increased rigidity of the PI PP macromolecule due to the absence of "oxygen hinge" between phenyl rings. This significantly decreases the mobility of PI PP and hampers ordering in formation of the film structure. The presence of the –O– hinge group in the polymer structure results in that thermal degradation of the polymer chain starts from this bond [9]. The onset of homolytic degradation of benzimide rings and formation of interchain crosslinking are observed in the same temperature range. The absence of a "hinge" in the chain hampers rearrangement of macromolecules, recorded as line narrowing in the ^{13}C NMR spectra of PI PM. This is supported by a decrease in the intensity of small-angle X-ray scattering with increasing pyrolysis time. The thermal degradation of macromolecules makes higher the mobility of intermediates, which, in turn, can assist to structural rearrangements resulting in that the density heterogeneity decreases. It is likely that the latter causes the decrease in the intensity of small-angle X-ray scattering in pyrolysis of PI PP films.

A high heterogeneity of the hypomolecular structure of the PI PP films and the intensive processes on both molecular and supramolecular levels, which occur in the course of pyrolysis, exert a strong influence on the structure and characteristics of these films. The films based on this polymer and carbonized at 900°C had low strength and high brittleness.

CONCLUSIONS

(1) The crystalline regions of PM polyimide films have high heat resistance up to 550°C. In the amorphous regions, thermolysis and carbonization of the sample are accompanied by an increase in the heterogeneity on the nanometer level.

(2) An increase in the molecular mobility of macromolecules of a PP polyimide film in comparison with a PM film leads to higher heterogeneity of the density of the film; its carbonization is accompanied by equalization of the densities of structural elements with a size of 1–5 nm.

Abstract—Atomic-force microscopy was used to study structural chemical transformations on the surface of polyvinyl chloride films subjected to modification with compounds based on acrylic acid derivatives, with preliminary activation of the polymer surface with a corona discharge.

DOI: 10.1134/S1070427206080192

Polymeric materials, e.g., polyvinyl chloride (PVC), find wide use in various industries, e.g., as components of modern packaging materials, owing to such properties as transparence, low density, and chemical stability.

It is [1] known that use of various methods of surface modification and, in particular, of those in which various functional groups and fragments of a different chemical nature are introduced into macromolecules enables control over properties of materials and favors considerable expansion of their application areas. To raise the surface activity of polymers, various physical treatments of a polymer: laser or UV irradiation, corona discharge, etc. are used prior to, or together with chemical modification [2]. The processes occurring in this case, result in that a positive or negative charge (electret effect) or new functional groups that can enter into chemical interactions with other modifying agents appear on the surface.

A promising way to improve the adhesion properties of polymers are various types of surface treatment, which should create stable active centers. As treatments of this kind can be classed vapor-phase chemical modification and, in particular, chemical vapor deposition onto the surface of a solid polymeric matrix of organic structures that make higher its polarity [3].

The aim of the present study was to examine chemical transformations that occur in PVC under the action of a corona discharge and upon the subsequent interaction with derivatives of acrylic and metacrylic acids and to analyze the influence of the surface organic structures synthesized on the adhesion properties of PVC.

EXPERIMENTAL

As objects of study served 200–300-μm-thick PVC films of Pentaprint brand (manufactured by Klöeckner Pentaplast GmbH). The surface of a prescribed composition was formed using a procedure based on the treatment of the polymer surface with a flow of charged particles and chemical vapor deposition of organic structures, derivatives of acrylic and methacrylic acids. The choice of the modifying agents was due to the necessity for use of a combination of substances that can enter into a photochemical chain reaction of polymerization, initiated on the polymer surface in the course of offset printing. To reveal the effect of modification on the PVC properties, the surface structure and free surface energy of the starting and final products were studied by atomic-force microscopy (AFM) [4].

Organic acryl structures were synthesized on a Coating Star industrial installation (Ahlbrandt GmbH, Germany), shown schematically in Fig. 1. A PVC film was modified in a reactor *1*, in which a corona discharge *2* was initiated in the range 2.0–2.5 W cm^{-1} at room temperature and atmospheric pressure. Vapors of reagents were delivered at a pressure of $(1.5–2.0) \times 10^5$ Pa and temperature of 35–38°C via systems for mixing (*3*) and spraying (*4*) into reactor *1* into the atmosphere of corona discharge *2*.

To preclude any rise in temperature in the reactor and in the corona discharge zone, a cooling system *5* was used. As modifying agents were used benzotriazole, polyethylene diacrylate, morpholine monoacrylate, and 6-ethoxy methacrylate. The results of surface modification with low-molecular-weight reagents were assessed by the degree of polarity and changes in the surface morphology of films.

The surface energy of PVC was studied on a DSA 100 instrument (Kruess GmbH), which measures the surface wetting angle for two control liquids with known surface tension energy in the dynamic mode. The supply rate of the control liquids was 8–10 μl min^{-1}. The free surface energy was calculated by the Owens–Wendt–Rabel–Kaelble method [5]:

$$\sigma_s = \sigma_{sl} + \sigma_l \cos\theta,$$

where σ_s is the surface energy of the solid phase, which depends on the angle θ of wetting of the solid by the liquid phase chosen for measurements, on the surface tension energy of the liquid phase (σ_l), and on the free energy of the solid–liquid interface (σ_{sl}).

The state of the initial surface and changes of its topography upon coating deposition were studied on a Solver P47 Pro scanning probe microscope (NT–MDT, Russia)[1] by the AFM technique in the tapping mode in air, with an NSG-01 silicon cantilever used. The samples were scanned in two modes, which yielded various kinds of information about the structure and properties of a material by measuring (i) topography and (ii) phase contrast. The latter approach revealed differences in the composition of different parts of the sample surface by analyzing data on the phase shift of the amplitude-frequency characteristic of the cantilever as a result of adhesion interactions [6].

It is known that irradiation of polymeric insulators with flows of charged particles results in a buildup of positive or negative charge [7, 8] on their surface and generates polar functional groups, such as carboxy, carbonyl, and hydroxy groups, as well as amino groups [9]. The aim of such a physical treatment of the polymer surface is to produce polar active centers that can be involved in chemisorption in deposition of subsequent layers, lamination, or printing. The stability and concentration of active centers of this kind is a function of the surface Gibbs free energy, which, in turn, depends on the chemical composition and structure of the polymeric material and its phase state [10].

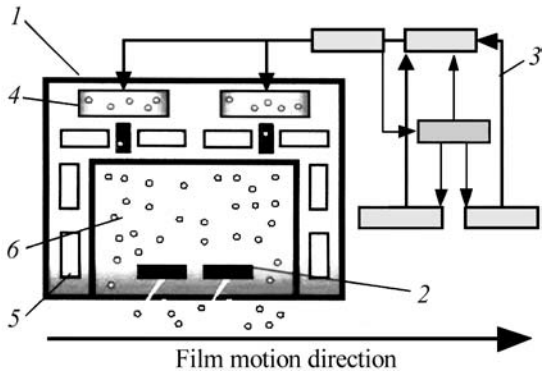

Fig. 1. Schematic of the installation for surface modification of PVC films. (*1*) Reactor, (*2*) electrodes and the corona discharge zone, (*3*) system for mixing and delivery of reagents, (*4*) system for spraying of the reagents, (*5*) reactor cooling system, and (*6*) area of coating deposition.

The table lists the results obtained in measuring the free surface energy of the initial and modified PVC. It follows from the data in the table that surface modification gives rise to new active centers and, accordingly, leads to comparatively high surface polarities. Prolonged measurements (up to 150 days) suggest that the modified surface is stable. The insignificant changes in the surface energy of modified films can be attributed to relaxation of active centers that did not enter into the reaction of chemical de-

position or to gradual neutralization in interaction with air of charged particles produced upon preliminary treatment of the surface with a corona discharge.

A study of the surface morphology of the initial PVC by the AFM method (Fig. 2a) revealed that the film has a sufficiently smooth surface with a roughness determined in accordance with DIN 4768 equal to 2–5 nm. Irregularly arranged rounded projections 150–200 nm in diameter and 10–20 nm high are observed over the entire surface (Fig. 3a). At the same time, surface scanning in the phase-contrast mode did not reveal any differences in adhesion properties between different parts of the surface (Fig. 3b), which indicates that the chemical composition and properties of the entire surface of the initial PVC film are uniform.

Chemical modification of a PVC film with a mixture of derivatives of acrylic and metacrylic acids in a corona discharge leads to a significant change in the topography of the material (Fig. 2b): separate structures of irregular shape, 8–15 μm in size and up to 0.5 μm high, appear on the surface in addition to smooth areas. At the same time, the surface roughness remains virtually unchanged (20–30 nm) as compared with the initial PVC.

A scanning in the phase-contrast mode revealed that chemical modification of a PVC film results in that two types of areas with different levels of the adhesion interaction with the silicon cantilever appear on its surface (Fig. 4). Comparison of the surface morphology and data obtained in scanning in the phase-contrast mode shows that the volume structures appearing on the surface have a chemical nature different from that of PVC and presumably belong to the organic coating formed as a result of this treatment. The polyvinyl chloride film is covered with the organic coating nonuniformly: areas with the initial

PVC film virtually completely covered with a newly formed of average thickness 100 nm (Fig. 4a) and those partly exposed (Fig. 4b) are observed.

The effect of chemical modification on the adhesion properties of the surface was assessed by a change in the interaction of the surface with an offset printing ink. Black and orange industrial offset inks of Sicpa brand with a high absorption coefficient of UV light were used for this purpose. It should be noted that offset printing is a complex physical process, which occurs at a high rate and imposes stringent requirements to the quality and structure of the surface of a solid support. It is known that the film surface is wetted by the ink in the initial stage of deposition. Then a photochemical chain reaction of polymerization is initiated by UV irradiation, which results in that offset inks are hardened and retained on the polymer surface by forces of the atomic-molecular interaction, which appear between the liquid and solid phases in the course of wetting [2, 9]. Figure 5 shows adhesion curves for the initial and modified PVC surfaces. The differences in the adhesion interaction forces between these two kinds of surfaces suggest that forces of not only physical, but also chemical, covalent nature exist in the case of a chemically modified surface. This confirms once more that organic functional groups interact with molecules of the solid-phase PVC surface.

CONCLUSIONS

(1) The results obtained in a physicochemical study of the products formed in interaction of a gaseous mixture of derivatives of acrylic and metacrylic acids with polyvinyl chloride films made it possible to suggest that organic functional structures are chemically grafted to reactive centers created by preliminary treatment of the polymer surface with a corona discharge.

(2) A study of the properties of the modified surface in offset printing and its analysis by atomic-force microscopy revealed that the grafted functional groups

are involved in the photochemical chain reaction of radical polymerization and the adhesion properties of the polymer toward the inks used in practice are improved.

Abstract—Film-forming polyimide nanocomposites containing 5 to 20 wt % nanoparticles were prepared from ferromagnetic Fe/Fe_3O_4 nanoparticles and a polyimide derived from 4,4'-bis(4-aminophenoxy)diphenyl sulfone and 1,3-bis(3,4-dicarboxyphenoxy)benzene dianhydride. The mechanical properties and magnetization of the nanocomposite samples were studied in relation to the nanoparticle concentration.

DOI: 10.1134/S1070427206080209

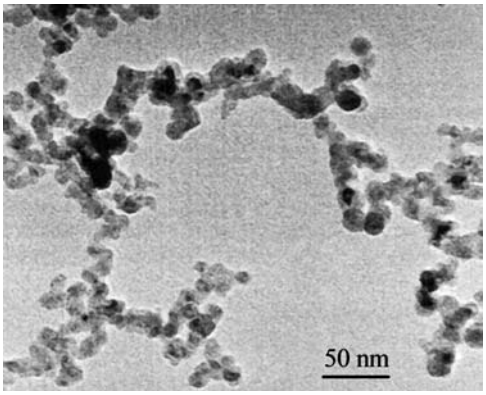
Introduction of nanosized inorganic fillers into polymers yields novel materials, so-called nanocomposites [1, 2]. With the progress of nanotechnologies, major attention is given to the development of new nanocomposites based on carbon-containing, metallic, or ceramic nanoparticles. These materials can be used for preparing protective antifriction coatings, components for high-frequency magnetic shields, and articles exhibiting optical, conducting, and other properties [3–5].

Polyimides (PIs), thanks to their high mechanical properties and heat resistance [6, 7], are of particular interest as a polymeric base for nanocomposites. Imide-containing magnetic composites filled with 75–100-μm magnetic particles (Nd–Fe–B) were prepared by a specially developed procedure involving synthesis in a melt [8–10]. This procedure makes it possible to prepare magnetic plastics at lower temperatures (220–240°C), compared to compacting of the corresponding polymeric composites at 350°C, using the powder metallurgy techniques, and to avoid oxidation of ferromagnetic particles. The use of a new kind of nanoparticles, magnetic iron nanoparticles in an oxide shell, will allow preparation of elastic highly heat-resistant magnetic nanocomposites under the conditions of traditional two-step procedure for synthesis of polyimides [11].

The goal of this study was to examine the possibility of introduction of magnetic iron nanoparticles in an oxide shell into a polyimide matrix and to analyse the mechanical and magnetic properties of the resulting materials in relation to the filler content.

EXPERIMENTAL

Fe/Fe_3O_4 nanoparticles were prepared by chemical vapor condensation [1]; they consist of an iron (Fe) core encapsulated in a 2–4-nm-thick magnetite (Fe_3O_4) shell [12]. These nanoparticles have an approximately spherical shape with a diameter of 15–25 nm (Fig. 1).



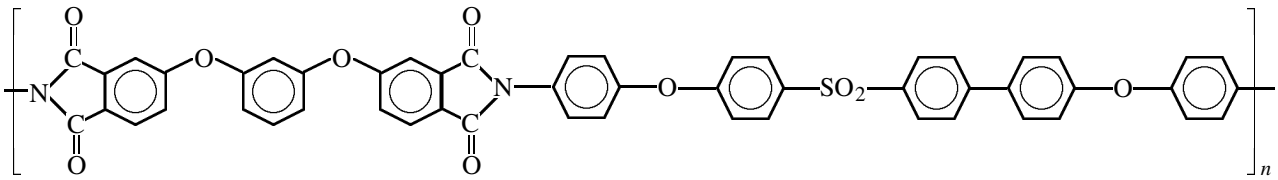


Fig. 1. Photomicrographs of Fe/Fe_3O_4 nanoparticles.

As a polymeric matrix of the composite material we used the polyimide derived from 4,4'-bis(4-aminophenoxy)diphenyl sulfone and 1,3-bis-(3,4-dicarboxyphenoxy)benzene dianhydride (PI P-SOD) [13]; its structural formula is given below:

The nanocomposite was prepared as follows. A round-bottomed flask was placed in an ultrasonic bath (40 kHz) equipped with a stirrer and a tube for feeding Ar. The flask was charged with the solvent, *N*-methyl-2-pyrrolidone (MP), in which the required amount of Fe/Fe_3O_4 nanoparticles (5–30 wt % relative to PI, depending on the desired concentration of the nanoparticles in the polyimide film) was dispersed for 1 h by ultrasonic treatment combined with stirring. Then the diamine, 4,4'-bis(4-aminophenoxy)diphenyl sulfone (SOD), was added. After the added diamine completely dissolved, an equimolar amount of 1,3-bis-(3,4-dicarboxyphenoxy)benzene dianhydride (P) was added, and the solution was stirred for 2 h in an argon flow, with the ultrasonic treatment continued until the dianhydride complete dissolved. The resulting solution of the prepolymer, polyamido acid (PAA), was applied onto glass plates as a thin layer. After the solvent evaporation at 60°C for 24 h, 40 ± 5-μm-thick PAA films were obtained; these films were subsequently imidized by stepwise heating (100°C, 1 h; 200°C, 1 h; 250°C, 1 h).

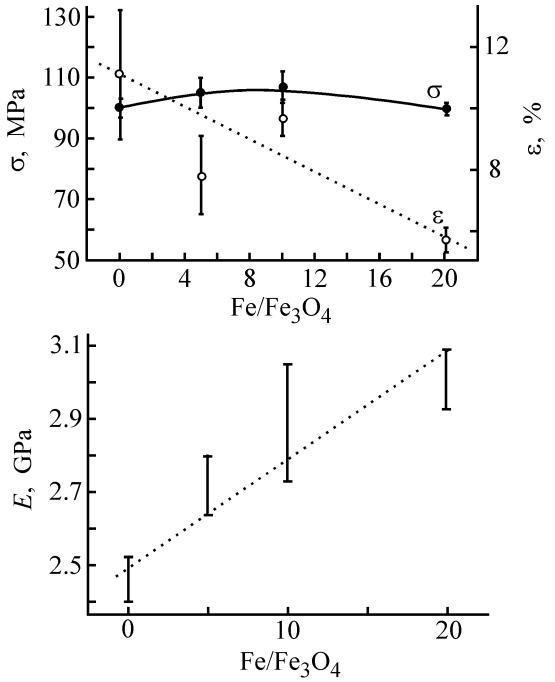

Fig. 2. Properties of samples of polyimide nanocomposites P-COD/Fe/Fe_3O_4 vs. the content (wt %) of the nanoparticles in the polyimide matrix. (σ) Ultimate tensile strength, (ε) relative elongation, and (*E*) Young's modulus.

The mechanical properties (tensile strength σ, Young's modulus *E*, and break elongation ε) of the film samples of the polyimide–metal nanocomposites were determined with a UMIV-3 tensile-testing machine (Russia). Samples of nanocomposites for mechanical tests were films of the following dimensions: thickness 40 ± 5 μm, width 2 mm, and base length 30 mm. Tensile tests were performed at room temperature in the active-loading mode at a rate of 1 mm min^{-1}.

The magnetic properties of the films were studied in fields of up to 10 kOe by vibration magnetometry using a Lakeshore 7400 standard magnetometer.

An optical microscopic examination of nanocomposite specimens revealed no inclusions or aggregates of the metallic powder, visible at ×500 magnification, at a filler content of up to 20 wt %. At the Fe/Fe_3O_4 content increased to 30 wt %, it appeared impossible to obtain a homogeneous distribution of the particles in the polymer matrix. The material is optically transparent at a filler content of 0 to 10 wt %.

Figure 2 shows how the mechanical properties of the nanocomposite films vary with the filler content. With an increase in the filler concentration, the film strength, 105 ± 2 MPa, remains unchanged within the measurement error. With an increase in the Fe/Fe_3O_4 concentration, the break elongation of the films somewhat decreases (from 11 to 6%), but remains sufficiently high to avoid brittle failure at bending. It should also be noted that, as the filler content is

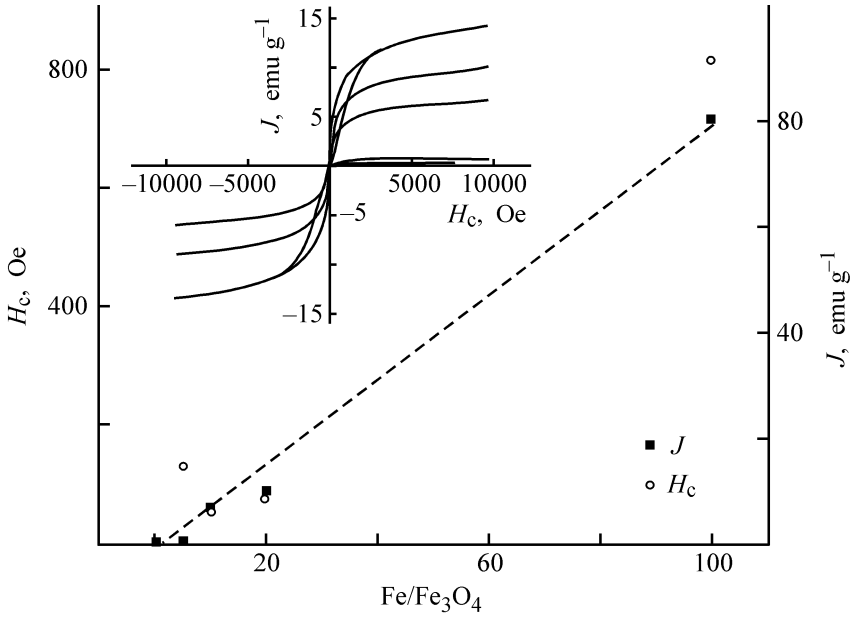

Fig. 3. Maximal magnetization J and coercivity H_c of samples of polyimide nanocomposites P-SOD/Fe/Fe_3O_4 vs. the filler content. Inset: characteristic hysteresis loops of the nanocomposites containing 20, 10, and 5 wt % nanoparticles.

raised from 0 to 20 wt %, Young's modulus increases from 2.4 to 3 MPa, with the elastic properties preserved.

The influence of the filler content on the maximal specific magnetization and coercivity of the composite material is illustrated by Fig. 3. The points corresponding to the initial nanoparticles (100% Fe/Fe_3O_4) are given for comparison. The inset shows the characteristic hysteresis loops.

The maximal specific magnetization of the material linearly increases with the concentration of ferromagnetic particles in the polyimide matrix. The coercivity of the nanocomposite is considerably lower than that of the initial powder and shows no definite correlation with the filler content. Apparently, at random orientation of single-domain particles and at their fixed arrangement in the polymer matrix, the coercivity will depend on the particle orientation (easy magnetization axis) relative to the measurement field, whereas at predominant orientation along the field it will have a maximum. In our experiment, the particles were oriented randomly, and, therefore, there was no pronounced correlation between the coercivity and filler content. Apparently, to obtain a high-coercivity material, it is necessary to provide definite orientation of particles in the matrix, e.g., by curing the polymer in a magnetic field.

CONCLUSION

Flexible ($\varepsilon \leq 10\%$) films of nanocomposites containing 5 to 20 wt % ferromagnetic Fe/Fe_3O_4 nanoparticles in a matrix of the polyimide derived from 4,4'-bis(4-aminophenoxy)diphenyl sulfone and 1,3-bis(3,4-dicarboxyphenoxy)benzene dianhydride were prepared. With an increase in the filler concentration, the magnetization of the film samples linearly increases, and Young's modulus grows from 2.4 to 3.0 GPa.

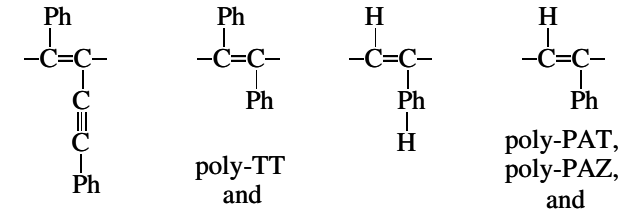
Abstract—Colored thin films with a thickness of 0.1–10 μm were prepared by the vacuum sputtering of phenyl-containing polyacetylenes. The mechanism of formation of ordered films was analysed. The characteristics of the films were studied and possible fields of their application were outlined.



DOI: 10.1134/S1070427206080210

The specific features of molecular structure and electrophysical, optical, and magnetic characteristics of polyacetylenes necessitate use of new procedures for production of various new materials based on homo- and copolymers of substituted acetylenes and acetylenecontaining oligomers [1–3]. For example, new approache have made it possible to prepare high-temperature composites and ceramics with carborane-containing acetylenesiloxanes [4], reactive elastomers containing two types of the C=C bonds using propyne and allene [5], films based on (*p*-*tert*-butyl-*o*,*o*'-dimethylphenyl)acetylene polymer allowing separation of oxygen and nitrogen [6], and liquid crystals based on acetylene-containing macromonomers [7].

Here we report first data on the formation of uniform thin films by vacuum sputtering of various polyphenylacetylenes. We also discuss the characteristics of films and possible fields of their application. The starting substances were polymers of diphenyldiacetylene (poly-DPDAC), *p*-diethynylbenzene (poly-DEBA), phenylacetylene (poly-PAT, poly-PAZ, poly-PAAC), and tolan (poly-TT and poly-TA) prepared by various procedures. The last letter (last letters in the case of poly-PAAC) in the abbreviation denotes the synthesis procedure: thermal polymerization (T), polymerization in the presence of acetylacetonate (AC), and anionic (A), Ziegler (Z), or cobalt-containing (C) catalysts.

EXPERIMENTAL

The polymers were synthesized by the following procedures: poly-DPDAC [8], poly-PAT [9], poly-PAZ [10], poly-PAAC [11], poly-TT [12], poly-TA [13], and poly-DEBA [14]. The initial polymers have the following structure of units:

Sputtering was performed on a VUP-2 vacuum setup at a pressure of 6.65×10^{-2}–1.33×10^{-3} Pa.

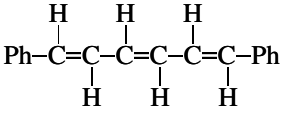
The molecular weights and molecular-weight distribution of polymers were studied on a Waters GPH-200 liquid chromatograph with styrogel columns. The solvent, tetrahydrofuran, was fed at a flow rate of 1 ml min^{-1}; temperature 25°C.

The photoelectric sensitivity was studied in the electrophotographic mode [15].

The quality of thin films and the rate of their preparation depended on the polymer type, vaporizer temperature, distance between the support and vaporizer, and residual pressure. An increase in the residual pressure (vacuum deterioration) resulted in that the sublimation rate decreased or the process terminated. The sublimation temperature was in the range 280–400°C for linear polymers and 500–700°C for cross-linked polymers (poly-DEBA); it was governed by the degradation temperature of the polymers. It was 10–15°C lower than the temperature of the onset of weight loss, determined from the TGA curve.

Raising the heater temperature resulted in an increase in the pyrolysis rate, rise in the flow of molecular fragments, and deterioration of the quality of the resulting film: appearance of loose areas and surface heterogeneity. A decrease in temperature below the optimum decelerated the film formation. Under the given conditions, the optimal distance between the heater and the support was 5–7 cm. An increase in the distance decelerated the process. A decrease in the distance significantly deteriorated the quality of the resulting film because of its contamination with coarse polymer particles carried away with the pyrolyzate flow, detectable even visually.

Certain difficulties arose in operation with soluble or thinly cross-linked poly-DEBA. Because of the strong exothermic effects arising from scission of the C≡C bonds, the polymer was scattered in the course of pyrolysis, and the quality of the thin film deteriorated. To prevent this phenomenon, the heater temperature was raised more slowly.



When the above-mentioned optimal conditions were observed, uniform colored (brown, light brown, yellow) thin films with a thickness of 0.1–10 μm were obtained on the supports of polished quartz, silicon, and aluminum. The polyphenylacetylene films had higher mechanical strength and adhesion to the support than the films prepared from a solution. All the films except the films from DEBA, were soluble in organic solvents, except alcohols and alkanes. This allowed us to monitor changes in the molecular weights of the polymers after their sublimation.

The coincidence of the IR spectra of the initial polymers and sputtered films in the range 400–3400 cm^{-1} suggests preservation of the basic molecular structure of the polymers after their sublimation and condensation. This fact confirms that the pyrolysis proceeds with the formation of volatile intermediate fragments consisting of 1–2 polymer units. This conclusion is consistent with the volatility of the low-molecular-weight compounds modeling the units of the polymers studied (stilbene, bp 123–125°C; 1,2,3,4-tetraphenyl-1,3-butadiene, bp 183–184°C; 1,6-diphenyl-1,3,5-hexatriene, bp 201–202°C):

Table 1. Molecular weight of polymers forming sputtered films

Polymer	$\overline{M}_n$	$\overline{n}^*$	$\overline{M}_w$	$\overline{n}^*$	$\overline{M}_w/\overline{M}_n$
Poly-TT:					
initial	1310	7.4	4990	28.1	3.79
after sublimation	1190	6.7	1440	8.1	1.20
Poly-TA:					
initial	1300	7.4	1460	8.2	1.11
after sublimation	1230	6.9	1340	7.5	1.09
Poly-PAT:					
initial	1400	13.8	1700	16.8	1.25
after sublimation	980	9.6	1210	11.9	1.23

* Average number of units in polymers.

A consideration of the number-average ($\overline{M}_n$) and weight-average ($\overline{M}_w$) molecular weights and also polydispersity $\overline{M}_w/\overline{M}_n$ of both the initial and sputtered polymers (Table 1) revealed certain specific features: (1) low-molecular-weight fractions are absent in all the initial samples; (2) all the initial polymers and polymeric sublimation products have unimodal molecular-weight distribution; (3) $\overline{M}_n$, $\overline{M}_w$, and $\overline{M}_w/\overline{M}_n$ decrease for all the polymeric sublimation products; (4) the polydispersity significantly decreases after the sublimation; and (5) the higher the initial $\overline{M}_n$ and $\overline{M}_w$ values, the greater the decrease in $\overline{M}_n$ and $\overline{M}_w$, i.e., the molecular weights are equalized.

These results confirm the assumption that, in sublimation, the initial polymer chains are first cleaved into identical short fragments (1–2 units). Then, short fragments diffuse into the gas phase toward the support. Finally, under the conditions preventing random recombination of these fragments, low-defective polymer chains with decreased polydispersity $\overline{M}_w/\overline{M}_n$ are formed at the supports. Thin films formed by this way from polyarylacetylenes are more ordered than films prepared by other procedures. Actually, it has been found [16] that the drift mobility of current carriers in these sputtered layers increases by many orders of magnitude, from 10^{-5} to 0.07–0.1 $cm^2\,V^{-1}\,s^{-1}$. The increase in the carrier drift mobility was attributed in [16] to ordering of the molecular structure and to the corresponding decrease in the concentration of deep traps for carriers.

The electron microscope images of thin polymer films (surface replicas) showed that the films have a dense uniform surface disturbed only when the sput-

tering conditions deviated from the optimum. The resulting uniform films can be suitable for various applications.

We studied some characteristics of thin films of polyphenylacetylenes, which can determine their possible application areas. We found that the polymer films have a photoelectric sensitivity. Some results of an electrographic study of thin films prepared on an aluminum support are presented in Table 2. An incandescent lamp of 1×10^3 lux was used as a light source. The increased photoelectric sensitivity of the layers based on poly-DPDAC is accounted for by the polyacene character of the intramolecular structure of the polymer molecules forming sputtered a poly-DPDAC film [8].

The sputtered films based on poly-TT were studied as protective coatings for electronics. For this purpose, we used test elements of three types: (1) devitrified glass supports with an applied photosensitive film based on PbCdS; (2) devitrified glass supports with active components with a size of 50, 125, 250, and 500 μm^2, formed by photosensitive film based on PbCdS; and (3) silicon plates with a thin SiO_2 layer and the subsequent Si_3N_4 layer with sputtered aluminum strips.

The protective characteristics of the sputtered films were tested by tenfold cyclic temperature action (from –60 to +60°C) on the samples at standard humidity and keeping time of 30 min. For the elements tested, uncoated and coated with the sputtered films, we measured and compared the following characteristics: dark resistance, photocurrent multiplied by the photoresistor resistance under conditions of short exposure, and noise voltage. It was shown that the photoresistor resistance increases after applying the polymer film; the main parameters of photoresistors (intensity of photosignal, signal-to-noise ratio) are improved or remain unchanged.

The features of the chemical structure of molecules forming sputtered films were the cause of their unusual behavior under UV irradiation under various conditions. It was found that fairly short UV irradiation of sputtered films in a vacuum through a phototemplate results in the appearance of a latent image due to intermolecular cross-linking of polymers in irradiated areas. After heating of the layers in a vacuum at the optimal temperature of 200–350°C, the nonirradiated non-cross-linked part of the polymers is evaporated. As a result, a visible contrast image is formed. This image does not appear if the development temperature is raised above the optimum because of the simultaneous degradation and evaporation of the cross-linked areas.

Table 2. Photoelectrical sensitivity of sputtered films

Polymer	Charge potential, V	Half-life of charge potential, s	
		in darkness	in light
Poly-DPDAC	410	120	35
Poly-PAT	290	225	175
Poly-PAZ	320	120	72

By contrast, prolonged UV irradiation of sputtered films through a phototemplate in air results in the disappearance of the areas of sputtered layers at the points of exposure to light and in the appearance of a contrast positive image. This process is accounted for by formation of ozone from atmospheric oxygen under UV irradiation and subsequent oxidation of unsaturated bonds of sputtered polymers by ozone. In this case, according to the rate constants of the reactions of ozone with organic compounds [17], the most probable is ozone attack on the C=C bonds of polyene chains.

Rate constants of the reactions of ozone with compounds

Compound	k, $1\ mol^{-1}\ s^{-1}$
Ethylbenzene	0.4
Phenylacetylene	60
Styrene	3×10^5
Stilbene	1.8×10^5
1,4-Diphenylbutadiene	9×10^4
1,2,3,4-Tetraphenylbutadiene	8×10^4
Poly-PAT	1.4×10^3

Actually, only the degradation of polyene chromophores (i.e., the main chains of polyphenylacetylenes) forming sputtered films gives rise to a visible image. This mechanism is additionally confirmed by the following fact. By applying some low-molecular-weight compounds, which model polyphenylacetylene units and readily react with ozone (stilbene. 1,6-diphenyl-1,3,5-hexatriene), to the support, we also obtained films though of lower quality. An image appeared on these films under prolonged UV irradiation.

Thus, sputtered films of polyphenylacetylenes are the first real example of the previously unknown class of photoresists, which can be both negative and positive, depending on the treatment conditions. These films can be used as visualizing materials for dry photolythography, a new promising approach in production of microelectronics items. Development and use of such technologies will allow elimination of solvents or etching agents. We believe that the sen-

sitivity of sputtered thin films can be improved by introducing fragments that enhance the photosensitivity of the materials.

CONCLUSIONS

(1) Uniform ordered colored films with a thickness of 0.1–10 μm were obtained on quartz, silicon, and aluminum supports by vacuum sputtering of polyphenyldiacetylene, poly-*p*-diethynylbenzene, and polytolan.

(2) It was shown that the polydispersity of polymers forming thin layers decreases in comparison with that of the initial polymers.

(3) It was found in the electrophotographic mode that the thin films of polymers have a photoelectric sensitivity.

(4) It was demonstrated that, under various conditions of UV irradiation, the polymer chains in the film cross-link or are broken with ozone. This results in appearance of images at the support surface.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermomechanical Properties of Composite Films of Polyacrylonitrile with Chitin and Chitosan

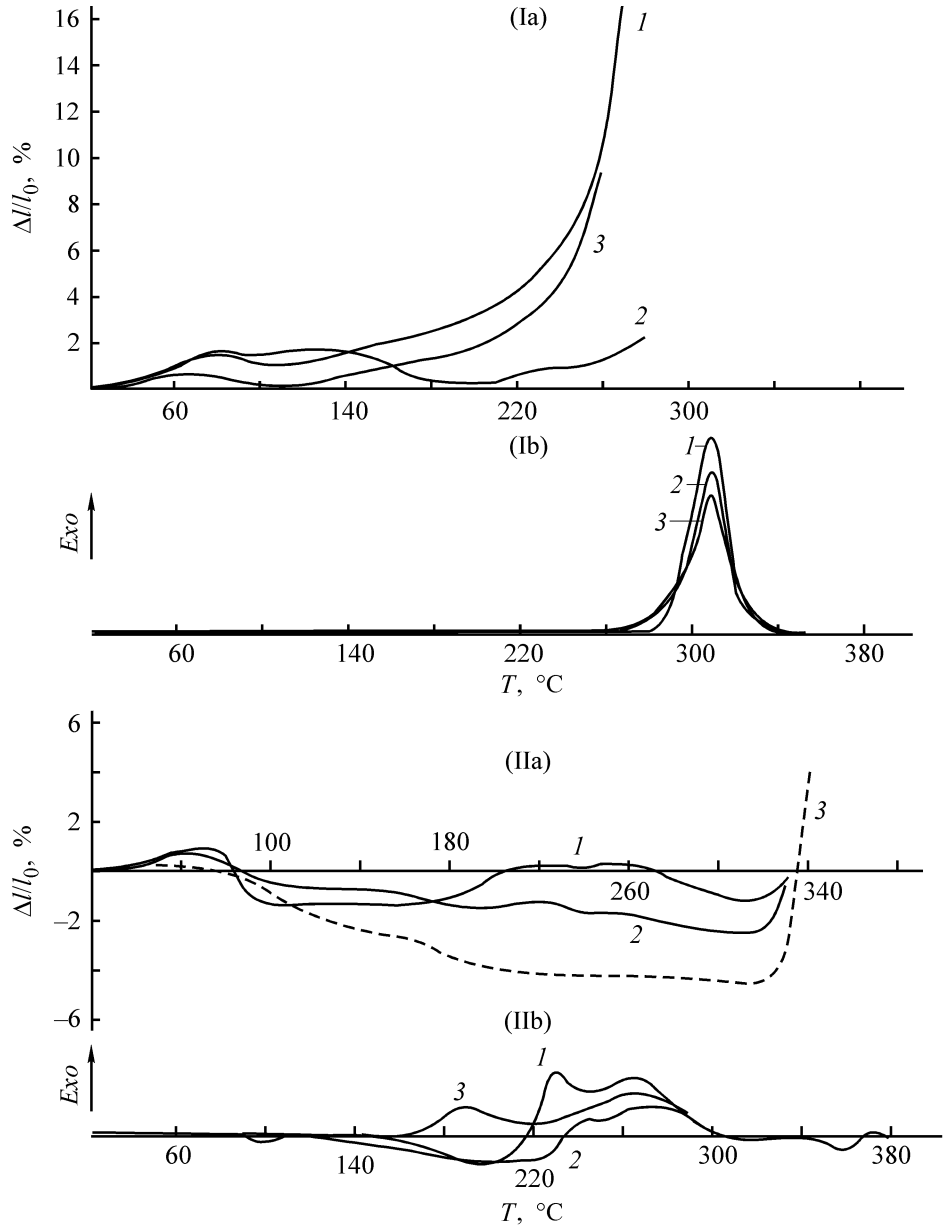
Abstract—Composite films were prepared from polyacrylonitrile synthesized by anionic and radical polymerization and combined with chitin or chitisan. The thermomechanical properties of the films were examined. The compatibility of polyacrylonitrile synthesized by radical polymerization with chitosan was studied by DSC over a wide temperature range 140–280°C.

DOI: 10.1134/S1070427206080222

In [1, 2] we examined the thermochemical reactions of blends of polyacrylonitrile (PAN) with chitin (CT) and chitosan (CTS) at temperatures within the range 0–900°C and demonstrated the possibility and promise of preparation of composite materials based on synthetic acrylonitrile polymers and CTS. This study was focused on preparation of films based on PAN synthesized by anionic and radical polymerization and modified with polysaccharides CT and CTS.

EXPERIMENTAL



We used previously characterized [1] acrylonitrile polymers R-PAN and A-PAN synthesized by radical (initiator $K_2S_2O_8$–$Na_2S_2O_8$) and anionic (initiator lithium alkoxide, in toluene) polymerization, respectively, as well as chitin and chitosan obtained from a crab shell: CT (ash content 1%) and CTS (degree of deacetylation 0.79), molecular weights 282 and 245 kD, respectively. The CT and CTS powders were partially dissolved by heating for 1 h at 140°C in dimethylformamide solutions of PAN at the 1 : 1 ratio (by weight) of the starting blend components. Films were cast from these solutions after filtration and dried at room temperature for three days. The content of CT and CTS in the films was calculated from the difference of the weights of their introduced and returned amounts.

The mechanical characteristics of the films (ultimate tensile strength, Young modulus, and elongation at break) were determined on a UMIV-3 universal setup at an extension rate of 5 mm min^{-1}, sample size of 35×2 mm, distance between the grips of 25 mm, and film thickness of 30–40 μm. The strength was calculated for the initial cross section of the sample. The Young modulus was determined at a strain of 1%. Results of 10 measurements were averaged.

The dilatometric measurements were carried out with a setup on which the changes of the longitudinal sizes of the films can be determined accurately to within 0.01 μm when heating the samples (30×4 mm, d = 40 μm) at a rate of 10 deg min^{-1} at temperatures within the range 20–400°C and a tensile stress of 3 kg cm^{-2}.

The calorimetric measurements in the same temperature range were carried out in a DSM-2M differential scanning microcalorimeter at a scanning rate of 16 deg min^{-1} and threshold sensitivity of 0.04 mW.

Since preparation of films based on PAN synthesized by radical and anionic polymerization entails a number of technological difficulties, we attempted to modify PAN with chitin and chitosan. To this end, we developed the conditions for preparation of composite films with satisfactory strength properties. The table lists the deformation and strength characteristics of the films formed by the basic polymer, AN, and its composites with CT and CTS of the formulations indicated. The data for experiment nos. 7 and 8 were identical to those for the A-PAN–BA copolymer containing 5% butyl acrylate. In all cases, the strength characteristics of the films were deteriorated to a certain extent in the presence of chitin

(a) Thermomechanical curves at the tensile stress of 3 kg cm^{-2} and (b) DSC curves of the films. ($\Delta l/l_0$) Relative size change and (T) temperature. (I) (*1*) A-PAN, (*2*) A-PAN + CT, and (*3*) A-PAN + CTS. (II) (*1*) R-PAN, (*2*) R-PAN + CT, and (*3*) R-PAN + CTS.

and chitosan. This can be due to a high-temperature (140°C) treatment of mixed polymer solutions from which the films were cast.

Figures Ia and Ib demonstrate the thermomechanical properties of films of A-PAN, A-PAN + CT, A-PAN + CTS. It is seen that, in the initial stage of the heat treatment (20–140°C), when the residual solvent is being eliminated (thereby increasing the probability of intermolecular interaction), the size of the films changes insignificantly. With a rise in temperature to above 140°C, the elongation of the A-PAN and A-PAN + CTS films increases, and films pass from the hyperelastic to the viscous-flow state, which is followed by break at 260°C. The break of the films corresponds to the onset of the A-PAN thermal cyclization (Fig. Ib) with T_{max} = 320°C. The appearance of the exothermic peaks suggests that this process is not complicated by other chemical reactions, i.e., the energy release is due to the cyclization reaction only. The ΔH parameters were estimated at 1060,

Composition and strength of the films

Experiment no.	Film composition	Ultimate tensile strength σ, MPa	Elongation at break ε, %	Young modulus *E*, MPa
1	R-PAN	72	2.6	3600
2	R-PAN + CT 6%)	52	2.0	3000
3	R-PAN + CTS 6%)	48	2.0	3000
4	A-PAN	65	2.7	3500
5	A-PAN + CT (12%)	55	2.2	2600
6	A-PAN + CT (20%)	45	1.5	3500
7	A-PAN · BA	65	3.3	3000
8	A-PAN · BA + CT (6%)	64	1.8	3300

770, and 690 kJ g^{-1} for A-PAN, A-PAN + CT, and A-PAN + CTS, respectively. Earlier, we have observed a similar phenomenon of fluidity in the thermograms of the films of anionic PAN synthesized in DMF [3]. This is, evidently, due to the structural and molecular-weight heterogeneity, stereoblock structure, and presence of nitrile groups with a high dipole moment, which make possible gradual formation of associates, mainly double helices, by the A-PAN macromolecules in solution. Interaction between them is much weaker than that between the A-PAN macromolecules inside the coils. The observed phenomena of the viscous-flow state of the A-PAN and A-PAN + CTS films, as well as the absence of heat effects (DSC) up to 260°C, suggest that no prominent intermolecular valence interactions occur in these films. The thermodilatogram of the A-PAN + CT film (Fig. I, curve *2*) shows a different pattern. The fact that the film length remains unchanged under these conditions suggests a significant amount of chemical intermolecular cross-links. The lack of a peak of exothermic effect on the corresponding DSC curve suggests that the cross-links appear during the heat treatment of the starting mixed solution (140°C, 1 h).

As to interaction with the polysaccharides examined, the R-PAN, as well as the R-PAN + CT and R-PAN + CTS, films have complex thermodilatograms and DSC curves (Figs. IIa, IIb). This is due to the known molecular-weight and structural heterogeneity of R-PAN, as well as to the presence of a significant amount of oxygen-containing fragments of the initiator in its macromolecules. The DSC curve of the R-PAN films after heat treatment exhibits two exothermic peaks and one endothermic peak (Fig. II, curve *1*).

The thermodilatogram of the same film showed that the initial heating stage (removal of the residual solvent) is characterized by insignificant absorption of energy, possibly due to the solvent evaporation. Above 200°C, chemical processes with a significant exothermic effect (T_{max} = 230°C) occur. The film elongation, which began earlier (180–200°C), ceases (Fig. II, curve *1*). The film length remains unchanged under heating to 270°C, whereupon the film contracts as a result of the thermal cyclization (250–300°C).

The chemical processes occurring in the R-PAN films during the heat treatment also occur in the composite films, now with the polysaccharide macromolecules involved. It should be noted that a gradual and more intensive contraction in comparison to the R-PAN film (Fig. IIa, curves *2*, *3*), observed in the thermodilatograms of the composite films, is partly due to the chemical intermolecular interactions already in the stage of preparation of mixed solutions (140°C, 1 h). The A-PAN + CT composite film (Fig. IIb, curve *2*) shows a weakly pronounced endothermic effect at 140–240°C due to removal of the residual solvent and an exothermic effect (240–300°C) corresponding to the R-PAN cyclization. A different DSC curve is exhibited by the R-PAN + CTS blend, for which oxidation reactions, clearly involving the amino groups of CTS, are observed at 190°C. In the same temperature range, this film contracts more intensively (Fig. IIa, curve *3*).

Notably, the thermocyclization of R-PAN in the composite films proceeds in the conventional temperature range (250–300°C), but with a much smaller heat effect, and is accompanied by a weakly pronounced contraction of the film. This suggests that this reaction involves a much smaller number of nitrile groups. Hence, some of them were already spent earlier in intermolecular interactions of the CN groups with the functional groups (>C=O, $–NH_2$, –OH, etc.), which can occur either in the concomitant impurities, or in the co-components, or in the molecular structure of the polymer proper. This is confirmed by the thermomechanical characteristics of sample no. 7 (see table).

Thus, the nature of the thermocyclization peak is indicative of the purity of the sample examined and of the presence/absence of structural defects in it. Moreover, the width of the thermocyclization peak allows judging of the molecular-weight homogeneity of PAN. This conclusion is consistent with our previous DTA data for the AN polymers synthesized under various conditions [4].

We showed that attaining the desired properties of the PAN-based composite materials being developed (semiconductor and carbon fibers) requires taking into account the structural and chemical features of the polymeric components used.

CONCLUSIONS

(1) Films with high deformation and strength characteristics were prepared from polysaccharides chitin and chitosan, combined with polyacrylonitrile.

(2) Polyacrylonitrile synthesized by radical polymerization enters into thermochemical reactions with the polysaccharide at 140–280°C, to form a composite.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Membrane Bioreactor with Immobilized Proteinase

Abstract—A procedure was developed for layer-by-layer immobilization of terrilytin proteolytic enzyme on track membranes and flat-membrane blocks. The hydrolysis of fibrinogen and casein was studied, and the possibility of using such a structure as an enzymatic bioreactor was demonstrated.

DOI: 10.1134/S1070427206080234

The development and use of bioreactors of a new generation with immobilized hydrolytic enzymes remains a topical problem of the modern fine biotechnology [1]. On the one hand, it is necessary to optimize the immobilization procedure, because the known methods of enzyme incorporation into a gel decrease the catalytic performance of the immobilized substance. This is due to hindered diffusion of the substrate and product in the gel phase; furthermore, this immobilization procedure is inapplicable at all to macromolecular substrates [2]. On the other hand, the bioreactor design should allow continuous specific hydrolysis of macromolecular viscous substrates and colloids whose solutions cannot be filtered [3]. Column bioreactors with enzymes immobilized on porous granular supports are unsuitable for treatment of such systems.

The most promising approach to the development of a modern enzymatic bioreactor involves immobilization of enzymes on microfiltration membranes and use of the design developed for membrane microfilters operating in the tangential filtration mode [4, 5].

Track membranes (TMs) based on poly(ethylene terephthalate) are widely used today in microfiltration of virus suspensions, fractionation of colloidal solutions, and also in new equipment for practical medicine. Previously, we have studied the microfiltration of viscous solutions of high-molecular-weight polysaccharides on PFM-800 plasmofilters using TM based on poly(ethylene terephthalate) as filtration material [4]. The PFM-800 unit is commercially produced for medicine and can be used without changes in the design as a support for immobilization of hydrolytic enzymes [6]. Preliminary studies have shown that some macromolecules (serum albumin, SA; heparin; urokinase) preserve their native structure and biological activity in the sorbed state on the surface of a TM based on poly(ethylene terephthalate) [7].

This study was aimed to develop a membrane bioreactor [in particular, a method for immobilization of terrilytin (microbial proteinase) on membranes of the plasmofilter] and to estimate the activity of the immobilized enzyme toward viscous solutions of macromolecular proteins, casein and fibrinogen.

EXPERIMENTAL

To develop an enzymatic bioreactor, we used track membranes with a rated pore size of 0.5 μm and PFM-800 plasmofilters based on these membranes (Plazmofil'tr Private Company, St. Petersburg).

As a hydrolytic enzyme we used terrilytin, a microbial proteinase preparation permitted for use in medical practice for therapy [8]. Terrilytin is a single-chain glycosylated protein with a molecular weight of about 27 kDa and isoelectric point at pH 4.6.

The enzymatic activity of terrilytin was determined by the method described above, with 1% solution of Hammersten-grade casein from Reanal in 0.05 M phosphate buffer (pH 7.6) as a substrate [9]. After a treatment of casein with proteinase at 37°C for 10 min, high-molecular-weight proteins were precipitated with 5% trichloroacetic acid (TCA), and the optical density of the TCA-soluble hydrolysis products was determined at λ = 280 nm. The activity of the enzyme was expressed in proteolytic units (PUs).

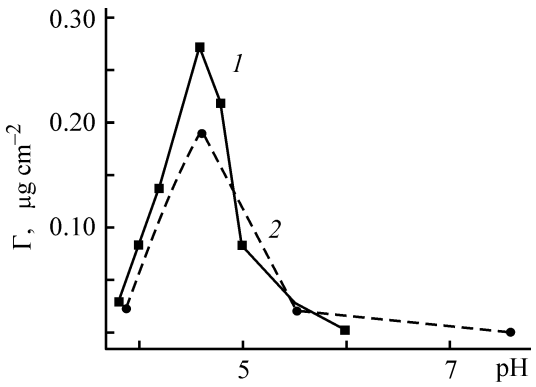

Fig. 1. Sorption capacity Γ of track membranes for (*1*) terrilytin and (*2*) serum albumin vs. solution pH.

The specific activity of the sample used in this study was 2 PU mg^{-1}, or 25 PU (mg protein)$^{-1}$.

The protein concentration was determined spectrophotometrically with the Coomassie reagent at λ = 595 nm [10].

To find the optimal conditions for immobilization of terrilytin on the surface of track membranes, we studied the pH dependence of the TM sorption capacity under static conditions by the procedure described previously [11].

To attain firm immobilization of terrilytin, we preliminarily modified the TM surface by the sorption of SA at pH 5.6 from a 1 mg ml^{-1} protein solution. It is known that SA is sorbed on the TM surface owing to hydrophobic interactions; as a result, the membrane surface acquires polyampholytic properties. After thorough washing of the membrane with a salt buffer solution to remove the free protein, terrilytin was sorbed onto the layer of sorption-bound albumin following the procedure described in [12], to obtain a two-layer protein coating. For irreversible fixation of this coating on the TM surface, the proteins were linked with each other by glutaraldehyde (GA) [13]. The immobilization of the enzyme on the PFM-800 membrane unit was performed similarly, by successive circulation of the above-mentioned solutions through the substrate and product chambers. It has been shown previously that successive deposition of monomolecular layers onto the TM surface does not noticeably affect the TM hydrodynamic characteristics. The filtering surface area of TMs in the plasmofilter was 800 cm^2, and the TM thickness, 10 μm; thus, the total volume of the phase with the immobilized enzyme (catalyst phase) inside the bioreactor was 0.8 cm^3.

The proteolytic activity of terrilytin immobilized on membranes was measured under static conditions. A 1-dm^2 piece of the membrane was kept in 10 ml of a 1% casein solution for 30 min at 37°C, with continuous rocking of the weighing bottle. Then the membrane was withdrawn from the solution and transferred into another weighing bottle with a fresh substrate solution and kept there for another 30 min. This procedure was repeated two times to monitor the affinity desorption of the immobilized enzyme with the substrate solution.

The proteolytic activity of terrilytin immobilized on a PFM-800 unit was measured under the dynamic conditions. A substrate solution was recirculated in the substrate chamber under a pressure head of 0.5 kPa at a pumping rate of 0.6 l h^{-1}. In the process, a part of the solution was filtered in the tangential mode through the filter to the hydrolyzate (product) chamber at a rate of 0.2 l h^{-1}. The volume of the circulating solution was kept constant by adding a fresh portion of the substrate. At 5-min intervals, the filtered solution was sampled, and its spectrophotometric analysis was performed to determine the content of TCA-soluble products (λ = 280 nm). As substrates for the hydrolysis in the bioreactor we used aqueous solutions of casein and fibrinogen (2.2 mg ml^{-1}). The choice of fibrinogen was governed by the fact that, according to our previous data, terrilytin shows maximal specific activity toward triple-helix structural proteins, such as collagen, fibrin, elastin, and fibrinogen [11, 14]. The fibrinogen hydrolysis products were collected at the reactor outlet, and the capability of the product to form a fibrin clot under the action of thrombin was monitored [15]. The error in measuring the activity of terrilytin in the free and immobilized states did not exceed 10 and 16%, respectively.

It is known that all the polymer surfaces are sorption-active toward hydrophilic or hydrophobic components present in solution, depending on the morphology and chemical composition of the polymer surface. We have shown previously that the sorption capacity of the surface of a TM based on poly(ethylene terephthalate) toward hydrophilic molecules is determined by the carboxy and hydroxy groups on the surface of these materials. In the case of irreversible physical adsorption, the sorbed macromolecules preserve their native conformation. Therefore, in sorption immobilization of enzymes on a polymer surface, their enzymatic activity can be preserved. However, upon a change in the external conditions (pH, ionic strength, presence of a displacing component), the enzyme is desorbed from the surface.

Figure 1 shows the dependence of the sorption capacity of a TM toward SA and terrilytin on pH of the protein solution. The best pH for the equilibrium sorption of these proteins on track membranes is 4.6 (isoelectric point of terrilytin).

Activity of immobilized terrilytin relative to casein at various immobilization procedures

Immobilization procedure	Enzyme amount, μg dm^{-2}	Calculated activity, PU dm^{-2}	Enzyme activity in statics, PU dm^{-2}	Percent ratio of activity to that calculated for standard conditions, %
TM~TRL*	20	0.5	0.35*	70
TM~(TRL)GA	20	0.5	0.28	56
TM~SA~TRL	11	0.28	0.44*	>100
TM~SA~(TRL)GA	11	0.28	0.38	>100

* In repeated measurements, the samples showed no enzymatic activity.

As can be seen from Fig. 1, the sorption capacity of intact track membranes for terrilytin at pH 4.6 is 0.2 μg cm^{-2}. With alkalization of the external solution, the enzyme desorption starts at pH 6 and is complete at pH 7.6, which does not allow use of this sorption-immobilized enzyme in neutral media, in which the enzyme is the most active [14].

An efficient method for firm immobilization of proteins on polymer surfaces is their fixation on a hydrophilic support, with the subsequent covalent cross-linking of the protein macromolecules with glutaraldehyde. The reaction involves formation of Schiff base fragments from primary amino groups of the protein and carbonyl groups of the aldehyde [16]:

$$\text{TM-terrilytin-NH}_2 + \text{HOC}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{COH} + \text{H}_2\text{N-terrilytin-TM}$$

$$\rightarrow \text{TM-terrilytin-N=CH-CH}_2-\text{CH}_2-\text{CH}_2-\text{HC=N-terrilytin-TM}.$$

To make milder the conditions of the enzyme immobilization, terrilytin was also sorbed on TM with a deposited SA monolayer. The sorption capacity of the intact TM for terrilytin in the absence of SA is 0.2 μg cm^{-2}. For the TM preliminarily modified with SA, the sorption capacity for terrilytin is 0.1 μg cm^{-2}. In other words, the enzyme macromolecules are situated sufficiently far apart from each other on the sorption surface in the SA layer, which excludes the possibility of autolysis. In addition, SA makes the sorption surface more hydrophilic, which favors preservation of the native structure of the enzyme molecule.

Comparative evaluation of the enzymatic activity of terrilytin at various types of immobilization is made in the table, where TM~TRL denotes terrilytin sorption-immobilized on intact TM; TM~(TRL)GA, terrilytin sorption-immobilized on intact track membrane and cross-linked with glutaraldehyde; TM~SA~TRL, sorption-immobilized layers of SA and TRL without cross-linking; and TM~SA~(TRL)GA, the same after cross-linking with glutaraldehyde.

The higher, compared to the calculated value, level of the enzyme activity is due to different conditions of the activity measurement: The contact time of the immobilized enzyme with the substrate solution was 30 min, against 10 min as for the enzyme in solution. The only conclusion following from this fact is that the immobilization of the enzyme on the monomolecular SA layer, followed by the covalent cross-linking, ensures better preservation of the terrilytin activity than the covalent cross-linking of terrilytin directly sorbed on TM (see table).

The highest activity of the enzyme is preserved in joint sorption with albumin followed by chemical cross-linking with GA. This procedure was used in immobilization of terrilytin on the plasmofilter membranes. The design of the bioreactor is shown in Fig. 2.

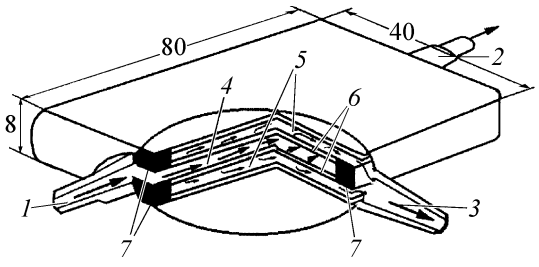

Fig. 2. Scheme and dimensions (mm) of the bioreactor: (*1*, *2*) tubes for inlet and outlet of the initial substrate solution, (*3*) outlet tube for the solution with hydrolysis products (filtrate), (*4*) chamber for pumping the substrate solution, (*5*) chamber for collecting the solution of hydrolysis products, (*6*) track membranes with immobilized terrilytin, and (*7*) sealant for sizing the reactor parts.

Scheme of separation of the high-molecular-weight rigid-chain substrate from low-molecular-weight hydrolysis products in the mode of tangential microfiltration of a mixture of substrate and products at high shear rates in the slit chamber: (*1*) substrate, (*2*) products, (*3*) substrate chamber, (*4*) product chamber, (*5*) track membrane, and (*6*) terrilytin immobilized on the filtering and pore surfaces of the track membrane. (*h*) Slit height.

The PFM-800 plasmofilter can be used as a support for immobilization of enzymes and as a bioreactor for continuous hydrolysis of high-molecular-weight proteins. The hydrodynamic conditions in the substrate resource chamber at tangential filtration lift the diffusion limitations and provide continuous removal of the low-molecular-weight hydrolysis products, i.e., fractionation of the substrate and products. Figure 3 shows the dynamics of the proteolytic hydrolysis of casein and fibrinogen; it indicates that the hydrolysis occurs in the steady-state mode.

The most important advantage of the bioreactor developed is the combination of two processes in one unit: enzymatic hydrolysis of a high-molecular-weight rigid-chain substrate (fibrinogen) and simultaneous removal of lower-molecular-weight globular hydrolysis products. The product solution is fully free of fibrinogen: Addition of thrombin and an increase in the calcium concentration do not induce formation of fibrin clots [15].

Fractionation of the solution components with respect to the shape and molecular weight is due to the hydrodynamic conditions in the slit chamber of the substrate, in which the slit height is 100 μm and the viscous liquid flows at high shear rates. Under these conditions, the rigid-chain macromolecules are oriented along the direction of the solution flow, which is confirmed by dynamooptical measurements [17]. As shown previously [4], such a flow is accompanied not only by the orientation but also by the shift of the highest-molecular-weight components to the center of the restricted flow, to the region of the highest linear velocities. Then the tangential flow of the filtrate removes from the substrate chamber only the hydrolysis products, as shown in Fig. 4.

The use of natural proteins and their intermolecular complexes in the formation of polylayer coatings of bioreactors is of large interest from the viewpoint of basic and applied problems of biotechnology.

CONCLUSIONS

(1) A new procedure for immobilization of proteolytic enzyme terrilytin was suggested: application onto a layer of serum albumin sorbed on track membranes, followed by covalent cross-linking of these proteins with glutaraldehyde.

(2) Terrilytin was immobilized by this procedure on a PFM-800 membrane unit with a capacity of 0.1 μg per 1 cm^2 of the filtering surface, which allowed this unit to operate as an enzymatic bioreactor.

(3) The developed membrane reactor with immobilized terrilytin hydrolyzes casein and fibrinogen in the steady-state mode and shows an activity comparable to that of the free enzyme.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Method for Determining the Molecular Weight of Hyperbranched Polymers

Abstract—A method for determining the molecular weight of hyperbranched polymers is developed, based on the measurement of the area of the monolayer at the water/air interface.

DOI: 10.1134/S1070427206080246

Intensive studies in the area of dendrimers and hyperbranched polymers, which include applied research and are generally interdisciplinary (macromolecular chemistry–catalysis, macromolecular chemistry–medicine, etc.), have created a need for developing fairly simple and efficient methods for measuring molecular weights, similar to the viscometry in the case of linear polymers. A possible way is to measure the area of a close-packed monomolecular layer of rigid-spherical hyperbranched or dendritic macromolecules, using the Langmuir film balance.

The goal of this study was to develop a method for determining the size of macromolecules, as applied to hyperbranched dendritic polymers, poly(perfluorophenylenegermane) and poly(methyldiallylsilane).

Poly(perfluorophenylenegermane) (PPG) was among the first hyperbranched dendritic polymers prepared by a single-stage synthesis from the Flory monomer AB_3 [tris(pentafluorophenyl)germane (PG)] [1, 2]. The units of this polymer consist of perfluorinated aromatic rings bonded to the germanium atom, C_6F_4Ge and C_6F_5Ge, the latter being terminal. The ratio between units of these types is 1 : 2 [3], which corresponds to a regular branched structure with the formula $[(C_6F_5)_2Ge(C_6F_4)]_n$ (Fig. 1). Starting from the third generation, the shape of the macromolecules is nearly spherical, which is supported by the sedimentation data obtained with an ultracentrifuge [4]. The polymer demonstrates high heat resistance and clearly pronounced antifriction properties [5].

EXPERIMENTAL

PPG was synthesized as follows. To a solution of 1 g of PG in 10 ml of a solvent, the estimated amount of triethylamine in THF was added with stirring over a period of 5 min, and the reaction mixture was further stirred for 5 h at 25°C. The yield was 75–85%, and increased with $[Et_3N] : [PG]$ ratio. The resulting PPG was purified by twofold reprecipitation from THF with methanol and then vacuum-dried to constant weight. We obtained three PPG samples with

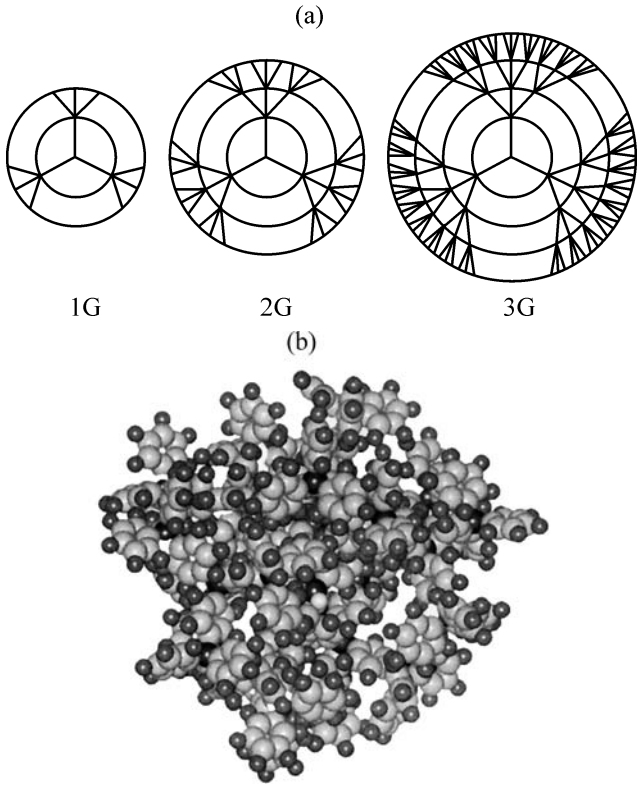

Fig. 1. (a) Chemical graph of the first to third generations and (b) scaled chemical model of hyperbranched PPG of the third generation.

MW 2×10^4, 3×10^4, and 8×10^4, determined by gel filtration and centrifugal sedimentation [4]. The surface pressure isotherms were obtained on a TsIDNP instrument, whose principle of operation and design have been described in detail elsewhere [6]. The surface pressure was measured by the Wilhelmy plate method. In order to approach the equilibrium conditions of formation of the monomolecular films, we used the discrete mode with intermittent interruption of the moving barrier for 10 min prior to each measurement. As a substrate, we used double-distilled water. The experiments were carried out at 20 ± 1°C. Chloroform was used as a solvent for PPG. The solution was applied onto water using a 50-μl syringe. Before the measurement, the surface covered with the polymer film was allowed to stand for 15 min, to remove the solvent. From the surface pressure isotherm, we determined A_0, the area occupied by 1 mg of PPG in the close-packed monolayer.

Figure 2 shows the surface pressure isotherms of hyperbranched PPG with MW 8×10^4. As can be seen, A_0 depends on the PPG concentration in the chloroform solution applied onto the water/air interface. For all the samples studied, the initial portion of this dependence is linear (Fig. 3). Therefore, we used in our calculations the parameter A_0^∞ obtained by extrapolation of A_0 to zero polymer concentration. From A_0 and the density of PPG ($\rho = 2.39$ g cm^{-3}) we estimated the effective thickness of the monolayer, equal to the effective diameter of the spherical macromolecule of PPG (d_{eff}):

$$h_{\text{eff}} = 1/\rho A_0,$$

To obtain a relationship between d_{eff} and MW, we employed computer simulation. Figure 1 shows the chemical graphs of the first three PPG generations, as well as the chemical model of the third generation obtained using the HyperChem code. Below are given the theoretical sizes of the PPG macromolecules d_{theor} for the first five generations and their molecular weights.

Generation no.	1	2	3	4	5
d_{theor}, nm	1.63	3.03	4.00	5.23	6.46
MW	2240	7200	22 200	67 200	202 000

This dependence is plotted in Fig. 4 along with the experimental data obtained using the Langmuir film balance for the PPG samples with molecular weights measured by gel filtration (with calibration by the centrifugal sedimentation data). The observed satisfactory agreement of the theoretical and experimental results suggests that the above procedure is well applicable to hyperbranched PPG.

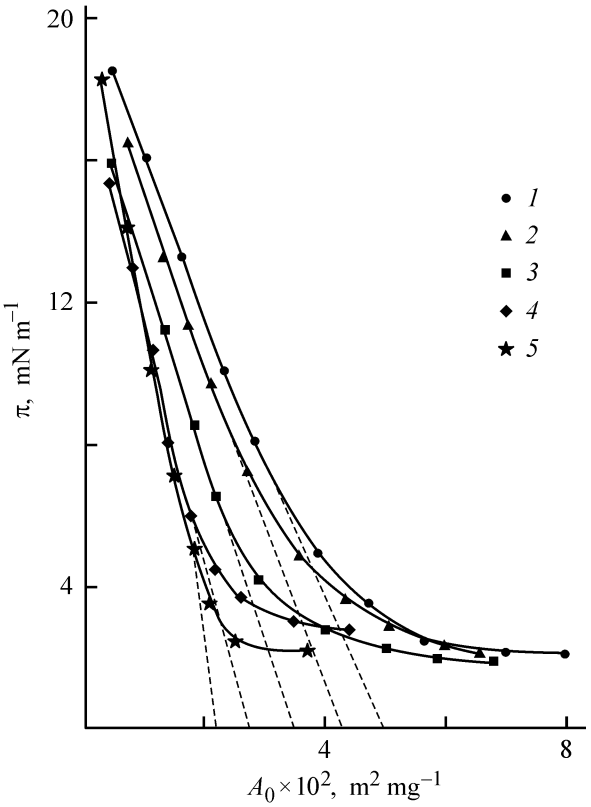

Fig. 2. Surface pressure isotherms of PPG (MW 8×10^4). (π) Surface pressure and (A_0) area occupied by 1 mg of PPG in the close-packed monolayer. PPG concentration (mg ml^{-1}): (*1*) 2, (*2*) 2.5, (*3*) 3, (*4*) 3.5, and (*5*) 4.

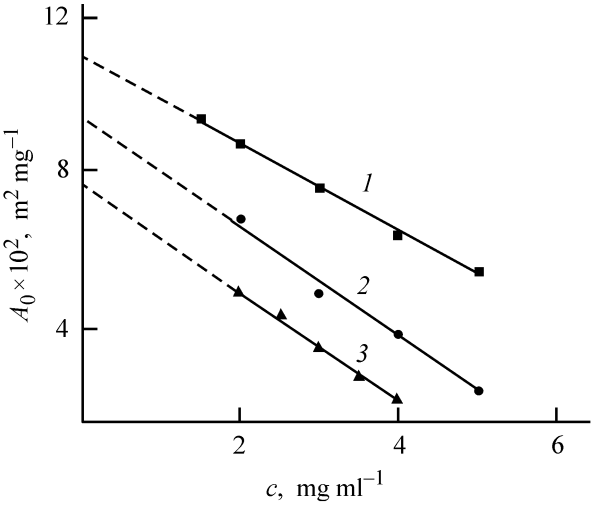

Fig. 3. Area occupied by 1 mg of PPG in the close-packed monolayer A_0 vs. PPG concentration c. MW $\times 10^4$: (*1*) 2, (*2*) 3, and (*3*) 8.

Similarly, we determined the size and MW of another hyperbranched polymer, poly(methyldiallyl-

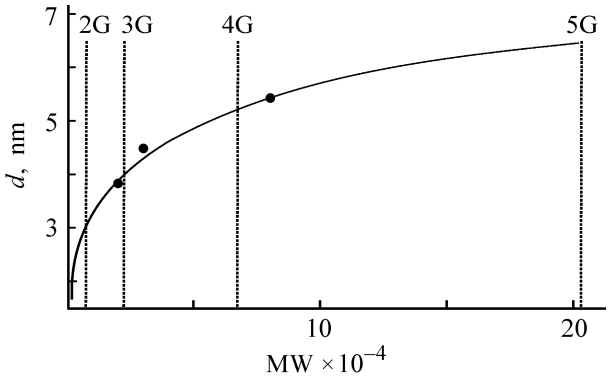

Fig. 4. Diameter d of hyperbranched PPG macromolecules vs. MW. *The solid line* represents the theoretical curve, and *the points*, experimental data. *The dotted lines* correspond to the generation number on the assumption of a regular structure.

silane), prepared by single-stage hydrosilylation [7]. For the polymer sample with MW 2.3×10^4 (determined by gel filtration), d_{eff} was found by the above procedure to be 7.0 nm. This value corresponds to MW 2.5×10^4, as obtained from the theoretical dependence of the diameter on MW, derived from the results of computer simulation, as in the case of PPG. In turn, this MW value corresponds to generation no. 6.6, i.e., to the imperfect seventh generation. Figure 4 shows that the structures of two of three PPG samples studied also have imperfect external generations. This phenomenon is typical of uncontrolled single-stage synthesis of hyperbranched polymers.

CONCLUSIONS

(1) The Langmuir film balance method was used to determine the size of two hyperbranched dendritic polymers, poly(perfluorophenylenegermane) and poly(methyldiallylsilane).

(2) The dependences of the diameter of the hyperbranched macromolecules on the molecular weight were obtained by computer simulation. The resulting theoretical dependences could be used to determine the molecular weight and generation number of dendritic polymers.

ACKNOWLEDGMENTS

The authors are grateful to A.M. Muzafarov for providing a sample of polymethyldiallylsilane.

The study was financially supported by the Russian Foundation for Basic Research (project no. 06-03-32872) and Federal Target Scientific and Technical Program "Research and Development in Priority Areas of Science and Technology in 2002–2006" (State contract no. 02.442.11.7487).

Abstract—The chemical composition of *Obelia longissima* hydroid polyp from mariculture system fouling community was examined. Conditions for chitin recovery and chitosan preparation thereof were developed. The initial raw material, chitin, and chitosan were characterized by electron microscopy, infrared spectroscopy, and X-ray diffraction analysis. Also, certain qualitative characteristics of these materials were determined.

DOI: 10.1134/S1070427206080258

Various marine organisms are responsible for fouling of hydrobiotechnical systems for mariculture cultivation. Among them a significant proportion (12–32.2%) belongs to *Obelia longissima* (*Hydrozoa*) hydroid polyp. The skeleton of the hydroid polyp is formed by a chitinoid substance. Large volumes of the fouling organisms, as well as the possibility of cultivation of the polyp, make reasonable an elucidation of its suitability as a source of chitin [1, 2].

In this study we identified the chemical composition of the polyp skeleton, elucidated the possibility of recovery of chitin thereof, developed a method for preparation of a chitin derivative, chitosan, and comprehensively characterized the resulting products.

EXPERIMENTAL

We examined marine biological fouling organisms, uncrushed *O. longissima* and its processing products, chitin and chitosan.

Chitin was recovered by successive extraction of the concomitant substances from the chitin-containing raw material. Extraction of protein substances (deproteinization) was carried out in 4% aqueous sodium hydroxide at the raw material : alkali fluid ratio M = 1 : 4 and temperature of 95–97°C for 60 min. Demineralization was carried out with 4% hydrochloric acid at room temperature for 30 min at M = 1 : 4. The deproteinization and demineralization stages were twice repeated in succession.

Chitosan was obtained by base deacetylation with 50% aqueous sodium hydroxide at M = 1 : 5 and temperatures of 80, 100, and 120°C for 10, 30, and 60 min.

The moisture and ash contents, as well as the content of protein substances (by the Kjeldahl method) in the initial raw material were determined in accordance with GOST (State Standard) 7636–85. The amount of lipids was determined by extraction with petroleum ether according to GOST 13893–68.

The content of protein substances in chitin was determined on a Biochrom-30 (Cambridge) amino acid analyzer after sample preparation by acid hydrolysis [3, 4].

The kinematic viscosity of the chitosan solutions was determined according to the appropriate TU (Technical Specifications) [5].

The changes of the microsctructure of the initial raw material during treatment with acid and base agents, as well as those of the microstructure of chitin and chitosan, were monitored with an SEM LEO-430 scanning electron microscope at the ×400 magnification. The electrically conducting coating was applied by vacuum thermal sputtering of carbon [6].

The IR absorption spectra of chitin in KBr pellets were measured on a Spectrum BX-II (Perkin Elmer) spectrometer, and the IR spectra of the chitosan films on calcium fluoride supports, on a Vector-22 (Bruker) IR Fourier spectrometer.

Aspergillus terricola	16.3	0.4	12.6	18.3	[18]

The content of free amino groups in chitosan was determined spectrophotometrically using tropeolin anionic dye [sodium 4-(2-hydroxy-1-naphthylazo)benzenesulfonate] in 1% acetic acid. It was estimated from the ratio of the intensity A_{1666} of the amide I absorption band to that of the band of the stretching vibrations of the hydoxy groups (A_{3440}) [7–9].

The molecular weight of the chitosan samples was determined viscometrically in 0.1 M aqueous acetic acid containing 0.2 M NaCl at 25°C [10–12]. The measurements were performed on an Ubbelohde viscometer [13] with a capillary diameter of 0.3 mm at 25 and 37°C. The chitosan concentration in solution was expressed in grams per cubic centimeter. The molecular weight was calculated by the formula [14]

$$[\eta] = 1.81 \times 10^{-3} M^{0.93}.$$

The X-ray diffraction patterns of the chitin and chitosan samples were measured on a DRON-2 diffractometer using Ni-filtered $Cu_{K_{\alpha 2}}$ radiation.

Table 1 compares the chemical composition of the raw material we used with those of other chitin-containing raw materials, taken from the literature.

As can be seen from Table 1, the content of chitin in the hydrobiont examined is 44.9%, which significantly exceeds that in the shells of a number of crustaceans. The content of protein substances is higher than that in the shell-containing raw materials, but the degree of mineralization is much lower. The content of lipids is insignificant (0.23%).

In the amount of chitin, *O. longissima* is superior to all the chitin sources from Table 1, including mycelial fungi. A comparatively low degree of mineralization makes this hydroid polyp a very promising source of chitin.

To find the best conditions for recovery of chitin, we treated the raw material by two schemes differing in the succession of deproteinization and demineralization stages and involving extraction of concomitant substances [15, 19]. In each scheme, we varied the number of treatment runs for the polyp. After each treatment run with acid and alkali and washing of the product, we determined the amount of the protein and mineral substances.

Scheme 1 involves two treatment runs with acid and base agents; the content of mineral substances is 0.3% (against 0.75% for one treatment run). At the same time, the protein content was about the same for procedures with one and two treatment runs, 12.53 and 11.06%, respectively.

In scheme 2, repeated treatment of chitin with acid and base agents was inefficient: The contents of protein and mineral substances were approqimately equal, 12.81 and 13.03 and 0.14 and 0.15%, respectively.

This makes reasonable the recovery of chitin by scheme 2 including one treatment run with alkali and acid in succession. The reason is the high content of protein in the initial raw material; removal of protein favors deeper demineralization. It should be noted that chitin is recovered from shell-containing raw materials by scheme 1 because of the high content of the mineral component in this raw material.

The chitin recovered consists of fine fibers, from white to light cream or light beige in color. The total

Table 2. Characteristics of chitosan in relation to the conditions of preparation from *O. longissima* chitin

Chitin quality parameter	Process temperature and duration, min								
	80°C			100°C			120°C

nitrogen content is 7.27% (against theoretical 6.90%). The fact that N_{tot} that we determined exceeds the theoretical value suggests the presence of residual protein; the mass fraction of chitin in the product is 92.2%.

Electron micrographs (Fig. 1b, 1c) show how the initial raw material is modified by treatment with acid and base agents. Before treatment with reagents (Fig. 1a), the skeleton of the polyp consists of 3–5 ring-shaped necks or has a smooth segment. The middle layer is obscured by the covering outer layer. Each treatment run with chemical reagents loosens the structure, making visible the middle layer (Figs. 1b, 1c). A small thickness (thin film) of the outer and inner layers of the skeleton, as well as of the skeleton proper, facilitates its deproteinization and demineralization during chitin recovery. This involves removal of the outer and inner layers and thinning of the middle layer of the skeleton, where longitudinal cords are prominent. The middle layer exhibits a fibrous structure comprised of a number of small vertical columns, each with transverse streakes. The small columns, evidently, consist of chitin fibers, in agreement with the data from [16]. That study involved an electron-microscopic examination of the chitin recovered from the cuticle of insects (locust, hornet), which contain uniform chitin fibers fixed in protein matrices, as well as fibrils aggregated into ordered layers.

The IR spectrum of the chitin recovered from the polyp contains absorption bands typical of the chitin of crustaceans [16]: band at 1640 and a shoulder at 1656 cm^{-1}, corresponding to the C=O groups of the acetamide moiety (amide I), as well as bands at 3267, 1554, and 712 cm^{-1}, belonging to the amide group (amide II).

The fact that, whatever the origin, chitin does not melt and dissolves in a limited number of aggressive or toxic solvents, makes preparation of films, fibers, and other items thereof a difficult task. More convenient for various applications (in medical, pharmaceutical, cosmetic, textile, paper, and other industries) is a chitin derivative, chitosan. It readily dissolves in dilute organic and monobasic mineral acids. Chitosan is typically prepared by alkaline treatment of chitin with heating [15, 20–23]. The alkali concentration, as well as the temperature and time of the process, depend on the kind of the raw material from which chitin was recovered.

Since the chitin we examined has a fine-fibered morphology, chitosan was recovered thereof under milder conditions, compared to those in recovering chitosan from crab chitin with a dense lamellar morphology. Chitin was treated with 50% aqueous sodium hydroxide at 80–120°C for 10–60 min. Table 2 summarizes the results.

Table 2 shows that, even at 80°C after 10 min, the degree of deacetylation (DD) was 70%, which is sufficient for complete dissolution of the product in 2% acetic acid. Raising the reaction temperature, like prolongation of the base treatment of chitin, causes a decrease in the DD, in parallel with a decrease in the molecular weight of chitosan and in the yield of the final

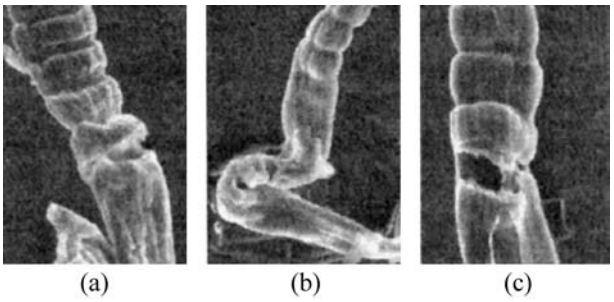

Fig. 2. Appearance and structure of chitosan obtained from *O. longissima* at τ = 60 min and temperature of (a) 80, (b) 100, and (c) 120°C (×400 magnification).

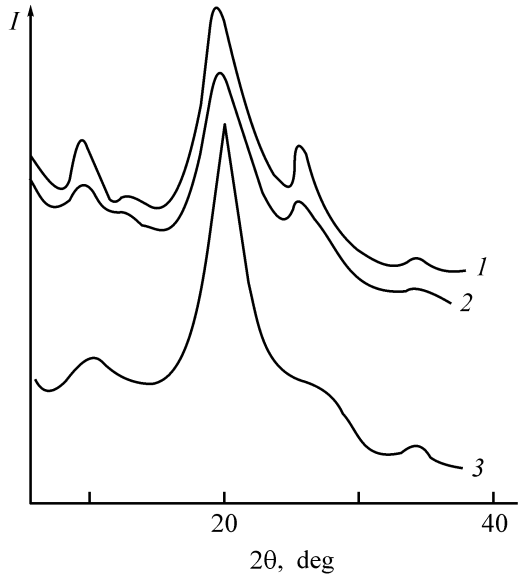

Fig. 3. X-ray diffraction patterns of chitosan obtained from *O. longissima* chitin at τ = 60 min and temperatures of (*1*) 80, (*2*) 100, and (*3*) 120°C. (*I*) Relative intensity and (2θ) reflection angle.

product. A decrease in the molecular weight is due to hydrolytic and oxidative degradation of the macromolecules, since the reaction was run in the presence of atmospheric oxygen. A decrease in the yield is due to the natural loss because of the elimination of the acetyl group, as well as to degradation to water-soluble oligomers, which are removed during purification of the product.

By varying the chitosan recovery conditions, it is possible to obtain a product with the desired DD of 70–87.8%, molecular weight of 270–660 kDa, and kinematic viscosity of $(333-881) \times 10^{-4}$ m^2 s^{-1}. Numerous application fields and different requirements imposed on chitosan give no way of specifying the optimality of these characteristics. Preparation of the most viscous chitosan solutions (881×10^{-4} m^2 s^{-1}) requires running the process at 80°C for 10 min. The resulting chitosan is identical in morphology and color to the initial chitin, namely, consists of fine fibers, from white to light cream or light beige in color.

The chitosan samples prepared at (a) 80, (b) 100, and (c) 120°C for 60 min were characterized by electron microscopy (Fig. 2), X-ray diffraction analysis (Fig. 3), and IR spectroscopy.

The electron micrographs of chitosan (Fig. 2) show that deacetylation of chitin leads to a general amorphization of the structure. A thin film of the middle layer of the skeleton is characterized by parallel arrangement of regular fibers with some gaps and disintegrations, which make visible an empty space inside the skeleton, suggesting the lack of protein.

The electron micrographs of the chitosan obtained at 120°C for 60 min (Fig. 2c) show that the particle surface is more uniform and is formed by wide fibrils and spherulites. The chitosan obtained at 80°C (Fig. 2a) exhibits a more defective and nonuniform structure with fine fibrils and spherulites and a lower degree of crystallinity, which agrees with published data [24–26].

An X-ray diffraction analysis of chitosan (Fig. 3) showed that it has the same crystal lattice as chitin, but is characterized by a lower degree of ordering of the macromolecules.

The reflections in the X-ray diffraction patterns of chitin and chitosan have identical positions, but those of chitosan are less intense. The diffraction patterns of chitosan consist of two fairly broad reflections at 2θ = 10° and 20°. The broadening of the reflections suggests lowering of the degree of ordering of the structure during deacetylation [26].

The diffraction patterns we obtained are similar to those of the chitosan samples obtained from crab, shrimp, and lobster shells [27, 28].

Figure 3 shows that, as the degree of deacetylation increases (curves *1*, *2*), the reflection at 2θ = 26.5° tends to decrease in intensity. It corresponds to the interplanar spacing of 0.334–0.343 nm and is the most intense third-order reflection (003) for chitin fibers. In curve *3*, the reflection in this range of angles disappears.

The changes in the X-ray diffraction pattern suggest that the samples with lower DDs (curves *1*, *2*) still contain fragments of ordered chitin. At higher DDs (samples with DD = 87.7%), this reflection degenerates, which suggests the lack of chitin fragments in

the chitosan structure; the residual acetamide groups are randomly spread along the macrochain and do not form an intrinsic structure. Similar changes in the X-ray diffraction patterns were observed in alkaline deacetylation of the chitin recovered from crab shell [29].

The IR spectra of the chitosan samples contain characteristic bands corresponding to vibrations of the carbonyl group of the acetamide moiety (amide I) at 1659–1660 cm^{-1}, bending vibrations of the amide groups (amide II) (NH and NH_2 groups) at 1552–1591 cm^{-1}, vibrations of carbonyl groups at 1377–1379 cm^{-1}, and vibrations of hydroxy groups at 3441–3450 cm^{-1}, which is consistent with published data [14, 29–31]. With DD increasing from sample 1 to sample 3, the absorption bands at 1659 and 1552–1591 cm^{-1} tend to decrease in intensity, which confirms removal of the N-acetyl groups. These bands are suggested for determination of the DD by IR spectroscopy [7–9].

CONCLUSIONS

(1) It was found that the hydroid polyp *Obelia longissima* contains up to 45% chitin and is weakly mineralized. Large volumes of *Obelia longissima* removed from mariculture systems and the possibility of its cultivation makes it suitable as a commercial source of chitin.

(2) A procedure for recovery of chitin from the hydroid polyp was suggested. It includes one treatment run with alkali for the raw material, followed by one treatment run with acid. Conditions for preparation of chitosan from chitin were developed.

(3) It was determined that the chitosan samples with deacetylation degrees of 70–87.7% and molecular weights of 270–660 kDa, prepared in the study, are soluble in dilute acids. The IR spectra and X-ray diffraction patterns of the chitin and chitosan samples correspond to those of the chitin and chitosan recovered from crab shells.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of a Self-Cross-Linking Copolymer from 2-Glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane and Maleic Anhydride

K. G. Guliev

Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgaiyt, Azerbaijan

Received May 4, 2006

Abstract—Radical copolymerization of 2-glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane with maleic anhydride in benzene was studied. The copolymerization constants, Alfrey–Price parameters, and complexation constant were calculated.

DOI: 10.1134/S107042720608026X

It is known that maleic anhydride (MA) forms molecular complexes with donor monomers, which promotes the formation of alternating copolymers [1]. The formation of donor–acceptor complexes was also detected in the copolymerization of MA with cyclic compounds [2–4].

This study was aimed to prepare a new self-cross-linking copolymer with epoxy and anhydride groups from 2-glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane and maleic anhydride and to examine features of radical copolymerization in the system.

High physicomechanical and thermal parameters of thermosetting polymers with pendant glycidyl groups are mainly determined by their chemical structure. Therefore, synthesis of such polymers and elucidation of the structure–property relationships for them is a topical problem of polymer chemistry. A characteristic feature of such polymers is also their capacity for self-curing.

These polymers are most often cured with di-, tri-, and polyfunctional compounds applied as curing agents for ordinary epoxy resins.

EXPERIMENTAL

The monomer, 2-glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane (M_1), was prepared according to [5] and had the following characteristics: bp 150–153°C/1 mm Hg, n_D^{20} 1.5220, d_4^{20} 1.04. Its purity, according to GLC analysis, was 99.9%.

The copolymerization of M_1 with MA was performed in benzene at 333 K, with AIBN as initiator (0.02 M).

The copolymers were precipitated with diethyl ether, filtered off, and vacuum-dried to constant weight. The copolymer composition was determined by potentiometric titration of anhydride groups; the structure was determined by IR spectroscopy. The copolymer yield was 87%.

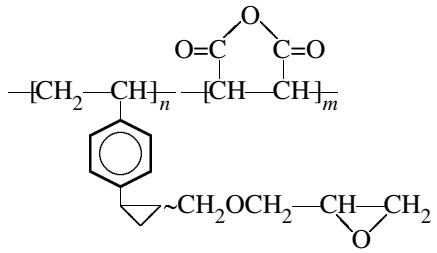
Found, %: C 69.20, H 6.30, O 24.70.
$C_{19}H_{20}O_5$.
Calculated, %: C 69.51, H 6.10, O 24.39.

The copolymerization kinetics was studied by dilatometry.

To study the complexation of M_1 with MA, we prepared isomolar series of their solutions in dioxane and recorded the electronic absorption spectra on a Specord UV-VIS spectrometer in the range λ = 300–400 nm at 298 K. The dependence of the optical density on the MA content was examined in the range λ = 330–370 nm.

The total concentration of M_1 and MA was constant (0.2 M), and their ratio was widely varied.

The structure of the macromolecular chain of the copolymers isolated at various conversions and the content of the units of both monomers were studied by IR spectroscopy. The spectra contain bands at 1500 and 1605 cm^{-1}, characteristic of the benzene ring, at 1035–1045 cm^{-1}, characteristic of the cyclopropane group, and at 1740–1780 cm^{-1}, characteristic of the anhydride moiety.



The IR spectrum of the monomer contains the absorption bands of the epoxy groups at 830–850 and

Table 1. Copolymerization of M_1 with MA (M_2) in benzene at 333 K ([M] = 0.5 M, [AIBN] = 0.1%)

$[M_1]$ in starting mixture, mol %	Yield, %	Acid number, mg KOH/g	Copolymer composition, mol %		r_1	r_2	r_1/r_2	Q_1	e_1
			M_1	M_2					
90	11.5	384	50.80	49.20	0.003	0.002	0.006	0.04	–1.16
75	7.3	388	50.20	49.80					
50	12.4	390	50.05	49.95					
25	6.4	394	49.90	50.10					
10	7.2	395	49.82	50.18					

1250–1260 cm^{-1} and those of the ether group at 1105–1110 cm^{-1}. These bands are fully preserved upon copolymerization. At the same time, the vinyl absorption bands at 1645 and 965 cm^{-1} disappear upon copolymerization.

The IR spectra and elemental analysis show that the polymerization involves the double bond of the vinyl group, with the cyclopropane and epoxy rings remaining intact:

This structure of the macromolecular chain units is confirmed by ^1H NMR spectroscopy. The ^1H NMR spectrum contains proton signals from the benzene ring (δ 6.85–7.25 ppm) and cyclopropane group (δ 0.75–1.75 ppm). The epoxy groups give signals at δ 2.5–3.0 ppm, and the anhydride groups, at δ 3.5 ppm.

The optical density of M_1 + MA solutions in dioxane at λ = 330–370 nm is plotted in Fig. 1 vs. the MA content. The plots pass through a maximum at a monomer ratio of 1 : 1.

This fact suggests formation of 1 : 1 molecular complexes in the M_1–MA system. The complexation can also be detected visually: On mixing solutions of M_1 and MA, the mixture becomes yellowish within 20–25 min, and the color becomes more intense in the course time (light yellow in 2 h).

Experiments on the copolymerization of M_1 with MA revealed the formation of a copolymer with a high degree of alternation of the monomeric units at any monomer ratio. From the ^1H NMR data, using the Ketelaar equation [6], we calculated the complexation constant: $K_e = 0.18 \pm 0.01$ $1\ mol^{-1}$.

The reactivities of M_1 and MA were evaluated using the Fineman–Ross method [7]. The results are listed in Table 1; they show that the monomers tend to undergo alternating copolymerization. The polarity (e) and specific activity (Q) parameters of M_1 were calculated by the Alfrey–Price scheme.

To elucidate the mechanism of formation of the alternating copolymer, we studied how the copolymerization rate depends on the composition of the reaction mixture and on the total concentration of the monomers (Fig. 2). The plot of the copolymerization rate vs.

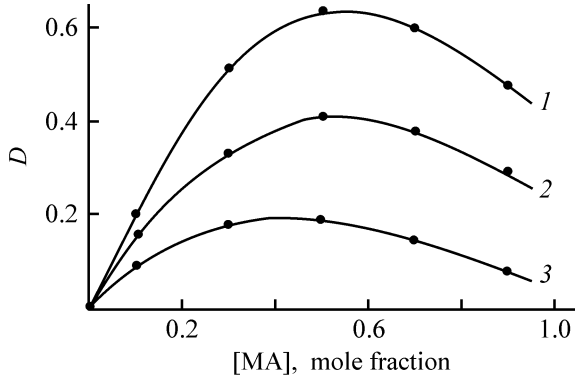


Fig. 1. Optical density D of M_1 + MA solutions in dioxane (total concentration 0.2 M) vs. the MA content in the mixture. λ, nm: (*1*) 350, (*2*) 355, and (*3*) 362.

reaction mixture composition suggests that the chain propagation involves both free monomers and monomers bound in a complex [8]. Owing to the structural features, these copolymers have specific favorable properties [9]. The presence of polar groups and of pendant functional groups regularly arranged along the macrochain imparts to the copolymer high physicomechanical and thermal properties, and also other specific properties, including the capacity for self-cross-linking. This copolymer is highly photosensitive, as can be seen from its behavior under UV irradiation.

The copolymer prepared by the procedure suggested is capable of thermal cross-linking without addition of a cross-linking component or catalyst. Therefore, the copolymer exhibits high physicomechanical properties. The copolymer is readily cross-linked at 100–150°C in a time from 10 min to 6 h. The yield of the cross-linked fraction is 10–99%.

The cross-linking of the linear copolymer was monitored by comparison of the IR spectra of the samples before and after the heat treatment. We found that the intensities of the absorption bands of the anhydride and epoxy groups decrease in the course of the cross-linking. The properties of the cross-linked copolymer are given in Table 2.

The high adhesion of the copolymer prepared to metals and glass makes it suitable for preparing water-resistant coatings with high levels of hardness and elasticity. Our experiments show that the copolymer of 2-glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane with maleic anhydride is cross-linked at a high rate, which allows preparation of materials with high physicomechanical and thermal properties. Furthermore, owing to structural features and polyfunctionality, the copolymer can be readily cross-linked by UV irradiation.

CONCLUSIONS

(1) The copolymerization of 2-glycidyloxymethyl-1-(*p*-vinylphenyl)cyclopropane with maleic anhydride occurs via complexation of the monomers.

(2) The monomers show a pronounced tendency toward alternation in the copolymer.

(3) The copolymer obtained is capable of thermal self-cross-linking.

Received March 7, 2006

Abstract—Radical copolymerization of *N*,*N*-diallyl-*N*'-benzoylhydrazine with acrylonitrile and sulfur dioxide was studied. The kinetic features of the copolymerization of these systems were examined, the relative activities of the monomers were determined, and the structure of the resulting copolymers was elucidated.

DOI: 10.1134/S1070427206080271

Polyfunctional polymers based on nitrogen-, oxygen-, and sulfur-containing vinyl and allyl monomers are of doubtless interest owing to their complexing and flocculating properties and to a wide spectrum of biological activities. These compounds are used as flocculants, growth-stimulating agents in plant growing, drugs in cattle breeding, aftertanning agents in leather production, etc. [1–4]. At the same time, the range of monomers commercially available in Russia for the synthesis of such polymers by radical (co)polymerization is very limited. Therefore, application of industrial facilities intended for production of specialty products (in particular, hydrazine derivatives) to the synthesis of *N*-containing monomers and to production on their basis of new structural types of polyfunctional polymers is a topical problem. Previously we have shown that copolymers of diallylhydrazines with vinyl monomers and sulfur dioxide can be, in principle, obtained [5].

This study deals with the radical copolymerization of *N*,*N*-diallyl-*N*'-benzoylhydrazine (DABH) with acrylonitrile and sulfur dioxide.

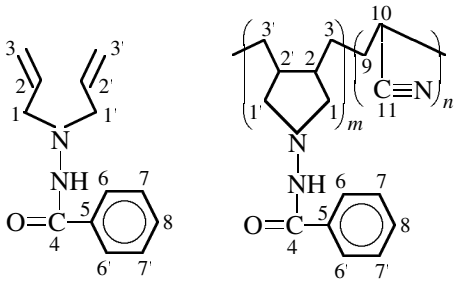
EXPERIMENTAL

N,*N*-Diallyl-*N*'-benzoylhydrazine was prepared by the reaction of benzoylhydrazine with allyl chloride:

$$2CH_2{=}CH{-}CH_2{-}Cl + NH_2{-}NH{-}C(O){-}C_6H_5$$

$$\rightarrow (CH_2{=}CH{-}CH_2)_2{-}N{-}NH{-}C(O){-}C_6H_5 + 2HCl.$$

The synthesis conditions are described in [6]. The purity was checked by elemental analysis and ^{13}C NMR spectroscopy.



Elemental composition, %	C	H	N
Found	71.71	7.93	12.84
Calculated	72.22	7.41	12.96

The chemical shifts (δ, ppm) and multiplicities of signals in the ^{13}C NMR spectrum of DABH are listed in the table (the ^{13}C NMR spectrum of the DABH–SO_2 copolymer was reported in [5]).

The comonomer (acrylonitrile, AN), initiators [azobis(isobutyronitrile), AIBN; benzoyl peroxide, BP], and solvents (dimethyl sulfoxide, DMSO; methanol; acetone] were purified by standard procedures, and their characteristics agreed with reference data. Sulfur dioxide was dried by passing through concentrated H_2SO_4 and freshly calcined $CaCl_2$.

The copolymerization of DABH with AN and SO_2 was performed to low conversions in the bulk and in DMSO in the presence of AIBN in evacuated ampules (with AN) or in a glass reactor [7] (with SO_2). The reaction mixture temperature was 80°C. The polymers were purified by twofold reprecipitation from the solvent (DMSO) into the precipitant (methanol with AN, acetone with SO_2). The purified polymers were vacuum-dried to constant weight at 50°C. The composition of the copolymers was calculated from the results of elemental analysis.

Chemical shifts and multuplicities of ^{13}C NMR signals of DABH and its copolymers with AN

Compound	Stereoisomer	C^1, $C^{2'}$	C^2, $C^{2'}$	C^3, $C^{3'}$	C^4	C^5	C^6	C^7	C^8	C^9	C^{10}	C^{11}
I	–	117.38 t	134.96 d	58.83 t	165.28 s	134.13 s	117.08 d	128.14 d	131.02 d			
II	*cis* *trans*	57.97 60.99 t	40.41 41.80 d	29.83 31.16 t	164.77 s	134.17 s	127.08 d	128.14 d	131.02 d	32.70 33.81 t	27.96 d	120.02 121.17 s

The NMR spectra were recorded on a Bruker AM-300 spectrometer at the operating frequency for ^{13}C of 75.46 MHz. The spectra were recorded in the broad-band proton decoupling and JMOD modes. DMSO-d_6 was used as solvent, and tetramethylsilane, as internal reference.

The UV spectra were measured with a Shimadzu UV-VIS-NIR 3100 spectrophotometer. The complexation was judged from the difference between the optical density of the solution of the monomer mixture and the sum of the optical densities of the solutions of the same monomers taken separately in the same concentrations. The composition of the complex was determined by the method of isomolar series [8].

DABH does not undergo radical homopolymerization in the presence of AIBN or BP and homopolymerizes only in the presence of H_3PO_4. Similar results (10% yield) were obtained in our previous study [5] of the homopolymerization of *N*,*N*-diallyl-*N*'-acetylhydrazine.

Our studies showed that DABH copolymerizes with AN in the presence of AIBN. The copolymerization of DABH (M_1) with AN (M_2) was studied at low conversions. Experiments showed that, irrespective of the conditions (in the bulk or in solution), the reaction yields copolymers with random distribution of the comonomer units in the polymer chain. The composition of the copolymers is plotted in Fig. 1 vs. the composition of the starting monomer mixtures. These data and the effective copolymerization constants calculated by the Mayo–Lewis method ($r_1 = 0$, $r_2 = 1.9 \pm 0.2$) indicate that DABH is considerably less active than AN. It is seen (Fig. 1) that the copolymers are enriched in the AN units in the entire range of the monomer ratios. Since the DABH molecule cannot add to a propagating radical with the DABH terminus, the copolymers cannot contain more than 50 mol % DABH units at any monomer ratio in the starting mixture.

A kinetic study of the copolymerization of DABH with AN at low conversions showed that an increase in the DABH content in the starting monomer mix-

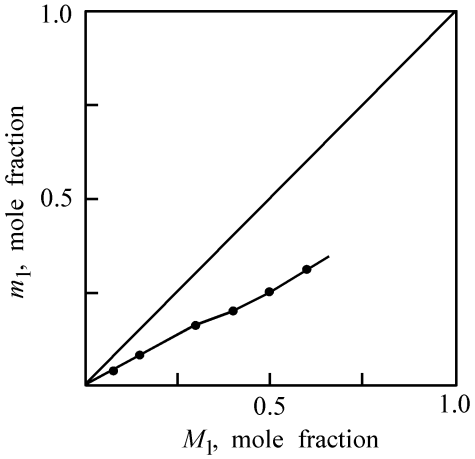

Fig. 1. Composition of DABH–AN copolymers vs. the composition of the initial monomer mixture. $[M_1 + M_2] = 2.2$, [AIBN] = 0.18 M; the same for Fig. 2. (M_1, m_1) Mole fractions of DABH in the starting mixture and copolymer, respectively.

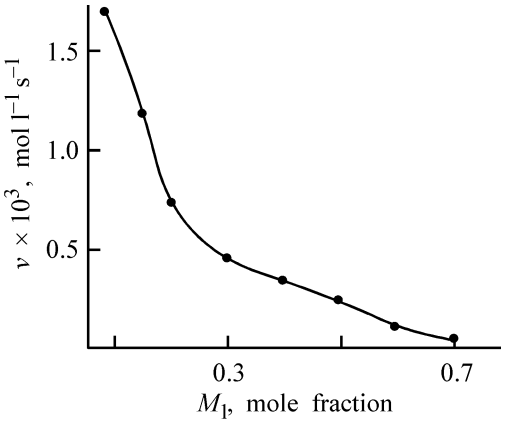

Fig. 2. Initial rate v of the copolymerization of DABH (M_1) with AN (M_2) vs. the composition of the starting monomer mixture. (M_1) Mole fraction of DABH in the starting mixture; the same for Fig. 3.

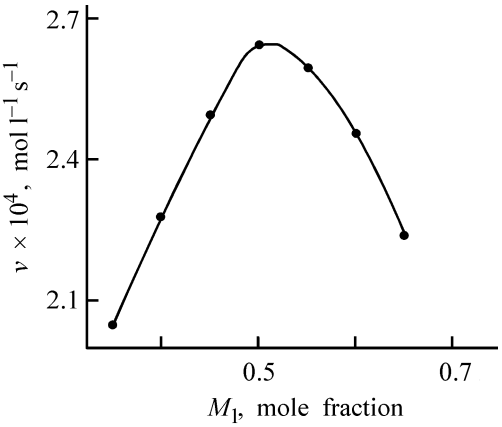

Fig. 3. Initial rate v of the copolymerization of DABH (M_1) with SO_2 (M_2) vs. the composition of the starting monomer mixture. $[M_1 + M_2] = 3.0$, [AIBN] = 0.18 M.

ture leads to a decrease in the reaction rate (Fig. 2), and at a DABH content exceeding 70 mol % the reaction is very slow.

DABH shows a considerably higher activity in the polymerization with SO_2, which exhibits high electron-withdrawing power. The copolymerization of DABH with SO_2 involves the formation of alternating copolymers of the equimolar composition, irrespective of the monomer ratio in the starting mixture, nature of the solvent (DMSO, methanol) and initiator (AIBN, BP), and reaction temperature (60–90°C). The constancy of the copolymer composition at any monomer ratios suggests that the copolymerization of DABH with SO_2 involves the formation of the complexes [DABH···SO_2]. To confirm these data, we studied this system by UV spectroscopy. We found that the electronic absorption spectra of DABH, SO_2, and their mixture in DMSO show noticeable deviations from the additivity: The sum of the optical densities of separately taken solutions of DABH and SO_2 differs from the optical density of the mixed solution, and the largest deviations from the additivity (0.8 in the D scale) are observed at the equimolar ratio of the monomers. These data confirm the occurrence of donor–acceptor interactions between the DABH and SO_2 molecules in the DMSO solution.

Although the reaction conditions do not affect the composition of the copolymers, they strongly affect the reaction rate and copolymer yield. In particular, in the copolymerization of DABH with SO_2 in DMSO at 80°C in the presence of 3 wt % AIBN, the copolymer yield is 70%, whereas with BP taken as initiator, virtually no copolymerization occurs under the same conditions.

The initial rate of the copolymerization of DABH with SO_2 as a function of the comonomer ratio passes through a maximum at the equimolar ratio of the monomers (Fig. 3). The decreased reaction rate at the monomer ratios differing from 1 : 1 is caused by the decreased concentration of the reactive complex in the system.

The overall activation energy of the copolymerization of DABH with SO_2, calculated from the Arrhenius plot using the data obtained for the range 60–90°C, is 103 ± 2 kJ mol^{-1}; this value is typical of radical polymerization.

The structures of the DABH copolymers obtained were studied by ^{13}C NMR spectroscopy. The spectra of the DABH–AN and DABH–SO_2 copolymers (see table) contain, along with the signals of carbon atoms of the –NH–C(O)–C_6H_5 group of the DABH unit, only three pairs of signals corresponding to two methylene groups and one methine group in two stereoisomeric structures, which is indicative of the symmetrical structure of the copolymers. Two pairs of low-field triplets correspond to the *cis*/*trans*-stereoisomeric carbon atoms C^1, $C^{1'}$ and C^3, $C^{3'}$, and the pair of doublets, to the stereoisomeric C^2 and $C^{2'}$ atoms. The chemical shifts and multiplicities of the signals show that the copolymerization of DABH involves opening of both double bonds and formation of symmetrical structures, five-membered pyrrolidine rings. The ratio of the *cis*/*trans*-stereoisomeric units of DABH in its copolymer with SO_2, estimated from the ^{13}C NMR spectrum, is approximately 4 : 1, whereas in the copolymer of DABH with AN, the *trans*-stereoisomeric units prevail.

The chemical shifts of the signals of the AN units in the spectrum of the DABH–AN copolymer virtu-

ally coincide with those in polyacrylonitrile (PAN) [9]. In the spectrum of the copolymer (recorded with broad-band proton decoupling), in contrast to the spectrum of PAN, the configuration multiplets of the pseudo-asymmetrical C^{10} atoms and the adjacent α-, β-C nuclei of the AN units are lacking. This fact indicates that the copolymer does not contain long AN blocks in a noticeable amount and has an ordered structure.

The copolymers obtained are soluble in DMSO and DMF and insoluble in other common solvents (methanol, acetone, tetrahydrofuran, benzene, ethyl acetate, etc.).

CONCLUSIONS

(1) *N*,*N*-Diallyl-*N*'-benzoylhydrazine copolymerizes with acrylonitrile in the presence of various radical initiators to form copolymers with random distribution of the comonomer units in the macromolecule. The relative activity of *N*,*N*-diallyl-*N*'-benzoylhydrazine is considerably lower than that of acrylonitrile, and the copolymers are enriched in the acrylonitrile units in the entire range of monomer ratios.

(2) *N*,*N*-Diallyl-*N*'-benzoylhydrazine copolymerizes with sulfur dioxide by the radical mechanism to form alternating copolymers of equimolar composition, irrespective of the monomer ratio in the starting mixture and reaction conditions. The reaction rate is the highest at the equimolar ratio of the monomers.

(3) The copolymerization of *N*,*N*-diallyl-*N*'-benzoylhydrazine is accompanied by intramolecular cyclization with the formation of pyrrolidine rings and involves both double bonds.

Abstract—The process of preservation of newspaper with aqueous solutions and dispersions of acrylic copolymers is considered from the instant of impregnation till removal of the polymeric preservative from paper.

DOI: 10.1134/S1070427206080283

Books and archival, artistic, and other materials on paper media are subject to intensive aging (and, occasionally, destruction), which may lead to their loss. Therefore, the process of their preservation and restoration as a porous colloid material should be based on fundamental scientific principles, with special preserving polymeric materials used.

The aim of this study was to examine the process of preservation of porous cellulose paper with water-soluble acrylic polymers. It was necessary to reveal fundamental aspects of impregnation and strengthening of news paper with polyacrylate solutions and find what structural changes occur in paper under the action of various factors.

EXPERIMENTAL

As paper preservatives served water-soluble copolymers of sodium salts (NaMAC, NaAC) of methacrylic (MAC) or acrylic acid (AC), whose backbone contains methyl acrylate (MA) or butyl acrylate (BA) as a second component. The composition of the copolymers is listed in Table 1. The copolymers were synthesized by radical polymerization of 20 wt % solutions of comonomers in water. For the copolymers obtained to exhibit a neutral reaction, a required amount of a 10% solution of sodium hydroxide was introduced into the reaction mixture, with pH adjusted to 7–7.5. The intrinsic viscosity was measured at 23°C in a 2 N aqueous solution of NaOH (the polyelectrolyte effect disappeared under these conditions). To impart biocide properties to paper, it was impregnated with polyacrylic biocide latexes. The latexes were synthesized by emulsion polymerization of methyl methacrylate (MMA) with BA and AC, and tributyltin methacrylate (TBTM) and zinc acetate methacrylate (AcZnMAC) were used as biocide components. The latexes of Sn- and Zn-containing copolymers were obtained in the presence of nonionogenic surfactants, emulsifying agents and water-soluble initiating agents [1].

As a preservation object served news paper manufactured by Balkhna pulp-and-paper combine [GOST (State Standard) 6445–74]. Paper is a capillary-porous colloid material. It has a heterogeneous structure constituted by interwoven cellulose fibers. The fibers have different lengths and their cross-section is the key factor determining the size of pores [2]. The average pore radius of the news paper under study was calculated from the rate of the capillary rise of water by the Washburn equation

$$\frac{dh}{dt} = \frac{2\sigma r \cos\theta}{8\eta h},$$

where h is height; t, time in which a fluid moves up in the capillary; σ and η, surface tension and viscosity of the fluid, respectively; θ, wetting angle; and r,

96 NaAC–4 BA	0.93
94 NaAC–6 BA	0.70
92 NaAC–8 BA	0.96

capillary radius [3]. The average size of capillaries (pores) in news paper was found to be 78 nm.

The rate at which the polymeric solution penetrates into paper pores was evaluated by the method of capillary rise of the fluid along a paper sample 50 mm long and 10 mm wide, which was vertically suspended in a hermetically sealed vessel with a solution.

The physicomechanical properties of paper samples 10 mm wide and 80 mm long were tested at room temperature (~23°C) on an RMI-5 tensile-testing machine. Preliminarily, a polymeric solution was once deposited with a brush onto the paper surface along the sheet. Then, the solvent was removed from the paper in the convective-exchange mode at room temperature to constant weight of the sample.

The thermal aging of the paper samples under study was performed at 100 and 160°C in the course of 1–6 h; the thermooxidative destruction was carried out at 240°C, with changes in the sample weight monitored.

The microstructure of paper was examined with an MIM-7 microscope and a ×20 Huygens eye-piece. The image was magnified by a factor of 24.5 with an epiobjective with F-8.2 and A-0.37. The image was recorded with a portable video camera attached to the eye-piece and connected to a computer.

The study of the process of paper preservation included the following stages: (1) analysis of the rate of spontaneous impregnation (rise) of polymer solutions into pores of the paper; (2) examination of the effect of the composition of copolymers, their content in the impregnating solutions, and size of latex particles on the physicomechanical properties of reinforced paper; (3) study of the stability of paper preserved with polyacrylic copolymers against thermal, light, and biological treatments; (4) examination of the reversible removal of the preservative from paper.

Preservation of any porous body, including paper, begins with impregnation with a solution of a preservative, acrylic polymer in our case. It follows from Fig. 1 that, as the concentration of the impregnating polyacrylate solution increases, the viscosity η (mPa s) of this solution becomes higher and the rate V ($m^2\ s^{-1}$) of its capillary rise into the pores of the paper decreases. Both the increase in viscosity and decrease in the rate of solution penetration into paper are related to a change in the structuring of the polymer in solution. In a strongly diluted solution, the polymer is in the form of separate macrocoils, whereas in a moderately concentrated solution, these coils form coarse associates, which come in contact with one another in the concentrated solution to form a continuous structural network [4]. Consequently, the probability of

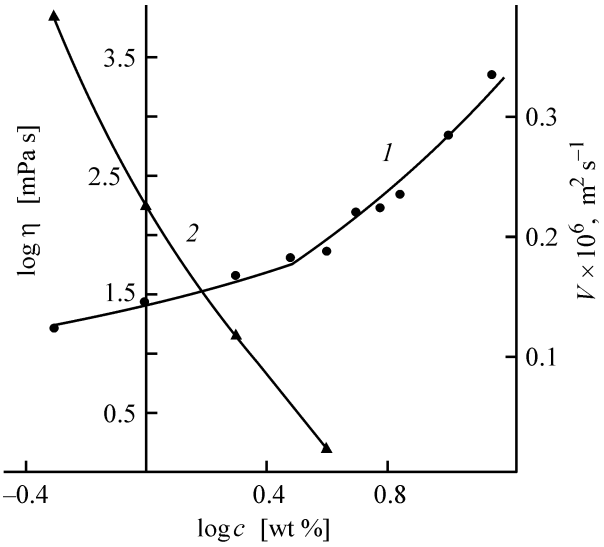

Fig. 1. (*1*) Viscosity η and (*2*) rate V of capillary rise of an aqueous solution of a copolymer composed of 96 wt % NaAC and 4 wt % MA into news paper vs. the concentration c of this solution.

penetration of coarse associates into the paper pores decreases, compared with that for separate macrocoils, whose size is very small. By contrast, a characteristic feature of latexes is that the rate of capillary rise of the fluid into paper pores increases with the size of colloid particles. For example, $V = 1.65 \times 10^{-6}\ m^2\ s^{-1}$ for water, $V = 0.75 \times 10^{-6}\ m^2\ s^{-1}$ for 1% latexes (40% TBTM–31% MMA–26% BA–3% AC) with a particle size of 90 nm , and $V = 0.95 \times 10^{-6}\ m^2\ s^{-1}$ for that with a particle size of 160 nm. Such a behavior of the latexes can be accounted for by the fact that it is more difficult for coarse particles to penetrate into the narrow paper capillaries, compared with finer particles.

An important result of paper preservation with a polymer is that its strength increases, compared with the initial paper. Figure 2 shows how the ten-

* Paper samples treated with 5% latexes.

sile strength σ_t (Pa) of paper samples reinforced with various polyacrylic copolymers depends on the concentration of the impregnating polymeric solution. The strength properties of the reinforced paper are strongly affected by the copolymer composition: introduction of MA units into the poly-NaAC backbone raises, and that of BA units, lowers the strength characteristics of polymer-treated paper, compared with poly-NaAC. This is apparently due to the rigidity of the poly-NaAC film. Introduction of MA units makes the rigidity lower, and BA, in addition, imparts to the polymeric film a considerable elasticity. In treatment of paper with latexes, its strength properties also depend on the physical state of the polymeric film and on the size of latex particles (Table 2). The data in the table show that the highest strength is observed for paper samples treated with latexes whose particle size is comparable with the size of pores in paper and the polymer in the film is in the highly elastic state at room temperature. The influence exerted by the size of latex particles on the strength properties of paper is confirmed by measurements of the strength of paper treated with latexes of composition 40% TBTM–31% MMA–26% BA–3% AC. For example, the tensile strength of paper treated with a 5% latex with a particle size of 90 nm is 240×10^5 Pa, whereas for paper treated with a latex of the same concentration but having a particle size of 160 nm, the strength decreases to 180×10^5 Pa. It can be assumed that fine latex particles penetrate into paper pores between its fibers and glue the fibers thereby improving the strength of paper.

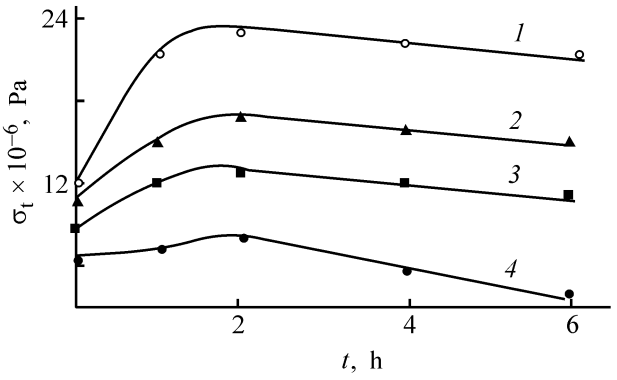

Fig. 3. Effect of the time t of thermal aging (T = 100°C) on the tensile strength σ_t of news paper samples treated with 2 wt % solutions of copolymers of various compositions. Copolymer composition (wt %): (*1*) 96 NaAC + 4 MA, (*2*) poly-NaAC, (*3*) 96 NaAC + 4 BA, and (*4*) paper wetted with water and dried at room temperature.

In the course of time, any paper is subject to aging, becomes fragile, is infested by microbes, looses whiteness, and changes composition. Various criteria are used to judge the paper aging. These are parameters related to mechanical, optical, and chemical properties of paper [5]. In the present study, the stability of paper samples treated with polyacrylic polymers against thermal aging was judged from changes in their strength parameters and from the loss of mass in the course of time under conditions leading to destruction of both the polyacrylate and cellulose. Figure 3 shows how the duration of heat treatment affects the strength of paper samples. It can be seen that the strength of all paper samples increases during 2 h, which is apparently due to evaporation of residual water serving as plasticizer of cellulose fibers of paper. The subsequent decrease in the strength of paper is, in all probability, due to aging of paper, with this process being faster for untreated paper, compared with that subjected to impregnation. This indicates that polyacrylates hinder aging of paper. A similar behavior of the strength of paper preserved with polyacrylates is observed at 160°C. The higher

stability of paper preserved with the acrylic polymers under study against high-temperature treatments is even more clearly indicated by the data in Fig. 4, which shows how the mass of paper samples varies under conditions of thermooxidative destruction of both the polymer and paper. As demonstrated by microstructural studies of paper samples (Fig. 5, thermal treatment leads to partial redistribution of the copolymer, and specifically its low-molecular-weight fractions, from coarse paper fibers (Fig. 5b) to fine fibrils (Fig. 5c), which protects from the action of heat.

Biocide tin- and zinc-containing latexes were tested for a wide spectrum of antimicrobial action. As test cultures served bacteria *Escherichia coli*, *Proteus vulgaris*, *Staphylococcus aureus*, *Streptococcus salivarius*, *Bacillus megaterium* and micromycetes *Aspergillus niger*, *Penicillium chrysogenum*, *Alternaria alternata, Fusarium moniliforme*, *Chaetomium globosum.* The choice of these cultures was determined by their predominance in biodestruction processes [6]. It follows from the data in Table 3 that Sn-containing copolymers are clearly pronounced fungicides, and Zn-containing copolymers, bactericides, whereas copolymers with Sn- and Zn-containing monomer units exhibit fungicide and bactericide activities simultaneously. It should also be noted that the bactericide activity of the copolymers studied toward associations of test cultures is lower than that toward each separate kind of bacteria, and the fungicide activity is, by contrast, higher toward associations of microscopic fungi, compared with their separate species. The mechanism of the biocide action of the copolymers obtained is due to splitting-off of their Sn- and Zn-containing pendant groups of hydrolysis products (hydroxides of tributyltin and zinc), which are lethal for various species of bacteria and microscopic fungi [1]. In this connection, the rate of release of hydrolysis products into the environment is 1.5–2.0 orders of magnitude lower than that in the case of low-molecular-weight biocides, which is undoubtedly ecologically important. It was found that paper treated with latexes of this kind is protected from the action of fungi, bacteria, and algae.

The latexes were tested and it was found that the preparations used do not adversely affect documents, preserve their authenticity, improve service properties of books, hinder their aging, and are harmless for users [7].

One of necessary conditions in preservation of any work of art is that the preservative should be removed from its material by prolonged storage ("reversibility" of preservation). In the present study, washing-out of acrylic polymers with water from paper samples impregnated with these polymers was examined both before and after thermal aging. The washing-out of

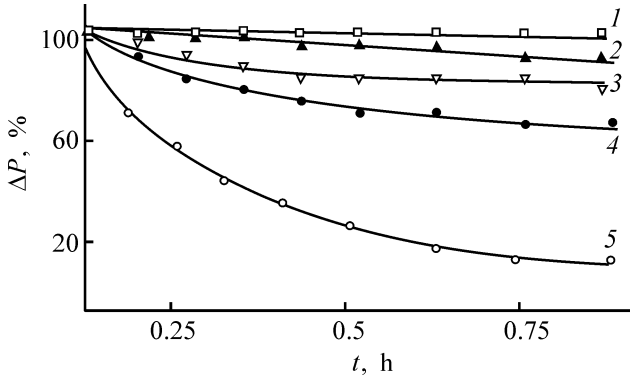

Fig. 4. Loss of mass, ΔP, by the paper–polymer composite in a time t of thermooxidative destruction at 240°C. Paper is impregnated with 2 wt % copolymer solutions. Copolymer composition (wt %): (*1*) 96 NaAC + 4 BA, (*2*) 96 NaAC + 4 MA, (*3*) 90 NaAC + 10 MA, (*4*) poly-NaAC, and (*5*) initial paper.

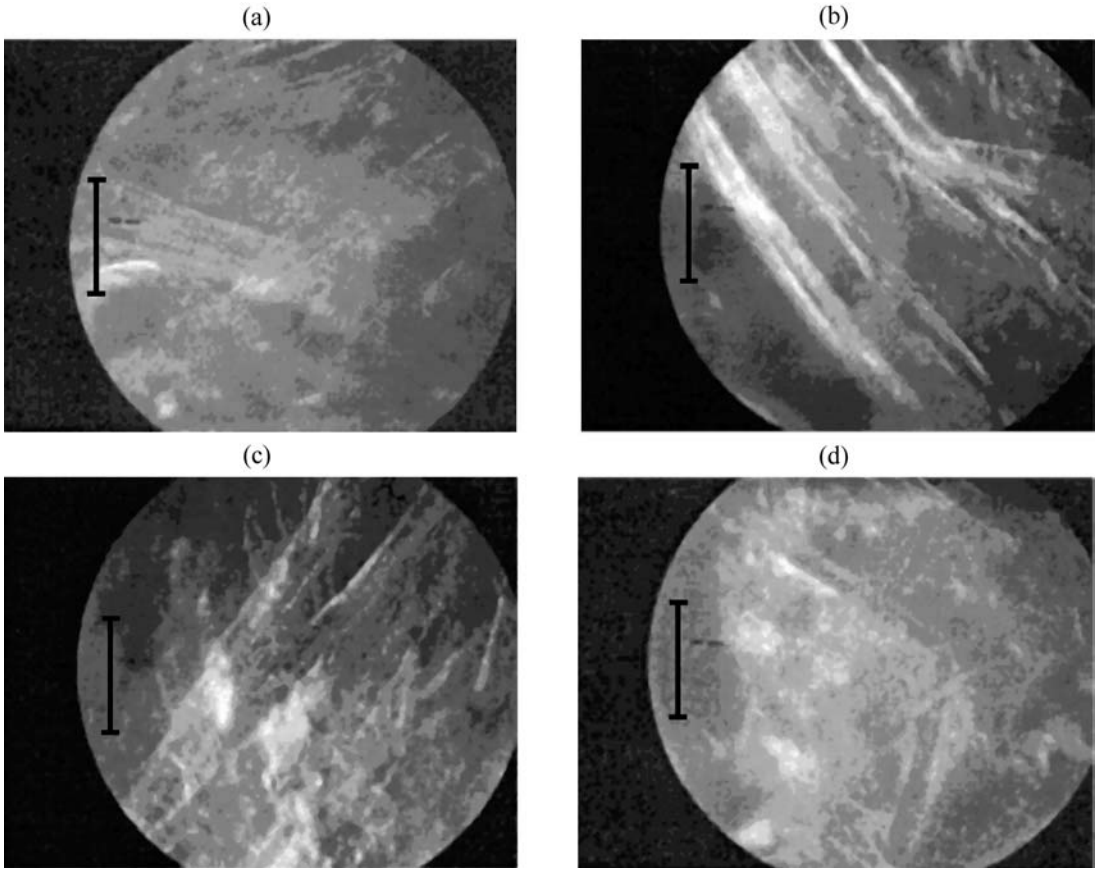

Fig. 5. Microstructure of news paper: (a) fibers of initial news paper and that (b) impregnated with a 5 wt % solution of the NaMAC copolymer, (c) impregnated with a 5 wt % solution of the NaMAC copolymer and aged at 100°C, and (d) with a 5 wt % solution of the NaMAC copolymer, aged at 100°C, and soaked in water for 24 h.

a polymer from paper sheets was judged from changes in their mass and in the microstructure of paper samples. It can be seen from Fig. 6. that the mass of paper samples impregnated and not impregnated with the polymer increases on their keeping in water for 1 h. This is due to capillary absorption of water by paper fibers and polymer. Further, during the subsequent 2–3 h, the mass of the samples dramatically decreases because of washing-out of the polymer from paper and diffusion of fine fibers into water. In the interval of 4–6 h from the beginning of the experiment, the mass of the samples again somewhat increases, probably because of penetration of water now into those fibers which were protected by the polymer before. The fact that the structure of a paper sample that was impregnated with the poly-NaAC copolymer, aged at 100°C for 6 h, and then soaked in water becomes more disordered, and the residual polymeric layer remaining on fibers becomes thinner. Analysis of Figs. 6 and 5d shows that the acrylic polymer protecting paper fibers does not chemically interact with cellulose even at high temperatures. Only a physical interaction (of adsorption type and via hydrogen bonds) is established between paper fibers and polyacrylate.

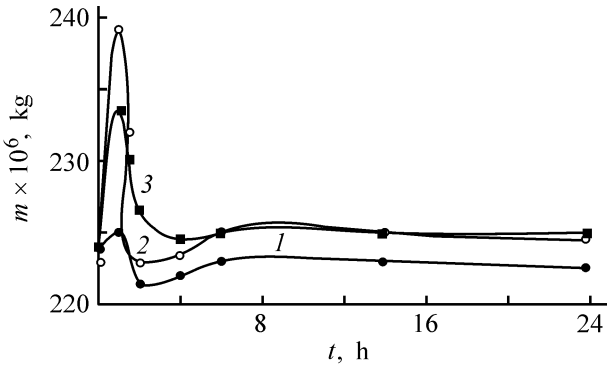

Fig. 6. Mass m of paper sample vs. the time t of their keeping in water. Paper: (*1*) initial, (*2*) treated with a 21 wt % solution of NaMAC copolymer, and (*3*) treated with the same polyacrylate solution, but subjected to thermal aging at 100°C for 2 h.

CONCLUSIONS

(1) The water-soluble acrylic polymers studied satisfy a number of requirements imposed by restorers on paper-preserving preparations. They are transparent and colorless, stable themselves, impart stability against thermal treatment to paper treated with these polymers, and, upon introduction of tin- and/or zinc-containing units, against biological destruction as well.

(2) The polyacrylates obtained reinforce paper and make it water-resistant, but can be removed from paper with water upon prolonged storage.

(3) The rate of penetration of a polymeric solution into paper pores depends on the relative sizes of paper pores and polymer particles (macrocoils or latex particles), as well as on the degree of structuring of the impregnating solution.

Abstract—Paraffin deposition on cold metallic surfaces in crude oil production, collection, and transportation is studied. Comparative analysis is made of the efficiencies of various paraffin inhibitors in West-Siberian paraffin oils. The mechanism of action of the additives is analyzed in relation to the phase and structural transitions in them in model systems.

DOI: 10.1134/S1070427206080295

Production of paraffin oils is complicated by increased hydraulic resistance and paraffin deposition (PD) in the production, collection, and transportation systems, resulting in death of oil field equipment [1]. The simplest and the most efficient solution of this problem is the use of depressor additives [2].

The goal of this study was to simulate the paraffin deposition in crude oil production and collection. We also made a comparative analysis of the efficiency of domestic and imported depressor additives in West-Siberian paraffin oils.

The experiments were carried out by the cold-rod method using a laboratory setup developed at the Tyumen Oil and Gas University [3]. As a simulated crude oil we used a hexane solution of Ceresin-80N [GOST (State Standard) 2488] and high-melting native paraffin deposits (NPD) collected from the Verkhnesalatskoe oilfield (Tomsk oblast, Russia). Certain physicochemical characteristics of the solid paraffins are given in Table 1.

Hexane as a model of liquid hydrocarbons of crude oil was selected taking into account that its boiling

Content of paraffin-naphthene hydrocarbons,* wt %	98.0	91.0	99.5	92.4	95.4	89.7
Content of aromatic hydrocarbons,* wt %	2.0	9.0	0.5	7.6	4.6	10.3

* Content of paraffin-naphthene hydrocarbons was approximately determined by desorption from silica gel with petroleum ether, and that of aromatic hydrocarbons, as the difference between the initial sample weight and the estimated amount of paraffin-naphthene hydrocarbons.

point (68.7°C) falls within the range of temperatures that occur along the whole length of throughout most of the oil wells in Western Siberia. As a hot heat carrier we used water at its boiling point, and as a cold heat carrier, ethanol at a temperature inside the cold rod from –15 to +5°C. Such a combination of the solvent (hexane) and heat carriers provides boiling of the simulated crude oil in the working space, thus imitating the motion of the oil, its degassing, and the diffusion of solid paraffins from the bulk to the surface of the cold rod. The hot heat carrier : working mixture weight ratio was accepted to be 2.5 : 1, taking into account the design factors of the laboratory setup.

We studied the effects of the nature of solid paraffins and their concentration in the simulated crude oil, and also of the process temperature and time on the paraffin deposition on cold metallic surfaces.

The experimental techniques have been described elsewhere [3]. The process parameters were as follows: water temperature 100°C, ethanol temperature 0°C, temperature gradient in the working space 14.3 deg mm^{-1}, and deposition time 60 min. The solid paraffin content in *n*-hexane was varied from 2.5 to 30 wt %.

The waxing of the cold rod was characterized by the yield of the deposit in grams, as influenced by the solid paraffin content of hexane. The specific yield of the deposit, G_{sp}, was estimated as the weight of the deposit related to the unit surface area of the oil-wet surface of the cold rod per unit time (g m^{-2} h^{-1}).

Data on the waxing of the cold rod (Table 2) show that G_{sp} the with the initial content of solid paraffins.

The yield of secondary PDs from NPD systems is considerably higher than that from the simulated systems (Ceresin in *n*-hexane), the increase in the PD yield being more pronounced in the former case. For some of the deposits obtained we determined Zhukov's melting point (Table 2). The melting point of PDs appears to be considerably higher than that of the initial Ceresin and NPDs. The melting point of the deposits approaches that of solid paraffins capable of forming complexes with urea (Table 1).

Evidently, higher-melting solid paraffins with long aliphatic radicals are preferentially deposited on the cold rod. These are *n*-paraffins and paraffin-naphthene and alkylaromatic hydrocarbons with long aliphatic radicals. The presence of such alkylaromatic hydrocarbons in the deposits was confirmed by both urea dewaxing and liquid chromatography on silica gel (Table 1).

** Deposition at higher content of solid paraffins in hexane was unfeasible because of limitations caused by the design factors of the experimental setup.

Deposition of solid paraffins was carried out using the above-described procedure at varied temperature or deposition time, all other parameters being fixed.

Table 3 shows that the PD yield only slightly depends on the cold rod temperature, being controlled essentially by the deposition time. The PD yield increases with the deposition time. Therefore, under

the actual conditions, the exploitation time is the factor controlling the paraffin deposition on the internal walls of oil field equipment. The PD yield is controlled by the nature of solid paraffin, all other conditions being equal. High-molecular-weight high-melting solid paraffins, which apparently belong to hydrocarbons capable of forming complexes with urea, are preferentially deposited.

We also made a comparative study of the efficiency of domestic and imported depressor additives in two samples of West-Siberian crude oil from the Tarkosalinskoe (Tyumen oblast) and Verkhnesalatskoe (Tomsk oblast) oilfields. Certain physicochemical characteristics of these samples are listed in Table 4.

As depression additives we used imported Visco-5351 (Nalko Company) and Flexoil WM-1470 (Servo Champion Company), and domestic DN-1, DN-MA [4], TyumII-77 [5], DP-65 [6], SNPKh-4002, two polyethylene waxes from industrial wastes VPEN and VPEA [TU (Technical Specifications) 6-05-1837–82], and additives DPM-12/05 and DPM-18/05 synthesized at the Laboratory of Petrochemical Synthesis, Tyumen State Oil and Gas University.

The efficiency of depressor additives was characterized by the decrease in the oil congelation temperature over the concentration range of the additives 0.005–1.0 wt %. The oil congelation temperature was determined according to GOST (State Standard) 20287–91. The results (Table 5) show that, regardless of the crude oil sample, the most efficient additives are Visco-5351, Flexoil WM-1470, DN-MA, and TyumII-77. The additives DPM-12/05 and DPM-18/05 are also quite efficient. The efficiency of the additives depends primarily on the characteristics of crude oil, such as the content of solid paraffins, resins, and asphaltenes.

To elucidate the paraffin inhibiting mechanism, we determined the parameters of phase transitions [7] in several model systems [depression additives in RT kerosene (GOST 10227)] (Table 6). The phase transition parameters were also determined for paraffin deposits from Verkhnesalatskoe crude oil (mp 91.2°C), T-1 solid paraffin [mp 54.5°C (GOST 23683)], and Ceresin-80N (Table 6). In making decision on solid paraffins, we proceeded from the fact that specifically these kinds of solid paraffins, contained in crude oil, control paraffin deposition on oil field equipment.

The phase transitions and structurization in the course of cooling of the model systems were studied in relation to the content of solid paraffins and depressor additives in kerosene c_s The solid phase content was varied from 0.1 to 5 wt %. Using standard procedures, we determined the congelation temperature t_g (GOST 20287–91) and cloud point t_c (GOST 5066–91). Based on the dependences of t_g and t_c on c_s, we constructed the phase transition diagrams.

Table 6. Parameters of phase transitions and structurization factor in model systems containing solid paraffins of crude oil and depressor additives in kerosene

Product	$c_1^{'}$, wt %	T_{CSCC}, °C	r_2, g l^{-1} min^{-1}	S_{CDS}, deg wt %
Paraffin deposit	0.1	46	3.7	609.5
Ceresin-80N	0.3	37	3.6	568.4
T-1 paraffin	0.2	1	3.3	70.4
Visco-5351	0.1	–11	7.0	141.5
Flexoil WM-1470	0.1	–2	8.6	50.0
TyumII-77	0.13	10	7.0	324.0
DP-65	0.08	34	11.5	463.2
VPEA	0.30	32	4.8	517.4
VPEN	0.10	28	3.8	516.3

Three distinctive regions were found in the diagrams: (*1*) molecular-disperse state (MDS) of solid paraffins and additives in kerosene (region above t_c), (*2*) colloidal-disperse state (CDS) (region between t_g and t_c), and (*3*) quasisolid state (QSS) (region below t_g). The degree of structurization of the dispersed particles of solid paraffins and additives was characterized by the area of the CDS region S_{CDS} (the higher S_{CDS}, the lower the degree of structurization).

The phase transitions were characterized by the critical spontaneous crystallization concentration $c_1^{'}$, cloud point at this concentration t_{CSCC}, and solid phase accumulation rate r_2 above t_{CSCC} [4]. Data on S_{CDS} and phase transitions (Table 6) show that all the parameters of phase transitions of the depressor additives considerably differ from those of the solid paraffins.

The structurization factor S_{CDS} decreases in the order Flexoil WM-1470 > T-1 paraffin > Visco-5351 >> TyumII-77 > DP-65 >> VPEN > VPEA > Ceresin-80N > PD.

What is common to depressor additives Visco-5351, TyumII-77, and DP-65 and polyethylene waxes is that they are characterized by a small degree of structurization in the colloidal-disperse state region, compared to T-1 paraffin, suggesting a weak intermolecular interaction in the additives in the CDS re-

gion and a high lubricity of the DA molecules brought in contact with the crystals of solid paraffin in one way or another.

Comparison of data on the phase transitions in the solid paraffins and additives, on the one hand, and the efficiency of the depressor additives in the crude oil samples investigated, on the other hand, shows that the common feature of the most efficient imported depressor additives is that they have lower t_{CSCC} as compared to that of paraffin deposits. Evidently, these additives operate by essentially the adsorption (lubrication) mechanism controlled by the low surface tension at the interface between the solid paraffin surface and the dispersion medium, thus minimizing the consumption of the additives, which is determined only by their expenditure for the formation of a monolayer on the surface of the paraffin crystals.

What is common to additives TyumII-77 and DP-65 and the waxes is that their t_{CSCC} is close to that of solid paraffins. It follows from the fact of different efficiencies of the additives and waxes that the latter, as isomorphous compounds, act by the purely cocrystallization mechanism. Additives TyumII-77 and DP-65 operate, presumably, by the mixed cocrystallization/adsorption mechanism.

The results obtained show that Visco-5351, DN-MA, TyumII-77, DP-65, DPM-12/05, and DPM-18/05 may be recommended as effective depressor additives for Verkhnesalatskoe crude oil. DPM-12/05 and DPM-18/05 show promise also as additives produced from available raw materials. Because of the lack of available higher fatty alcohols and synthetic fatty acids, domestic additives DN-MA, TyumII-77, and DP-65 currently cannot be produced n Russia.

Flexoil-WM is currently used as a paraffin inhibitor in Verkhnesalatskoe crude. Changing this additive for Visco-5351 should reduce the consumption of additives at least by half (Table 5). Because of the nearly the same cost of these additives, the charges for the depressor additive will be reduced by half also. Furthermore, Visco-5351 is a considerably more efficient additive in relation to the depression of the congelation temperature. Therefore, its use should reduce not only the consumption of the additive, but also the frequency of paraffin removal from oil field equipment and collection systems. Changing Flexoil-WM for DPM-12/05 or DPM-18/05 is also economically sound, since the cost of the domestic additives is lower by about half, and the efficiency of, e.g., DPM-18/05, taken in amount of 0.5 wt %, is considerably higher.

Abstract—Activities of iron and nickel in the copper-rich part of the Cu–Fe–Ni system in the liquid state at 1350°C were calculated using model concepts from data on the boundary binary systems.

DOI: 10.1134/S1070427206080301

In the last two decades, calculation methods have been acquiring increasing importance in thermodynamic description of ternary and more complex liquid metallic systems. A larger part of the calculation techniques are based on the assumption that pair interactions in the systems consisting of three and more components give a major contribution to values of the integral thermodynamic functions of multicomponent systems. This makes it possible to describe with a sufficient reliability the concentration dependence of the thermodynamic characteristics of these systems, leaning only upon experimental data for boundary binary systems. A sufficiently good agreement between calculated and experimental data has been confirmed by the example of the iron–nickel–cobalt system [1].

Our previous publications reported calculations of integral molar thermodynamic characteristics of liquid alloys in the copper–iron–nickel system at 1600°C [2] and of the activity of copper in these alloys [3]. In this study, we compared calculated activities of iron and nickel (1350°C) in alloys of the Cu(1)–Fe(2)–Ni(3) ternary system with the available published experimental data on the activity of the components in the copper-rich part of the system [4, 5]. As it was done in [3], we used equations following from Toop's method [6] to calculate the activities of the components. Equation (1) was used for component 2 (iron), and equation (2), for component 3 (nickel).

$$\log \gamma_2 = \left[\frac{x_1}{1-x_2}\log \gamma_{2(1)} + \frac{x_3}{1-x_2}\log \gamma_{2(3)}\right]_{x_2} + (1-x_2)^2\left[\frac{\Delta G_{13}^{ex}}{2.303RT}\right]_{x_1/x_3},$$

$$\log \gamma_3 = \left[\frac{x_2}{1-x_3}\log \gamma_{3(2)} + \frac{x_1}{1-x_3}\log \gamma_{3(1)}\right]_{x_3} + (1-x_3)^2\left[\frac{\Delta G_{21}^{ex}}{2.303RT}\right]_{x_2/x_1}.$$

Here x_1, x_2, and x_3 are the mole fractions of the components in a liquid alloy; γ_2 and γ_3, activity coefficients of components 2 and 3 in a ternary alloy; and $\gamma_{i(j)}$, activity coefficient of component i in a boundary binary alloy i–j.

When calculating the activity coefficients of iron and nickel by Eqs. (1) and (2), we used the available published data on the boundary binary systems Cu–Fe, Fe–Ni, and Ni–Cu. A detailed analysis of studies concerned with the thermodynamic properties of liquid

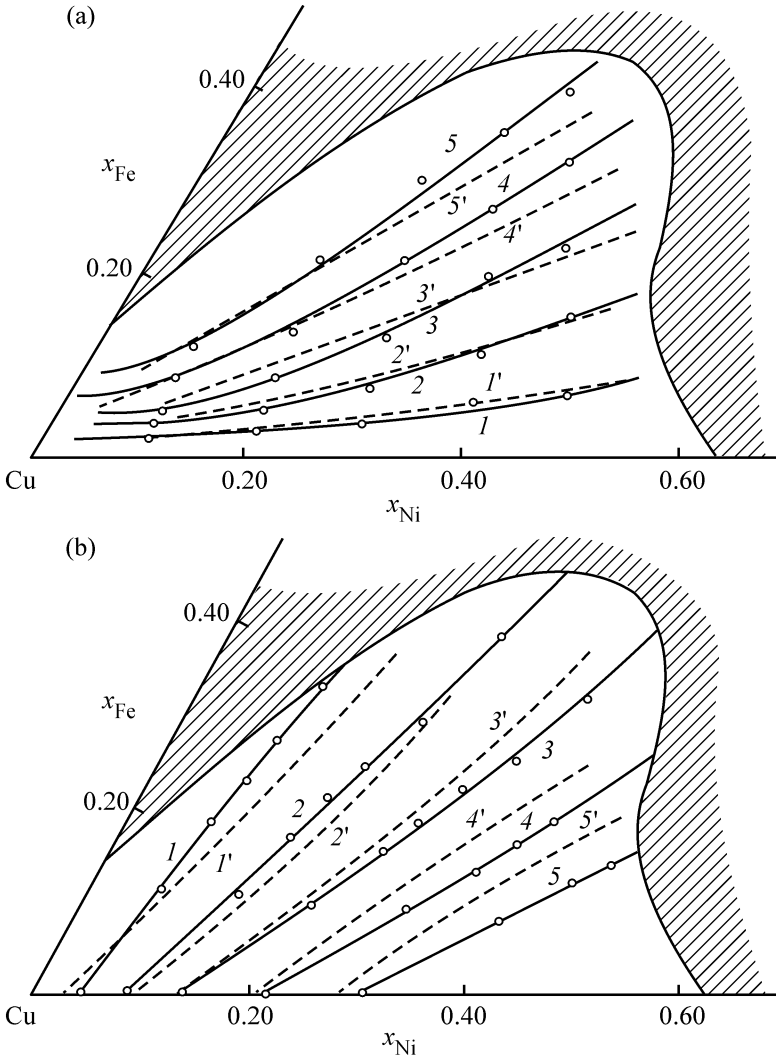

Fig. 1. Lines of equal activities of (a) iron and (b) nickel in liquid alloys of the Cu–Fe–Ni system at 1350°C. The solid lines were plotted by calculated points and the dashed lines were plotted in [5] on the basis of experimental data. Activity: (*1, 1'*) 0.1; (*2, 2'*) 0.2; (*3, 3'*) 0.3; (*4, 4'*) 0.4; and (*5, 5'*) 0.5. Standard state, pure liquid metals (iron and nickel in a supercooled state); the two-phase region is shaded.

alloys in these systems is given in [7]. For the calculations concerning the Cu–Fe system we used the data of [8], where the thermodynamic properties of liquid alloys were studied using the electromotive-force method and calorimetric measurements. These results are recommended as reference data in the monograph [9] and reference book [10]. The data of [8] on the activity of the components in liquid alloys agree with the results obtained in later studies of this system [11, 12].

When calculating the activity of the components of the ternary system, we used the data for the boundary Ni–Cu system, obtained by Kulkarni and Johnson [7, 14] by the electromotive-force method with an electrolyte exhibiting conduction by oxygen (ZrO_2 + 3 wt % of MgO). The thermodynamic properties of liquid alloys of the Fe–Ni system have been studied repeatedly, a detailed analysis of the results obtained can be found in [15]. In the calculations, we used the data from the reference book by Hultgren and coworkers [16] and from the monograph [9].

The activities of nickel and iron in the homogeneity region of liquid alloys of the Cu–Fe–Ni system at 1350°C, specified in [4, 5], for seven secants with a fixed ratio $x_{Ni} : x_{Cu}$ (when calculating γ_{Fe}) and $x_{Fe} : x_{Cu}$ (when calculating γ_{Ni}). As can be seen from the figure, the calculated isoactivity lines of iron and nickel rather well agree with the experimental results of the Japanese authors [4, 5]. The boundaries of the region of liquid alloys in the Cu–Fe–Ni system

at 1350°C, given in [4, 5] are close to those reported in reference publications [17].

CONCLUSION

The activities of iron and nickel at 1350°C in liquid alloys of the system Cu–Fe–Ni, calculated using model concepts, agree with the available published experimental data.

Thermodynamics of Reactions of Iron with Oxygen in the Presence of Water Vapor

A. I. Demidov and M. S. Kokhatskaya

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received July 4, 2006

Abstract—Changes in the standard Gibbs energies of the reactions of iron and iron oxides with pure oxygen and oxygen saturated with water vapor were calculated.

DOI: 10.1134/S1070427206080313

A study of the reactions of iron with oxygen at different humidities is of considerable interest for explaining the atmospheric corrosion of metal and for substantiating measures for corrosion protection [1, 2].

This study presents the results of a thermodynamic analysis of the reactions of iron with pure oxygen and oxygen saturated with water vapor. In performing the calculations, we used published data [3, 4] on changes in the standard Gibbs energies (see table). The reactions of iron with oxygen at a standard temperature of 298.15 K can be described by the following equations:

$$Fe + 1/2O_2 = FeO,\ \Delta G^0_{298} = -244.3\ kJ; \quad (1)$$

$$3Fe + 2O_2 = Fe_3O_4,\ \Delta G^0_{298} = -1014.2\ kJ; \quad (2)$$

$$2Fe + 3/2O_2 = Fe_2O_3,\ \Delta G^0_{298} = -741.0\ kJ. \quad (3)$$

The thermodynamic calculation of the standard Gibbs energies of reactions (1)–(3) per mole of a compound gives the most negative value for reaction (2) [5]. Consequently, the yield of the product in this reaction is the highest [5].

In calculation of reactions (1')–(3') per mole of oxygen, the most negative value of the change in the standard Gibbs energy was obtained for reaction (2'):

$$2Fe + O_2 = 2FeO,\ \Delta G^0_{298} = -488.6\ kJ; \quad (1')$$

$$3/2Fe + O_2 = 1/2Fe_3O_4,\ \Delta G^0_{298} = -507.1\ kJ; \quad (2')$$

$$4/3Fe + O_2 = 2/3Fe_2O_3,\ \Delta G^0_{298} = -494.0\ kJ. \quad (3')$$

In a thermodynamic analysis of heterogeneous condensed systems, the thermodynamic parameters are, as a rule, calculated per mole of the alloy or solution or per gram-atom of the constituted substance this compound [6, 7]. Therefore, we calculated the change in the standard Gibbs energy for the reactions of iron with oxygen per mole of the atoms of starting substances [reactions (1")–(3")]:

$$1/2Fe + 1/4O_2 = Fe_{0.5}O_{0.5},$$
$$\Delta G^0_{298} = -122.15\ kJ\ mol^{-1}; \quad (1")$$

$$3/7Fe + 2/7O_2 = Fe_{0.429}O_{0.571},$$
$$\Delta G^0_{298} = -144.89\ kJ\ mol^{-1}; \quad (2")$$

$$2/5Fe + 3/10O_2 = Fe_{0.4}O_{0.6},$$
$$\Delta G^0_{298} = -148.2\ kJ\ mol^{-1}. \quad (3")$$

As can be seen from the data presented, reaction (3") has a more negative change in the standard

Changes in the standard Gibbs energy of various substances and ions according to the data of [3, 4]

Formula	ΔG^0_{298}, kJ mol^{-1}	Formula	ΔG^0_{298}, kJ mol^{-1}
Fe	0	α-FeOOH	–490.0
FeO	–244.3	γ-FeOOH	–460.2
Fe_3O_4	–1014.2	O_2	0
Fe_2O_3	–741.0	H_2O	–237.2
$Fe(OH)_2$	–483.7	$Fe_3O_4 \cdot 4H_2O$	–1892.8
$Fe(OH)_3$	–694.5		

Gibbs energy. Consequently, the yield of the product in this reaction is the highest. The difference in the results obtained by thermodynamic analysis of reactions (1)–(3), (1')–(3'), and (1'')–(3'') is due to the fact that the Gibbs energy is an extensive quantity and its change is dependent on the number of substances involved in the reactions. Different numbers of moles were taken when writing the reactions per mole of a compound, and different numbers of moles of iron, when writing the reactions per mole of oxygen. When writing the reactions per mole of atoms of the starting substances, the total amount of these substances in all of the reactions considered was constant.

In turn, iron(II) oxide and a double iron(III)–iron(II) oxide can react with oxygen. When writing the reactions per mole of atoms of the starting substances, we obtain

$$3/7FeO + 1/14O_2 = Fe_{0.429}O_{0.571},$$
$$\Delta G^0_{298} = -40.19 \text{ kJ mol}^{-1}. \quad (4)$$

$$2/5FeO + 1/10O_2 = Fe_{0.4}O_{0.6},$$
$$\Delta G^0_{298} = -50.48 \text{ kJ mol}^{-1}. \quad (5)$$

$$2/15Fe_3O_4 + 1/30O_2 = Fe_{0.4}O_{0.6},$$
$$\Delta G^0_{298} = -12.97 \text{ kJ mol}^{-1}. \quad (6)$$

Iron(III) oxide can be reduced with iron to a double iron(III)–iron(II) oxide:

$$4/21Fe_2O_3 + 1/21Fe = Fe_{0.429}O_{0.571},$$
$$\Delta G^0_{298} = -3.74 \text{ kJ mol}^{-1}. \quad (7)$$

The reaction of double iron(III)–iron(II) oxide with iron shows a positive change in the standard Gibbs energy, and, consequently, has a small yield of the reaction product:

$$1/8Fe_3O_4 + 1/8Fe = Fe_{0.5}O_{0.5},$$
$$\Delta G^0_{298} = 4.62 \text{ kJ mol}^{-1}. \quad (8)$$

Thus, iron(III) oxide, which can be reduced to a double iron(III)–iron(II) oxide when brought in contact with iron, is the most stable compound in the Fe–O system. The oxide film formed on iron at room temperature can consist either of a single Fe_2O_3 layer, or of two layers, the outer Fe_2O_3 layer and the inner Fe_3O_4 layer. According to the data [8], oxide films formed on iron at room temperature consist of γ-Fe_2O_3 or of a cubic oxide, whose composition lies between pure γ-Fe_2O_3 and a 20%Fe_3O_4 + 80% γ-Fe_2O_3 mixture.

The reactions of double iron(III)–iron(II) oxide and iron(III) oxide with deoxygenated water, written per mole of atoms of the starting substances

$$[Fe_3O_4 + 4H_2O = 2Fe(OH)_3 + Fe(OH)_2] : 19,$$
$$\Delta G^0_{298} = 4.75 \text{ kJ mol}^{-1}. \quad (9)$$

$$[Fe_2O_3 + 3H_2O = 2Fe(OH)_3] : 14,$$
$$\Delta G^0_{298} = 4.54 \text{ kJ mol}^{-1}, \quad (10)$$

show small positive changes in the standard Gibbs energy, and, consequently, have a small yield of the reaction products.

In oxygen saturated with water vapor, oxidation of a double iron(III)–iron(II) oxide involves water:

$$[4Fe_3O_4 + O_2 + 6H_2O = 8\alpha\text{-FeOOH} + 4\gamma\text{-FeOOH}] : 48,$$
$$\Delta G^0_{298} = -17.29 \text{ kJ mol}^{-1}. \quad (11)$$

Thus, at a certain humidity and sufficient access of oxygen, Fe_2O_3, α-FeOOH, and γ-FeOOH can be formed on the oxidized surface of iron.

If iron is oxidized in the presence of water, then water is involved in the oxidation processes:

$$[Fe + 1/2O_2 + H_2O = Fe(OH)_2] : 5,$$
$$\Delta G^0_{298} = -49.3 \text{ kJ mol}^{-1}. \quad (12)$$

$$[3Fe + 2O_2 + 4H_2O = Fe(OH)_2 + 2Fe(OH)_3] : 19,$$
$$\Delta G^0_{298} = -48.63 \text{ kJ mol}^{-1}. \quad (13)$$

$$[2Fe + 3/2O_2 + 3H_2O = 2Fe(OH)_3] : 14,$$
$$\Delta G^0_{298} = -48.39 \text{ kJ mol}^{-1}. \quad (14)$$

The resulting iron(II) hydroxide is unstable and can be easily oxidized:

$$[4Fe(OH)_2 + O_2 = 2\gamma\text{-FeOOH} + 2Fe(OH)_3] : 22,$$
$$\Delta G^0_{298} = -17.03 \text{ kJ mol}^{-1}. \quad (15)$$

$$[4Fe(OH)_2 + O_2 = 4\gamma\text{-FeOOH} + 2H_2O] : 22,$$
$$\Delta G^0_{298} = -17.29 \text{ kJ mol}^{-1}. \quad (16)$$

Gamma iron metahydroxide is the first and the main crystalline product of iron corrosion in a low-corrosive atmosphere [1]. At a certain humidity, the hydroxides formed by reactions (12)–(15) can interact with each other to yield double iron(III)–iron(II) oxide tetrahydrate:

$$[Fe(OH)_2 + 2Fe(OH)_3 = Fe_3O_4 \cdot 4H_2O] : 19,$$
$$\Delta G^0_{298} = -1.06 \text{ kJ mol}^{-1} \quad (17)$$

or

$$[Fe(OH)_2 + 2\gamma\text{-FeOOH} = Fe_3O_4 + 2H_2O] : 13,$$
$$\Delta G^0_{298} = -6.50 \text{ kJ mol}^{-1}. \quad (18)$$

In turn, double iron(III)–iron(II) oxide tetrahydrate is oxidized by the reaction

$$[2(Fe_3O_4 \cdot 4H_2O) + 1/2O_2 = 6\alpha\text{-FeOOH} + 5H_2O] : 39,$$
$$\Delta G^0_{298} = -8.73 \text{ kJ mol}^{-1}, \quad (19)$$

with α-FeOOH crystallized [1]. α-Metahydroxide can be formed by the reaction:

$$[Fe(OH)_3 = \alpha\text{-FeOOH} + H_2O] : 7,$$
$$\Delta G^0_{298} = -4.67 \text{ kJ mol}^{-1}. \quad (20)$$

Thus, the results of the thermodynamic analysis performed confirm the experimentally established fact [1] that only α-FeOOH and γ-FeOOH are formed on the surface of iron at a certain humidity and sufficient access of oxygen.

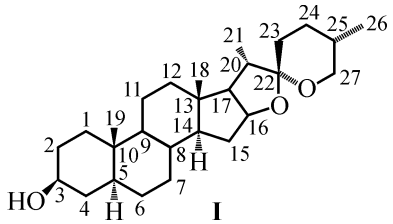
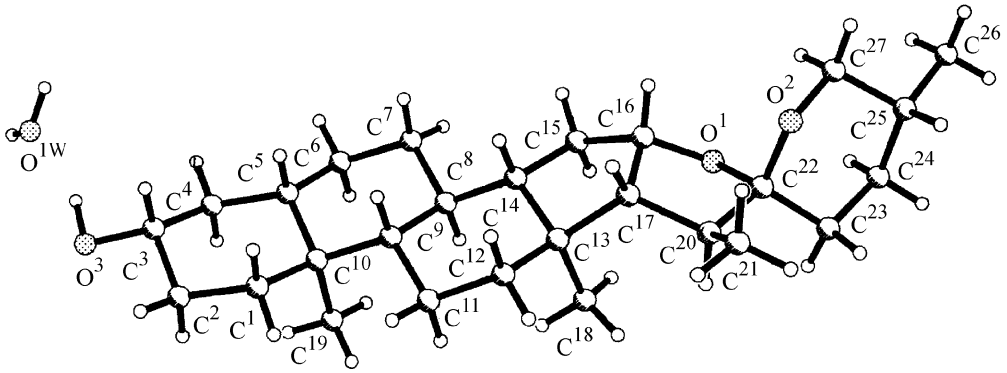
Received April 12, 2006

Abstract—Tigogenin [(25R)-5α-spirostan-3β-ol] was isolated from *Digitalis lanata Ehrh.*, and its crystal and molecular structure was determined by single crystal X-ray diffraction.



DOI: 10.1134/S1070427206080325

Digitalis lanata Ehrh. is one of promising sources of cardenolides [1]; it also contains steroid saponins [2]. Preparations from the *Digitalis lanata Ehrh*. tops are widely used in medicine as cardiotonic agents [3]. Tigogenin [(25R)-5α-spirostan-3β-ol] has been previously found in *Digitalis lanata Ehrh*. [4] and in some other plants [5, 6].



A TLC analysis and acid hydrolysis (5% H_2SO_4 in 1,3-dioxane–water, 1 : 1, 4 h, refluxing) showed that the tops of *Digitalis lanata Ehrh*., collected in the flowering period from the cultivated plants (herb seed growing nursery of the Institute of Phytochemistry, Ministry of Education and Science of the Republic of Kazakhstan, Karaganda), contain both tigogenin and, apparently, its glycosides.

The vegetable raw material was extracted with 70% ethanol; lipophilic components were removed from the extract by treatment with petroleum ether. Then the extract was hydrolyzed as described above. From the hydrolysis products, we isolated (25R)-5α-spirostan-3β-ol by column chromatography on alumina. The product was identified by its melting point and the melting point of its acetate [4].

We found no data on the crystal and molecular structure of **I** in the Cambridge Crystallographic Database [7], and, therefore, we studied its structure by single crystal X-ray diffraction.

The general view of the molecule of **I** is shown in the figure. The bond lengths (Table 1) are common, whereas the bond angles (Table 2) differ from the ideal tetrahedral values [8], varying from 101(4)° ($C^{14}C^{13}C^{17}$) to 121.8(5)° ($C^{20}C^{17}C^{13}$). All the six-membered rings have a slightly distorted chair conformation. For example, for $C^1C^2C^3C^4C^5C^{10}$ ΔC_S^{10} = 1.4° and $\Delta C_2^{1,10}$ = 1.8°; for $C^5C^6C^7C^8C^9C^{10}$ ΔC_S^7 = 2.0° and $\Delta C_2^{7,8}$ = 1.6°; for $C^8C^9C^{11}C^{12}C^{13}C^{14}$ ΔC_S^{14} = 0.9° and $\Delta C_2^{13,14}$ = 2.3°; for $O^2C^{22}C^{23}C^{24}C^{25}C^{27}$ ΔC_S^{24} = 3.7° and $\Delta C_2^{2,27}$ = 0.5°.

The heteroring $O^1C^{16}C^{17}C^{20}C^{22}$ has a conformation intermediate between a distorted envelope (with out-of-plane O^1 atom) and a distorted 1,22-half-chair (ΔC_S^1 = 8.3° and $\Delta C_2^{1,22}$ = 10.5°); the conformation of the five-membered ring $C^{13}C^{14}C^{15}C^{16}C^{17}$ is also intermediate between a distorted envelope (with out-of-plane C^{14} atom) and a distorted 13,14-half-chair (ΔC_S^{14} = 11.9° and $\Delta C_2^{13,14}$ = 8.3°). The methyl groups at C^{20} and C^{25} and the hydroxy group at C^3 are equatorial, whereas the methyl groups at C^{10} and C^{13} are axial.

The molecules in the crystal are linked in infinite ribbons oriented along the crystallographic axis $2_1(0, y, 0)$ by hydrogen bonds O^3–H $(x, y, z)\cdots O^{1W}$ (x, y, z) (∠OHO 160.98°; distances O^3–H = 0.98, $O^3\cdots O^1$ = 2.71, $H\cdots O^{1W}$ = 1.77 Å), O^{1W}–H^{1W} $(x, y, z)\cdots O^{2*}$ $(-2 - x, y - 0.5, -z)$ (∠OHO 163.02°; distances O^1–H^1 = 0.87, $O^1\cdots O^2$ = 2.89, $H\cdots O^2$ = 2.05 Å), and O^{1W}–H^{2W} $(x, y, z)\cdots O^{3**}$ $(-2 - x, y - 0.5, 1 - z)$ (∠OHO 175.04°; distances O^1–H^2 = 0.81, $O^3\cdots O^1$ = 2.79, $H\cdots O^3$ = 1.99 Å).

EXPERIMENTAL

The unit cell parameters and intensities of 2391 unique reflections were measured with a Bruker P4 diffractometer (Mo_{K_α} radiation, graphite monochromator, θ/2θ scanning, 2θ < 50°). The crystals are monoclinic; a = 10.282(7), b = 7.374(5), c = 16.637(11) Å, β = 94.72(5)°, V = 1257.1(1) Å^3, Z = 2 ($C_{27}H_{44}O_4$), d_{calc} = 1.143 g cm^{-3}, space group $P2_1$.

The structure was solved by the direct method and refined by the full-matrix least-squares method in the anisotropic approximation for all nonhydrogen atoms. The hydrogen atoms of water of hydration and hydroxy group were revealed by differential synthesis and refined in the isotropic approximation; the positions of the other H atoms were calculated geometrically and fixed in the rider model. In the calculations, we used 1467 reflections with $I > 2\sigma(\mathbf{I})$.

The final divergence factors are as follows: R = 0.0615, ${}_WR_2$ = 0.1513. The structure was solved and refined using SHELXS-97 and SHELXL-97 software. The atomic coordinates are listed in Table 3.

(25R)-5α-Spirostan-3β-ol. The air-dry raw material (1 kg) of *Digitalis lanata* tops was extracted with 8 l of 96% ethanol. The extraction was performed four times. The extracts were combined and evaporated to dryness on a rotary evaporator at 45–50°C. A thick extract was obtained (490 g). The extract was dissolved in 1 l of a 2 : 1 water–ethanol mixture and treated with petroleum ether (6 × 500 ml) to remove nonpolar components. The water-soluble components were removed by extraction of the aqueous-alcoholic phase with isobutanol (5 × 500 ml). The isobutanol extract was evaporated to dryness, and residual isobutanol was removed by repeated dissolution of the residue in 96% ethanol, followed by vacuum evaporation of the solvent; the extract was dried in a water-jet-pump vacuum. A fraction (153.5 g) containing steroid glycosides was obtained. The isobutanol fraction was dissolved in 600 ml of a 1 : 1 1,3-dioxane–water mixture containing 5 wt % H_2SO_4; the solution was heated on a water bath at 95°C for 4 h. After that, the solution was diluted with 300 ml of a saturated aqueous NaCl solution, neutralized with 10% Na_2CO_3 to pH 7, and extracted with five 500-ml portions of isobutanol. The combined isobutanol extracts were washed with 300 ml of a saturated aqueous NaCl solution and vacuum-evaporated to dryness. The residue (87 g) was chromatographed on a column packed with 1.5 kg of alumina (Brockmann grade II, weight ratio of the sum of the components to the sorbent 1 : 17.5), using chloroform as eluent. White crystals of (25R)-5α-spirostan-3β-ol **I** were obtained; mp 209–211°C (ethanol), yield 0.52% based on the air-dry raw material. IR spectrum, KBr, ν_{max}, cm^{-1}: 900 (C–O in spirostanol system), 1050 (C–OH), 1620 (C=C), 2950 (CH), 3300–3500 (OH).

Abstract—Cationic polymerization of redox monomers derived from monoethanolamine vinyl ether and various chlorinated quinones in aqueous–organic solutions in the presence of HCl was studied. Optimal reaction conditions were found, and the kinetic characteristics of the reactions were calculated.

DOI: 10.1134/S1070427206080337

The new redox monomers prepared from monoethanolamine vinyl ether (MEAVE) and chlorinated quinones (chloranil, CA; 2,3-dichloro-1,4-naphthoquinone, DCNPQ; 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, DCDCQ) [1] can be classed with substituted vinyl ethers (VEs) CH_2=CHOR, namely, with ethanolamine VEs. It is known [2] that the polymerization activity of VEs depends on the structure of the organic residue. For example, aliphatic VEs polymerize considerably more readily than vinyl aryl ethers. Also, introduction of a halogen substituent into the monomer molecule enhances its activity in polymerization [2]. Furthermore, chlorine substituents significantly alter the properties of a polymer, especially its solubility and softening point, which are higher compared to the unsubstituted analog.

Vinyl alkyl ethers polymerize most readily under the action of ionic, in particular, acid catalysts [2]. It has been shown [3, 4] that radical homopolymerization of vinyl ethers occurs considerably more difficultly than the cationic polymerization. Therefore, it is interesting to study how the chemical structure of redox monomers affects their reactivity in cationic polymerization.

In this study, we examined the features of cationic polymerization of redox monomers in the DMF–water mixture in the presence of HCl.

EXPERIMENTAL

Redox monomers derived from MEAVE and chloranil (disubstituted derivative MEAVE–CA–MEAVE), MEAVE and 2,3-dichloro-1,4-naphthoquinone (MEAVE–DCNPQ), and MEAVE and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (MEAVE–DCDCQ) were prepared as described in [1].

The polymerization of the redox monomers was performed at 7–27°C for 2–7 h in DMF–water mixtures, volume ratio from 4 : 0 to 1 : 3, in the presence of HCl (0.07–0.61 M). The reaction progress was monitored by polarographic measurement of the concentration of the unchanged monomer and by gravimetric determination of the precipitated polymer.

The polarograms were recorded on a PU-1 polarograph in a temperature-controlled cell at 25 ± 0.5°C, using a mercury dropping electrode with the open-circuit capillary characteristic $m^{2/3}t^{1/2}$ = 4.38 $mg^{2/3}$ $s^{-1/2}$; the supporting electrolyte was a phosphate buffer solution (pH 7.4) in 25% DMF. Saturated calomel electrode was a reference electrode. The solutions were deoxygenated by bubbling of argon for 5 min.

Ethanolamine vinyl ethers are considerably less active than vinyl alkyl ethers in reactions occurring by the ionic mechanism [5], because of the pres-

Table 1. Optimal conditions of cationic polymerization of redox monomers

Monomer	DMF : H_2O (by volume)	$c_{monomer}$, g l^{-1}	c_{HCl}, M	T, °C	τ, h	Polymer yield, %
MEAVE–CA–MEAVE	1 : 2	20	0.11	21	2	96
MEAVE–DCNPQ	1 : 3	35	0.11	21	5	94
MEAVE–DCDCQ	1 : 2	25	0.29	21	5	83

ence of double bonds and two centers (O, N) capable of forming onium compounds. As indicated in [6], the relative activity increases with the enhancement of the electron-donor power of substituents. We found that, despite the fact that the quinones themselves [7] and their functional groups –C≡N, –Cl are strong electron acceptors, the redox monomers show capacity for cationic polymerization. The reaction was performed in DMF–water mixtures in the presence of HCl. We examined the influence of the water content, concentrations of the monomers and HCl (catalyst), and reaction temperature and time on the yield of the polymers (Fig. 1).

Figure 1 shows that these factors affect the cationic polymerization of MEAVE–CA–MEAVE, MEAVE–DCNPQ, and MEAVE–DCDCQ differently, with the last monomer showing a distinctive behavior. Its polymerization requires a higher HCl concentration. Table 1 shows the optimal conditions of the polymer synthesis by cationic polymerization, found from the experimental data.

Table 1 shows that MEAVE–DCDCQ is less reactive than the other redox monomers. To obtain more detailed quantitative data on their activity under optimal conditions, we studied the kinetics of the cationic polymerization of MEAVE–CA–MEAVE, MEAVE–DCNPQ, and MEAVE–DCDCQ.

To calculate the rate constants of the overall polymerization process, we determined the reaction order. We found that the cationic polymerization of the redox monomers is a first-order reaction with respect to the monomer, as indicated by the linear dependence of the logarithm of its concentration on the synthesis time. The rate constants of the cationic polymerization of the redox monomers, calculated from the first-

T_{synth}, °C	Monomer	$k \times 10^3$, min^{-1}	E_a, kJ mol^{-1}	Monomer	$k \times 10^3$, min^{-1}	E_a, kJ mol^{-1}	Monomer	$k \times 10^3$, min^{-1}	E_a, kJ mol^{-1}
7	MEAVE–CA–	12.40	14.42	MEAVE–	2.72	63.32	MEAVE–	2.63	63.75
14	MEAVE	14.30		DCNPQ	5.20		DCDCQ	5.25	
21		16.80			10.68			11.35	

Table 3. Physicochemical characteristics of the chlorinated polymers synthesized

Monomer	η, dl g^{-1} (DMF, 25°C)	T_m, °C	SEC_{HCl}	RC	E_0, V
			mg-equiv g^{-1}		
MEAVE–CA–MEAVE	0.18–0.20	190	2.12	5.32	0.58
MEAVE–DCNPQ	0.10–0.12	172	2.60	5.88	0.39
MEAVE–DCDCQ	0.16–0.18	145	2.42	4.86	0.40

order rate equation [8], and the activation energies of the process, estimated from the Arrhenius dependence (Fig. 2b), are listed in Table 2.

Table 2 shows that all the redox monomers are active in the cationic polymerization. The most reactive is the disubstituted derivative of MEAVE and CA. With respect to the reactivity in the cationic polymerization, the monomers are ranked in the following order: MEAVE–CA–MEAVE > MEAVE–DCNPQ > MEAVE–DCDCQ.

The structure of the monomers affects not only their reactivity, but also the properties of the resulting polymers. Some physicochemical properties of the polymers prepared are given in Table 3.

The polymers are colored powders readily soluble in polar solvents. The low intrinsic viscosity is apparently due to the formation of oligomers, which is typical of vinyl ethers [4, 6]. Thanks to the relatively high redox capacity (RC), these polymers can find application in hydrometallurgy and other branches of industry as redox resins with complexing properties.

CONCLUSIONS

(1) Optimal conditions were found for the cationic polymerization of redox monomers derived from monoethanolamine vinyl ether and various chlorinated quinones in an aqueous–organic solution in the presence of HCl.

(2) The reaction kinetics was studied, and the rate constants and activation energies were determined. The disubstituted chloranil derivative is the most reactive.

Abstract—Mechanisms of orientation for the solutions of polyacrylonitrile synthesized under conditions of radical and anionic polymerization were studied. The effect of the fractal-matrix structuring agent developed by the AIRES foundation on the correlation parameters of the solution density and average squared fluctuation polarizability, which can be used to determine how the supramolecular structure changes by "self-orientation" and "induced orientation" mechanisms, was analyzed.

DOI: 10.1134/S1070427206080349

Polyacrylonitrile (PAN) is one of the most important and widely industrially used polymers. It serves to obtain various polymeric materials with unique properties (thermal stability, strength, electrical conductivity, hydrophilicity, etc.). This is determined by specific structural features of the PAN molecule, whose quantitative and qualitative parameters depend on preparation techniques and methods of its modification [1, 2]. Various methods of acrylonitrile polymerization can be used to obtain polymers with predominance of 3*D* structures of atactic, isotactic, and syndiotactic types [3–5]. Stereoisomers of this kind possess various properties and differently behave in forming and under thermal treatment. The "wet" method is for the most part used in the industry to form PAN fibers, and, therefore, the spatial orientation of polymer chains of PAN in solution is important. As a rule, spinning solutions of PAN are oriented by mechanical treatment in fiber forming on a technological line.

The aim of this study was to orient PAN solutions of varied genesis with a fractal-matrix structuring agent (FMSA) developed by AIRES foundation. Previous studies have shown that FMSA exerts an orienting influence on the spatial organization of certain inorganic compounds in the liquid state [6–8]. A noticeable influence of the structure on the crystallization and polymorphism of the compounds studied has been revealed for the examples of water and metal salts and alloys.

EXPERIMENTAL

As starting objects served solutions of PAN in dimethylformamide (DMFA), produced by radical (R-PAN) and anionic (A-PAN) polymerization [9], with the solution concentration equal to 0.5%. The light-scattering method [10] was used to examine during 14 days the variation of the parameters $\overline{\eta}^2$ (average square of polarizability fluctuations) and α_v (correlation dimensions of the solution density at a given point). Two cuvettes were subjected to the action of FMSA, and two others served as controls.

The processes under study were affected with FMSA having the form of a complex curvilinear diffraction grating whose image was transferred by precision optical lithography onto optically polished glass substrates. A diffraction grating of this kind has a fractal-matrix topology in the form of a fractally assembled matrix comprising a set of self-similar units, each of which is a graphical image of a planar cross-section of a multilevel spatial geometric structure.

Figures 1a and 1b shows the experimentally found dependences of α_v and $\overline{\eta}^2$ on the time of keeping on FMSA and without it. It can be seen that, immediately after solution preparation, the system is microisotropic, with the value of $\overline{\eta}^2$ for R-PAN solutions exceeding that for A-PAN. This indicates that the R-PAN solution contains particles with larger heterogeneity dimensions, i.e., the R-PAN solution is more heterogeneous than the A-PAN solution. Hence follows

a conclusion that the supramolecular organizations of PAN solutions produced by radical and anionic polymerization are different. It is known [11] that R-PAN is characterize by larger molecular weight, broader molecular weight distribution, and a more pronounced branching, compared with A-PAN, and, therefore, it is these factors that lead to a higher heterogeneity of R-PAN solutions.

Further variation of the optical parameters of R-PAN and A-PAN solutions with the time of keeping at room temperature reflects the effect of FMSA on the supramolecular organization of PAN macromolecules in solution. A study of this effect demonstrated that the parameters $\overline{\eta}^2$ and α_v change with time, compared with the control experiments. It is well seen that the influence is exerted not only by the FMSA, but also by methods used to synthesize PAN. For example, the supramolecular structure remains unchanged during 14 days ($\overline{\eta}^2$ and α_v remain constant). During the same time, an R-PAN solution subjected to the action of FMS becomes more heterogeneous ($\overline{\eta}^2$ grows), whereas the heterogeneity dimensions (α_v) remain virtually unchanged and the solution structure remains isotropic.

In contrast to R-PAN, the control solution of A-PAN spontaneously changes its structure in the course of time. It becomes more heterogeneous and the heterogeneity dimensions decrease (α_v value falls), i.e., the supramolecular formations present in the initial solution become denser and more compact. This behavior of A-PAN solutions is in an agreement with (i) data on the stereoblock structure of A-PAN, which predetermines the high packing density, and (ii) with the formation, in solution, of associates having the form of a double helix via interaction of two nitrile groups of adjacent A-PAN chains and CN groups with α-atoms of hydrogen [12]. After the end of the testing period (14 days), measurements of the asymmetry of anisotropic light scattering by the control A-PAN solution demonstrate that the solution becomes anisotropic (α_n = 335 Å, $\delta^2 \times 10^9$ = 78). An additional specificity of the behavior of the control A-PAN solution is that the time dependence of $\overline{\eta}^2$ changes and becomes similar to that of an R-PAN solution subjected to the action of FMSA.

Thus, a kind of similarity between the temporal "self-organization" of A-PAN and the organizing effect of FMSA for the R-PAN solution is observed. The effect of FMSA on the A-PAN solution, judged from changes in $\overline{\eta}^2$ and α_v relative to that of the control sample, is less pronounced than that for the R-PAN solution. Probably, two competing tendencies associated with its orientation exist for the A-PAN solution. These are the self-organization well seen for the control sample and the organization "induced" by FMSA, for which large values of the anisotropic parameters are observed (α_n = 390 Å, $\delta^2 \times 10^9$ = 82). It can be assumed that the mechanism of orientation of the A-PAN solution under the action of FMSA differs from the mechanism of self-organization. However, the available experimental data are insufficient for a hypothetical substantiation of this difference.

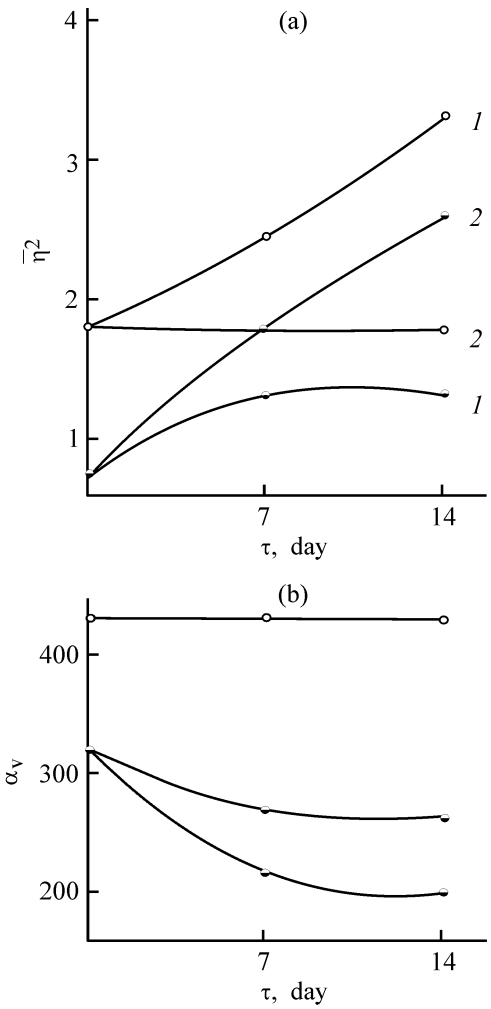

Fig. 1. (a) Average square of the polarizability, $\overline{\eta}^2$, and (b) α_v of R-PAN and A-PAN solutions vs. (*1*) time τ of keeping on FMSA. (*2*) Control run.

CONCLUSIONS

(1) A study by the light scattering method of the effects of organization of polyacrylonitrile solutions in relation to the keeping time, methods of polymer preparation, and action of the fractal-matrix structuring agent developed by the AIRES founda-

tion demonstrated that the polyacrylonitrile solutions produced by radical polymerization change their structure only under the action of the structuring agent to become more heterogeneous in the course of time, but their structure remains isotropic.

(2) Solutions of polyacrylonitrile produced by the anionic method undergo self-orientation in the course of time and their structural parameters change under the action of the structuring agent. Prolonged treatment with the structuring agent gives rise to anisotropic structures.

Abstract—Kinetic parameters of the reaction of polyisobutylene modification with acrylonitrile and vinyl acetate were calculated. The reaction rate constants were obtained for three temperatures, and the activation energies and the preexponential factor were determined for modification of polyisobutylene with acrylonitrile and vinyl acetate. The effect of the $AlCl_3$ concentration on the kinetic parameters of the reaction of polyisobutylene modification was studied.

DOI: 10.1134/S1070427206080350

The development of methods for modification of polyisobutylene (PIB) with polar monomers in the presence of Lewis acids opens up wide opportunities for control over its properties, which extends the synthetic capacity of polymer chemistry.

Polymers of isobutylene are large-tonnage products that find wide use in various areas of industry and technology. Polyisobutylene belongs to the class of saturated polyolefins, which determines their comparatively high stability against corrosive media (acids, alkalis).

It is a common knowledge that Lewis acids (Friedel–Krafts catalysts) are used in organic chemistry and carbocation polymerization of olefins and dienes as catalysts of electrophilic reactions. It has been found, however, that, under mild conditions (20–60°C), strong Lewis acids ($AlCl_3$, $AlEtCl_2$) cause activation of polyisobutylene and butyl caoutchouc by the free-radical mechanism [1–4]. EPR spectroscopy and quantum-chemical calculations confirmed that paramagnetic centers are formed in catalytic destruction of PIB [2, 3].

As evidence in favor of the radical-chain mechanism of destruction served results of calorimetric and ^{13}C NMR studies of samples of destructed PIB [5, 6], which demonstrated that polyolefins (?PIB) with branched structure are formed. The data obtained were used to develop a method for synthesis of isobutylene copolymers with polar monomers, acrylonitrile (AN) and vinyl acetate (VA) [7]. Therefore, construction of a kinetic model of PIB modification with AN and VA on the basis of the data obtained and calculation of the kinetic parameters of these processes seem to be necessary for solving the problem of development of a polymeric material on their basis.

The paper reports the results of kinetic studies of the reaction of PIB modification with polar monomers AN and VA in *n*-hexane in the presence of the acid $AlCl_3$ (Tables 1, 2).

The reaction rate is described by the equation

$$-\frac{\mathrm{d}([\mathrm{AN}]_0 - [\mathrm{AN}]_c)}{\mathrm{d}t} = k([\mathrm{AN}]_0 - [\mathrm{AN}]_c)([\mathrm{PIB}]_0 - [\mathrm{PIB}]_c), \quad (1)$$

which gives, with account of the initial conditions, the following equation for the rate constant of the reaction of PIB modification with acrylonitrile:

$$k = \frac{1}{t}\,\frac{1}{[\mathrm{AN}]_0 - [\mathrm{PIB}]_0}\ln\frac{[\mathrm{PIB}]_0([\mathrm{AN}]_0 - [\mathrm{AN}]_c)}{[\mathrm{AN}]_0([\mathrm{PIB}]_0 - [\mathrm{AN}]_c)}. \quad (2)$$

Here, $[AN]_0$ and $[PIB]_0$ are the initial concentrations of AN and PIB in the reaction mixture (g g^{-1}); $[AN]_c$ and $[PIB]_c$, concentrations of AN and PIB in the copolymer (g g^{-1}); and t, time (h).

Equations similar to (1) and (2) were also derived for the reaction of PIB modification with vinyl acetate. In this case, $[VA]_0$ and $[VA]_c$ are substituted for $[AN]_0$ and $[AN]_c$ in Eqs. (1), (2).

Table 1. Experimental kinetic data for the reaction of PIB modification with acrylonitrile and vinyl acetate {reaction with AN: amount of the solvent (hexane) 77.91 ($AlCl_3$ 1.8%) and 78.88 wt % ($AlCl_3$ 0.92%), $[PIB]_0$ = 6.12% and $[AN]_0$ = 14%; Reaction with VA: amount of the solvent (hexane) 80.77 ($AlCl_3$ 2.23%) and 81.93 wt % ($AlCl_3$ 0.76%), $[PIB]_0$ = 8% and $[VA]_0$ = 9%; the same for Table 2}

The data in Table 1 were used to determine the reaction rate constants, activation energies E, and pre-exponential factors A for various concentrations of $AlCl_3$, and AN and VA monomers (Table 2). The activation energies E and pre-exponential factors A were determined using the Arrhenius equation.

Thus, it was found that, irrespective of the reaction stage, the rate constant remains constant within the experimental error of 1–6%. An increase in the catalyst content from 0.76 to 2.2 wt % results in that, at temperatures of 20, 40, and 60°C, the rate constants increase by factors of 2.59, 2.53, and 2.49, respectively, in the case of the reaction with AN and by factors of 1.9, 2.0, and 2.2 for the reaction with VA.

CONCLUSIONS

It was found that the activation energies of the reactions of polyisobutylene modification with acrylonitrile in the temperature range 20–60°C have the values E = 3760 (amount of the catalyst 0.92 wt %) and 3000 J mol^{-1} (amount of the catalyst 1.8%), and those in modification with vinyl acetate, E = 4190 (amount of the catalyst 2.23%) and 5206 J mol^{-1} (amount of the catalyst 0.76%) in the same temperature range.

Abstract—A procedure was developed for preparing 4-cyanofluoren-9-one by intramolecular cyclization of 9,10-phenanthrenequinone monooxime benzenesulfonate.

DOI: 10.1134/S1070427206080362

Fluorenones, mainly 2- and 4-substituted, are widely used in electrophotography [1] and as drugs [2]. In particular, Grintsev et al. studied a series of fluorenones [3] and synthesized a novel antiviral agent, Florenal [4]. It is widely used in medical practice against herpesis and adenoviruses. However, the lack of facile routes to 4-substituted fluorenones hinders the development of this novel group of antiviral agents.

Fluorenones are usually prepared from 2-arylbenzoic acids by the Friedel–Crafts reaction or its modifications [1]. Even 2'-cyanodiphenyl-2-carboxylic acid in thionyl chloride forms, along with the corresponding acid chloride, also 4-cyanofluoren-9-one [2]. Experiments on the Beckmann rearrangement of the second kind of 9,10-phenanthrenequinone monooxime **1** have shown that suspensions of this compound in ether under the action of PCl_5 give 4-cyanofluoren-9-one **3** in a low yield [3]. Proceeding with studies of *o*-quinone monooxime sulfonates, we found that 9,10-phenanthrenequinone monooxime benzenesulfonate **2**, when melted (~215°C) or crystallized from ethyl acetate, forms traces of a new substance with mp 238–240°C (dec.), whose mass spectrum was consistent with the structure of 4-cyanofluoren-9-one. Prolonged refluxing of **2** in ethyl acetate or (which is better) in butyl acetate always gives fluorenone **3** in a good yield:

1 **2** **3**

An attempt to perform the reaction with 9,10-phenanthrenequinone monooxime propionate or benzoate resulted in the recyclization.

EXPERIMENTAL

The purity of the compounds was checked by TLC on Silufol UV-254 plates, solvent system tetrachloromethane–ethyl acetate, 3 : 1; the spots were developed with iodine vapor. The mass spectra were recorded on MAT-1303 and MAT-212 devices (Varian-MAT) at ionizing electron energies of 50 and 70 eV, respectively, with direct sample input. The elemental composition of the major ions was determined with an MAE-212 device at high resolution ($M/\Delta M$ = 10000).

9,10-Phenanthrenequinone monooxime 1 was prepared by the procedure described in [4]; mp 157°C. Mass spectrum, *m/z* (*I*, %): 223 (96), 207 (20), 206

(100), 179 (11), 178 (34), 177 (15), 166 (7), 165 (40), 164 (149), 163 (20), 151 (18).

9,10-Phenanthrenequinone monooxime benzenesulfonate 2. To a solution of 22.3 g (0.1 mol) of **1** and 17.66 g (0.1 mol) of benzenesulfonyl chloride in 50 ml of acetone was added, with cooling to 0–5°C, a solution of 4.8 g (0.12 mol) of NaOH in 50 ml of water. The mixture was stirred for 10 min and then diluted with 50 ml of cold water. The precipitate was separated by vacuum filtration, washed with ice-cold water, and dried at room temperature. Yield 21 g (78%); yellow-orange compound, mp 140–141°C (from methyl ethyl ketone); R_f = 0.58.

Found (%): C 66.27, H 3.41, N 3.92, S 8.54.
$C_{20}H_{13}NO_4S$.
Calculated (%): C 66.11, H 3.58, N 3.85, S 8.81.

Mass spectrum, *m*/*z* (*I*, %): 363 (6) M, 299 (4) (M – SO_2), 222 (7) (M – $PhSO_2$), 206 (100) (M – $PhSO_3$), 179 (11) (M – $PhSO_3$ – HCN), 178 (24) (M – $PhSO_3$ – CO), 177 (21), 163 (6), 151 (20), 141 (9), 77 (43).

9,10-Phenanthrenequinone monooxime propionate was prepared similarly to **2** from 4.46 g (0.02 mol) of **1** in 40 ml of acetone, 2.8 g (0.03 mol) of propionyl chloride, and 1.6 g (0.04 mol) of NaOH in 10 ml of water. Yield 4.45 g (80%), mp 109.5–110°C (acetonitrile), R_f = 0.46.

Found (%): C 73.40, H 4.65, N 4.86.
$C_{17}H_{13}NO_3$.
Calculated (%): C 73.11, H 4.69, N 5.02.

9,10-Phenanthrenequinone monooxime benzoate was prepared similarly to **2** from **1** and benzoyl chloride; yield 60%, mp 172–174°C (butanone), R_f = 0.70.

Found (%): N 4.32.
$C_{21}H_{13}NO_3$.
Calculated (%): N 4.28.

4-Cyanofluoren-9-one 3. A mixture of 3.63 g (0.01 mol) of **2** and 30 ml of anhydrous butyl acetate was refluxed on an oil bath at 100°C for 6 h until sulfonate **2** was completely consumed (chromatographic monitoring). The solvent was distilled off by half, the mixture was cooled, and the precipitate was separated by vacuum filtration and crystallized from benzene. Yield 1.23 g (60%), mp 238–240°C (published data: mp 240°C [1]), R_f = 0.43. Mass spectrum, *m*/*z* (*I*, %): 205 (100) M, 177 (57) (M – CO), 176 (8), 175 (5), 150 (17) (M – CO – HCN), 149 (5), 127 (4), 124 (3), 89 (10), 75 (16), 74 (9).

BRIEF COMMUNICATIONS

Asphalt Adsorption in Relation to the Surface Area of the Mineral Filler and Content of Aromatic Oils

N. V. Maidanova and D. A. Rozental'

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received April 24, 2006

Abstract—The composition and properties of asphalts were examined in relation to the time of keeping at 160°C of asphalt–granite and asphalt–gabbro-diorite blends. The time of filling of the filler surface with the adsorbed asphalt components was established. A criterion was suggested for estimating the properties of asphalt during preparation and pouring of asphalt concrete.

DOI: 10.1134/S1070427206080374

We have shown previously [1, 2] that oil asphalts are instable dispersion systems whose properties are modified by both storage and contact with mineral fillers. The reason is that the overall process of asphalt oxidation consists in that molecules of oils, which cannot form a solid phase under the oxidation conditions, are used to produce molecules of asphaltenes, which can form solid particles via association. The rate of formation of the asphaltene molecules significantly exceeds that of their association into supramolecular structures. As a result, the products yielded in arbitrarily terminated asphalt oxidation contain a certain amount of unassociated asphaltene molecules that tend to form a solid phase. This process also occurs at low temperatures, though at a lower rate, which modifies the asphalt structure. Hence, after storage for a certain period even at room temperature, the commercial characteristics of asphalt correspond to those of a more rigid brand.

When asphalt comes in contact with mineral fillers, especially at elevated temperatures, its liquid components are selectively adsorbed on the surface of the mineral material. This leads to a decrease in the amount of the dispersion medium in the nonadsorbed asphalt, thereby increasing its rigidity. The commercial characteristics of asphalts vary with the amount of their components adsorbed. Determination of the amount of the adsorbed asphalt is a labor-consuming and arbitrary process; it is more convenient to monitor its outcome from the change in such commercial characteristics of asphalts as penetration P_{25} and softening point T_s.

Evidently, adsorption is limited by two factors, the surface area and activity of the adsorbent and the amount of the asphalt components that can be adsorbed by this material (sorbent). The sorption capacities of granite (G) and gabbro-diorite (GD) (typical fillers for asphalt concrete) were examined in experiments with an 80 : 20 (wt %) blend of these fillers (2–3-mm granules) with BDUS 70/100 asphalt (after 6-month storage in a hermetically sealed flask, the penetration P_{25} was 41 dmm, and the softening point T_s, 60°C). Such an excess of asphalt should afford the necessary amount of sorbable components. Table 1 summarizes the results of our experiments.

Our results suggest that the adsorption equilibrium was established after a 2-h keeping. In this case, the limiting factor was the surface area of the ma-

terials examined. To validate this conclusion, granite was transferred onto a screen after a 2-h keeping and, after excess asphalt completely drained off at 160°C, was once again placed in the reaction vessel, and a fresh portion of asphalt was added.

The asphalt isolated after a repeated 2-h keeping had the same quality characteristics as those before pouring into the reaction vessel.

Similar data were obtained for other asphalts (Table 2). Tables 1 and 2 show that the quality characteristics of asphalts were modified most profoundly after 2-h keeping at 160°C. To identify the asphalt components responsible for a such modification, the component composition of the initial asphalt was analyzed, as well as that of the asphalt after keeping for 2 and 5 h at 160°C with fillers. The results are summarized in Table 3. It is seen that the only component whose amount decreases is that constituted by aromatic oils. Hence, specifically this component is responsible for the adhesion between the asphalt and mineral materials.

CONCLUSIONS

(1) There exists an adsorption limit for asphalt–mineral filler system, which is determined by the specific surface area of the filler.

(2) Aromatic oils are the asphalt component responsible for its adsorption on mineral fillers.

(3) The change in the commercial characteristics of asphalt brought in contact with the mineral filler at elevated temperatures can be regarded as a criterion of modification of the properties of asphalt during preparation and pouring of asphalt concretes.

ANNIVERSARIES

Professor Dmitrii Aleksandrovich Rozental' (To His 80th Birthday)

DOI: 10.1134/S1070427206080386

Dmitrii Aleksandrovich Rozental' was born on August 9, 1926, in Novosibirsk into the family of office workers. In 1933, Rozental's father was transferred to work in Leningrad as a senior hydrographer at Glavsevmorput' (Central Administration of the Northern Sea Route). The family moved to Leningrad. Rozental's mother became a senior comptroller at Lenkombank (Leningrad Commercial Bank).

Rozental's father was subjected to repressions in 1937 and died in 1941. He was rehabilitated in 1958.

In 1941, Dmitrii Aleksandrovich finished the seventh grade of secondary school. In April 1942, he was evacuated, together with his mother, to Tatarstan. In November 1943 he was enlisted in the Soviet army and served in air defense of the Far-Eastern front. In 1949, he finished tenth grade at the regional extramural secondary school in Ussuriisk.

After demobilization of 1950–1951, Dmitrii Aleksandrovich worked as collector at Leningrad Geological Prospecting Institute. Rozental' entered Lensovet Technological Institute in Leningrad in 1951, successfully graduated from the institute in 1956, and was recommended for postgraduate education. In 1960, he defended his candidate dissertation (technical sciences). He defended his doctoral dissertation in 1972 and became a professor in 1975. Dmitrii Aleksandrovich combines his pedagogical activities with research work. Rozental' has been given the rank of Honorary petrochemist of the USSR, he is a leading scientist in the field of structure and properties of heavy oil residues.

He has the badge of a resident of the besieged Leningrad.

During the forty-five years of his scientific activities, he has introduced new fundamental concepts concerning the oxidation and aging of bitumens, formation of asphaltenes, and their molecular and supramolecular structure. He elucidated the role of the adsorption factor in manufacture of asphalt concrete. Rozental' is the author of numerous formulations and technological procedures for production of polymer–bitumen formulations with a wide application area.

The results of Rozental's pedagogical and research activities are reflected in 280 publications and 34 inventor's certificates and patents. Thirty-two postgraduate students and applicants have defended their candidate dissertations under his supervision, he was a scientific consultant of an applicant who successfully defended his doctoral dissertation. Professor Rozental' has been cooperating with the editorial office of *Zhurnal Prikladnoi Khimii* (*Russian Journal of Applied Chemistry*) and has been refereeing and publishing articles devoted to bitumens and chemistry of high-molecular-weight compounds.

Rozental' was deputy head of the chair of technology of petrochemical and coal-chemical industries diring 20 years and headed the chair in 1990–1991.

Professor Rozental' has been decorated with government awards for his services as a soldier and pedagogue.

Dmitrii Aleksandrovich is a very well-wishing and responsive person, true friend, and patriot. Numerous generations of students, post-graduates, teachers, and research workers are thankful to him for help and support.

Staff members of the chair of technology of petrochemical and coal-chemical industries, St. Petersburg State Technological Institute

Editorial board staff members of the Editorial office of Zhurnal Prikladnoi Khimii

BOOK REVIEWS

B. V. L'vov, *Termorazlozhenie tverdykh i zhidkih veshchestv* (Thermal Decomposition of Solid and Liquid Substances),

St. Petersburg: Politekhn. Univ., 2006, 278 pp.

DOI: 10.1134/S1070427206080398

Thermal decomposition of solid and liquid substances is a process that underlies most of natural phenomena and industrial technologies. Active studies of decomposition processes and attempts to explain their mechanism and kinetics were commenced in the second half of the XIX century and were continued in the subsequent years. The certain success achieved in understanding of thermal decomposition phenomena is associated with works of J. Van't-Hoff (1852–1911), S. Arrhenius (1859–1927), H. Hertz (1857–1894), I. Langmuir (1881–1957), and other prominent chemists and physicists.

The interesting monograph brought to readers' notice, written by B.V. L'vov (Polytechnic University, St. Petersburg), a known specialist in atomic-absorption spectroscopy, presents the results of many years' studies of the mechanism and kinetics of thermal decomposition of solid and liquid substances belonging to a wide variety of classes of compounds (crystal hydrates, oxides, hydroxides, nitrides, azides, nitrates, carbonates, sulfates). In the framework of the original approach based on a thermochemical analysis of the processes under study, developed by the author of the monograph, reliable kinetic characteristics have been obtained and the mechanism of reactions of thermal decomposition of the substances studied have been interpreted.

The book comprises a preface, list of abbreviations, introduction, fifteen chapters grouped into three parts, conclusion, and supplement. Bibliographic lists are given at the end of each chapter. The monograph has a subject index. The brief preface (pp. 7 and 8) notes that the monograph presents a new approach to the mechanism of decomposition reactions, their kinetics, and methodology of their examination. The approach is based on a thermochemical analysis of the process. This approach has been formed during the last 25 years on the basis of author's studies, with methods of electrothermal atomic-absorption spectroscopy, mass spectrometry, and thermal analysis. The results of L'vov's studies have been for the most part published in foreign journals (principally in Thermochimica Acta). Generalization and analysis of these studies within a single monograph should be considered rather useful and timely. The list of the accepted designations and abbreviations, given (pp. 9–11) after the preface, facilitates the reading of the monograph.

The introduction (pp. 12–22) specifies the main areas of industrial application of the results obtained in studies of the mechanism and kinetics of thermal decomposition of solid and liquid substances, describes the historical aspect of the development of research in this field, and briefly describes the purpose of the monograph and objectives of each of its parts.

The first part of the book (pp. 23–79) comprises three chapters describing the starting physicochemical concepts: mechanism, kinetics, and methodology, which are used in further presentation to interpret the specific features and fundamental aspects of the processes studied. The author proceeds from the concept that the decomposition of substances occurs in all cases by the common mechanism described by the scheme of congruent dissociative evaporation, which, in the case of formation of hardly volatile substances, includes an additional stage of their condensation. In addition to this fundamental concept, two assumptions are made. According to the first of these, primary decomposition products may differ from their equilibrium forms. According to the second assumption, the energy released in condensation of a hardly volatile product in the reaction zone, partly reduces the enthalpy of the full decomposition reaction. When discussing the kinetics of decomposition processes, the author gives preference to the approaches of Hertz, Knudsen, and Langmuir, compared with the most widely used Arrhenius equation and later dependences based on the theory of the transition state. L'vov convincingly demonstrated that Langmuir's evaporation equations open up far better opportunities for describing thermal decomposition processes, compared with other approaches. Comparison of three different methods that can be used to determine the enthalpy of the heterogeneous decomposi-

tion process (method of Arrhenius plots, method of the second law, and method of the third law) in accordance with the results of L'vov's studies shows that the method based on the third law of thermodynamics is beyond competition in every respect. It manyfold exceeds the other two methods in accuracy, adequacy of results, and productivity of measurements. These conclusions are in complete agreement with the opinion commonly accepted in data processing in equilibrium thermochemistry. The author analyzes the possible reasons why the third-law method has not found wide acceptance in studies of the kinetics of decomposition processes until very recently.

The second part of the book (pp. 80–161), which comprises nine chapters (from 4th to 12th), is devoted to interpretation and quantitative analysis of the effects, phenomena, and fundamental aspects of processes of thermal decomposition of various classes of substances. The author, in particular, discusses the relationship between the decomposition temperature and molar enthalpy of the process, the effect of various factors on the molar enthalpy, specific features of decomposition of carbonates in the presence of CO_2, and decomposition of crystal hydrates in the presence of H_2O vapor. Particular attention is given to the effect of self-cooling in endothermic reactions of thermal decomposition, to anomalous changes in the rate of dehydration of crystal hydrates upon an increase in the water vapor pressure (Topley–Smith effect), and to the effect of vapor condensation on the enthalpy. Of considerable interest are data on the influence exerted by the crystal structure of a substance on the composition of primary decomposition products and interpretation of the low values of the evaporation coefficients for quite a number of substances.

The third part of the monograph (pp. 162–254, chapters 13–15) describes apparatus for thermogravimetric measurements and the procedures involved and reviews the results obtained in studies of evaporation and thermal decomposition of a large group of widely diverse substances. Of importance is the section that discusses methods for evaluation of the absolute decomposition rate in relation to the type of the substance studied: crystals, powders, melts.

The final part of the monograph (pp. 254–258) makes certain general conclusions. Among the most important results directly associated with the concept of congruent dissociative evaporation, being developed by the author, the following can be mentioned: the fact that hardly volatile products appear in the gas phase at the instant of decomposition was established by mass spectrometry, the shape of kinetic curves was identified, and the mechanism of nucleation via formation of a hardly volatile product over the reagent surface was substantiated. The author gives a simple physical interpretation of the parameters of the Arrhenius equation for the evaporation process and revealed the relationship between the rate constant and the absolute evaporation rate.

It should be noted once again that the same thermal decomposition mechanism for different substances, Hertz–Langmuir evaporation model, and method based on the third law of thermodynamics underlie the approach developed by the author. The larger part of the whole body of experimental data has been obtained using the above-mentioned atomic absorption spectroscopy, mass spectrometry, and thermal analysis. L'vov's monograph is very well written, all the concepts put forward by the author are logically substantiated and experimentally confirmed. The author mentions as the most controversial issues the mechanism of energy transfer in condensation of a hardly volatile product to the reagent and the influence exerted by the crystal structure of the reagent on the composition of gaseous decomposition products.

The book is well published, includes 114 rather informative tables, and 43 figures. The total number of references for all the chapters is 474.

L'vov's monograph is of interest for a wide audience of specialists, and for researchers working in the field of physical chemistry, geochemistry, inorganic materials science, and metallurgy in the first place. The simplicity and clearness of presentation make it possible to recommend the book to postgraduates and senior students of the corresponding specialties.

BOOK REVIEWS

P. I. Chernousov, V. M. Mapel'man, and O. V. Golubev, *Metallurgiya zheleza v istorii tsivilizatsii: Uchebnoe posobie* (Metallurgy of Iron in the History of Civilization: Textbook), Moscow: Mosk. Inst. Stali Splavov, 2006, 350 pp.

DOI: 10.1134/S1070427206080404

The history of humankind is intimately associated with the development of manufacture of metals. Already in ancient times, people mastered extraction and processing of, first, native metals and then copper, its alloys, and iron. Metals and their alloys form foundation of the modern civilization and their consumption will continue to increase in the foreseeable future. A particular place, in occurrence and manufacture scale, among metals is occupied by iron, with which both the development of the material culture and the progress in all areas of public manufacture are closely connected. The textbook written by P.I. Chernousov and co-authors and published by Moscow Institute of Steel and Alloys summarizes evidence concerning the development of the metallurgy of iron, beginning from the ancient times and till the end of the medieval era (end of the XVI century).

The book comprises a preface, eight chapters, bibliographic list, and three supplements. In a very brief preface (p. 6), the authors emphasize the importance for future metallurgists of a historical study of their specialty in a relationship with the history of the society. The first chapter (pp. 7–62) is devoted to the origin of metallurgical industries and includes sections about use of metals in different periods of development of the civilization, use of the most widely occurring minerals in manufacture of metals, and gradual mastering of production of new metals and materials. To metals known from the ancient times belong gold, meteoritic iron, silver, lead, mercury, copper, tin, and some alloys (bronze, brass).

The second chapter (pp. 63–114) contains the available archeological evidence concerning the development of metallurgy in various civilizations of the Ancient World: Celts, Hetts, Etruscans, and discusses specific features of the development of metallurgy in Egypt, Assyria, Roman Empire, Ancient China, and Ancient India. The third chapter (pp. 115–146) describes the technologies used in the early stages of development of metallurgy (crucible melting, hearth melting, and simplest techniques for metal processing). Particular attention is given in the chapter to manufacture of metallic coins in various countries. The very brief fourth chapter (pp. 147–153) discusses the ancient metallurgical terminology. The fifth chapter (pp. 154–186) considers the advances in metallurgy in the Middle Age, depending on the type of iron ore deposits in different regions. The same chapter gives a detailed description of the use of metals for manufacture of various kinds of armor, armaments, and other articles of this kind.

The sixth chapter (pp. 187–211) is devoted to the development of high-quality metallurgy in the Middle Ages (VI–XVI centuries). The appearance of processes for corrosion protection of steel and for manufacture of high-quality armament steel (Damascus steel, forging and hardening of steel) is considered. In the seventh chapter (pp. 212–275), the authors describe the development of firearms and of the related cannon-casting industries (at the turn of the XV century).

The eighth chapter (pp. 276–290) contains evidence concerning the activities of known scientists of the Middle Age: Italian chemist and metallurgist V. Biringuccio (1480–1539) and German metallurgist and mineralogist G. Agricola (1494–1555). The former is the author of a classical work *The Pirotechnia* in ten books (1540), which contains a vast body of metallurgical and chemical evidence. In particular, methods for recovery of gold and silver, amalgamation technique, and method for synthesis of nitric acid are described. Agricola generalized in his treatise *De Re Metallica Libri XII* (Twelve Books on Metals, published posthumously in 1556) the many centuries' experience of recovery of metals from ores, developed foundations of processing of copper, lead, and silver ores, described preparation of a number of salts and technology of manufacture of glass, and described the fundamentals of assaying.

The bibliographic list (p. 291) includes references to 18 recent publications (1985–2005) of mostly popular-science type.

The supplements (pp. 292–349) include laboratory manuals, control questions, and a metallurgical crossword. The book is well published and equipped with clear illustrations and schemes. The use of studying the history of science and technology at technical higher-school institutions is beyond any doubt. As noted by the authors in the preface, the textbook under discussion is based on the course of lectures "The History of the Metallurgy of Iron," which has been delivered at Moscow Institute of Steel and Alloys since 1993. The textbook describes a huge period in the history of humankind, from the Stone Age till the late medieval era. Probably, it would be desirable that the introductory chapter for the textbook of this kind should be written by a specialist in the history of material culture of that time or archaeology. Reading the textbook under discussion creates an impression that is primarily based on popular-science publications.

The book by Chernousov, V.M. Mepel'man, and O.V. Golubev is approved by the educational-methodological association on education in metallurgy as a textbook for students of higher-school institutions training bachelors and licensed engineers specialized in metallurgy and physical materials science. As regards the manner of presentation, the book is well understandable for pupils of senior grades and students of technical schools.

Abstract—Mechanisms of radiation aging of poly(methyl methacrylate) and methods for enhancing its resistance to high-energy radiation are considered.

DOI: 10.1134/S1070427206090011

Poly(methyl methacrylate) (PMMA) is one of the most important materials in production of structural-decorative elements in building, of machines and devices, of items for medicine, of consumer's goods, and also as structural material in nuclear and space engineering where it is exposed to ionizing radiation. Poly(methyl methacrylate) is also exposed to radiation in the course of radiation sterilization of medical equipment, which is a widely used procedure.

High-energy radiation induces changes in physical, physicomechanical, and chemical properties of polymeric materials, resulting in deterioration of their service characteristics [1, 2]. The radiation resisance of PMMA items requires enhancement. This goal can be accomplished by introducing special protecting additives (antirads) preventing the development of undesirable radiation-chemical reactions and this preventing or considerably reducing changes in the structure and properties of the polymer upon irradiation.

As radiation protectors are used aromatic hydrocarbons and aromatic amines, urea and thiourea derivatives, alkyl mercaptans, and organophosphorus and sulfur-containing heterocyclic compounds [1–5]. The range of compounds used for radiation protection of PMMA steadily expands; various methods are used for their introduction into polymeric items or incorporation into macromolecules [6–9]. Development of new approaches to the radiation stabilization of PMMA remains an urgent problem.

This review summarizes and correlates published data on the search for high-performance radiation-chemical inhibitors of PMMA aging and on the development of scientific principles of their choice and introduction into the polymer.

RADIATION AGING OF PMMA

Irradiation of a substance results in generation of free electrons, cations, and excited molecules. Transformations of these intermediates yield the second generation of active intermediate species (excited molecules, cations and anions, free radicals, radical ions) according to the scheme [4]

$$AB \rightarrow AB^+ + e,\ AB \rightarrow AB^*,\ AB^+ + e \rightarrow AB^*,$$

$$AB + e \rightarrow AB^-,\ AB^* \rightarrow A^\bullet + B^\bullet,\ AB^* \rightarrow AB^+ + e,$$

where the asterisk denotes electronically excited state.

Free-radical reactions make the major contribution to radiation-chemical transformations of polymers. The generation of primary radicals and subsequent radical chain processes are responsible [10] for the chemical cross-linking and degradation of macromolecules under γ-irradiation.

Irradiation of PMMA causes random cleavage of the backbone; the number of breaks is proportional to the radiation dose [1]. The contribution of depolymerization to the radiation-induced degradation is very small compared to pyrolysis involving the depolymerization by the radical-chain mechanism. The monomer, methyl methacrylate (MMA), is not released until the polymer is heated to 398 K and higher temperatures [11]. Simultaneous action of heat and radiation (irradiation with an electron beam at 498–598 K) causes thermal and radiation degradation. The gaseous products released in the process mainly consist of MMA [12]. The activation energy of the thermal degradation of PMMA decreases from E = 140 without irradiation to E = 5 kJ g^{-1} under irradiation [12].

The mechanism of radiation aging of PMMA was studied at low temperatures (≤100 K) with the aim to elucidate the primary events in the interaction of the radiation with the substance [10, 13, 14]. At these temperatures, the effect of secondary processes associated with the migration and diffusion of the primary active species is reduced to a minimum. At 77 K, low-molecular-weight radicals $\dot{C}HO$, $\dot{C}H_3$, and $\dot{C}OOCH_3$

are formed; they are indicative of the elimination and decomposition of the ester group and elimination of the methyl group. Macroradicals such as ~CH_2–$\dot{C}(COOCH_3)$–CH_2~ or ~CH_2–$C(CH_3)$–$(COO\dot{C}H_2)$~ [10] are also formed. Terminal radicals ~CH_2–$\dot{C}\cdot(COOCH_3)(CH_3)$ were not detected at low temperatures. They are formed either upon irradiation at temperatures above 250–270 K or on heating γ-irradiated PMMA samples [10]. The terminal macroradicals are stable at room temperatures and start to decay only at T ~350 K along the disproportionation pathway [15].

The mechanism of aging at $T \geq 273$ K is discussed in [16–26]. It is believed [18] that the radiation degradation of PMMA occurs in two steps one of which is fast,

$$M^*_{n+m} \rightarrow M_n + M_m, \quad (1)$$

and the other is slow:

$$M^{\bullet}_{n+m} \rightarrow M_n + M^{\bullet}_m, \quad (2)$$

where M^*_{n+m} is an excited or ionized polymer molecule, and $M^{\bullet}_{n+m}$, polymer radical arising from elimination of a pendant group from the polymer molecule.

In irradiation in air, reaction (2) is suppressed because of the reaction of the primarily formed radical $M^{\bullet}_{n+m}$ with O_2 molecules [18].

It is known that the structure and properties of irradiated polymers largely depend on the kind of the radiation. The radiation yield of degradation (G_S) of the polymer chain, defined as the number of breaks in the polymer chain per 100 eV of absorbed energy, is independent of the dose rate (varied in the range 2.2–18.0 kGy h^{-1}) but depends on the absorbed dose and kind of the radiation. In γ-irradiation of PMMA in a vacuum, G_S is 1.93 at room temperature and 1.63 at 333 K; in neutron irradiation, G_S is 1.09 both at room temperature and at 333 K [18, 27]. The degradation of PMMA under α-irradiation is less intense than under γ-irradiation. The ratio G_α/G_γ of the radiation yields of PMMA degradation and of free radicals under α- and γ-irradiation is 0.067 and 0.55, respectively [28].

When PMMA is irradiated at temperatures below 273 K to doses of up to 30 kGy, the radiation yield of the degradation is independent of temperature and equal to 1.5 [29]. In the interval 293–333 K, it is temperature-independent also [27].

For G_S at 77 K, different authors give the values from 1.2 to 2.2; the most probable value is 1.9 ± 0.3 [19, 30]. The scatter of these data is caused by different times of keeping the irradiated sample after the irradiation [30]. The terminal radicals formed by cleavage of the macromolecule can recombine. The recombination rate strongly affects the polymer properties, because it determines the rate of "healing" of damaged sites in macromolecules in reactions of radicals with the environment [10]. The total yield of radicals G_R at 77 K is 4.8, whereas the yield of breaks in the backbone is 0.5–1 [10] (G_R is the number of radicals arising upon absorption of the radiation energy of 100 eV). The effective activation energy of the radical recombination is 84 kJ mol^{-1} [10]. Decomposition of atactic PMMA in the temperature interval 273–453 K is characterized by $E_a \approx 4.2$ kJ mol^{-1}. This fact suggests that the mechanism of the chain break is monomolecular [31]. In the interval 273–173 K, E_a approaches zero [32, 33].

It is known that, when PMMA is irradiated at $T \leq 270$ K, the curve of macroradical accumulation flattens out. This trend is attributed to the decay of macroradicals in the course of irradiation: At sufficiently high absorbed doses, the polymer radicals are no longer isolated and can react with each other or with hydrogen atoms, and also take up mobile electrons [4, 10, 13]. The existence of limiting concentrations is also explained by the heat release in the recombination of two radicals, leading to the decay of the neighboring radical pairs, and also by radiation-induced microheating [10].

At $T \geq 300$ K, the concentration of macroradicals grows with an increase in the irradiation dose, reaches a maximum, then slowly decreases to a certain minimum, after which it increases again [16]. The ratio of the local concentration of radicals to their average concentration, $[R]_{loc}/[R]_{av}$, in PMMA is 10–100 [16], i.e., the distribution of radicals is nonuniform [10]. It is believed [16] that at $T > 273$ K the macroradicals are accumulated as clusters in the interglobular space.

Belichenko et al. [24] believe that initially (at $0.1 < D < 0.7$ kGy) degradation of macromolecules involves break of the "weak" bonds formed by radical polymerization in the bulk, after which, at $0.7 < D < 10$ kGy, "common" bonds start to break. Upon irradiation of PMMA to a dose of 10 kGy (T = 300 K), new bands appear in the spectrum at 325–330 and 420 nm, and the polymer becomes less transparent [25]. Taraban et al. [26] attributed these changes to the appearance of terminal alkyl (λ_{max} = 410–412 nm) and allyl (λ_{max} = 425 nm) macroradicals. The ESR spectra recorded immediately after the irradiation in a vacuum at room temperature are determined by the terminal alkyl macroradicals. After postradiation storage for

200–300 h, the signals of macroradicals of the allyl and polyenyl types become prevalent in the ESR spectra, i.e., the radicals undergo mutual transformations [26]. The appearance of allyl macroradicals in PMMA irradiated at $T \geq 253$ K is attributed to the decay of terminal radicals [16]. The PMMA degradation leading to a decrease in the molecular weight (MW) of the polymer is also associated with terminal radicals [16, 26].

Schnabel and Sotobayashi [19] showed that the initially broad molecular-weight (MWD) distribution of PMMA becomes narrower upon γ-irradiation at 293 K, and vice versa. In all the cases, the ratio $b = \overline{M}_w/\overline{M}_n$ (where $\overline{M}_w$ and $\overline{M}_n$ are the weight-average and number-average molecular weights, respectively) tends to a limit $b = 2$, which is attained at doses of about 100 kGy and corresponds to random MWD [18]. In the dose range 100–300 kGy, $G_S = 1.75$ [19]. Comparison of the amount of paramagnetic centers and number of radiation damage sites (final numbers of breaks determined from a decrease in the MW of the polymer upon irradiation) shows that radicals generated by the irradiation initiate the degradation [16]. Initiation of the degradation is enhanced with a decrease in the concentration of terminal radicals.

The radiation resistance of PMMA is determined by its morphology and supramolecular structure. It is known that the degradation of PMMA in the crystalline phase is less intense than in the amorphous phase [34]. γ-Irradiation of partially crystalline isotactic PMMA in air at 303 K leads to a decrease in the crystallinity with increasing dose (0.7–2.90 MGy) [23].

The isotactic polymer is more sensitive to irradiation than the syndiotactic polymer [35]. Changes in the chemical structure of polymeric molecules cause changes in the supramolecular structure of the polymer. Upon high-temperature (293, 353, 383 K) γ-irradiation of PMMA, the content of isotactic triads (mm) in the isotactic polymer decreases (from 0.98 in the nonirradiated polymer to 0.55 in the polymer irradiated to a dose of 500 Gy), and the content of syndiotactic (rr) and heterotactic (mr) triads increases (from 0 to 0.23 and from 0.02 to 0.22, respectively). The transformation of the isotactic polymer into the syndiotactic and atactic polymer in the crystalline state prevails over the chain break [34]. With an increase in the temperature, changes in the polymer tacticity become more pronounced [36]. The radiation-chemical yield of the chain break G_S in isotactic PMMA irradiated at 353 and 303 K is 18.6 [37] and ~15 events/100 eV [23], respectively.

In the course of the degradation, the macromolecule is broken into smaller fragments. As a result, the MW of the polymer decreases, its solubility increases, and the flow point decreases [2, 34, 38, 39]. Upon irradiation, the strength, transparency [1, 2], refractive index, and density of PMMA decrease (the density, from 1.187 to 1.185 g cm^{-3} at a dose of 100 kGy), and the dielectric permittivity passes through a maximum at a dose of 10 kGy [22]. The creep [40], mechanical loss tangent, dynamic elastic modulus, and low-frequency speed of sound [41] change. The dielectric loss tangent decreases to 10% upon irradiation in air to a dose of 500 kGy [42]. Changes in the refractive index, density, and dielectric constant upon X-ray irradiation are linear in the dose range 15–120 kGy at various temperatures [43].

The degradation of PMMA macromolecules deteriorating the physicomechanical properties of the polymer can be prevented or considerably reduced by introducing special additives, antirads, providing the radiation protection of polymeric materials.

RADIATION PROTECTION OF PMMA

Antirad additives can be subdivided into two groups with respect to the mechanism of their action. Additives of the first group ensure the energy transfer from the polymer to the additive without chemical changes in the polymer. In the process, the additive either dissipates the energy or undergoes transformations or decomposition. Antirad additives of the second groups can heal the damaged site.

If irradiation causes ionization of macromolecules, additive A can act as an electron donor or electron acceptor and participate in the charge transfer:

$$M^+ + A \xrightarrow{k_1} M + A^+,$$

whereas in the absence of an antirad the polymer molecules degrade:

$$M^+ + e \xrightarrow{k_2} M^* \rightarrow R_1^\bullet + R_2^\bullet.$$

The capability of compounds to inhibit the degradation of PMMA by this pathway is attributed in [44] to their ionization potentials: The rate constant ratio k_1/k_2 is higher for compounds with the lower ionization potential I. In the series tetramethylphenylenediamine–diphenyldiamine–*p*-nitroaniline–stilbene–naphthalene–benzophenone–benzoic acid, k_1/k_2 is 68.5, 56, 52, 46, 30, 24, and 10, and the ionization potentials

Table 1. Classes of antirads [5]

Radiolysis step	Protection mechanism	Class of antirads
Intra- and intermolecular transfer of absorbed ionizing radiation energy in the form of electronic excitation	(A) The electronic excitation energy taken up by the additive is dissipated as heat or long-wave electromagnetic radiation	Compounds containing aromatic fragments, aromatic hydrocarbons
Ionization of the molecule with formation of electron and ion, followed by recombination of geminal ions leading to excitation and dissociation of the molecule	(B) Electron is transferred to the polymeric ion without subsequent excitation (B') Electrons are accepted by the additive, and the probability of neutralization with formation of excited states decreases	Aromatic amines, diamines, polysubstituted phenols and polyphenols Nitro- and halo-substituted organic compounds, quinones, quinone imines
Bond cleavage, generation of free radicals, reactions of free radicals	(C) Transfer of hydrogen atom to the macroradical, reactions with free radicals with formation of inactive radicals and stable molecules	Aromatic amines and phenols, sulfur-containing compounds, phosphites, sterically hindered piperidine derivatives, spin traps

are 6.6, 7.25, 7.7, 7.95, 8.10, 9.45, and 9.5 eV, respectively. For PMMA, the charge transfer is energetically unfeasible, because the ionization potentials of these additives are lower than that of PMMA (I = 10.5 eV).

The arising macroradicals can be deactivated by the addition of antirads. It is known that aromatic compounds (anthracene, acridine) and quinones (benzoquinone, tetrachlorobenzoquinone) add to terminal radicals $\dot{C}H_2$–$C(CH_3)(COOCH_3)$ even at 100 K [45]. In degrading PMMA, additive A can link two terminal macroradicals and thus heal the radiation-induced damage:

$$R_n^{\bullet} + A + R_m^{\bullet} \rightarrow R_n\text{–A–}R_m.$$

Also possible are substitution reactions involving abstraction of an H atom by a polymeric radical from low-molecular-weight compounds containing labile C–H, N–H, and S–H bonds with the formation of a low-active radical:

$$AH + R_n^{\bullet} \rightarrow A^{\bullet} + R_nH.$$

In the abstraction of hydrogen atoms from phenols, amines, and mercaptans, the terminal radicals $\sim C(CH_3)(COOCH_3)\dot{C}H_2$ are more active than $\sim CH_2$–$\dot{C}(CH_3)(COOCH_3)$ [45].

The classes of antirads protecting the polymer by one or another mechanism are listed in Table 1 [5]. In addition, we should note deactivation of macroradicals in their reaction with radicals formed by radiolysis of the antirad (e.g., of sulfur-containing compounds) and restriction of the mobility of the macroradicals by cross-linking of the macromolecules. As seen from Table 1, the protection mechanism is determined by the type of compounds used as antirads.

Protection with aromatic compounds. One of the major quantities characterizing the radiation resistance of polymers and polymeric materials is the radiation-chemical yield of paramagnetic centers G_R, which is equal for PMMA at 77 K to 3.4 [46] or 4.8 [15] radicals per 100 eV. At 298 K, G_R is 2.6 [47]. Aromatic compounds introduced into PMMA decrease the yield of radicals and enhance the stability of the polymer [13]. On introducing 1 wt % pyrene, *p*-terphenyl, or benzene, the degradation (relative to pure PMMA) is 0.694, 0.694, and 0.886, respectively [48] (hereinafter, the content of antirads in PMMA is given in wt %). With *p*-terphenyl, the resistance of PMMA to γ-radiation is also enhanced: The number of breaks per macromolecule in the presence of 0.25% *p*-terphenyl decreases from 12.9 to 12.7 (at a dose of 42 kGy) [6].

Owing to their π-electron system, aromatic compounds such as anthracene, phenanthrene, benzanthracene, etc. [1] act as "energy sponges," absorbing the energy from the main substance being irradiated and dissipating this energy as heat or fluorescence. These substances provide intermolecular energy transfer and, in so doing, undergo no appreciable transformations. The majority of compounds used as luminescent additives in plastic scintillators based on this polymer [49] protect PMMA just by this mechanism. In the presence of naphthalene, *p*-terphenyl, 2,5-diphenyloxazole, 1,4-di[2-(5-phenyloxazolyl)]benzene (POPOP), or 1,1,3-trimethyl-3-phenylindan (TMPI), the concentration of radicals causing the degradation of the irradiated polymer decreases [6], and the thermomechanical properties do not change up to irradiation doses of 40 kGy (the flow point starts to decrease

at doses exceeding 40 kGy, and the glass transition point, at doses exceeding 250 kGy).

Calculations made using the data from [50] show that naphthalene introduced in an amount of 15% into the polymer in the course of its synthesis decreases from 11.5 to 4.4 the number of breaks arising in the macromolecule upon γ-irradiation to a dose of 42 kGy and limits the growth of the optical absorption and decrease in the light output [50]. The G_S of PMMA (determined from a decrease in the MW of the polymer) decreases from 0.79 to 0.35 on adding 12% naphthalene and to 0.26 on adding 10% pyrene [52].

The radioprotective effect on aging of PMMA is enhanced when additives are used in a combination. The number of breaks in PMMA containing 15% naphthalene and γ-irradiated to a dose of 42 kGy decreases to 4.2 on adding 0.2% POPOP [50]. In γ-irradiated PMMA containing 0.2% TMPI, the maximal concentration of paramagnetic centers is 1.2 times lower than in the polymer without this additive. The number of breaks per macromolecule upon irradiation to a dose of 42 kGy is 12.9 without additives and 2.2 with addition of 24% TMPI [6, 49]. On adding 0.01% POPOP to this formulation, it decreases further to 2.1; on adding 0.2% *p*-terphenyl, to 2.0; and on adding 0.01% POPOP + 0.2% *p*-terphenyl, to 1.9 [6]. Owing to a decrease in the amount of the radiolysis products in the presence of such antirads, the optical properties of PMMA upon γ-irradiation are deteriorated to a lesser extent than in their absence [49, 51].

The radiation-induced degradation of PMMA is inhibited by aromatic amines whose protective effect is attributed to the electron transfer from amines to the polymer being irradiated [53–55]. β-Naphthol and diphenyl ether also exert a protective effect. In their presence, the number of breaks decreases by a factor of 1.5–3.0 [54]. The radioprotector activity characterized by the relative protection coefficients [44] increases in the series trinitrobenzene–benzoic acid–benzophenone–naphthalene–chloranil–stilbene–*p*-nitroaniline–diphenylamine–tetramethyl-*p*-phenylenediamine.

Enhancement of the radiation resistance of a polymer by introducing aromatic compounds that are not incorporated into the macromolecule is external protection. The degradation can also be inhibited by incorporating appropriate units (aromatic rings) directly into the PMMA macromolecules, e.g., by copolymerization of MMA with styrene and α-methylstyrene (internal radiation protection).

The intramolecular protection (e.g., in copolymer of MMA with α-methylstyrene) is more efficient than intermolecular protection (in a mixture of PMMA with *n*-propylbenzene) [4]. The radiation-induced degradation of MMA–styrene copolymer (61 : 39 by moles) starts with the break of the backbone in MMA units with the generation of the free radicals ~CH_2–$\dot{C}(CH_3)(COOCH_3)$ [56]. Longer γ-irradiation results in the generation of radicals in the styrene units also, ~CH_2–$\dot{C}(C_5H_5)CH_2$~; the ratio of their concentration to that of the radicals in MMA units increases from 0 to 9. The viscosity-average molecular weight decreases during radiolysis more slowly, compared to pure PMMA, with increasing dose, and the yield of radicals in the polymer is lower [56]. In the copolymers, the excitation energy is transferred intramolecularly from MMA to styrene units. O'Donnell and Pomery [14] showed that about 50% of the excitation energy is dissipated on styrene units in styrene–MMA copolymer (51 : 49 by moles). The G_R values for the copolymer are lower than the additive value calculated for the given molar ratio of the comonomers. Whereas the yield of radicals in PMMA and polystyrene at 77 K is 0.58 ± 0.2 and 0.05 ± 0.02 per 100 eV, respectively, in the copolymer it is 0.18 per 100 eV [14]. Owing to the high radiation resistance, the 1 : 1 (by moles) styrene–MMA copolymer with additions of naphthalene (15%) and POPOP (0.2%) loses only 11% of the light output upon γ-irradiation to a dose of 40 kGy, whereas in PMMA with the same additives the loss is 25% [25].

There is no energy transfer between the polystyrene and PMMA molecules [57]. This fact, together with the incompatibility of the polymers, is apparently responsible for the lack of the protective effect of polystyrene in its blend with PMMA in γ-irradiation from a ^{60}Co source [58, 59].

In [7] we described the radioprotective properties of 1,4-phenylene-1,2-diphenylvinylene oligomer incorporated in PMMA as a comonomer. We found that the relative change in the flow point, $(T_f^0 - T_f)/T_f^0$, upon γ-irradiation to a dose of 10 kGy of the PMMA block sample containing this oligomer (1%) is 0.11, whereas for the polymer without additives this quantity is 0.19 (T_f^0 and T_f are the flow points of the nonirradiated and irradiated samples, respectively). The flow point of the irradiated polymer as a function of the stabilizer concentration passes through a maximum due to a change in the relative contributions of the inhibition and initiation of PMMA chain degradation with the oligomer and its radiolysis products [7]. At low concentrations of the stabilizer, virtually all the radicals formed by its decomposition are spent for the deactivation of the PMMA macroradicals. With an increase in the oligomer content, the increasing

amount of radicals start to participate in the degradation initiation.

Sulfur-containing compounds known as radioprotectors of biological systems also exert a protective effect on polymeric materials [3].

Protection with sulfur-containing compounds. One of specific properties of sulfur-containing compounds is the capability of bivalent sulfur atoms to protect the alkyl substituent in the molecule from the radiation impact. Sulfur exerts the protective effect not only on the adjacent atoms but also on molecules [60], including macromolecules. The protection mechanism may involve migration of the charge and/or excitation from the alkyl moiety to the sulfur atoms [13]. The possibility of the energy migration in this direction is due to the low energy of the excitation of the sulfur *d* orbitals (the sulfur atom has five vacant 3*d* orbitals which can accept more than eight electrons). The excitation of electrons to the *d* orbitals leads to the energy dissipation, which considerably reduces the probability of the bond dissociation. The effect of bivalent sulfur compounds on the PMMA aging may be due not only to the transfer of the energy or charge from the polymer to the additive, but also to the reaction of the additive with radicals. Owing to relatively easy homolysis of S–S and C–S bonds, these compounds generate the corresponding thiyl radicals. The most labile bonds are S–H in thiols, C–S in sulfides, and S–S in disulfides [61]. Aliphatic and aromatic compounds generate thiyl monoradicals, and sulfur-containing cyclanes generate biradicals capable of deactivating polymeric radicals responsible for the degradation [62].

The protective function of allylthiourea, di-*m*-tolylthiourea, dithienyl disulfide, and ethyl mercaptan was demonstrated in [1, 3, 4, 37]. The number of chain breaks in PMMA decreases on adding S-containing compounds. In PMMA without additive, γ-irradiated at 313 K to a dose of 100 kGy, this number is 12.0, whereas in the presence of 1.4% ethyl mercaptan it decreases to 3.3. When the irradiation is performed at 77 K, the number of breaks is 4.2 and 1.2, respectively [62].

The radioprotector activity of S-containing compounds depends on the procedure of their introduction not only into the polymeric formulation, but also into the macromolecule [47]. The presence of impurities of organosulfur compounds in PMMA containing 1,3,5,7-tetramethyl-2,4,6,8-tetrathiaadamantane (compound with highly stable rings) exerts no noticeable influence on the properties of the irradiated polymer [47]. The stabilizing effect of S-containing compounds is manifested only when they are incorporated into the macromolecule being protected.

Incorporation of sulfur-containing fragments in the PMMA macromolecule as terminal groups by polymerization of MMA in the presence of a chain-transfer agent, 3,5,7,9,9'-pentamethyl-1-mercapto-2,4,6,8-tetrathiaadamantane, and as pendant groups by copolymerization with 3,5,7,9,9'-pentamethyl-1-amethacryloylthio-2,4,6,8-tetrathiaadamantane slightly enhances the radiation resistance of the polymer. The quantities $(T_f^0 - T_f)/T_f^0$ of these samples after γ-irradiation to a dose of 50 kGy are equal, 0.20 (for the polymer without additive, 0.24) [47]. Sulfur(VI) compounds (sulfolanes) incorporated in the macromolecule as pendant groups do not alter the radiation resistanc of PMMA. Incorporation in the pendant group of a thioether fragment containing S(II), along with the sulfolane fragment [in copolymer of MMA with 3-methacryloyloxy-4-(1'-thia)hexyltetrahydrothiophene dioxide], appreciably enhances the stability: $(T_f^0 - T_f)/T_f^0$ decreases to 0.22 [47].

Sulfur(II) compounds exert the strongest protective effect when incorporated in the macromolecule backbone, as can be shown by the example of 3,6-dimethyl-1,4,5-trithiacycloheptane and elemental sulfur (S_8) [47, 63]. The quantity $(T_f^0 - T_f)/T_f^0$ for PMMA containing these additives (0.5%) and irradiated to a dose of 50 kGy is 0.11 and 0.15, respectively (without additive, 0.24) [47]. The radiation yield of radicals in PMMA at 305 K upon incorporation of 0.1% S_8 decreases from 2.9 to 1.9 per 100 eV [63]. In the presence of S_8, the number of radiation-damaged sites in the PMMA macromolecule after γ-irradiation to a dose of 80 kGy is smaller than the number of chain breaks responsible for the generation of radicals. Irradiation to a dose of 20 kGy causes 2.5 breaks per macromolecule, and 1.0 damaged site remains by the time of molecular weight determination. In the absence of the additive, 2.8 breaks formed upon irradiation give rise to 4.3 residual damaged sites, i.e., initiation of the degradation by radicals takes place [63]. Stabilization of the polymer in the presence of sulfur-containing additives is due to the recombination of terminal macroradicals with thiyl radicals formed by radiolysis [63]. Their reaction is more probable within one molecule. The restricted diffusion in solid samples and nonuniform distribution of the additive (present as an impurity) in the polymer complicate the contact of these radicals and require higher concentrations of antirads.

The polymer protection can also be accomplished by varying its structure.

Structural protection. Along with the chemical structure, the radiation resistance of a polymer is influenced by the structure and mobility of chains. A decrease in the mobility of macromolecules due to their cross-linking (occurring along with the degradation) under the action of γ-radiation is responsible [64] for the lower yield of chain breaks ($G_S \approx 2.41$) determined from a decrease in the molecular weight, compared to the value ($G_S = 2.82$) calculated from the volumes of the isolated gaseous products released from poly(cyclohexyl methacrylate).

Apparently, this mechanism is operative in the protection of PMMA by carboranes, which are relatively inert, thermally stable, electron-deficient boron compounds of polyhedral structure in which one or more boron atoms in the molecular core are replaced by carbon atoms [65, 66]. Addition of 10% 1,2-dibenzyl-*o*-carborane as a mechanical admixture to PMMA leads to an increase in its glass transition point upon γ-irradiation to a dose of 80 kGy from 369 to 389 K, which is attributed to cross-linking of the macromolecules in the course of irradiation, decreasing their segmental mobility. Cross-linking can also result from the reaction of the carborane or its radiolysis products with oxygen-containing ester groups (–$COOCH_3$) in PMMA [8]. Degradation is inhibited in the presence of the carborane, which is manifested in a less intense decrease in the flow point of the polymer compared to the polymer without additive: The flow point of PMMA containing 10% additive decreases from 570 to 480 K upon γ-irradiation to a dose of 10 kGy, whereas without additive it decreases to 460 K. The polymer protection is also provided, apparently, by the capability of carborane groups (and aromatic fragments) to absorb and dissipate the radiation energy owing to the presence of delocalized electrons.

The inhibition of the radiation-induced degradation of PMMA may due to cross-links that not only arise in the course of irradiation but also may be present initially. For example, copolymers of MMA with *trans*-1,2-dimethacryloyloxycyclohexane (DMCH) and 3,4-dimethacryloyloxysulfolane (DMS), whose macromolecules are cross-linked by cyclohexane and sulfolane groups, are more resistant to high-energy radiation than PMMA [67]. The flow point of the copolymers decreases under γ-irradiation considerably less intensely than that of PMMA [67]. The quantity $(T_f^0 - T_f)/T_f^0$ at an irradiation dose of 50 kGy is 0.24 for PMMA, 0.19 for its copolymer with DMS, and 0.20 for the copolymer with DMCH (comonomer content 2.75 mol %). In sulfolane groups, all the six valence electrons of the S atom participate in the formation of the S–O and C–S bonds in contrast to S(II) compounds, and there are no electrons capable of transition to the *d* level upon excitation. Therefore, the absorbed energy is not dissipated. The cyclohexane fragment contains no conjugated double bonds and therefore is also incapable of the redistribution of the absorbed energy. In radiolysis, these groups do not decompose into species capable to deactivate macroradicals. The stabilization of these copolymers is apparently due to structural features of their macromolecules.

Cross-links decrease the mobility of the macromolecules and favor stabilization of radicals; therefore, the concentrations and radiation yields of radicals in these copolymers are higher than in PMMA [67]. The cross-links hinder the decay of radicals both by thermal recombination (responsible for inhibition of degradation) and by disproportionation, and also by direct interaction with the radiation (leading to degradation of the polymer, e.g., by dissociation of the radicals with formation of stable molecules and hydrogen atoms recombining with the nearest radicals [13]). The rate constant of the decay of radicals in irradiated MMA–DMS copolymer by interaction with the radiation is 0.023 kGy^{-1}, whereas in straight PMMA it is 0.037 kGy^{-1} [20]. The activation energy of the decay of radicals by the bimolecular mechanism in PMMA is 110, and in the copolymer, 146 kJ mol^{-1}. The inhibition of the recombination of radicals in the copolymer is attributed to a decrease in their "rotational" mobility in the cage and in the probability of their escape from the cage [20]. Owing to the decreased mobility of macromolecules, radicals arising in one molecule cannot induce degradation of another molecule. In PMMA, $\dot{C}H_2$–$C(CH_3)(COOCH_3)$~ radicals can disappear by abstraction of an H atom from a neighboring chain [15]. The radicals arising in the process decompose:

$$\sim(CH_2\text{–}C(CH_3)(COOCH_3)\text{–}\dot{C}H\text{–}C(CH_3)(COOCH_3)\text{–}CH_2\sim$$

$$\rightarrow \sim CH_2\text{–}C(CH_3)(COOCH_3)\text{–}CH{=}C(CH_3)(COOCH_3)$$

$$+ \dot{C}H_2\text{–}C(CH_3)(COOCH_3)\sim.$$

Cross-links of macromolecules hinder these reactions. The stability of PMMA is considerably enhanced by cross-linking of the macromolecules with anthracene fragments in the copolymer of MMA with 9,10-dimethacryloyloxymethylanthracene (DMMA) owing to participation of the aromatic nuclei in the redistribution of the incident energy [67]. The radiation yield of radicals in this copolymer (per 100 eV) is

lower than in PMMA and copolymers of MMA with DMS and DMCH: 2.9 in PMMA, 3.0 in copolymer with DMS (2.75 mol %), 3.2 in copolymer with DMCH, and 1.4 in copolymer with DMMA [67]. The quantity $(T_f^0 - T_f)/T_f^0$ for the latter copolymer is as small as 0.15 upon γ-irradiation to a dose of 50 kGy [67]. To evaluate the relative performance of antirads in radiation protection, it is suggested to use the protection factors F (%) defined [1] as

$$F = (1 - r_0/r) \times 100,$$

where r_0 and r are the ionizing radiation energies required to attain the same radiation effect in the absence and in the presence of an antirad, respectively.

The protection factors of some antirads given in [5] and calculated from the experimental data of [6–8, 63, 67] are listed in Table 2. Table 2 shows that polycyclic hydrocarbons, aromatic amines, and sulfur-containing compounds exhibit high radioprotecting effect. A particular place among them is occupied by thiacyclanes. The protection factor of 70–93% is attained on their introduction into PMMA in concentrations 8–20 times lower than the concentrations of aromatic hydrocarbons providing the same effect.

CONCLUSION

Degradation processes occurring in poly(methyl methacrylate) under the action of high-energy radiations can be controlled by introducing into the polymer aromatic hydrocarbons, aromatic amines, carbo-

ranes, and sulfur-containing compounds. The radioprotective performance of these compounds depends on their capability to be incorporated in the polymer chain and on their arrangement in the chain. When structural units responsible for the radioprotecting effect are incorporated directly in the polymer chain, the protecting effect is stonger than when radioprotectors are introduced as mechanical admixtures that do not form chemical compounds with the macromolecule. Compounds incorporated in the polymer backbone are more effective antirads than those incorporated as terminal, pendant, or cross-linking groups.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Physicochemical Properties of Silver Nanoparticles Stabilized by Acid Gelatin

A. V. Vegera and A. D. Zimon

Moscow State University of Technology and Management, Moscow, Russia

Received July 8, 2006

Abstract—Silver nanoparticles were synthesized by the reduction of silver nitrate with sodium borohydride at widely varied concentrations of the starting reagents. A physicochemical study of the synthesized nanosystems was carried out. The stabilizing ability of acid gelatin in the systems under study was considered. The stability diagram in the coordinates initial concentration of silver nitrate–concentration of gelatin was constructed.

DOI: 10.1134/S1070427206090023

The preparation of stable concentrated aqueous dispersions with preset physicochemical properties, based on silver nanoparticles, is a necessary step in the development of nanostructural materials applied in microelectronics, electrochemistry, synthesis of electrooptical sensors, pigments, etc. Owing to the bactericidal properties of silver ions, its nanodispersions can form a basis for the development of new classes of bactericides and various medicinal substances.

The preparation of a disperse system with the required stability in time and resistance to the action of external factors remains the major problem. In this connection, our goal was to study how the conditions of the synthesis of silver nanoparticles affect the stability of silver nanodispersions. To characterize properties of the synthesized nanodisperse silver systems, we used a number of methods. The transmission electron microscopy and computer analysis of the resulting images of nanoparticles allowed us to determine the size distribution of particles under various synthesis conditions. The concentration of silver ions in the systems was determined by atomic absorption spectroscopy, and optical properties of silver nanodispersions, by spectrophotometry. The stability diagram of the silver nanoparticle sol was constructed using a combination of the three above-mentioned methods. The stability of the systems was determined in relation to two parameters: initial concentration of silver ions in the reaction mixture and concentration of gelatin in the dispersion medium.

EXPERIMENTAL

Silver nanoparticles were synthesized by the reduction of aqueous solutions of silver nitrate. The process follows the scheme

$$AgNO_3 + [\text{reductant}] \rightarrow \text{silver nanoparticles}.$$

In the study we used chemically pure grade silver nitrate (Reakhim). To make the constructed stability diagram of the system more reliable, we determined gravimetrically the metal content in the reagent. For this purpose, three weighed portions of the starting salt were heated in crucibles at 120°C to constant weight. Sample weights were measured accurate to 1×10^{-4} g. From the data obtained, we have found that the content of silver nitrate in the starting preparation was 83.00%. These data were confirmed by atomic adsorption spectroscopy.

As reductant we used chemically pure grade sodium borohydride (Reakhim) without additional purification; in the process, it is oxidized to borate. The following reaction scheme is presumed:

$$2AgNO_3 + 2NaBH_4 + 6H_2O \rightarrow 2Ag + 7H_2\uparrow + 2NaNO_3 + 2H_3BO_3.$$

As the stabilizer of silver nanoparticles we used photo A grade acid gelatin without additional purification (isoelectric point 4.9, average molecular weight 94 kDa). In all experiments we used double-distilled water.

Physicochemical properties of silver nanoparticles. Properties of a colloidal solution, including that of silver nanoparticles, are determined by the possibility of coagulation and recrystallization, i.e., by the aggregation stability, and also by the sedimentation stability [1, 2] and the possibility of oxidation with atmospheric oxygen.

An examination of the published data [1, 2, 8, 9] showed that several methods can be used to describe the stability of silver nanodispersions in time. The visual observation can reveal preliminary and general trends in the relative stability of a dispersion under study. A change in the system color and(or) the formation of a precipitate can be detected. The average particle size correlates with the sol color. The color of silver nanoparticles varies from red (yellow-brown) to gray and even black. The visual observation can play a decisive role in studying the sedimentation stability.

The optical method based on recording the visible absorption spectrum of the system under study is one of reliable instrumental methods (Fig. 1). The occurrence of coagulation and recrystallization can be suggested when a shoulder or a new maximum appears in the long-wavelength part of the spectrum [3, 4]. A quantitative characteristic of the aggregation stability can be obtained by electron microscopy, which makes it possible to determine the distributions of particles with respect to the size and shape, and also to estimate the arrangement of nanoparticles in space (separate or coagulated particles) (Fig. 2).

In the system under study, several pathways of nanodispersion breakdown are possible, namely, the oxidation of metal particles accompanied by their dissolution, aggregation of particles, and also sedimentation.

A wide spectrum of silver sols was synthesized in the initial concentration range 1×10^{-5}–2×10^{-3} M. We will consider the results of studying physicochemical properties of the synthesized silver nanosystems. First of all, as the initial concentration of silver ions increases, the size of the forming nanoparticles and the range of their distribution in size increase from 3–9 nm for the 1×10^{-5} M concentration of silver ions to 5–50 nm for the concentration of 2×10^{-3} M. Let us consider specific features of silver sol depending on the initial concentration of the reagent (silver nitrate) in the concentration range 1×10^{-5}–1×10^{-4} M. The solution color changes from red to yellow within 10–14 days. Three hours after the synthesis, nanoparticles have the size from 3 to 9 nm, and the particle size distribution is normal. After 48 h, the distribution of nanoparticles in size changes. Particles of size 9 nm make up 48%. Due to the aggregation and recrystallization, the number of particles decreases from $(7.5 \pm 0.8) \times 10^{14}$ to $(1.1 \pm 0.5) \times 10^{14}$ particles per liter, i.e., by a factor of approximately 7.

At the initial silver concentration of 2×10^{-4}–3×10^{-4} M, the diameter of nanoparticles varies from 5 to 40 nm. The content of nanoparticles 15 nm in diameter is about 23%. After 3 months, the particle size distribution slightly changes. The range of the sizes is 5–50 nm. The most probable diameter is 20 nm (18% of such particles). The concentration of particles decreases from $(5.7 \pm 0.6) \times 10^{14}$ to $(2.1 \pm 0.5) \times 10^{14}$, i.e., by a factor of approximately 2.5. The system is more stable to aggregation than the previous system.

At the initial concentration of silver ions of 2×10^{-3} M, the initial size distribution of nanoparticles is asymmetric. The diameter of nanoparticles varies from 5 to 50 nm, and the most probable value is 30 nm (20% of particles). Coagulation structures consisting of large asymmetric particles and more symmetric small particles are formed (Fig. 3).

Stabilization of silver nanoparticle by gelatin. In time, the aggregation of nanoparticles occurs, their concentration decreases, and their size increases. The aggregation stability stability can be enhanced by adding gelatin. This additive substantially prevents the aggregation and reduces the average size of nanoparticles (particle size in the range from 3 to 17 nm).

The stability diagram of the synthesized silver nanodispersion consists of three regions (Fig. 4). In region *A*, the nanosystems show limited stability. In this region, the dispersion systems are broken down by oxidation (dissolution) of metallic particles under the action of oxygen dissolved in the dispersion medium. Region *B* is the area of stable systems. In region *C*, the systems are unstable. The stability is lost due to the coagulation and the subsequent sedimentation of the aggregates formed.

As the gelatin concentration increases, the stability of silver dispersion against oxidation (dissolution) increases. The properties of the adsorption layer play the decisive role. The curve separating regions *B* and *C* characterizes the increase in the system stability with increasing concentrations of gelatin and silver ions. The gelatin adsorption under these conditions (adsorbate concentration of 0.1–0.5% and adsorption surface area of 0.3–0.8 m^2 in 100 ml of the system) is polylayer [4]. When the gelatin mass is thickened in the adsorption layer, its concentration can increase to 30%.

According to the phase diagram of the gelatin–water system, such a change in the gelatin content results in the gel formation [5]. Gelatin gels envelop nanoparticles. The gelatin adsorption layer affects the mass-transfer process and the formation of other concentration gradients of the system components, in contrast to systems without gelatin. The surface-active properties of gelatin should also be taken into account. Its adsorption results in a decrease in the interfacial tension, which leads to overall lyophilization of the system.

The stability of the colloidal solution of nanoparticles depends on the concentration of silver ions in the starting solution. We chose two systems for the analysis, the first with the concentration of silver

Fig. 3. Electron micrograph of silver nanoparticles. Initial concentration of silver nitrate 2×10^{-3} M, concentration of gelatin 0.0%; 3 h after the synthesis.

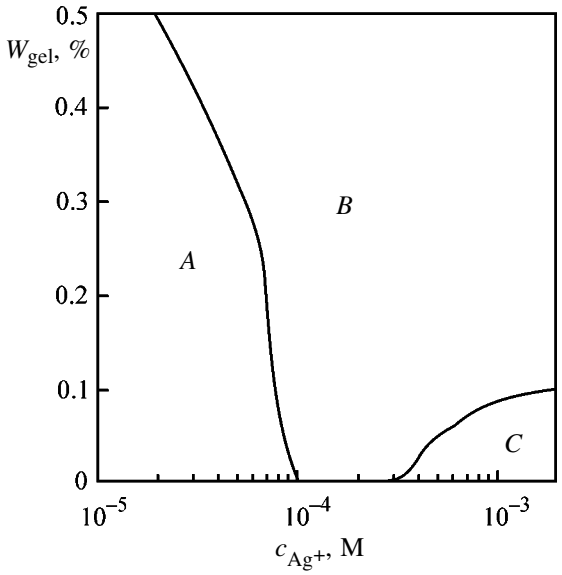

Fig. 4. Stability diagram of silver sol at T = 293 K and pH 8.0. Regions in the diagram: (*A*) relatively stable, (*B*) highly stable, and (*C*) unstable.

nitrate of 2×10^{-4} M, which corresponds to formation of the stable system (Fig. 4, region *B*), and the second, aggregation-unstable, with the concentration of 8×10^{-4} M (Fig. 4, region *C*).

The dependence of the concentration of silver ions in solution on the time elapsed after the synthesis of

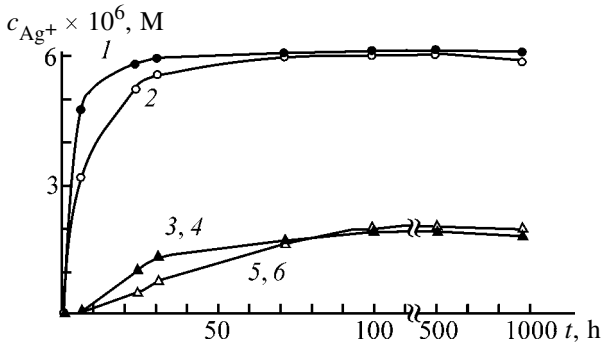

Fig. 5. Concentration of silver ions c as a function of the storage time t of nanodispersion samples with the initial content of silver ions of (*1, 3, 5*) 2×10^{-4} and (*2, 4, 6*) 8×10^{-4} M. Gelatin concentration, %: (*1, 2*) 0, (*3, 4*) 0.1, and (*5, 6*) 0.3. T = 293 K, pH 6.7.

nanoparticles is given in Fig. 5. In the system without gelatin with the initial concentration of 8×10^{-4} M, the content of free silver ions increases faster (Fig. 5, curve *2*) than in the system containing 2×10^{-4} M silver ions (Fig. 5, curve *1*). This trend agrees with the general dependence of kinetic parameters of chemical reactions on the initial concentration of the substance. It should be noted that equal Ag^+ concentrations, $(6.3 \pm 0.3) \times 10^{-6}$ M, are attained within 70 h in both systems.

The addition of gelatin to the system results in a sharp decrease in the concentration of silver ions (by a factor of approximately 3.5) in the systems with the initial concentrations of silver ions of both 2×10^{-4} and 8×10^{-4} M, and gelatin concentrations of 0.1% and 0.3% (curves *3, 5* and *4, 6*). A stationary concentration of silver ions was observed in the systems containing silver nanoparticles of different sizes.

In the presence of gelatin, during a certain initial period of time, free silver ions are not detected in the system (detection limit 1×10^{-7} M). Stationary concentrations are attained within 72 h. Irrespective of the initial concentrations of silver ions and gelatin, the quasi-equilibrium concentration of silver ions is the same, $(1.7 \pm 0.2) \times 10^{-4}$ M. Such a behavior of the system is apparently caused by the influence of the gelatin adsorption layer hindering the oxidation of metallic silver.

CONCLUSIONS

(1) The sizes and shapes of silver nanoparticles synthesized by the reduction of aqueous solutions of silver nitrate with sodium borohydride were determined by electron microscopy.

(2) The size distributions of nanoparticles in the range of the initial concentrations of silver nitrate of 10^{-5}–10^{-3} M were determined.

(3) The possibility of stabilization of the nanoparticles by acid gelatin was demonstrated.

(4) Aggregation- and sedimentation-stable nanodispersions were obtained at appropriate gelatin concentrations.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of Intrinsic Viscosity of Polyelectrolytes in Salt-Free Solutions

G. M. Pavlov, A. S. Gubarev, I. I. Zaitseva, and M. A. Sibileva

Fock Research Institute of Physics, St. Petersburg State University, St. Petersburg, Russia

Received June 5, 2006

Abstract—Comparative analysis of the methods for determination of the intrinsic viscosity of both neutral and polyelectrolyte molecules is made.

DOI: 10.1134/S1070427206090035

The intrinsic viscosity remains among the most significant molecular-hydrodynamic characteristics of polymers. A relatively simple and descriptive viscometric method is widely used in the molecular physics of polymers and rheology and technology of macromolecular compounds for studying polymer solutions [1–4].

The intrinsic viscosity $[\eta]$ is related to the molecular characteristics of a linear-chain macromolecule by the well-known Flory equation [1, 2]

$$[\eta] = \Phi\langle h^2\rangle^{3/2}/M, \quad (1)$$

where $\langle h^2\rangle$ is the mean-square chain length; M, molecular weight of the investigated sample or fraction; and Φ, Flory parameter (mol^{-1}).

Kuhn–Mark–Houwink–Sakurada relationship (2) is also widely used in the polymer science and technology [2, 5, 6]:

$$[\eta] = K_\eta M^a, \quad (2)$$

where a and K_η are the parameters tabulated for a variety of systems polymer–solvent [5].

Analysis and normalization of the Kuhn–Mark–Houwink–Sakurada relationships are presented in [7].

There is a number of extrapolation procedures allowing estimation of $[\eta]$ for neutral macromolecules [1, 4, 6]. The most common among them is the Huggins equation [8]

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c + ..., \quad (3)$$

where c is the polymer concentration in the solution ($g\ cm^{-3}$); $\eta_{sp} = \eta_r - 1 = (\eta/\eta_0) - 1$; η and η_0 are the dynamic viscosities of the solution and solvent, respectively; η_r and η_{sp}, relative and reduced viscosities of the solution; and k is the Huggins dimensionless parameter.

Kraemer equation (4) is considered in a combination with the Huggins equation [9]:

$$\ln \eta_r/c = [\eta] + k''[\eta]^2 c + ..., \quad (4)$$

where k'' is the Kraemer dimensionless parameter.

It should be pointed out that German researchers often prefer Schulz–Blaschke equation (5) to determine $[\eta]$ [10]:

$$\eta_{sp}/c = [\eta] + k_{sb}[\eta]\eta_{sp} + ... \quad (5)$$

Equations (3)–(5) cover the range of dilute polymer solutions with $\eta_r \le 2.5$ (Fig. 1a).

Recently Fedors has derived a relationship, linear over a wide concentration range ($1 < \eta_r < 100$), allowing determination of $[\eta]$ from the slope of the plot presented in Fig. 1b:

$$[2(\eta_r^{1/2} - 1)]^{-1} = ([\eta]c)^{-1} - ([\eta]c_m)^{-1}, \quad (6)$$

where c_m is the concentration corresponding to the maximally dense packing of rigid equivalent hydrodynamic spheres.

At the same time, it is well known [3, 4, 12] that the dynamic viscosity of a polymer over a wide concentration range can be written as

$$\eta = \eta_0 e^{[\eta]c}. \quad (7)$$

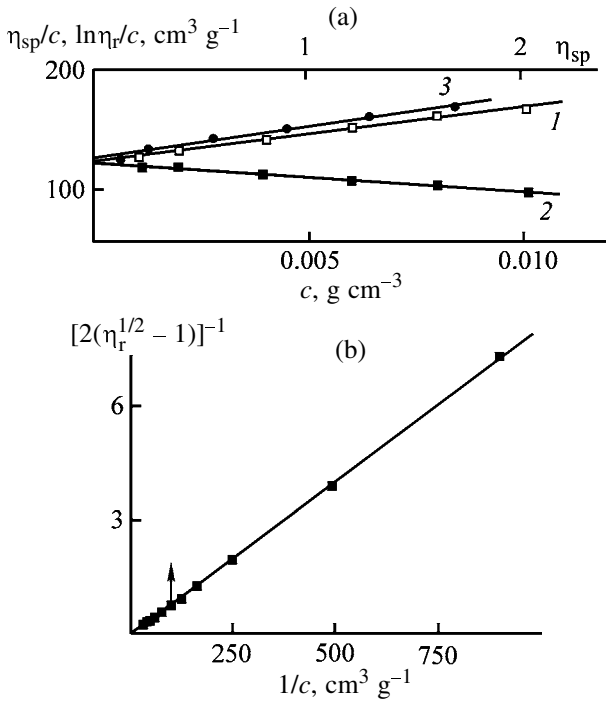

Fig. 1. Various methods for processing viscometric data for aqueous solutions of neutral PVP. (c) Concentration. (a) Concentration range in which $\eta_r \le 2.5$. Data processing according to (*1*) Huggins [Eq. (3)], (*2*) Kraemer [Eq. (4)], and (*3*) Schulz–Blaschke [Eq. (5)]. (b) Data processing by Fedors [Eq. (6)] over the entire concentration range. The arrow indicates the concentration at which $\eta_r = 2.5$. The range of dilute solutions is to the right of the arrow, and the range of moderate concentrations, to the left.

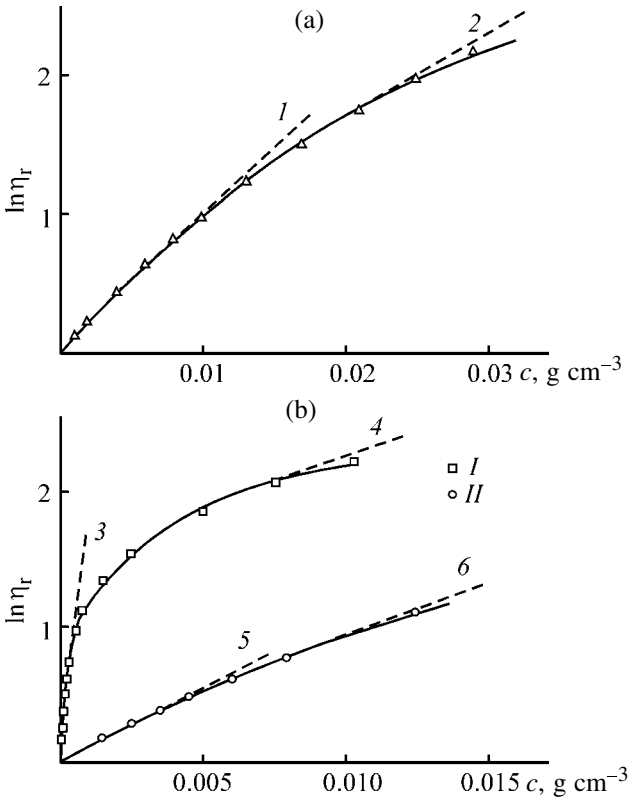

Fig. 2. Dependence of $\ln\eta_r$ on c for (a) PVP and (b) PSSN-1 solutions. (*I*) Aqueous salt-free solution and (*II*) 0.2 M NaCl. The slopes at given concentrations $c \times 10^2$ correspond to the following intrinsic viscosities $[\eta]^*$ (cm^3 g^{-1}): (a) (*1*) c = 0.6, $[\eta]^*$ = 95 and (*2*) c = 2.1, $[\eta]^*$ = 60; (b) (*3*) c = 0.021, $[\eta]^*$ = 1510 and (*4*) c = 0.76, $[\eta]^*$ = 70 (*I*); (*4*) c = 0.25, $[\eta]^*$ = 110 and (*6*) c = 0.87, $[\eta]^*$ = 75 (*II*).

It follows from Eq. (7) that $\partial\ln\eta_r/\partial c$ can be considered as the current intrinsic viscosity in any point of the dependence of $\ln\eta_r$ on c (Fig. 2) [12, 13]:

$$[\eta]^* \equiv \partial\ln\eta_r/\partial c. \quad (8)$$

It is clear that, at $c \to 0$, $[\eta]^*$ corresponds to the initial slope of the plot $\ln\eta_r$–c, coinciding with $[\eta]$ [Eq. (4)] for the isolated macromolecule.

At a finite polymer concentration, $[\eta]^*$ characterizes the specific volume occupied by the probe macromolecule placed into a solution with a uniform distribution of all other macromolecules. Such an approach can be considered as an experimental realization of the middle field concept. The $[\eta]^*$ changes with variation of the polymer concentration.

The method of determination of the intrinsic viscosity using Eq. (8) was employed in [12, 14] when analyzing the effect of compaction of the globules in flexible-chain polymers on passing to the moderate polymer concentration range in solvents of various thermodynamic quality, and also when interpreting the hydrodynamic behavior of rod-shaped macromolecules.

In our experiments we studied a sample of neutral poly(vinylpyrrolidone) (PVP, *MW* 400×10^3) [15]; samples of polystyrenesulfonates of various molecular weights: PSSN-1 (*MW* 920×10^3), PSSN-2 (*MW* 740×10^3), and PSSN-6 (*MW* 50×10^3) containing amino groups in each monomeric unit [16]; and a sample of sulfated *meta*-aromatic polyamide (*m*-PASA, *MW* 250×10^3) [17]. The viscosity was measured at 25°C on an Ostwald viscometer, and also on a Zimm–Crothers low-gradient viscometer [18, 19].

The table summarizes the results of processing of the viscometric data for PVP in water and for PSSN and *m*-PASA in 0.2 M NaCl. In the latter case, the primary polyelectrolytic effects in the PSSN and *m*-PASA chains are suppressed. It is seen that the $[\eta]$ values obtained by different methods [Eqs. (3)–(8)]

Intrinsic viscosity estimated by Eqs. (3)–(8) for poly(vinylpyrrolidone) in water and polystyrene sulfonates and sulfated *meta*-aromatic polyamide in 0.2 M NaCl at 25°C

Polymer/solvent	$[\eta]$, $cm^3\ g^{-1}$	k'	$[\eta]$	k''	$[\eta]$	k_{SB}	$[\eta]$	c_m, $g\ cm^{-3}$	$[\eta]^*$, $c \to 0$

are in satisfactory agreement. For polyelectrolytes (charged macromolecules), at $\eta_r < 2.5$, Eqs. (3)–(5) are nonlinear. In salt-free solutions, it is difficult to estimate $[\eta]$. At low polyelectrolyte concentrations, $\ln \eta_r/c$ and η_{sp}/c increase with decreasing c as a result of the polyelectrolytic effect (Fig. 3). This effect is caused by the fact that, with dilution, the volume in which the counterions are spread increases, thus reducing the screening of the charges fixed on the chain and strengthening their mutual repulsion. As a result, the size of the polyion increases. Thus, with decreasing ionic strength of the solution μ, the chain size increases by virtue of electrostatic repulsion between the monomeric units [20, 21].

For weak polyelectrolytes, with further decreasing concentration, we observed a maximum in the concentration dependences of $\ln \eta_r/c$ and η_{sp}/c. The nature of this maximum was discussed in [22, 23]. The data related to the ascending portion of these dependences can be linearized using the Fuoss empirical relationship [20, 24]:

$$c/\eta_{sp} = [\eta]^{-1} + (B/[\eta])c^{1/2}. \quad (9)$$

In the coordinates c/η_{sp}–$c^{1/2}$, the portion cut off on the abscissa is considered as the reciprocal intrinsic viscosity of a polyelectrolyte. However, the Fuoss equation is not always valid (Fig. 4).

As a more reasonable procedure for the determination of $[\eta]$ of polyelectrolytes, the isoionic dilution method was suggested [20, 25, 26]. In this case, the initial salt-free solution is characterized by the ionic strength controlled by the polyelectrolyte concentration and by the degree of dissociation of ionic groups. The polyelectrolyte solution is diluted with a solution of a low-molecular-weight salt whose ionic strength is equal to that of the initial salt-free solution of the polyelectrolyte. In practice, the concentration of the low-molecular-weight salt is selected so that the dependence of η_{sp}/c (or $\ln \eta_r/c$) on c be linear. Under-

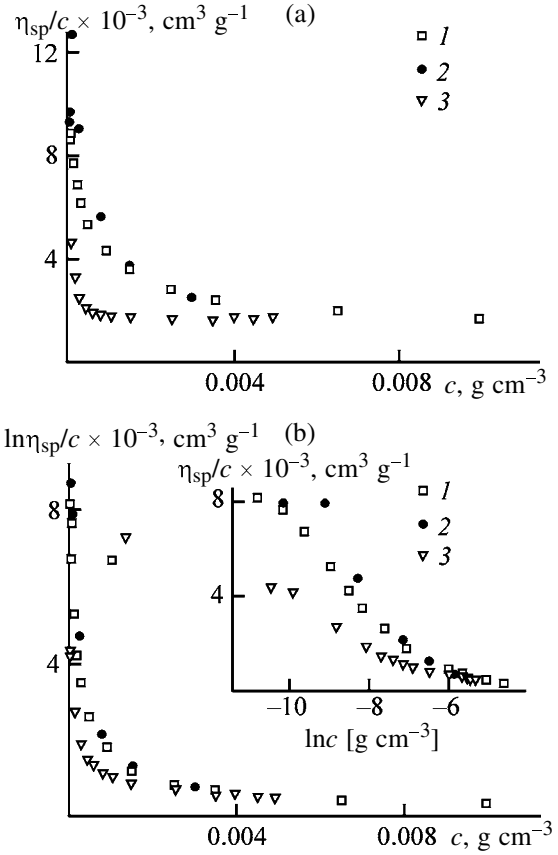

Fig. 3. Dependences of (a) η_{sp}/c and (b) $\ln \eta_r/c$ on c for polyelectrolytes in aqueous salt-free solutions. (*1, 2*) PSSN-1 and (*3*) *m*-PASA. Measuring technique: (*1, 3*) Ostwald capillary viscometer and (*2*) low-gradient rotary viscometer. In the insert (Fig. 3b), a logarithmic scale is used for the abscissa.

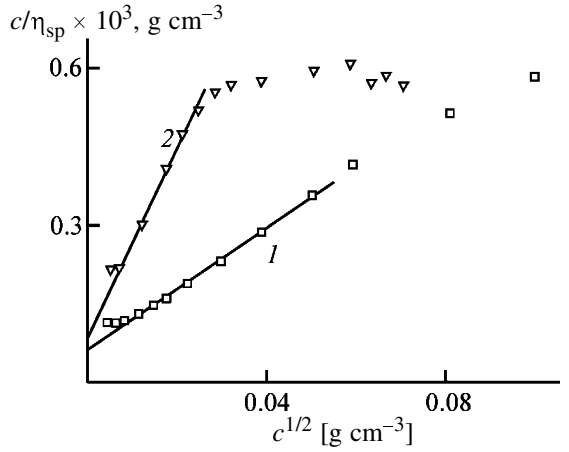

Fig. 4. Fuoss representation of data from Fig. 3: (*1*) PSSN-1 and (*2*) *m*-PASA.

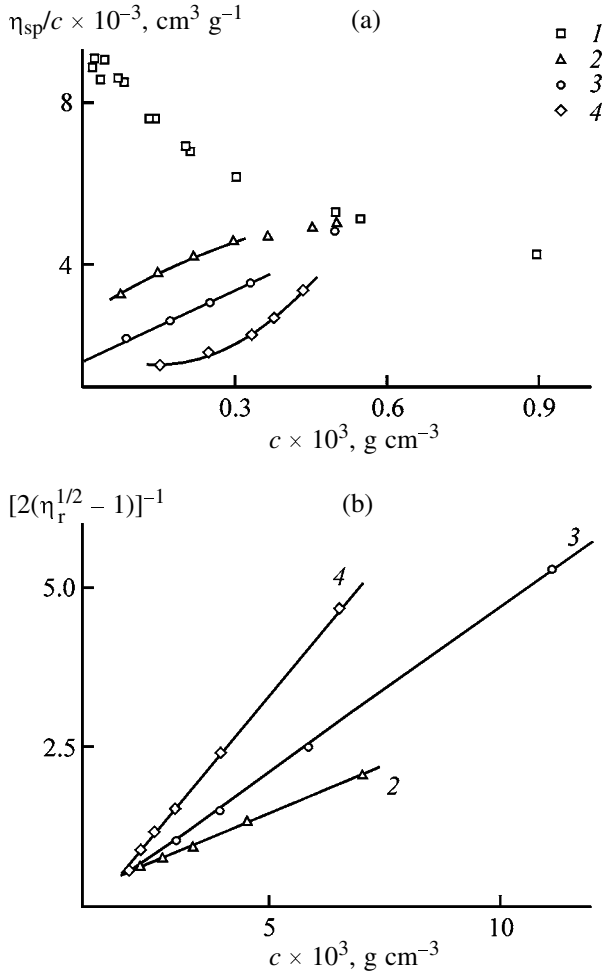

Fig. 5. (*1*) η_{sp}/c as a function of c in aqueous salt-free solution; (a) optimization of isoionic dilution conditions for PSSN-1 solution at the polymer concentration c = 0.5 mg cm^{-3} and (b) Fedors representation of data from Fig. 5a [Eq. (6)]. C_{NaCl}, mM: (*2*) 0.20 (undersalting of the buffer electrolyte), (*3*) 0.64 (isoionic dilution), and (*4*) 2.14 (oversalting of the buffer electrolyte).

or oversalting of the solvent distorts the linearity of the indicated dependences. The resulting dependences are well reproduced by second-order polynomials with opposite signs of the coefficients at c^2 (Fig. 5a). Therefore, the goal of optimization is to obtain a dependence with $\partial^2(\eta_{sp}/c)/\partial c^2 = 0$. In this case, the resulting dependence of η_{sp}/c (or $\ln \eta_r/c$) on c will be linear, allowing determination of $[\eta]$ at a fixed ionic strength.

We found that, in all cases of underestimation or overestimation of the ionic strength of the solvent containing a low-molecular-weight salt, and also in the case of isoionic dilution, the Fedors representations were linear (correlation factor $r > 0.9995$) over the entire concentration range of the polyelectrolyte (Fig. 5b). In this case, the dependence of thus obtained $[\eta]$ on the ionic strength was consistent with the dependence of the intrinsic viscosity obtained for flexible-chain polymers ($[\eta] \sim \mu^{-1/2}$) [27].

In our case, the NaCl concentration corresponding to the isoionic dilution was determined as an average between the concentrations meeting the conditions $\partial^2(\eta_{sp}/c)/\partial c^2 = 0$ and $\partial^2(\ln \eta_r/c)/\partial c^2 = 0$. The relative error of determination of this concentration was within 20%. Using the isoionic dilution method and Fedors representation, we determined $[\eta]$ of polystyrene sulfonate over the ionic strength range from 0.1 to 2.4 mM.

For PSSN-1, in the range of polyelectrolytic effects, very high intrinsic viscosities ($[\eta] > 2000$ cm^3 g^{-1}) are expected with isoionic dilution. In this case, the effect of the flow velocity gradient on the viscosity of the polymer solutions should be taken into account. This effect was examined on a Zimm–Crothers low-gradient viscometer [18]. The results are presented in Fig. 6 for the gradient range $0.1 \le g \le 7$ s^{-1}. The viscosity of the polymer solution appeared to be practically independent of the velocity gradient. The $\ln \eta_r$ values thus obtained are compared in Fig. 3 with the values obtained with the Ostwald capillary viscometer ($g \approx 700$ s^{-1}). As seen, these values are in satisfactory agreement.

As a rule, the concentration dependences of the relative viscosity in the salt-free solutions were measured with the Ostwald viscometer at 10–15 concentrations. At low concentrations, the concentration step was about 1×10^{-4}, and at high concentrations, 20×10^{-4} g cm^{-3}, allowing reliable determination of the slopes of the concentration dependences ($\partial \ln \eta_r/\partial c$) over the entire experimental concentration range including limiting dilution. With increasing polyelectro-

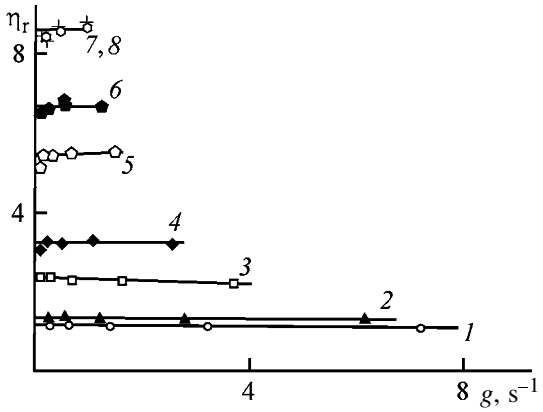

Fig. 6. Gradient dependences of the relative viscosity η_r in salt-free aqueous PSSN-1 solutions at various concentrations c (mg cm^{-3}): (*1*) 0.020, (*2*) 0.040, (*3*) 0.110, (*4*) 0.252, (*5*) 0.806, (*6*) 1.511, and (*7, 8*) 2.992. (*g*) Velocity gradient.

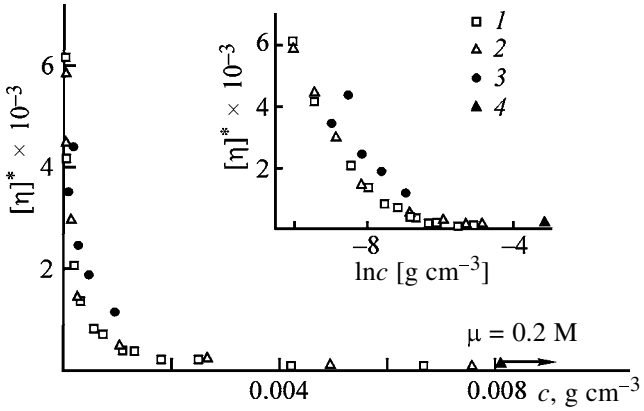

Fig. 7. Current intrinsic viscosity η^* as a function of the PSSN-1 concentration c in salt-free aqueous solution. (*1, 2*) Two independently prepared solutions, (*3*) intrinsic viscosity obtained in the isoionic dilution experiment, and (*4*) intrinsic viscosity obtained in 0.2 M NaCl. In the insert, logarithmic scale is used for the abscissa.

lyte concentration in water, the ionic strength of the solution increases, resulting in a decrease in the diameter of the globules and η^*. We have made a comparative analysis of $[\eta]^* = (\partial \ln \eta_r/\partial c)$ and $[\eta]$ obtained in the isoionic dilution experiment. These values appeared to be well consistent (Fig. 7).

Note also that $[\eta]$ obtained by the Fuoss extrapolation [when it is possible, i.e., when relationship (9) is linear] is, on the average, twice that obtained as $[\eta]^*_{c\to 0} = (\partial \ln \eta_r/\partial c)_{c\to 0}$, suggesting that the Fuoss extrapolation procedure provides overestimated volume occupied by the polyelectrolyte molecule at the infinite dilution in the absence of additional counterions.

To conclude, the viscometric data obtained in dilution of salt-free polyelectrolyte solutions were analyzed in terms of the current intrinsic viscosity using the Fedors and Fuoss relationships. Comparative analysis of the current intrinsic viscosity $[\eta]^* \equiv \partial \ln \eta_r/\partial c$ with the results obtained by the isoionic dilution method showed practical identity of the results obtained by these two methods. Therefore, in addition to the isoionic dilution method, we can recommend this considerably less time-consuming method for determination of the intrinsic viscosity of polyelectrolyte in salt-free solutions or at low ionic strengths.

CONCLUSION

The current intrinsic viscosity $[\eta]^* = \partial \ln \eta_r/\partial c$ proved to be an adequate parameter to describe the molecular properties of polyelectrolytes in salt-free solutions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Physicochemical Study of the Structure of Inorganic Electron and Ion Exchanger Based on Zirconium(IV), Molybdenum(VI), and Silicon(IV)

T. S. Bondarenko and E. S. Boichinova

Abstract—To elucidate the character of binding of water and hydroxy groups with a substance, the activation energy and the order of the dehydration reaction of an inorganic electron and ion exchanger based on zirconium(IV), molybdenum(VI), and silicon(IV) were calculated from the weight loss curve in the maximal loss region. To determine the structure of the synthesized electron and ion exchanger, its physicochemical properties were studied by X-ray phase analysis and electron microscopy.

DOI: 10.1134/S1070427206090047

To properly choose and efficiently perform the processes, it is necessary to calculate the parameters of sorption columns and the optimal amounts of sorbents absorbing various materials, which, in turn, requires knowledge of the physicochemical potential of the exchanger. We have shown previously that coprecipitation of zirconium(IV), molybdenum(VI), and silicon(IV) salts in a weakly acidic medium yields a compound differing from zirconium, molybdenum, and silicon oxides [1]. It was conventionally named zirconium silicomolybdate (ZSM). The synthesized granular product, according to IR and derivatographic data, is an individual inorganic compound containing residues of silicomolybdic heteropoly acid and exhibiting ion-exchange and redox properties, i.e., it is an inorganic electron and ion exchanger (EIE) [2]. The complicated IR spectrum and an ambiguous interpretation of thermal effects in the thermogravimetric curve called for a more detailed consideration of the ZSM dehydration, and the elucidation of the ZSM transformations and of the structure formation in the temperature regions corresponding to the main thermal effects required an X-ray phase analysis of samples and their electron microscopic examination.

The activation energy and reaction order (Table 1; Figs. 1, 2) for the ZSM dehydration suggest that the strengths of binding of water and OH groups in the exchanger are different. This assumption is supported by the comparison of the results of thermogravimetric analysis with certain published data (Tables 2, 3).

It was proved in [6] by IR spectroscopy that glassy tungsten-containing acids contain two types of H-bonds. Additional absorption frequencies related to nonequivalent water H-bonds were found in the spec-

tra. In papers concerning dehydration of hydrated titanium dioxide and tin hydroxide [7, 8], it was also concluded that water and OH groups are bound with different strengths in the sorbents under study.

The nature of transformations in ZSM and the formation of a structure were judged from the diffraction patterns of an air-dry sample and samples subjected to the corresponding thermal treatment in the regions of peak temperatures (Fig. 3). The interplanar spacings calculated from the diffraction patterns are given in Table 4; the ZSM thermogravimetric curve, in Fig. 4; and the interplanar spacings of individual compounds, in Table 5.

Figure 4 shows that a crystalline phase appears only on heating to 490°C and higher temperatures. The diffuse character of reflections in the diffraction pattern suggests the presence of a considerable fraction of X-ray amorphous phases. A comparative analysis of the reflections in diffraction pattern *3* (Fig. 3) and interlayer spacings in the polymeric modification of molybdenum oxides and in molybdenum trioxide, and also of zirconium dioxide reveals appearance of diffraction maxima at reflection angles of 6°–8°, 11.65°, and 13.5°. The first of them is rather weak and two other are better pronounced and can be assigned to molybdenum trioxide. According to published data [4], the first line of MoO_3 is of a medium intensity, and two other lines are strong. Apparently, a superposition of thermal transformations associated with a change in the state of the heteropoly anion structure is observed against the background of the formed crystalline structure on heating of ZSM at 490°C. Two

crystalline forms, polymeric molybdenum oxide and molybdenum trioxide, are apparently formed, which is supported by the fact that the sample acquires a pink color with a metallic tint. The behavior of individual silicomolybdic heteropoly acid on heating has been described in [5] (Table 3). The intensive line at 11.65° most likely belongs to a mixture of both forms of the oxides. The crystalline phase is less clearly manifested at reflection angles of 25°–27°.

After calcination at a higher temperature (620°C), the polymeric form of molybdenum oxide predominates in the diffraction pattern (Figs. 3, curve 4), and the sample becomes violet. In this range, an endothermic effect appears in the derivatogam (Fig. 4) without a noticeable weight loss. Apparently, the oxygen content in the system changes at this temperature, Mo(VI) is partially reduced to Mo(V), and one modification of molybdenum oxide transforms into another. Furthermore, an endothermic effect can take place without weight loss if, e.g., a finely crystalline phase transforms into a coarsely crystalline phase. The reflections characteristic of molybdenum trioxide become weak and smoothed. The diffraction maxima at 6°–8° and 13.50° become poorly discernible. Most likely, an additional energy consumption is associated with the transformation of the finely crystalline fraction existing at a lower temperature into a coarsely crystalline fraction (broad peak at 18.50°, smeared at the base).

The polymeric form of molybdenum oxide predominates and reflections of a mixture of modifications (monoclinic and tetragonal) of crystalline zirconium oxide become more distinct in the diffraction pattern of the ZSM sample obtained after calcination at 820°C. The sample transforms from a violet form into a white form with a grayish tint. The appearance of an exothermic effect in the thermogravimetric curve is associated most likely with the formation of a crystalline phase of zirconium oxide. Thus, the X-ray phase analysis shows that the character of the ZSM structure is retained on heating in the temperature range under study. The analysis also confirms that the compounds are individual and undergo complex phase transformations on heating.

The electron micrographs of the air-dry starting and reduced ZSM samples and of the samples regenerated from the reduced form have shown that all the three samples have a rather developed surface (Figs. 5a–5c). A predominantly finely porous structure with apparently smoothed parts is observed along with porous regions, which is clearly seen in the image of the sample oxidized again after regeneration. This conclusion agrees well with a low value of the total ZSM porosity of 0.02 $cm^3\ g^{-1}$ [9]. The apparent smoothness of surface regions is attributable to an insufficient magnification for microporous subjects studied in the microdiffraction mode. All the three abovementioned ZSM forms were studied. We were able to obtain a diffraction pattern only for the reduced ZSM sample (Fig. 5, Table 6). The interplanar spacings calculated from the diameters of rings point to a higher degree of crystallization of the reduced form, especially when we take into account the fact that the X-ray analysis is less sensitive compared to the electron microscopy.

EXPERIMENTAL

The activation energy and reaction order were calculated by the Freeman–Carroll method [10] for the part of the thermogravimetric curve corresponding to the heating to 200°C, where the weight loss is maximal (Fig. 4). The first endothermic peak is in the same region. The calculated data and plots are presented in Figs. 1, 2 and in Table 1. The calculations were performed as follows. Two dependences were constructed: $\log R$–$\log W$ and $\log R$–$1/T$. In both cases they are linear. The reaction order n was determined from the logarithmic dependence of the transformation rate on the weight using the slope of the straight line to the abscissa. The rate constant of the process k was

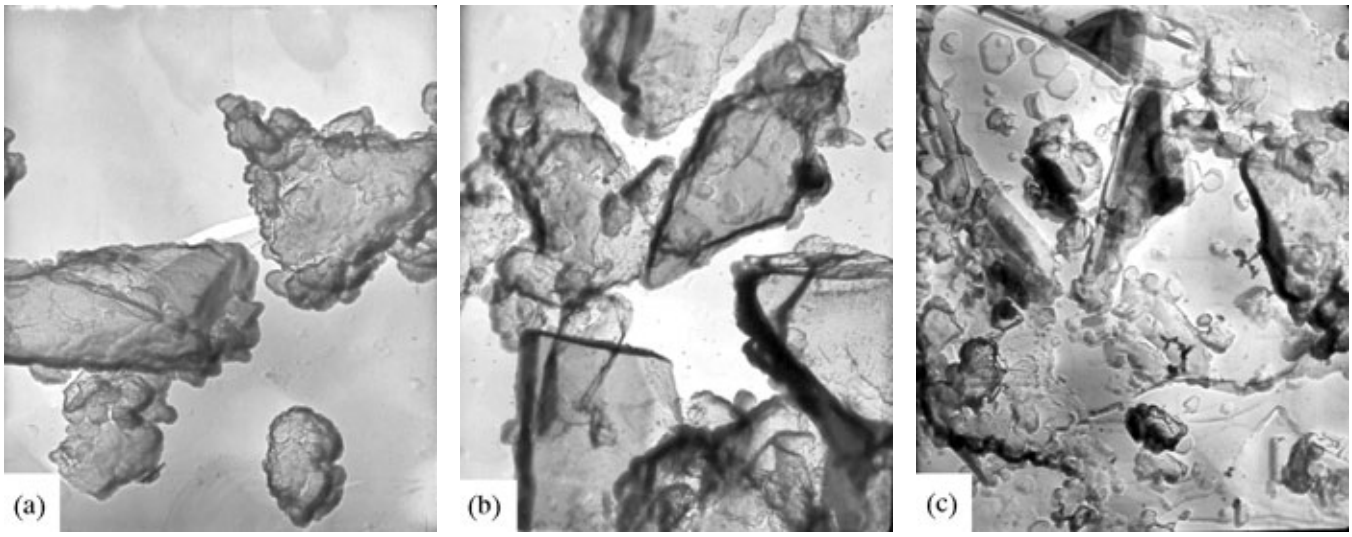

Fig. 5 . Electron micrographs of ZSM surface: (a) oxidized form, starting air-dry sample; (b) reduced form, air-dry sample; and (c) oxidized form regenerated from air-dry reduced form.

determined from the semilog dependence of the transformation rate on reciprocal temperature. According to the Arrhenius equation,

$$k = Ze^{E_a/RT},$$

where Z is the preexponential factor; E_a, activation energy of the process (kJ mol^{-1}); R, universal gas constant (J K^{-1} mol^{-1}); and T, absolute temperature (K).

From the above equation, we can find E:

$$\log k = E_a/2.303R \times 4.187.$$

The X-ray phase analysis was carried out on a DRON-2 diffractometer using nickel-filtered copper radiation. The diffraction patterns of the starting sample and the samples preliminary calcined at the temperatures corresponding to the main thermal effects in the thermogravimetric curve were recorded. The measurement rate was 3 deg min^{-1}. The error of the intensity determination was 3–5%. The reflection angles found from the diffraction pattern were transformed to interplanar spacings using Tolkachev's tables [11].

Table 6. Diffraction pattern of reduced ZSM form

Ring no.	Ring radius $2r$, mm	d, Å	Intensity
1	8.0	5.85	Strong, smeared
2	12.0	3.88	Strong, clear
3	18.0	2.59	Fairly clear
4	21.0	2.22	Weak, fairly clear
5	24.5	1.90	Weak, less clear
6	32.0	1.46	Weak, smeared
7	42.0	1.11	Weak, smeared

Parts of ZSM surface were detected as micrographs obtained by the method of carbon replicas with spraying or with extraction on an EVM-1000L electron microscope [12]. Magnification ×20 000. In the first case, hydrofluoric acid was used as a solvent, and in the second case it was a mixture of nitric and hydrochloric acids.

The samples of the reduced form and samples regenerated from this form were obtained by the technique described in [2].

The diffraction patterns were obtained in the microdiffraction mode [9]. As a standard for a device constant we used a plate of aluminum having a face-centered cubic lattice. Interplanar spacings d (Å) were calculated by the formula [13]

$$d = 46.6/2r,$$

where r is the radius (mm) and 46.6 is the device constant (mm Å).

CONCLUSIONS

(1) The calculations of the activation energy and the order of the reaction of zirconium silicomolybdate dehydration showed that binding energies of water and hydroxy groups are different.

(2) It was proved for the first time by X-ray phase analysis that zirconium silicomolybdate is an individual inorganic compound with its own structure.

(3) The surface structure of zirconium silicomolybdate was examined by electron microscopy, and the diffraction pattern of the reduced sample was obtained.

SORPTION AND ION-EXCHANGE PROCESSES

Recovery of Rhenium from Sulfuric Acid Solutions with Activated Coals

Abstract—Equilibrium and kinetic characteristics of rhenium sorption from sulfuric acid solutions (pH 2) by activated coals produced from coal raw materials (China) were studied. Constants of the Henry equation describing isotherms of rhenium sorption by activated coals were calculated. The effective diffusion coefficients of rhenium in the coals were determined. The dynamic characteristics of rhenium sorption and desorption were determined for the activated coal with the best capacity and kinetic characteristics.

DOI: 10.1134/S1070427206090059

Metallic rhenium and its alloys and compounds have unique physicochemical properties, owing to which they are applied in various high-technology branches of industry [1]. The fact that rhenium is a rare metal, and hence its concentrations in ores are low, complicates its recovery.

The hydrometallurgical processing of rhenium-containing raw materials produces sulfuric acid solutions in which rhenium is in the form of perrhenate ions. It is recovered by sorption on weakly basic and strongly basic anion exchangers [2]. From dilute solutions, rhenium is sorbed with activated coals, which allows its deep recovery [2]. The best results are obtained in acid solutions (pH 2–3).

In this study we examined the sorption characteristics of activated coals (ACs) with respect to rhenium. The coals were produced from coal raw material by Ningxia Hui Autonomous Region Import and Export Corporation (China) [3]. The choice of these coals is caused by their rather high specific surface area and low cost.

EXPERIMENTAL

The main characteristics of the activated coals used are given in Table 1. The capacity properties of the coals were studied under static conditions at room temperature with model sulfuric acid solutions (rhenium concentration 0.1 g dm^{-3}, pH 2) at a phase ratio (g : dm^3) coal : solution (S : L) = 1 : 0.5. The time of contact of coals with the solution was no less than 8 days. Desorption was carried out with 8% ammonia solution at a phase ratio S : L = 1 : 0.06. The rhenium content in the aqueous phase was determined photocolorimetrically according to the standard technique [4].

We obtained the rhenium sorption isotherms by varying the rhenium concentration in solutions within the range 50–200 mg dm^{-3}. The isotherms were processed using the Henry equation [5].

The kinetics of rhenium sorption by activated coals from sulfuric acid solutions was studied by the method of limited solution volume under the conditions described above (rhenium concentration in the initial solution was 0.1 g dm^{-3}). The integral kinetic curves of rhenium sorption were obtained within the time of the sorbent contact with solution from 5 to 11 520 min (8 days).

The rhenium diffusion coefficients were calculated using the equation taking into account the half-conversion time $\tau_{0.5}$ [6]. These coefficients were calculated by the formula

$$\bar{D} = \frac{kR^2}{\pi\tau_{0.5}},$$

where $\bar{D}$ is the effective coefficient of rhenium diffusion from the sorbent (m^2 s^{-1}); k, a coefficient depending on the size and shape of the coal particle; R, radius of a particle or of a sphere equivalent to the particle [4] (m); and $\tau_{0.5}$, half-conversion time (s).

The dynamics of rhenium sorption from sulfuric

Table 1. Characteristics of activated coals

Activated coal	Ash content, no greater than, %	Moisture, no more than, %	Density, no less than, %	Capacity for iodine, mg g^{-1}	Bulk weight, g dm^{-3}

AC-14	29.0	690	58	22.0	57
AC-15	28.8	678	58	11.3	40
AC-16	11.5	149	23	13.2	44

* (*a*) Weight capacity with respect to rhenium, (α) degree of sorption, and (β) degree of desorption.

The volume of activated coal in the column was 7 cm^3. The rhenium content was determined in the solution at the column outlet.

After the saturation of the coal with rhenium, it was washed with water to remove the residual initial solution. Rhenium was desorbed with an 8% ammonia solution, which was passed at a rate of 34 column volumes h^{-1}.

It is seen from the sorption–desorption characteristics of the coals (Table 2) that more than 50% of rhenium is recovered from solution by activated coals AC-1, -3, -4–7, -12, -14, and -15. Rhenium is efficiently eluted from coals AC-1, -4, -5, and -11–14. Thus, activated coals AC-1, -4, -5, -12, and -14 have the best sorption–desorption characteristics with respect to rhenium.

To compare the capacity characteristics with respect to rhenium in a wide range of its equilibrium concentrations, we have taken the rhenium sorption isotherms from sulfuric acid solutions (pH 2) with activated coals AC-1, -4, -5, -12, ad -14, and also with NORIT (the Netherlands) (for comparison), which exhibits high capacity (Fig. 1).

The resulting isotherms have a linear shape and are described by the Henry equation [4]. The Henry constants K (dm^3 g^{-1}) are given in Table 3.

The rate of rhenium sorption by the coals under study decreases in the order AC-4 > AC-12 > AC-1 > NORIT ≫ AC-14 > AC-5. The diffusion coefficients of activated coals are given in Table 4.

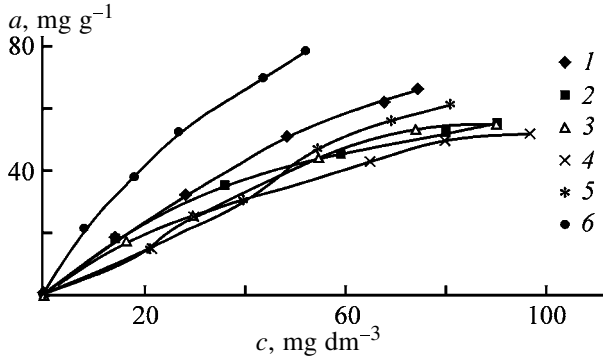

Fig. 1. Isotherms of rhenium sorption by activated carbons from sulfuric acid solutions (pH 2). (a) Weight capacity and (c) rhenium concentration in solution. Activated coal: (*1*) AC-1, (*2*) AC-4, (*3*) AC-5, (*4*) AC-12, (*5*) AC-14, and (*6*) NORIT.

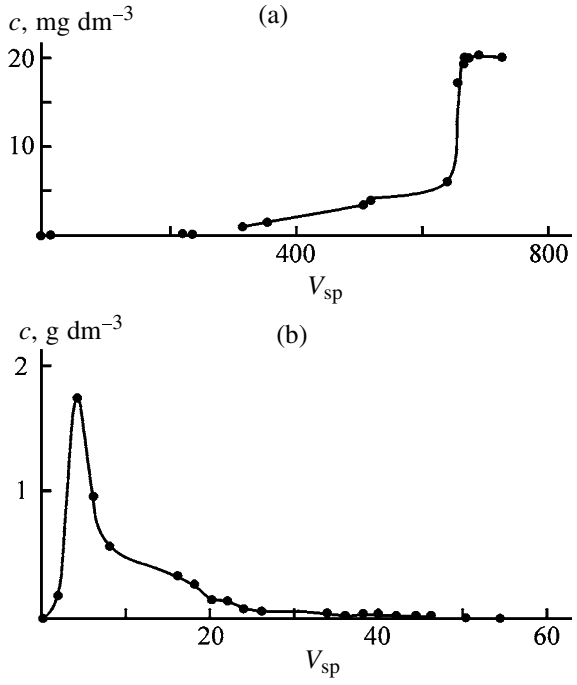

Fig. 2. (a) Breakthrough curve for rhenium sorptoin from sulfuric acid solution (pH 2) on AC-1 activated coal and (b) curve of rhenium desorption with 8% ammonia solution. (*c*) Rhenium concentration in solution and (V_{sp}) number of specific (column) volumes.

Table 3. Constants of the Henry equation

Activated coal	K, dm^3 g^{-1}	R^2	S
AC-1	0.90±0.06	0.986	2.9×10^{-3}
AC-4	0.66±0.06	0.978	7.5×10^{-3}
AC-5	0.69±0.07	0.967	10.5×10^{-3}
AC-12	0.57±0.03	0.989	1.8×10^{-3}
AC-14	0.77±0.03	0.993	6.9×10^{-4}
NORIT	1.6±0.21	0.948	22.4×10^{-3}

Table 4. Rhenium diffusion coefficients in activated coals

Activated coal	$\tau_{0.5}$, s	$\bar{D}$, m^2 s^{-1}
AC-1	780	1.3×10^{-11}
AC-4	480	2.6×10^{-11}
AC-5	1710	6.6×10^{-12}
AC-12	720	1.7×10^{-11}
AC-14	1800	7.1×10^{-12}
NORIT	1260	7.7×10^{-12}

For the AC-1 coal with the best sorption–desorption characteristics, we have taken the rhenium breakthrough curves (Fig. 2a) and desorption curves (Fig. 2b).

Figure 2a shows that rhenium is almost completely absorbed by AC-1 active coal from the first 320 specific volumes of the passed solution. The total dynamic exchange capacity for rhenium was 33 mg g^{-1}.

Rhenium is virtually completely washed out in a 20-column eluate volume, 80% of rhenium being concentrated in 3–5 column volumes.

We found that eluates with a rhenium concentration of 0.9–1 g dm^{-3} can be obtained by one sorption–desorption cycle when rhenium is recovered by AC-1 activated coal from a sulfuric acid solution (pH 2) containing 0.02 g dm^{-3} of rhenium.

We have carried out cyclic experiments on rhenium sorption–desorption by AC-1 activated coal under static conditions. Rhenium was sorbed from sulfuric acid solutions (pH 2) at a phase ratio (g ml^{-1}) S : L = 1 : 500; the desorption (two contacts) was carried out by 8% ammonia solution at a phase ratio S : L = 1 : 60. After three sorption–desorption cycles, the activated coal keeps its capacity characteristics: the degree of rhenium recovery (approximately 60%) has not changed.

CONCLUSIONS

(1) Among the examined activated coals (16 samples) produced from coal raw material (China), AC-1, -4, -5, -12, and -14 coals have the best sorption–desorption characteristics for rhenium extraction from sulfuric acid solutions.

(2) The use of AC-1 activated coal makes it possible to concentrate rhenium by a factor of 50 in one sorption–desorption cycle.

Abstract—The carbon material MNS, produced from shungite-III by successive alkaline and acid treatment, was studied. Cavitational treatment of an aqueous dispersion of the MNS material in the field of a standing acoustic wave converts a part of the substance into a material with a developed surface and a sorption capacity for hydrogen of up to 1.5%.

DOI: 10.1134/S1070427206090060

Development of inexpensive and reversible hydrogen accumulators is a topical task of modern science and technology because of the prospects for replacement (at least partial) of liquid fuels with hydrogen [1–3]. High hopes are pinned in this context on materials with considerable content of carbon nanotubes and other nanoparticles. However, on obtaining the first encouraging results [4–7] (not confirmed, but not refuted conclusively, either), an opinion was established that unmodified carbon nanoparticles can hardly provide a hydrogen accumulation level exceeding 1.5–2 wt % under atmospheric pressure [8]. With account of the high cost of carbon nanotubes, such a sorption capacity is insufficient for economically feasible applications. However, for an inexpensive material containing a nanocarbon component, e.g., industrial waste or abundant natural material, a capacity of 1–2% at 1 atm can be a starting figure for studies of the possible modifications of this material. The most promising, as regards the content of the nanocarbon component, among natural materials is shungite, which contains, together with noncrystalline carbon, also aluminosilicates and a minor amount of a bitumen-like organic material. Shungite-I [9] is the richest in carbon (up to 90%), but its cost is rather high, and resources, low. We believe that more promising for various applications, including hydrogen accumulation, is shungite-III with a carbon content of 30–40% [9] (the rest, 60–70%, is mainly constituted by aluminosilicates). The total amount of shungite rocks in the Onega basin exceeds 1 billion tons [10], and the resources of the largest Zazhoginskoe deposit are about 150 million tons.

The presence of the nanocarbon component (fulleroid structures of the type of multilayer nanotubes, nanobarrels, nanobulbs, etc.) in both shungite-I and shungite-III was first demonstrated in [11, 12]. As the shungite carbon as a whole, these structures are firmly bound to the aluminosilicate matrix [13], with both phases uniformly present even in a particle produced by micrometer grinding of a sample. Therefore, the application of shungites as catalyst supports [14], additives to concrete, etc. [15] is primarily based on grinding, rather than chemical treatment of the starting material. However, it is clear now that even a shungite of this kind is exceedingly promising.

An optimized technology for recovery of the carbon (hereinafter, nanocarbon) component of shungites markedly extends the potentialities of the resulting material, but does not lead to any significant rise in its cost.

The main technique for processing of the starting shungite-III included the following stages. A coarsely ground material (with particle size of up to several centimeters) was treated with molten NaOH in a graphite crucible at 500–520°C for 12 h in order to remove the aluminosilicate and silicate components.

Elemental chemical composition of the materials produced by chemical treatment of shungite-III

Processing method	Content, wt %								
	Na	Mg	Al	Si	S	Cl	K	Ca	Fe
Alkali without preliminary grinding and subsequent mild acid treatment (boiling HCl); MNS	0.5	<0.1	0.4	13.2	0.1	0.2	0.4	0.1	0.3
Treatment with HF/HNO_3 mixture without preliminary alkaline treatment	0.8	1.4	5.4	0.2	0.1	<0.1	0.5	2.2	0.8
Alkali with preliminary grinding to 50–100 μm, subsequent mild acid treatment (boiling HCl); MNS1	0.2	0.1	0.5	3.5	0.3	0.6	0.8	0.4	0.1

Further, the carbon phase was washed with water to remove trace amounts of the alkali and sieved to obtain a powder with grain sizes of 80–100 μm. The resulting material was subjected to a mild acid treatment in boiling nitric acid to remove metals, as well as metal oxides and poorly soluble salts, and to dissolve amorphous carbon and, partly, graphite, and washed with water to remove the residual acid.

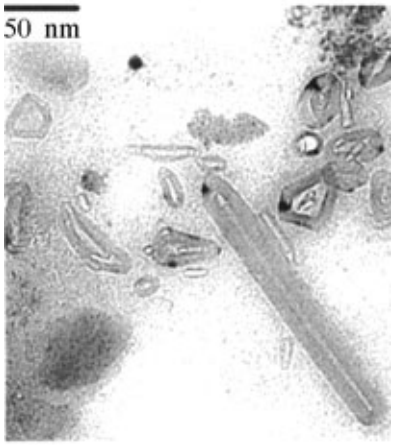

Fig. 1. TEM micrograph of modified shungite-III.

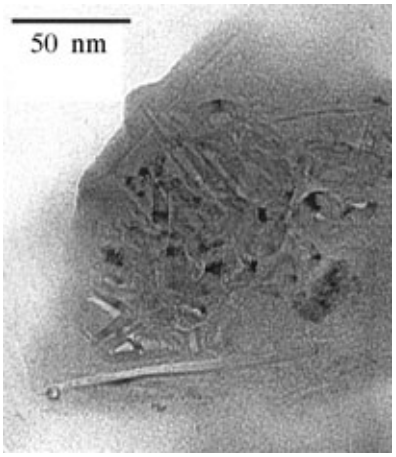

Fig. 2. TEM micrograph of a fragment of unmodified shungite-III.

The elemental composition of the thus obtained material (in what follows, MNS, modified nanoshungite) is presented in the table. It can be seen that, as a result of the treatment, the sample loses virtually the whole amount of aluminum, but retains a considerable amount of silicon (13 wt %). This content of Si yields the upper limit to the content of "concealed" carbon, judged from the approximate relative amounts of carbon and silicon in the starting shungite.

Typical electron micrographs of the nanostructures are shown in Fig. 1. The analysis was made on a JEOL JEM-100S transmission electron microscope (Japan) at magnifications of 10000–100000. Figure 1 illustrates a compact aggregation of nanoparticles nonuniformly distributed throughout the bulk of the material. It shows a hollow multilayer tube closed on both ends, with a large number of layers, channel diameter of about 3 nm, outer diameter of approximately 20 nm, and length of about 0.2 μm, and a set of nanobarrels and nonhollow nanobulbs. All the structures mentioned above are clearly separate from the silicate matrix. For comparison, Fig. 2 shows a fragment of the shungite material, which remained unsplit and has numerous fulleroid particles embedded in the aluminosilicate phase (naturally, the contrast of this micrograph is poorer than that of the preceding image).

The total amount of nanoparticles in the MNS material is up to 2%. The main structural motif of the rest of the carbon substance is constituted by short stacks of graphite-like layers [12]. Therefore, the carbon of this kind, which is different from that in

nanoparticles, is further designated as "graphite-like component," even though it is not subject to graphitization.

The possible enrichment of the MNS material with nanotubes and other nanoparticles must be due to removal of both this carbon and residual amounts of silicon. However, attempts of more thorough removal of silicon in order to improve the quality of the material proved to be inefficient. For example, treatment of the MNS material with a boiling $HF–HNO_3$ mixture (which is used, e.g., in decomposition of granites) results in that the amorphous and graphite components are effectively removed, as indicated by gravimetric measurements, but the amount of nanoparticles decreases dramatically. A similar pattern is observed in acid treatment of shungite not subjected preliminarily to the action of alkali, although silicon is removed in this case much more effectively (see table). The nanotubes preserved have a characteristic chopped structure, with the channels of the nanotubes not, nevertheless, cleaned (Fig. 3).

The possible reason for the inefficiency of the acid treatment is as follows. In contrast to nanoparticles synthesized in an arc or chemically grown by methods such as CVD [16] or HIPCO [17], shungite nanoparticles have the structure of imperfect, nearly amorphous fullerene caps [11, 12]. They are effectively destroyed by nitric and other strong acids. The nanoparticles are no less vulnerable than the graphite-like or amorphous component.

Similarly to the acid treatment, additional alkaline treatment of the MNS material fails to give positive results. The more effective removal of silicon is accompanied by a decrease in the amount of nanoparticles.

For example, a material richer in fulleroid particles and lower amount of silicates can be obtained from shungite-III, but this can only be done upon preliminary grinding of shungites to 50–100 μm. In this case, even a shorter alkaline treatment (three times in an hour) provides more effective removal of silicon than a three times longer treatment of unground shungite (see table). Also noticeable is the improvement of the material as regards the amount of nanoparticles, which now increases approximately twofold (to 3–4%).

The sorption capacity of MNS was studied by the volumetric method, using a version described, e.g., in [18]. The installation was intended for use in the static mode at pressures of up to 16 atm and temperatures of 20–30°C. The pressure drop in the gas medium upon introduction of a solid body was measured. A weighed portion of a shungite under study was placed in the adsorber and hydrogen was let-in from an auxiliary calibrated vessel (i.e., that in which the pressure, temperature, and volume were known). After equilibrium was attained by the system, the pressure in the adsorber and the amount of adsorbed hydrogen per unit mass of the sorbent were measured. The results obtained were used to plot hydrogen adsorption isotherms in the coordinates adsorption–absolute pressure.

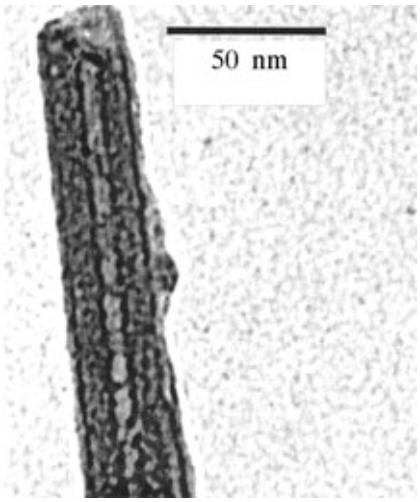

Fig. 3. Typical appearance of carbon nanotubes present in the shungite-based MNS material after an acid treatment with an $HF–HNO_3$ mixture.

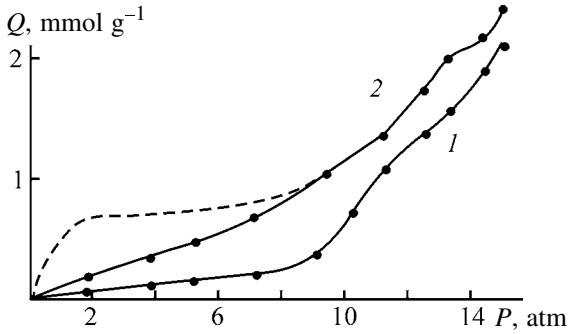

Fig. 4. Typical thermal desorption curves. (*Q*) Capacity and (*P*) pressure. Sample: (*1*) MNS and (*2*) MNS1. Dashed line, behavior observed for some MNS1 samples.

Typical thermal desorption curves are shown in Fig. 4 for MNS (curve *1*) and MNS1 (curve *2*) materials. At low pressures, curve *2* runs higher: at 2 atm the sorption capacity of the sample is about 0.05 wt %. If the whole capacity α_m is considered to be related to the nanocarbon component, then, in terms of this component, $\alpha_m \approx 1.2\%$, in agreement with the value commonly accepted for nanoparticles. Interestingly, a characteristic step was observed for some MNS1

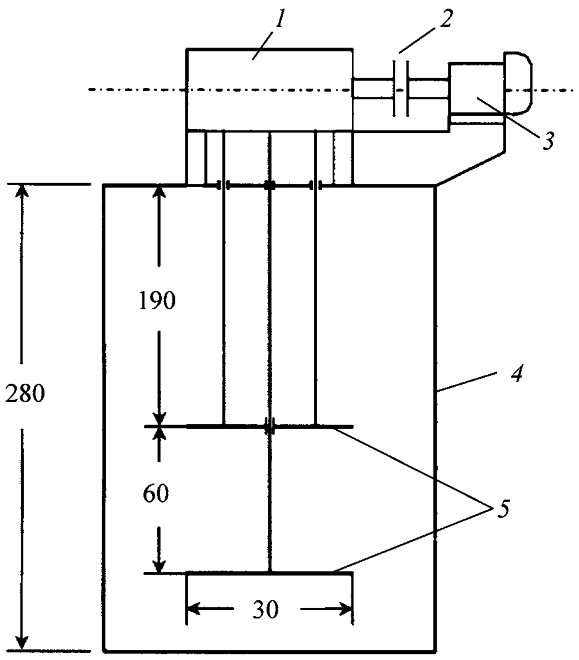

Fig. 5. Scheme of the vibrocavitational installation: (*1*) gearbox, (*2*) sleeve coupling, (*3*) UMT-22 electric motor, (*4*) frame, and (*5*) plates. The dimensions are given in millimeters.

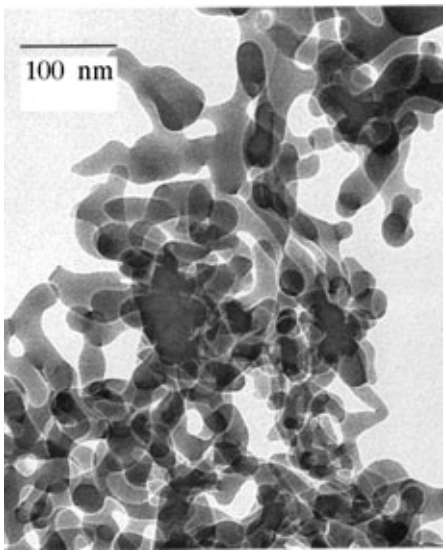

Fig. 6. TEM micrograph of a sample obtained upon vibrocavitational treatment of the MNS material.

samples at low pressures, and it seems natural to attribute it to the most actively sorbing component, the nanocarbon component. The height of the step in terms of the nanocarbon component may be as large as 3–4%, which corresponds to the best parameters for unmodified nanotube materials at moderate pressures.

Thus, the opportunity to use a shungite-based material for hydrogen accumulation may be furnished by separation of the nanocarbon component. However, the efficiency of such a separation is, as shown above, low. Nevertheless, attempts to stimulate the recovery of fulleroid particles from shungite yielded an unexpected side effect. In an experiment, an aqueous dispersion of a chemically treated shungite was placed in the field of a standing acoustic wave of rather low power (~60 W), which was created by plates oscillating in antiphase in water at a sonic frequency. The vibrocavitational installation for such treatment is shown schematically in Fig. 5. The total treatment time was 2.5 h. Then the suspension was allowed to settle and both fractions were analyzed: those settled at the bottom and floating on the surface. As can be seen from the electron micrograph of the floating fraction (Fig. 6), a totally different structure appears in addition to the usual shungite structure. Its "looseness" stands out: the structure is constituted by nanopores 5–20 nm in size and short wormlike projections 30–100 nm in size. A detailed study of the projection structure requires a resolution better than that available.

The structure of the material obtained is specific to shungite (e.g., a ground cathode deposit, enriched in nanotubes as a result of chemical treatment, formed a different nanoporous structure upon vibrocavitational treatment). The mechanism of its appearance may be as follows. In the course of a vibrocavitational treatment, part of graphitized stacks not fastened by the aluminosilicate matrix as a result of chemical etching fall out into the aqueous dispersion. After the action of the cavitator is complete, the energy of interaction between these stacks, associated with the dangling bonds at edges of graphite planes, must be at a minimum if the stacks are arranged "butt-to-butt" and further form a globule.

The share of the given fraction, floating up to the surface after each treatment session of the shungite material, does not exceed several percent so far, despite attempted optimization. Tentative measurements of the sorption capacity for hydrogen show that it reaches a value of 1.5% even under atmospheric pressure, the adsorption isotherm is of the Langmuir type, and the sorption process is reversible.

CONCLUSIONS

(1) Chemical treatment of shungite-III with a molten alkali and an acid can destroy to a considerable extent the carbon–silicon matrix and, simultane-

ously, preserve a large part of fulleroid (or nano-) structures contained in the starting shungite. In the process, the content of nanostructures not bound to silicon can be brought to the level of 1–2%.

(2) The method of treatment with preliminary grinding of shungite-III into ~100-μm fractions can raise the content of unbound nanostructures to 3–4%.

(3) The sorption capacity for hydrogen of the material produced upon such grinding and subsequent chemical treatment is high, but only conditionally, in terms of the nanocarbon component: 1.5–2 wt % at a pressure of 2 atm. However, real separation of fulleroid particles is difficult because of their high chemical activity, which does not noticeably differ from the chemical activity of the carbon component of shungites as a whole.

(4) A material with a high true sorption capacity for hydrogen (up to 1.5 wt %) can be produced from shungites by vibrocavitational treatment of preliminarily chemically modified shungite-III.

SORPTION AND ION-EXCHANGE PROCESSES

Specific Features of Modification of Activated Carbons with Steam and Hydrogen Peroxide Vapor at High Temperatures and Pressures

V. V. Sidorchuk

Institute of Sorption and Endoecological Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received February 14, 2006

Abstract—The effect of high-temperature treatment of activated carbons with water and hydrogen peroxide solutions on their pore structure, surface structure, and adsorption properties was studied.

DOI: 10.1134/S1070427206090072

It is known that steam treatment at 700–950°C is frequently used in the activation stage in preparing carbons from various raw materials [1–3]. Also, there is published evidence that the adsorption capacity of some carbon materials increases upon their modification in a flow of steam or as a result of treatment in an autoclave [4–6]. This apparently occurs both via development of a porous structure in these materials and because of an increase in the concentration of surface oxygen-containing functional groups [6, 7]. At the same time, no systematics studies concerned with this issue have been reported. Here we report certain results of autoclave modification of two carbons of different origins.

EXPERIMENTAL

Two kinds of carbons were subjected to vapor-phase treatment in a 45-ml autoclave: A2PS fruit-kernel carbon manufactured in Poland and SKN carbon prepared from an organic polymer. Distilled water, 10–30% aqueous solutions of hydrogen peroxide, and 10% aqueous ammonia served as modifying media. The treatment temperature was 250–350°C, and treatment duration, 3 h.

To calculate the pore structure parameters, nitrogen adsorption isotherms were measured with a Sorptomat instrument. These isotherms were used to determine by the methods described in [8] the following parameters: BET specific surface area, S_{BET}; surface area of micropores, S_{mi}, found by the de Boer method from *t*-plots; surface area of mesopores, S_{me}, determined by the Dollimore–Hill method; and volumes of micro- and mesopores, V_{mi} and V_{me}. Also, isotherms of adsorption of benzene and water vapor were obtained by gravimetry and used to calculate by the BET technique the specific surface area for benzene, $S_{C_6H_6}$ and the limiting-sorption pore volume for benzene, V_s, and to find the geometric surface area for water, S_g [9]. The adsorption of water vapor was also used to calculate the concentration of primary adsorption centers (PAC) [10]. The same installation served to measure adsorption isotherms of gaseous NH_3 and CO_2 in order to characterize the adsorption capacity of carbons in relation to the nature and concentration of functional groups on their surface.

Table 1 lists parameters of the porous structure of A2PS carbon upon its treatment at 250–350°C. It can be seen that, depending on the modification temperature and medium, a rather intricate pattern is observed and it is difficult to reveal any fundamental aspects. However, certain trends can be traced.

First, the specific surface area somewhat grows as the temperature and hydrogen peroxide concentration are made higher, because of the appearance of an additional microporosity, which is indicated by an increase both in the surface area of micropores by 120–200 $m^2 g^{-1}$ and in their volume by 0.05–0.07 ml g^{-1}. This is also indicated by the simultaneous steady rise in the combustion loss by the modified carbons to 10–12%. The micropore width was estimated [11, 12] to be 0.8–1.1 nm, and the mesopore size varied within the range 35–45 nm.

Second, the mesoporous component of the porosity (both S_{me} and V_{me}) remains virtually unchanged under the conditions studied, whence follows the con-

Table 1. Effect of the treatment conditions of A2PS carbon in an autoclave on its pore structure parameters

clusion that microporosity of carbon bodies is not converted into mesoporosity under hydrothermal condition, in contrast to oxide systems, in which this conversion is one of the principal aspects of hydrothermal modification of the pore structure. This is possibly due to difference between the mechanisms of porosity transformation in oxides and carbons. In highly dispersed oxide bodies, the pore structure parameters change through mass transfer over the surface and via solution and because of phase transformations at a constant mass of the solid. At the same time, treatment of carbons leads to intensive oxidation of the surface layer and partial gasification of the substance, with a decrease in the mass of the solid, i.e., a combustion loss by the carbons is observed, as in their activation [1, 2]. As indicated by the results of this study, the burning-out of carbon mostly occurs via appearance of new micropores, rather than at the surface of mesopores. At the same time, further oxidation is hindered by accumulation of gaseous products in the autoclave and decomposition of hydrogen peroxide. Therefore, a more significant change in porosity possibly requires a multiple treatment or an increase in the H_2O_2 concentration.

One more natural consequence of the oxidation of carbon is that the concentration of surface oxygen-containing groups considerably increases. The fact that the surface structures of the starting carbon and those modified under dissimilar conditions are different is demonstrated by the following experimental evidence.

(1) The difference between the values of S_{BET} and $S_{C_6H_6}$, on the one hand, and S_g, on the other, becomes less pronounced as the treatment temperature and H_2O_2 concentration are raised. This indicates that, simultaneously, the surface density of oxygen-containing groups increases and, consequently, the landing area for water molecules approaches the value characteristic of a hydroxylated surface [8].

(2) The shape of isotherms of water vapor adsorption changes after the treatment of carbons. Figure 1 shows that the adsorption isotherm for the starting sample is concave, i.e., belongs to type III by the BDDT classification, whereas upon modification in an autoclave, it tends to become a type-II isotherm with a convex shape in the initial portion [8].

To verify the assumptions made, the concentrations of PAC, which characterize the presence of just oxygen-containing functional groups on the carbon surface [10], were calculated from the isotherms of

* The value of μ was calculated by dividing the concentration c by the specific surface area found by BET from nitrogen adsorption isotherms.

water vapor adsorption. The data obtained for A2PS and SKN carbons are listed in Table 2. It can be seen that, as the treatment temperature and the concentration of the oxidizing agent are raised, the content of PAC on the surface of the carbons of both types steadily grows (both c and μ). The only exception is provided by samples modified with a 30% solution of hydrogen peroxide, for which a sharp decrease in the PAC concentration is observed upon treatment at 350°C, compared to the samples treated at 300°C. This may, in particular, be due to a more intensive H_2O_2 decomposition at the autoclave walls, rather than on the carbon surface, with a dramatic buildup of pressure at 350°C. Noteworthy is the fact that the absolute concentrations of PAC (per unit surface area) are, as a rule, rather close for both of the carbons under study upon treatment under identical conditions.

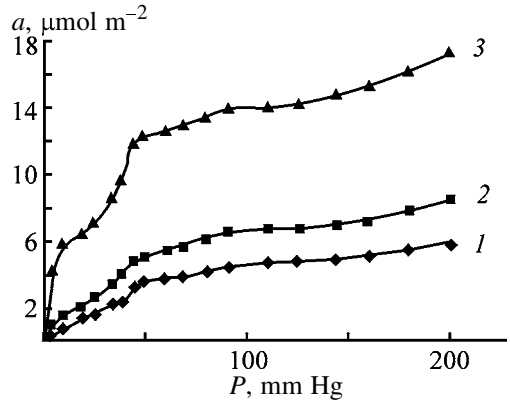

Fig. 2. Adsorption isotherms of gaseous ammonia at 20°C for A2PS carbon. (*a*) Adsorption and (*P*) ammonia pressure.

To elucidate the nature of the functional groups formed on the carbon surface in the course of treatment, the adsorption of gaseous ammonia and carbon dioxide was studied as suggested in [6]. The resulting absolute adsorption isotherms of gaseous NH_3 are shown for A2PS carbon in Fig. 2. The figure demonstrates a significant increase in the concentration of oxygen-containing groups upon modification with steam (curve *2*) and, especially, with a 10% solution of hydrogen peroxide (curve *3*), with the appearing functional groups having the acid nature. The steplike shape of the ammonia adsorption isotherms indicates that at least three types of acid adsorption centers are present on the surface of both starting and modified carbons and these centers are the most clearly pronounced upon modification of the carbon with an H_2O_2 solution. The strength of these acid centers corresponds to carboxy, phenolic, and lactone groups [1]. However, their unambiguous identification requires an additional study by other physicochemical methods.

As expected, treatments of carbon, including that in 10% ammonia, have virtually no effect on the surface concentration of basic groups.

CONCLUSIONS

The autoclave modification of activated carbons, and primarily that in hydrogen peroxide solutions, promotes noticeable development of their microporosity on raising the temperature and H_2O_2 concentration, with the mesoporosity remaining unchanged. Also, a significant rise in the concentration of acid functional

groups on the surface of carbons is observed in the process.

SORPTION AND ION-EXCHANGE PROCESSES

Chemisorption of Vapors of Organic Substances on a Modified Silica Gel

L. N. Grigor'ev and O. A. Shanova

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received March 31, 2005; in final form, December 2005

Abstract—Experimental data on the equilibrium and dynamics of chemisorption of vapors of organic substances on a silica gel modified with color reagents are presented.

DOI: 10.1134/S1070427206090084

Adsorption, which mainly proceeds by the physical mechanism, is widely used in industry for treatment of discharged gases to remove vapors of organic substances [1]. In recent years, the adsorption-catalytic method has found application. This method employs not only industrial catalysts [2], but also chemically active adsorbents [3–6]. Chemically active adsorbents are widely used in sampling (concentration of contaminants) of gases for analysis and directly in analysis of gases by proximate techniques, of which the linear-coloristic method is the best known [7]. This method consists in the following. A certain volume of a gas to be analyzed is passed in an evacuated vessel through a bed of an adsorbent (commonly, silica gel) saturated with a color reagent, and the reaction of the color agent with the adsorbed contaminant results in that a band of width L_{st} proportional to the concentration c_0 of the contaminant being analyzed changes its coloration. For the method to be used in practice, it is sufficient to construct the calibration plot characterizing the dependence $c_0 = kL_{st}$ (k is the proportionality factor). However, the linear dependence of the concentration of a substance being determined on the width of the colored band is not observed, especially at low concentrations. In this case, the relative error in determining the contaminant concentration may be as large as 60% [8]. In this context, it is of interest to obtain information about specific features of chemisorption of contaminants in the sampling and analysis of gas samples by the linear-coloristic method. Such information could not only improve the method (by diminishing the determination error), but also provide additional insights into the adsorption process and lead to the development of methods for calculation of adsorption processes accompanied by a chemical reaction on the surface.

The aim of this study was to reveal specific features of chemisorption of vapors of organic substances on a silica gel modified with color reagents.

The choice of color reagents (substances that change their coloration in reaction with contaminants) for modification is due to their practical use in systems for sampling (concentration) and analysis of gases and to the resulting simplification of the experimental procedure: if color reagents are used, variations of the amount of an adsorbed substance can be monitored visually, by changes in the bed coloration.

KSKG silica gel of the $(0.11–0.16) \times 10^{-3}$-m fraction, preliminarily heat-treated at 473, 673, and 973 K, served as an adsorbent (color reagent carrier). The silica gel was prepared for experiments and modified by the procedure described in [9]. A sulfuric acid solution of potassium dichromate was used as a modifying agent for determining the concentration of ethanol; sulfuric acid solution of potassium iodate, for toluene; and sulfuric acid solution of chromium trioxide, for acetone and diethyl ether (DE). A flow of a vapor–air mixture (VAM) was passed, using a UG-2 gas analyzer [9], through a bed of a modified adsorbent (indicator powder) charged into a glass tube with an inner diameter of 0.0026 m. In the process, the time in which a band of prescribed width (0.005–0.020 m) acquired coloration was measured. To determine the degree of saturation of the indicator powder in relation to the sampling duration, a VAM flow with contaminant concentrations of 200, 400, 600, 800, and 1000 mg m^{-3} was passed through tubes with an indicator powder (bed height 0.080 m), with the process duration varied in the range 5–230 s. The amount of the absorbed contaminant was found from the gain in the weight of the indicator powder during an experi-

673	$a = 0.22c$ ($a = 0.70c$)	$a = 0.60c$ ($a = 0.40c$)	$a = 0.15c$ ($a = 0.82c$)	$a = 0.28c$ ($a = 0.33c$)
973	$a = 0.18c$ ($a = 0.70c^{0.85}$)	$a = 0.52c$ ($a = 0.33c^{0.95}$)	$a = 0.21c$ ($a = 0.68c$)	$a = 0.52c$ ($a = 0.26c$)

ment. With the specific features of gas sampling with a UG-2 gas analyzer taken into account, model VAMs were prepared in the static mode, with the error in VAM preparation not exceeding 2.8%.

The adsorption isotherms of the contaminant vapor were plotted using the results of chromatographic measurements [11] with a Chrom-5 chromatograph equipped with a heat-conductivity detector (carrier gas helium). Figure 1 shows a chromatogram of toluene on unmodified silica gel preliminarily heat-treated at 473 K. The reproducibility of the peak areas was 1.39% in the case of introduction of 1 μl of the contaminant and 10.62% for 0.06 μl. Figure 2 shows the adsorption isotherm of a toluene vapor, plotted using the data of Fig. 1 with account of the conditions in which the chromatogram was measured: column temperature 353 K, flow rate of helium under the working conditions 17.5 ml min^{-1}, weight of the adsorbent in the packed microcolumn 0.012 g.

Table 1 lists the data obtained in processing of chromatograms of toluene and ethanol on silica gel calcined at various temperatures in terms of the Freundlich equation: $a = kc^{1/n}$, where a is the amount of adsorbed substance (mg g^{-1}); c, its concentration in the gas (mg m^{-3}); and n, k, constants. The processing was done with chromatographic peaks whose areas corresponded to contaminant concentrations in the range 10–200 mg m^{-3} and temperatures of 333–353 K. These values are the most typical for industrial ventilation gases [12]. The relative error in calculation of a by the equations listed in Table 1 does not exceed 5.24%.

It can be seen in Table 1 that, in the examined interval of the concentrations of ethanol and toluene vapors, the isotherms are linear: the exponent $1/n$ is equal or close to unity. For unmodified silica gels, the constant k decreases as the adsorption temperature increases, and also as the temperature at which the starting silica gel is calcined becomes higher. Similar dependences are observed in adsorption of toluene on the modified silica gel; in adsorption of ethanol, however, the constant k increases with the silica gel calcination temperature. A probable reason is that the chemical component of the process in adsorption of

* τ is the duration of coloring; w, linear velocity of the color change front in the bed; and L, width of the band of primary coloration.

toluene decreases as the concentration of the modifying agent becomes lower, which is favored by an increase in the temperature at which the silica gel is calcined. In addition, it is known that an elevated calcination temperature leads to formation of Si–O–Si siloxane bridges, which are not favorable to specific adsorption [13] of toluene (and do not promote the nonspecific adsorption, either). At the same time, no decrease in k is observed in the case of ethanol. This is presumably due to partial dissociation of siloxane bonds (at temperatures below 473 K) in adsorption on a calcined silica gel, which results in the formation of free radicals (≡Si–O$^{\bullet}$, ≡Si$^{\bullet}$) [14] with which ethanol can react.

Visual monitoring of how the coloration of the indicator powder varies in adsorption of vapors of ethanol, toluene, acetone, and DE from a VAM whose flow rate changed in the course of the experiment from the initial value to virtually zero demonstrated the following. The width of the colored band reaches its final value virtually at the initial instant of time, and then the coloration grows in intensity within the already formed colored band, with the most intense coloration observed in the first, along the VAM flow direction, portions of the bed.

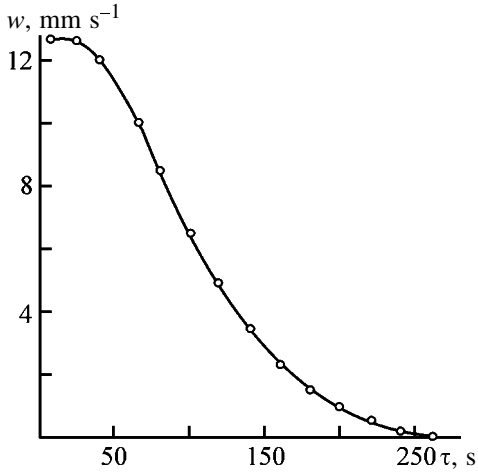

Fig. 3. Linear velocity w of the color change front in the bed of the indicator powder through which a VAM is passed vs. time τ.

The manner in which the sorbent coloration varies during the initial period of time after the VAM flow starts can be judged, in relation to the contaminant concentration, from the data in Table 2. These data suggest that the minimum time τ in which the primary coloration band is formed is 20 to 5 s for the concentrations c_0 ranging from 200 to 1000 mg m^{-3}, respectively.

Figure 3 shows that, at the initial instant of time (20 s) corresponding to the formation of the primary coloration band, the linear velocity of the color change front in the bed is virtually constant and has the maximum value. Further, the velocity decreases, which is accompanied by a decrease in the width of the color change band and, consequently, in the length of the mass-transfer zone. It is the variation of these parameters that is responsible, in the authors' opinion, for the above-mentioned deviation of the calibration plot from the straight line.

It has been shown previously [15] that the linearity of the calibration plot can be achieved if the rate at which the VAM flow is passed is maintained constant. It follows from Fig. 3 that this condition can be satisfied if the gas is sampled during a short time (20–25 s). In this case, the dependence $c_0 = k_0 l/\tau$ (where τ is the time in which a band of prescribed width is colored, and k_0 is the proportionality factor), which was suggested in [10] for the calibration plot, becomes substantiated. In view of the fact that, as follows from Fig. 1, τ should not be large, there is no need to pass the whole volume of the gas in its sampling for analysis and, for obtaining the desired result, it suffices to record the time in which the coloration changes in a band of a prescribed width l. In this case,

$l \ll L$ and, consequently, smaller amounts of fresh silica gel and modifying agent (color reagent) are necessary if the calibration plot in the c_0–l/τ coordinates is used to determine the contaminant concentration. This, in turn, leads to a decrease in the resistance of the VAM sampling system and allows use of electric aspirators instead of the commonly employed mechanical air-sampling devices of the bellows and piston types.

Figure 4 shows how the width of the colored band formed in the initial stage after the gas flow starts to be passed depends on the contaminant concentration.

The experimental results were processed using the Shilov–Mecklenburg equation in the following form:

$$c_0 = a_0/w\tau(l - h) = k'(l - h), \quad (1)$$

$$l = (c_0/k') - h, \quad (2)$$

where $k' = a_0/w\tau$ characterizes the amount of substance absorbed along the unit length of the sorbent when a unit volume of the gas is passed; a_0, amount of the contaminant absorbed when a primary colored band is formed; l, width of the band in which the coloration changes in time τ; h, unused bed height; and w, linear flow velocity of the gas in the free cross section of the tube filled with the sorbent.

The above formulas and data in Fig. 4 were used to find, for ethanol, toluene, acetone, and diethyl ether, values of h and k' (Table 3), which make it possible to determine the minimum width of the colored band for any c_0.

Also of interest in a study of the chemisorption of contaminants on the indicator powder is the time distribution ($\tau > 20$ s) of the concentrations of the substance being determined within the band in which coloration was formed at the initial instant of time.

The experimental and calculated data, presented in Table 4 and Fig. 5, made it possible to assess the manner in which the coloration of the adsorbent bed varies when the whole volume of VAM is passed through it. For example, the data for ethanol (V = 0.4 l) are given in Table 4.

A verification of whether the K_{eth} values belong to the same sample by the test [16]

$$Q = \frac{K_X - K_N}{K_M - K_1},$$

(K_X, questionable value of K; K_N, neighboring value of K; K_M and K_1, extreme values of K in a sample arranged in the order of increasing numerical values) demonstrated that all values of K belong to the same sample. The average value of K is (0.043 ± 0.005) s^{-1}.

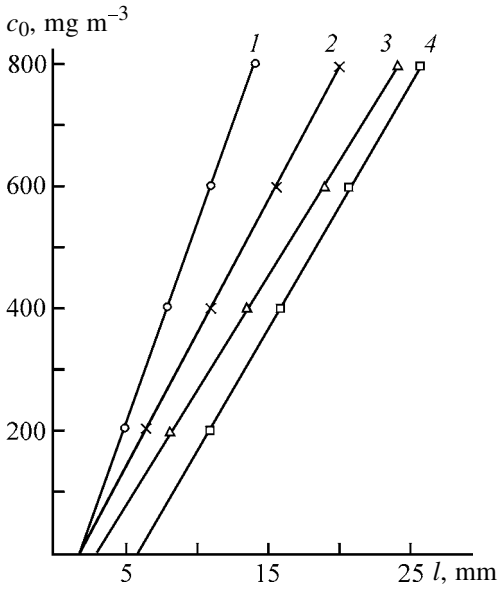

Fig. 4. Effect of the contaminant concentration c_0 on the width l of the colored band formed in the initial stage after the gas flow starts to be passed. (*1*) Ethanol, (*2*) diethyl ether, (*3*) toluene, and (*4*) acetone.

Thus, it can be taken that, in the concentration range 200–1000 mg m^{-3}, K is constant at a confidence level of 0.95.

Table 3. Values of h and k' for organic substances of various classes

Substance	h, mm	k', g m^{-3} m^{-1}
Ethanol	2.0	42.6
Toluene	2.5	36.4
Acetone	6.5	52.6
Diethyl ether	1.6	60.6

Table 4. Parameters of chemisorption of the ethanol vapor*

c_0, mg m^{-3}	ν, ml s^{-1}	v, ml	$K = \nu/v$, s^{-1}
200	0.00130	0.0265	0.050
400	0.00175	0.0424	0.041
600	0.00223	0.0583	0.038
800	0.00328	0.0848	0.038
1000	0.00530	0.1113	0.047

* ν is the flow rate; v, volume of the indicator powder in which the coloration changed; and K, rate constant of the coloration variation.

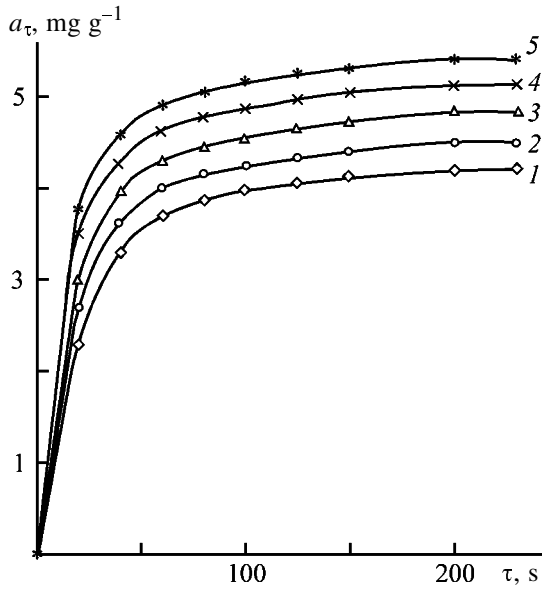

Fig. 5. Time distribution of the ethanol concentration (bed height l = 5 mm). (a_τ) Dynamic adsorption value and (τ) time during which the VAM flow is passed. c_0, mg m^{-3}: (*1*) 200, (*2*) 400, (*3*) 600, (*4*) 800, and (*5*) 1000.

Figure 5 shows how the amount of ethanol absorbed by the indicator powder varies with the initial concentration and time during which the VAM flow is passed.

The type of the curves in Fig. 5 allows the variation of the ethanol concentration in the indicator powder, a_τ, to be represented as the equation

$$a_\tau = a_0(1 - e^{-0.043\tau}), \quad (3)$$

where a_0 is the amount of ethanol absorbed by unit weight of the indicator powder for the time in which the whole volume of VAM is passed.

Equation (3) furnishes an opportunity to calculate the amount of adsorbed substance for different instants of time.

The aforesaid suggests, with account of the fact that the flow rate of VAM was varied in the experiments from the initial value to zero, the following: the resistance to the process from the gas phase is at a minimum because the value of K is independent of the linear velocity (flow rate) of the VAM and, in all probability, depends on the type of surface and color reagent, temperature, and presence of concomitant substances in the vapor–gas mixture.

Similarly to the example of ethanol, Eq. (3) is valid for other substances (K_{toluene} = 0.026, K_{acetone} = 0.032, K_{DE} = 0.034 s^{-1}).

It should be noted that expression (3) is valid at times longer than 20 s. In the initial period of time (0–20 s), when the fraction of the active surface is at a maximum, the rate of conversion (of change in coloration) is virtually independent of the concentration of the substance being determined.

For example, at the initial instant of formation of the coloration front, the expression for the conversion rate w has the form

$$w = 19.47c_0^{0.225}, \quad (4)$$

where 19.47 is the rate constant of color variation.

The maximum error of calculation by Eq. (4) is 5.31%.

CONCLUSIONS

(1) The rate constants of the Freundlich isotherm equation were determined for describing the adsorption of vapors of organic substances of various classes on unmodified silica gel and that modified with oxidizing agents, and the manner of their variation with the adsorption temperature and the temperature of calcination of the starting silica gel was revealed.

(2) It was found that, at temperatures in the range 60–80°C, the constant 1/n is independent of the type of contaminants and adsorption temperature, and the constant k decreases as the adsorption temperature is raised for all classes of substances. As the calcination temperature is raised, the constant k decreases for the unmodified silica gel, and decreases or increases in adsorption of, respectively, nonpolar (toluene) or polar (acetone, ethanol, diethyl ether) substances for the modified silica gel.

(3) The conditions under which vapors of toluene, ethanol, acetone, and diethyl ether are chemisorbed (minimum bed height of a modified silica gel; duration of coloration variation within a prescribed bed height) were determined. These conditions can be used in analytical determination of the concentrations of these substances in a vapor–air mixture by the linear-coloristic method at a lower inaccuracy of the final result.

(4) An equation was suggested for calculating the amount of a contaminant absorbed in chemisorption in relation to time and its concentration in the flow of a vapor–air mixture.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Molybdenum Oxide and Its Structural Characteristics

Abstract—The cathodic processes in electroplating of compact molybdenum oxide coatings onto supports made of 12Cr18Ni9Ti steel and aluminum are considered along with the physicochemical characteristics determining their service properties.

DOI: 10.1134/S1070427206090096

Electrolytic molybdenum oxide is a promising cathode material for lithium batteries, because it has satisfactory tendency to cycling and stable reversible capacity within 200–250 mA h g^{-1} [1]. The conditions of its preparation have been considered in [2, 3]. The electrosynthesis method is advantageous in that it allows preparation of both fine deposits and compact coatings on the support made of stainless steel or aluminum. This makes it possible to manufacture effective ballastless cathodes by the direct oxide deposition onto the body of the cell of a chemical power source.

In the above studies, problems concerning the mechanism of the cathodic deposition of oxide molecules, formation of molecular crystalline deposit, and its physicochemical characteristics were not considered. These data seem also useful for optimizing the synthesis conditions and refining the existing concepts in the field under consideration. This was the subject of the present study.

The electrochemical characteristics of the electrolytic molybdenum oxide are a subject of a separate study not considered here.

Test deposits were prepared in the form of compact coatings on smooth plates of $10 \times 20 \times 0.3$ mm size made of 12Cr18Ni9Ti steel and AMG-6 aluminum. The electrolysis was performed in saturated (0.2–0.25 M) and dilute (0.005–0.01 M) solutions (pH 6.5–7.0) of ammonium molybdate $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ at 80–85 and 20–25°C, respectively, and a cathodic current density of 3.5–7.0 mA cm^{-2}. Preliminarily, the steel plates were degreased with Vienna lime and activated in concentrated hydrochloric acid for 3–5 min. Aluminum plates were etched in a 5–6 M NaOH solution and activated in dilute HCl solution (1 : 4). The aluminum plates were loaded into the cell under the current. The polarization curves in the range I_c = 1–50 mA cm^{-2} were measured relative to a silver chloride reference electrode using a Ts-413 digital voltammeter. The partial curves were constructed on the basis of the nominal current efficiencies by molybdenum oxide (ox-Mo) (CE_{nom}) [3]. The adhesion and mechanical resistance of the deposits were determined qualitatively from the weight loss of the sample with an oxide coating after a 180° bending. The microstructure of the surface of the coatings (1.5–3.5 μm thick) on a 12Cr18Ni9Ti steel support was studied by the atomic-force microscopy (AFM) on a nanoscope. The phase composition of the deposits was determined by X-ray diffraction (CoK_α radiation, DRON-2 diffractometer). The chemical composition of the deposits was determined by thermogravimetric and spectral analyses.

The possibility of depositing ox-Mo in a quantitative yield by cathodic reduction during electrolysis of an aqueous solution of ammonium molybdate salt under the practicable conditions has been established in [2, 3]. The product containing the nonstoichiometric oxide compound of the composition $Mo_4O_{11} \cdot nH_2O$ as major component is deposited on the cathode [3]. This fact indicates that the discharge of MoO_4^{2-} ions and the phase transition with formation of the three-dimensional molecular lattice, which are the interrelated processes occurring on the cathode, have the complex kinetic character. The process starting from the molybdate ion discharge and terminating when a compact ox-Mo deposit is formed on the cath-

ode involves three steps: (1) discharge of MoO_4^{2-} ions and formation of the intermediate oxide radicals (MoO_2^+, MoO_2, MoO^-_3, and other radicals), (2) adsorption of intermediate oxide radicals on the cathode surface, and (3) simultaneous formation of a Mo_4O_{11} structural fragments and molecular crystal lattice.

The mechanism of this process is not clearly understood yet. At the same time, it is evident that it can be realized exclusively by multistep formation of a complex molecular compound ox-Mo.

The total (curve *1*) and partial polarization curves of the ox-Mo deposition (curves *3*–*5*, *5*') and hydrogen evolution (curve *2*) from ammonium molybdate solutions in the E–$\log I$ coordinates are shown in Fig. 1. All the dependences are strictly straight lines. The slopes and positions of the curves depend on the solution concentration and temperature. An increase in these parameters leads to a shift of the ox-Mo deposition curves toward lower cathode potentials (curves *3, 4*). The slope of the curves of the H_2 evolution from concentrated solution (curve *2*) and those of the ox-Mo deposition from concentrated solution (curves *3, 4*) is the same ($\partial E/\partial \log I$ = 0.58 V). For the curve of the ox-Mo deposition from dilute solution (curve *5*) this value is abnormally high (1.15 V). The partial curves of the ox-Mo deposition have an inflection whose position with respect to the $\log I$ axis depends on the solution concentration and temperature and corresponds to the limiting attainable current. The sections of the curves above the inflection points have different slopes corresponding to the rate at which the main process occurs in the limiting region under the given conditions of the electrolysis. The total curve *1* taken in dilute solution lies at a certain angle with respect to the partial H_2 evolution curve taken in the same solution. Hence, it follows that, in the limit, the main process is completely replaced by the H_2 evolution.

The high values of the slope coefficients of these dependences do not fit well into the known theory [4]. At the same time, satisfactory interpretation for the observed phenomenon can be given. For example, delayed migration, mainly via convection and molecular diffusion, of MoO_4^{2-} ions toward the cathode surface is likely to make the major contribution to the $\partial E/\partial \log I$ coefficient. This is clearly seen in the partial curve of ox-Mo deposition from dilute solution (curve *5*). The slope of the curve (1.15 V) decreases to 0.87 V after vigorous stirring of the solution (curve *5*'). Similar effect is attained with increasing solution concentration and electrolysis temperature (under other conditions equal). In this case, the corresponding dependences (curves *3, 4*) are shifted to lower cathode potentials and the slopes decrease to 0.58 V. Theoretically, this effect is substantiated by the known relationship of the electrochemical kinetics accompanied by concentration polarization [5]. The large slopes of the curves may also be due to the multistep character of the cathode process, typical of electrodeposition of some metals [6]. In the given case, the same role can be played by the filling of the cathode surface with adsorbed hydrogen, oxide molecules, and intermediate oxide radicals [4]. These factors, along with the mutual influence of conjugate cathodic reactions proceeding simultaneously, can also be responsible for the large slope of curve *2* of the H_2 evolution.

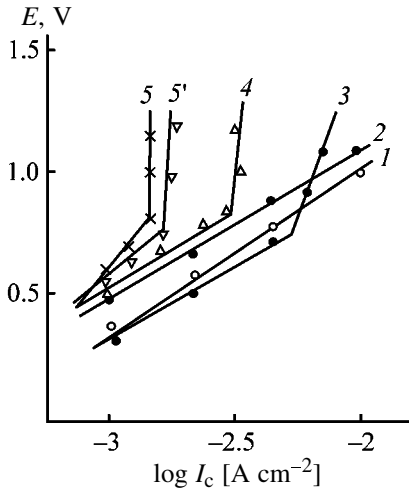

Fig. 1. Cathode potential E vs. $\log I_c$ of the molybdenum oxide deposition from ammonium molybdate solution (pH 6.5–7.0). Concentration of ammonium molybdate solution, M: (*1, 2, 5, 5*') 0.01 and (*3, 4*) 0.25. Curves: (*1*) total, (*2*) partial of H_2 evolution, (*5, 5*') partial of ox-Mo deposition at 20°C with and without stirring the solution, respectively, and (*3, 4*) partial of ox-Mo deposition at 80 and 20°C, respectively.

The complex kinetic behavior of the processes studied substantially impedes determination of the true value and character of the cathode polarization. Approximate estimate of the latter, based on the difference between the initial potential of the ox-Mo deposition (about –0.4 V) and the rest potential of the molybdenum oxide electrode on the 12Cr18Ni9Ti support (–0.12 V) in a 0.25 M test solution shows that the ox-Mo cathodic deposition proceeds at a fairly high polarization. Evidently, the MoO_4^{2-} ion discharge, whose rate largely depends on the intensity of the leading reaction of H_2 evolution, is the potential-determining stage in this case.

Approximate limiting thicknesses of ox-Mo coatings on 12Cr18Ni9Ti and aluminum supports, corresponding to break and complete failure of the sample along bending lines

Conditions of ox-Mo electrodeposition	Limiting coating thickness, μm, at indicated annealing temperature, °C			
	no annealing	180	250	350
Solutions:				
saturated	15–20	5–7	2–3	0.5–1.5
	45–55	25–30	10–15	5–7
dilute	10–15	3–5	1.5–3	0.5–1.0
	35–50	25–30	7–12	2–5

The Mo_4O_{11} molecule, primary product of the electrochemical phase transformation localized on the cathode surface, is a small three-dimensional unit "crystal" constituting the unit cell. Based on the atomic representation of the crystal nucleation, such a "crystal" may be considered as the initial crystallization center with a large excess of free energy [7]. The energy stability of the "center" and its fixation to the cathode surface are attained after applying an additional potential, which compensates the work spent for the destruction of the center. This "superpotential" simultaneously ensures spontaneous development of the nucleus to a certain size corresponding to the minimum of the free surface energy of the system. Apparently, this process is facilitated by the three-dimensional structure of oxide molecules. Indirectly, the superpotential may also be manifested in the higher slopes of the ox-Mo deposition curves.

Irrespective of preparation conditions, the ox-Mo coatings prepared on 12Cr18Ni9Ti steel supports have smooth black surface with a slight bluish tint. No visible defects such as cracks, voids, porosity, or thrown-on particles were found. The deposits prepared from saturated ammonium molybdate solutions at 80–85°C are slightly lustrous, and those prepared from dilute solutions on an aluminum support at low temperatures are relatively dull. The nonannealed deposits are compact coatings. Such coatings 20–25 μm thick on stainless steel support have fairly high mechanical resistance including that against mechanical abrasion. Heat treatment considerably deteriorates the coating characteristics.

The approximate values of the thickness of the electrolytic ox-Mo coatings on a stainless steel support, above which the sample is broken completely along the bending line, are presented in Table 1 as results of many tests. For the same coatings on aluminum support, these values are higher by a factor of 2–3, but are insufficiently reproducible. The values presented determine the limiting thickness of ox-Mo coating, above which the adhesion and mechanical resistance are zero for the given conditions of their deposition and subsequent heat treatment. The higher the annealing temperature, the smaller the coating thickness below which satisfactory adhesion and inner volume mechanical resistance are preserved. The impossibility of depositing thicker coatings may be caused by simultaneously occurring processes: coarsening of crystals upon annealling and weakening of bonds between grains along their boundaries owing to the different linear thermal expansion of the coating and the support. Along with this, the above characteristics of the nonannealed deposits may also get worse under the influence of the internal stresses, which increase and lead to a brittle failure with increasing coating thickness.

The morphology of the surface of the ox-Mo oxides studied is shown in Fig. 2. We found no strong correlation between the morphology, the nature of a solution, and the electrolysis conditions. Finely grained compact deposits are formed from hot saturated solutions of ammonium molybdate. More coarsely crystalline deposits are formed from dilute solutions and from solutions of sodium molybdate. However, the structure of both deposits, consisting of small poorly faceted crystals with random crystallographic orientation, differs insignificantly (Fig. 2a). With increasing temperature, the ordering of the deposit structure consisting in growth of coarser crystalline grains in a certain normal orientation takes place (Fig. 2b). The deposits heat-treated above 250°C are characterized by intense twinning of crystals with their clearly resolved layer-by-layer growth (Fig. 2c). This fact shows that, in the given case, the main mechanism of the formation of crystalline grains of the deposit is the normal layer-by-layer growth of the molecular crystalline aggregates-nuclei. The deposits heated above 600°C have coarsely crystalline structure consisting of ag-

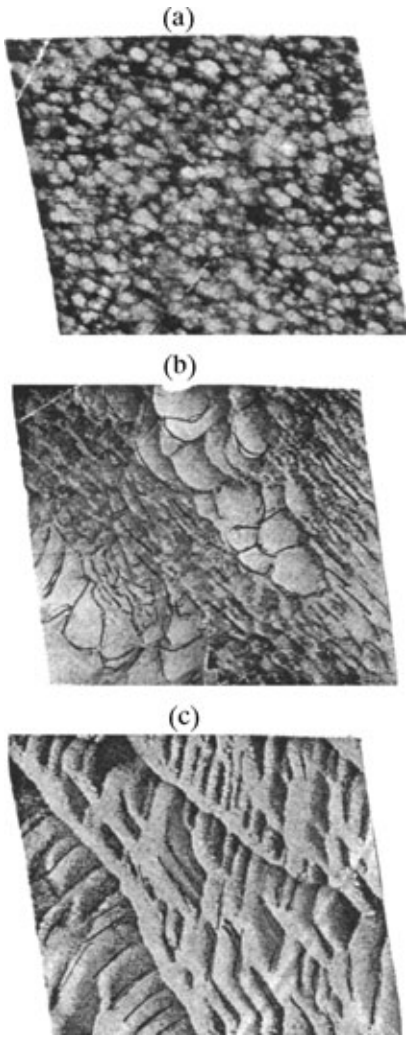

Fig. 2. Morphology of the surface of ox-Mo deposited from a 0.25 M ammonium molybdate solution: (a) drying at 20°C; annealing temperature in air, °C: (b) 280 and (c) 420. Magnification 50000.

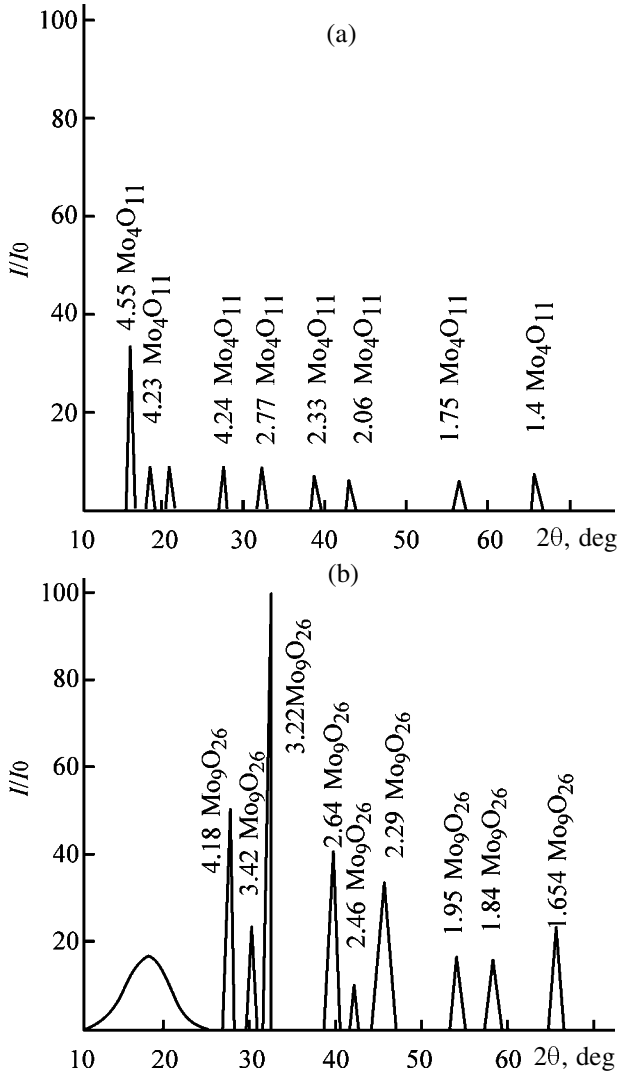

Fig. 3. X-ray diffraction patterns of electrolytic ox-Mo deposits obtained from a 0.25 M solution. (I/I_0) Relative intensity and (2θ) Bragg angle. (a) After drying at 20°C for 16 h and (b) after annealing at 260°C for 7 h. Interplanar spacings in Å are indicated.

glomerates of randomly oriented white grains with yellowish tint, typical of molybdenum(VI) oxide MoO_3, which is associated with the oxidation of the Mo_4O_{11} molecule with atmospheric oxygen by the reaction

$$Mo_4O_{11} + 1/2O_2 \xrightarrow{600°C} 4MoO_3.$$

According to the thermogravimetric and IR spectral analyses of the deposits studied, the chemical compound of the composition $MoO_x \cdot nH_2O$ (x is the homogeneity region within 2.75–2.88) may be present in them as the main phase. The amount of water of hydration lies within n = 1.33–1.35. The thermal effects observed in the differential thermogravimetric curve show that the main weight loss occurs within 160–180 and 260–300°C and is likely due to the removal of water and ammonia, part of which is incorporated in the deposit [8, 9].

According to the X-ray diffractoin analysis, molybdenum oxide is deposited on the cathode in the form of a nonstoichiometric intermediate oxide corresponding to the formula Mo_4O_{11} (Fig. 3a). The phase composition of the deposits can be affected by the electrolysis conditions. At increased values of the current density and pH, the additional phases, Mo_3O_8, Mo_3O_{23}, and Mo_9O_{26}, appear in the deposits, along with the indicated oxide phase. The reproducibility in this case, however, was poor. The deposits annealed

at 250°C and higher temperatures in air contain Mo_9O_{26} as the major phase, which is confirmed by intense reflections in the corresponding X-ray diffraction pattern (Fig. 3b). Evidently, this is associated with the absence of amorphous constituents of the deposits, which exist owing to the presence of hydrated oxide compounds. From this viewpoint, it is more correct in this case to consider electrolytic ox-Mo as a mixed system of the continuous oxide series MoO_x (x = 2.75–2.88). Nonetheless, thid does not exclude the possibility of controlling the phase composition of ox-Mo deposits by choosing appropriate electrolysis parameters and annealing conditions.

CONCLUSIONS

(1) Analysis of the total and partial E–$\log I$ dependences for molybdenum oxide deposition from ammonium molybdate solutions at different concentrations and temperatures shows that these parameters exert a decisive effect on the positions and slopes of the curves.

(2) The abnormally high $\partial E/\partial \log I$ values can be attributed to the delayed diffusion of MoO_4^{2-} ions and to the influence of concomitant factors of the cathodic process.

(3) The adhesion and mechanical resistance of molybdenum oxide electroplated on stainless steel or aluminum support is inversely proportional to the coating thickness and annealing temperature. The annealed deposits have more coarsely grained and more ordered structure. The chemical composition of the deposits changes upon annealing. The complex oxide compounds MoO_x transform into the homogeneous oxide MoO_3.

Abstract—The surface morphology of V_2O_5, Co_2O_3, and MnO_2 electroplated under different electrolysis conditions was studied. The nature of the electrocrystallization of these materials was suggested on the basis of the analysis results.

DOI: 10.1134/S1070427206090102

Electrolytic deposition of compact coatings and dispersed deposits of vanadium and cobalt oxides and of two-phase systems based on manganese dioxide onto anode in a quantitative yield from aqueous solutions of appropriate salts was considered previously from the scientific and technological standpoints [1–5]. These oxide compounds are promising materials of lithium batteries. They have high electrochemical activity and a satisfactory tendency to cycling at stable and reasonably high reversible capacity [6, 7]. In the above studies, the electrosynthesis of the above materials was not considered in the aspect of the structural characteristics of the deposits obtained and the related phase formation processes. Here this problem was considered by analyzing the surface morphology of electrolytic V_2O_5, Co_2O_3, and MnO_2 deposits.

The deposits were prepared in the form of compact coatings 1.5–3.5 μm thick on smooth plates made of 12Cr18Ni9Ti steel (surface finishing grade 8). The surface morphology of the deposits was studied by atomic-force microscopy on a IIIa nanoscope (Digital Instruments). The compositions of the solutions for preparing deposits and the electrolysis parameters are given in the table.

The surface morphology of the deposits studied is shown in Fig. 1. All the deposits have a crystalline structure. The exception is vanadium oxide V_2O_5 prepared from solution no. 1 of oxovanadium sulfate, with fine-grained, nearly amorphous structure (Fig. 1a). In this case, a pronounced relief formed by accumulation of randomly projecting comb-like aggregates is observed on the V_2O_5 surface. Such a crystallization character is possible at continuous degeneration of crystals in the step close to the nucleation and may be favored by the high sorption capacity of V_2O_5 [8], which is responsible for the overgrowth of the deposited oxide molecules with atomic and molecular oxygen and with water molecules. The adsorption layer forming in the process impedes the three-dimensional growth of the crystalline nucleus because of hindered access of discharging VO^{2+} ions toward the active sites on the anode surface and retarded attachment of the forming oxide molecules to the nucleus.

When sodium ions are added to solution no. 1 (solution no. 2), the character of the V_2O_5 crystalliza-

Composition of solutions and electrolysis parameters for deposition of oxide compounds at 80–85°C

Oxide	Solution no.	Solution, M	pH	I_a, mA cm^{-2}

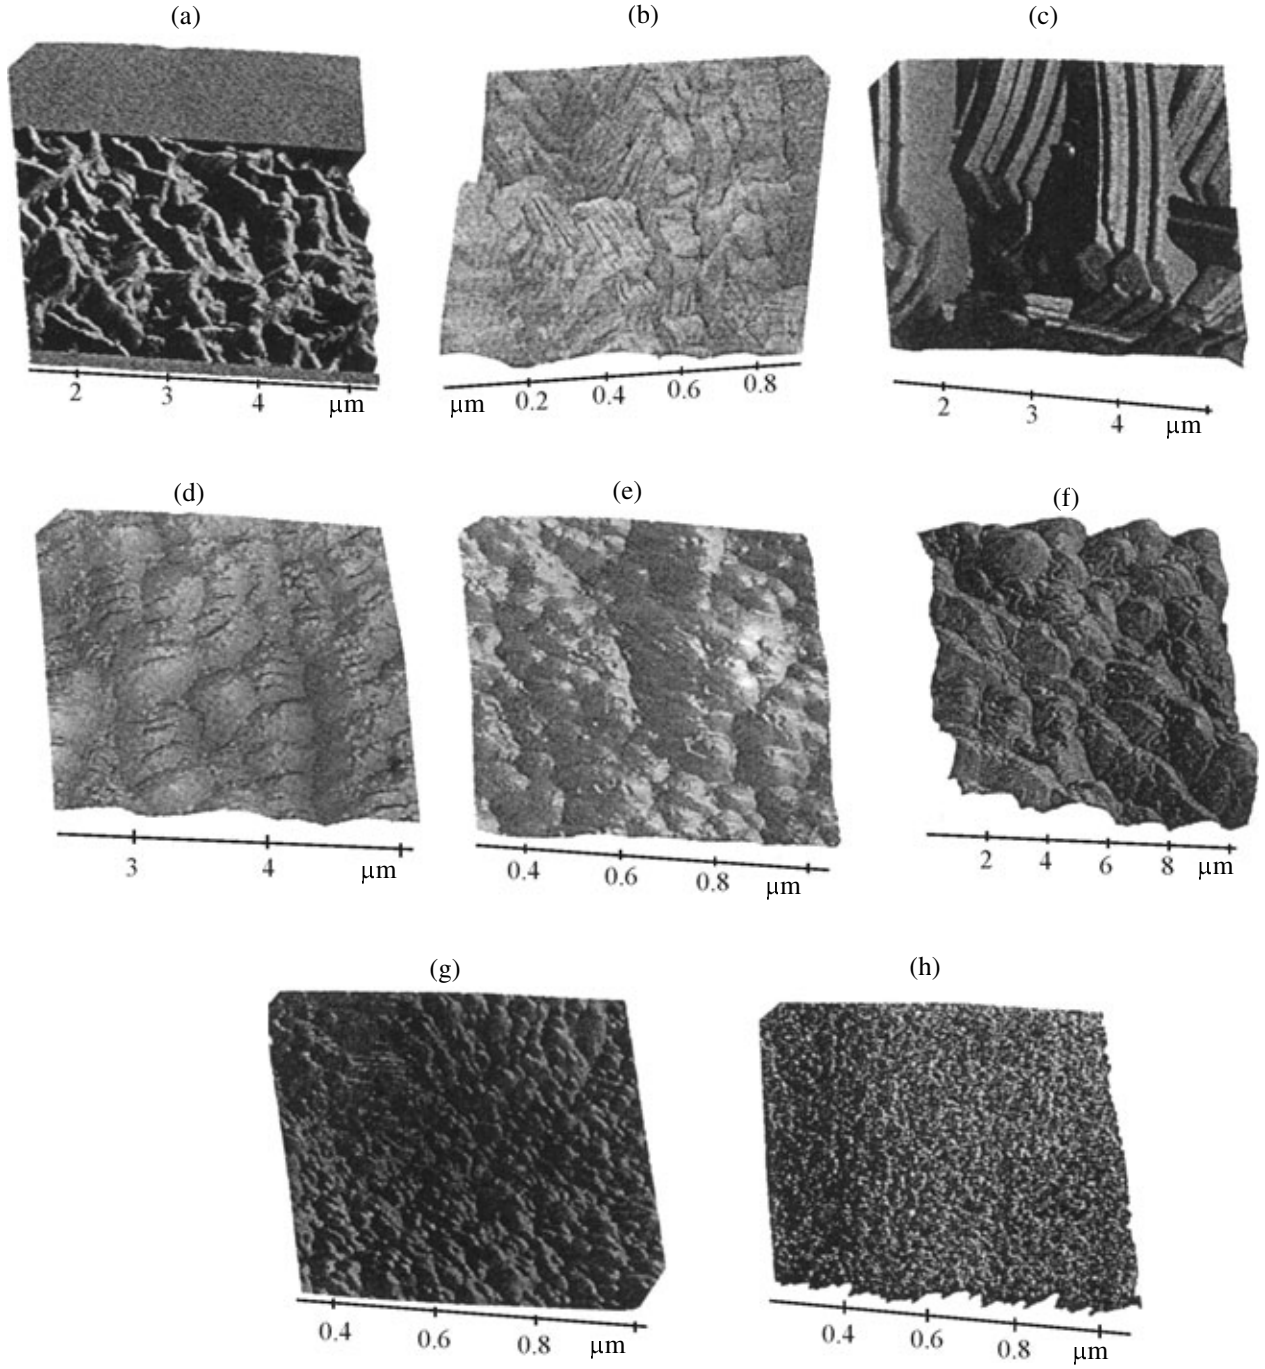

Fig. 1. Surface morphology of electrolytic deposits of V_2O_5, Co_2O_3, and MnO_2: (a) V_2O_5 formed from oxovanadium sulfate solutions; (b) the same as in (a), in the presence of Na^+ ions; (c) V_2O_5 deposited from ammonium metavanadate solutions; (d) the same as in (c), in the presence of Co^{2+} ions; (e) Co_2O_3 deposited from $CoSO_4$ solution; (f) MnO_2 deposited from sulfate solution; (g) the same as in (e), in the presence of Cr^{3+} ions; (h) the same as in (f), in the presence of Cr^{3+} ions in higher concentration.

tion and the structure of the anodic deposit change markedly (Fig. 1). The deposit has a crystalline structure consisting of densely packed crystals growing layer-by-layer in the form of well-defined steps. In this case, sodium atoms may participate in the formation of the energy barrier making the sorption activity of V_2O_5 molecules lower, which creates favorable conditions for the ordered crystal growth. The reaction of sodium ions with vanadium oxide forming on the anode yields a compound belonging to the class of

vanadium bronzes of the composition $Na_xV_2O_5$ (x = 0.23–0.28), which is confirmed by X-ray analysis of the deposits [9]. In this case, the formation of the deposit decelerates considerably, probably because of the hindered discharge of VO^{2+} ions due to a qualitative change in the energy state of the support [2].

Large-block crystalline deposits are formed on the anode from ammonium vanadate solution no. 3, with steps of crystal growth clearly edged and the sequentially superposed stacks having a smooth facet surface (Fig. 1c). The stacks have nearly the same thickness and are arranged so that their frontal facets are shifted at a nearly equal distance from each other. Such a structure suggests fairly fast development of primary two-dimensional crystalline aggregates growing in one plane, with the volume crystal growth by the sequential deposition of the molecular layers. This mechanism can be realized when the concentration conditions and the direction of growth of the step are strongly coordinated. In our case, this may be facilitated by the joint action of two mechanisms of the V_2O_5 formation:

coagulation

$$2HVO_3 \rightarrow V_2O_5 + H_2O$$

and electrochemical mechanisms:

$$2VO^{2+} + H_2O - 2e \rightarrow V_2O_5 + 6H^+ \text{ [3].}$$

The coagulation mechanism, which is mainly due to the electrostatic interaction, involves no energy consumption and promotes the crystal growth owing to direct formation of molecular crystalline aggregates on the anode surface. Their further growth is evidently provided via both the first and the second mechanisms. In this case, dark orange or brownish deposits are formed, unlike light orange crystalline V_2O_5 deposits formed by the traditional thermochemical method, which confirms the above suggestion.

In the presence of Co^{2+} ions (solution no. 4), the surface morphology of the V_2O_5 deposit electroplated from ammonium vanadate solution changes essentially (Fig. 1d). Break of the large-block structure of crystalline grains with simultaneous decrease in their size and transformation into the qualitatively new globular structure is responsible for this result. In the process, the deposits acquire a dark gray color. However, finely grained dark orange deposits are observed along the grain boundaries. These formations probably originate from the fact that, in the step close to the onset of nucleation, the growth of V_2O_5 crystals is suppressed by jointly deposited Co_2O_3 molecules. The presence of Co_2O_3 in these deposits was confirmed by X-ray diffraction analysis [3]. This makes it possible to consider these deposits as an interstitial solid solution of Co_2O_3 in V_2O_5. Probably, the globular structure of the deposits is formed owing to the fact that growth of V_2O_5 crystals is decelerated with adsorbing Co_2O_3 molecules and they are deposited between the growth steps at the limited supply of Co^{2+} ions toward the anode surface.

The Co_2O_3 deposits electroplated from solution no. 5 also tend to form spheroidal crystalline structures (Fig. 1d). This may be due to the fact that the strict geometry of the step growing at the frontal face of the crystal is broken at the limited and nonuniform supply of oxide molecules toward its active points. In this case, a certain role may be played by the structure of Co_2O_3 molecules, whose rhombic structure is likely to facilitate their packing in aggregation.

The MnO_2 deposits electroplated from solution no. 7 have a lamellar structure (Fig. 1d). Each "lamella" is a multilayer dense stack with projecting growth steps. Some of these superimposed steps form coarser crystalline grains. The size distribution of the lamellas over the deposit surface is fairly uniform. This structure suggests a specific mechanism of the phase formation, largely dependent on the structure of the oxide lattice. This lattice belongs to the γ-MnO_2 modification having a complex polymolecular rhombic structure. Therefore, it may be suggested that the nucleation and growth of MnO_2 crystals and the formation of the three-dimensional structure of the crystal lattice occur simultaneously. A two-dimensional nucleus, or layer, forming in the process is actually a three-dimensional formation with the height equal to the corresponding lattice parameter. If the crystal growth is a diffusion-controlled process, the limit of the oxide molecules formed electrochemically in the adjacent region of the solution will be rapidly exhausted, which will restrict the growth of molecular layers in the stack.

The introduction into the Co_2O_3 and MnO_2 electroplating solutions (solutions nos. 5, 7) of chromium ions (solutions nos. 6, 8, respectively), results in an essential change in the phase composition and crystal structure of the deposits. The crystalline grains become considerably finer, and the surface morphology changes. The Co_2O_3 deposits plated in the presence of Cr^{3+} ions consist of rather uniformly distributed fine aggregates in the form of layered petal-shaped stacks, with growth steps projecting on the end

faces (Fig. 1g). The crystalline grains have random crystallographic orientation. The formation of such a structure is likely due to the blocking of the frontal boundary of a growing stack with Cr_2O_3 molecules. As a result, its development is inhibited as the concentration of Co_2O_3 molecules in the growth zone decreases.

Increasing the concentration of the Cr^{3+} ions in the solution results in a marked change in the crystal structure of the deposits (cf. Figs. 1g and 1h, solution nos. 8 and 6). The deposits consist of fine close-packed pillared crystalline grains forming a fairly uniform surface. Apparently, the formation of this structure is due to a strong effect of jointly deposited Cr_2O_3 molecules on the formation and growth of nascent MnO_2 crystals. The Cr_2O_3 molecules confine the development of nuclei in layers in the longitudinal direction by blocking their frontal faces in the initial steps of the formation. This creates the favorable conditions for their sequential superposition and for the growth of pillared crystals in the direction normal to the electrode surface.

The analysis of the surface morphology of electrolytic V_2O_5, Co_2O_3, and MnO_2 deposits showed that the electrocrystallization of these oxides has a number of common features determining their crystal structure and the energy balance in their formation. For example, according to the voltammetric characteristics of the deposits [1–4], the corresponding anodic polarization, determined from difference between the potential of the onset of the oxide deposition and the standard electrode potential, lies within 0.07–0.15 V, decreasing in the order $Na_xV_2O_5 > Co_2O_3 > V_2O_5 > MnO_2$. This implies that the given oxide systems are deposited at a moderate overvoltage of the electrode process. The energy consumption in the process may be partly compensated at the expense of the energy liberated upon phase transformation. This effect may be associated with the influence of chemisorbed oxygen on the mechanism of the anodic deposition of the oxide, facilitating the electron transfer. For example, in the case of V_2O_5 formation, this process can occur by the scheme

$$VO^{2+} + (M–O) - e \rightarrow VO_2^+ + M,$$

$$VO^{2+} + VO_2^+ + 2(M–O) - e \rightarrow V_2O_5 + 2M;$$

and in the case of Co_2O_3 formation, by the scheme

$$Co^{2+} + (M–O) - e \rightarrow CoO^+ + M,$$

$$2CoO^+ + (M–O) \rightarrow Co_2O_3 + M.$$

Thus, the electrocrystallization of the oxide compounds under consideration is determined by the electrolysis conditions, on the one hand, and by the crystal lattice structure, on the other hand. This is clearly seen in the case of electrolytic V_2O_5, whose crystallization depends directly on the composition of a solution and electrolysis conditions. The correlation with the oxide crystal system is reflected in essentially different crystal structures of the corresponding electrolytic deposits.

CONCLUSIONS

(1) The morphology of the surface of electrolytic V_2O_5, Co_2O_3, and MnO_2 deposits was analyzed. The probable mechanisms responsible for the deposition and formation of the corresponding crystalline structures were suggested. It was assumed that a comparatively low overvoltage in formation of the oxides considered is due to the three-dimensional molecular structure facilitating crystal nucleation through the intermediate oxide radicals in the course of interaction with adsorbed oxygen.

(2) The formation of crystalline structures of the deposits depends on the electrolysis conditions and crystal lattice structure of the oxide.

CATALYSIS

Effect of the Paste Molding Pressure on the Activity of Iron Oxide Catalyst in Dehydrogenation of Methylbutenes

Abstract—The effect of the paste molding pressure on the activity of an iron oxide catalyst in dehydrogenation of methylbutenes was studied. The study involved detailed analysis of the pore structure of the samples by mercury porosimetry and determination of the mode of the catalytic process (kinetic or diffusion control). The range of pore sizes in which dehydrogenation reactions occur was determined.

DOI: 10.1134/S1070427206090114

Olefins and alkylaromatic hydrocarbons are commonly dehydrogenated in the presence of iron oxide catalysts [1–4], which contain alkali metal ferrites as active components [5, 6]. It has been shown [7, 8] that dehydrogenation on an iron oxide catalyst proceeds under diffusion control and is limited by mass transfer in its porous system, i.e., by the rates of reagent supply and reaction product removal. Therefore, it is important to determine the optimal pore structure of iron oxide catalysts, which have low specific surface area (3–9 $m^2 g^{-1}$) and low porosimetric volume (0.1–0.5 $cm^3 g^{-1}$).

The porous structure is formed in all stages of catalyst synthesis, including that of molding of catalyst pastes. This stage predetermines not only the texture characteristics, but also the physicomechanical properties of the finished catalyst. However, published information on how the molding conditions affect the properties of iron oxide catalysts is insufficient [9, 10]. There are only patents [11, 12] which suggest that grains of various noncylindrical shapes (trifoliate, starlike, perforated, etc.) should be formed by extrusion in order to improve the efficiency of the catalysts.

The aim of this study was to examine the influence exerted by the molding pressure on the pore structure parameters of the iron oxide catalyst and on its catalytic properties.

EXPERIMENTAL

Catalyst samples were synthesized by "wet" mixing of the starting components containing iron oxide and compounds of potassium, magnesium, calcium, and other metals. Then the suspensions obtained were dried at 150–200°C, after which the powder was moistened to 10% humidity, weighed into 4-g portions, and molded on a Maekawa Testing Machine MFG hydraulic press at pressures of 50, 150, and 275 MPa. The samples (pellets 20 mm in diameter) were obtained at different compaction pressures but had the same chemical composition. After the compaction, the samples were calcined in air under the similar conditions.

The catalysts were tested in dehydrogenation of methylbutenes into isoprene. The tests were performed in a laboratory flow-through reactor with a catalyst charge of 40 cm^3 at reaction temperatures of 600–615°C, space velocity of methylbutenes equal to 1 h^{-1}, atmospheric pressure, dilution of the raw material with steam, and molar ratio $C_5H_{10} : H_2O$ = 1 : 20. The compositions of gaseous products and the isoamylene fraction were determined chromatographically on two gas–liquid chromatographs with heat-conductivity detectors, with subsequent processing of the analytical results. The accuracy with which the composition of the dehydrogenation products was determined was evaluated using methods of mathematical statistics [13], developed for a small number of determinations ($n < 30$). The relative root-mean-square error was ±2%.

To preclude condensation of C_5 hydrocarbons, the gaseous mixture was sampled for analysis into an aspirator with a brine of density 1.2. The aspirator

was preliminarily filled with argon, so that the sample-to-argon ratio was 1 : 4. The composition of the gas was calculated with account of the dilution factor.

The composition of low-boiling gases (H_2, O_2, N_2, CH_4, and CO) was determined on a column packed with NaX molecular sieves, and that of the hydrocarbon mixture and CO_2, on a column with a sorbent composed of 30% TEGNM on a diatomite of the 0.16–0.25-mm fraction.

As the catalyst activity factor $A_{C_5H_8}$ (%) we took the yield of isoprene based on the methylbutenes passed, which was calculated by the formula

$$A_{C_5H_8} = \frac{c_{C_5H_8}(\text{gas.prod.})}{c_{C_5H_{10}}(\text{feed}) + c_{C_5H_8}(\text{feed})} \times 100.$$

As the selectivity factor by isoprene $S_{C_5H_8}$ (%) we took the yield of isoprene based on decomposed isoamylenes, calculated by the formula [14]

$$S_{C_5H_8} = \frac{c_{C_5H_8}(\text{gas.prod.})}{[c_{C_5H_{10}}(\text{feed}) + c_{C_5H_8}(\text{feed})] - c_{C_5H_8}(\text{gas.prod.})} \times 100.$$

The texture characteristics of the catalysts were studied by mercury porosimetery on a Micromeritics Auto-Pore 9200 instrument (the United States). The porosity ε of the catalysts was calculated from the pellet density ρ_c and the specific pore volume V_p by the formula $\varepsilon = \rho_c V_p$ [15].

The X-ray phase analysis (XPA) was performed on a DRON-2 diffractometer with CuK_α radiation and a monochromatic filter. The range of recording angles 2θ was 5°–60°.

The dehydrogenation of methylbutenes involves both the target (synthesis of isoprene) and side reactions (decomposition of isoamylenes and isoprene to give low-boiling hydrocarbons and coke) [16]. The results of the catalytic tests at dehydrogenation temperatures of 600 and 615°C of samples having the same chemical and phase composition (according to XPA), but molded at different pressures of 50 (sample no. 1), 150 (sample no. 2), and 275 MPa (sample no. 3), are listed in Table 1.

As follows from Table 1, the samples produced at pressures of 50 and 150 MPa exhibit approximately the same activity at a reaction temperature of 600°C, with the conversion of methylbutenes, $K_{C_5H_{10}}$, equal to 51.14 and 50.44 wt %. Raising the process temperature from 600 to 615°C is accompanied by a significant rise in $K_{C_5H_{10}}$ (by 10%). The selectivities to isoprene of sample nos. 1 and 2 are at the same level (~87%); however, their values differ from those ini-

tially observed (at 600°C). The sample molded at 275 MPa exhibits a somewhat higher conversion of methylbutenes at 600°C, which increases by approximately 6.5% as the process temperature is raised to 615°C, without any change in the selectivity to isoprene. The differences between the increments in the conversion of methylbutenes, observed as the process temperature is elevated, suggest that the pressure of catalyst molding affects the nature of the rate-determining step of the reaction.

To determine the reaction mode (diffusion or kinetic control) and the kinetic parameters of the process, the following quantities were calculated: effective rate constant k, temperature coefficient β of the process rate, effective activation energy E_a, and Thiele modulus. The effective rate constant was calculated from the degree of conversion of methylbutenes to isoprene, $K_{C_5H_{10}}$, at temperatures of 600, 610, and 615°C [17], after which the effective activation energy was found by the graphical method [18]. The results of calculation of the kinetic parameters are listed in Table 2.

The Thiele modulus, whose value was used to determine the reaction mode, was calculated from the integral characteristics of the pore structure of the catalyst, found by mercury porosimetry: specific surface area S_{sp}, porosimetric volume V_p, and average pore radius R_{av}; also, the diffusion coefficient D_{eff} and the rate of dehydrogenation of methylbutenes, $W_{C_5H_{10}}$, at T = 600 and 615°C were calculated.

The results obtained (Table 3) demonstrate that the dehydrogenation of methylbutenes with samples molded at pressures of 50 and 150 MPa is diffusion-controlled ($\Psi < 0.5$) and the degree of surface utilization is close to unity [17], i.e., virtually the whole catalyst surface is involved in dehydrogenation of methylbutenes. At higher molding pressures (275 MPa), the process mode shifts to inner diffusion control ($\Psi > 2.5$), in which case the degree of surface utilization becomes considerably lower (~0.5–0.6) [14], and, according to the dependence reported in [19], the effective activation energy of the process corresponds to half the activation energy in the case of kinetic control (Table 2). It is for this reason that, in contrast to sample nos. 1 and 2, an increase in the reaction temperature by 15°C for sample no. 3 leads to a less pronounced rise in the conversion of methylbutenes.

Comparison of the integral texture characteristics of the samples (Table 1) suggests that the higher conversion of methylbutenes (at 600°C) for the sample molded at 275 MPa is due to its considerably larger specific surface area. Probably, an interval of optimal pore diameters in which the main reaction occurs must exist for the diffusion-controlled process. In this case, the process rate is proportional to S_{sp} corresponding to this range of pore diameters.

In order to study in more detail the effect of the pore structure on the mode of the reaction control and on kinetic parameters, the texture characteristics of the catalyst samples described above were analyzed.

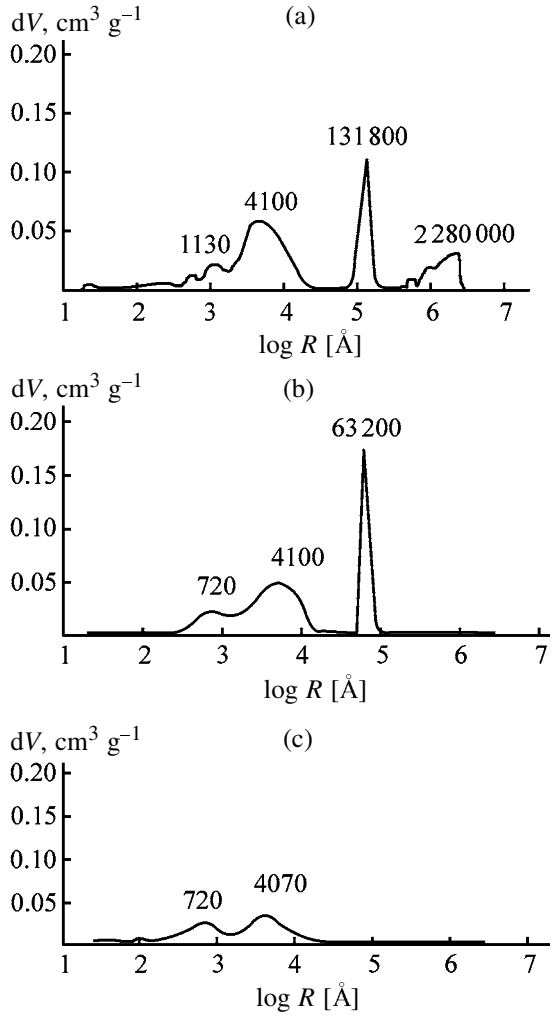

Fig. 1. Distributions of the pore volume over radii R for catalyst samples obtained by single-side compaction. Pressure, MPa: (a) 50, (b) 150, and (c) 275.

The porograms measured by mercury porosimetry for the samples studied are shown in Fig. 1. Three regions can be distinguished in the pore volume distribution for different pore radius intervals (Fig. 1, Table 4): fine-porous with $R < 0.2$ μm, medium-porous with the radii in the range 0.2–3.5 μm, and coarse-porous at $R > 3.5$ μm.

The starting sample no. 1 (P = MPa) has a polymodal pore structure with pore volume distribution peaks at radii of 228, 13.8, 0.41, 0.11, and 0.005 μm (Fig. 1a). The value of V_p is largely determined by pores with radii exceeding 3.5 μm (0.22 $cm^3 g^{-1}$), and S_{sp}, by pores with radii smaller than 0.2 μm (6.7 $m^2 g^{-1}$).

In the case of molding at 150 MPa (sample no. 2), the peak at R = 228 disappears from the porograms and, simultaneously, the peak at R = 13.18 μm shifts to smaller radii (6.32 μm), with its intensity increasing by 38%.

The disappearance of coarse pores and the appearance of additional pores with smaller radius lead to a 17% decrease in the porosimetric volume in the coarse-porous range and cause an insignificant change (<1%) in the specific surface area. In the medium-porous range, the intensity of the peak at R = 0.41 μm decreases, which leads to a significant (by 24%) decrease in the porosimetric volume at pore radii in the range 0.2–3.5 μm. In the range of fine pores, the peak at R = 0.11 μm shifts toward smaller radii (R = 0.07 μm), with the result that the specific surface area increases from 6.7 to 7.2 $m^2 g^{-1}$.

Thus, an increase in the molding pressure to 150 MPa strongly affects the transformation of pores in the medium- and coarse-porous ranges, but does not lead to significant changes in the integral characteristics V_p and S_{sp}. The latter may be due to densification of the material as a result of void disappearance and particle disintegration under the action of stresses and structural and shear deformations caused by the pressure applied [20]. Comparison of the results obtained in catalytic tests (Table 1) and analysis of the texture characteristics shows that transformation of pores with radii exceeding 3.5 μm has no effect on the activity of samples in dehydrogenation of methylbutenes. However, these pores strongly affect the physicomechanical properties of extrudates [21].

Molding of samples at a pressure of 275 MPa (sample no. 3) leads to disappearance of pores with $R > 3.5$ μm (0.02 $cm^3 g^{-1}$) and to a decrease in the intensity of the peak at R = 0.41 μm from 0.05 to 0.03 $cm^3 g^{-1}$. The polymodal pore structure becomes bimodal. A low-intensity peak appears in the range of fine pores at R = 0.009 μm, and the contribution of this peak to the specific surface area is 17.5% (2.28 $m^2 g^{-1}$). The increase in the molding pressure results in that S_{sp} at $R < 0.2$ μm grows by 43% (from 7.2 to 12.6 $m^2 g^{-1}$) and V_p at $R > 3.5$ μm falls by 90% (from 0.18 to 0.02 $cm^3 g^{-1}$) at an insignificant change in the sample density.

For a closer analysis of the pore structure, the range from 2 to 3000 nm was considered in more detail. The data obtained are listed in Table 5. It can be seen that the increase in the specific surface area with the molding pressure is due to formation of an additional number of pores at $R < 50$ nm, with more than 60% of S_{sp} accounted for by pores with $R < 5$ nm (8 out of 13 $m^2 g^{-1}$).

275	13.0	4.85	37.3	3.46	26.6	2.72	20.9	0.67	5.2	0.73	5.6	0.52	4.0

The data of Table 5 were used to find the "working" range of pore radii, for which the specific surface area is proportional to the conversion of methylbutenes. The conversion $K_{C_5H_{10}}$ correlates with S_{sp} for mesopores with radii in the range 15–50 nm. The specific surface area has too widely varying values at smaller radii (5–15 nm) and remains virtually unchanged at larger radii (50–100 nm).

At the same time, it may be suggested that the increase in S_{sp} at 5–15 nm gives rise to steric hindrance as a result of formation of a large number of pores with radii smaller than the "working" value and transfers the process from kinetically controlled to diffusion-controlled mode. Pores with radii smaller than 5 and larger than 50 nm do not affect the reaction control mode significantly.

CONCLUSIONS

(1) The paste molding pressure affects the parameters of the pore structure of a catalyst, and reaching a certain pressure (~250 MPa) leads to a shift from kinetically to diffusion-controlled process.

(2) It was suggested that the catalytic process mostly occurs in pores of radius 15–50 nm, which is indicated by the correlation between the conversion of methylbutenes and the specific surface area in this range of pore radii.

(3) The results of catalytic tests and the texture characteristics were compared and it was demonstrated that pores with radii smaller than 5 and larger than 50 nm affect the activity of the catalyst samples, but cannot govern their physicomechanical properties.

Abstract—The effect of the paste molding pressure on the physicomechanical and texture characteristics of catalysts was studied. An indirect criterion is suggested to evaluate the molding pressure in industrial extruders, whose optimal value ensures good physicomechanical properties of the catalysts and kinetic control over the catalyzed reaction. The results obtained were verified in paste molding on various industrial extruders, and this enabled the optimal choice of the molding equipment.

DOI: 10.1134/S1070427206090126

The preceding paper was concerned with the effect of the molding pressure on the activity of catalysts in the dehydrogenation of methylbutenes. It was shown that the molding pressure of the catalyst paste can predetermine the limiting stage of the process. An assumption was made that the dehydrogenation reaction mostly proceeds within the "working" pores of the catalyst, which have radii in the range from 15 to 50 nm. This is indicated by the correlation between the conversion of methylbutenes and the specific surface area S_{sp} in this range. An increase in the molding pressure results in that S_{sp} grows in the pore radius range 5–15 nm, which gives rise to steric hindrance caused by the formation of a large number of pores of size smaller than the "working" value and shifts the process from kinetic to diffusion control mode. Pores with radii exceeding 3.5 μm have no significant effect on the reaction control mode, but can determine the physicomechanical properties of the catalyst.

Iron oxide catalysts are used under industrial conditions in reactors with large unit power and charges exceeding 60 t. Therefore, one of the most important parameters of a catalyst is its mechanical strength, which is known to be determined by the chemical composition and pore structure. The latter, in turn, depends on the molding pressure of the catalyst paste, which can hardly be found for domestic industrial extruders.

The aims of this study were as follows: to find out how the molding pressure affects the pore structure and mechanical strength of iron oxide catalysts; to reveal an indirect criterion for evaluating the molding pressure in industrial extruders and substantiate its optimal values; and to verify the reliability of the results under industrial process conditions.

EXPERIMENTAL

Catalyst samples were synthesized by "wet" mixing [2] of the starting components containing iron oxide and compounds of potassium, magnesium, calcium, and other metals. Then the suspensions obtained were dried at 150–200°C, after which the powder was moistened and molded on a Maekawa Testing Machine MFG hydraulic press at pressures of 50, 150, and 275 MPa and on extruders of various types. The samples having the same chemical composition were calcined in air under identical conditions.

The cleavage strength was determined with a PPK-1 semiautomatic device with a knife with a blade width of 0.1 mm [3]. The cleavage strength coefficient K_G was calculated as the ratio of the breaking load to grain diameter or height of a catalyst pellet.

The texture characteristics of the catalysts were studied by mercury porosimetry (MP) on a Micromeritics Auto-Pore 9200 instrument (the United

States). The porosity ε of the catalysts was calculated from the pellet density ρ_c and the specific pore volume V_p by the formula $\varepsilon = \rho_c V_p$ [4].

The physicomechanical and integral parameters of the pore structure of the catalyst samples obtained at different molding pressures P on a hydraulic press are listed in Table 1. As the parameter characterizing the mechanical strength was taken K_G, which allows comparison of pellets and grains. It can be seen from the dependence shown in Fig. 1 that, as the molding pressure is raised from 50 to 300 MPa, the pellet strength coefficient increases from 2.04 to 3.81 kg mm^{-1}, which is due to denser packing of catalyst particles. This is also indicated by data on the variation of the density ρ and porosity ε of the pellets obtained and of the number n of contacts between the particles [2], listed in Table 1. Because the dependence $K_G = f(\rho)$ is linear, the pellet density was taken as the main criterion for assessing how the molding pressure affects the pellet strength.

Important factors in pellet molding include not only the value of the compaction pressure, but also the duration τ of the action of this pressure on the material being compacted. This is indicated by the dependences of the pellet density on the molding pressure at τ = 3, 15, and 30 s (Fig. 2). It can be seen that, as the compaction time increases from 3 to 15 and 30 s at compaction pressures lower than 150 MPa, the catalyst paste is markedly densified, which results in that the density of the finished catalyst increases by a factor of approximately 1.2. At higher pressures (>150 MPa), the compaction time has virtually no effect on the density of the samples. Consequently, the time during which a load is applied to the catalyst paste will largely determine the texture of the finished catalyst at P < 150 MPa.

Figure 3 shows that the density–pressure dependence is described by a curve that tends to level-off and consists of two portions: that at P = 50–200 MPa,

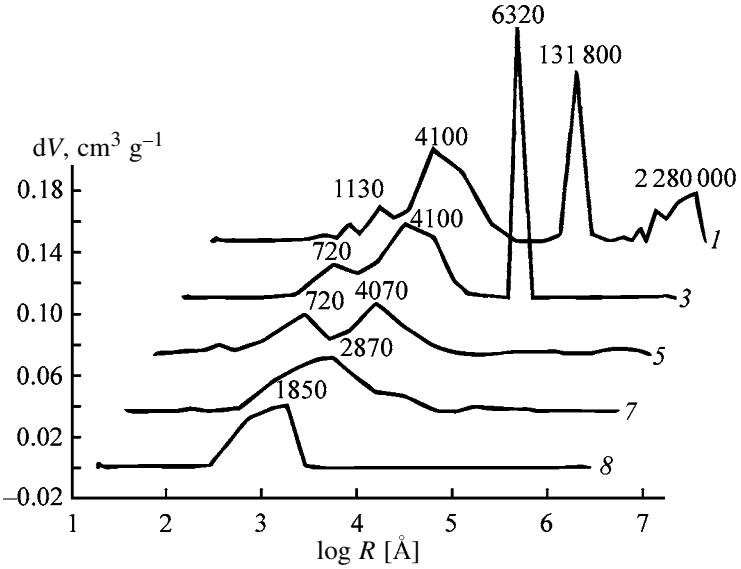

Fig. 4. Pore volume (V) distribution with respect to pore radii R for the catalyst samples obtained on the hydraulic press. Curve nos. are sample nos. in Table 1.

in which the pellet density varies in proportion to the pressure applied, and the portion at P = 200–300 MPa, in which the density variation is insignificant. These data indicate that the pore structure transforms in different ways, depending on the compaction pressure. Therefore, the texture characteristics of samples obtained at pressures lower (Table 2, sample nos. 1, 3) and higher (sample no. 5) than 200 MPa were analyzed by mercury porosimetry.

In the programs of the samples under study (Fig. 4), three regions of pore volume distributions can be distinguished at different pore radii (Table 2): fine-porous (R < 0.2 μm), medium-porous (R = 0.2–3.5 μm), and coarse-porous (R > 3.5 μm).

Sample no. 1, molded at a pressure of 50 MPa, has a polymodal structure. Macropores are observed in the coarse-porous region with peaks at radii of 228 ($\log R$ = 6.4) and 13 μm ($\log R$ = 5.1), whose joint contribution to the total porosimetric volume is 47.6% (0.22 $cm^3\ g^{-1}$). In the fine- and medium-porous regions, peaks in the pore volume distribution are observed at radii of 0.1 and 0.4 μm, which account for 0.08 and 0.14 $cm^3\ g^{-1}$, respectively.

As the compaction pressure is raised to 150 MPa (sample no. 3), the coarsest pores with radii of 228 and 13 μm disappear from the catalyst, and finer pores with R = 6.32 μm ($\log R$ = 4.8) appear, which account for 0.18 $cm^3\ g^{-1}$ in the total pore volume. The height of the peak at R = 0.4 μm decreases from 0.07 to 0.05 $cm^3\ g^{-1}$, with the porosimetric volume for pores with R = 0.2–3.5 μm decreasing from 0.14 to 0.10 $cm^3\ g^{-1}$.

Thus, pronounced transformations of coarse pores are observed at pressures of up to 200 MPa, which lead to a decrease in V_p by 18% for pore radii exceeding 3.5 μm. The changes observed may be due [5] to densification of the material being compacted via disappearance of voids and particle disintegration, which are caused by stresses and structural and shear deformations induced by the pressure applied.

The pore structure of a sample molded at a pressure exceeding 200 MPa (sample no. 5) becomes bimodal. The MP curves show no peaks at radii larger than 3.5 μm ($\log R \approx 4.5$). Raising the molding pressure leads to a decrease in the height of the peak in the medium-porous range at a radius of 0.41 μm, which is 0.06 $cm^3\ g^{-1}$ (37.5% of V_p), and to a 43% increase in S_{sp} at R < 0.2 μm (from 7.2 to 12.6 $m^2\ g^{-1}$). This is due to an elastoplastic compression of the porous agglomerate at pressures exceeding 200 MPa. The contacting surfaces approach to a distance not exceeding the action radius of intermolecular forces. Jointing bridges are intensively formed between particles and the surface area of the contacts formed increases [5].

Thus, a pellet density exceeding 2.49 $g\ cm^{-3}$ (Fig. 3, $P \geq 200$ MPa) is reached because of the disappearance of the coarse-porous component (R > 3.5 μm) in samples obtained at molding pressures higher than 200 MPa. Therefore, to obtain catalyst pellets with high physicomechanical parameters (K_G =

3.38–3.81 kg mm^{-1}), the molding should be done at pressures of no less than 200 MPa.

At the same time, it has been shown previously [1] that a large number of fine pores with radii smaller than 15 nm appear in a sample in the stage of molding of the catalyst paste at P = 275 MPa (ρ = 2.53 g cm^{-3}), which shifts the catalytic process from the kinetic to diffusion control mode. It follows from the aforesaid that the optimal range of pressures for molding of the catalyst paste on a hydraulic press is 200–250 MPa, which corresponds to a pellet density of about 2.49–2.51 g cm^{-3}.

Under the industrial conditions, iron oxide catalysts are commonly molded on worm extruders, for which it is difficult to determine the molding pressure. As shown above, the pellet density can be used as a parameter that enables evaluation of the molding pressure. To verify the reliability of the results obtained under industrial conditions, grains were molded on two different extruders. The densities of the samples obtained were 2.48 (Table 1, sample no. 7) and 2.76 g cm^{-3} (Table 1, sample no. 8), which corresponds to molding pressures higher than 200 MPa. The lower values of the strength coefficients (2.09 and 3.07 kg mm^{-1}) for the extruded samples, compared to those pelletized, may be due to the fact that different methods were used to mold the catalyst paste. Probably, the shape of the curves describing the pore volume distribution with respect to pore radii for the extruded samples and pelletized catalyst (sample no. 5) is about the same. In order to examine the pore structure of sample nos. 7 and 8 in more detail, their texture characteristics were analyzed by mercury porosimetry.

Table 3. Kinetic, catalytic, and texture parameters of catalysts obtained on different extruders

$A_{C_5H_8}$, wt %	42.3	38.9
$S_{C_5H_8}$, wt %	87.9	85.6
Ψ	1.61	3.26
E_a, kJ mol^{-1}	64.6	49.4
S_{sp}, $m^2 g^{-1}$, in indicated range of pore radii (nm):		
5–15	0.52	0.66
15–50	0.22	0.21

* For formulas for calculating $A_{C_5H_8}$, $S_{C_5H_8}$, Ψ, and E_a, see [1].

The pore volume distributions with respect to pore radii are shown in Fig. 4. The extruded sample nos. 7 and 8 show a unimodal pore size distribution with peaks at R = 0.29 and 0.18 μm, respectively. As expected, the samples have virtually no pores with radii R > 3.5 μm, which predetermines their high density.

Sample no. 7, molded on extruder no. 1, has a total pore volume of 0.18 $cm^3 g^{-1}$ and specific surface area of 4.3 $m^2 g^{-1}$. Approximately equal contributions to the porosimetric volume are made by fine and medium pores (approximately 50% each). S_{sp} is 0.22 $m^2 g^{-1}$ in the "working" range of pore radii (15–50 nm) and 0.52 $m^2 g^{-1}$ at smaller radii (5–15 nm) (Table 3).

Sample no. 8, molded on extruder no. 2, has a porosimetric volume of 0.13 $cm^3 g^{-1}$ and specific surface area of 9.6 $m^2 g^{-1}$. The largest part (94.6%) of the porosimetric volume is distributed over the range of pore radii R < 0.2 μm. The specific surface area is 0.21 $m^2 g^{-1}$ in the range 15–50 nm (Table 3) and 0.66 $m^2 g^{-1}$ at pore radii of 5–15 nm, which suggests that steric hindrance appears and the catalytic process

is diffusion-controlled. To verify this assumption, the mode (diffusion or kineic control) of the dehydrogenation of methylbutenes was determined from the results of catalytic tests of the samples (Table 3) and from the integral characteristics of the pore structure (Table 1).

A calculation of the Thiele modulus (Table 3), which is used to determine the type of control over the catalytic process [2], demonstrated that the dehydrogenation on sample no. 7 proceeds under mixed control ($\Psi = 0.5–2.5$), and that on sample no. 8, under inner-diffusion control ($\Psi > 2.5$), which confirms the assumption made.

The higher catalytic activity of sample no. 7 (42.3%) may be due to the presence of an additional number of pores with radii in the range 0.2–3.5 μm, which is indicated by the value of the specific surface area (Table 2).

It is known that the activity of a catalyst decreases in the course of its operation, which is compensated for by raising the reaction temperature by 2–3°C every 20–100 h. Because a catalytic process occurring under kinetic control is more sensitive to a rise in temperature, it is preferable to mold the catalyst paste on extruder no. 1 to obtain extrudates with a density of 2.40–2.46 g cm^{-3}.

CONCLUSIONS

(1) The paste molding pressure affects the physicomechanical and texture characteristics of the catalysts obtained. The disappearance of pores with $R > 3.5$ μm at molding pressures $P > 200$ MPa leads to formation of high-strength catalysts.

(2) The catalyst molding pressure affects the type of control over the reaction. This is due to formation of pores with radii of 5–15 nm at high molding pressures (>250 MPa), which gives rise to steric hindrance and shifts the reaction from the kinetic to diffusion control mode.

(3) It was suggested to use the density of extrudates to control the catalyst molding pressure in industrial extruders. The optimal densities (for the given composition of the catalyst paste) fall within the range 2.40–2.46 g cm^{-3}, which provides high physicomechanical properties of the catalysts and kinetic control over the reaction.

(4) The results obtained were verified in paste molding on two different industrial extruders, demonstrated a high degree of reliability, and enabled the optimal choice of the molding equipment.

CATALYSIS

Effect of Iodine-Containing Promoter on the Catalytic Activity of Silver in the Course of Ethylene Glycol Oxidation

Abstract—Surface morphology and catalytic properties of electrolytic silver crystals in partial oxidation of ethylene glycol into glyoxal were studied.

DOI: 10.1134/S1070427206090138

Glyoxal is widely used in industry for preparing high-quality paper, films, adhesives, various polycondensates, and pharmaceuticals [1]. Being the nearest analog of formaldehyde, glyoxal surpasses it in chemical properties. Partial oxidation of ethylene glycol on polycrystalline silver catalysts, performed in the continuous flow mode, is the most ecnomically feasible and facile procedure for preparing glyoxal. In this case, the alcohol conversion is as high as 90%, and the selectivity with respect to glyoxal reaches 55–60% [2, 3]. Promotion of the surface or introduction of certain additives into the reaction mixture with the subsequent treatment of the catalyst are the best ways to enhance the activity of the catalytic systems. Various promoters are used in catalysts for partial oxidation of organic compounds, e.g., alkali metals [4] and phosphorus-containing compounds [5]. The promoting effect of halogen-containing hydrocarbons on the partial oxidation of methanol to formaldehyde in the presence of silver catalysts was studied in [6, 7]. It was found that, with addition of microamounts of iodine-containing promoters into the reaction mixture, the alcohol conversion and yield of formaldehyde increase, whereas the yield of the products of deep oxidation decreases. Taking into account that the processes of partial oxidation of methanol and ethylene glycol are largely similar, in this study we examined the catalytic synthesis of glyoxal in the presence of ethyl iodide promoter.

EXPERIMENTAL

Silver crystals were prepared at the Institute of High-Temperature Electrochemistry (Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia) by electrolysis of a $KNO_3 + NaNO_3 + AgNO_3$ melt in an open electrolysis bath using rotating cathode [8]. The crystal surface was finely cleaned by the procedure described elsewhere [9]. The catalyst was prepared by pressing of silver crystals with paraformaldehyde and subsequent annealing in an air flow at 650°C for 3 h.

The catalytic activity of silver was studied in a flow catalytic installation with a fixed catalyst bed by the procedure described in [10]. The height of the catalyst bed was 20 mm, and the reactor diameter was 16 mm. The gaseous and liquid products obtained in the course of oxidation were analyzed chromatographically [11, 12].

The surface morphology of the silver samples was studied using a JEOL 6460LV field-emission high-vacuum scanning electron microscope (energy of the primary electron beam 20 keV). To improve the image contrast, the sample surface was coated with gold (film thickness up to 0.05 μm).

Data on the partial oxidation of ethylene glycol into glyoxal in the absence of ethyl iodide and with its addition to the reaction mixture in relation to the oxygen content in the reaction mixture are plotted in Fig. 1a. The molar content of the promoter added was 6 ppm with respect to ethylene glycol. The oxygen/ethylene glycol (O_2 : EG) molar ratio was varied from 0.8 to 1.8. As seen, with increasing oxygen content in the promoter-free reaction mixture the alcohol conversion increases (Fig. 1a, curve *1*), whereas the selectivity of the glyoxal formation passes through a maximum (Fig. 1a, curve *3*). Addition of the promoter into the reaction mixture improves the selectivity with respect to the desired product in a broader range of

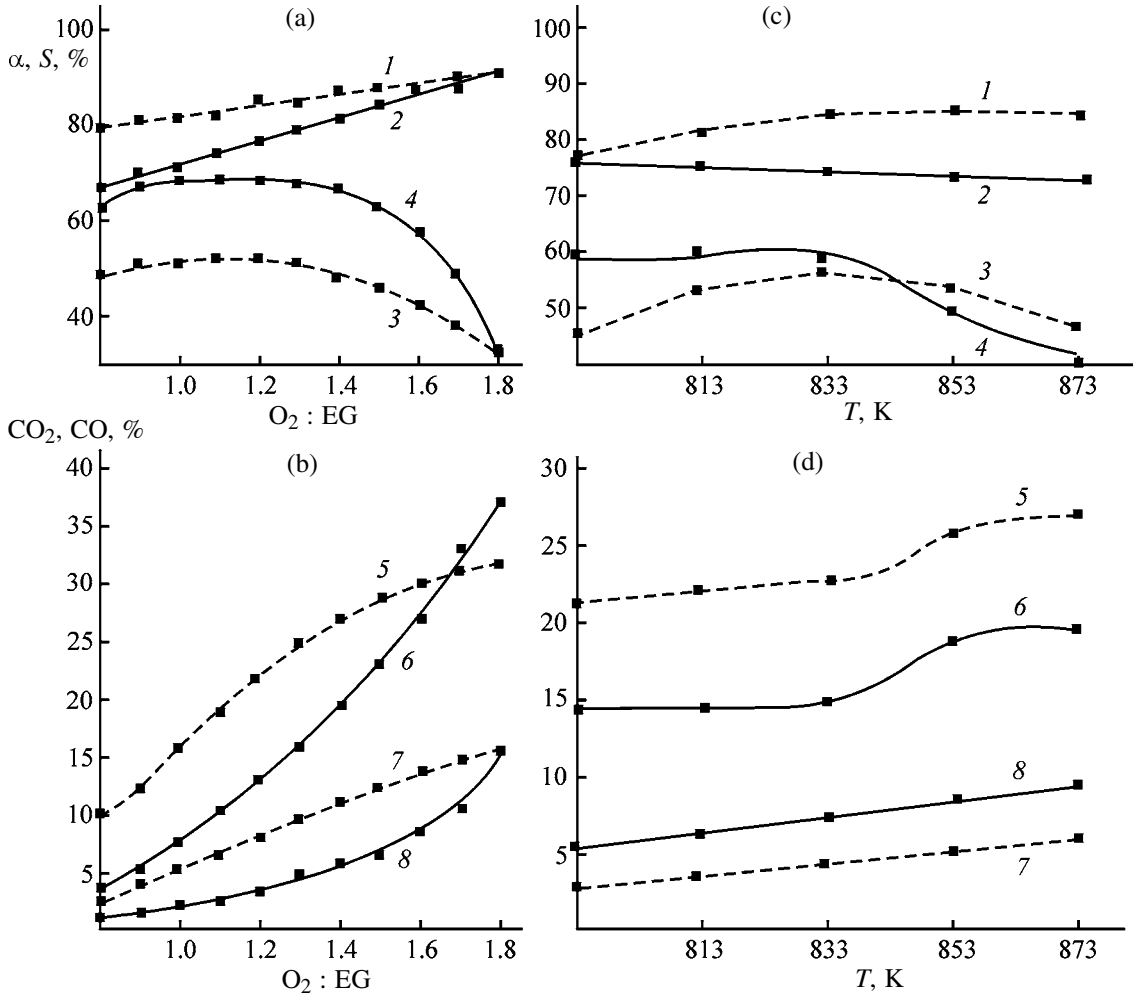

Fig. 1. (*1, 3, 5, 7*) Catalytic activity of silver catalyst without iodine-containing promoter and (*2, 4, 6, 8*) with addition of promoter into the reaction mixture as a function of the (a, b) O_2 : EG molar ratio and (c, d) temperature *T*. the compositions of the reaction mixture as compared to the initial sample (Fig. 1a, curve *4*).

It should be noted that, with addition of the iodine-containing promoter into the reaction mixture, the yields of the products of deep oxidation decrease (Fig. 1b), which is probably due to changes in the chemical composition of the silver crystal surface. Atomic iodine formed by the ethyl iodide decomposition is adsorbed on the silver surface and, occupying the adsorption centers, decreases adsorption of the oxygen atoms responsible for the deep oxidation [13]. This assumption is confirmed by certain decrease in the ethylene glycol conversion in the presence of the promoter (Fig. 1a, curve *2*).

The effect of temperature on the activity of the silver catalyst in the course of ethylene glycol oxidation is illustrated in Figs. 1c and 1d. As seen, with increasing temperature of treatment of the silver catalyst with the promoted reaction mixture, the selectivity with respect to glyoxal decreases (Fig. 1c, curve *4*), whereas the conversion of ethylene glycol remains essentially constant (Fig. 1c, curve *2*). This decrease in the selectivity with respect to glyoxal is probably due to the increasing rate of the iodine desorption from the catalyst surface and rearrangement of the centers of deep oxidation.

In the case of promoted reaction mixtures, the yields of the products of deep oxidation are lower than those in the promoter-free systems at the same temperatures (Fig. 1d). These data suggest that, in the presence of the promoter, the process is stable in the broader range of experimental conditions. On the whole, the silver catalyst in the presence of the iodine-containing promoter is characterized by higher yield

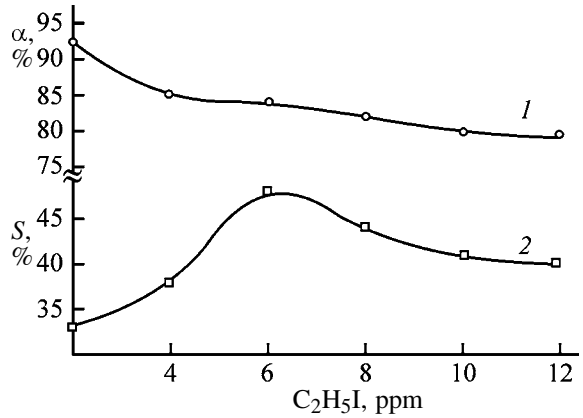

Fig. 2. Catalytic activity of silver as a function of the promoter (C_2H_5I) concentration in the reaction mixture (molar ratio to ethylene glycol). Composition of the reaction mixture: EG : O_2 : N_2 : H_2O 1.0 : 1.0 : 10.0 : 3.4, *T* 560°C. (α) (*1*) Conversion and (*S*) (*2*) selectivity.

of the desired product and high stability in a wide range of experimental conditions.

The dependence of the catalytic activity of silver on the content of the iodine-containing promoter in the reaction mixture is shown in Fig. 2. As seen (Fig. 2, curve *1*), the ethylene glycol conversion decreases with increasing promoter content in the reaction mixture. This is probably due to the fact that iodine competing with oxygen in the adsorption on the silver surface decreases the content of adsorbed atomic oxygen which provides selective oxidation of ethylene glycol. Also, poisoning of the catalyst surface with iodine due to excess removal of oxygen cannot be excluded.

The dependence of the selectivity with respect to glyoxal on the promoter concentration passes through a maximum, which is observed at a molar ratio of ethyl iodide to ethylene glycol of about 6 ppm (Fig. 2, curve *2*). This is probably due to the following reasons. At a molar ratio smaller than 6 ppm, the promoter content is insufficient for the selective conversion, i.e., at low concentrations of the promoter in the reaction mixture significant amounts of oxygen are retained on the catalyst surface in the form of surface oxide Ag_2^SO, which can participate in further oxidation of the final product by the following reaction:

$$C_2H_2O_2 + 3Ag_2O \rightarrow 2CO_2 + H_2O + 6Ag.$$

On the other hand, at molar ratios of ethyl iodide to ethylene glycol higher than 6 ppm, the catalyst activity decreases due to poisoning of both the oxidation centers on the silver surface participating in the deep oxidation and oxygen-containing centers of the O_α type participating in the selective oxidation of ethylene glycol into glyoxal. Participation of the O_α centers of adsorbed oxygen in the glyoxal formation was confirmed in [14].

Upon prolonged treatment of the catalyst with the reaction mixture containing ethyl iodide in amounts greater that 6 ppm, the process characteristics deteriorate owing to poisoning of the active centers on the silver surface. We studied the possibility of the regeneration of catalyst after prolonged treatment with the iodine-containing promoter. For this purpose, the spent catalyst was annealed in an air flow at 600°C. After this treatment, the experiments on the catalytic oxidation were repeated; the results are listed in the table.

Catalytic activity of the silver samples before and after regeneration; composition of the reaction mixture: EG : O_2 : N_2 : H_2O 1.0 : 1.0 : 10.0 : 3.4, *T* 560°C

Sample	Ethylene glycol conversion, %	Selectivity to glyoxal, %
Ag	90	55
Ag/I	80	66
Ag/I:		
prolonged treatment	70	45
after regeneration	80	64

As seen from the table, annealing in an air flow at 600°C ensures almost complete regeneration of the activity of the silver catalyst. This is probably due to the iodine desorption from the sample surface and regeneration of the centers of alcohol selective oxidation. Thus, we found that the catalyst activity can be enhanced by adding an iodine-containing promoter (ethyl iodide) and the spent silver catalyst can be readily regenerated.

An electron-microscopic examination was performed to study the mechanism of promotion of the iodine-containing additive and the effect of the reaction mixture containing ethyl iodide on the morphology of the silver catalyst. The surface of the initial sample is shown in Fig. 3a. The samples prepared by electrolysis of the silver nitrate melt are elongated particles (5–7 μm wide and 40–60 μm long). The particle surface is smooth and well-rounded along the edges. The structure of the sample surface is determined by the side topochemical processes occurring during electrolysis of the molten mixture of KNO_3, $NaNO_3$, and $AgNO_3$ [15].

The surface morphology of the silver catalysts strongly changes after treatment with both initial and promoted reaction mixtures (Figs. 3b and 3c). As seen, after treatment with the initial reaction mixture $EG : O_2 : N_2 : H_2O = 1.0 : 1.0 : 10.0 : 3.4$ at 873 K, channels 0.2–1.0 μm in diameter are formed on the silver catalyst surface (Fig. 3b), and their amount upon treatment in the presence of the iodine-containing promoter is significantly smaller (Fig. 3c). It was found [14, 16] that these channels are formed in the near-surface silver layers in the course of treatment due to the adsorption of C-containing reagents providing accumulation of the oxocarbon structures able to diffuse into the sample bulk with increasing temperature. Under the action of the oxygen-containing reaction mixture, the oxocarbon fibers formed in the near-surface layer are burnt out, causing formation of channels.

In accordance with the electron-microscopic data, prolonged contact of the catalyst with the reaction mixture leads to the formation of carbon deposits (particles about 2 μm long and 0.5 μm thick, Fig. 3d). This effect is due to the adsorption of carbon-containing reagents participating in the catalytic process [17]. Addition of ethyl iodide does not cause changes in the silver crystal morphology (Fig. 3e). No pronounced carbonization was observed after treatment under the conditions similar to that of the initial sample.

Moreover, we observed almost no adsorption of carbon structures, no formation of the carbonization products, and no development of channels upon treatment of silver with the iodine-containing reaction mixture. This is most probably due to a decrease in the content of oxygen adsorbed on the catalyst surface, which directly participates in carbonization, because no accumulation of the carbonization products on the silver surface is observed in the oxygen-free systems [14].

In the reaction of ethyl iodide with the oxidized silver surface, along with competitive adsorption, removal of the surface oxygen is also possible by the following reactions:

$$2Ag_2O + 4C_2H_5I \rightarrow 4AgI + 2C_4H_{10} + O_2,$$

$$\Delta G_{298} = -564 \text{ kJ};$$

$$Ag_2O + 2C_2H_5I \rightarrow 2AgI + 2C_4H_{10}O, \Delta G_{298} = -450 \text{ kJ}.$$

In a study of the interaction of ethyl iodide with the surface of a preoxidized silver single crystal, the reaction products (butane, diethyl ether) used in the ther-

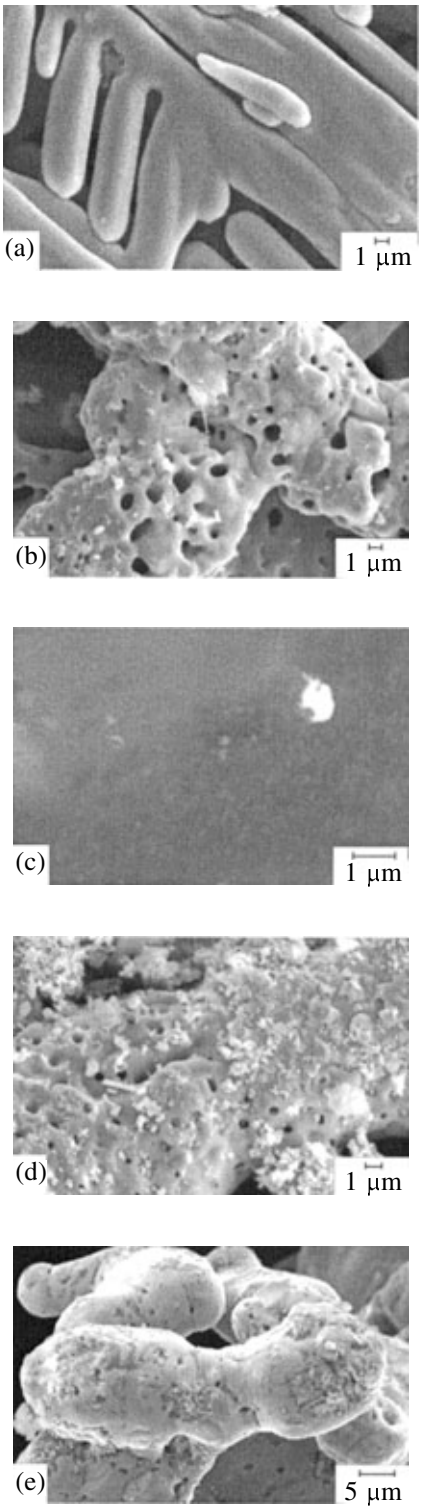

Fig. 3. Morphology of the silver catalyst surface: (a) initial sample, (b) sample treated with the initial reaction mixture, (c) catalyst treated with the promoted reaction mixture, (d) sample treated with the initial reaction mixture for a long period, and (e) sample treated with the promoted reaction mixture a long period.

mochemical calculations were detected by gas chromatography–mass spectrometry [18].

CONCLUSIONS

(1) The catalytic and physicochemical experimental data showed that addition of an iodine-containing promoter into the reaction mixture increases the selectivity with respect to glyoxal by 5–10%.

(2) The catalytic activity increases owing to a decrease in the contribution of the carbonization and profound oxidation in the presence of the iodine-containing additives.

(3) Promoter decreases the concentration of the centers of adsorbed oxygen responsible for the formation of carbonization products and occurrence of deep oxidation of ethylene glycol. In this case, the amount of oxygen participating in the selective conversion of alcohol decreases only slightly, leading to only insignificant decrease in the ethylene glycol conversion.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Refined Estimates of the Effect of Jet Discharges from Launch Vehicles on the Kinetics of the Stratospheric Ozone

O. V. Yatsenko

Don State Technical University, Rostov-on-Don, Russia

Received November 15, 2004; in final form, April 2004

Abstract—The kinetic model of perturbations of the stratospheric ozone by propulsive jet discharges of modern launch vehicles was modified, which made it possible to refine theoretical estimates of the accompanying physicochemical processes and to improve the reliability and consistence of the basic parameters. The natural and artificial mechanisms of turbulent dissipation of the rocket trace in the stratosphere and their dependence on the altitude were taken into account. The mass–energy and specific characteristics of the propulsive jet discharges of rockets were factorized. The agents, factors, and mechanisms determining the scale, level, and dynamics of the perturbation of stratospheric ozone in launches of liquid-propellant launch vehicles were revealed and a small-scale kinetic–diffusion model was suggested for engineering estimates.

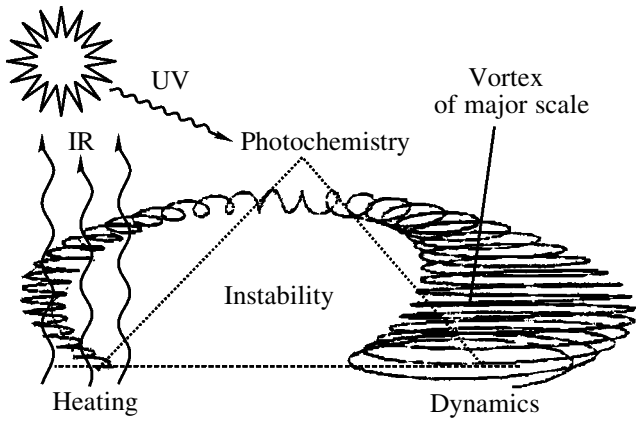
DOI: 10.1134/S107042720609014X

The stratosphere, or ozonosphere, is an atmospheric layer lying at altitudes of 15–50 km [1]. Preventing penetration of the ultraviolet solar radiation with wavelengths $\lambda \leq 300$ nm, this layer provides the existence of the present-day biosphere. The main agents absorbing the detrimental photons are molecular oxygen and ozone. Oxygen molecules O_2 (principal stratospheric absorber of UV photons with $\lambda \leq 220$ nm) is one of the main components of the atmosphere at these altitudes and its content cannot differ significantly from 21%, whereas O_3 is minor chemically active admixture whose relative concentration does not exceed 10^{-5} (a collective term minor gas components of the stratosphere, MGCS, is used for these substances [1]). It is of fundamental importance that the stratosphere is a multicomponent distributed dynamic system with strong chemical nonlinearity, multiscale transfer, and long-range radiative coupling, classified as dissipative (see scheme in Fig. 1). The evolution of systems of this kind is unstable and stochastic, and their response to external impacts may have a trigger nature [2]. Although the theory of dissipative dynamic systems is a priority area of mathematical research, the achievements made fail to satisfy the increased requirements of natural-science applications.

The modern economical activities involve risk of triggering the stratospheric processes into the alternate stable mode and thereby causing a global environmental disaster and extinction of the biosphere. Because the chemically active gases discharged by terrestrial industrial sources do not reach the stratospheric altitudes [1], the propulsive jets of launch vehicles seem to be one of the main artificial hazards to the ozone layer of the Earth.

The published results of experimental studies [3–9] are largely contradictory, which is due to the exceedingly complicated and interdisciplinary nature of the problem. When classifying the imperfections of modern models of evolution of the rocket trail in the stratosphere, the following should be distinguished: (1) incompleteness and thermochemical inconsistency of the kinetic schemes proper of (photo)reactions; (2) insufficiently detailed description of turbulent motions in that part of the ozonosphere which is perturbed by launch vehicles; and (3) contradictory evidence concerning the thermochemical parameters and, in particular, the degree of departure from equilibrium of the gas in the propulsive jets of launch vehicles. In addition, no attempts to construct versatile small-scale models of perturbation of the stratospheric O_3 in vehicle launches have been known, despite that models of this kind are exceedingly useful as a means of engineering evaluation of the environmental damages and risks accompanying the launches.

The aim of this study was to reveal processes, factors, and circumstances that determine the qualitative features and quantitative parameters of the influence exerted by rockets on the stratospheric ozone.



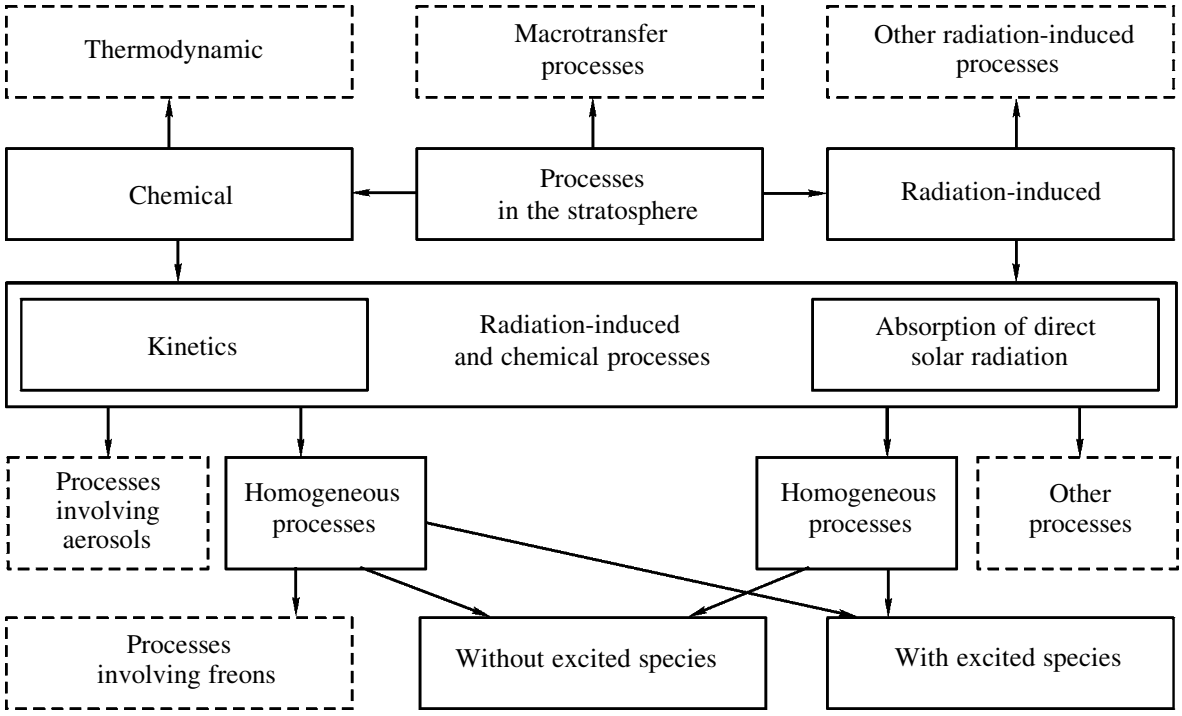


Fig. 1. Scheme of dissipative photochemical and mechanical processes in the ozonosphere.

This was done by means of theoretical analysis and systems synthesis based on computer simulations with high-resolution information models free of disadvantages 1–3. The problems solved in the framework of the research program specified above consist in construction of appropriate equations and reaction schemes, development of efficient methods for their numerical integration and asymptotic study, selection and systematization of the initial characteristics of the rocket trail, and factor analysis of detailed computer models of disturbed stratosphere and their subsequent "reduction" to minimum overall models suitable for fast, including scenario-type, assessments of the environmental consequences of rocket launches.

Model of a stratosphere perturbed by rocket jets. Thorough analysis [1, 10, 11] shows that the energy supply of all the stratospheric processes (Fig. 1) occurs via the photochemical cycle of ozone. This circumstance, in particular, accounts for the term "ozonosphere," equivalent to stratosphere. At the same time, this fact serves as a basis for setting up the physical or energetic hierarchy of processes and scales in construction of mathematical models of the ozonosphere dynamics. The characteristic parameters of the stratosphere are the density $0.001–0.1\rho_0$ (ρ_0 is the air density at the sea level) and concentration of ozone $10^{11} < [O_3] < 3 \times 10^{12}$ cm^{-3}, which is at a maximum at the altitude $H \approx 25$ km. In these conditions, the mean free path l of molecules is within the range 10^{-4}–10^{-2} cm, and the Knudsen number $Kn = l/L$ falls within the range 10^{-6}–10^{-4} for the minimum rocket trail scale $L = 1$ m, i.e., the dynamics of the ozonosphere perturbed by launch vehicles is adequately described by the models of a continuous medium and equilibrium chemical kinetics [12].

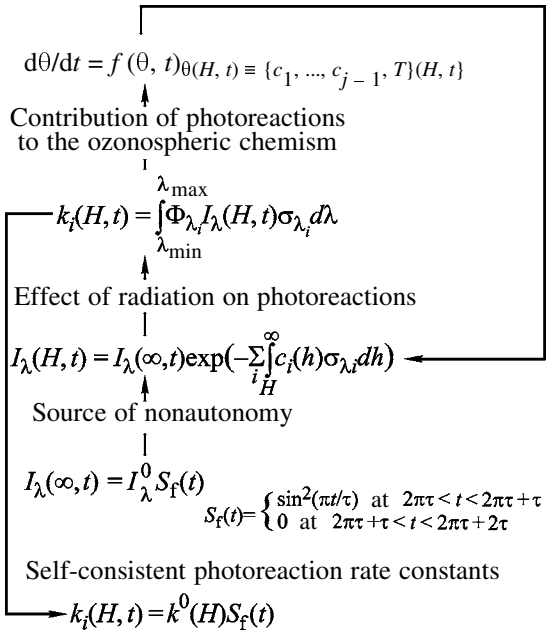
The computer simulations performed in this study are based on a detailed model of photochemical processes in the ozonosphere perturbed by rocket discharges. This model, successfully tested and described

Scheme 1.
Physicochemical processes in the ozonosphere perturbed by propulsive jets of launch vehicles

in detail in [13–15], includes more than 1100 (or 550 pairs of mutually reverse) elementary chemical reactions and 32 elementary photo processes involving photons in the spectral range λ = 180–740 nm. The structure and composition of the photochemical unit of the model are presented in Scheme 1. The unaccounted-for physicochemical processes (delimited by dashed lines in Scheme 1) can be included in the model when necessary, which is provided by the open structure of the photochemical unit and is supported by the means of automated kinetic modeling, developed by the author [16, 17]. The neglect of the atmospheric macroscopic transfer (winds, circulation, convection, large-scale turbulent diffusion) limits the adequacy of the model to the time interval corresponding to the so-called synoptic scale of ~10 days [1, 10]. At the same time, the very detailed photochemical unit [13, 15] can be used as an element of more intricate and versatile models.

Because the stratosphere is permanently stratified (temperature increases with altitude, which hinders vertical agitation), the turbulent transfer occurs virtually exclusively in the horizontal direction. Hence it is, in principle, appropriate to regard the overall rocket-induced perturbation of the ozonosphere as a superposition of perturbed dynamics of its separate layers. This circumstance makes it possible to reduce by a factor of at least N^2 the necessary volume of computation by dividing the stratosphere into N quasi-homogeneous zones along its height, and, as a result, the problem comes within the powers of modern computers. The technical problem of stratification of the ozonosphere dynamics is solved by "decoupling" of the kinetics of photoreactions and of the radiative transfer. If we denote the set of concentration variables $c_i(H, t)$ (subscript i designates a particular substance, i = 1, ..., I – 1) and temperature $T(H, t)$, which form a pseudovector, by $\theta(H, t)$, the kinetics of unperturbed ozonospheric (photo)reactions is described by the system of equations

$$d\theta/dt = f(\theta, t), \quad (1)$$



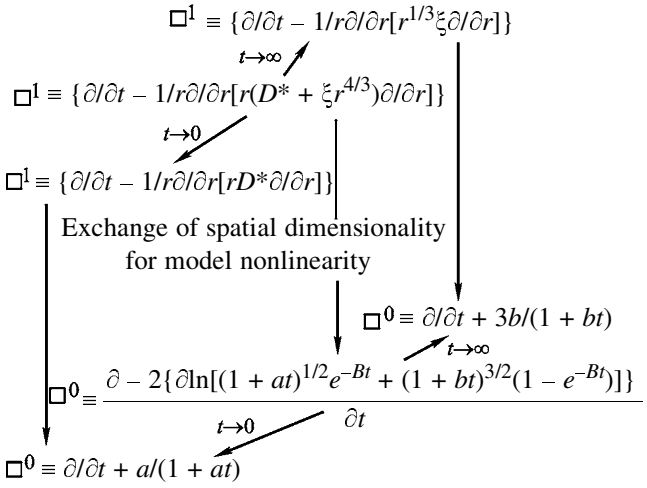
which implicitly includes, via the nonautonomy of the right-hand parts of (1), the field of solar radiation in the stratosphere. The iteration procedure, described in detail in [13, 15] and presented in Scheme 2, enables factorization of the altitude- and time-related components in the models of rate constants of the photoreactions

$$k_i(H, t) = k_i^0(H) S_f(t). \quad (2)$$

The altitude dependences of the photoconstants $k_i^0(H)$, amplitude I_λ^0, and averaged time dependence

Scheme 2.

Scheme of model stratification of the ozonosphere perturbed by rocket discharges via introduction of effective photoreaction constants



Note: $I_\lambda(H, t)$ is the intensity of direct solar radiation with wavelength λ at altitude H (20 to 50 km) at instant of time t; c_i, concentration of a substance decomposing in ith process; and σ_{λ_i} and Φ_{λ_i}, cross section and quantum yield of a photoreaction. Here, the common numbering of substances and photoreactions is used because, in the given case, each component decomposes in only a single process.

of the intensity of solar radiation [$S_f(t)$] were reported in [13–15].

An additional important improvement of, in particular, the models reported in [13–15] is associated with the refinement of the magnitude and altitude profile of the turbulent transfer coefficient ζ for the stratospheric conditions. In [13–15], this parameter of the stratosphere was assumed to be altitude-independent and was determined on the basis of the following considerations. Stratospheric gases, mainly ozone, almost fully absorb the solar radiation in the spectral range 200–300 nm. An energy of about 1.8×10^4 erg cm^{-2} comes every second to the ozonosphere with this radiation. The mass of a column in the stratosphere, with a base of area 1 cm^2, is about 100 g. With the alternation of day and night accounted for by the factor 1/2, we obtain an altitude-average dissipation of solar energy in the stratosphere $\langle\varepsilon\rangle$ = 90 cm^2 s^{-3} and an ozonosphere-average turbulent transfer coefficient $\langle\xi\rangle = \langle\varepsilon\rangle^{1/3}$ = 4.5 cm$^{2/3}$ s^{-1} [1, 18]. Relating these consideration to the experimentally

Scheme 3.

Hierarchy of models of the turbulent dissipation of the rocket trail in the ozonosphere

known [1] daily heating of the ozonosphere, $\Delta T(H)$, we obtain

$$D(H) = 15e^{H/16}[\mathrm{cm^2\ s^{-3}}],$$

$$\xi(H) \approx 2.5e^{H/48} \approx 1.4 + 0.11H\ [\mathrm{cm^{2/3}\ s^{-1}}]. \quad (3)$$

According to (3), the value of ξ at the upper boundary of the stratosphere is twice that at the lower boundary and equals 7 $\mathrm{cm^{2/3}\ s^{-1}}$. Relation (3) makes the model more realistic by refining the duration of smearing of the rocket trail by the atmospheric turbulence proper.

Model of evolution of a rocket trail in the stratosphere. If we assume that the flight of a launch vehicle does not directly distort the stable stratification and the radiation regime of the ozonosphere, the evolution of a rocket trail is described by a system of quasilinear differential equations [15] for the concentration-temperature field $\theta(r, t) \Leftarrow \theta_H(r, t) \Leftarrow \theta(r, H, t)$, which has, if we take into account (1), the form

$$\square^n\theta = f(\theta, t), \quad (4)$$

where $\square^n$ is the operator responsible for impurity dispersal in the box-type ($n = 0$) and spatially unidimensional ($n = 1$) centrally symmetric formulations; r, distance from the trajectory axis; and $f(\theta, t) \Leftarrow f(\theta_H, t)$, i.e., the altitude H is regarded as a parameter.

Model (4) of rocket trail dissipation is adequate upon termination of the impact-wave stage of its evolution or approximately a second after the fly-by of a launch vehicle [19]. It should also be noted that integration of the solution to (4) over the altitude does not involve any additional difficulties, because the trajectories of modern launch vehicles in the stratospheric part (up to altitudes of 42–45 km) are virtually vertical.

Analysis of the mechanisms of stratospheric [1, 18] and artificial, generated by a propulsive jet [20], turbulence makes it possible to construct a generalized model that adequately reflects the dynamics of the early and late stages of the evolution of a rocket trail. In this model, the differential evolution operators $\square^n$ have the form

$$\square^0 \equiv \frac{\partial - 2\{\partial \ln[(1 + at)^{1/2}e^{-Bt} + (1 + bt)^{3/2}(1 - e^{-Bt})]\}}{\partial t},$$
$$\square^1 \equiv \{\partial/\partial t - 1/r\partial/\partial r[r(D^* + \xi r^{4/3})\partial/\partial r]\}, \quad (5)$$

where r and t are the spatial and temporal variables, respectively; D^*, effective coefficient of quasimolecular diffusion, whose value (for modern launch vehicles $D^* \approx u_0 d \approx 10^8$ $\mathrm{cm^2\ s^{-1}}$, where $u_0 \approx 3 \times 10^5$ $\mathrm{cm\ s^{-1}}$ is the outflow velocity of propulsive gases; $d \approx 3 \times 10^2$ cm is the initial jet diameter) is many times the coefficient of truly molecular diffusion, D, which does not exceed 10^3 $\mathrm{cm^2\ s^{-1}}$ under the stratospheric conditions; $a = D^*/r_{\mathrm{ini}}^2$, $b = \xi(3r_{\mathrm{fin}}^{2/3})$, reciprocals of the characteristic swelling time of the trail cloud in the early and final stages of evolution; r_{ini} and r_{fin}, minimum radii of the trail cloud in the initial and final turbulent-diffusion stages of dissipation of the rocket trail; constant $B \approx (\xi/D^*)^{1/2}$ characterizes the rate of change of the dispersal mechanism, from that motivated by the kinetic energy of propulsive gases to the mechanism due to purely atmospheric motions.

In the early stage of dissipation of the rocket trail, when gas agitation is due to the residual energy of the propulsive jet, we have the starting asymptotic of turbulent motions [15] and

$$\square^0 \equiv \partial/\partial t + a/(1 + at),$$
$$\square^1 \equiv \{\partial/\partial t - 1/r\partial/\partial r[rD^*\partial/\partial r]\}. \quad (6)$$

After the dissipation of the trail cloud becomes associated with the energy balance of the atmospheric turbulence, these operators degenerate in another way. The corresponding asymptotic has the form [13–15]

$$\square^0 \equiv \partial/\partial t + 3b/(1 + bt),$$
$$\square^1 \equiv \{\partial/\partial t - 1/r\partial/\partial r[r^{7/3}\xi\partial/\partial r]\}. \quad (7)$$

Equations (5) degenerate into (6) at $Bt \ll 1$, and into (7) at $Bt \gg 1$. Taken together and arranged in a certain order, Eqs. (5)–(7) constitute the hierarchy of models of evolution of the rocket trail in the ozonosphere (Scheme 3).

As the initial conditions specifying model (5) should be chosen

$$\theta(0) = \theta_H + \Delta\theta_H \text{ at } r \le r_{ini} \text{ and } \theta(0) = \theta_H \text{ at } r > r_{ini},$$

$$\text{if } n = 0;\ \theta(r,0) = \theta_H + \Delta\theta \exp[-(r/r_{ini})^2] \text{ at } n = 1. \quad (8)$$

Relations (8) were derived on the assumption that the mass fraction of the impurity in the trail cloud is small. Below, we suggest a way to set the initial parameters of propulsion discharges of particular launch vehicles, which implements the idea of dividing the characteristics of primary rocket-induced perturbations of the ozonosphere into quantitative and qualitative.

Versatile model and real parameters of rocket discharges. The trajectories of all modern launch vehicles are closely similar in their stratospheric part: here, the close run of altitude–velocity dependences $v(H)$ of different rockets of the same purpose is meant. This statement is a result of an analysis of the trajectory data published in [4, 6, 8, 9, 21–24]. These data, plotted in Fig. 2, allow a simple approximation

$$v(H) \approx 25(H - 5) \text{ m s}^{-1}. \quad (9)$$

The universality of constraint (9) is due to the following. The phase portrait of a rocket trajectory, $v(H)$, is defined as a solution to a first-order ordinary differential equation. The structure of this equation is such that the solution is very smoothly dependent on two parameters. Endowed with the physical meaning of a thrust-to-weight ratio (possible acceleration typically equal to 30 ± 5 m s^{-2}) and the Lock number (ratio of aerodynamic to inertia forces, which is proportional to the mass of the launch vehicle to the 1/3 power and, consequently, shows a scatter by a factor of less than 2) of the rocket, these parameters virtually coincide for launch vehicles of different types. This is not surprising because those who develop aerospace facilities are forced to fit the common, and rather narrow, ranges of design parameters of engines and constructions in order to make compromise solutions satisfying a wide variety of contradictory requirements.

The extensive characteristic of a particular jet, the total per-second flow rate of combustion products, appears in the initial conditions of the problem of dissipation of the trail cloud via the parameter r_{ini}: as the power of a launch vehicle increases, the propulsion trail reaches in a longer time, and farther from the nozzle exit, the thermal gas-dynamic conditions chosen as those of universal nature. Using the theory of turbulent jets [20] and neglecting the impact-wave

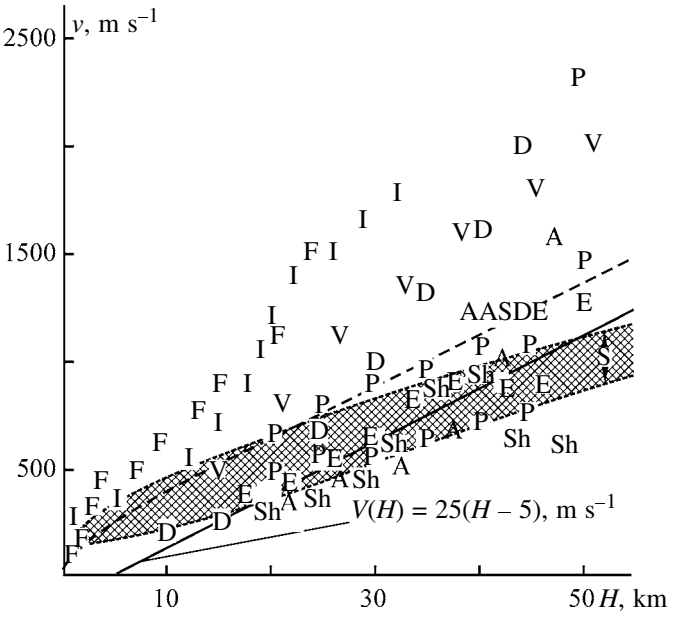


Fig. 2. Phase portraits of rocket trajectories according to [4, 6, 8, 9, 21–24]. (v) Velocity and (H) altitude. Launch vehicles: A, Ariane V; P, Proton; S, Saturn 5; Sh, Space Shuttle; E, Energiya. AASDE, approximate analytical solution to the dynamics equation of an averaged rocket.

processes in the near trail of a launch vehicle [19, 20], we can express r_{ini} as a function of the gas-dynamic parameters of the jet and concurrent flow:

$$r_{ini} = \left[\frac{[u_0 - v(H)]\dot{m}}{u_s^2 \rho_0}\right]^{1/2} e^{H/16}, \quad (10)$$

where $u_0 \approx 3700$ m s^{-1}, $u_s \approx 300$ m s^{-1}, and $\rho_0 \approx 1.29$ kg m^{-3} are, respectively, the outflow velocity of the propulsive jet, speed of sound in air, and density of the atmosphere near the Earth's surface; $\dot{m}$ is the per-second expenditure of fuel during the working period of the first stage of a launch vehicle.

When deriving formula (10), we assumed that the value of r_{ini} corresponds to the thermal gas-dynamic state of an expanded jet, in which the kinetic energy of its directed motion is at a level of 10% relative to the thermal energy of the surrounding atmospheric gases. It was also considered that the remaining 90% of the energy of the propulsive jet is transformed into heat by that time.

Combining (9) and (10), we obtain the altitude dependence of the initial radius of the rocket trail

$$r_{ini}(H, \dot{m}) \approx 0.1(3 - 0.03H)^{1/2} e^{H/16} (\dot{m})^{1/2}. \quad (11)$$

Energetic and ecological characteristics of first stages of modern launch vehicles

Type a launch vehicle (number and make of engines)	Fuel expenditure, kg s^{-1}	Content in propulsive jet, mole fraction, of indicated combustion product of rocket fuels				
		Cl_2	HCl	Al_2O_3	NO	OH
Proton, 6×RD-253	3200	–	–	–	7.6×10^{-3}	1.6×10^{-4}

	9800	–	–	–	8.8×10^{-4}	2.1×10^{-4}
Ariane V	1900*	5×10^{-4}*	0.12	0.18	3×10^{-4}*	2.0×10^{-4}
Titan-IV	2250*	5×10^{-4}*	0.19	0.019	3×10^{-4}*	3.3×10^{-4}

* The parameters of the propulsive jets of launch vehicles were obtained by combination of data from various sources, with account of the common constraints (9)–(15).

Equation (11) factorizes the universal altitude–velocity and the specific extensive components of the initial conditions of the problem concerning the turbulent dissipation of a cylindrically symmetrical cloud of a chemically active impurity in the stratosphere.

The levels of the initial perturbation of the concentration–temperature field, $\Delta\theta \equiv \{\Delta c_i, \Delta T\}$, which are necessary for integration of the evolution equations (5)–(8) of the rocket trail, and the overall contamination and densification are evaluated by the formulas [15, 20] that express the conservation laws in the theory of submerged turbulent jets:

$$\Delta c_{i,H}(0,0)/\Sigma c_{i,H} = \Delta c_{i,H}(0)/\Sigma c_{i,H} \approx 1000/[\mu_i(145 - H) \times (H - 5)], \quad (12)$$

$$\Delta T_H/T_H \approx [u_0 - v(H)]/[v(H)] \approx (145 - H)/[4(H - 5)], \quad (13)$$

$$\Delta\rho/\rho_H = u_s^2/\{\pi[v(H)(u_0 - v(H))]\} \approx 40/[(145 - H)(H - 5)], \quad (14)$$

$$\Delta c/c = \Sigma\Delta c_{i,H}/\Sigma c_i \approx \Delta\rho/\rho \approx 40/[(145 - H)(H - 5)]. \quad (15)$$

The most widely used are two-component liquid rocket propellants (LRP) whose chemical energy is contained in substances or mixtures, fuel and oxidant, separately stored and fed into the combustion chamber. Typical liquid rocket fuels are liquid hydrogen, hydrazine N_2H_4, unsymmetrical dimethylhydrazine $N_2H_2(CH_3)_2$, kerosene T-1, and synthetic hydrocarbon fuel RJ-1, as well as Al and Mg dispersed in liquid fuels (present in fuels as free metals or hydrides AlH_3, MgH_2). As oxidants commonly serve liquid oxygen O_2, concentrated nitric acid HNO_3, or nitrogen tetraoxide N_2O_4 [21, 23, 24]. The products formed in the combustion of liquid rocket fuels include ozone-depleting species: NO, OH, and Al_2O_3.

Composite solid rocket propellants (CSRP) are based on an oxidant, commonly, ammonium perchlorate NH_4ClO_4, and more rarely, ammonium dinitramide $NH_4N(NO_2)_2$ and nitrates of alkali metals. As the main metallic fuel serves aluminum Al or AlH_3, with the mass fraction of the fuel in CSRP reaching 18%. In combustion, CSRP release, together with nitrogen and aluminum oxides, also ozone-depleting chlorine compounds, HCl and Cl_2.

It has been found [4–7, 13–15] that the stratospheric chemistry essentially differently "responds" to launches of liquid- and solid-propellant launch vehicles: in the former case, the perturbed ozonosphere comparatively rapidly relaxes to the initial (dynamic) state via local reactions, whereas in the latter, the relaxation is exceedingly slow and occurs exclusively via vertical transfer of untypical substances. Accordingly, simulation of these varieties of perturbation requires that specific approaches should be used. Similarly to the models from [4–7, 13–15], the set of models considered in this study is adapted to description of sharp, locally eliminable perturbations of the ozonosphere, i.e., those caused by launches of various liquid-propellant launch vehicles, which yield combustion products containing no chlorine compounds.

Considered together with formulas (8)–(15), the initial parameters of perturbation of the ozonosphere by various types of launch vehicles are readily combined into a table. The table summarizes the specific energetic and ecological parameters of the most widely used launch vehicles [4, 6, 8, 9, 21–24]. Because of the wide scatter of published data, the content of separate components in the rocket trail is given in the form of interval estimates. The reliability of these

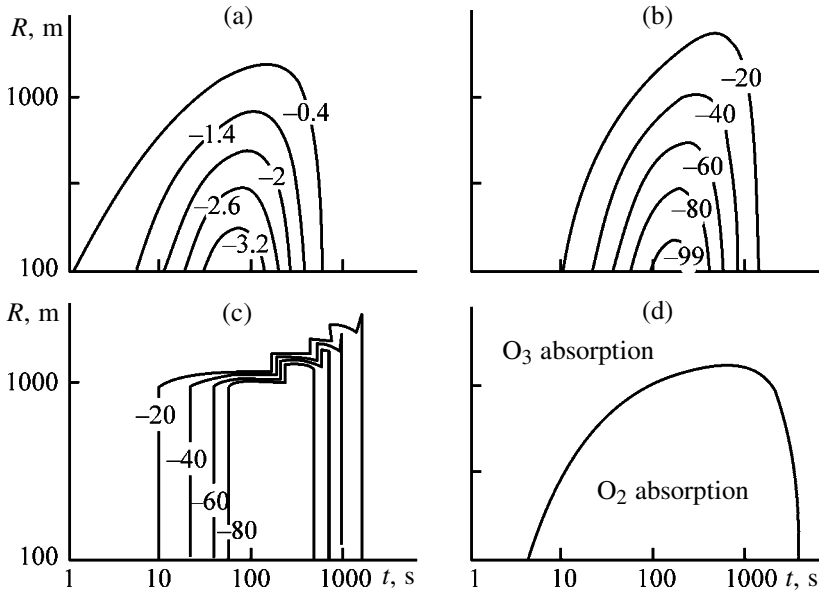

Fig. 3. Dynamics of an integral perturbation of stratospheric ozone (in percent relative to the unperturbed value) in a single launch of Proton launch vehicle. (*R*) Distance from the axis of the rocket trail and (*t*) time.

data well justifies the assumptions on which the estimates (8)–(15) are based.

It is noteworthy that the table lists the launch vehicles and substances that are the most important for the photochemistry of stratospheric ozone. If the estimates of the content of ozone-depleting substances in the primary rocket trail, made by different authors [4, 6, 8, 9, 21–24], show a wide scatter, preference is given either to better confirmed (both directly and indirectly) estimates or to those producing the least optimistic impact scenario. When it is impossible to range the reliability of published data [4, 6, 8, 9, 21–24], the table gives the upper bound. Because changes of the working modes of rocket engines cannot be correctly taken into account, either, data on the expenditure of fuel components and on the composition of combustion products are averaged. It is noteworthy that the tabulated content of NO and OH in discharges from liquid-propellant launch vehicles corresponds to the real nonequilibrium composition of combustion products, but exceeds by three to four orders of magnitude the equilibrium values previously used in a number of studies [5, 7]. As shown below, this refinement of previous estimates is the most important factor.

The launch of the main Russia's launch vehicle Proton is accompanied by discharge into the ozone layer of considerable amounts of NO, the main ozone-depleting species (factorial analysis of the model shows that hydroxide is of secondary importance in the given case). Analysis of recent domestic and foreign publications [4, 6, 8, 9] and the chemical composition of the propulsive jet, specially calculated by the author, indicate that the level of this specific factor was strongly underrated in previous estimates [5, 7]. The reason for this frequently occurring error is that nitrogen oxide forming in the combustion chamber does not have enough time to relax to the equilibrium concentration in the fast outflow from the nozzle. Therefore, the content of NO in the propulsive jet virtually coincides with that in the combustion chamber and, accordingly, is determined by thermodynamic parameters in the most thermally loaded part of the rocket engine. If this circumstance, first discovered by Zel'dovich and named "quenching" [25], is taken into account, the initial level of the NO-related perturbation is approximately four orders of magnitude higher, the spatial scale of the perturbed region increases by approximately $4^{1/2} = 2$ orders of magnitude, and the dispersal time becomes longer by $4^{1/3}$ orders of magnitude, i.e., by a factor of approximately 40. The result of a numerical integration of rate equations (4) and (5) with initial conditions (8)–(15) for a single launch of Proton launch vehicle (see table) is shown in Fig. 3.

The calculation is performed on the assumption that the combustion products have equilibrium (according to [7], Fig. 4a) and nonequilibrium (according to data in the table, Figs. 3b–3d) chemical composition. Separately are presented the computed detailed

kinetics of ozone depletion (Fig. 3b), its approximation with a small-scale model [15] (Fig. 3c), and the physical size of the ozone hole, the region in which molecular oxygen becomes the main absorber of the UV radiation with wavelengths λ = 221–235 nm (Fig. 3d).

The results of a detailed computer simulation, shown in Fig. 3, indicate that the impact is local and short (compared with the synoptic scale), which well justifies the assumptions made when constructing the model. An analysis of the results of the numerical experiment demonstrated that the principal refinement of the models of rocket-induced perturbations of the ozonosphere dynamics [5, 7] is due to taking into account the chemically nonequilibrium state of the propulsion gases, caused by quenching of NO. If the dynamic model and initial data, refined in this study, are used, the magnitude of the integral (across the entire thickness of the ozonosphere) perturbation increases by approximately one and a half orders of magnitude, and the time of relaxation of the stratosphere to the initial state and the transverse size of the ozone hole grow severalfold. This result is in good agreement with the above elementary estimates based on the conservation laws and properties of a developed turbulence, the dynamic mode of the stratosphere. The perturbation of ozone at any fixed altitude is stronger and shorter than the integral perturbation shown in Fig. 3. The refinement of the spatial profile of the ozone hole shows itself in a later stage, when the $[O_3]$ perturbation level becomes insignificant and comparable with diurnal, seasonal, or solar-activity variations. In this case, the addition of an artificial mechanism of dispersal of the trail cloud in the early stage of its evolution is more important that that refinement of the model which is associated with transition from the box dissipation scheme to that realistically distributed [$\square^0 \Rightarrow \square^1$ in the evolution equations (4), (5)]. The results obtained actually point to the priority of refining the models of the reactions between the rocket fuel components, with account of the gas dynamics in the nozzle and detailed data on mixing of the propulsive jet with air.

The practice of modern engineering-ecological calculations acutely needs methods for extension of the results of detailed computer simulations to a wide variety of similar situations without performing labor-consuming computations in each particular case. As applied to short-time ozonosphere perturbations caused by launches of liquid-propellant launch vehicles, this demand can be satisfied by analytical models suggested in [7] and further developed in [13, 15]. The numerical result obtained (Fig. 3b) is in good agreement with the two-component box model [15], in which ozone is decomposed by NO, and NO is decomposed on certain third species in parallel turbulent dispersal of both substances in the horizontal direction. Dropping the rearrangements reported in [15], we obtain the law of evolution of the whole amount of stratospheric ozone upon a rocket-induced perturbation:

$$[O_3](r,t) = \{[O_3]_0 + k_{O_3}[O_3]_{ph}[NO]_0/(k_{NO}[M]) \times [\exp(-k_{NO}[M]t) - 1]\}S^n(r,t),$$

$$S^n(r,t) = \begin{cases} \operatorname{sign}[r_{ini}^{2/3}(1+bt) - r^{2/3}]/(1+bt)^3 \text{ at } n = 0, \\ 6e^{-r^{2/3}/[(r_{ini}/6)^{2/3}(1+bt)]}/(1+bt)^3 \text{ at } n = 1. \end{cases} \quad (16)$$

In Eqs. (16), the subscript ph refers to unperturbed or background concentrations; k_{O_3} and k_{NO}, effective constants of ozone depletion in the set of reactions involving NO and loss of NO in reactions with various substances M; $S^n(r_{ini},0)$, initial distribution of impurity components (products of complete and incomplete combustion of liquid rocket fuels) in the stratosphere, which provides existence of self-simulating solutions to problem (16).

If (16) is regarded as a model of an overall perturbation of the ozonosphere by Proton liquid-propellant launch vehicle, it is necessary to find values of the effective kinetic coefficients. To do this, we use the calculated data in Fig. 3b and an appropriate optimization method. We use the least-squares procedure to find $k_{NO}[M] \approx 10^{-2}$ s^{-1} and $k_{O_3}[O_3]_{ph} \approx 10^{-4}$ s^{-1}, $[O_3]_0/[O_3]_{ph} \approx 0.01$–$0.03$, $[NO]_0/[O_3]_{ph} \approx 30$–$100$. The first two values are in good agreement with the results of [1, 10, 11], and the last two, with the stratosphere-average parameters of the primary rocket trail in the detailed model (4)–(15) (see table). To initialize Eqs. (16) using the results of computer simulations in terms of the detailed kinetic model (4), (5), (8)–(15), it was necessary to include r_{ini} in the set of fitting parameters. Variation of the initial size of the perturbed region makes it possible to take into account the asynchronous action of a launch vehicle on different layers in the stratosphere. The altitude-averaged value $r_{ini} \approx 1000$ m exceeds by an order of magnitude the local initial radius of the trail. This means that, as the launch vehicle reaches the upper boundary of the ozone layer, the size of the ozone hole has enough time to grow, across a considerable thickness of

lower-lying layers, to

$$R \sim \{\xi(H_{max} - H_{min})/v[(H_{max} + H_{min})/2]\}^{3/2} \approx 3 \times 10^2 \text{ m}. \quad (17)$$

This value is in good agreement with the result of identification (16) based on the results of detailed calculations (Fig. 3b); the difference of half an order of magnitude is readily accounted for by the neglect, in deriving (17), of the fact that the launch vehicle is comparatively slowly moving in the lower part of the stratosphere, where the main part of ozone is concentrated. The relative difference of the numerical results (Fig. 3b) from their approximation in terms of the small-scale model (16) does not exceed $3^{1/2}$, which points to simplicity and predictability of ozonosphere perturbations caused by launches of liquid-propellant launch vehicles.

It should be noted that the extensive characteristic of the discharge, $d\dot{m}/dt$, has effect only on the size of the perturbed region, whereas the content of ozone-depleting components (NO in the case in question) in the combustion products of liquid rocket fuels affects not only the size r_{ini} of the primary trail cloud, but also the peak perturbation level $[NO]_0/[O_3]_{ph}$.

However, the simplified approach cannot, despite the advantages mentioned above, completely replace a computer simulation of the process in terms of high-resolution models. This is due to the fact that the minimum model (16) is based on analytical solutions to systems of two quasilinear equations [15] and can serve as a convenient projection of real, strongly nonlinear systems of high dimension in a strictly limited range of parameters. When going beyond the admissible limits, the reduced model loses adequacy: such a complex dynamic system as the ozonosphere differently responds to impacts of the same type, but of different levels. The mechanism of rapid neutralization of weak external impacts, which exist in systems of this kind, fail when the impacts become too strong and the response (counteraction) is effected by more powerful and, simultaneously, more sluggish mechanisms. In the case in question, the small-scale model (16) is identified by the response of the detailed model to a strong impact and the kinetic parameters of the homeostatic mechanism of the corresponding level are calculated. It would be expected that the response of the simplified model to a weak impact will be delayed (computer calculations confirm this conclusion). If, however, the small-scale model is identified by the weakly perturbed dynamics of the detailed model (4)–(15), we run the risk of overlooking the organization of the ozonospheric homeostasis, which is responsible for the structural-dynamic integrity of the ozonosphere upon external destructive impacts and is characterized by a hierarchy of connectedness. Therefore, small-scale models of the type (16) are parametrically local: their purpose is to explain particular results, rather than to make long-term predictions.

CONCLUSIONS

(1) Taking into account the nonequilibrium state of the products formed in combustion of liquid rocket fuels is the main way to improve models of local impact of launch vehicles on the stratospheric ozone.

(2) The corresponding refinements of prototype models show that the degree of local ozone depletion in launches of Proton launch vehicle is close to 100%, rather than to 3%, and it is absolutely necessary to take into account the risk of biological objects being damaged by UV radiation near rocket trajectories.

(3) The situation with the key role of the chemically nonequilibrium state is "robust," i.e., it does not change on making the models more detailed, e.g., by incorporation of more realistic descriptions of the turbulence.

(4) The models of rocket-induced perturbations of the ozonosphere can be factorized with respect to extensive and specific parameters, which gives reason to "compress" the information and make engineering-ecological estimates by similarity methods.

(5) Taking into account the artificial or propulsive mechanism of dissipation of the rocket trail in the early stage of its evolution is the priority way to modify the model by detailing the spatial distribution of trail substances.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Treatment of Wastewater to Remove Ammonium Ions by Precipitation

S. A. Lobanov and V. Z. Poilov

Perm State Technical University, Perm, Russia

Received April 12, 2006

Abstract—The process of wastewater treatment to remove ammonium ions by precipitation in the form of ammonium magnesium phosphate was studied. The fundamental aspects of the chemical precipitation process were examined. The effect of various factors on the efficiency of wastewater treatment was experimentally analyzed.

DOI: 10.1134/S1070427206090151

At present, numerous industrial plants encounter the problem of wastewater treatment to remove ammonium ions. The large amount of ammonium nitrogen in industrial sewage leads to oxygen starvation of plants and adversely affects the flora and fauna of water reservoirs.

One of the most promising methods of wastewater treatment to remove ammonium ions is precipitation of ammonium in the form of insoluble ammonium magnesium phosphate hexahydrate (AMP), struvite $MgNH_4PO_4 \cdot 6H_2O$ (SP = 5.5×10^{-14} [1]). This method provides a high degree of purification and enables secondary use of ammonia, because AMP is a valuable product and can be used as a fertilizer [2]. At present, the operation of some sewage treatment facilities in various countries is based on removal of ammonium and phosphate ions from sewage by their precipitation as AMP. The precipitate obtained is in demand at the world market as an integrated mineral fertilizer [3, 4].

Available publications show that the high efficiency of wastewater treatment is achieved at pH 8–9 and a stoichiometric ratio of the reacting components, or at their minor excess [3, 4]. The most frequently used in wastewater treatment are magnesium chloride and soluble phosphates of alkali metals as precipitating reagents, and sodium hydroxide as an alkaline agent [4].

The fundamental aspects of the AMP crystallization process and the influence exerted on this process by various factors have been insufficiently studied. An analysis of this kind is necessary for control over the crystallization process and production of a precipitate with prescribed parameters. In view of the fact that wastewater is a multicomponent system, it is also necessary to take into account the effect of various impurity substances on wastewater treatment to remove ammonium ions, because some of these substances can impair the efficiency of the process. The role of impurities in AMP precipitation is played by ions of potassium and calcium. At a high content of calcium ions in wastewater, part of phosphate ions is consumed for formation of difficultly soluble calcium phosphates, which impairs the treatment efficiency [4]. In the presence of a large amount of potassium ions, they can substitute ammonium ions in AMP to form magnesium potassium phosphate $MgKPO_4 \cdot 6H_2O$ with identical structure and properties [5, 6]. In addition, the problem of wastewater treatment to remove ammonium ions is topical for plants manufacturing urea, and, therefore, a study of the influence exerted by urea impurity on the wastewater treatment process is of practical interest. It is known that urea can undergo hydrolysis in an alkaline medium to form ammonium ions, which may diminish the degree of wastewater purification.

The aim of this study was to analyze the fundamental aspects of chemical precipitation (crystallization) of AMP to give crystals with certain dispersity at a high degree of wastewater purification and to examine the effect of impurities on the degree of wastewater purification.

To study the wastewater treatment process, we analyzed the precipitation of AMP with sodium hydrophosphate, sodium hydroxide, and magnesium chloride. The precipitation occurred by the reaction

$$MgCl_2 + NH_4Cl + Na_2HPO_4 + NaOH + 5H_2O = MgNH_4PO_4 \cdot 6H_2O + 3NaCl.$$

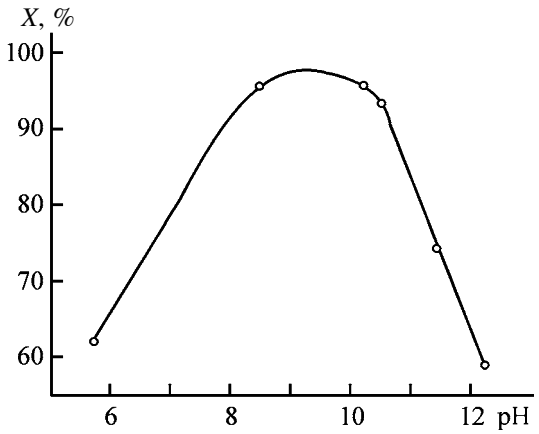
* Time of reactoin completion. ** Time of chemical precipitation.

To a certain amount of a simulated wastewater solution with a 2 $g\ l^{-1}$ concentration of NH_4^+ ions in a transparent reactor placed in a nephelometer, we added with stirring a stoichiometric amount of an equimolar solution of sodium hydrophosphate (concentration 15.778 $g\ l^{-1}$), a certain amount of a 1% NaOH solution, and then a stoichiometric amount of a $MgCl_2$ solution (10.589 $g\ l^{-1}$) The resulting suspension was stirred for 20 min. In the course of the process, the pH value and transmission of light through the transparent reactor were recorded. In accordance with the reaction equation, the pH value decreases in the course of AMP precipitation, and this circumstance was used to judge the reaction rate from the variation of pH with time. The transmission of light through the reactor served to judge how the degree of chemical precipitation varies with time. The completion of the chemical reaction and chemical precipitation was judged from time dependences of the pH value and degree of chemical precipitation: as the time of completion of the process we took the time after which the pH value and degree of precipitation remained virtually unchanged. After keeping the suspension, the rate of sedimentation of the resulting precipitate was measured in the course of settling in a volumetric cylinder. After the settling, the suspension was filtered and the filtrate was analyzed for the content of ammonium ions. The precipitate was dried and subjected to chemical, optical-microscopic, and X-ray phase analyses.

The results of experiments in which the AMP precipitation was studied are listed in Table 1. At low pH values, the degree X of wastewater purification was not high (62%). At final pH values of 8.5 and more, higher degrees of purification (~95%) are achieved. This is due to the low solubility of AMP in alkaline media. As demonstrated by an analysis of the data on the rate of the chemical reaction, the AMP formation is complete in less than 3 min (Table 1), and the higher the pH value, the faster the reaction, which does not contradict the law of mass action. However, rather high pH values adversely affect the treatment efficiency. Table 1 shows that the degree of purification remains rather high (93%) at final pH 10.5 (run no. 4), whereas at pH 12.3 (run no. 5) it drastically decreases to 59%. Hence, it may be concluded that AMP is soluble in an excess of alkali. This does not contradict published evidence [1] that equilibrium is

reached at pH 10–11. The pH dependence of the degree of wastewater purification is shown in the figure. It can be seen that the maximum degree of purification is reached at pH 8.5–10.

The chemical precipitation is fast and virtually complete in 10 s (Table 1). As expected, the higher the pH value in the course of the reaction, the faster the formation of precipitate particles. This is due to a decrease in the solubility of AMP, observed on raising the pH to a certain value.



However, high pH values adversely affect the sedimentation rate because the alkaline medium leads to a low solubility of the precipitate and to a high supersaturation. This favors a high rate of nucleation and low rate of crystal growth, which, in turn, leads to the formation of a finely dispersed suspension whose settling and filtration are slow.

An optical microscopic analysis of the precipitates confirmed the results obtained in the study of the sedimentation rate of the suspensions. At low pH, a coarsely crystalline precipitate is formed, with prismatic and so-called twin crystals characteristic of AMP [8]. At higher pH values, fine needle-like crystals, which are commonly formed in the presence of free ammonia [8], are observed.

To create a minor supersaturation and obtain a coarsely crystalline precipitate, experiments with batch supply of reagents by a peristaltic pump at a rate of 8.5 $cm^3\ min^{-1}$ were performed at the optimal pH 8.5. Also, the order in which the reagents should be supplied was analyzed. In the case of a direct order of reagent supply, a solution containing Mg^{2+} ions was introduced into that containing NH_4^+ and PO_4^{3-} ions and an alkali. In the case of a reverse order of reagent supply, a solution containing PO_4^{3-} ions and an alkali was introduced into that containing NH_4^+ and Mg^{2+} ions.

The results of experiments with various modes of reagent supply showed that the degree of purification to remove ammonium ions was high and approximately equal (91–94%) in all the experiments (run nos. 6–9). The reaction was complete in 2–3 min in all the reagent supply modes. The chemical precipitation was fast, and in the experiments with instantaneous supply of reagents the maximum degree of crystallization was reached within less than 2 s. A longer time was necessary in the case of a gradual supply (10–15 s), which is due to the low rate of delivery of precipitants.

The highest sedimentation rate was observed for the suspension obtained with reverse batched supply of reagents. However, this suspension was polydisperse (contained both coarse and fine crystals), which was confirmed by optical microscopic examination. This is probably due to the fact that the pH value was low at the beginning of supply of a mixture of Na_2HPO_4 and NaOH solutions into the reaction vessel, which favored formation of a coarsely crystalline precipitate. As the reagents were introduced into the reaction mixture, the pH increased and this led to a high rate of nucleation and low rate of crystal growth and, consequently, to formation of a finely crystalline precipitate. A high sedimentation rate was also observed for the suspension obtained with instantaneous reverse supply of reagents, and this rate exceeded that in the case of a direct batched supply. The suspension obtained with a direct batched supply of reagents was finely dispersed and flocculent and had a low sedimentation rate. Thus, suspensions with unsatisfactory properties are formed in the case of a batched supply of reagents, and this hinders the suspension separation. Therefore, it is more appropriate to use the instantaneous supply of reagents.

Degree X of wastewater purification as a function of the final pH value in precipitation of AMP.

Also, experiments aimed to study the effect of an excess of precipitants with respect to ammonium in direct and reverse supply of reagents were carried out (run nos. 10 and 11). Table 1 shows that a higher degree of purification (95%) is achieved in the case of a direct supply of reagents in a minor excess (6.7%), i.e., with a $MgCl_2$ solution introduced into a mixture of NH_4Cl, Na_2HPO_4, and NaOH solutions.

Thus, the optimal treatment mode is that with direct instantaneous supply of precipitants in a minor excess with respect to ammonium ions. This mode provides both a high degree of wastewater purification (95%) and high rates of chemical precipitation and sedimentation of the resulting suspension. Further experiments devoted to analysis of the effect of vari-

ous factors on the wastewater treatment process to remove ammonium ions were performed under the optimal conditions found.

An X-ray phase analysis of a precipitate obtained in the optimal mode confirmed that the precipitate is ammonium magnesium phosphate hexahydrate with a minor impurity of magnesium phosphate and hydrophosphate $Mg_3(PO_4)_2 \cdot 8H_2O$ and $MgHPO_4 \cdot 3H_2O$.

A study of the influence exerted by the initial concentration of ammonium ions on the treatment process revealed that wastewater containing ammonium ions in high concentration will be purified to a greater extent than low-concentrated wastewater. In addition, the AMP precipitate obtained in processing of highly concentrated wastewater is coarsely dispersed and its separation from the liquid phase in the stage of settling and filtration is simpler. It was found that the wastewater treatment at elevated temperatures (>80°C) leads to a low degree of purification (66%). This is due to an increase in the solubility of the AMP precipitate upon heating; furthermore, the precipitate obtained has a low sedimentation rate.

Experiments on AMP precipitation in the presence of impurities were performed in the optimal reagent mode at the optimal pH with saturated solutions of the precipitants taken in a 5% excess relative to the stoichiometry. Solutions of precipitants with the following content of the main component were used (%): Na_2HPO_4 solution 10.32, $MgCl_2$ solution 32, and NaOH solution 16. The results of the experiments on the wastewater treatment are listed in Table 2.

In a study of the influence exerted by a urea admixture on the wastewater treatment process, the simulated solution contained, in addition to ammonium ions, urea in a concentration of 30 g l^{-1}. The experiments performed (Table 2) demonstrated that urea is not noticeably hydrolyzed in alkaline solutions under the conditions specified during the time prescribed. The urea admixture does not affect the efficiency of wastewater treatment to remove ammonium ions and the process of chemical precipitation and sedimentation of the precipitate obtained. X-ray phase and optical microscopic analyses of the precipitate obtained in the presence of urea demonstrated that the precipitate was AMP hexahydrate virtually free of any impurity phases.

Presence of a large amount of potassium ions in wastewater (68 g l^{-1}) reduces the purification efficiency from 95 to 89% (Table 2). The precipitate obtained in this case is only 89% composed of AMP hexahydrate. An X-ray phase analysis of the precipitate demonstrated that no new phases and, in particular, $MgKPO_4 \cdot 6H_2O$ were present. Because magnesium potassium phosphate is formed under the same conditions as AMP, it may be assumed that magnesium potassium phosphate forms a solid solution with AMP, rather than a separate phase. Magnesium potassium phosphate hexahydrate is isostructural with AMP hexahydrate, both substances crystallize in the orthorhombic crystal system [6, 9], and the radius of the ammonium ion is close to that of the potassium ion. The precipitate obtained contains coarse prismatic and needle-like crystals, in contrast to the fine needle-like crystals characteristic of AMP, which resulted in a higher rate of sedimentation of the suspension obtained.

The strongest influence on the process of wastewater treatment to remove ammonium ions by precipitation of AMP is exerted by calcium ions. It has been found [10] that mostly AMP is formed in precipitation at ion concentration ratios $[Ca^{2+}] : [Mg^{2+}]$ in wastewater lower than 0.25 : 1. For comparison, experiments were performed at $[Ca^{2+}] : [Mg^{2+}] = 1 : 1$. It was found that at $[Ca^{2+}] : [Mg^{2+}] = 0.25:1$ the degree of wastewater purification decreased, but, nevertheless, remained fairly high (90%). An analysis of the precipitate formed in this case demonstrated that mostly AMP was formed (88%). At $[Ca^{2+}] : [Mg^{2+}] =$

1 : 1, the degree of wastewater purification drastically decreased (66%). An X-ray phase analysis demonstrated that the precipitates were mostly composed of AMP hexahydrate; however, the intensity of its lines was somewhat lower, compared to the pure substance. No lines associated with calcium phosphates were found. Because the precipitates contain low amounts of the main substance, it may be assumed that an X-ray amorphous calcium phosphate $Ca_3(PO_4)_2$ was formed in addition to struvite. An optical-microscopic analysis demonstrated that most of crystals had an indeterminate shape, different from the needle-like appearance characteristic of struvite.

It is known [4] that hydroxylapatite, having the lowest solubility product ($SP = 3.2 \times 10^{-59}$), is the most thermodynamically stable phase among all forms of calcium phosphate; however, intermediate phases, including amorphous calcium phosphate, can be formed in primary nucleation. A study of the formation rate of the precipitates demonstrated that, at $[Ca^{2+}] : [Mg^{2+}] = 0.25 : 1$, the reaction of AMP formation is fast (complete in 25 s), whereas at $[Ca^{2+}] : [Mg^{2+}] = 1 : 1$, the rate markedly decreases, suggesting the occurrence of a side reaction (formation of calcium phosphates). A small addition of Ca^{2+} has no effect on the sedimentation process. However, as the relative content of this additive increases, the sedimentation rate significantly decreases. This behavior can be accounted for by the nature of the precipitate formed (calcium phosphate).

CONCLUSIONS

(1) The maximum degree of wastewater purification to remove ammonium ions by precipitation of ammonium magnesium phosphate hexahydrate with sodium hydrophosphate and magnesium chloride (>95%) is reached at pH 8.5–10 and a minor excess of precipitants (5%).

(2) The optimal mode of precipitation of ammonium magnesium phosphate hexahydrate is that with direct instantaneous supply of reagents, which consists in that, first, Na_2HPO_4 and NaOH solutions are added to wastewater, and then a $MgCl_2$ solution. This way of reagent delivery provides a high degree of wastewater purification and high rates of chemical precipitation and sedimentation of the resulting precipitate of ammonium magnesium phosphate hexahydrate.

(3) Wastewater containing high concentrations of ammonium ions is purified better and the precipitate of ammonium magnesium phosphate hexahydrate, obtained in treatment of such a wastewater, is coarsely dispersed and its separation from the liquid phase in the stage of settling and filtration is simpler. Performing the process at elevated temperatures leads to a low degree of wastewater purification and to formation of a finely dispersed suspension of ammonium magnesium phosphate hexahydrate.

(4) Presence of high concentrations of urea in wastewater has no effect on the efficiency of its treatment. In the presence of potassium ions, the efficiency of wastewater treatment to remove ammonium ions decreases because of the partial consumption of precipitating agents for the formation of a magnesium potassium phosphate precipitate. The presence of a minor amount of Ca^{2+} ions in wastewater ($[Ca^{2+}] : [Mg^{2+}] = 0.25 : 1$) somewhat reduces the efficiency of wastewater treatment. At larger amounts of calcium ions in wastewater, the degree of purification markedly decreases because of the formation of calcium phosphate.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

^{13}C NMR and ESR Study of Structural and Functional Group Characteristics of Macromolecular Compounds of Soils

E. D. Lodygin and V. A. Beznosikov

Abstract—The structure of macromolecular compounds of soils is studied by ^{13}C NMR and ESR. Data on the structural and functional group characteristics and paramagnetic activity of humus compounds may provide a basis for developing methodological approaches to parametric characterization of the environmental potential of the soil organic matter.

DOI: 10.1134/S1070427206090163

Characterization of the structure and functionalities of humus compounds, including the quantity into quality transformation, and development of theoretical principles for the soil organic matter are topical problems of the soil science. Studies of the structure of humic acids, including intramolecular ordering in systems that were previously considered as chaotic, may provide a basis for developing a quantitative approach to evaluation of the main environmental functions of soils.

Further progress of the chemistry of soil organic matter requires employment of up-to-date techniques for studying the molecular structure and functionalities of humus compounds (HCs) [1, 2]. The common methods ranging from characterization of the group and functional composition to examination of the properties of humus acids are arbitrary in many respects, resulting occasionally in discrepancy of both experimental results and their interpretation [3].

Therefore, in this study we examined the qualitative and quantitative composition of some molecular fragments of humic (HAs) and fulvic acids (FAs) by ^{13}C NMR and ESR.

EXPERIMENTAL

Humus compounds were studied with an example of soils of a microcatena (typical podzolic, podzolic surface-gleyic, and peaty-podzolic-gleyic soils), arable podzolic soil, and paleopedorelicts. The samples of paleopedorelicts were collected from the knap at the Maksimov Station of the Institute of Biology, Komi Science Center, Ural Division, Russian Academy of Sciences. The morphological description and physicochemical and biological characteristics of the investigated soils were reported elsewhere [4].

Samples of humic and fulvic acids were separated following Kononova and Bel'chikova [3]. The elemental analysis of HAs was determined on an EA 1110 CHNSO analyzer (Italy). The solid-state magic angle spinning (CPMAS) ^{13}C NMR spectra of humus compounds were recorded on a Bruker CXP-100 pulse NMR spectrometer (25.18 MHz). The ESR spectra were recorded on an SE/X2547 Radiopan spectrometer (microwave power in the cavity 20–40 mW; microwave frequency 9.372 GHz) using diphenylpicrylhydrazyl (DPPH) as a reference with fixed radical concentration. The concentration of paramagnetic centers in the samples was estimated relative to the reference peak intensity using the relationship $(\Delta H)^2 Y$, where ΔH and Y are the line width and amplitude, respectively. The absolute error of determination of the free radical concentration by ESR is 10–20% [5].

To study the structural features and functionalities of the organic matter of podzolic and peaty-podzolic-gleyic soils, we recorded the ^{13}C NMR spectra of HAs and FAs separated from the upper genetic horizons (Fig. 1).

As seen from Table 1, NMR spectroscopy allows identification of various functional groups and molecular fragments in HAs and FAs. The relative contents of the basic functional groups and molecular fragments of HAs and FAs were estimated from the NMR

spectra by integration of the areas under the corresponding peaks (Table 2).

Analysis of the ^{13}C NMR spectra of humus acids allowed assignment of chemical shifts to carbon atoms of various functional groups and molecular fragments of HAs and FAs (Table 1) [1, 4, 6, 7].

In analysis of the extensive information obtained from the ^{13}C NMR spectra, we used the aromaticity index defined as the ratio of the amount of the aromatic carbon atoms to the total amount of the aromatic and aliphatic carbon atoms [AR/(AR + AL)]. In this case, the signals of the aromatic carbon atoms were summed over the ranges 105–164 and 183–190 ppm [2, 8].

Comparative analysis of the molecular structures of humic and fulvic acids revealed that FAs are enriched with oxygen-containing fragments, which explains their higher solubility in water and mobility. High carboxy group content (up to 27.1%) causes high acid reactivity of FAs with respect to soil minerals, as well as the tendency to complexation with iron, aluminum, and other metal cations, resulting in the formation of soluble species. High content of the carbohydrate fragments (up to 23.2%) makes the FA molecules more preferable nutrient for soil microorganisms, as compared to HAs, the latter being constituted by more than half by aliphatic chains and aromatic fragments, so that their oxidation is less profitable [3].

The data obtained on the functionalities of humic acids show that, in all the soils studied, their structure considerably changes on passing from the organogenic to mineral horizon. Humic compounds of upper horizons (A_0 and O_1) demonstrate high aromaticity in both podzolic and peaty-podzolic-gleyic soils. The reason is that humus acids of the organogenic horizons are presented by not humic and fulvic acids proper, but by prohumic and profulvic acids, i.e., by the compounds that are still only slightly humified and preserve (at least partly) the molecular structure of the compounds composing the plant residues. Therefore, only the compounds extracted from the mineral horizons (A_1A_2h and A_2hg) represent, in fact, HAs and FAs.

Comparison of the molecular structure of HAs of variously hydromorphic soils shows that HAs extracted from podzolic soil are more enriched in aromatic fragments than HAs from peaty-podzolic-gleyic soil. Furthermore, for podzolic soil, we observed an increase in the fraction of oxygen-containing functional groups (COOR, C_{ar}=O, and C=O) in the HA molecules on passing from horizon A_0 to A_1A_2h. On the contrary, in peaty-podzolic-gleyic soil, the fraction of these groups decreases on passing from horizon O_1 to A_2hg (Table 2). The point is that, in podzolic soil, aerobic conditions typical of them favor oxidation reactions, while in peaty-podzolic-gleyic soil, in which anaerobiosis dominates, reduction reactions are preferable.

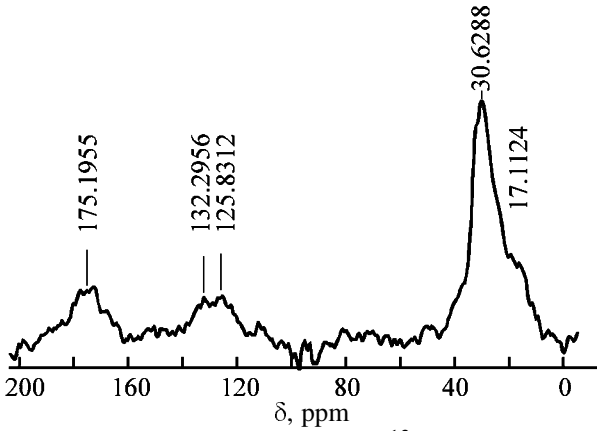

Fig. 1. Typical solid-state CPMAS ^{13}C NMR spectrum of humus compounds obtained with an example of humic acid separated from peaty-podzolic-gleyic soil (horizon A_2hg). (δ) Chemical shift; the same for Fig. 2.

The change in the functional group composition of FAs on passing from automorphic to hydromorphic soils is even more clearly pronounced. In this case, the tendency to increase in the aromaticity of FAs on passing from peaty-podzolic-gleyic soil to typical podzolic soil is preserved. The content of oxygen-containing groups also increases by 14.5% on passing from horizon A_0 to A_1A_2h in podzolic soil, but decreases by 5.2% in peaty-podzolic-gleyic soil on passing from horizon O_1 to A_2hg.

Thus, in podzolic soil, humification of plant

residues proceeds more intensively, promoting the formation of aggressive humus acids rich in oxygen-containing functional groups and aromatic fragments. On the contrary, humus compounds of peaty-podzolic-gleyic soil are characterized by lower aromaticity, consisting primarily of unoxidized aliphatic fragments, which, in combination with anaerobic conditions, favors gleyzation.

Comparative analysis of the experimental results obtained for humus acids of podzolic and peaty-podzolic soils of the north-east of the European part of Russia and of data on the functional group composition of humus compounds extracted from soils of other climatic zones showed that the investigated HA samples are richer in aromatic structures than spodisols (Spodic Cryosols), but poorer as compared to soils of south regions, such as grey forest soils and chernozems [1]. The indicated trends are associated with the humification rate: in north regions, this rate is lower, and in the south regions, higher, resulting in the latter case in the formation of more "mature" humus compounds [3].

To study the effect of farming, we examined HA samples extracted from horizon A_p of arable podzolic soil (Fig. 2). The effect of farming on the relative contents of functional groups and molecular fragments is shown in Fig. 3.

Comparison of data on the structure of HAs (Figs. 2, 3) shows that, on passing from virgin to arable podzolic soils, the total amount of aliphatic chains decreases, which is accompanied by an 8.4% increase in the aromatic fraction (aromaticity of HAs of arable soils is higher by a factor of 1.5). It was demonstrated that ploughing decreases the contents of COR groups of alcohols, ethers, and carbohydrates in the HA structure, which is due to the fact that farming enhances the microbiological activity, resulting in degradation of the readily hydrolyzable fraction of humus compounds consisting essentially of carbohydrate fragments.

Data on the functional group composition of the core of HAs of young soils and paleopedorelicts show (Fig. 3) that relict HAs differ significantly from young HAs. The 17% increase in the aromaticity of HAs of paleopedorelicts is accompanied by the increase in the fraction of oxidized fragments of both aliphatic (carbonyl and carboxy groups) and aromatic (phenolic and quinone fragments) nature. Furthermore, all the peaks in the ^{13}C NMR spectrum of relict HAs are relatively smoother, suggesting that the carbon skeleton of HAs in paleopedorelicts is characterized by higher thermodynamic stability and uniformity.

To determine the concentration of free radicals in humus compounds in relation to the degree of soil hydromorphism and amelioration, we recorded

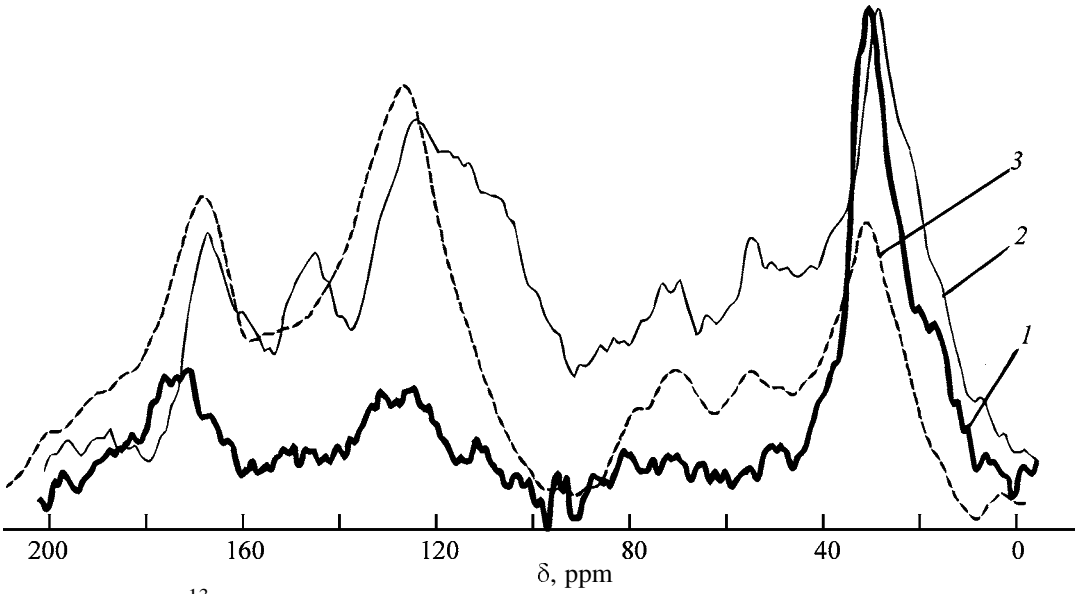

Fig. 2. Solid-state CPMAS ^{13}C NMR spectra of HA samples extracted from (*1*) virgin and (*2*) arable podzolic soils, and (*3*) paleopedorelict.

the ESR spectra of HAs and FAs. The spectra show a single broad peak with g = 2.003, clearly suggesting the presence of free radicals in the humus compounds. The indicated g factor is close to that of free electron (g = 2.0023), revealing either the occurrence of a strongly delocalized molecular orbital or of such state in which the orbital component of the magnetic moment of electron is close to zero [2, 9, 10]. The estimates made for the integral intensity of the absorption band allowed evaluation of the concentration of unpaired electrons in humus compounds. It was demonstrated that the concentration of paramagnetic centers in the HA molecules of peaty-podzolic-gleyic soil is nearly twice that in HAs of podzolic and podzolic surface-gleyic soils.

Figures 4 and 5 show the variation of the free radial concentration in HAs and FAs of variously hydromorphic soils. As can be seen (Fig. 4), the concentration of free radicals in HAs from any horizon of peaty-podzolic-gleyic soil increases with increasing soil moisture content. This is caused by the biohydrothermal conditions of humus formation in peaty-podzolic-gleyic soil, under which all the biochemical processes are inhibited, thus favoring the accumulation of free radicals in the HA molecules. In the three-component soil catena of the top soil (typical podzolic–podzolic surface-gleyic–peaty-podzolic-gleyic), podzolic surface-gleyic soil is found to be similar to typical podzolic soils in the concentration of paramagnetic centers in HAs and FAs. It was demonstrated that, for all the investigated soils, the free radical concentration in HAs decreases with the depth of the soil profile, suggesting higher thermodynamic stability of the HA molecules of the mineral horizons, as compared to HAs of the organogenic horizons. The only exception is HAs of the litter and peaty soil in which the free radical concentration is lower than in the underlying horizons. Evidently, this can be

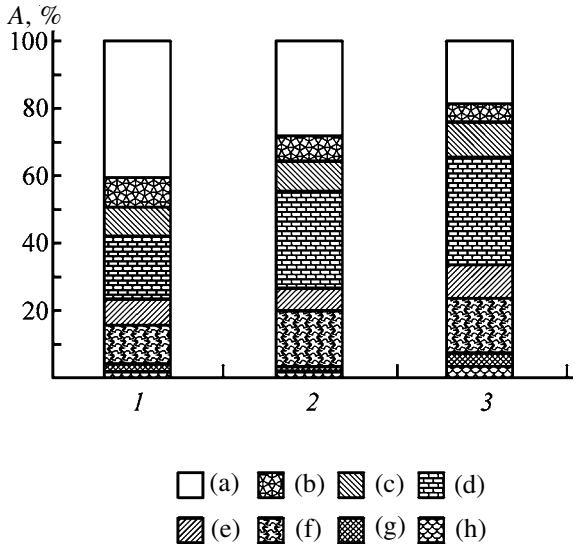

Fig. 3. Relative contents of structural fragments A in HA samples extracted from (*1*) virgin and (*2*) arable podzolic soils, and (*3*) paleopedorelict. (a) Aliphatic CH, CH_2, and CH_3 groups; (b) C atoms of amino groups and O–CH_3 structures; (c) COR groups of carbohydrates, alcohols, and ethers; (d) C atoms of aromatic structures; (e) C_{ar}–O of phenols; (f) COOR groups; (g) C_{ar}=O groups of quinones; and (h) C=O groups of aldehydes and ketones.

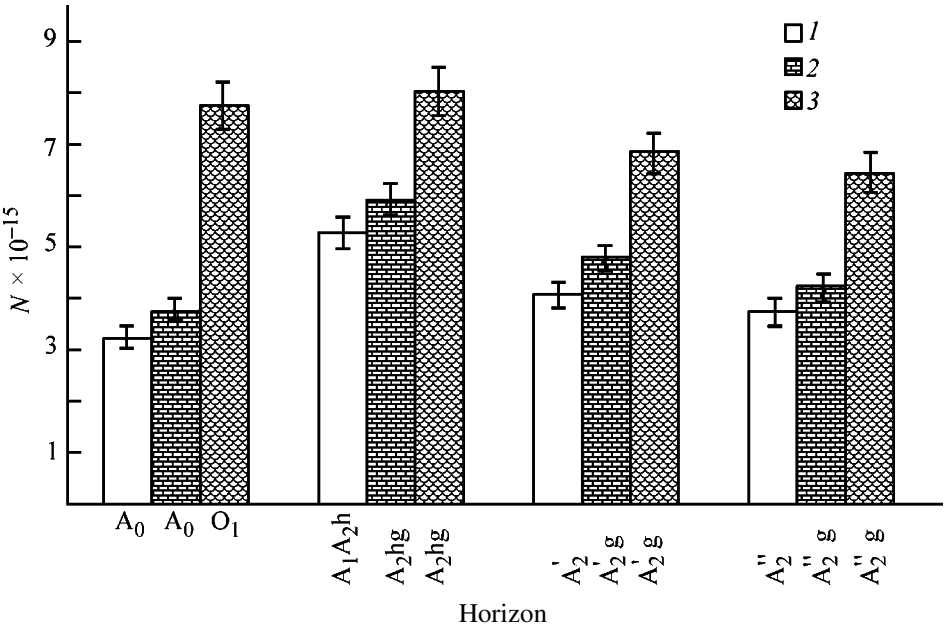

Fig. 4. Concentration of free radicals N in humic acids of variously hydromorphic soils: (*1*) podzolic, (*2*) podzolic surface-gleyic, and (*3*) peaty-podzolic-gleyic (n = 5, P = 0.95); the same for Fig. 5.

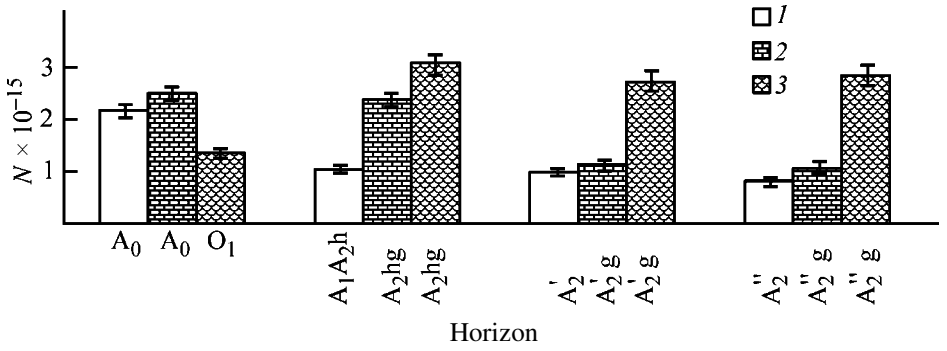

Fig. 5. Concentration of free radicals N in fulvic acids of variously hydromorphic soils.

attributed to the fact that these HAs are actually represented by prohumic acids, and the free radical content in their structure is caused primarily by the properties of the litter input. Somewhat different trends were observed for the FA samples (Fig. 5). In FAs of podzolic soils, the free radical concentration in the organogenic horizons is more than twice that in the mineral horizons. Therefore, it may be concluded that, in podzolic and podzolic surface-gleyic soils, FAs of the mineral horizons are more thermodynamically stable than those of the organogenic horizons.

In peaty-podzolic-gleyic soil, on the contrary, the amount of paramagnetic centers in FAs abruptly increases on passing from the organogenic (O_1) to mineral (A_2hg) horizon, and then slightly decreases with the depth of the soil profile, i.e., the trend in the variation of the free radical concentration in FAs and HAs of peaty-podzolic-gleyic soil with depth is similar.

To study the effect of farming on the concentration of free radicals in humus acids, we examined the HA and FA samples extracted from arable podzolic soil. The results show that ploughing has a stronger effect on the free radical concentration in FAs (Table 3).

Table 3 shows that the concentration of paramagnetic centers in HAs of the plough layer approximately corresponds to the mean concentration of free radicals in horizons A_0 and A_1A_2h. Unlike HAs, FAs of arable podzolic soil are less thermodynamically stable, demonstrating a stronger tendency to biodegradation. In turn, this causes more extensive transformation of the FA molecules in the course of soil

Table 3. Concentration of free radicals in humus acids

Soil, horizon	Free radical concentration $N \times 10^{-15}$, spin g^{-1}	
	HAs	FAs
Podzolic (virgin):		
A_0	3.24 ± 0.19	2.17 ± 0.13
A_1A_2h	5.26 ± 0.3	1.05 ± 0.06
Podzolic (arable), A_p	4.05 ± 0.24	Traces
Paleopedorelict, A_b	1.45 ± 0.09	Traces

improvement, resulting in a significant decrease of the free radical concentration (to trace amounts). There is no common view of the effect of soil improvement on the free radical concentration in humus acids. For example, Chukov believes that the concentration of paramagnetic centers in HAs is inversely proportional to their biothermodynamic stability and degree of humification, and in ploughing, the paramagnetic activity of humus compounds decreases [2]. The opinion of other researchers is that inclusion of residues of some crops in humus matter could increase the amount of free radicals [11].

Data on structural and functional group characteristics and paramagnetic activity of humus compounds may provide a basis for developing methodological approaches to parametric characterization of the environmental potential of the soil organic matter. Some attempts to develop such approaches for soils were made previously [2]. Our thought is that the environmental potential of the soil organic matter can be evaluated from combined data on the structural and functional group characteristics and paramagnetic activity of humus compounds.

CONCLUSIONS

(1) In the structure of humus acids we identified carboxy, carbonyl, and aliphatic groups of alcohols, ethers, and carbohydrates; and phenolic, quinone, and aromatic fragments. Aliphatic structures dominate in fulvic acids, and aromatic structures, in humic acids.

(2) Excessive moistening affects not only the amount of accumulated humus compounds, but also their molecular structure: in semihydromorphic peaty-podzolic-gleyic soil, it stimulates accumulation of humus compounds enriched in aliphatic structures. In combination with anaerobic conditions, the presence of unoxidized aliphatic fragments in the structure of humus acids promotes gleyzation. Soil development promotes transformation of the molecular structure of humus compounds, reflected in a relative increase in the fraction of aromatic fragments and decrease in the fraction of the carboxy and ester groups. As a result, acids become less aggressive, which favors their accumulation in the plough layer.

(3) Humic acids of paleopedorelicts are enriched in aromatic fragments and oxygen-containing functional groups, which is indicative of their thermodynamic stability.

(4) The concentration of free radicals in humic acids of the investigated soils is higher by a factor of 1.5–5 than that in fulvic acids. As a result, they demonstrate a strong tendency to polymerization and complexation by the radical mechanism. The concentration of paramagnetic centers in humic acids decreases with depth, suggesting higher stability of their molecules in the mineral horizons as compared to humic acids from the organogenic horizons.

(5) Farm production decreases the paramagnetic activity of humus compounds by more than 20% as compared to the corresponding virgin soils as a result of accumulation of more humified (more thermodynamically stable) compounds in the plough layer.

Abstract—The mechanism of initiation of cationic and anionic polymerization of methylenecyclobutenes, yielding different polymeric products, was studied quantum-chemically on the basis of electronic excitation in an elementary chemical process, using the formalism of free valence indices. In the cationic polymerization, the polymer chain consists of cyclobutene fragments linked by methylene bridges, and in anionic polymerization, of saturated cyclobutane fragments linked directly to each other and containing exocyclic methylene substituents.

DOI: 10.1134/S1070427206090175

Cationic and anionic polymerizations are traditionally belileved to occur by essentially different mechanisms. In the first case, the monomer molecule adds to the electrophilic carbon atom C^+ (C^+–X^- in the general case) of the propagating chain, and in the second case it is inserted into the C^-–Me^+ bond [2]. The cationic polymerization is initiated by Friedel–Crafts acid catalysts and Brønsted acids acting as electron acceptors, whereas anionic polymerization is initiated by electron-donor compounds, e.g., organolithium compounds. At the same time, both mechanisms have common features; their elementary process involves electron transfer (excitation) [3] giving rise to chemically active radical or radical ion species. Stable reaction products are formed by recombination of radical species in accordance with the free valence indices on atoms of the reacting molecules.

Previously we studied the mechanism of polymerization of 1-cyanobicyclobutane and 1-cyano-3-vinylbicyclobutane [4] involving thermal electronic excitation of monomer molecules into the low-lying biradical state. It is known that incorporation of cyclic fragments in a polymer chain increases the melting point and crystallinity and improves the mechanical properties of polymeric films, fibers, and structural materials [5]. Interesting possibilities for thermochemical and photochemical modification of polymers, in particular, for imparting to them electrical conductivity by doping with electron-donor or electron-acceptor admixtures, are provided by unsaturated C=C bonds present in the polymers.

This paper deals with a theoretical analysis of specific features of cationic and anionic initiation of polymerization of methylenecyclobutenes. In this case, the products formed with anionic and cationic initiators are different [5]:

The observed difference can be readily accounted for using the formalism of the free valence indices and assuming the electron transfer (excitation) in the elementary reaction step.

Ab initio quantum-chemical calculations of the electronic and steric structure and vibration spectra were made by restricted and unrestricted Fartree–Fock methods for closed (RHF) and open (ROHF) electronic shells using the GAMESS program package [6] (version pcGAMESS 6.2 [7]) in the 6-31G* basis set.

Chemical bonds between atoms are characterized by equilibrium internuclear distances and bond indices [8, 9]:

$$I_{A,B} = \mathrm{Spur}[(PS)_{AB}(PS)_{BA}], \quad (1)$$

where A and B are atom numbers.

Matrix P in formula (1) consists of coefficients of expansion of the electron density matrix $\rho(\mathbf{r}|\mathbf{r}')$ [10]

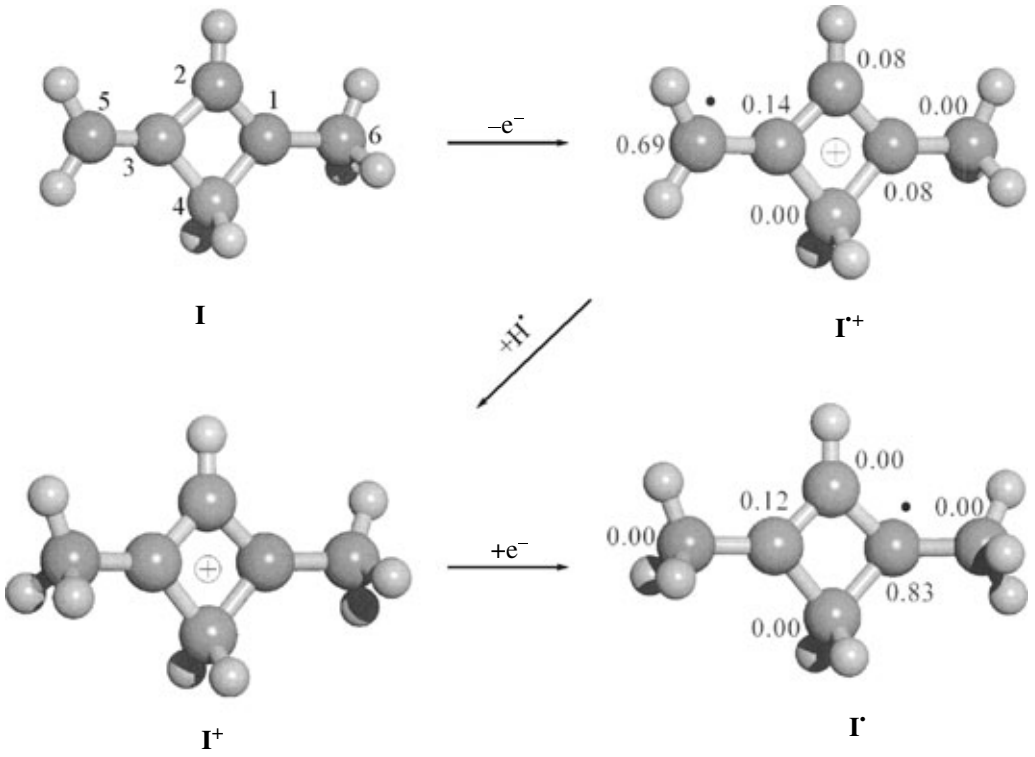

Fig. 1. Structure of primary intermediates of cationic polymerization of 1-methyl-3-methylenecyclobutene and distribution of the free valence in the triplet state.

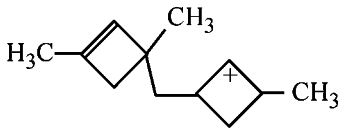
in terms of pair products of atomic orbitals; S is a metric matrix. The diagonal elements of the matrix product PS are identified with the electronic populations of AOs, $n_a^{\mathrm{M}} = (PS)_{aa}$ [11, 12].

Comparison of the sum of the bond indices with the valence index suggested in [13],

$$V_A = \mathrm{Spur}[2(PS)_{AA} - (PS)_{AA}(PS)_{AA}] \quad (2)$$

allows determination of the free valence of each atom as the difference

$$F_A = V_A - \sum_{B(\neq A)} I_{AB}. \quad (3)$$



The indices F_A, designated as D_A, were suggested for the first time in [14] without connection with the valence indices V_A.

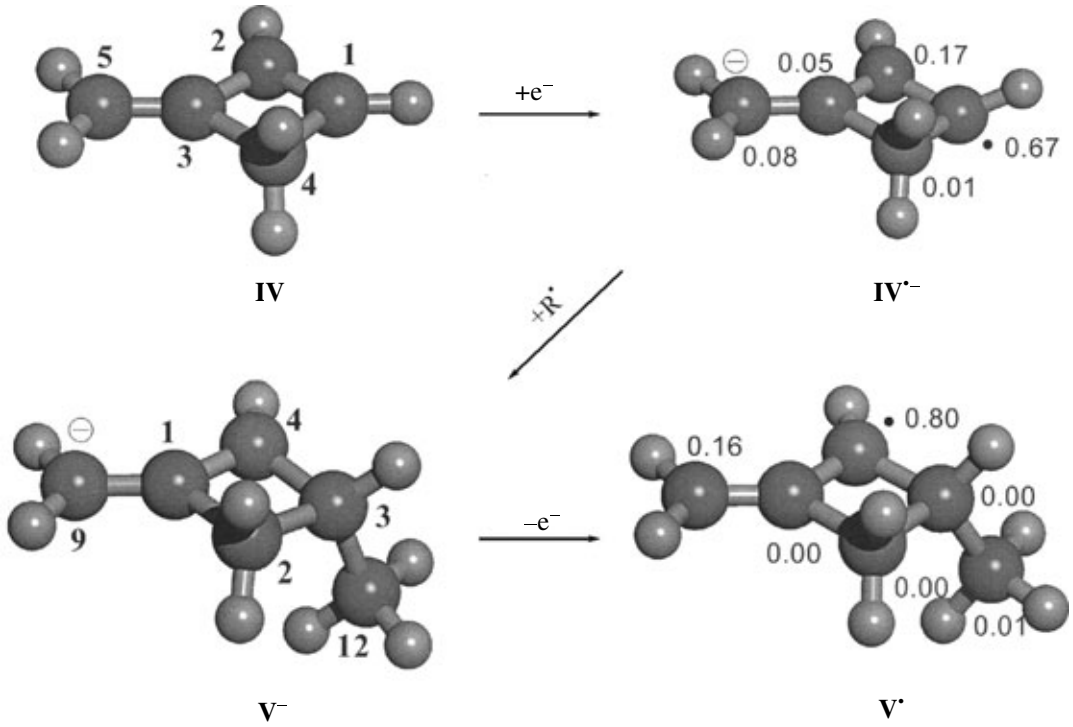
Another quantity of interest is the total valence of a molecule or radical, defined as the sum of the valences of atoms minus doubled sum of the indices of the intraradical chemical bonds [15]:

$$V_{\mathrm{mol}} = \mathrm{Spur}(2PS - PSPS) = \sum_A (V_A - \sum_{B(\neq A)} I_{AB}) = \sum_A F_A = F_{\mathrm{mol}}. \quad (4)$$

In accordance with formula (4), free valences F_{A} are additive quantities characterizing the distribution of the total valence of a chemical compound (free radical or excited molecule) and revealing its reactive centers. Not also that the same quantity $V_{\mathrm{mol}} = F_{\mathrm{mol}}$ is obtained from the alternative formula defining the valence of an atom represented as a region of a real three-dimensional space [16].

Cationic polymerization of 1-methyl-3-methylenecyclobutene. Cationic (acid) initiation involves as the first step oxidation of the monomer (1-methyl-3-methylenecyclobutene **I**) to radical cation $\mathbf{I}^{\bullet+}$, which in the second step recombines with the oxidant-initiator in the form of free radical (in Fig. 1, with the hydrogen atom $H^{\bullet}$). Then the resulting cation $\mathbf{I}^{+}$, which is a strong electron acceptor, oxidizes another molecule of monomer **I** to form a diradical cation pair $\mathbf{I}^{\bullet}\mathbf{I}^{\bullet+}$. Recombination of its constituent radicals in accordance with the free valence distribution (Fig. 1) gives as the reaction product 1-methyl-3-methylenecyclobutene dimer in the cationic form, $\mathbf{II}^{+}$:

$\mathbf{II}^{+}$



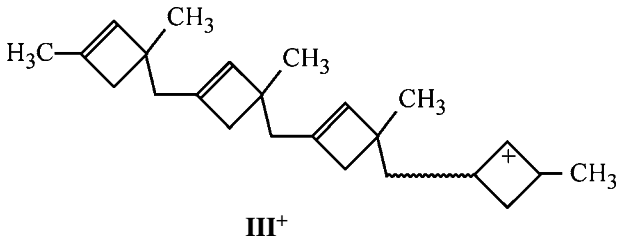


Fig. 2. Structure of primary intermediates of anionic polymerization of methylenecyclobutene and distribution of the free valence in the triplet state. Structures **V** and **V•** are shown with methyl radical as R•.

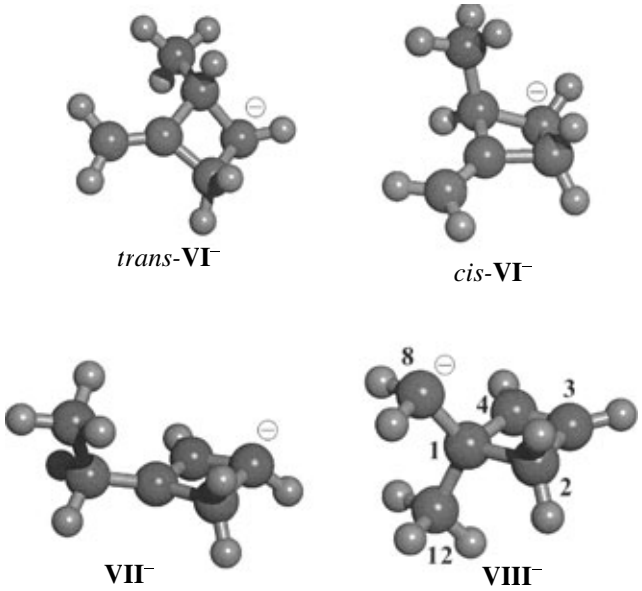

At a sufficiently high concentration of the monomer in solution, dimeric cation $\mathbf{II}^+$ can oxidize new molecules of 1-methyl-3-methylenecyclobutene, with the propagation of the polymer chain by the mechanism shown in Fig. 1. The resulting polymer consists of cyclobutene fragments linked by methylene bridges:

$\mathbf{III}^+$

Anionic polymerization of methylenecyclobutenes. Anionic initiation with organolithium compounds LiR involves as the first step reduction of the monomer (methylenecyclobutene **IV**) to radical anion $\mathbf{IV}^{\bullet -}$. In the second step, radical anion $\mathbf{IV}^{\bullet -}$ recombines with radical R• (methyl radical in Fig. 2). In accordance with the free valence distribution, this should lead to the formation of anion $\mathbf{V}^-$.

Alternative pathways of addition of radical R• lead to the isomeric anions *trans*-$\mathbf{VI}^-$, *cis*-$\mathbf{VI}^-$, $\mathbf{VII}^-$, and $\mathbf{VIII}^-$ (Fig. 3) whose energies are higher than that of anion $\mathbf{V}^-$ in a vacuum by 22.5, 24.4, 23.8, and 33.6 kcal mol^{-1}, respectively. Taking into account the hydrocarbon medium as a polarizable continuum (PCM) with the dielectric characteristics of heptane alters these differences insignificantly: to 21.6, 23.2, 22.7, and 31.2 kcal mol^{-1}, respectively. Thus, both

trans-$\mathbf{VI}^-$ *cis*-$\mathbf{VI}^-$ $\mathbf{VII}^-$ $\mathbf{VIII}^-$

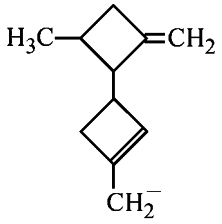

Fig. 3. Structure of anions $\mathbf{VI}^-$, $\mathbf{VII}^-$, and $\mathbf{VIII}^-$ (one of two possible enantiomers is shown).

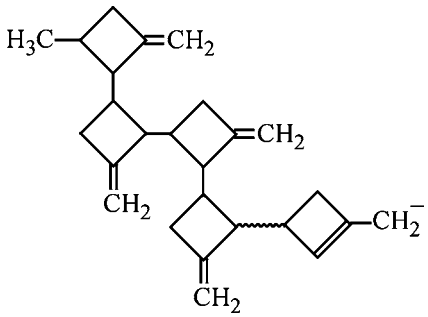
Charges on carbon atoms in methylenecyclobutene **IV** and intermediates $\mathbf{V}^-$ and $\mathbf{VIII}^-$ (for atom numbering, see Figs. 2 and 3)

Species	C^1	C^2	C^3	C^4	C^5	C^8	C^9	C^{12}
IV	–0.20	–0.17	**+0.10**	–0.36	–0.48			
$\mathbf{V}^-$	+0.24	–0.35	–0.11	–0.42			**–0.67**	–0.44
VIII	+0.04	–0.31	–0.23	–0.12		**–0.61**		–0.44



methods for determination of the possible products of the radical recombination, use of the free valence indices and direct calculation of the energy of the products, give the same result: Anion $\mathbf{V}^-$ should be the only reaction product.

Then anion $\mathbf{V}^-$ as a strong electron donor reduces another molecule of monomer **IV** to give a diradical anion pair $\mathbf{V}^{\bullet}\mathbf{V}^{\bullet-}$. The recombination of its constituent radicals in accordance with the free valence distribution (Fig. 2) leads to methylenecyclobutene dimer in the anionic form $\mathbf{IX}^-$:

$\mathbf{IX}^-$

At a sufficiently high concentration of the monomer in solution, dimeric anion $\mathbf{IX}^-$ can reduce new molecules of methylenecyclobutene, with the propagation of the polymer chain by the mechanism similar to that shown in Fig. 2. The resulting polymer, in agreement with the experimental data [5], consists of cyclobutane fragments linked directly to each other and containing exocyclic methylene groups:

$\mathbf{X}^-$

It should be noted that, when the reaction centers in the anionic polymerization of methylenecyclobutene **IV** are revealed on the basis of atomic charges (see table), in accordance with popular views, formation of anion $\mathbf{VIII}^-$ would be expected; the energy of this species is considerably higher than that of $\mathbf{V}^-$, and therefore its formation is improbable. If anion $\mathbf{VIII}^-$ were formed despite its relatively high energy, the largest (in the absolute value) negative charge in it (–0.61) would be localized on the exocyclic C^8 atom (Fig. 3), and, according to the charge control principle, the chain would propagate just at this atom.

Application of the charge control principle to anionic intermediate $\mathbf{V}^-$ leads to the same erroneous conclusion that the exocyclic carbon atom is incorporated in the backbone. Indeed, in $\mathbf{V}^-$, the C^9 atom bears the largest (in the absolute value) negative charge (–0.69) (Fig. 2). However, according to the experimental data [5], actually reactive in the polymerization of methylenecyclobutene **IV** is the C^4 atom characterized by the largest free valence (0.80) in radical intermediate $\mathbf{V}^{\bullet}$ arising from the intermolecular electron transfer.

CONCLUSIONS

(1) The role of electron transfer between the monomer and initiator as primary elementary step of the anionic and cationic polymerization is demonstrated by the example of methylenecyclobutenes.

(2) The structure of the polymer predicted on the basis of a quantum-chemical calculation of the free valence indices in radical intermediates of the anionic and cationic polymerization is consistent with the experimental data.

(3) Two procedures for quantum-chemical determination of the reaction product, by calculation of the free valence of the radical intermediates and by direct calculation of the energies of the expected products, give the same result.

Received June 5, 2006

Abstract—Samples of sodium polystyrenesulfonate of molecular weights varying in a 20-fold range were synthesized. The hydrodynamic behavior of the samples was studied in a 0.2 M NaCl solution in which the initial polyelectrolyte effects are suppressed. Relationships between the molecular weight and the translational friction coefficient and intrinsic viscosity were obtained. The theory describing the hydrodynamic behavior of wormlike chains with taking into account both the percolation effects and the excluded-volume effects was applied to estimation of the length of the statistical segment and the cross section of the sodium polystyrenesulfonate molecules in 0.2 M NaCl solution.

DOI: 10.1134/S1070427206090187

Ionic macromolecules, polyelectrolytes, play an important role in animate nature and in various industrial processes [1–4]. Studies of polyelectolytes are of great interest, since their macromolecules are represented by chains with variable equilibrium rigidity governed by the linear charge density, ionic strength of solution, and the structure of the monomeric unit. Recently the interest in studies of charged macromolecules increased again; new theoretical approaches were developed that describe the behavior of this class of polymers, more complex than neutral polymers [1–6]. At the same time, systematic quantitative studies of the molecular characteristics and properties of polyelectrolytes are much less in number than those in the databank describing the behavior of neutral polymers.

In this study we extended the scope of many-year studies of water-soluble polymers and examined the hydrodynamic and molecular characteristics of sodium polystyrene-4-sulfonate (SPSS).

EXPERIMENTAL

Polymerization of styrene-4-sulornate was carried out in an H_2O : DMF = 1 : 1 solution at 60°C for 24 h with various concentrations of AIBN in sealed ampules. The resulting polymer was precipitated into acetone and dried in a vacuum to constant weight.

The hydrodynamic characteristics were studied in 0.2 M NaCl solution. The translational diffusion was studied in a Tsvetkov's diffusometer [12] by the classical method of formation of solution–solvent boundary, which was fixed at regular intervals with a polarization interferometer [12, 13]. The diffusion interferograms were processed by the maximal ordinate and area method [12]. The diffusion coefficient $D = (\Delta\sigma^2/\Delta t)/2$ was estimated from the slope of the experimental dependences of the variance σ^2 of the diffusion boundary on the time of experiment t (Fig. 1).

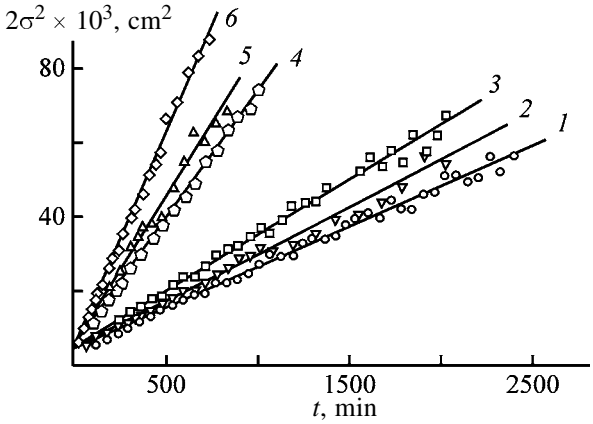

Fig. 1. Dependence of the variance of the diffusion boundary σ^2, cm^2, on the diffusion time t, min, for sodium polystyrene sulfonate samples in 0.2 M NaCl solution at 25°C. Figures at straight lines correspond to sample nos. in the table; the same for Figs. 2 and 3.

The table presents the refractive index increment $\Delta n/\Delta c$, estimated from the average areas enclosed by the diffusion curves (Fig. 2). The average refractive index increment $\Delta n/\Delta c$ was estimated at 0.144 ± 0.002 $cm^3\ g^{-1}$. The intrinsic viscosities [η] were determined from the Huggins plots [12] $\eta_{sp} = [\eta] + k'[\eta]^2 c$ (Fig. 3), where $h_{sp} \equiv (\eta - \eta_0)/\eta_0 = (t - t_0)/t_0$; η and η_0, viscosity of the solution and solvent, respectively; and t and t_0, time of flow of the solution and solvent in an Ostwald viscometer, respectively.

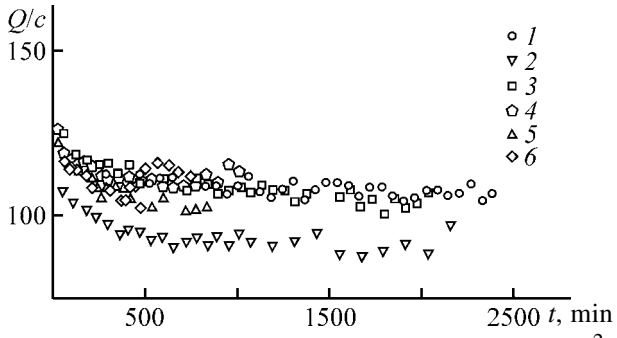

Fig. 2. Area enclosed by the interference curve of Q, cm^2, divided by the polymer concentration c, g cm^{-3}, vs. the diffusion time t.

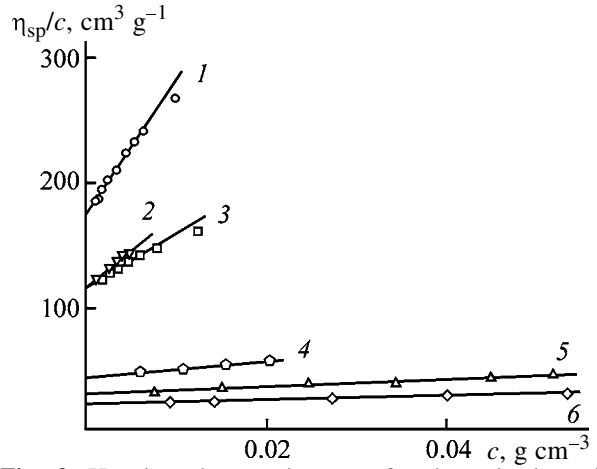

Fig. 3. Huggins plots η_{sp}/c vs. c for determination of the intrinsic viscosity of sodium polystyrenesulfonate in 0.2 M NaCl solution at 5°C.

The intrinsic viscosities [η] and the Huggins parameters k' are presented in the table. The average k' was estimated at 0.32 ± 0.02.

Based on the translational diffusion coefficient D_0 and the intrinsic viscosity [η], using the concept of hydrodynamic invariant A_0 and the average A_0 for flexible-chain polymers of 3.2×10^{-10} g $cm^2 \times (s^2\ deg\ mol^{1/3})^{-1}$ [12], we estimated the molecular weights of the samples examined using the relationship

$$M_{D_\eta} = (A_0 T/\eta_0 D_0)^3/[\eta],$$

where T is absolute temperature, and η_0, viscosity of the solvent (in our case, $\eta_0 = 0.91 \times 10^{-2}$ P).

In calculation of the molecular weight M we used the [η] values expressed in 100 $cm^3\ g^{-1}$ units. Figure 2 shows that the areas enclosed by the diffusion curves weakly change with the diffusion time (after the first 3 h of diffusion), which indicates that the samples are relatively monodisperse.

Analysis of the log–log plots of M vs. D_0 and M vs. [η] (Fig. 4) yields a relationship similar to the Kuhn–Mark–Houwink–Sakurada relationship for sodium polystyrenesulfonate molecules in 0.2 M NaCl solution at 25°C:

$$[\eta] = 1.17 \times 10^{-2} M^{0.69 \pm 0.06} \quad (r = 0.9849),$$

$$D_0 = 2.18 \times 10^{-4} M^{-(0.57 \pm 0.02)} \quad (r = -0.9977).$$

In view of the error in determination, the exponents relating the intrinsic viscosities and the diffusion coefficients b_η and b_D to the molecular weight satisfy the relationship $|b_D| = (b_\eta + 1)/3$, typically valid for linear polymer homologs.

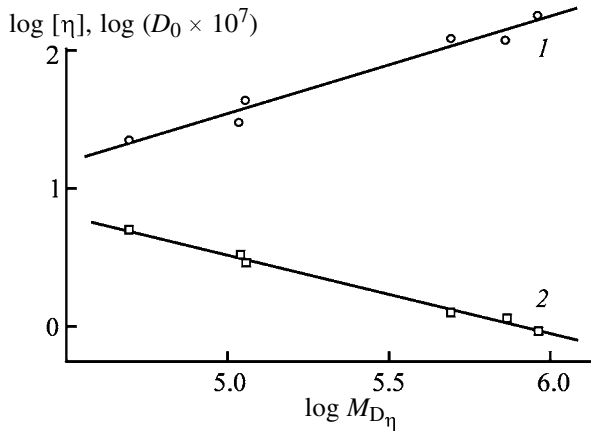

Fig. 4. Kuhn–Mark–Houwink–Sakurada plots (*1*) $\log[\eta]$–$\log M_{D_\eta}$ and (*2*) $\log(D_0 \times 10^7)$–$\log M_{D_\eta}$ for sodium polystyrenesulfonate in 0.2 M NaCl solution at 25°C.

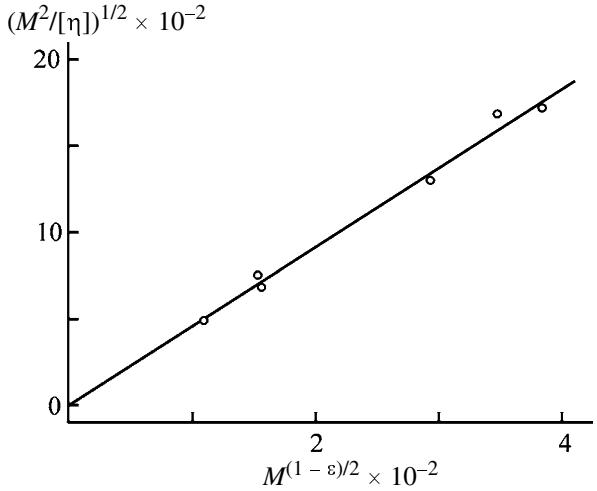

Fig. 5. $(M^2/[\eta])^{1/3}$–$M^{(1-\varepsilon)/2}$ plot at $\varepsilon = 0.133$, used for estimation of the Kuhn segment length and the hydrodynamic diameter d of the sodium polystyrenesulfonate molecules.

The resulting relationship for [η] agrees well with the similar relationship obtained by Takahashi et al. [14] for polytstyrenesulfonate in 0.1 M NaCl solution. They estimated the molecular weights at $2300 < M_w \times 10^{-3} < 400$ by the static light scattering method.

We will attribute the fact that the exponents b_η and $|b_D|$ differ from 0.50 to long-range effects in the SPSS chains. We estimated the parameter $\varepsilon = 2(|b_D| - 1) = (2b_\eta - 1)/3$ describing the thermodynamic quality of the solvent at 0.133 ± 0.007, on the average, and used it in the subsequent interpretation of the hydrodynamic characteristics. The length of the Kuhn statistical segment and the hydrodynamic cross section of the macromolecule were determined by the relationship

$$(M^2\Phi_0/[\eta])^{1/3} = [3/(1-\varepsilon)(3-\varepsilon)](M_L^{(1+\varepsilon)/2}/A^{(1-\varepsilon)/2})M^{(1-\varepsilon)/2} + (M_L P_0/3\pi)[\ln A/d - (3A/d)^{-1} - \varphi(\varepsilon)], \quad (1)$$

where $\Phi_0 = 2.87 \times 10^{23}$ mol^{-1} is the Flory viscosity parameter; $P_0 = 5.11$, hydrodynamic Flory parameter; M_L, weight of the unit length of the polymeric chain; A, statistical segment length; d, hydrodynamic diameter of the chain; and $\varphi(\varepsilon) = 1.431 + 2.64\varepsilon + 4.71\varepsilon^2$ [15].

The relationship (1) was obtained by substituting the $[s]N_A P_0 = (M^2\Phi_0/[\eta])^{1/3}$ variables in the equation describing the dependence of the sedimentation coefficient of a wormlike necklace, taking into account the long-range effects and the intramolecular percolation (Gray–Bloomfield–Hearst theory) [16]. Relationship (1) was first suggested for interpretation of the viscometric data for polyvinylpyrrolidone [7], whereupon it was successfully applied to other polymeric systems [8–11].

Figure 5 presents the plot corresponding to relationship (1). The points are fitted by a straight line with a good linear correlation ($r = 0.9946$). This straight line is described by the following parameters: slope $dy/dx = 4.5 \pm 0.2$ and intersept $-67 < y_0 < 59$. Using the weight of the unit length of the chain $M_L = 206/(2.52 \times 10^{-8}) = 8.17 \times 10^9$ g cm^{-1} mol^{-1}, we estimate from the slope the statistical segment length $A = 3.9 \pm 0.4$ nm. The intersept y_0 is determined with a large scatter, and the parameter $3\pi/M_L P_0) \times (M^2\Phi_0/[\eta])^{1/3}_{M\to 0}$ was estimated at ca. 50% of $\varphi(\varepsilon) = 1.842$. Therefore, the cross section of the SPSS molecules is estimated in this case with a large error, $d = 0.9 \pm 0.6$ nm.

The estimated A parameter for SPSS is 2 times that for the macromolecules of unsubstituted polystyrene (PS). In discussion of this value we will take into account, above all, the electrostatic component of A.

The polyelectrolyte theory [17, 18] considers two characteristic lengths, the Bjerrum radius λ_B and the Debye–Hückel radius of shielding $æ^{-1}$. The Bjerrum radius $\lambda_B = (e^2/4\pi\varepsilon_0\varepsilon kT)$ characterizes the shielding effect of the solvent. The Debye–Hückel shielding radius $k^{-1} = (8\pi\lambda_B\mu)^{-1/2}$ is the distance covered by the effect of the electric field of an individual charge, placed in a medium containing other charges. Here, e is the elementary charge; ε_0, dielectric constant; ε, dielectric permittivity of the medium; k, Boltzmann constant; T, absolute temperature; $\mu = (1/2)\Sigma n_i Z_i^2$, ionic strength of solution; n_i, number of ith ions per unit volume; and Z_i, charge of ith ion in e units.

For solutions of salts of univalent ions $\mu = c_s \times 10^{-3} N_A$ cm^{-3}, where c_s is the molar concentration of the salt. In our case, $c_s = 0.2$ M, $\lambda_B = 0.71$ nm, and $æ^{-1} = 0.68$ nm. The charges occurring at a distance $l < æ^{-1}$ along the chain are responsible for additional electrostatic short-range effects, which cause the chain rigidity to increase by A_{el}. The latter depends on the linear charge density and the ionic strength of the solution. A linear polyelectrolyte is characterized by the dimensionless parameter Q_{el}, which is the product of the Bjerrum radius and the linear charge density (Z/L) : $Q_{el} = (\lambda_B Z)/L$. The general expression for A_{el} was obtained by Odijk [19]; at $L/æ^{-1} \gg 1$ and $Q_{el} > 1$ it takes a simple form $A_{el} = æ^{-2}/2\lambda_B$.

In our case, $Q_{el} \approx 2.8$, and the electrostatic component of the statistical segment length A_{el} was estimated at 0.35 nm. In the case of polyelectrolytes, the concept of additivity of the chain rigidity is considered [17, 18]. The total equilibrium rigidity of a chain is the sum of the structural and electrostatic components: $A = A_{str} + A_{el}$. It is seen that the electrostatic component contributes with approximately 10% to the total length of the statistical segment ($A \approx 4$ nm). Thus, we estimated the structural component A_{str} at ≈ 3.6 nm. The fact that A_{str} for SPSS chains exceeds that for chains of unsubstituted PS ($A \approx 2$ nm) [20] suggests that the SPSS chains are characterized by more hindered rotation than PS and/or that the theory of polyelectrolytes underestimates the contribution from the electrostatic short-range effects to the statistical segment length. Elucidation of this question requires further quantitative studies, in particular, over a wide range of ionic strengths.

CONCLUSIONS

(1) A number of samples of sodium polystyrene sulfonates with molecular weights within $50 < M \times 10^{-3}$ g mol^{-1} < 920 were synthesized by radical polymerization of sodium styrene-4-sulfonate.

(2) Kuhn–Mark–Houwink–Sakurada relationships were obtained for 0.2 M NaCl solution; the Kuhn statistical segment length A was estimated at 3.9 nm, and the hydrodynamic diameter of chains d, at 0.9 nm.

(3) It terms of modern theories of polyelectrolyte solutions, the electrostatic contribution to the statistical segment length does not exceed 10%.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Supramolecular Polymeric Complexes of Calix[8]arenes

Abstract—Formation of ionic complexes of calix[8]arenes with polymers of various basicities was studied, and previously unknown ternary polymeric complexes of calix[8]arenes of the ion–ion (polymer–calixarene–uranyl ion) and ion–hydrophilic molecule–hydrophobic molecule (polymer–calixarene–fullerene) types were prepared.

DOI: 10.1134/S1070427206090199

Calixarenes exhibit unique properties from the viewpoint of the host–guest complex chemistry [1, 2]. Firstly, methods have been developed for facile synthesis of calixarenes of the required size under properly chosen condensation conditions. Secondly, calixarenes have internal cavities of different size formed by a belt of phenyl rings; these cavities are capable to accommodate a guest molecule of a definite size, which allows their use in molecular recognition. It should be noted that calixarenes form complexes both with neutral organic molecules and with ions. Furthermore, calixarenes can be readily functionalized, which allows variation of their affinity for a guest molecule. Finally, expenses for the preparation of calixarenes from *p*-substituted phenols and formaldehyde are relatively low, which is an important factor for practical applications. For example, calixarenes can be used as specific ligands in analytical chemistry, sensor techniques, medical diagnostics, and synthesis of new materials in supramolecular chemistry.

For many technical applications, it is desirable to combine in one sample the useful properties of both calixarenes and polymers. Synthesis of polymers based on calixarenes is a challenging problem, because these are polyhomofunctional compounds and preparation of di- and monofunctionalized derivatives suitable as monomers for polymerization or polycondensation is difficult. However, the presence in calixarenes of functional groups capable of deprotonation (e.g., hydroxy groups) suggests the possibility of formation of ionic complexes of calixarenes with basic polymeric carriers.

In this study we examined the possibility of preparation of binary and ternary complexes of calixarenes with ionic monomers of various basicities. As investigation objects we chose octa-*p-tert*-butylcalix[8]arene and octa-*p*-nitrocalix[8]arene, polymers of various basicities (polyalkyleneacetamidines and poly-4-vinylpyridine), and fullerene C_{60} and uranyl ions UO_2^{2+} as guest species. The choice of the guest species was governed by the complementarity of their size and the size of the calix[8]arene cavity, and also by the pronounced tendency of many calixarene derivatives to form complexes with uranyl cation. Owing to the latter property, sulfo derivatives of calixarenes were suggested as a sensor element [3] in determination of the uranium content in radiochemical production wastes.

EXPERIMENTAL

p-tert-Butylphenol, paraform, and solvents were used without additional purification. To prepare the complexes, we used polyamidines ($M_w = 2 \times 10^3$, $M_w/M_n = 2.2$) and poly-4-vinylpyridine (Acros, $M_w = 1.6 \times 10^4$).

The NMR spectra were recorded on Bruker AC200 (200 MHz) and Bruker AC300 (300 MHz) spectrometers from solutions in DMSO and chloroform. The UV spectra were taken with Varian Cary 100 and SF-26 spectrophotometers. The luminescence spectra were excited with the nitrogen laser radiation (λ = 337 nm, pulse length 6–8 ns) and were recorded during the persistence time of 1 μs after the excitation pulse at T = 300 K. To measure the linear-optical properties of the samples, we used a Nd–garnet pulse laser with the emission wavelength of 1.06 μm. The laser operated in the modulated Q-factor mode; the

pulse length was 15 ns. The dynamic light scattering was measured with a Brookhaven BI-200SM goniometer and a Brookhaven BI-9000AT correlator. As a light source we used a He–Ne laser (λ = 632.8 nm).

***p*-Nitrocalix[8]arene.** To 10 ml of a 1 : 1 mixture of 65% HNO_3 and 98% H_2SO_4, cooled to +3°C, 1 g (7.7×10^{-4} mol) of *p-tert*-butylcalix[8]arene [4] is gradually added with stirring, keeping the temperature of the reaction mixture in the interval 3–5°C. The product is precipitated by adding 40 ml of water. The yellow precipitate is treated with 20 ml of boiling methanol; the solution is cooled and filtered. This treatment is repeated two times. By so doing, two fractions (soluble and insoluble in methanol) are obtained. As follows from the ^1H NMR data, the fraction soluble in methanol is a mixture of partially degraded or incompletely substituted cyclic and acyclic products. The fraction insoluble in methanol is the target product; yield 0.25 g (27%), mp >360°C. ^1H NMR spectrum (300 MHz, DMSO, 25°C), δ, ppm: 7.97 s (2H, C_{ar}–H), 5.13 br (1H, OH), 4.00 s (2H, CH_2).

Ternary complex poly-1,8-octamethyleneacetamidine–octa-*p*-nitrocalix[8]arene–$UO_2(OH)_2$. Nitrocalix[8]arene (0.02 g, 1.6×10^{-5} mol) is dissolved in 2 ml of acetone, and $UO_2(OH)_2$ (0.015 g, 0.5×10^{-4} mol) is suspended in 2 ml of acetone. Mixing of the solution and suspension results in formation of a soluble binary complex. To the resulting solution, 2 ml of an alcoholic solution of poly-4-vinylpyridine (0.06 g, 0.5×10^{-3} mol) is added. The ternary complex is isolated on cooling as a dark orange precipitate. Films of the complex are obtained by casting onto a rotating support (3000 rpm, 30 s).

Ternary complex polymer–calixarene–fullerene. Such ternary complexes can be prepared by two procedures differing in the order of combining the components.

(1) A solution of *p-tert*-butylcalix[8]arene and poly-1,8-octamethyleneacetamidine (1.2×10^{-3} mol) (calixarene : polymer ratio 1 : 40) in ethanol is prepared. A polymer film is prepared by casting onto a rotating support. After drying over concentrated H_2SO_4, the film is placed in a hot 1.5×10^{-3} M solution of fullerene (2 mg) in toluene (2 ml). The ternary complex is formed within 24 h as a gray-brown film. The product is extracted with two 2-ml portions of boiling toluene and vacuum-dried.

(2) Fullerene (1 mg) is dissolved in 2 ml of toluene on refluxing for 2 h. To the refluxing solution, 2 mg of *p-tert*-butylcalix[8]arene is added to obtain a 1.5×10^{-3} M solution. The solution is filtered while hot and allowed to slowly cool over a period of 24 h. The black precipitate is separated by centrifugation and dissolved in 5 ml of toluene. A polymer film is prepared by casting a solution of 0.2068 g (1.2×10^{-3} mol) of poly-1,8-octamethyleneacetamidine in 1.2 ml of alcohol onto a rotating support; the film is dried over concentrated H_2SO_4, placed in the hot solution of the calixarene–fullerene complex (see above), and allowed to stand for 4–6 h in a closed weighing bottle. The ternary complex is formed as a gray-brown film. The product is extracted with two 2-ml portions of boiling toluene and vacuum-dried.

Octa-*p-tert*-butylcalix[8]arene was prepared as described in [4] by the condensation of *p-tert*-butylphenol with paraform in the presence of sodium oxide. According to published data, the simplest route to octa-*p*-nitrocalix[8]arene is *ipso* nitration of octa-*p-tert*-butylcalix[8]arene with acetyl nitrate [5] or with a mixture of anhydrous HNO_3 and H_2SO_4 [6]. However, we failed to reproduce these procedures. In the case of nitration with acetyl nitrate, it appeared impossible to add the reagent to a solution of octa-*p-tert*-butylcalix[8]arene in methylene chloride because of extremely low solubility of the macrocycle in this solvent (in agreement with data of [4]). Nitration of octa-*p-tert*-butylcalix[8]arene under the conditions described in [6] yields octa-*p*-nitrocalix[8]arene heavily contaminated with decomposition products; the suggested purification procedure, reprecipitation from 2 M Na_2CO_3 into dilute HCl, results in tarring and total decomposition of octa-*p*-nitrocalix[8]arene. In this connection, we suggested a modification of this method, allowing preparation of the desired compound in a reasonable yield (up to 30%). We found that *ipso* nitration does not occur at temperatures below 3°C, whereas above 10°C the reaction becomes uncontrollable and leads to the ring opening. When the reaction is performed in the interval 5–7°C, >97% pure octa-*p*-nitrocalix[8]arene can be isolated by selective extraction with methanol.

The possibility of preparing double polymer–calixarene complexes was examined with octa-*p-tert*-butylcalix[8]arene and octa-*p*-nitrocalix[8]arene as calixarene components, and polyoctamethyleneacetamidine and poly-4-vinylpyridine, differing in the basicity of nitrogen-containing moieties, as polymer components.

p-tert-Butylcalix[8]arene is insoluble in ethanol but soluble in an alcoholic solution of polyamidine (pK ~11), which suggests the deprotonation of the macrocycle and formation of an ionic bond between the calixarene and polymer. As seen from Fig. 1, in a rel-

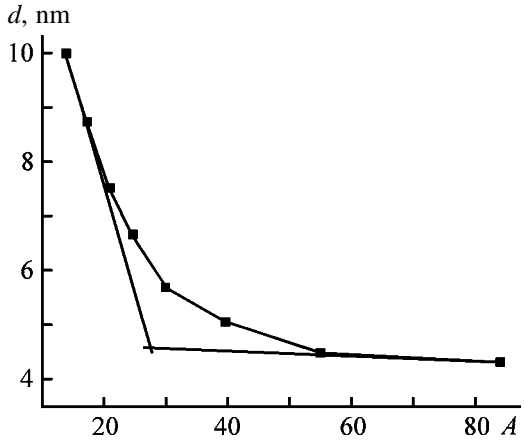

Fig. 1. Diameter d of particles of polyoctamethyleneacetamidine–octa-*p*-*tert*-butylcalix[8]arene complex as a function of the polymer : macrocycle ratio A.

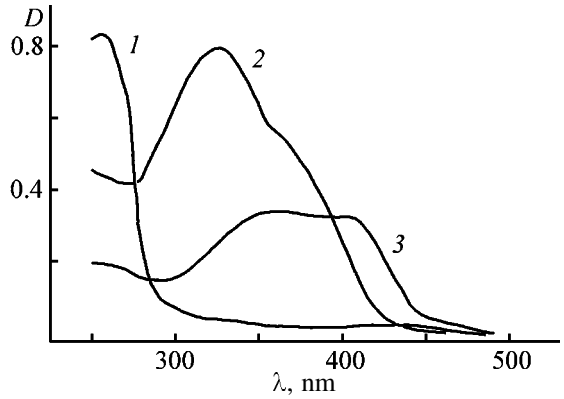

Fig. 2. Absorption spectra of (*1*) polyoctamethyleneacetamidine, (*2*) octa-*p*-nitrocalix[8]arene, and (*3*) their complex. (D) Optical density and (λ) wavelength; the same for Figs. 3 and 5.

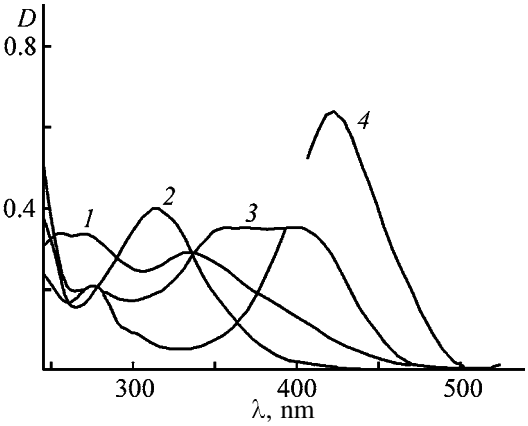

Fig. 3. Absorption spectra of octa-*p*-nitrocalix[8]arene at pH (*1*) 6.0, (*2*) 0, (*3*) 9.7, and (*4*) 13.

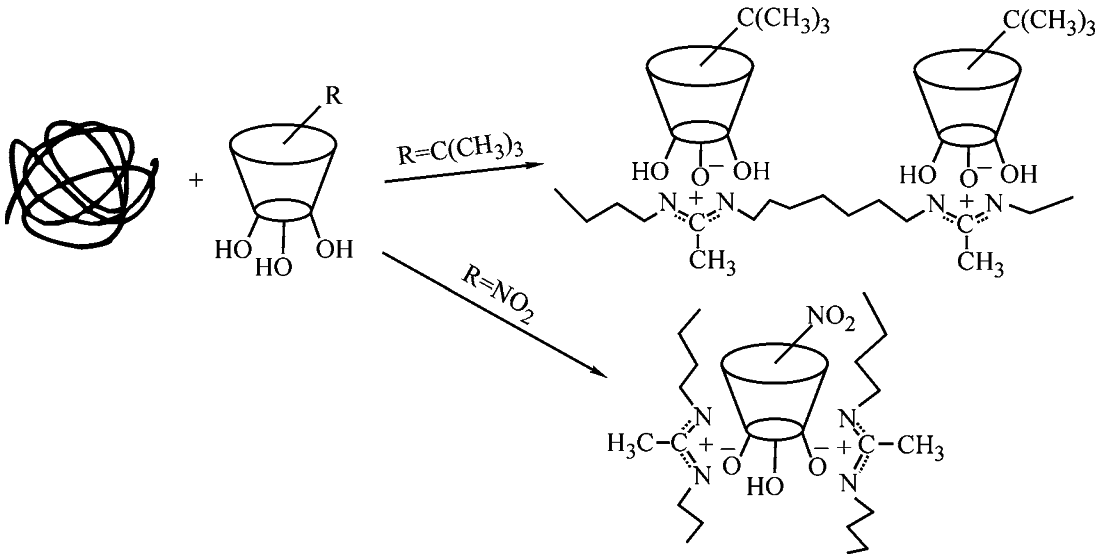
atively wide range of calixarene : polyamidine ratios (up to 1 : 40, counting for functional groups), no colloidal particles are formed, which suggests monodeprotonation of the macrocycle and formation of a comb-shaped ionic complex. Apparently, owing to the steric factors associated with the size and shape of the calixarene, the maximal capacity of the polymer for the calixarene should be considerably lower than the theoretical value (1 mol of polymer units per mole of calixarene). Polarization-optical examination of the complexes shows that the system becomes two-phase at polymer : calixarene ratios less than 30 : 1, which is in good agreement with the dynamic light scattering data.



Mixing of an alcoholic solution of poly-4-vinylpyridine with *p*-*tert*-butylcalix[8]arene does not lead to their reaction, because of insufficient basicity of the polymer (pK ~9).

Octa-*p*-nitrocalix[8]arene (pK_1 <0, pK_2 2.6, pK_3 7.2 [6]) is sparingly soluble in ethanol (~3.2×10^{-3} M). On mixing alcoholic solutions of the macrocycle and a polymer (both polyamidine and poly-4-vinylpyridine), a polymer–calixarene complex precipitated, suggesting the binding of the polymer with the calixarene via several hydroxy groups and formation of a three-dimensional ionic network. Figure 2 shows the spectra of the starting polyamidine, octa-*p*-nitrocalix[8]arene, and their complex in DMF solutions. As seen, the spectrum of the complex differs essentially from those of the components, confirming the ionic interaction in the system. Figure 3 shows that the electronic spectra of octa-*p*-nitrocalix[8]arene depend on pH strongly and in a complex fashion, suggesting successive deprotonation of several hydroxy groups. It should be noted that the number of deprotonated groups in the nitrocalix[8]arene molecule is as follows [6], at pH 0, 0; at pH 6.0, 1; at pH 9.7, 2 or 3; and at pH 13.0, 4 or more. Comparison of the electronic spectrum of the complex with those of octa-*p*-nitrocalix[8]arene suggests that the interaction involves two or three hydroxy groups of the macrocycle.

Thus, our data show that variation of the basicity of the polymer and acidity of the hydroxy groups of calixarene can lead to the formation of both comb-shaped and cross-linked structures (Scheme 1).

The possibility of formation of ternary ion–ion complexes in a calixarene–polymer–metal ion system was examined with the system poly-4-vinylpyridine–octa-*p*-nitrocalix[8]arene–UO_2^{2+} as example. The choice of this system was governed by the fact that the less acidic octa-*p*-*tert*-butylcalix[8]arene does not form sufficiently stable complexes with uranyl ion, as judged from the identity of the luminescence spectra of a mechanical mixture of octa-*p*-*tert*-butylcalix[8]-arene and the residue after evaporation of a solution of

Scheme 1. Formation of binary complexes

the components in DMSO–ethanol. However, the reaction of an alcoholic solution of octa-*p*-*tert*-butylcalix[8]arene with $UO_2(OH)_2$ is accompanied by the dissolution of $UO_2(OH)_2$, formation of a 1 : 1 complex (according to elemental analysis), and disappearance of the characteristic luminescence spectrum of the uranyl ion, consisting of several well-resolved lines (Fig. 4). The high acidity of octa-*p*-nitrocalix[8]arenes (first, $pK_1 < 0$, and second, pK_2 2.6, dissociation steps) suggests that two hydroxy groups of the macrocycle act as anionic ligands for UO_2^{2+}, four less acidic OH groups act as donor–acceptor ligands, and the remaining two phenolic groups do not participate in the complexation. It should be noted that the equivalence of all the hydroxy groups of the macrocycle does not allow us to clearly distinguish the role of each particular OH group of the calixarene in the complexation.

On mixing alcoholic solutions of the polyamidine and UO_2^{2+}–octa-*p*-nitrocalix[8]arene complex, the ternary complex UO_2^{2+}–octa-*p*-nitrocalix[8]arene–polyamidine precipitates. Its qualitative composition is suggested by a broad band with a maximum at about 500 nm, appearing in the luminescence spectrum (Fig. 4). The appearance of the luminescence is probably associated with the electron density redistribution in the interaction of the UO_2^{2+}–octa-*p*-nitrocalix[8]-arene complex with highly basic polyamidine, resulting in the deprotonation of the hydroxy groups of the macroring that are not involved in ionic bonding with uranyl ions (Scheme 2).

The possibility of preparing ternary polymeric complexes of calixarenes in which the components are bound by a combination of ionic and hydrophilic–hydrophobic interactions was examined with the octa-*p*-*tert*-butylcalix[8]arene–poly-1,8-octamethyleneacetamidine–C_{60} system as example. The complexes were prepared by two pathways: treatment of the octa-*p*-*tert*-butylcalix[8]arene–poly-1,8-octamethyleneacetamidine complex with a boiling solution of fullerene in toluene and treatment of the polyamidine with a hot solution of the calixarene–fullerene complex in toluene. Both procedures yielded the ternary complexes. Figure 5 shows the electronic spectra of the binary complexes fullerene–octa-*p*-*tert*-butylcalix[8]arene and poly-1,8-octamethyleneacetamidine–octa-*p*-*tert*-butylcalix[8]arene and of the ternary complex. It is seen that the spectrum of the ternary complex fuller-

Scheme 2. Formation of ternary (a) hydrophilic-hydrophobic and (b) ion–ion complexes

ene–poly-1,8-octamethyleneacetamidine–octa-*p-tert*-butylcalix[8]arene is a superposition of the spectra of the binary complexes. This fact indicates that both procedures allow preparation of ternary complexes combining the ionic and hydrophobic–hydrophilic binding of the components (Scheme 2).

Both procedures for preparing the ternary complex yield a stable film resistant to the action of boiling hydrocarbons (toluene, xylene) but partially degrading under the action of boiling ethanol. Such a behavior is also indicative of the formation of a ternary complex, taking into account the fact that the fullerene–*p-tert*-butylcalix[8]arene complex is soluble in toluene and decomposes in polar solvents [7].

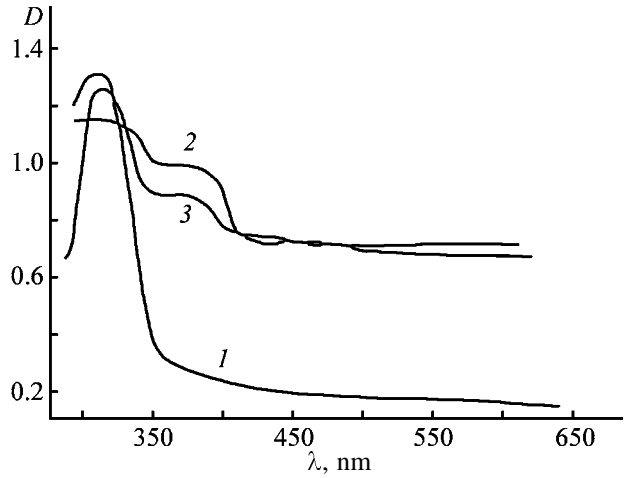

Fig. 5. Electronic spectra of the binary complexes (*1*) fullerene–octa-*p-tert*-butylcalix[8]arene and (*2*) poly-1,8-octamethyleneacetamidine–octa-*p-tert*-butylcalix[8]arene; (*3*) spectrum of the ternary complex.

Thus, calixarenes are capable of forming ternary complexes by simultaneous interactions with the functional groups of ionic polymers and guest molecules; the acidity–basicity ratio for the polymer–calixarene system strongly affects the possibility of formation of ion–ion and ion–hydrophobic component–hydrophilic component supramolecular structures. We believe that the suggested route to polymer systems containing fullerenes can find use in the development of new materials for optoelectronics and of polymeric sensors for environmental monitoring.

CONCLUSION

The formation of ionic complexes by interaction of ionic polymers with calix[8]arenes was studied in relation to the basicity of functional groups of the polymer and acidity of those of the macrocycle. The possibility of formation of ternary supramolecular complexes ion–ion (polymer–calixarene–uranyl ion) and ion–hydrophilic component–hydrophobic component (polymer–calixarene–fullerene) was shown.

Abstract—The interaction of cyanoethyl hydroxyethyl cellulose with acetone, methylene chloride, and trifluoroacetic acid in the temperature range 10–50°C was studied by the solvent vapor sorption technique. The temperature and concentration dependences of the Flory–Huggins parameter for polymer–solvent interaction χ_1 and the mechanism of the structural rearrangement in the systems were determined.

DOI: 10.1134/S1070427206090205

Growing attention is paid today to studying the structure and physicochemical characteristics of polymers having increased rigidity of macrochains and able to form mesophase on dissolution in appropriate solvents. It is well known [1] that cellulose ethers can form both lyotropic and thermotropic liquid crystals (LCs). Hydroxyethyl (HEC) and hydroxypropyl cellulose (HPC) are typical representatives of such ethers. It was shown [2] that HEC forms lyotropic cholesteric LC and thermotropic LC only in the case of high molar substitution (7–8 mol oxirane per glucose unit). It is assumed that introduction of bulky substitutes into anhydroglucose units of cellulose increases the equilibrium rigidity of macrochains of the polymer due to decreasing mobility of anhydroglucose units (vibration amplitudes) relative to the β-glucoside bond. Cyanoethylation of cellulose and HEC (introduction of strongly polar groups into cellulose macromolecules and, in the case of HEC, at unsubstituted hydroxy groups of anhydroglucose units and, probably, at terminal primary OH groups of hydroxyethyl substituents) is an efficient way to increase the equilibrium rigidity of macrochains and alter the intermolecular interaction between them.

Despite extensive experimental and calculated data obtained on lyotropic polymeric LC systems [1–3], the thermodynamic features of the interaction of cellulose ethers with solvents were not adequately studied.

Experimental determination of complete phase diagrams for systems of this type using only one instrumental method is difficult. Additional problems arise from the existence of higher and lower critical solution temperatures in solutions of some cellulose derivatives in a series of solvents. The structural features of anisotropic solutions and ranges of phase transitions are studied by polarization microscopy. Sorption methods can also give information on the structure and molecular dynamics of LC polymers [4]. It should be noted that any structural transitions in a polymer sample are necessarily reflected in the shape of absorption curves of a sorbate. Thus, studying features of solvent vapor sorption is a necessary link between studying the behavior of macromolecules in solutions and the supramolecular structure and physicomechanical characteristics of polymers in solids.

In this study we examined the features of formation of an ordered LC mesophase by cyanoethyl hydroxyethyl cellulose in concentrated solutions in a series of organic solvents. To elucidate the features of mesophase formation and interaction of polymer with the solvent, we evaluated various thermodynamic parameters from the experimental data on sorption.

EXPERIMENTAL

Cyanoethyl hydroxyethyl cellulose (CEHEC) samples were synthesized under laboratory conditions by cyanoethylation of HEC with acrylonitrile according to the procedure described previously [5–7]. We used commercial HEC with degree of polymerization DP = 900 and molar substitution MS = 2.0. On completion

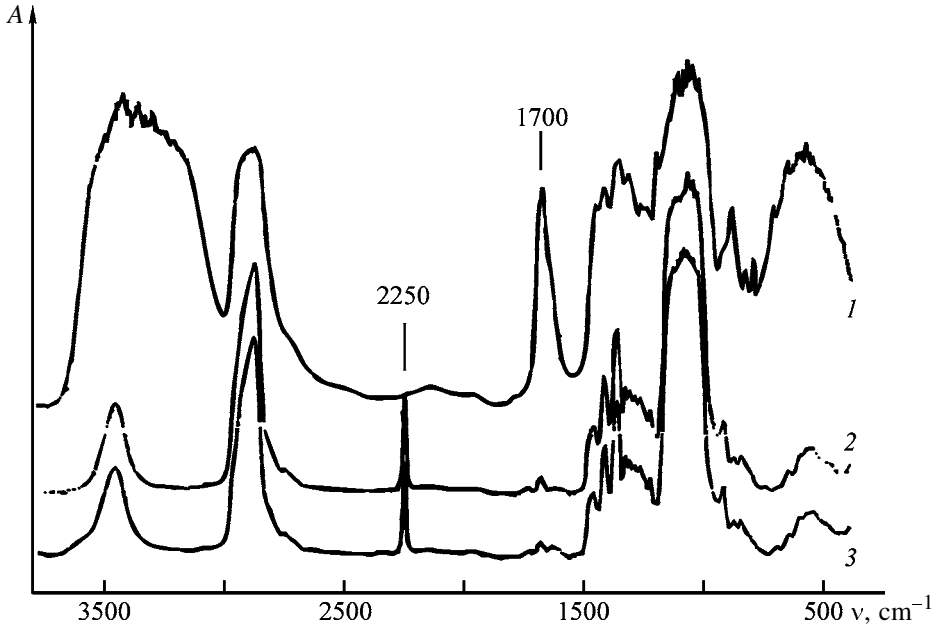

Fig. 1. Fourier IR spectra of films: (*1*) HEC from a solution in TFAA, (*2*) CEHEC from a solution in methylene chloride, and (*3*) CEHEC from a solution in TFAA. (*A*) Absorption and (ν) wavenumber.

of the synthesis, the CEHEC samples were washed to remove alkali with 10% aqueous acetic acid, water, and ethanol, after which the samples were dried to constant weight and analyzed for the nitrogen content by the Kjeldahl method [8]. The degree of substitution with respect to cyanoethyl groups was evaluated by the formula

$$DS = \frac{216y}{1400 - 53y}, \quad (1)$$

where y is the nitrogen content (wt %), 216 is the molecular weight of HEC unit, and 53 is the increase in the molecular weight of HEC upon addition of one cyanoethyl group.

We used a CEHEC sample with MS with respect to ethylene oxide of 2.0 and degree of substitution with respect to cyanoethyl groups DS = 2.0.

CEHEC formation was also proved by Fourier IR spectroscopy. The IR spectra of the samples were recorded in films on a Bruker FS-88 spectrophotometer.

As the main method of the study we used commonly accepted sorption measurements with a high-vacuum McBain balance with a sensitivity of the quartz spiral of 0.5–0.7 mg mm^{-1}. The sorption kinetics was measured under isobaric–isothermal conditions in films prepared by isothermal evaporation of the solvent from 1% polymer solutions. The film thickness was 50–100 μm. The residual content of the solvent in the films did not exceed 0.02 wt %.

The X-ray diffraction patterns of the initial CEHEC samples and those after sorption of the solvent vapor were obtained by small-angle scattering of polarized light. Changes in the X-ray patterns were observed in polarized light using an MIN-8 microscope. The polaroids were crossed at an angle of 45°.

The rheological characteristics of the solutions were studied at 20°C on a Rheotest-2 rheoviscometer with a cylinder–cylinder operating unit in the range of shear stress τ 3–600 Pa.

As sorbates we used the solvents in which CEHEC forms a lyotropic phase: acetone, methylene chloride, and trifluoroacetic acid (TFAA). The CEHEC films were prepared from the same solvents. These solvents interact with functional groups of CEHEC by different mechanisms: dispersion and dipole-dipole interactions and hydrogen bonding [9]. Thus, the specific interactions of solvent molecules with various functional groups can promote rearrangement of polymer macrochains to form an ordered LC structure of the polymer matrix.

The Fourier IR spectra of the samples of HEC and CEHEC films prepared from polymer solutions in the solvents studied are shown in Fig. 1. In the IR spectrum of HEC, there is an absorption band at 1700 cm^{-1} which suggests that, in dissolution of HEC in trifluoroacetic acid (TFAA), trifluoroacetate groups replace primary OH groups [10]. This is also typical for unsubstituted cellulose in its dissolution in TFAA.

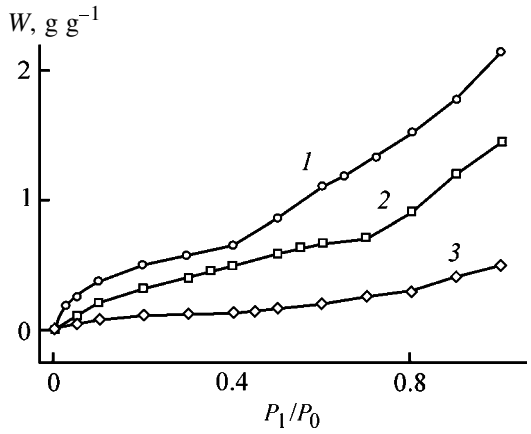

Fig. 2. Isotherms of solvent vapor sorption with CEHEC films. (W) Amount of solvent sorbed with polymer and (P/P_0) relative vapor pressure. Solvent: (*1*) TFAA, (*2*) methylene chloride, and (*3*) acetone; the same for Figs. 3–6.

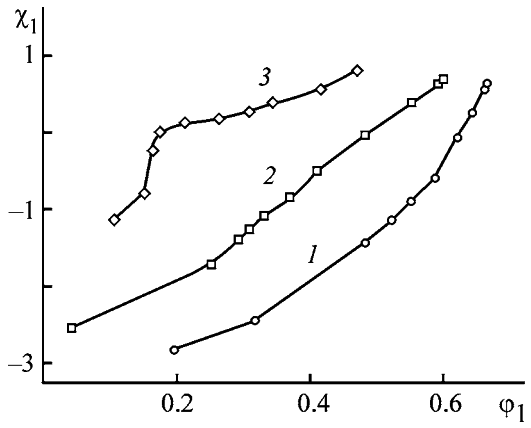

Fig. 3. CEHEC–solvent interaction parameter χ_1 as a function of the volume fraction φ_1 of the solvent.

To remove unstable trifluoroacetic substituents, the films should be treated with water. In the IR spectra of CEHEC, an absorption band appears in the range 2240–2250 cm^{-1}. This band belongs to stretching modes of the CN group, which suggests the presence of cyanoethyl groups in the polymer.

In introduction of cyanoethyl groups into HEC macromolecule, the intensity of the absorption band of OH groups significantly decreases and its shape changes (range 3000–3700 cm^{-1} for free OH groups of the polymer and OH groups bound by intra- and intermolecular hydrogen bonds). This is caused by a small amount of residual unsubstituted hydroxy groups. The absence of the absorption band at 1700 cm^{-1} in the IR spectrum of the CEHEC film prepared from a TFAA solution suggests that most of the primary OH groups remaining in anhydroglucose units and terminal OH groups of hydroxyethyl substituents were substituted in the course of cyanoethylation of HEC. Therefore, in the course of dissolution of CEHEC and TFAA, unstable trifluoroacetate substituents are not formed, in contrast to cellulose and HEC [10]. Therefore, the experimental data obtained were further interpreted assuming no chemical transformations of CEHEC in its interaction with the solvent vapor.

The sorption isotherms were obtained from the equilibrium amounts of the solvent sorbed in the sample at 20°C and the corresponding pressures of the solvent vapor. For all the solvents the S-shaped sorption isotherms [11] are observed (Fig. 2). It is seen that, with respect to the amount of the sorbed substance, the solvents can be ranked in the order TFAA > methylene chloride > acetone.

According to the Flory–Gibbs–Di Marcio theory [12] considering formation of ordered structures in the polymer–solvent system, variation of the thermodynamic affinity of the polymer for the solvent with the temperature and solution concentration significantly affects the ability of the system to pass into the LC state. The influence of the above factors on the formation of a mesophase in CEHEC was studied by sorption of the solvent vapor.

The polymer–solvent interaction parameter χ_1 was evaluated from the classical Flory–Huggins equation [10]

$$\ln a_1 = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \qquad (2)$$

where a_1 is the solvent activity governed by the relative pressure of the solvent vapor and φ_1 and φ_2^2 are the volume fractions of the solvent and polymer, respectively.

The volume fraction of the polymer in swollen samples φ_2 was evaluated by the relationship

$$\varphi_2 = \frac{1}{1 + (d_2/d_1)W}, \qquad (3)$$

where d_2 and d_1 are the densities of the dry polymer and solvent, respectively, and W is the amount of solvent absorbed with the polymer (grams of solvent per gram of dry polymer).

The dependences of the polymer–solvent interaction parameter χ_1 on the volume fraction of the solvent absorbed by polymer are shown in Fig. 3. With increasing solvent concentration, the quantities $\chi_1 = f(\varphi_1)$ change sign from negative to positive, which is in good agreement with published data for a series of

cellulose ethers [11–13]. Apparently, as in the case of some other cellulose derivatives [14], the negative values of χ_1 are caused by the microporous structure of CEHEC films and adsorption in micropores. In this case, the most porous structure is typical for CEHEC films prepared from TFAA.

At the saturated vapor pressure of the solvents, the Flory–Huggings interaction parameters are 0.63 for TFAA, 0.68 for methylene chloride, and 0.8 for acetone. We found that TFAA molecules are more active with respect to the polymer in comparison with acetone and methylene chloride molecules. All the three solvents can interact with functional groups of CEHEC by the dispersion and dipole–dipole mechanism and through formation of hydrogen bonds. The dipole moments of the solvents increase in the order methylene chloride < TFAA < acetone (1.5 < 2.3 < 2.7). Contrary to methylene chloride and TFAA, acetone molecules can be only proton acceptors in formation of hydrogen bonds with functional groups of the polymer. It should also be noted that TFAA molecules form stronger hydrogen bonds than do methylene chloride molecules. The presence of a small amount of hydroxy groups in CEHEC and a large amount of polar groups (hydroxyethyl, cyanoethyl) suggests that the solvents used interact with the functional groups of the polymer predominantly by the dispersion mechanism and hydrogen bonding. In the case of dipole–dipole interactions, it should be expected that the activity of acetone should be higher than that of methylene chloride (based on dipole moments).

From the rheological characteristics of the polymer solutions, we determined the concentration conditions for the formation of lyotropic LC in the CEHEC–solvent system. The solutions of CEHEC in TFAA up to a concentration of 15 wt % behave as ordinary isotropic systems (Fig. 4). At a concentration above 15 wt %, the viscosity of the solutions decreases, which is typical for transition into the LC state [1]. The critical concentration corresponding to the maximum in the concentration dependence of the viscosity, is taken as the concentration at which LC is formed in the solution. Under these conditions, two processes start to compete in the flow: shear ordering of the domains formed and further packing of chains to form domains. When accumulation of LC domains becomes predominant, the viscosity starts to increase again with increasing concentration of the solution. In methylene chloride solutions, LC domains are formed in CEHEC at a concentration of 20 wt %, which is higher than in TFAA. In the concentration range

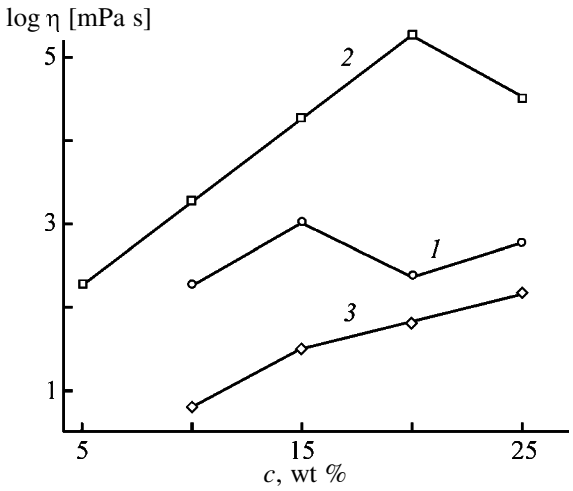

Fig. 4. Dependence of log η on solution concentration *c*.

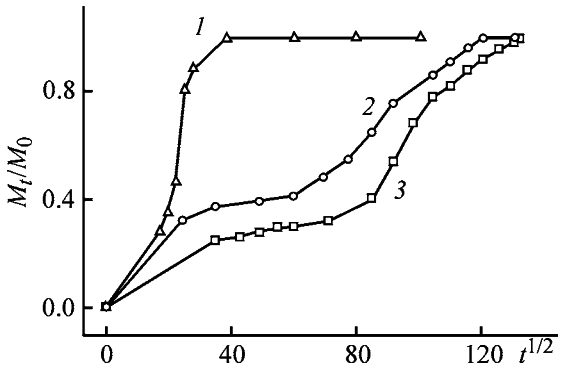

Fig. 5. Kinetic curves of solvent vapor sorption by CEHEC at 20°C and the saturated vapor prassure.

studied, we did not observe transition into the LC state in acetone solutions. It is likely that the lyotropic phase is formed at a higher concentration of the polymer.

Any structural transformations are inevitably reflected in the shape of the kinetic curves of the sorbate adsorption with the polymer. The kinetic curves of the solvent vapor sorption at the saturated vapor pressure at 20°C are shown in Fig. 5. It is seen that with TFAA the standard S-shaped curve is observed, whereas with methylene chloride and acetone there are two portions in the kinetic curves (two stages of sorption). Abnormal sorption kinetics can be caused by both relaxation processes in rearrangement of the polymeric structure under the action of the solvent and by the nonequilibrium structure of the polymer matrix [4, 18, 19].

It can be assumed that, in the systems studied, there are two mechanisms of structural rearrangement of polymer macrochains. In the CEHEC–TFAA system, this rearrangement is a transition from the perfect

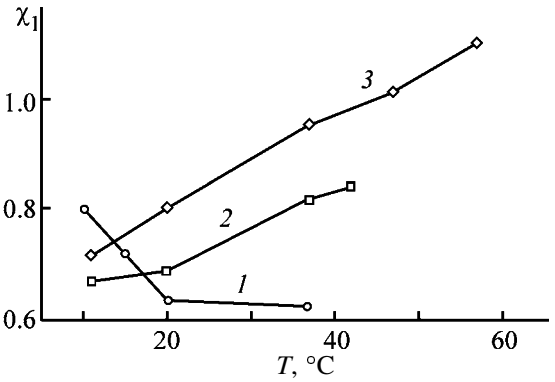

Fig. 6. Polymer–solvent interaction parameter χ_1 as a function of temperature T.

LC structure to the isotropic state (from the evidence of the X-ray study, the CEHEC films prepared from TFAA have the most perfect packing in the mesophase). In the systems CEHEC–methylene chloride and CEHEC–acetone, the mesophase formation becomes complete (i.e., in placing of the polymer into the medium causing swelling, the nonequilibrium bent macromolecules become straight and the ordering of the mesophase system increases) [20, 21]. The initial structure of the CEHEC films and the film structure after the sorption of the solvents were studied by small-angle scattering of polarized light. The analysis of the radial distribution of the intensity and radial scattering angle θ at azimuthal scattering angles μ 0° and 90° showed that the intensity monotonically decreased with increasing θ from zero and higher values (i.e., it was established that the mesophase is characterized by four-petal reflections of small-angle light scattering with the intensity uniformly decreasing with the radial angle). As in the case of cyanoethyl cellulose [16], disordered fibrillar anisotropic formations whose optical axis does not coincide with the direction of the longest axis of fibrils are responsible for diffraction. In this case, the most ordered structure is observed in the initial CEHEC films prepared from solutions in TFAA. After sorption of TFAA vapor, this structure becomes diffuse. On the contrary, in acetone and methylene chloride solutions the ordering in the initial films is lower than that after sorption of solvent vapor, which confirms the above assumption on different mechanisms of structural rearrangement in the systems studied.

To characterize the features of formation of liquid-crystalline state, it is of interest to study the temperature dependence of the thermodynamic affinity of solvents for the polymer (Fig. 6). The amount of the sorbed solvent as a function of temperature was determined at saturated vapor pressure (the solvent activity is 1). In sorption of acetone and methylene chloride vapors with CEHEC, the amount of the sorbed solvent decreases and the polymer–solvent interaction parameter χ_1 increases with heating. Such trends indicate that these systems have a lower critical temperature of solution.

The opposite pattern is observed for sorption of TFAA: the amount of the sorbed solvent increases with heating and the interaction parameter χ_1 decreases, which, in turn, indicates that the system has an upper critical temperature of solution.

Thus, the specific interactions of solvents with various functional groups of CEHEC (as in the case of cellulose acetates [22]) result in formation of polymer materials with different supramolecular structures from the same cellulose ether.

CONCLUSIONS

(1) Sorption studies of the thermodynamic features of formation of liquid-crystalline order in concentrated solutions of cyanoethyl hydroxyethyl cellulose in acetone, methylene chloride, and trifluoroacetic acid in the range 10–50°C show that the systems cyanoethyl hydroxyethyl cellulose–acetone and cyanoethyl hydroxyethyl cellulose–methylene chloride have a lower critical temperature of solution. The system cyanoethyl hydroxyethyl cellulose–trifluoroacetic acid has an upper critical temperature of solution.

(2) There are two different mechanisms of structural rearrangement in the systems cyanoethyl hydroxyethyl cellulose–acetone and cyanoethyl hydroxyethyl cellulose–methylene chloride: for cyanoethyl hydroxyethyl cellulose–trifluoroacetic acid, transition from perfect liquid-crystalline structure into isotropic state and for cyanoethyl hydroxyethyl cellulose–methylene chloride, completion of the mesophase during sorption of the solvent.

(3) Variation of the solvent from which cyanoethyl hydroxyethyl cellulose film is prepared and the action of vapor of various solvents during sorption provide a possibility of preparing polymer materials with different characteristics from the same cellulose ether.

Abstract—Cationic polymerization of a monomer derived from allylamine and 1,2-naphthoquinone was studied by polarography. The optimum conditions and kinetic characteristics of the process were found.

DOI: 10.1134/S1070427206090217

Allyl monomers form a wide class of fairly accessible compounds with various functional groups: –OH, $–NH_2$, –COOR, and –C≡H [1, 2]. Therefore, their conversion into polymer products at acceptable rates is of practical importance. The activity of allyl compounds is mainly governed by the substituent in the chain. For example, attempts to prepare polymers from diallylamine or diallylalkylamine using radical initiators failed [3]. Introduction into diallylamines of substituents containing electron-acceptor groups directly bonded to the nitrogen atom enhances the reactivity of monomers in radical polymerization. Kabanov and coworkers [3] explain this fact by displacement of the π-electron density under the action of electron-acceptor substituents, which causes activation of the allyl bond. It is well known [2, 4] that quinones have electron-acceptor power; therefore, the derivative of allylamine and 1,2-naphthoquinone [5] should be more active than the initial monomer which polymerizes at a low rate and only at radiation initiation.

This paper deals with a polarographic study of the polymerization of a monomer derived from allylamine and 1,2-naphthoquinone in the presence of hydrochloric acid.

EXPERIMENTAL

The monomer derived from allylamine and 1,2-naphthoquinone (AA–1,2-NPQ) was synthesized by the procedure described previously [5].

We used concentrated hydrochloric acid of ultrapure grade, d 1.179 g cm^{-3}. Dimethylformamide (DMF) was purified by the procedure described in [6].

The redox monomer was polymerized by the ampule method in the presence of hydrochloric acid in a DMF–water mixture. A weighed portion of AA–1,2-NPQ was placed into a glass ampule, DMF and hydrochloric acid were added, and, after dissolution of the monomer, water was added. The reaction conditions were varied in the following limits: temperature, 7–28°C; duration, 0.5–5.0 h; monomer concentration, 10–50 g l^{-1}; c_{HCl}, 0.04–0.29 M; and H_2O : DMF volume ratio, (0–3) : 1. The reaction course was judged from the concentration of unreacted monomer, which was determined polarographically. The polarograms were recorded with a phosphate buffer solution (pH 7.4) in 25% DMF in a temperature-controlled cell at 25°C on a PU-1 polagraph using mercury dropping electrode with a capillary characteristic at open circuit $m^{2/3}t^{1/6}$ = 4.38 mg$^{2/3}$ s$^{-1/2}$. AA–1,2-NPQ was determined from the wave with a half-wave potential $E_{1/2}$ = –0.54 V, whose amplitude is in direct proportion to monomer concentration in the range 10^{-4}–10^{-3} M.

Contrary to vinyl monomers readily polymerizing under the action of radical initiators to macromolecular compounds, monoallyl monomers with the general formula CH_2=CH–CH_2–X polymerize by the radical mechanism at extremely low rates with formation of oligomeric products [1, 2]. Allyl radicals add to low-active double bond of the monomer at a high rate only at a temperature higher than 300–400°C or under a pressure of 5–20 kbar and also under the action of γ-irradiation.

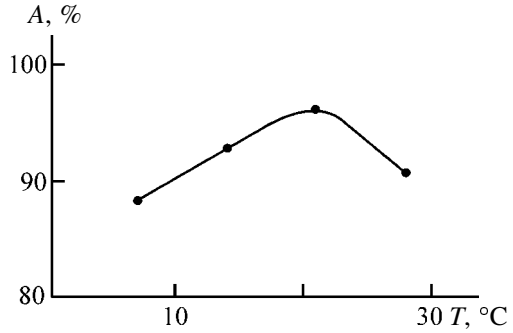

Fig. 4. Influence of temperature *T* on the conversion of AA–1,2-NPQ in its cationic polymerization.

It is well known [1, 2] that, on adding protonic acids to allyl monomers, the rates of their radical polymerization and molecular weights of the resulting polymers significantly increase. In this case, the reaction is initiated predominantly by the radiation-chemical procedure, since many of the initiators used readily undergo heterolytic decomposition in the presence of protonic acids. Reservation of the radical nature of the process is confirmed by the fact that the reaction occurs only in the presence of a source of free radicals and is inhibited by radical inhibitors.

A possibility of polymerization of AA–1,2-NPQ monomer in the presence of hydrochloric acid without radical initiators was established and the process conditions were studied (Figs. 1–5).

Figure 1 shows that, due to its proton-donor power, water activates polymerization of AA–1,2-NPQ. Apparently, the chain propagation constant increases as a result of formation of H-complexes of the monomer and propagating AA–1,2-NPQ radicals with water molecules [2]. Figure 2 shows that the polymer is formed with the maximum yield in the presence of 0.04 M HCl and further increase in the amount of the catalyst results in insignificant decrease in the yield. Figures 3 and 4 show that polymerization of AA–1,2-NPQ proceeds better at its concentration in the solution of 30 g l^{-1} and at a temperature of 21°C. Insignificant dependence of the process yield on temperature (Fig. 4) suggests that the activation energy of this reaction should be low. Figure 5 shows that polymerization of AA–1,2-HPQ proceeds at a fairly high rate in the first 0.5 h and then the process decelerates.

Thus, the polymer is formed with the maximum yield of 96% in the presence of 0.04 M HCl at a

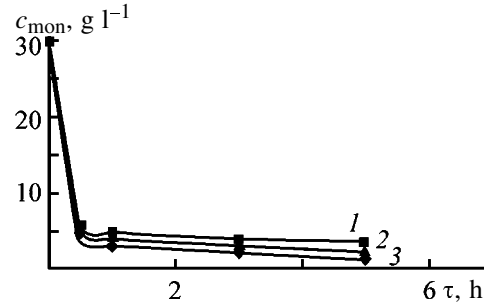

Fig. 5. Kinetics of expenditure of AA–1,2-NPQ monomer c_{mon} in cationic polymerization at various temperatures. H_2O : DMF = 3 : 1, c^0_{mon} = 30 g l^{-1}, c_{HCl} = 0.04 M. (τ) Time. Temperature, °C: (*1*) 7, (*2*) 14, and (*3*) 21.

volume ratio H_2O : DMF = 3 : 1, monomer concentration of 30 g l^{-1}, temperature of 21°C, and synthesis duration of 5 h.

The kinetics of AA–1,2-NPQ polymerization under optimum conditions was studied. The kinetic curves (Fig. 5) show that the process is first-order with respect to the monomer concentration. We evaluated the reaction rate constants at various temperatures using the appropriate equation [6] and determined the activation energy (see table) from the Arrhenius plot (Fig. 6).

As we assumed, the activation energy of this reaction was fairly low. Hence, the monomer synthesized from allylamine and 1,2-naphthoquinone shows a high reactivity in polymerization. Since the reaction occurs in the absence of radical initiators and is activated by hydrochloric acid, we can conclude that the reaction occurs by the cationic mechanism [8]. The resulting polymer is a dark cherry-brown powder with mp 152°C and $[\eta]$ = 0.12 dl g^{-1}. Its redox capacity with respect to 0.1 N solution of $Fe_2(SO_4)_3$ is 2.9 mg-equiv g^{-1}.

Thus, a new redox polymer containing groups capable of redox reactions (>C=O) and complex formation (–NH–) was synthesized by cationic polymerization under mild conditions. The possible areas of its application are hydrometallurgy (for separation and concentration of metal ions), water treatment (for removal of oxygen and chlorine), chemical industry (for purification and removal of organic compounds), and medicine [9, 10].

Kinetic characteristics of cationic polymerization of AA–1,2-NPQ monomer

T, K	k, s^{-1}	$\log k$	E_{act}, kJ mol^{-1}
280	0.00094	–3.03

294	0.00112	–2.95	

CONCLUSIONS

(1) The optimal conditions of cationic polymerization of a derivative of allylamine and 1,2-naphthaquinone were found.

(2) The kinetics of this reaction was studied, and the reaction constants and activation energy were evaluated.

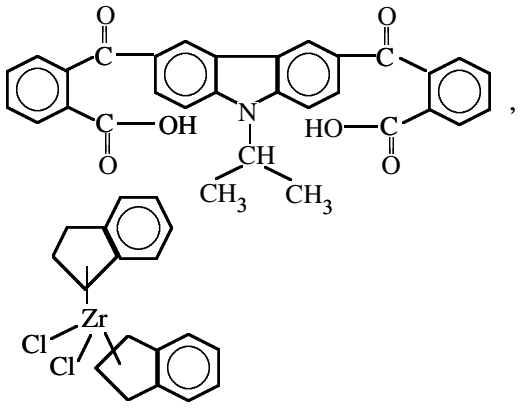
Abstract—The effect of ternary initiating systems benzoyl peroxide–ferrocene–3,6-bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole and benzoyl peroxide–di-η^5-indenylzirconium dichloride–3,6-bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole on the radical polymerization of methyl methacrylate and on the heat resistance and microstructure of the resulting polymers was examined.

DOI: 10.1134/S1070427206090229



The main goal of macromolecular chemistry is preparation of polymeric materials with required properties. This goal can be accomplished by performing the process in the presence of initiating systems that contain, along with other components, organometallic compounds [1]. Organic compounds of transition metals find growing use not only as catalysts of ionic-coordination polymerization of olefins and dienes, but also as agents controlling the radical polymerization of vinyl monomers [2].

It is known [3–5] that the use of certain metallocenes (ferrocene, titanocene dichloride, etc.) in combination with initiators [benzoyl peroxide, azobis(isobutyronitrile)] not only accelerates the polymerization, but also allows preparation of poly(methyl methacrylate) (PMMA) with a narrower molecular-weight distribution and increased content of syndiotactic seqeunces in the polymer chain.

At the same time, study of initiating systems containing heteroaromatic diketo carboxylic acids showed that they, especially 3,6-bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole, catalyze the decomposition of benzoyl peroxide [6]. The effect of 3,6-bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole on the microstructure of the polymer is so strong that it is manifested at concentrations 1–2 orders of magnitude lower than the peroxide concentration and exceeds the effect of metallocene systems [3, 4, 6, 7].

However, peroxide–nitrogen-containing compound systems are characterized by deceleration of the polymerization [8], which makes them hardly suitable for commercial production of polymeric materials. It can be expected that combination of a metallocene and a nitrogen-containing compound in one initiating system would not only preserve their stereoregulating functions but also accelerate the polymerization and improve the thermal characteristics of the polymers obtained.

Here we report on the radical polymerization of methyl methacrylate (MMA) initiated by ternary systems benzoyl peroxide (BP)–3,6-bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole (DCN)–ferrocene (FC) and BP–DCN–di-η^5-indenylzicronium dichloride (DIZD) and on the heat resistance and microstructure of the resulting polymers.

EXPERIMENTAL

MMA was shaken with a 5–10% KOH solution to remove the stabilizer, washed with water to neutral reaction, dried over $CaCl_2$, and double-distilled in a vacuum. Benzoyl peroxide was recrystallized three times from methanol and dried at room temperature in a vacuum to constant weight; mp 108°C (dec.). Ferrocene was prepared as described in [9] and purified by sublimation. 3,6-Bis(*o*-carboxybenzoyl)-*N*-isopropylcarbazole was prepared and purified by the procedure described in [10]. Diindenylzirconium dichloride was prepared according to [11] and purified by sublimation.

The polymerization was performed in the bulk [12]; the temperature was maintained with an accuracy of ±0.05°C.

Dynamic TGA was performed on a Q-1000 derivatograph (MOM) in air; heating rate 5 deg min^{-1}, sample weight 100 mg.

The content of syndio- and isotactic sequences in the macromolecules was determined by ^1H NMR spectroscopy [13–15] on a Bruker AM-300 device; solvent $CDCl_3$, operating frequency 300 MHz.

Experiments on the polymerization of MMA initiated by ternary systems BP–FC–DCN and BP–DIZD–DCN showed that, in the entire temperature range studied (30–60°C), the initial reaction rate increased relative to the samples without additives (Fig. 1). The polymerization initiated by the BP–FC–DCN system was considerably faster than that initiated by the binary system BP–DCN. However, the reaction rate was considerably lower compared to the polymerization initiated by the binary system BP–FC (Fig. 1). Apparently, the metallocene exerts a predominant effect on the kinetic parameters of the process.

The apparent activation energy of the polymerization in the presence of the BP–FC–DCN system, calculated from the temperature dependence of the rate constant, appeared to be 12±0.5 kJ mol^{-1}, which is appreciably lower than in the initiation with BP only (80 kJ mol^{-1}) [16] or with the BP–FC system (48.3 kJ mol^{-1}) [17]). The ternary initiating system decreases primarily the activation energy of the polymerization initiation, because the activation energies of the chain propagation and termination are insignificant.

A study of the MMA polymerization initiated by the BP–DIZD–DCN system revealed a synergistic effect of the additives, caused by the competition for the coordination sites of the Zr atom and by the mutual influence of the additives as ligands. The MMA polymerization initiated by the BP–DIZD–DCN system is conbsiderably faster than that initiated by the BP–DIZD or BP–DCN system (Fig. 1). The apparent activation energy of the polymerization is 50 kJ mol^{-1}. Hence, in this case we can speak of formation of a ternary initiating system.

Polymers prepared with ternary initiating systems BP–FC–DCN and BP–DIZD–DCN exhibit high heat resistance and stereoregular structure.

Both ferrocene and DIZD, when added to the initiating system BP–DCN, appreciably enhance the heat resistance of the PMMA obtained. The temperature of the decomposition onset ($T_{o.d}$) increases by approximately 40–50°C compared to the polymers prepared without additives (Fig. 2).

The use of ternary systems BP–FC–DCN and BP–DIZD–DCN results in the disappearance of the low-temperature peak from the DTG curves of the poly(methyl methacrylate) obtained (Fig. 2). Apparently, the additives affect the polymer degradation in the low-temperature step. The PMMA degradation occurs very rapidly within a narrow temperature range (280–380°C) and is accompanied by heat release, according to DTA (Fig. 3). The exothermic peak in the DTA curves of the samples prepared with the DIZD-containing initiating system is observed only at synthesis temperatures of 30 and 45°C.

The heat resistance of PMMA prepared with the ternary initiating systems is higher ($T_{o.d}$ is higher by 20–30°C) than that of PMMA prepared with the binary systems [6, 14] (Fig. 2). An increase in the ferrocene concentration at a fixed content of DCN and BP results in an increase in the temperature of the decomposition onset, which tends to a certain limit (Fig. 4). A different pattern is observed with an increase in the DCN concentration. Addition of 0.5×10^{-4} M DCN to the polymerizing system increases $T_{o.d}$ of PMMA. However, further increase in the DCN concentration causes a decrease in the heat resistance (Fig. 4b). The $T_{o.d}$ of PMMA prepared using the benzoyl peroxide–DIZD–DCN system does not appreciably change with an increase in the DIZD content in the polymerizing system. The effect of DCN on the heat resistance of the polymer is the same as with the FC–DCN–BP system. The relative increase in $T_{o.d}$ as a function of the temperature of the MMA polymerization is maximal for the polymers prepared at 30°C and minimal for those prepared at 60°C, with both ternary initiating systems.

An increase in the heat resistance of PMMA prepared in the presence of a metallocene and a tertiary amine can be due to a decrease in the amount of unsaturated terminal groups formed as a result of chain termination by disproportionation [18, 19], and also to formation of more stable metallocene and diketo carboxylic acid fragments on the ends of the polymer chain. Furthermore, the stabilizing effect of a diketo carboxylic acid on the depolymerization of PMMA was noted previously [6].

Examination of the structure of PMMA macromolecules formed in the simultaneous presence of a metallocene (ferrocene, DIZD) and a tertiary amine (DCN) revealed an increased content (up to 70%, see table) of the syndiotactic structures. The polymers prepared using the ternary systems have a noticeable content of isotactic fragments. This fact suggests that not only free radicals but also radicals bound in a

complex are formed in the system, initiating the polymerization [20]. Hence, the polymerization of MMA in the presence of the FC–DCN and DIZD–DCN systems occurs by the radical complex mechanism. Apparently, the stereospecificity of the MMA polymerization in the systems under consideration is primarily due to interaction between the components of the initiating systems.

CONCLUSION

A study of ternary initiating systems allows not only acceleration of the methyl methacrylate polymerization but also preparation of polymers with enhanced heat resistance and regular microstructure.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Cobalt(III) Dimethyldithiocarbamate Complexes on Styrene Polymerization Initiated by *tert*-Butyl Perbenzoate

N. V. Khitrich, I. I. Seifullina, Yu. K. Epimakhov, and P. A. Ivanchenko

Mechnikov National University, Odessa, Ukraine

Received March 1, 2006

Abstract—Kinetic features of radical polymerization of styrene initiated by *tert*-butyl perbenzoate in the presence of tris(*N,N*-dimethyldithiocarbamato)cobalt(III) (CoL_3) and its adduct with iodine ($CoL_3 \cdot 2I_2$) were studied. The optimal concentration ratios of the activators and *tert*-butyl perbenzoate, providing fast styrene polymerization at 338–368 K, were determined.

DOI: 10.1134/S1070427206090230

Previously we prepared tris(*N,N*-dimethyldithiocarbamato)cobalt(III) (CoL_3) [1] and its molecular complex with iodine ($CoL_3 \cdot 2I_2$) [2]. The structure of these complexes and their physicochemical properties were determined. This paper continues the study of the synthesis, structure, and properties of these complexes. The goal of this study was to examine the catalytic effect of these complexes on the decomposition of initiators under the conditions of radical polymerization of styrene. This study was stimulated by the following facts.

First, organic compounds containing dithiocarbamate groups are effective agents for living polymerization. They are iniferters, i.e., compounds that simultaneously initiate, transfer, and terminate chains [3, 4].

Second, cobalt(III) dithiocarbamates can be reduced to cobalt(II) compounds or can be oxidized to cobalt(IV) complexes [5–7]. For example, CoL_3 is electrochemically oxidized in acetonitrile by the mechanism [6]

$$CoL_3 \rightleftarrows [CoL_3]^+ + e^-,$$

$$2[CoL_3]^+ \rightarrow [Co_2L_5]+ + \text{oxidized ligand},$$

$$[Co_2L_5]^+ + 2CH_3CN \rightarrow CoL_3 + [CoL_2(CH_3CN)_2]^+.$$

The products, CoL_3 and $[CoL(CH_3CN)_2]^+$, can be repeatedly oxidized. Therefore, cobalt(III) dithiocarbamates can catalyze decomposition of organic initiators, thus accelerating polymerization of vinyl monomers initiated by these systems. However, no data on the use of CoL_3 and $CoL_3 \cdot 2I_2$ for this purpose are reported. Since $CoL_3 \cdot 2I_2$ contains weakly bound molecular iodine, which is an active scavenger of free radicals [8], this complex can both inhibit and catalyze styrene polymerization.

The aim of this study was to examine the influence of $Co[S_2CN(CH_3)_2]_3$ and $Co[S_2CN(CH_3)_2]_3 \cdot 2I_2$ complexes on styrene polymerization initiated by different compounds, to reveal the difference in the kinetic features of the polymerization, and to determine the optimal polymerization conditions at moderately low temperatures. The results of this study can be used to decrease the power consumption and the possibility of occurrence of side reactions.

EXPERIMENTAL

Styrene was treated with 10% KOH to remove hydroquinone, washed with water to neutral washings, dried over $CaCl_2$, and fractionally distilled in Ar at a pressure of 1.3 kPa.

Tris(*N,N*-dimethyldithiocarbamato)cobalt(III) was prepared by the reaction of cobalt(II) chloride with a stoichiometric amount of sodium *N,N*-dimethyldithiocarbamate in an aqueous solution. The product was recrystallized twice from a chloroform–ethanol mixture [1]. The molecular complex $CoL_3 \cdot 2I_2$ was prepared by the reaction of CoL_3 with a threefold excess of iodine in a chloroform–diethyl ether mixture [2]. The content of the main compound in *tert*-butyl perbenzoate (TBPB) was 97.5%.

The kinetics of bulk styrene polymerization was studied dilatometerically [9]. The concentration of cobalt(III) complexes and *tert*-butyl perbenzoate was 10^{-4}–10^{-3} and 10^{-2}–10^{-1} M, respectively. Polymerization was performed at 338, 353, and 368 ± 0.1 K. The polymerization rate under the steady-state condi-

tions was calculated from the slope of the degree of polymerization (S) vs. time (τ) curves using the Excel software.

To determine the molecular weight, polystyrene samples obtained at 20% conversion of the monomer were reprecipitated twice from a benzene solution with methanol and dried to constant weight in a vacuum at room temperature. The intrinsic viscosity of benzene solutions of the polymers was measured on an Ubbelohde viscometer at 298 ± 0.1 K. The molecular weight of polystyrene was calculated by the Mark–Kuhn–Houwink equation $[\eta] = KM^{\alpha}$, where $K = 2.7 \times 10^{-4}$, $\alpha = 0.66$ [10].

The electronic absorption spectra of the solutions of the polymerization systems were recorded on a Specord UV–VIS spectrophotometer in 1-cm quartz cells.

To determine the most effective initiation system, we studied first the influence of typical commercial initiators on the rate of styrene polymerization in the presence of CoL_3. We found that the polymerization rate and the polystyrene molecular weight remained virtually the same when 2,2-azobisisobutyronitrile (AIBN) and dicumyl peroxide were used as the initiators. The polymerization decelerates in the presence of benzoyl peroxide and accelerates when TBPB or isopropylbenzene hydroperoxide is used as the initiator. Subsequent experiments were performed using TBPB as an effective initiator. Styrene polymerization in the presence of this initiator is faster that that in the presence of isopropylbenzene hydroperoxide, all other conditions being the same.

A kinetic study of styrene polymerization initiated by CoL_3–TBPB (**I**) and $CoL_3 \cdot 2I_2$–TBPB (**II**) systems showed that the shape of the initial portions of the kinetic curves was determined by both the qualitative composition and the quantitative ratio of the components of the initiating systems (Fig. 1).

(1) The first steps of the polymerization initiated by system **I** in which the TBPB concentration was substantially higher than that of CoL_3 (Fig. 1, curve *2*) were slightly slower than in the polymerization initiated by TBPB without CoL_3 (Fig. 1, curve *1*). Then the polymerization accelerates, reaching a high constant rate up to a monomer conversion of >75%, without pronounced gel effect.

(2) The kinetic curves became S-shaped with increasing CoL_3 concentration in the system (Fig. 1, curve *3*). As in the first case, the initial polymerization steps were somewhat slower compared to the initiation by TBPB without CoL_3. Polymerization substantially accelerated with time and then gradually decelerated.

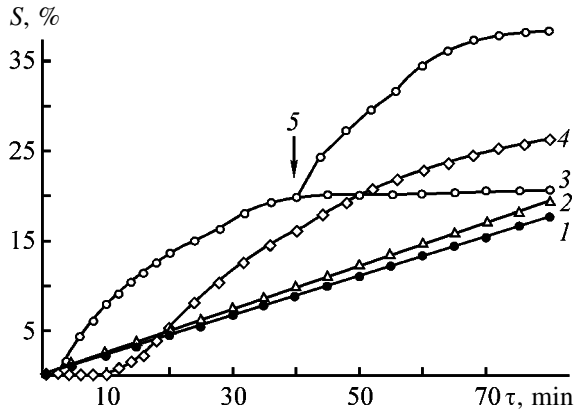

Fig. 1. Kinetic curves of styrene polymerization at 368 K. TBPB concentration 5×10^{-2} M. (S) Degree of polymerization and (τ) time. Concentration of cobalt(III) complexes, M: (*1*) 0, (*2*) 2.5×10^{-3} CoL_3, (*3*) 10^{-4} CoL_3, and (*4*) 2.5×10^{-3} $CoL_3 \cdot 2I_2$; (*5*) additional introduction of TBPB.

(3) The feature of the polymerization initiated by system **II** is a well-defined inhibition period during which no polymerization is observed (Fig. 1, curve *4*). After the completion of this time, the shape of the polymerization curves was similar to that of the kinetic curves of styrene polymerization initiated by system **I**.

Analysis of these data suggests that the insignificant deceleration of styrene polymerization in the first steps is due to the reaction of CoL_3 with TBPB (or its decomposition product) to form reactive intermediates [CoL_3···TBPB] which generate free radicals in the system more readily than does TBPB, thus accelerating the polymerization. The occurrence of the reaction of CoL_3 with TBPB (or its decomposition products) is unambiguously proved by changes in the ESR spectra of solutions of the initiating systems in styrene (Fig. 2), recorded immediately after their preparation and after heating at 368 K for 5–15 min (onset time of the polymerization acceleration).

The electronic absorption spectra of the freshly prepared solutions (Fig. 2, curves *1, 2*) contain weak bands at ~15 600 cm^{-1} assigned to hte $^1A_{1g} \rightarrow {}^1T_{1g}$ transition typical for low-spin octahedral cobalt(III) complexes. The shoulder at ~21 000 cm^{-1} in the spectrum of **I** is due to the second spin-allowed $^1A_{1g} \rightarrow {}^1T_{2g}$ transition. In the case of system **II**, the band of this transition is obscured by the band of free iodine formed by partial dissociation of $CoL_3 \cdot 2I_2$. Strong bands in the short-wave region are due to intraconfigurational transitions in the central atoms and to

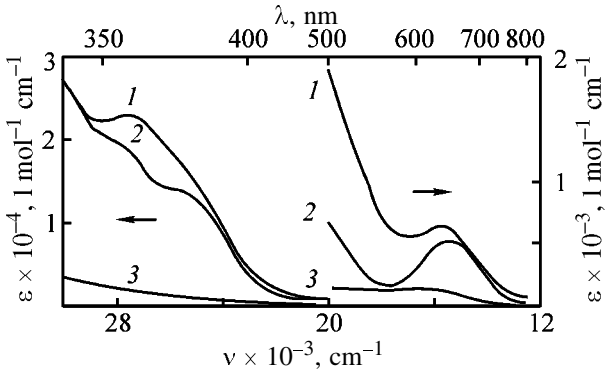

Fig. 2. Electronic absorption spectra of solutions of the initiating systems in styrene. Concentrations, M: cobalt(III) complexes 2.5×10^{-3} and TBPB 5×10^{-2}. (ε) Molar extinction coefficient, (*n*) wavenumber, and (λ) wavelength. (*1*) $CoL_3 \cdot 2I_2$–TBPB, (*2*) CoL_3–TBPB immediately after preparation of the solutions, and (*3*) $CoL_3 \cdot 2I_2$–TBPB or CoL_3– TBPB after heating of the solutions at 368 K for 15 and 5 min, respectively.

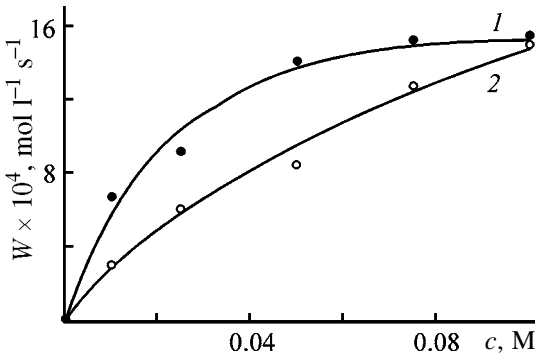

Fig. 3. Rate of styrene polymerization *W* initiated by (*1*) CoL_3–TBPB and (*2*) $CoL_3 \cdot 2I_2$–TBPB systems at 368 K as a function of the TBPB concentration *c*. Concentration of cobalt(III) complexes 2.5×10^{-3} M.

charge transfer between the cobalt atom and the dithiocarbamate group. In the case of system **II**, these bands are masked by a strong charge-transfer band at ~27800 cm^{-1} typical for complexes of thiocarbonyl compounds with iodine.

Heating of the solutions of the initiating system causes the hypsochromic shift of the *d–d* bands and the hypochromic effect for all the bands. The spectra of the solutions of systems **I** and **II** become similar (Fig. 2, curve *3*), which suggests formation of [CoL_3···TBPB] intermediates in both cases.

When the concentration of cobalt(III) dimethyldithiocarbamate complexes in the initiating system increases, the polymerization accelerates and then decelerates with time (Fig. 1, curve *3*). The higher the $c_{Co(III)} : c_{TBPB}$ ratio, the sharper is deceleration of styrene polymerization at the smaller conversion. We suggest that the polymerization decelerates owing to fast consumption of TBPB. To confirm this assumption, a small amount of TBPB was added to one of the dilatometers after deceleration of the polymerization. This resulted in acceleration of the process (Fig. 1, curve *5*). Hence, [CoL_3···TBPB] intermediates formed by the reaction of CoL_3 with TBPB (or its decomposiiton products) catalyze the generation of radicals after introduction of additional portions of TBPB. The S shape of the kinetic curves of polystyrene accumulation under the conditions when the rates of formation and consumption of [CoL_3···TBPB] intermediates are comparable indicates that these intermediates are involved in the polymerization.

The well-defined inhibition period observed when the polymerization is initiated by system **II** (Fig. 1, curve *4*) is caused by the presence of molecular iodine (radical "counter") formed by dissociation of $CoL_3 \cdot 2I_2$. This assumption is confirmed by the shape of its electronic spectrum (Fig. 2, curve *1*) and by our previous data [2]. The induction period is directly proportional to the concentration of $CoL_3 \cdot 2I_2$ and inversely proportional to the TBPB concentration and temperature. The constancy of the $c_{CoL_3 \cdot 2I_2}/\tau_{inhib}$ ratio suggests that iodine is consumed only in reaction with primary radicals generated by the TBPB decomposition. After the end of the inhibition period (complete consumption of molecular iodine), the polymerization accelerates and occurs similarly to the polymerization initiated by system **I**. Thus, $CoL_3 \cdot 2I_2$ both inhibits and catalyzes the TBPB decomposition, which allows the control over the kinetics and temperature of the first polymerization steps.

Polymerization of styrene accelerates with increasing TBPB concentration in systems **I** and **II** at a constant content of the cobalt(III) dimethyldithiocarbamate complexes (Fig. 3). At the same time, the dependence of the polymerization rate on the concentration of these complexes at a constant content of TBPB passes through a maximum (Fig. 4) at $c_{CoL_3} : c_{TBPB}$ and $c_{CoL_3 \cdot 2I_2} : c_{TBPB}$ ratios of 1 : ~20 and 1 : ~30, respectively. The molecular weight of polystyrene decreases from 1.38×10^5 to 2.2×10^4 with an increase in the content of the cobalt(III) complexes in the initiating systems (Fig. 5). Apparently, the cobalt(III) complexes are involved at least in catalysis of TBPB decomposition and in termination of the polymeric chains. The fact that the rate of styrene polymerization initiated by the CoL_3–AIBN system and the molecular weight of the resulting polymer are similar to those in the presence of AIBN without CoL_3 suggests that CoL_3 has no effect on the chain propagation.

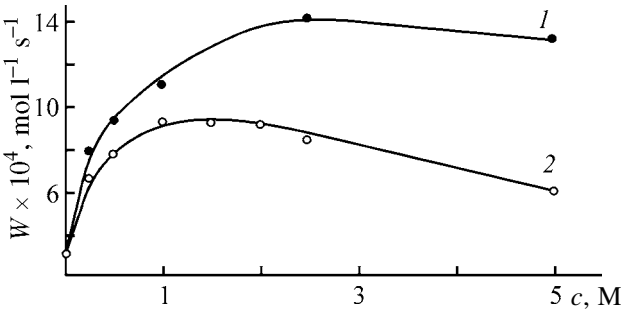

Fig. 4. Rate of styrene polymerization W initiated by (*1*) CoL_3– TBPB and (*2*) $CoL_3 \cdot 2I_2$–TBPB systems at 368 K as a function of the concentration of the cobalt(III) complexes. TBPB concentration 5×10^{-2} M.

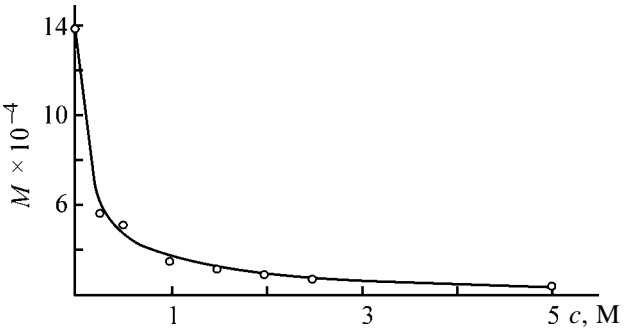

Fig. 5. Molecular weight of polystyrene M as a function of the $CoL_3 \cdot 2I_2$ concentration c. Polymerization temperature 368 K, 20% conversion, TBPB concentration 5×10^{-2} M.

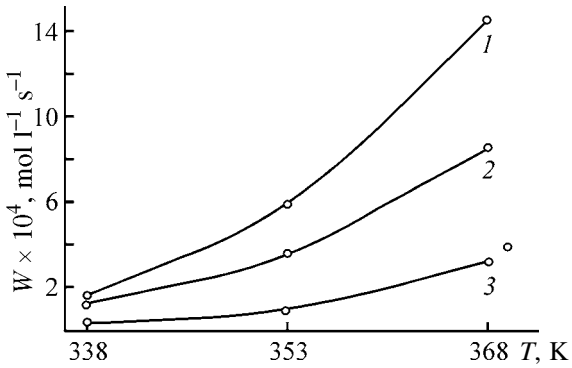

Fig. 6. Rate of styrene polymerization W initiated by (*1*) CoL_3– TBPB and (*2*) $CoL_3 \cdot 2I_2$–TBPB systems, and (*3*) by straight TBPB as a function of temperature T. TBPB concentration 5×10^{-2} M, concentration of cobalt(III) complexes 2.5×10^{-3} M.

The temperature dependence of the styrene polymerization rate (Fig. 6) clearly demonstrates the advantage of initiating systems **I** and **II** over straight TBPB. As seen from Fig. 6, in the presence of these systems styrene rapidly polymerizes at moderately low temperatures. The apparent activation energy of the polymerization in the presence of TBPB and systems **I** and **II** is 93, 76, and 69 kJ mol^{-1}, respectively.

CONCLUSIONS

(1) The kinetic features of bulk styrene polymerization initiated by CoL_3– and $CoL_3 \cdot 2I_2$–*tert*-butyl perbenzoate systems are determined by the qualitative composition of the components of the initiating systems and their quantitative ratio.

(2) Reactive intermediates [CoL_3–*tert*-butyl perbenzoate], which readily generate free radicals in the system and can be repeatedly used, provide fast styrene polymerization.

(3) The $CoL_3 \cdot 2I_2$–*tert*-butyl perbenzoate system inhibits the first steps of styrene polymerization owing to formation of molecular iodine by dissociation of $CoL_3 \cdot 2I_2$ and then catalyzes the process.

(4) The cobalt(III) dimethyldithiocabamate complexes are effective catalysts of *tert*-butyl perbenzoate decomposition into free radicals. Initiating systems containing these complexes can be used to catalyze styrene polymerization at moderately low temperatures. The optimal activator-to-*tert*-butyl perbenzoate concentration ratios for the CoL_3–*tert*-butyl perbenzoate and $CoL_3 \cdot 2I_2$–*tert*-butyl perbenzoate systems are 1 : ~20 and 1 : ~30, respectively.

Abstract—The effect of fullerene black introduced (after extraction of light fullerenes from the black with toluene) into polytetrafluoroethylene F-4 on its wear resistance and antifriction properties in sliding over steel at contact pressures in the range 0.2–2.0 MPa was studied.

DOI: 10.1134/S1070427206090242

Polytetrafluoroethylene (PTFE) is one of the best antifriction polymeric materials [1]. However, its use is restricted by cold flow and poor wear resistance. Introduction of various solid fillers into PTFE leads to a certain compromise: the wear resistance increases at a certain deterioration of antifriction properties. Composites based on PTFE are used in manufacture of plain bearings, guiding devices, and seals, including those working without additional lubrication in vacuum and corrosive media [1].

It was shown in [2–4] that introduction of fullerene C_{60} into liquid lubricating oils improves their antifriction and wear-resistant properties in sliding friction of metals. Moreover, introduction of fullerene blacks into oils (even upon extraction of most of fullerenes from the blacks) also markedly improves the tribological properties of lubricants [3]. The possible reason is that a large amount of fullerenes, especially higher fullerenes, remains in the black upon extraction of the larger part of fullerenes with aromatic solvents [5]. Use of various blacks of other origins produces no effects of this kind. At the same time, the fullerene black is a considerably less expensive material than pure fullerenes and, upon extraction of fullerenes, is a waste from the fullerene production, which has not found wide use so far.

The aim of this study was to examine the effect of fullerene black on the tribological properties of PTFE; it was intended to use fullerene black from which fullerenes were already extracted as additive to materials in order to obtain data on the possibility of its practical application.

EXPERIMENTAL

We used as starting materials for tribological tests polytetrafluoroethylene F-4 [GOST (State Standard) 10007–80]. The starting fullerene black was obtained in electric-arc plasma by the Krätschmer–Huffman method [6]. Extraction with toluene as a solvent was used to recover from the black an 8% amount of a mixture of fullerenes (mostly C_{60} and C_{70} in a 75 : 25 ratio). The fraction of residual fullerenes remaining in the fullerene black after the extraction, found by additional prolonged extraction, did not exceed 0.2–0.3%. However, published data suggest that the residual amount of higher fullerenes remaining after primary extraction with toluene in the black we used (designated as FB) is rather high [5, 7].

We introduced 1 wt % FB into the bulk of F-4 in conformity with the same technical specifications which were used in introduction of coal coke and production of F-4K20 material [TU (Technical Specification) 6-05-1412–76]. As shows practical experience [8], there is no point in introducing fullerene C_{60} or a fullerene black into lubricants in an amount exceeding 1–3 wt %. Part of samples were coated with a thin film of fullerene C_{60} by drying a toluene solution of C_{60} directly on the sample surface. The thickness of this film, evaluated by the concentration of the solu-

tion and the area being coated, did not exceed 1 μm. It was natural to assume that such a thin film will be rapidly worn-out in friction, and only the effect of residual amounts of fullerene C_{60} in the gap of the tribocontact on the process of further friction and wear would be expected to occur.

The study was performed on a standard 2070 SMT-1 roller friction machine. A sample being tested had the form of a flat plate with a rectangular cross section and thickness of 10 mm. A roller 46 mm in diameter and 16 mm wide, made of 18Kh2NChMA (GOST 4543–71) chromium–nickel–molybdenum steel and rotating at 400 rpm, which corresponded to a linear sliding velocity of 1 m s^{-1}, was brought to the plate. The roller always exceeded the sample in width.

Two schemes of the initial friction contact were used. In scheme A, the initial cylinder–plane contact between counter bodies was created along the generatrix of the mobile cylindrical roller. Further, a normal load F_N, maintained constant during the entire test (300 s), was applied to the sample and all the tribological characteristics measured were related to this load. In scheme B, a wear groove of area 30–50 mm^2 was preliminarily produced on the sample surface, so that further tests were performed on conformal counter bodies with a worn-in friction contact. A steadily increasing normal load F_N was applied to a sample. The test duration at each load was 300 s. The tests were carried out without lubrication (dry friction mode). Other details of the procedure used to measure tribological characteristics have been described previously [9].

Figure 1 shows dependences of the friction coefficient on the contact pressure for the starting F-4 samples and those filled with a fullerene black, obtained using test scheme B. It can be clearly seen that, upon introduction of the fullerene black, the friction coefficient decreases in the whole range of pressures studied.

Similar results were obtained in tests by scheme A. In addition, longer tests were performed by scheme A (during 30 min) at various initial loads. At each load, the friction coefficient is always smaller (by a factor of 1.2–1.6) for black-filled samples, compared with samples of pure F-4 (Fig. 2).

Introduction of fullerene black FB markedly reduces the volume wear. A similar conclusion that the antiwear properties are improved by introduction of the black can be made on the basis of other wear characteristics. For example, the linear wear intensity

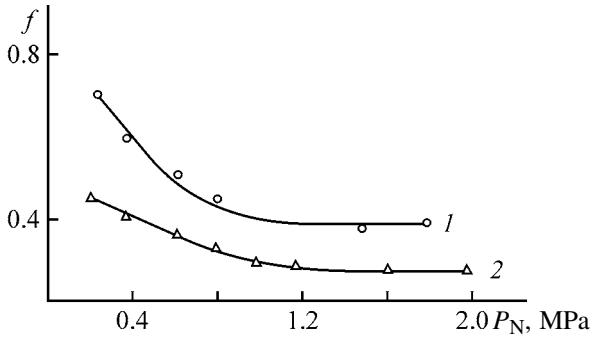

Fig. 1. Sliding-friction coefficient f of F-4 fluoroplastic over steel vs. normal pressure P_N in a friction contact. (*1*) Starting F-4 and (*2*) F-4 + 1% FB; the same for Fig. 2.

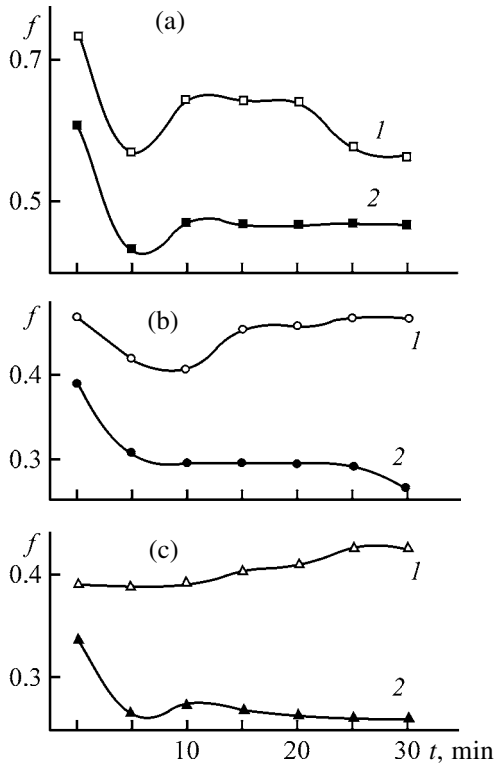

Fig. 2. Sliding-friction coefficient f of F-4 fluoroplastic over steel vs. testing time t at initial loads on the linear constant, F_N, of (a) 40, (b) 120, and (c) 200 N.

I_h is the smallest for F-4 fluoroplastic filled with a fullerene black in the entire range of pressures studied.

The I_h–P_N curves are S-shaped, which is characteristic of transitions between two different wear mechanisms. However, I_h is directly proportional to the contact pressure, rather than being constant, even within the same wear mechanism. Therefore, the wear process is better characterized, in our opinion, by the energy-related wear intensity I_W [10–12], which is equal to the volume worn-out upon expenditure of unit energy.

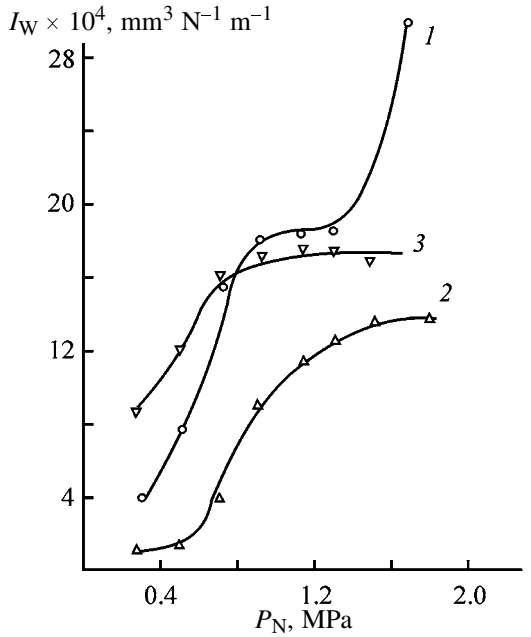

Fig. 3. Energy-related wear intensity I_W vs. normal pressure P_N on a friction contact in dry sliding friction over steel of (*1*) F-4, (*2*) F-4 + 1% FB, and (*3*) F-4 coated with a thin layer of C_{60} fullerene.

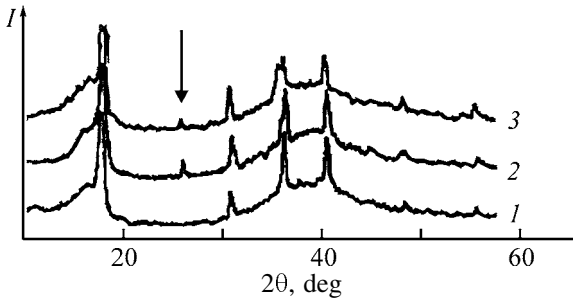

Fig. 4. Wide-angle X-ray diffraction patterns of (*1*) F-4, (*2*) F-4 + 1% FB, and (*3*) F-4 + 3% FB. CuK_α radiation. The arrow shows the reflection corresponding to the strongest 002 reflection from the graphite lattice. (*I*) Reflection intensity and (2θ) Bragg angle.

The constancy of I_W values, frequently observed experimentally on varying the external conditions, is the criterion of a constant wear mechanism. At a given friction path L, the values of I_W and I_h are related by [11, 12]

$$I_W(L) = I_h(L)/f(L)P_N(L).$$

All the dependences of I_W on the contact pressure (Fig. 3) flatten out, which characterizes transition to a mode with a constant wear mechanism. However, only in curve *1* this is followed by a steep rise in I_W at high pressures. In the rest of the cases, the transition to intensive wear, characteristic of scuffing, is apparently shifted to higher pressures, and, therefore, is not seen in the range of the pressures used. This extends the range of working pressures, which should be attributed to the positive effect of fullerenes.

It was assumed previously [2, 3] that, owing to their quasispherical shape, molecules of C_{60} fullerene can serve as a kind of molecular "rollers" on friction surfaces and thereby favor a decrease in the friction and wear coefficients. Further studies of friction surfaces demonstrated that the mechanism of action of C_{60} fullerene in a mineral oil consists in that it initiates formation on friction surfaces of a thin protective polymeric film composed of naphthene and paraffin oligomers present in oils [13, 14]. However, the present study is concerned with dry friction and, consequently, the mechanism by which the wear resistance of F-4 is improved should be different. It should be noted here that fullerene black is present in the F-4 matrix as a separate phase; because of the small amount of the black, only the strongest 002 reflection from the lattice of graphite contained in the black slightly appears in the X-ray diffraction patterns of the samples studied (Fig. 4).

It is known that mechanical degradation of polymer chains occurs at mouths of the forming cracks in mechanical disintegration of polymers. A similar process apparently occurs in mouths of numerous cracks leading to formation of wear particles. The degradation generates free radicals, which can readily add to fullerene molecules to form a fullerene–polymer network. The fact that the polymer radicals formed by thermal degradation of polymers readily react with C_{60} has been demonstrated by numerous examples (polystyrene, polymethyl methacrylate, polyethylene glycol, and poly-*N*-vinylpyrrolidone) [15, 16]. Therefore, the formation of a network from PTFE and fullerenes is rather probable. Consequently, it may be assumed that microscopic cracks that appear in the course of tests close up (are healed) at fullerene molecules because of their high electron-acceptor capacity, rather than go around the fullerene-containing particles as ordinary inclusions. The chain-type free radicals generated by mechanical degradation of F-4 are bound to fullerene molecules by covalent bonds.

It follows from general considerations that the better the properties of the starting material, the lower the efficiency of additives aimed to improve these properties. An effect of this kind with respect to antifriction and antiwear properties was observed upon introduction of fullerene-containing additives into liquid lubricating oils. Therefore, the improvement of the antifriction properties of F-4 fluoroplastic upon

introduction of fullerene black opens up prospects for improvement of tribological properties of other polymeric materials (polyamides, polyimides, epoxy resins, other fluoroplastics, etc.) that are used in friction units [1], but do not possess such good antifriction properties as F-4.

CONCLUSIONS

(1) Introduction of 1 wt % fullerene black (after extraction of light fullerenes from the black with toluene) into the highly antifriction material F-4 leads to an additional decrease in the dry sliding friction coefficient of F-4 over steel by 25–35% at contact pressures in the range 0.2–2.0 MPa. The antiwear properties of F-4 are also noticeably improved upon introduction of fullerene black. Introduction of fullerene black can be recommended for F-4 working as an antifriction material in dry sliding friction units.

(2) The dependences of the energy-related wear intensity on the contact pressure, $I_W(P_N)$ have a flat region within which the wear mechanism is invariable in the corresponding pressure range. Introduction of fullerene black extends the flat region of $I_W(P_N)$ and shifts it to higher pressures, i.e., the load-bearing capacity of the friction unit is raised.

(3) The improvement of the antifriction properties of F-4 fluoroplastic upon introduction of fullerene blacks opens up prospects for enhancement of the antifriction properties of other polymeric materials used in friction units.

ACKNOWLEDGMENTS

The study was carried out in the framework of scientific program no. 14 (coordinator Acad. I.G. Goryacheva) of basic research of the Division of Power Engineering, Machine Building, Mechanics, and Control Processes, Russian Academy of Sciences. It was supported by the International Science and Technology Center (project T-1145).

Abstract—The efficiency of aluminum oxide nanoparticles as a sorbent for removing residual formaldehyde from urea–formaldehyde resin was studied.

DOI: 10.1134/S1070427206090254

Urea–formaldehyde resins (UFRs) are large-tonnage commercial products widely used in production of wood chipboards (WCs), amino- and foam plastics, decorative paper-laminated plastics, synthetic veneer sheet, and moisture-resistant paper, and also in textile industry. However, application of these materials for interior finish and furniture production is restricted by strong liberation of toxic formaldehyde in the course of service of these articles [1]. To decrease the free formaldehyde content, sorbents are introduced into the resin. These sorbents should strongly chemisorb formaldehyde and should be compatible with urea–formaldehyde resins.

Introduction of finely divided silica into UF adhesive substantially decreases the formaldehyde release into the environment [2]. For this purpose, silica sol prepared by acid treatment of "liquid glass" (technical-grade sodium metasilicate) was used. Silica particles strongly sorb up to 15 wt % of formaldehyde released in curing of UF adhesive, and formaldehyde liberation in the course of the use of the resins does not exceed the maximum permissible concentration (MPC). A decrease in MPC of formaldehyde in production and domestic premises make the requirements for UFR materials more stringent. The UFR production process should solve this problem.

Sorbents used for this purpose should rapidly and irreversibly sorb formaldehyde even when the system contains no strong acids, bases or oxidizing agents capable of decomposing the resin structure [3]. In this connection, silica is not optimal sorbent since its surface silanol groups are strongly acidic (pK 2) [4]. Hence, introduction of silica particles with strongly acidic surface can result in premature curing of the resin or its structural degradation.

Since aluminol groups of alumina are moderately strong acids and bases and have no destructive effect on the resin, alumina is a more promising sorbent for residual formaldehyde. Previously we found [5] that alumina sol irreversibly sorbs formaldehyde owing to formation of strong bonds with it. In addition, alumina sol is well compatible with UFR. Formaldehyde is incompletely desorbed form the sol under rigorous conditions. The product of reaction of alumina and formaldehyde, treated in a vacuum (3×10^{-3} Pa) at 220°C, contains approximately 20% organic component.

In this study we examined the influence of alumina nanoparticles used as sorbent of free formaldehyde on the properties of UFR.

An aqueous formaldehyde solution used in production of UFR contains an equilibrium mixture on monomeric formaldehyde and polyoxymethylene glycols $HO(CH_2O)_nH$ [6]. These compounds readily interact with the OH groups of finely divided particles of alumina sol [7], thus providing good compatibility of the polymeric UFR matrix and alumina nanoparticles. Since the carbonyl group of formaldehyde is highly nucleophilic, formaldehyde readily enters into addition reactions. The monomer polymerizes in the presence of almost all base catalysts. Adsorption of formaldehyde on the surface of alumina particles involves acid–base interaction of the surface OH groups with formaldehyde oligomers on the pseudoliquid interface to form strong bonds [8]. Formation of the organic film at the interface decreases the interface

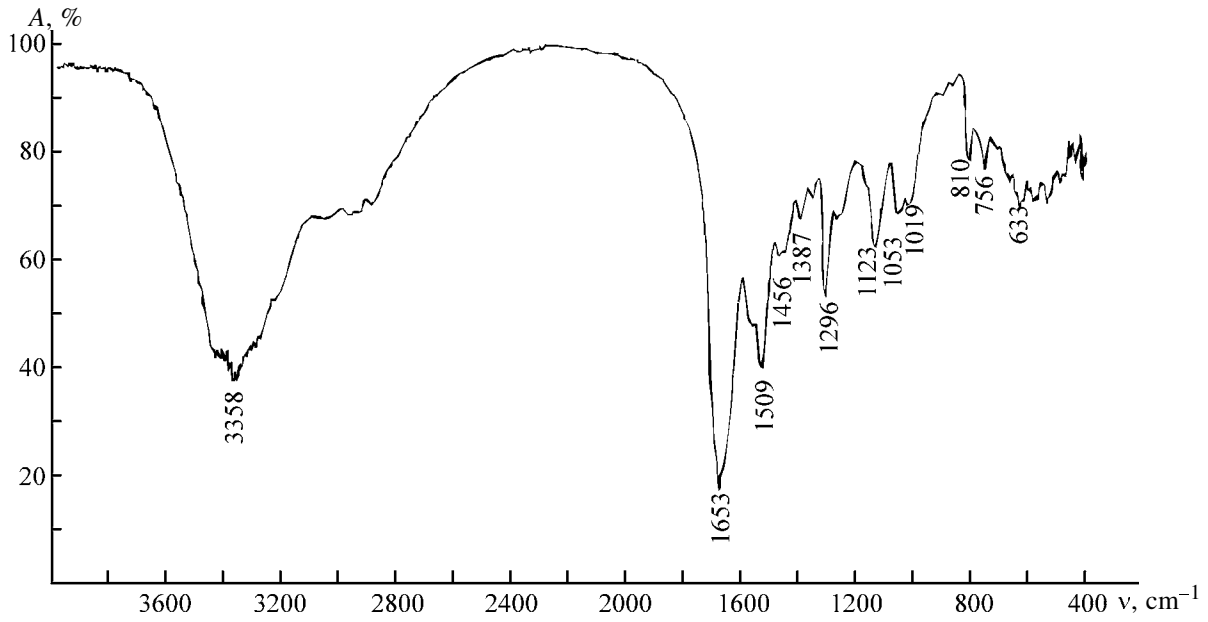

Fig. 1. IR Fourier spectrum of UFR containing alumina particles. (*A*) Transmission and (ν) wavenumber.

surface energy at the liquid-solid boundary, and the loose fractal structure of alumina sol [9] favors absorption of formaldehyde oligomers in the bulk of the sorbent to form interpenetrating polymer networks. It should be noted that materials in which the organic component forms a cross-linked structure in the primary network structure of the inorganic component or vice versa or in which both components form interpenetrating network structure with covalent or ionic bonds are of great interest [10].

Several compounds can be formed in the urea–formaldehyde system. The content of these compounds is determined by the process parameters. Complex structure of UFR is caused by high functionality of urea (4) and formaldehyde (2), which favors formation of diverse condensation products [11]. Polycondensation of urea and formaldehyde in moderately basic solutions yields methylol urea derivatives (mono- and dimethylolurea) which polymerize in neutral or weakly acidic solutions to form cross-linked polymers. The presence of alumina particles with the above properties should promote formation of these polymers.

Sorption of formaldehyde on the nanoparticle surface is accompanied by hydrophobic–hydrophilic effects caused by interactions between the surface and formaldehyde oligomers. The stability of the resulting structure is determined by the balance of these forces.

The number and the frequency of the bands in the IR spectrum of UFR are similar to those in the typical spectrum described in [12]. In the presence of alumina particles, the bands of the NH and C=O groups in the spectrum of UFR are shifted toward the long waves owing to formation of bonds between these groups and the alumina surface.

The photomicrographs of UFR containing alumina nanoparticles (ω = 5%, transmitted light, magnification 400) are shown in Fig. 2. The samples have fairly uniform microstructure; the components are uniformly distributed in the material.

The microstructure of UFR prepared in the presence of aluminum isopropoxide (Fig. 3a) substantially differs from that described above. The sample contains relatively large blocks with a highly uniform structure. We suggest that the blocks are formed owing to the presence of the alcohol which is a chain-

Fig. 2. Photomicrograph of UFR containing alumina particles.

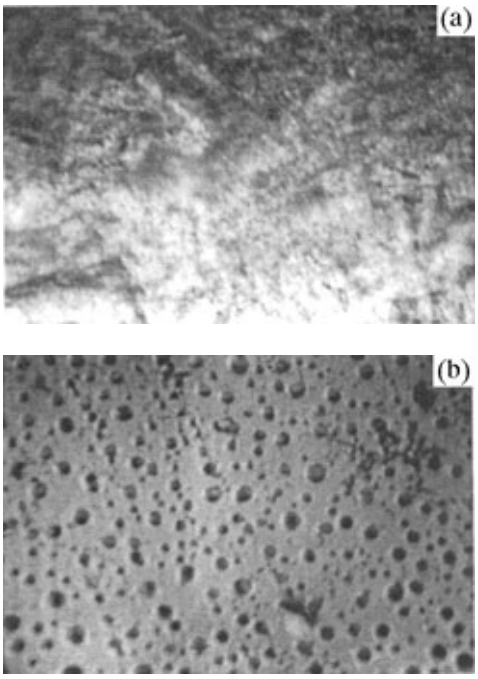

Fig. 3. Microstructure of UFR prepared using (a) aluminum isopropoxide (transmitted light, magnification 400) and (b) aluminum salt (reflected light, magnification 400), alumina content ω = 10%.

transfer agent. The other reason is hydrophobic interaction of formaldehyde oligomers and the alkoxide hydrolysis products, leading to the formation of compact microconstituents of the structure [13], which minimize the contact with the medium. These microstructures can be considered as hydrophobic areas consisting of associates of hydrophobic molecules. The presence of interface between the blocks is a disadvantage of the material.

Polymerization of UFR containing more than 8% alumina nanoparticles yields a milk-white solid. The sample is brittle and tends to exfoliate owing to the segregation of the inorganic salt in some areas. The photomicrograph of the exfoliated surface, taken by optical microscopy in the transmitted light, is shown in Fig. 3b.

The UFR samples prepared by the procedures described in the Experimental section exhibit different stability with respect to water. The weight loss in 2 days of the resin free of alumina particles and of the alumina-containing resins prepared by hydrolysis of the salt and of aluminum isopropoxide is 23, 17, and 9%, respectively. These data correlate well with the content of free formaldehyde in the samples, which is 0.01 and 1.1% in the resin containing alumina nanoparticles and free of them, respectively.

The free formaldehyde content in UFR samples modified with alumina particles is lower by two orders of magnitude than that in the reference samples and by an order of magnitude compared to the published data [14].

EXPERIMENTAL

We used 5–10-nm alumina particles prepared by chemical condensation in a solution. To modify the resin with alumina nanoparticles, a powder prepared by hydrolysis of an aluminum salt in an ammonia formaldehyde solution was introduced into the reaction mixture. The product is spontaneously dispersed in an aqueous formaldehyde solution. The weight fraction of alumina in UFR was determined by the weighed portion of the preparation.

Modified UFR was prepared from formaldehyde containing alumina nanoparticles by the procedure described in [15]. To a formaldehyde solution, ammonia was added to pH 7. Urea (1/2 of the total amount) was added at continuous stirring and heating. The remaining amount of urea was added in portions. The urea : formaldehyde molar ratio was 1 : 2. Water was distilled off, and the syrupy liquid was applied onto a plastic support. The resin was polymerized at 50°C for more than a day. The product had no formaldehyde odor. The concentration (ω) of Al_2O_3 particles in UFR samples ranged from 5 to 10%.

Modification of UFR with alumina nanoparticles using aluminum isopropoxide was performed by the following procedure. To a formaldehyde solution, an ammonia solution was added. Then aluminum isopropoxide was added dropwise. A flaky precipitate that formed in the solution disappeared on stirring, and a sol was formed. A white syrupy liquid was obtained after heating with continuous stirring. To this product, urea was added as described above. The resin was polymerized at 50°C for more than a day. The product had no formaldehyde odor. The alumina content (ω) in the samples was 0.1, 0.4, 0.8 and 1.5%. The samples are water-insoluble bluish or milk white plates in transmitted light, depending on the alumina content.

CONCLUSION

Alumina nanoparticles prepared by sol–gel procedure effectively sorb free formaldehyde in urea–formaldehyde resins, thus decreasing their toxicity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Compatibilizer Additives on the Technological and Performance Characteristics of Biodegradable Materials Based on Starch-Filled Polyethylene

O. A. Ermolovich and A. V. Makarevich

Abstract—The deformation and strength characteristics, as well as rheological properties and biodegradability of film materials prepared by hot pressing and slot extrusion methods from polyethylene–plasticized starch–compatibilizer blends were examined. Polyethylene with grafted itaconic acid served as compatibilizer. The formulation and technological parameters of preparation of biodegradable film materials were optimized to meet the technical performance criteria.

DOI: 10.1134/S1070427206090266

The need to solve the problem of contamination of the environment with industrial and domestic plastic waste (packaging and agricultural films, containers, disposables, etc.) stimulated, in particular, the development of biodegradable polymeric materials (BPMs). Waste BPM products are capable of degradation when exposed to natural factors (soil and atmospheric microorganisms, ultraviolet radiation) and water-soluble chemical reagents [1–3].

A large group of BPMs is based on biopolymers belonging to polysaccharides, as well as on their composites with synthetic thermoplastics. Polysaccharides are isolated from renewable plant (corn, potato, and rice starchs, cellulose) and animal (chitin, chitosan) raw materials [4, 5]. An important place in the BPM group of interest is occupied by composites based on starch (St) and polyethylene (PE).

Nonpolar PE is thermodynamically incompatible with polysaccharides whose macromolecules contain polar groups [6]. This is responsible for the fact that an increase in the St content deteriorates the process parameters, above all, the fluidity of PE/St melts, as well as the physicomechanical characteristics of the products thereof. At the same time, the St concentration in a blend with PE should be fairly high to make the composite biodegradable. The development of BPMs combining high biodegradability with good deformation and strength characteristics still remains an important problem in materials science and polymer composite technology.

One way to solve this problem is to use starch-filled composites of functionalized PE, with polar functional groups grafted to its macromolecules, as the polymeric binder. Today, reactive extrusion of polymers is actively introduced into industry [6]. For example, PE is chemically modified by grafting polar vinyl monomers (maleic anhydride, itaconic acid, etc.) to the PE macromolecules occurring in the viscous-flow state [7]. The macromolecules of modified PE contain carboxy groups and exhibit enhanced thermodynamic compatibility with the polar polysaccharide filler, which intensifies the interphase interactions. The mechanism of the latter is virtually not understood; this is a multifactor physicochemical process affecting the structural organization and properties of composites [8]. Chemical reactions between the carboxy groups grafted to the PE macromolecules and the hydroxy groups of St and the plasticizer [typically, glycerol (Gl)] can proceed via formation of ester and hydrogen bonds (the energy parameters of the latter are determined, in particular, by the proton-donating and proton-accepting powers, as well as by the concentration of the reacting groups).

Full replacement of PE by expensive functionalized PE in BPM like PE/plasticized starch (PSt) is economically unfavorable. In this study we suggested compatibilization of the PE/PSt blend by introducing functionalized PE as the third component of the blend (compatibilizer). Polymeric compatibilizers are reactive copolymers or chemically modified polymers

X–Z (where Z is a long-chain reactive segment or a functional group attached to the main chain) that can compatibilize the polymeric pair of X and Y provided that Z can chemically react with polymer Y [6]. This will increase the concentration of the biopolymeric filler in the composite and, hence, the biodegradability of the latter without deteriorating its physicomechanical characteristics.

In this study we established the physicochemical and technological relationships in formation of PE/PE–itaconic acid (ItA)/PSt film composites having a high biodegradability and good deformation and strength characteristics.

EXPERIMENTAL

The base for hot-pressed film BPMs was 16 803–070 brand powdered LDPE; the compatibilizer was functionalized PE with grafted itaconic acid [TU RB (Technical Specifications of Belarus Republic) 03 535 279.015–97]; and the biodegradable filler was native corn St [GOST (State Standard) 7697–82)].

Starch was dried at 110°C for 5 h and introduced into PE in concentrations from 5 to 50 wt %. Technological, in particular, rheological, characteristics of mixed PE/St melts were poorer than those of PE melts, evidently, because of a large grain size of St and its low compatibility with PE. The workability of the compositions was improved by plasticization with glycerol. The choice of Gl as plasticizer was dictated by its high plasticizing power with respect to St and a satisfactory plasticizing power with respect to PE, as well as nontoxicity and a fairly high thermal stability [9]. The Gl concentration in the compositions was constant, 10 wt %. The polymer blends were prepared in two stages: (1) mixing St with the plasticizer to obtain a homogeneous mass and (2) mixing PSt with LDPE and PE with grafted ItA (PE–ItA). The film samples were prepared by hot pressing on a hydraulic press with heated plates (pressing temperature 180 ± 5°C, pressure 10–15 MPa) or by reactive extrusion on a Haake Rheocord 90 single-screw extruder equipped with a sheet die (temperature range over the cylinder zones and on the sheet die of the extruder 160–180°C).

The deformation and strength parameters of the BPMs were determined according to GOST 14 236–81 on an Instron (the United States) tensile-testing machine at a sample extension rate of 5 mm min^{-1} at 25°C. Before testing, the samples were kept for 24 h in a desiccator over silica gel.

The melt flow index (MFI) was measured on an IIRT-AM (GOST 11 645–73) extrusion plastometer at a load of 5 kg at 190°C. After drying, the granules of the compositions were charged into the heated cylinder of the setup and kept for 4 min before application of the load. The melt flow index was determined by the formula

$$\mathrm{MFI} = m600/\tau,$$

where m is the weight of the melt that flows out from the cylinder within time τ, s.

The MATIR IR spectra of the composite BPMs and their components were recorded on a Nicolet 5700 IR Fourier spectrophotometer. The components were analyzed as granules (PE, PE–ItA), powder (St), or liquid (Gl), and the composites, as films formed by hot pressing.

The microstructure of the samples was examined by scanning electron microscopy (a CamScan-4 microscope).

Biodegradation of the composite film BPMs was examined by microbiological testing. Strains of *Aspergillus (A.) niger, Penicillium (P.) funiculosum, Trichoderma viride, Azotobacter sp., Bacillus megatherium, Bacillus brevis*, and *Pseudomonas sp.* microorganisms, available from the collection of the St. Petersburg Pharmaceutical Institute, served as test cultures. These microorganisms were recommended by GOST 9.049–91 for testing the bioresistance of polymeric materials. The microbial strains were cultivated for tests on a Czapek agar [10].

First, we identified the most active degrader microorganisms for BPMs. The film samples examined were most rapidly fouled with mycelium of *A. niger* and *P. funiculosum* microscopic fungi. In subsequent experiments we used *A. niger* culture. According to GOST 9.049–91, *A. niger* was cultivated for 28 days in Petri dishes with BPM placed in them on an agar lawn. We recorded the broadening in time of the zone covered with mycelium of *A. Niger* formed over the sample perimeter.

Figure 1a presents the ultimate tensile strength σ and the relative elongation at break ε of the films pressed from PE/PSt binary polymeric blends vs. the filler concentration c. It is seen that the parameters σ and ε of the film samples monotonically decrease with increasing c. This trend is due, evidently, to an increase in their imperfection. Apparently, extension causes the composite samples to fail at the interface of poorly compatible binder and filler phases, and the

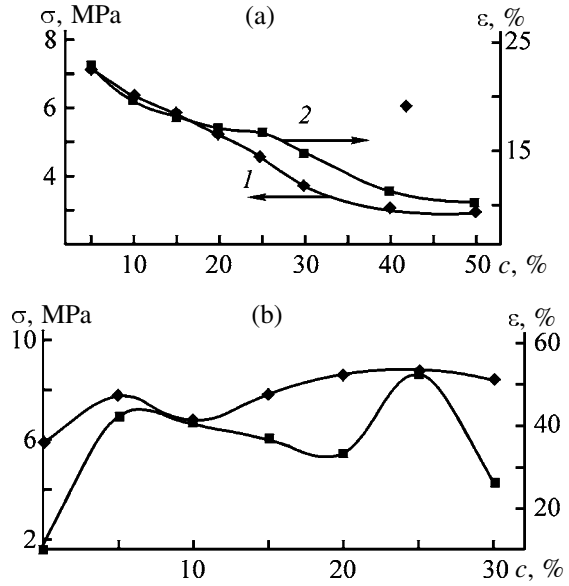

Fig. 1. (*1*) Ultimate tensile strength σ and (*2*) relative elongation at break ε of (a) PE/PSt film samples vs. St concentration *c* and (b) PE/PE–ItA/25 wt % St film samples vs. PE–ItA concentration *c*. (a) Glycerol content in the samples 10 wt %.

surface area of the interfaces increases with increasing St concentration.

To estimate the deformation and strength characteristics of the films pressed from the PE/PE–ItA/PSt ternary blends as influenced by the compatibilizer concentration, the content of St in them was fixed at 25 wt %, ensuring high degradability of the materials. We examined the deformation and strength characteristics σ, ε of the films in relation to the PE–ItA concentration (Fig. 1b). It is seen that, with increasing content of the compatibilizer, the ultimate tensile strength of the films passes through a flat maximum corresponding to c = 20–30 wt %. This is, evidently, due to formation at the PSt–binder interfaces of a new phase involving PE–ItA. An increase in c to 20 wt % is accompanied by a directly proportional increase in σ owing to strengthening of the interfaces. At c = 20–30 wt %, the strength of the films is virtually constant, since further increase in the number of the bonds between PSt and LDPE does not lead to strengthening of the interfaces. At c > 30 wt %, the strength begins to decrease by exponent. This is due to an increase in the content of the PE–ItA component in the composition, less strong than LDPE. Because of enhanced barrier properties of the compatibilizer, this adversely affects the biodegradability of the materials.

The maxima in the plot of the elasticity of the films are also due to formation of a new phase between the PSt particles and the binder. Increase in the elasticity up to concentrations c of 8–9 wt % is due to strengthening of the interfaces, which is responsible for ever more active participation of the binder in deformation of the samples. At c = 8 wt %, the strength reserve of LDPE is exhausted, and rigid binder–filler interfaces are involved into film deformation, thereby decreasing ε. At 20 < c < 25 %, ε tends to increase, since a new factor, increase in the content of the LDPE + PE–ItA polymeric phase at a fixed PSt concentration of 25 wt %, begins to operate. A subsequent (c > 25 wt %) decrease in the elasticity of the films is due to the fact that the properties of the composition are dominated by those of the PE–ItA compatibilizer.

Thus, 25 wt % can be considered as the optimal concentration of PE–ItA in the compositions examined, ensuring satisfactory deformation and strength properties of the hot-pressed BPM films.

In the subsequent series of experiments we compared the σ and ε parameters of the film samples in which PE–ItA was absent (Fig. 1) or present in a constant concentration (25 wt %) (see table), and the St content increased at the expense of a decrease in the PE concentration. Comparison of the data in Fig. 1 and in the table suggests that, at a constant St concentration, the compatibilized composites surpass noncompatibilized samples in the mechanical strength and elasticity. Thus, increase in the PE–ItA concentration in the PE/PSt blends to a certain level allows the degree of filling of the composites with the biodegradable filler to be increased without substantially deteriorating their strength.

Poorer deformation and strength parameters of the composites prepared by pressing compared to those prepared by extrusion can be attributed to imperfection of their structure. This is due, above all, to aggregation of the polysaccharide filler particles and nonuniform distribution of the aggregates over the polymeric pressed matrix. By contrast, the structure of the samples prepared by extrusion is distinguished by high uniformity, with the binder macromolecules oriented in the extrusion direction, as suggested by the electron-microscopic data. Evidently, this is specifically responsible for a high tensile strength and elasticity of the films prepared by extrusion.

The technological properties of the compositions were estimated from the MFI. In the absence of compatibilizer, the MFI of the PE/PSt blends with a high filler (starch) content was 0.15–0.22 g $(10\ \text{min})^{-1}$, which is markedly lower than that of melts of commercial thermoplastics (for various LPDE brands

* Samples prepared by (A) hot pressing and (B) extrusion.

prepared by extrusion, this parameter varies within 0.3–2 g (10 min)$^{-1}$ [11]). The dependence of MFI *y*, g (10 min)$^{-1}$, on the St concentration *x*, %, for binary PE/PSt blends is satisfactorily described by the linear correlation (r = 0.86)

$$y = 22.23 - 0.54x.$$

The compatibilized PE/PE–ItA/PSt compositions are characterized by appreciably higher MFI parameters that noncompatibilized samples (see table). An increase in the St content in the former at the PE–ItA concentration fixed at 25 wt % causes the MFI of the composite melts to decrease, though to a technologically acceptable level.

Thus, the experimental data we obtained suggest that the ternary PE/PE–ItA/PSt blends differ favorably from the binary PE/PSt blends in the MFI and the deformation and strength characteristics of films thereof. The reason is, evidently, the favorable effect of the compatibilizer on the compatibility of the blend components and structure of the composite films. At the PE–ItA concentrations of 25 wt % in the PE/PE–ItA/PSt blends, the composites exhibit the highest MFI and the best deformation and strength characteristics over a wide range of the St concentration. This makes the blends with optimized formulation suitable for extrusion processing into film BPMs.

We assumed that improvement of the parameters of interest for the PE/PE–ItA/PSt composites relative to PE/PSt samples is due to the fact that, in the presence of the compatibilizer, the interphase interactions are intensified via involvement of the polar groups of the PE–ItA and St molecules. The diphilic PE–ItA molecules in the compositions are, evidently, localized at the PE/PSt interface with their polar groups oriented toward the filler surface. The oxygen-containing groups in the PE–ItA molecules are able of both physicochemical and chemical interaction with the functional groups in St and Gl. These assumptions were confirmed by an IR study of the molecular structure of the composites.

Extensive interpretation of the vibrational spectra of the composites of interest and their components was beyond the scope of this study. We analyzed selected spectral ranges in which the expected chemical reactions of the components could be manifested.

We compared the IR spectra of PSt, PE, and PE–ItA samples, as well as of the binary PE/PSt and PE–ItA/PSt and ternary PE/PE–ItA/PSt blends (Fig. 2). The spectra essentially differ in the frequency range 1600–1800 cm^{-1} (Fig. 2a), where the characteristic absorption bands of the carbonyl groups (in particular, in carboxylic acids, esters) are usually manifested, and also in the 1000–1300 cm^{-1} range (Fig. 2b), where the bands of the stretching vibrations of the C–O–C bond in ethers and esters can appear [12].

The spectrum of PE–ItA (Fig. 2a, curve *4*) contains the absorption band ν(C=O) at 1743 cm^{-1}, apparently belonging to the stretching vibrations of the carboxy groups of itaconic acid grafted to the PE macromolecules. The carboxy groups are, evidently, hydrogen-bonded, as suggested by the shift of their ν(C=O) band to lower frequencies [13]. In the spectrum of the initial PE (Fig. 3a, curve *2*), the ν(C=O) band belonging to the oxidized form of the polymer [14] is weakly manifested. The vibrational spectrum of PSt (Fig. 2a, curve *1*) contains no characteristic absorption bands in the range of interest. At the same time, the IR spectrum of the binary PE–ItA/PSt blend (Fig. 2a, curve *5*) contains, along with the absorption band with

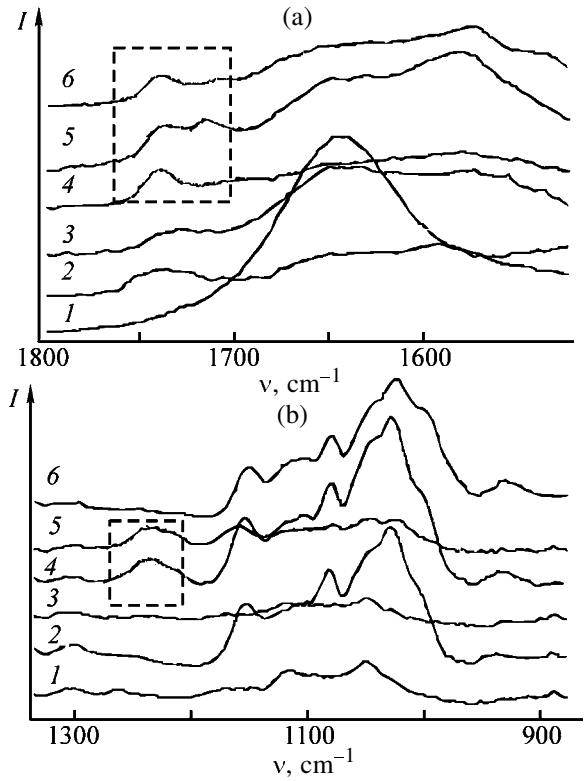

Fig. 2. IR spectra of the compositions and their components in various frequency ranges. (*I*) Intensity and (ν) wavenumber. (a) 1500–1880 cm^{-1}: (*1*) PSt, (*2*) PE, (*3*) PE/PSt, (*4*) PE–ItA, (*5*) PE–ItA/PSt, and (*6*) PE/PE–ItA/PSt; (b) 900–1300 cm^{-1}: (*1*) PE, (*2*) PE/PSt, (*3*) PE–ItA, (*4*) PE–ItA/PSt, (*5*) PE–ItA/Gl, and (*6*) PE/PE–ItA/PSt.

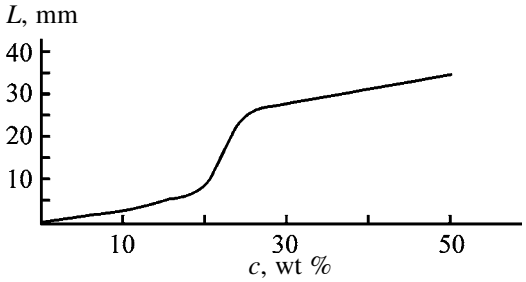

Fig. 3. Width *L*, mm, of the zone of fouling of the PE/PSt film samples with *A. niger* mycelium vs. the St concentration *c* after 7 days of cultivation.

a maximum at 1740 cm^{-1}, a new band at 1720 cm^{-1}. The latter band, probably, corresponds to ν(C=O) of the ester groups formed by the chemical reaction of PE–ItA and PSt. This reaction, most likely, involves the carboxy groups of PE–ItA and hydroxy groups of Gl, as well as of St. The ν(C=O) band of the carboxy groups of PE–ItA participating in esterification does not disappear completely, but decreases in intensity. Hence, despite excess of the esterification agent (PSt), esterification proceeds only partially. The fact that the carboxy groups of the PE-grafted itaconic acid are chemically bound to the hydroxy groups of Gl and St is confirmed by the appearance in the spectra of PE–ItA/PSt and PE–ItA/Gl blends (Fig. 2b, curves *4* and *5*) of the absorption band corresponding to the stretching vibrations ν(C–O–C) of the ester groups at 1230 cm^{-1}. The spectra of the PE/PE–ItA/PSt ternary blend (Figs. 2a, 2b, curves *6*) contain both (though less pronounced) characteristic absorption bands of ester groups [ν(C=O) at 1720 cm^{-1} and ν(C–O–C) at 1230 cm^{-1}]. Thus, the IR data suggest chemical bonding of the polysaccharide filler and compatibilizer in the composites examined. IR monitoring of the possible compatibilization by hydrogen bonding of the molecules of the components of the compatibilized blends [15] proved to be a complicated task because of overlap of the characteristic bands of the hydroxy groups in these molecules. Hydrogen bonding is suggested by a low-frequency shift of the bands corresponding to the stretching vibrations of the carboxy groups of the PE–ItA molecules and the ester groups formed at the PE–ItA/PSt interface.

The microbiological experiments revealed a rapid (manifested even on the third day) growth of the *A. niger* mycelium over the surface of starch-flled PE films. By contrast, no fouling was observed for the PE samples. The results obtained on the seventh day (Fig. 3) suggest correlation between the *A. niger* growth intensity and the St concentration in the PE/PSt film samples. Introduction of the compatibilizer into the PE/PSt compositions insignificantly accelerated biodegradation of the film samples thereof.

It can be assumed that degradation of the starch-filled composite films by *A. niger* soil fungus is due to the mechanical impact by the proliferating mycelium, as well as to the chemical impact of the microbial metabolites on the polymeric components of the films. The metabolites are secreted by the growing fungus and promote degradation of the macromolecules. With time going, the material becomes an ever more accessible feed source for the microorganisms.

CONCLUSIONS

(1) Filling of polyethylene with starch, a biodegradable polysaccharide agent, sharply decreases the fluidity of the polymer melt, whose viscosity grows with increasing concentration of starch in the polyethylene–starch blend. Introduction into this blend of a compatibilizer, polyethylene with grafted itaconic acid, causes the fluidity of the composite melt to increase to technologically acceptable levels. This

allows easy processing of the polyethylene/polyethylene with grafted itaconic acid/plasticized starch compositions into films on standard extrusion equipment. Also, the physicomechanical characteristics of the biodegradable film polymeric materials prepared from the compatibilized compositions are significantly improved.

(2) Satisfactory technological parameters (melt uniformity and fluidity) of the polyethylene/polyethylene with grafted itaconic acid/plasticized starch compositions with the optimized formulation (St 20–25 wt %, PE–ItA 25 wt %), as well as high performance characteristics (tensile strength, elasticity, and biodegradability) of the films thereof make these compositions suitable as the basis for preparation of biodegradable film polymeric materials and other biodegradable items intended for short-term application.

(3) Examination of the structure of the compositions showed that better technological and physicomechanical parameters of the compatibilized composites examined (compared to noncompatibilized composites) are due to a better compatibility of their components, owing to more intense physicochemical interactions and arising chemical interactions at the polymer binder–compatibilizer–biodagradable filler interface.

Received April 26, 2006

Abstract—Mechanical degradation of gelatinized starch upon hydroacoustic treatment in a rotary pulse installation was studied by spectrophotometry of the iodine–starch complexes and analysis of the concentrations of the terminal reducing groups. The energy efficiency of hydroacoustic and ultrasonic mechanical degradation was estimated.

DOI: 10.1134/S1070427206090278

Starch is widely used in various branches of industry not only for preparing gel-like accessory (thickening, gluing, binding, finishing, etc.) materials, but also as environmentally safe precursor of new preparations. When gel-like materials are prepared from starch products, it is necessary to break down its primary structure formed by swollen starch granules, and when starch is used as a precursor for organic and enzymatic synthesis, its preliminary depolymerization (liquation) is required. These processes can be enhanced by hydroacoustic treatment (HA treatment) using rotary pulse installations (RPIs), which provides a significant decrease in the preparation time and total energy consumption and excludes chemical and enzymatic cleaving agents [1–3]. Cavitation and high shear stresses are the decisive factors enhancing the hydromechanical, physicochemical, and chemical processes upon HA treatment [4–6]. The contribution of each factor to hydroacoustic pulverization of starch hydrogel granules was studied in [6]. However, chemical effects of HA treatment such as degradation of starch macromolecules were not taken into account in that study.

In this study we examined some relationships of mechanical degradation of gelatinized starch treated in a rotary pulse installation and the possibility of predicting the process, taking into account the imparted mechanical energy.

EXPERIMENTAL

Experiments were performed with corn starch [GOST (State Standard) 7697–82]. The starch hydrogels for subsequent mechanical treatment were prepared by heating a starch suspension on a water bath at 90°C for 15 min.

The starch hydrogels were treated on a laboratory RPI whose working chamber is formed by a stator and a rotor, both equipped with special units. The gap between the rotating and stationary elements of the working chamber at a given rotation rate determines the tangential stresses in the treated liquid-phase material. The rotation rate was varied in the 1000–5000 rpm range, which corresponds to the shear rate gradient of $(0.5–17.4) \times 10^4$ s^{-1}.

The starch hydrogels were exposed to ultrasonic treatment in a UZDN-2T disintegrator (22 kHz). The volume density of the acoustic energy determined by the calorimetric procedure was 1.34 W cm^{-3}.

The content of the water-soluble fraction A (%) in the starch was determined by hot extraction; the extract composition was analyzed spectrophotometrically using complexation with iodine. The optical densities of the solutions were measured on a Spekol-221 spectrophotometer (λ 400 nm).

The viscosity of the initial and mechanically treated starch hydrogels was measured with a VPZh-2 capillary viscometer at 80°C in accordance with GOST 33–66.

Study of the mechanical degradation of the gelatinized starch is complicated by the fraction and phase heterogeneity of the starch hydrogels, by the presence of various impurities [7, 8], and by impossibility of monitoring the process using common viscometric procedures. The latter problem is due to the fact that the mechanical treatment provides degradation of the

initial hydrogel, which decreases its viscosity. In this study, the degradation of starch hydrogels upon HA treatment in RPI was studied by two complementary methods: spectrophotometry of the iodine–starch complexes and analysis of the concentrations of the terminal reducing groups.

It is known that corn starch consists of amylopectin (75%) and linear amylose (25%). The iodine complexes of corn starch amylose and amylopectin are characterized by the absorption bands at 620 and 540 nm, respectively. Superposition of these two spectra gives the spectrum with a peak at 590 nm, which corresponds to the product of interaction between iodine and starch. Degradation of starch fractions shifts λ_{max} toward higher frequencies [9]. The degree of degradation in the mechanically treated starch was evaluated using the experimental calibration curve $\lambda_{max} = f(P)$ obtained in [9] and plotted in Fig. 1. The absorption spectra of the iodine–starch complexes of (*1*) initial hydrogel and (*2*) hydrogel treated in RPI for 60 s at a shear rate gradient of 1.1×10^5 s^{-1} are shown in Fig. 2. As seen, the mechanical treatment of the starch hydrogels affects the spectra of their iodine complexes; we observed a decrease and a hypsochromic shift of the absorption maxima and an increase in the absorption in the 520–550 nm range.

Changes in the absorption spectra of iodine–starch complexes reflect changes caused by the mechanical treatment in the amylose and amylopectin starch fractions. The most informative are the spectra of the iodine complexes of the water-soluble fraction prepared by hot extraction of the initial and acoustically treated starch hydrogels. The water-soluble fraction involves predominantly the macromolecules of amylose (most soluble starch fraction), which is confirmed by the absorption maximum at λ_{max} 614–618 nm. The degree of polymerization of corn starch amylose reaches 900–1000. It is known that the mechanical degradation of any polymer is a nonrandom process. It is believed [10] that, in the course of mechanical degradation, the longest macromolecules are broken first, predominantly in their middle. Hence, mechanical degradation of a linear amylose molecule can cause only an insignificant hypsochromic shift of the absorption maximum in the spectra of the iodine–amylose complex. An increase in the absorption in the short-wave range suggests accumulation of short amylose chains formed by elimination of side L- and S-chains of amylopectin. These side chains are the amylose fragments with the degree of polymerization less than 50 [10], and their complexes with iodine exhibit

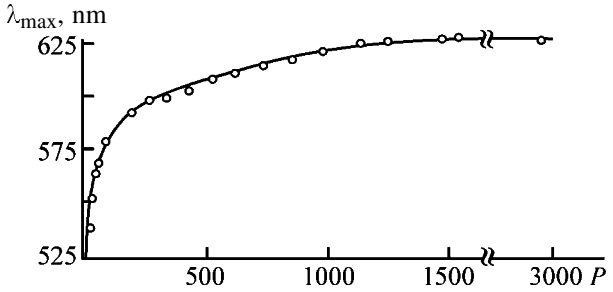

Fig. 1. λ_{max} in the absorption spectra of the iodine–amylose complexes as a function of the degree of amylose polymerization *P*.

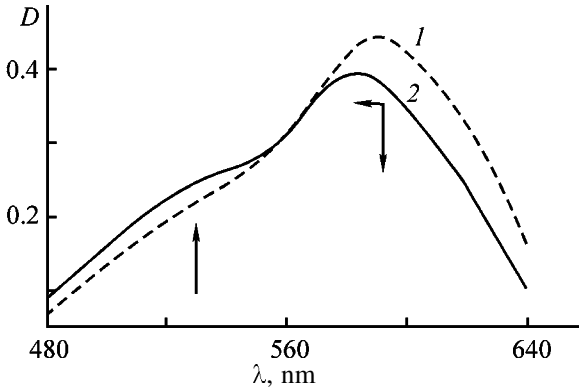

Fig. 2. Absorption spectra of starch hydrogels: (*1*) initial and (*2*) hydroacoustically treated in RPI (γ 1.1×10^5 s^{-1}, *t* 60 s). (*D*) Optical density and (λ) wavelength.

the absorption spectra with $\lambda_{max} < 550$ nm (Fig. 1). The ratio of the optical densities D_{530}/D_{max} can be used for quantitative evaluation of the degree of mechanically induced debranching of amylopectin.

The hypsochromic shifts of the absorption maximum λ_{max} and D_{530}/D_{max} ratios in the absorption spectra of iodine–amylose complexes (water-soluble fraction), and also the concentrations of the terminal reducing groups and viscosities of the treated hydrogels, in relation to the time of mechanical treatment in RPI of 3 and 8% starch solutions, are listed in the table. As seen, the content of the reducing groups in the treated hydrogels first increases due to the breakdown of macromolecules across the glycoside bonds and then decreases with increasing treatment time. This is probably due to the mechanically activated oxidation of the forming terminal aldehyde groups. In accordance with the experimental data, even in first seconds of the mechanical treatment, the absorption maximum λ_{max} shifts from 617 to 602 nm ($\Delta\lambda_{max}$ 15 nm) in the spectra of the iodine–amylose complexes, which corresponds to a decrease in the degree of amylose polymerization from 890 to 430. No changes in the absorption spectra were observed upon

longer mechanical treatment (up to certain level), which suggests attainment of the degradation limit.

It should be noted that hydrogels of different concentrations show essentially different changes in the characteristics with time. For example, at a lower hydrogel concentration (3 wt %), λ_{max} (after initial decrease and attainment of a certain plateau) again slightly decreases with increasing treatment time. The optical density of 3% hydrogels, after the initial decrease at the start of the treatment due to the breakdown of starch grains, then increases again with increasing treatment time. As shown in [12], this behavior is probably associated with the phase transformations in the hydrogel caused to the shear stresses. Most probably, short chains act as nucleating centers of the solid phase [13].

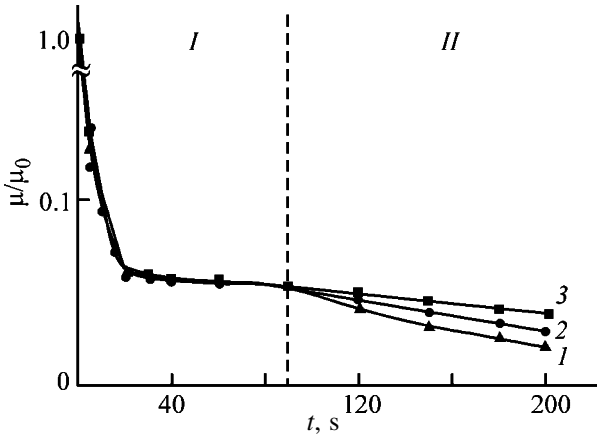

Fig. 3. Relative viscosity μ/μ_0 of the starch hydrogel (9 wt %) as a function of treatment time t in RPI. Temperature, °C: (*1*) 70, (*2*) 40, and (*3*) 20. Steps: (*I*) mechanical degradation and (*II*) activated hydrolysis.

Phase transitions (appearance of turbidity) lead to a decrease in the content of the short chains in the amylose fraction recovered by hot extraction; as a result, the absorption maximum in the spectra of the iodine–amylose complexes again shifts to the long-wave region. For hydrogels with a higher starch content (c > 7 wt %), showing weaker tendency to phase transitions, $\Delta\lambda_{max}$ monotonically decreases with increasing treatment time.

The dependences of the viscosity of 9% starch hydrogel on the time of mechanical treatment, recorded at three different temperatures, are shown in Fig. 3. As seen, even in the first seconds of mechanical treat-

ment, the hydrogel viscosity sharply decreases; then, after reaching a certain value, it remains constant for some time, and in this period all the curves recorded at various temperatures of mechanical treatment coincide. With a further increase in the treatment time, the hydrogel viscosities decrease at a rate growing with an increase in the temperature. This experimental fact can be accounted for as follows. Small amounts of hydrogen peroxide formed by cavitation of aqueous solutions of organic compounds in air can oxidize these organic compounds. As a result, carboxy groups are accumulated in the system owing to mechanically activated oxidation of starch and organic impurities. For example, no increase in the amount of carboxy groups was observed upon mechanical treatment for 4–30 s, whereas after treatment for 60 s the content of the carboxy groups increased from 0.07 (initial starch) to 0.15% (treated hydrogel). Under the cavitation conditions, even insignificant amounts of carboxy groups catalyze hydrolytic degradation of starch. Cavitation causes formation of the starch macroradicals which, in contrast to valence-saturated macromolecules, are hydrolyzed even at pH 6.5 [14]. Hence, our experimental data allow us to distinguish two steps of degradation of the gelatinized starch exposed to HA treatment in the presence of air. The time periods corresponding to different steps of the degradation are shown in Fig. 3.

The first step (Fig. 3, *I*) is the step of only mechanical promotion of the starch degradation (mechanical degradation proper), characterized by the independence of the process rate from temperature, attainment of the degradation limit, and nonrandom degradation course.

The occurrence of nonrandom degradation, i.e., predominant breakdown of the longest macromolecular chains in their middle, is confirmed by the constant width of the absorption bands in the spectra of the iodine–amylose complexes, because in the case of random degradation the width of the spectral band should increase due to the random distribution of the chain length.

The second step (Fig. 3, *II*) is the step of mechanically activated hydrolysis, whose characteristics are the positive temperature coefficient, random character of the process, absence of the degradation limit, and dependence on pH of the medium.

The dependence on pH of the medium apparently explains the separation of the steps in time, because accumulation of some minimal amount of the carboxy groups and attainment of the required pH require certain time (pH of the initial hydrogel 7.5). This step may be autocatalytic.

As shown previously, in the course of single-cycle treatment in RPI, the gelatinized starch was exposed to only short HA treatment for a period shorter than 1 s. Therefore, the first mechanically activated step of degradation is of particular importance from the practical viewpoint. We consider it proved that the degradation at the beginning of treatment of the starch hydrogel with concentrations of 5–9% proceeds through mechanical activation, e.g., it proceeds predominantly due to cavitation (acoustic component) and shear stresses. It was of interest to reveal the decisive factor at various concentration of starch in the hydrogels. For this purpose, the process was performed simultaneously in the RPI working chamber and in the ultrasonic disintegrator.

Mathematical treatment of the absorption spectra of iodine–amylose complexes using the experimental dependences of λ_{max} and extinction coefficients on the degree of amylose polymerization [9] allowed us to evaluate changes in the degree of polymerization of amylose chains and to calculate the number of breaks of macromolecular chains in starch hydrogels of various concentrations caused by HA treatment in the RPI working chamber.

At low starch concentrations (1–3 wt %), the mechanoacoustic yields calculated as the ratio of the number of breaks to the amount of the absorbed acoustic energy using Eq. (1) was 0.03–0.05 breaks per 100 eV:

$$G = \frac{c(P^{-1} - P_0^{-1}) \times 100 N_A}{W_{ac} t}, \quad (1)$$

where c is the starch concentration in the hydrogel (wt %), P and P_0 are the initial and final degrees of the starch polymerization, N_A is the Avogadro number, W_{ac} is the acoustic capacity (W), and t is the time of the mechanical treatment (s).

Approximately the same mechanoacoustic yields were obtained at ultrasonic treatment of these hydrogels in the UZDN-2T ultrasonic disintegrator. This result suggests that, at small starch concentrations, the ultrasonic cavitation is the major factor causing the degradation of starch macromolecules. At HA treatment of hydrogels with the starch concentration exceeding some critical limit (4 wt %), at which the fluctuation physical network can appear in the starch, the yields calculated only from the amount of the absorbed ultrasonic energy increase proportionally to the hydrogel viscosity, which sharply grows with an

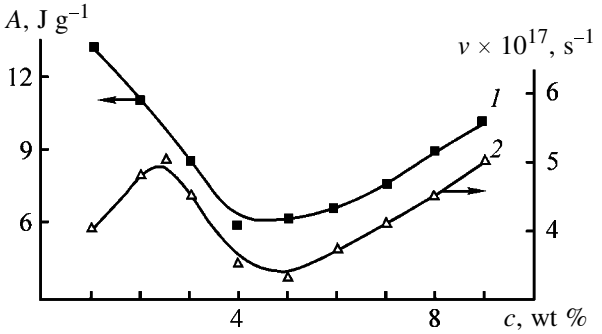

Fig. 4. (*1*) *g* Factor *A* and (*2*) rate of mechanical degradation *v* as functions of the starch concentration *c* in hydrogels upon HA treatment in RPI (γ 1.1×10^5 s^{-1}, *t* 4 s).

increase in their concentration. This fact suggests that, with increasing viscosity of starch hydrogels, the contribution of the shear stresses to the degradation increases.

To predict the process of mechanical degradation of gelatinized starch upon hydroacoustic treatment, it is necessary to evaluate the dependences of the degradation rate on the amount of the absorbed mechanical energy. Taking into account the strong dependence of this process on the starch concentration in hydrogels, we used the volume density of the total mechanical energy divided by starch concentration as the energy parameter of the HA treatment (*g* factor):

$$g = E_m t/Vc, \quad (2)$$

where E_m is the mechanical energy (J) and *V* is the volume of the RPI working chamber (ml).

As seen from Eq. (2), *g* factor is the amount of the total mechanical energy per unit weight of the polymer. The values of *g* factor for hydroacoustic treatment were calculated from the total energy of ultrasonic and shear contribution using the following equation:

$$g = \frac{l}{cV}\left[W_{ac} + \frac{\pi^3 n^2 \mu R_r^2 h(R_r + R_s)}{900\delta}\right], \quad (3)$$

where *n* is the rotor rotation rate (rpm), R_r and R_s are the radii of the rotor and stator, respectively (m), δ is the radial gap (m), and μ is the dynamic viscosity (Pa s^{-1}).

The dependences of the calculated *g* factor and rate of mechanical degradation (number of breaks in macromolecules per second) on the starch concentration in hydrogels is shown in Fig. 4. As seen, these dependences show similar trends. The deviation at low starch concentrations can be accounted for as follows. Starch hydrogels are microheterogeneous systems with swollen starch grains as the dispersed phase particles. Breakdown of these swollen particles in starch hydrogels into smaller fragments probably promotes degradation processes occurring simultaneously. It is known that the efficiency of the cavitation grinding of the disperse systems decreases with decreasing concentration of dispersed phase particles, due to the effect of the probability factor [15]. As a result, there is no correlation between the number of the chain breaks and *g* factor at low concentrations of starch hydrogels. Since the final λ_{max} values of the iodine–amylose complexes are independent of the presence of radical acceptors and the degree of polymerization of amylose becomes constant after attainment of a certain degradation limit, the contribution of the radical mechanism to the initiation of degradation is insignificant.

CONCLUSIONS

(1) At short hydroacoustic treatment of starch hydrogels at concentrations exceeding the critical concentration of gelation, cavitation and shear stresses are the decisive factors of mechanical degradation.

(2) The degree of degradation initiated by hydroacoustic treatment of starch hydrogels is determined by the total mechanical energy absorbed per unit weight of the polymer.

(3) Two steps of mechanical degradation of gelatinized starch at hydroacoustic treatment in the presence of air can be distinguished: mechanical initiation and activated hydrolysis.

Abstract—The lipid composition of the waste fine fraction (dust) from rice and buckwheat production was studied.

DOI: 10.1134/S107042720609028X

Efficient utilization of vegetable wastes with exhaustive recovery of valuable components is an important problem of modern chemistry [1–9].

Rice and buckwheat husk accumulated at plants for groats production usually contains particle of size less than 2 mm (2–11 wt %) consisting of fruit shells, corns, and rice husking product (dust). The weight and chemical composition of fine fractions in the waste depends on the plant strain and on the processes and equipment used. Analysis of the fine fractions of such wastes suggests the possibility of preparing from them more valuable products: drugs [10], food additives [11], rice oil [12], phytin [13], γ-oryzanol antioxidant [14], and others [15].

This study continues our systematic research concerning the chemical composition of wastes from rice

Table 1. Composition and content of total lipids in wastes from rice (RH) and buckwheat (BH) production*

and buckwheat production [1–3, 6, 7, 13], aimed to develop an efficient scheme of their processing, and deals with the composition of the lipid fractions.

EXPERIMENTAL

Samples of rice husk (RH) and buckwheat husk (BH) were taken in 2001–2004 from corn husking plants. Samples were sieved, and the fraction with the particle size ≤1.5 mm was taken. As reference materials we used soybeans (a well studied material [16]) and oat dust from Amur oblast.

All the samples were analyzed for the content of total lipids (TLs) and fatty acids (FAs). Among TLs, we determined neutral (NLs) and polar (PLs) lipids. The weighed portion of the raw material for the TL recovery was 20 g.

The TL extraction was performed with ethanol and chloroform following the Bligh–Dyer procedure [17]. The qualitative composition of TLs was determined by uni- and two-dimensional TLC on commercial Sorbfil plates (100 × 100 mm, silica gel STKh-1A sorbent, grain size 5–17 μm, silica sol binder, aluminum support).

To separate TLs, we used the solvent system hexane–diethyl ether–formic acid, 80 : 20 : 2. The lipids were identified using reference samples and by comparing the R_f values with the published data [18, 19].

The chromatograms were developed using both specific and nonspecific (sulfuric acid in methanol) agents. Polar lipids were separated by two-dimensional micro-TLC on 5 × 5-cm Sorbfil plates in the solvent systems chloroform–acetone–methanol–formic acid–water, 100 : 40 : 20 : 20 : 3 and acetone–benzene–formic acid–water, 200 : 30 : 3 : 10.

The qualitative composition of phospholipids (PLs) in TLs was determined spectrophotometrically [20, 21].

The TL content in the examined RH and BH samples is given in Table 1. Their yield is 1.45–1.80% for RH and 0.97–2.46% for BH. The soybean sample contains 2.43% TLs. Experiments show that the TL yield depends primarily on the amount of corn particles in the waste, i.e., on the technology for removing flower films from rice and buckwheat corns.

Analysis shows that all the samples have a similar set of NLs (Table 1).

For rice waste, on the whole, the list of NLs coincides with data of [22]. However, we additionally detected unidentified lipids in RH (R_f 0.23 and 0.34)

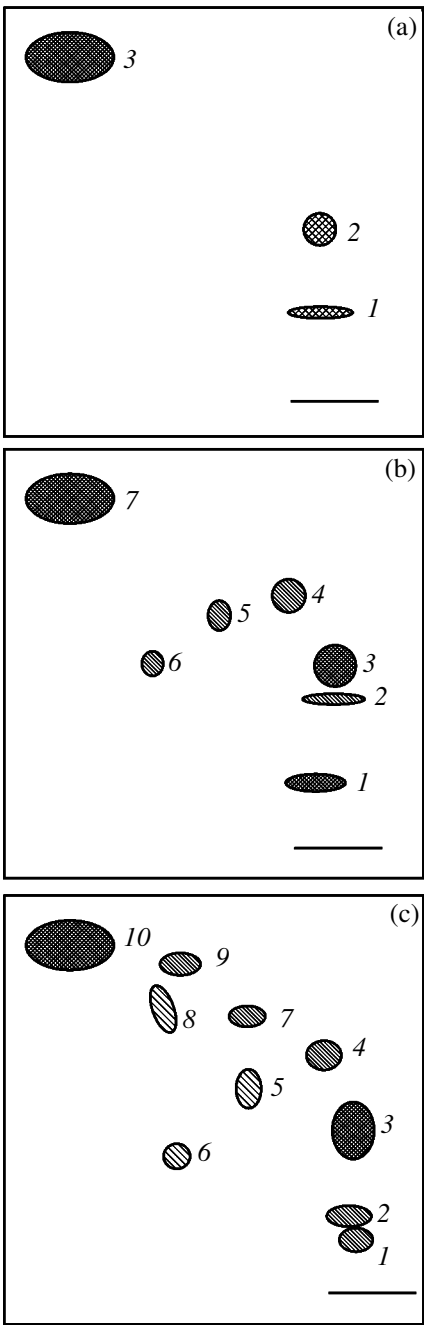

Fig. 1. Two-dimensional micro-TLC of polar lipids of (a) RH-13, (b) BH-1, and (c) soybean samples. (a) (*1*) Phosphatidyl inositol, (*2*) phosphatidyl choline, and (*3*) monogalactosyl diglycerides; (b) (*1*) phosphatidyl inositol, (*2*) phosphatidyl serine, (*3*) phosphatidyl choline, (*4*) phosphatidyl ethanolamine, (*5*) phosphatidyl glycerol, (*6*) sulfoquinovosyl diacyl glyceride, and (*7*) monogalactosyl diglycerides; (c) (*1*) phosphatidyl inositol, (*2*) phosphatidyl serine, (*3*) phosphatidyl choline, (*4*) phosphatidyl ethanolamine, (*5*) phosphatidyl glycerol, (*6*) sulfoquinovosyl diacyl glyceride, (*7*) diacylglycerotrimethylhomoserine, (*8*, *9*) unidentified lipids, and (*10*) monogalactosyl diglycerides.

Table 2. Content of phospholipids in rice and buckwheat husk samples

Sample	TL content, wt %	PL yield (based on TLs)	
		mg	wt %
RH-14	1.65	0.57	0.22
RH-13	1.80	0.37	0.12
RH-15	1.45	0.27	0.32
RH-16	1.54	0.68	0.22
BH-1	0.97	0.95	0.49
Soybeans	2.43	4.41	1.20

and in BH (R_f 0.25 and 0.23) samples. The qualitative composition of the set of neutral lipids in RH and BH is similar to that in the reference sample, soybeans. In BH-6 and BH-7 samples we found increased content of wax.

The qualitative composition of phospholipids (PLs) determined by two-dimensional micro-TLC (Figs. 1a–1c, Table 1) indicates that the rice processing waste contains two representatives of the PL group: phosphatidyl choline (PC) and phosphatidyl inositol (PI). The set of PLs in the buckwheat waste is more diverse, and the content of some components is even higher than in soybean PLs [16]. For example, soybeans contain only traces of PI, whereas in buckwheat husk its content is as high as that of PC. Thus, the buckwheat production waste can be considered as a quite real source for preparative recovery of the individual PI fraction.

In all the RH and BH samples studied, the major component is a glycolipid, monogalactosyl diacyl glyceride (MGDG). The composition of the acyl residues R_1 and R_2 was not studied. However, it is known that the length and degree of unsaturation of the chains in the acyl groups affect the chromatographic mobility of glycerides [23]. Since in TLC separation of glycolipids (GLs) and PLs MGDG forms a single spot (Figs. 1a–1c, spots *3*, *7*, and *10*, respectively), the acyl residues R_1 and R_2 in this component are presumably similar. This result can be used for preparing a homogeneous MGDG compound from rice production waste in which the set of PLs is minimal compared to BH and soybeans.

The content of phospholipids in the samples is given in Table 2.

The fatty acids (FAs) were analyzed by GLC on an Agilent 6850 Series device. Fatty acid methyl esters (FAMEs) were prepared as described in [21]. An HP-5MS capillary column was used; l = 30 m, d = 0.25 mm, stationary phase 5% phenyl methyl siloxane, carrier gas He, flow rate 25 ml min^{-1}, column temperature 220°C. Mass-spectrometric analysis of FAMEs was performed on a Hewlett–Packard device (HP 6890 GC, HP 5973 MSD).

Up to 12 fatty acids were detected in rice and buckwheat wastes (Table 3). The major components are palmitic acid (16:0) and C_{18} acids. The similar FA composition was found in bran of Japanese rice strains [24]. In contrast to RH and BH, oat dust (Table 3) is characterized by a high content of eicosenoic acid (20:1). Thus, the set of FAs in rice and buckwheat

Table 3. Content of major fatty acids

production wastes is diverse and can be of interest for preparation of lipid products with the known content of individual acids. Modern achievements in the development of new lipid products with improved biological and physicochemical properties [25] show that unsaturated FAs are responsible for the most important therapeutic and prophylactic effects.

Thus, the major lipid components of wastes from rice and buckwheat production are monogalactosyl diacyl glycerides and phospholipids, which are important biologically active substances. Since such compounds are in demand in medicine and in food and pharmaceutical industry and the cost of individual products is relatively high, it seems appropriate to recover them in the course of integrated processing of rice and buckwheat production wastes.

CONCLUSIONS

(1) The content of total lipids in rice and buckwheat production wastes was determined; it varies in the range 0.97–2.46% relative to the dry matter weight depending on the kind of plants. The compositions of polar and neutral lipid fractions and the content of phospholipids (0.12–0.49 wt % relative to total lipids) were determined.

(2) The qualitative composition of the phospholipids was studied. Rice waste contains two phospholipids (phosphatidyl choline and phosphatidyl inositol), and buckwheat waste, up to six components depending on the plant strain. All the samples are characterized by a high content of monogalactosyl diacyl glyceride.

(3) The composition and content of fatty acids in rice and buckwheat husk were studied. Twelve fatty acids were detected; the major components are palmitic acid (16:0) and C_{18} acids.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Recovery of Wool from Flax Fibers Using Nitric Acid

M. V. Shishonok and V. I. Shadrina

Belarussian State University, Minsk, Belarus

Received June 4, 2006

Abstract—The principal possibility of preparing wool from cottonized flax fibers using nitric acid both in the course of cooking and in the bleaching step was studied. The influence of the nitric acid concentration and cooking time on the extent of flax delignification was examined.

DOI: 10.1134/S1070427206090291

About 12% of cellulose is produced in the world from annual plants, including flax [1]; according to estimates [2], by 2010 this share can reach 19.8%. For Belarus and Russia, flax is a domestic raw material capable to replace imported cotton. National and international programs concerning integrated processing of flax are being realized in Germany, Finland, Denmark, Sweden, and the United States [3].

Flax contains from 60 to 90% cellulose; the lignin content varies from 2 to 5%, reaching 37% in flax boon [3, 4]. Only long flax fibers, accounting for only 1/5 of the total, are suitable for production of high-quality textiles; the remaining flax fibers are short and are either processed to obtain heat-insulating materials or burnt [5]. At the same time, short fibers are a valuable source of cellulose. Thus, recovery of cellulose from substandard flax fibers with the aim to produce useful materials (in particular, wool) is an urgent problem. Flax wool is characterized by high sorption activity, hygroscopicity, antiseptic and hemostatic properties, and good air permeability [6]; it is even more hygroscopic than cotton wool [6].

Only 1/3 of wool consumed in Russia is produced at domestic plants; the raw material is expensive cotton [7]. The demand of Belarus for wool is about 2000 t annually. The use of local resources, primarily flax, would allow partial replacement of imported cotton fibers.

Flax fiber is produced in industry by alkaline cooking followed by hypochlorite bleaching [8]. From the economical and environmental viewpoints, Ryzhkov [8] considers it appropriate to replace chlorine-containing agents by peracetic acid. Methods for production of flax wool by oxidative bleaching with complexones [9] and by reductive cooking of flax followed by peroxide bleaching in an alkaline medium [10] have been patented.

It is known [11–15] that nitric acid is an excellent delignifying agent for nonwood fibrous raw materials, such as straw of cereals, cane, or manioc. Reaction of nitric acid with lignin involves electrophilic substitution in the aromatic ring (nitrosation, nitration), electrophilic displacement, aliphatic substitution, addition, and oxidation [11]. The thus modified lignin is extracted with a dilute alkali solution. According to Nikitin [11], 3–5% HNO_3 is the most suitable for cooking of nonwood plant materials. It was shown previously [13] that the optimal HNO_3 concentration for nitric acid cooking of rye straw is 2.0%. As for flax fibers, we found no systematic data on the recovery of flax cellulose with nitric acid; only superficial information about delignification of flax with nitric acid was available [3].

This study deals with optimization of the conditions of nitric acid cooking of flax fibers with the aim to obtain wool.

EXPERIMENTAL

As starting material we used cottonized flax fibers (Groniteks State Unitary Enterprise, Grodno, Belarus). The weight fraction of boon and foreign impurities in the cottonized fiber was 1.0%, and the mean fiber length, 30.0 mm. The lignin content was 6.2%; Kapp number, 18.1; content of pentosans, 3.7%; and ash residue, 1.4%. Nitric acid delignification of fibers involved impregnation of the flax fiber with an aqueous HNO_3 solution (for 30 min at liquid : solid ratio of 20 ml g^{-1} and room temperature), cooking of the swollen fibers in the same HNO_3 solution at 60°C,

Table 1. Results of delignification of flax fiber with HNO_3 solutions of various concentrations (cooking time 2 h)

HNO_3 concentration	Cellulose yield	Lignin content [17]	Kapp number [18]	DD, %
%				
2.0	83	3.7	8.3	51.1
3.0	80	3.6	7.9	54.2
4.0	78	2.7	7.0	66.7
5.0	81	2.7	7.0	65.3

and extraction of the modified lignin with a 1% NaOH solution (2 h, 80°C, liquid : solid ratio 20 ml g^{-1}). After the cooking and extraction, the pulp was washed with hot water to neutral reaction. The cooking and extraction were performed in a temperature-controlled flask equipped with a reflux condenser.

We varied the HNO_3 concentration (2, 3, 4, 5%) and cooking time (1, 2, 3, 4, 5 h). All the experiments on studying the influence of the HNO_3 concentration and cooking time on the extent of delignification were performed under identical conditions of impregnation and extraction. These conditions were a fortiori favorable for the nitric acid delignification [13, 16].

The lignin content in the samples was determined by Komarov's modification of Klasson's method [17], and also from the Kapp number [18]. The degree of delignification (DD, %) of flax fibers was calculated by the formula [19]

$$DD = 100 - YL/L_{in},$$

where DD is the degree of delignification, %: Y, cellulose yield, %; and L_{in} and L, lignin content in the fiber before and after the treatment, respectively (%).

The content of pentosans in the samples was determined by the TAPPI standard method [20], and the α-cellulose content [21] and ash residue [22], by according to the corresponding state standards.

The degree of polymerization (DP) of cellulose was determined from the viscosity of its solution in Cadoxen [23]. The water-retaining power (WRP) was evaluated in accordance with [24].

Experiments on flax fiber cooking at varied HNO_3 concentration were performed for 2 h at 60°C. When planning the experiment, we tried to minimize the cooking temperature, because elevated temperatures stimulate undesirable hydrolytic degradation of cellulose. The choice of the temperature is based on the data that the mean glass transition point of dry lignin is 195°C, and in lignin with 27.1% moisture content it decreases to 90°C [25]. Aqueous HNO_3 solution apparently plasticizes lignin more strongly than does water and decreases the glass transition point of lignin to a still greater extent. It is reasonable to assume that lignin in an HNO_3 solution at 60°C gets devitrified and passes into a hyperelastic state. Hence, reactive centers of lignin become more accessible, and the reactivity of lignin as a whole increases.

The extent of delignification was evaluated by three parameters: residual lignin content, Kapp number, and degree of delignification. The results are listed in Table 1.

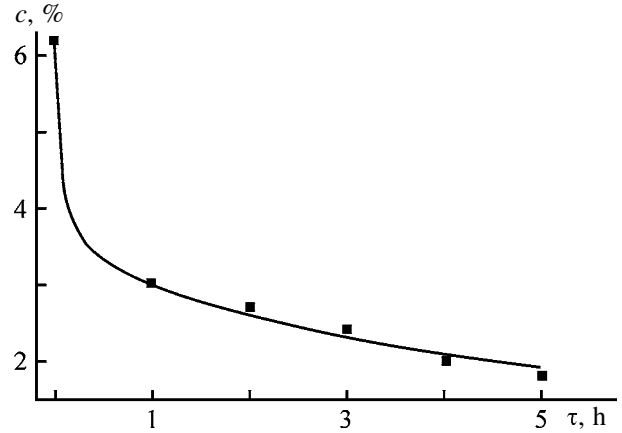
Table 1 shows that delignification with dilute (2–5%) HNO_3 solutions provides high (up to 83%) yield of unbleached cellulose. After cooking with 4–5% HNO_3, the lignin content decreases by a factor of more than 2: from 6.2% in the initial fiber to 2.7%. The maximal degree of delignification calculated from the yield and residual lignin content is 66.7%. The cellulose hardness, i.e., the capability for bleaching determined by the Kapp number, also regularly decreases (by 1.3 units) with an increase in the acid concentration (Table 1).

Thus, upon cooking with 4–5% acid, the hardness of flax fibers decreases by a factor of approximately 2.6 relative to the initial value. Since the Kapp number characterizes the residual lignin content, the agreement between the results of the two independent methods of lignin determination [17, 18] confirms their reliability. Thus, the HNO_3 concentration of 4.0% is sufficient to provide relatively high degree of delignification.

The next step of our experiment involved examining the influence of the cooking time on the extent of delignification, at the HNO_3 concentration of 4.0%. We found that the influence of the cooking time on the yield of flax cellulose is insignificant. Even after prolonged cooking (4–5 h), the yield remained as high as 77–78%.

The dependence of the residual lignin content in

Table 2. Characteristics of flax wool



Delignification procedure	Yield, %	Lignin content, %	Kapp number	α-Cellulose content, %	Content of pentosans, %	DL, %	DP	WRP, %
Nitric acid	70	1.5	2.6	91.0	2.9	83	1300	52
Alkaline	75	1.8	–	95.0	3.4	78	2000	42

unbleached flax fiber on the time of cooking in 4% HNO_3 is plotted in the figure. It is seen that the kinetics of the nitric acid delignification of flax is characterized by the fast initial step. Within the first minutes of cooking, the lignin content in the fiber decreases by a factor of almost 2, after which the process decelerates. After 4 h, the residual lignin content in the unbleached cellulose is 2.0, and after 5 h, 1.8%, i.e., it decreases by a factor of approximately 3.5 relative to the initial fiber.

With increasing cooking time, the degree of flax delignification regularly increases, reaching 74.8% in 4 h and growing insignificantly after 5 h. Naturally, the cellulose hardness decreases upon 4–5-h cookings (by a factor of ~3.4 relative to the initial fibers).

Further study involved preparation of wool from flax fibers delignified under the optimal cooking conditions (HNO_3 concentration 4.0%, cooking time 4 h).

Preparation of wool proper involves bleaching of unbleached flax cellulose, i.e., removal of residual lignin. The activity of nitric acid toward lignin and the selectivity of its action provide relatively low content of residual lignin (2.0%) even after the first cooking step. Owing to its efficiency, it is also appropriate to use nitric acid treatment in the step of bleaching of flax cellulose. Correspondingly, we developed a delignification scheme involving both nitric acid cooking and nitric acid bleaching. This approach was suggested and tested previously in delignification of rye straw [13].

Kinetic curve of nitric acid delignification of flax fiber: (*c*) lignin content and (τ) cooking time.

We suggest a three-step scheme of bleaching of flax cellulose obtained by nitric acid treatment. The first step is treatment of unbleached fibers with 20% nitric acid followed by alkaline extraction of modified lignin; the second step is final bleaching with hydrogen peroxide; and the third step is souring with acetic acid. To generate nitrogen oxides which intensify delignification, we added reductants (sodium nitrite, sodium sulfite) to nitric acid in the first bleaching step. It is appropriate to combine the second step, final bleaching of the fiber with hydrogen peroxide, with the step of alkaline extraction of modified lignin. The third step (souring) is performed to neutralize the medium and, as noted in [12], to stabilize the cellulose whiteness.

The wool quality was evaluated by its chemical purity (content of residual lignin, pentosans, and α-cellulose) and hygroscopicity, and also by the mean degree of polymerization of cellulose. As reference material we used flax wool recovered from the same cottonized fibers by alkaline delignification at the Groniteks enterprise (a part of a semicommercial batch). The characteristics of flax wool prepared by our procedure (nitric acid process) and of Groniteks wool are compared in Table 2.

Table 2 shows that the yield of wool prepared by nitric acid delignification is about 70%, which is close to the yield of the semicommercial wool (75%). Semicommercial wool is characterized by a somewhat higher content of pentosans, i.e., by lower chemical purity. On the whole, the wool prepared by our procedure appreciably surpasses the semicommercial material in the extent of delignification evaluated by the residual lignin content and DD.

An important characteristic of wool is the degree of polymerization of cellulose. Low-molecular-weight fractions of cellulose decrease the strength and adhesiveness of the fibers. According to the State Standard [26], the weight fraction of short fibers and so-called "dust" in wool should not exceed 0.2%. Low-molecular-weight fractions of cellulose may induce inflammations caused by penetration of short fibers inside

a wound. It should be noted that cotton wool prepared by alkaline delignification contains 95% α-cellulose, i.e., 95% high-molecular-weight fractions, and in this parameter it surpasses the sample prepared by the nitric acid procedure (Table 2). The lower content of high-molecular-weight fractions in the nitric acid treated sample is apparently caused by degradation of cellulose in the course of bleaching. Upon removal of the major fraction of lignin in the cooking step, the cellulose structure becomes more accessible to attack of agents causing degradation.

The mean degreee of polymerization of the resulting nitric acid flax cellulose is 1300 (Table 2). The degree of polymerization of flax cellulose recovered by nitric acid delignification in [2] (the treatment conditions are not indicated) is as low as 400–450. The relatively high degree of polymerization of flax cellulose in our experiment shows that we actually found acceptable conditions for the nitric acid delignification of flax fibers. Indeed, the suggested scheme provides high selectivity of the reactions of nitric acid with the lignin–polysaccharide complex and limits the acid-catalyzed hydrolytic degradation of cellulose in the cooking step.

Medical wool is used as exudate absorbent and a reservoir of liquid medicinals. In engineering and in homes, the use of wool as wiping and moisture-collecting material is of no less importance. Table 2 shows that flax wool prepared by nitric acid delignification considerably surpassed in the water-retaining power the wool prepared by alkaline delignification: 52% against 42%. This result is quite predictable, because nitric acid treatment causes appearance of cracks on the fiber surface [27], which, apparently, enhances the water-retaining power.

CONCLUSIONS

(1) The suggested scheme of nitric acid delignification followed by nitric acid bleaching of cottonized flax fibers ensures high yield of chemically pure wool with a high hygroscopicity.

(3) The main parameters of the wool prepared by the suggested procedure are similar to or exceed the parameters of the semicommercial flax wool.

CHEMISTRY OF FOSSIL FUEL

Direct Atomic-Absorption Determination of the Ni and V Content in Oil

Abstract—A direct (without sample pretreatment) atomic-absorption method of V and Ni determination in oil with electrothermal atomization and Zeeman correction of background was developed.

DOI: 10.1134/S1070427206090308

About 30 metals were detected in oil, among which V, Ni, Fe, Cu, Al, Cr, and Zn are the most abundant. Vanadium and nickel were the first metals detected in oil. The content of these metals in oil can reach tenth parts of percent, which makes recovery of vanadium and nickel from oil economically attractive [1]. Approximately 40% of vanadium and nickel exist in oil as vanadyl and nickel porphyrins and are concentrated in oil fractions with boiling points above 300°C, i.e., in raw material of catalytic cracking, black oil, and tar [2]. The presence of vanadium and nickel in these fractions is undesirable because of catalyst poisoning and corrosion of boiler parts with vanadium(V) oxide, which is formed in the course of fuel combustion.

Vanadium and nickel compounds are the most hazardous among all metals discharged into the environment from petrochemical plants. They have toxicological, immunopathological, and carcinogenic effect on a human body.

The vanadium and nickel content in oil and in its heavy fractions is usually determined by various instrumental methods [3, 4]. There is a standard method of vanadium determination [5], in which oil samples are preliminarily treated with concentrated sulfuric and nitric acids, or elemental sulfur, or samples are burnt. The ash is treated with acids, which is followed by photometric determination of vanadium as a tungstate complex at 436 nm. The standard method of determination of metals in oil in the United States involves oil sample treatment with concentrated sulfuric acid, followed by heating to 525°C in muffle, or sample dissolution in a complex mixture of aromatic solvents. The final determination is performed on atomic absorption spectrometers with flame atomization or on atomic emission spectrometers with inductively coupled plasma [6].

In this study, we developed a method of vanadium and nickel determination in oil on a atomic absorption spectrometer with electrothermal atomization and Zeeman correction of the background.

EXPERIMENTAL

An MGA-915 Zeeman atomic absorption spectrometer produced by Lyumeks Limited Liability Company, Massman graphite cells with L'vov's platform, and 5–50 mm^3 single-channel pipettes (batcher) were used; the measurement error did not exceed 5%.

We used a 1 g dm^{-3} aqueous solution of nickel [GSO (State Reference Sample) 8001–93(8003–96), Water Research and Control Center], a 0.1 g dm^{-3} aqueous solution of vanadium (GSO 7267–96, Ural Research Institute of Metrology), distilled water [GOST (State Standard) 6709–72], double-distilled water (the metal content should not exceed 30% of the lower boundary of the interval determined), ultrapure grade palladium nitrate (10 g dm^{-3}) as a modifier, ultrapure grade concentrated nitric acid (GOST 11 125–84), and calibration solutions of Ni and V(IV) (10 and 20 μg dm^{-3}) prepared in double-distilled water.

To plot the calibration dependence of the analytical signal on the element weight, before each measurement 20 mm^3 of a 1 g dm^{-3} modifier solution was introduced with a batcher into a graphite cell of the MGA-915 atomic absorption spectrometer and dried for 40 s at 110°C. Then the required volume (5–

40 mm^3) of 10 μg dm^{-3} nickel and vanadium calibration solutions and 30–40 mm^3 of 20 μg dm^{-3} calibration solutions were introduced. Then, the corresponding integral analytical signals were measured; each measurement was repeated 5 times with calculation of the arithmetic mean.

The calibration dependences were plotted for each element. These dependences are linear within the 100–800 pg range for vanadium and within the 40–80 pg range for nickel.

For oil sample preparation, a 0.1–0.2-g oil sample was dissolved in heptane (~5 cm^3). The solution was quantitatively transferred into a 10 cm^3 volumetric flack, and heptane was added to the mark.

Then, 20 mm^3 of modifier solution with a metal concentration of 1 g dm^{-3} was introduced into a graphite cell with the batcher and dried for 40 s at 110°C, and then 5 mm^3 of an oil sample diluted with heptane depending of the expected metal content was introduced. Then the measurement was performed in accordance with the selected mode of the spectrometer operation.

Atomic absorption analysis of oil is complicated by noises generated by sample components, e.g., chemical effects or high level of nonselective absorption. The latter is caused by broad-band molecular absorption of evaporated components of the sample or light scattering on the particles of the products of the matrix decomposition [7]. To take into account nonselective absorption in atomic absorption spectrometers with electrothermal atomization, various background corrections are used; Zeeman correction realized in MGA-915 spectrometer is the most efficient [8, 9].

However, background correction in the analysis of complex objects is insufficient. Optimization of the temperature–time program of furnace heating and chemical modification should also be used. In our study, both approaches were applied simultaneously.

In spite of numerous papers on successful application of modifiers, modifiers for metal determination in a specific matrix in most cases are still chosen empirically [7]. We studied three modifiers: palladium(II) nitrate, hydrogen hexachloroplatinate(IV), and magnesium nitrate (in a concentration of 1 g dm^{-3}). The first two compounds are readily reduced to the elemental state on the surface of the graphite furnace. They form intermetallic compounds with V and Ni, which provides elevation of the pyrolysis temperature. Magnesium nitrate forms high-temperature oxide in the course of the pyrolysis in the furnace zone that does not contact graphite; this oxide provides thermal stabilization of nickel and vanadium oxides. The maximal analytical signal of V and Ni, maximal temperature of pyrolysis, and minimal nonselective absorption were obtained with palladium(II) nitrate used as modifier. Probably, this modifier provides more complete ashing of the oil organic matrix.

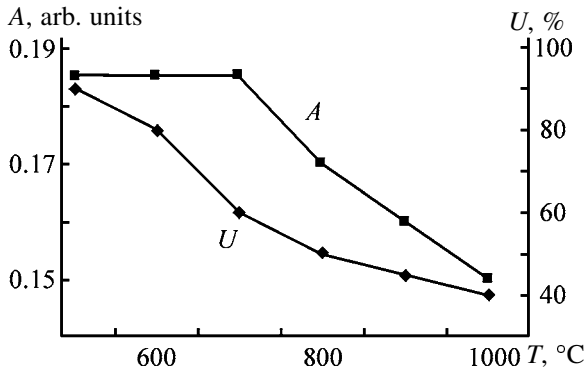

Fig. 1. Dependence of the analytical signal A and the level of the nonselective absorption U on the pyrolysis temperature T for Ni.

Properly chosen mode of the oil sample drying is of great importance for attaining well reproducible results. The temperature and drying duration depend on the solution type. In the case of heptane, we chose the temperature of 60°C and drying time of 40 s.

The pyrolysis stage in many respects determines the accuracy of the analysis and elimination of nonselective absorption. The dependence of the integral analytical signal on the pyrolysis temperature is shown in Fig. 1. Insufficient temperature of the pyrolysis does not allow complete decomposition of the organic matrix, whereas too high pyrolysis temperature leads to partial loss of the elements. As seen from Fig. 1, at 700°C for both nickel and vanadium the ratio between the analytical signal and nonselective absorption is optimal.

The optimal temperature of the nickel and vanadium atomization stage is the minimal temperature producing the maximal analytical signal. At lower temperature, atomization of the oil sample is incomplete, which decreases the analysis sensitivity. At too high temperature, the loss of vaporous nickel and vanadium atoms is observed. This decreases the intensity of the analytical signal and, moreover, drastically shortens the lifetime of the graphite atomizer. The dependence of the integral analytical signal of V and Ni on the atomization temperature is shown in Fig. 2.

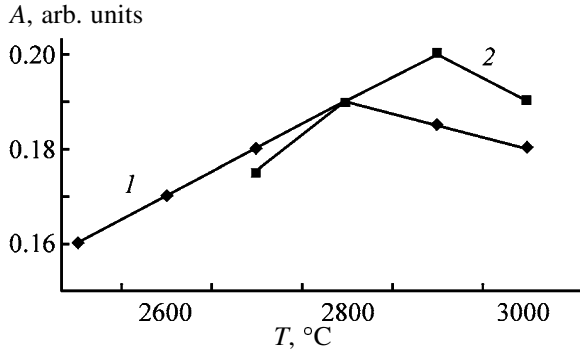

Fig. 2. Dependence of analytical signal A of (*1*) nickel and (*2*) vanadium on the atomization temperature T.

As seen, the optimal atomization temperature is 2900°C for vanadium and 2800°C for nickel.

The optimal temperature–time parameters of the analysis of oil samples are listed in Table 1. To determine the error characteristics of the method, we used the reference sample (RS) of oil composition SRM 1634-c (producer NIST, the United States). The vanadium and nickel content in it is 28.20 and 17.25 mg kg^{-1}, respectively, at standard deviation of the analysis of 0.21 (RS no. 1). To cover the whole interval of V and Ni contents, we also used the sample diluted with heptane by a factor of 2, 4, 5, 10, 20, 50, and 100 (RS nos. 2–8, respectively).

The interval of the measured contents was 0.3–28.2 and 0.2–3.5 mg kg^{-1} for vanadium and nickel, respectively. The random component of the error was estimated from 10 replicate determinations. The characteristics of the random component of the error are listed in Table 2., where $\bar{c}$ is mean content of V and Ni in RS, and S_r, relative standard deviation of the analysis results.

As seen, for vanadium concentration ranges 0.3–0.6 and 0.6–28.2 mg kg^{-1}, the relative standard deviation does no exceed 15 and 10%, respectively, and for nickel it amounts to 20 and 12% within the concentration ranges 0.2–0.4 and 0.45–3.5 mg kg^{-1}, respectively. The fixed component of the error was determined using the above RSs of the oil composition. The results obtained are shown in Table 3, where c_{cf}

Deposit, oil well no.	Concentration ±Δ, mg kg^{-1}	
	vanadium	nickel
Asar, 49	3.17 ± 0.34	9.70 ± 0.62
Burmasha, 3	1.64 ± 0.12	2.40 ± 0.28
Zhetybai, 1068	0.80 ± 0.08	16.80 ± 1.20

is the content of the element in RS in accordance with the certificate; c, measured content of the element in RS; S, standard deviation of the replicate measurements; and $\theta = c - c_{cf}$ and t_c are the calculated values of the Student test for the confidence level $P = 0.95$ and the number of replicate measurements 10.

Table 3 shows that the calculated Student test for $P = 0.95$ and the number of degrees of freedom $f = n - 1 = 9$ within the whole range of metal contents for both V and Ni does not exceed the tabulated value $t_{0.95,9} = 2.26$. Hence, the fixed component of the method error is insignificant. Thus, the method proposed for the direct determination of V and Ni in oil provides correct and well reproductible results. The content of vanadium and nickel was determined by this method in samples of various oils (Table 4).

CONCLUSION

A method of the direct atomic-absorption determination of vanadium and nickel in oil was developed. This method can be recommended for express determination of V and Ni in oil.

BRIEF COMMUNICATIONS

Mechanism of Chemical Deposition of Nickel–Boron Coatings in Tartrate–Glycine Solutions

V. V. Rogozhin and E. Yu. Anan'eva

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received April 17, 2006

Abstract—The effect of glycine additive on the deposition of nickel–boron coatings from tartrate–glycine solutions was studied.

DOI: 10.1134/S107042720609031X

Nickel–boron coatings, compared to nickel–phosphorus coatings, are more resistant to high temperatures in air, show better barrier properties against diffusion of metal atoms of the substrate, and can be subjected to high-quality soldering and welding.

At the same time, wide practical application of borohydride solutions, recommended for chemical deposition of nickel–boron coatings by GOST (State Standard) 9308–84, is seriously impeded by the presence of ethylenediamine constituent, which is a known carcinogen, and by the use of heavy metal salts as stabilizing additives. The compositions of tartrate–glycine solutions of chemical nickel plating have been recommended in [1–3].

In this study, we examined how glycine additive affects the mechanism of the deposition of nickel–boron coatings from the above solutions. The initial solution was tartrate–glycine solution [2] containing (g l^{-1}) nickel sulfate 25, K–Na tartrate 50, glycine 50, sodium hydroxide 80, sodium borohydride 1.0, and stabilizers. A nickel–boron coating containing about 3.0% boron is deposited from such solution at an average rate of 7–9 μm in 30 min.

EXPERIMENTAL

The electrochemical study was performed in a standard YaSE-2 cell using PI-50 and P-5848 potentiostats. The coating thickness was calculated from the gain in the coating weight per visible surface of the electrode. Mercury oxide electrode was used as reference. The potentials were recalculated relative to standard hydrogen electrode. The experiments were performed at 85°C for 30 min.

The electrochemical mechanism of the chemical deposition of nickel–boron alloy from tartrate–glycine solution was confirmed by the dependence of the nickel plating rate on the potential, which passes through a maximum (Fig. 1). The deposition rate is maximal in the vicinity of the compromise potential of chemical nickel plating, when the steps of cathodic deposition of the coating and anodic oxidation of the reductant are kinetically compensated. These steps are actually interrelated: the shift of the electrode potential to the negative direction from the compromise potential of the chemical nickel plating considerably decreases the rate of the coating deposition. Acceleration of the external electroplating of the coating is far from compensating the decrease in the rate of the chemical process.

Evidently, this fact indicates that the adsorbed reductant, borohydride, whose reactivity in the region of electronegative potentials is decreased, exhibits the

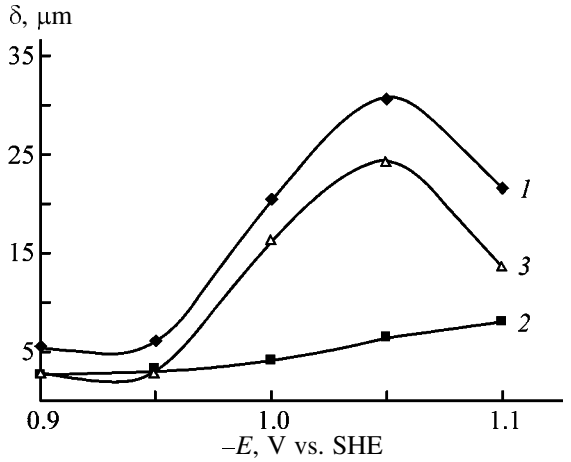

Fig. 1. Coating thickness δ in nickel deposition from initial solution vs. potential *E*. (*1*) Total curve; partial curves: (*2*) external electroplating and (*3*) chemical deposition.

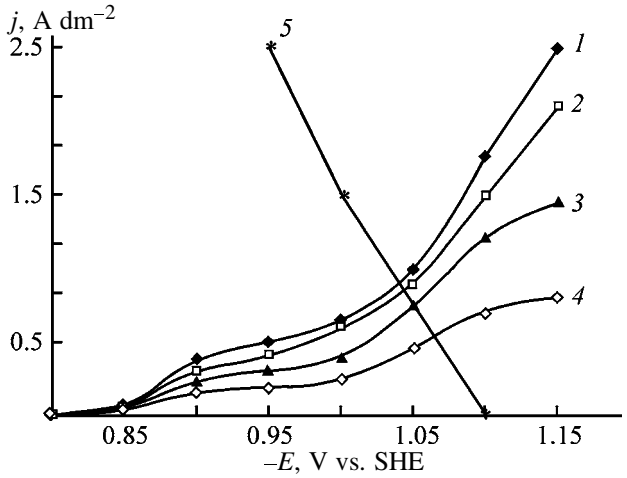

Fig. 2. Polarogram of the chemical nickel plating. (*j*) Current density and (*E*) potential. (*1–4*) Cathodic curves (solutions without borohydride) at glycine concentration, g l^{-1}: (*1*) 25, (*2*) 50, (*3*) 75, and (*4*) 100; (*5*) anodic curve (solution without nickel salt).

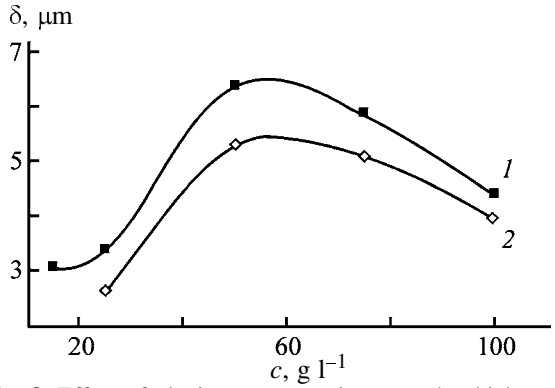

Fig. 3. Effect of glycine concentration *c* on the thickness δ of the nickel–boron coatings. Thickness, μm: (*1*) experimental and (*2*) calculated from conjugation of the cathodic and anodic curves.

inhibiting effect, which should be taken into account in electrochemical simulation of steps of the chemical nickel plating process.

Variations of the rate of the nickel partial deposition with varying the potential are considerably more pronounced in solutions without reductant, which shows that the reductant inhibits the cathodic deposition of nickel at electronegative potentials (Fig. 2). In this case, the rate of the nickel deposition is markedly affected by the glycine concentration in the solution, which, as additional ligand for nickel ions, considerably increases the rate of the chemical deposition of nickel–boron coatings. Glycine, taken in optimal concentrations (40–60 g l^{-1}), facilitates the cathodic nickel deposition (Fig. 2) not only owing to the formation of a [Ni(Tart)(Gly)] complex but also owing to rearrangement of the dense part of the electrical double layer with increasing ψ' potential, as it was shown previously in [4].

A possibilty of stepwise simulation of the deposition of nickel–boron coatings based on the conjugation of cathodic and anodic steps is confirmed by the fact that the coating thicknesses calculated from the currents at the point of intersection of the polarization curves of its cathodic and anodic model steps (Fig. 2) and the actual thicknesses of the coatings prepared by the chemical nickel deposition from solutions differing in the glycine concentrations are close (Fig. 3). The latter thickness also passes through a maximum at a glycine concentration of 40–60 g l^{-1}.

In the course of the chemical nickel deposition, its compromise potential first passes a peak at about 20 mV, which is evidently due to the difficulty in formation of a new phase, and then gradually shifts toward positive potentials, attaining the steady-state values of –1040 to –1050 mV. This shift may be accounted for by consumption of adsorbed particles of the reductant and by retardation of surface adsorption stages.

CONCLUSION

The chemical nickel deposition in tartrate–glycine solutions proceeds by the electrochemical mechanism based on the conjugation of the anodic (borohydride oxidation) and cathodic (nickel deposition) steps. The latter process is affected by the glycine additive, which, on the whole, determines the rate of the chemical nickel deposition.

Density of Organic Phases in the Extraction System Tributyl Phosphate–Phosphoric Acid

V. M. Lembrikov, L. V. Konyakhina, V. V. Volkova, G. P. Zhavoronkova, and B. T. Kunin

Voskresensk Research Institute of Fertilizers and Phosphoric Acid, Joint-Stock Company, Voskresensk, Moscow oblast, Russia
Ivanovo State University of Chemical Technology, Ivanovo, Russia

Received January 11, 2006

Abstract—Data on the density of phosphoric acid solutions in crude TPB and TBP-based commercial extractant for purification of wet-process phosphoric acid are tabulated over the phosphoric acid concentration range 0.62–27.74 wt % (recalculated to P_2O_5).

DOI: 10.1134/S1070427206090321

One of the methods for purification of wet-process phosphoric acid (WPPA) is extraction with organic solvents. At the Voskresensk Institute of Fertilizers and Phosphoric Acid (Voskresensk, Moscow oblast, Russia), an industrial process has been developed for purification of WPPA by TBP extraction [1]. The process conditions (reagent consumption, temperature, and compositions of the liquid phases) were reported elsewhere [2]. In this process, phase separation in the pulsating columns and settlers is accomplished under the action of gravity, i.e., the driving force of the process is the density difference between the organic and aqueous phases.

In this study, we report the densities of phosphoric acid solutions in the commercial TPB-based extractant. The major impurities in the extraction system are as follows (wt %): sulfate (0.056), fluorine-containing compounds (0.035), humics (0.15), and other foreign compounds present in WPPA produced from Khibiny concentrate and transferred into TBP in the course of extraction. For comparison, we measured the density of crude TBP solutions [3] and commercial phosphoric acid (analytically pure grade).

The phosphoric acid concentration in the solutions was varied from 0.62 to 27.74 wt % (recalculated to P_2O_5). The acid concentration was determined potentiometrically [4].

The density of solutions was measured pycnometrically over the temperature range 10–70°C. In the experiments, the temperature was controlled to within 0.5°C.The results are summarized in Tables 1 and 2.

The graphical analysis and data processing showed that the temperature dependence of the density can be described by the Mendeleev equation [5]

$$\rho_t = \rho_{23}(1 - k\Delta t), \quad (1)$$

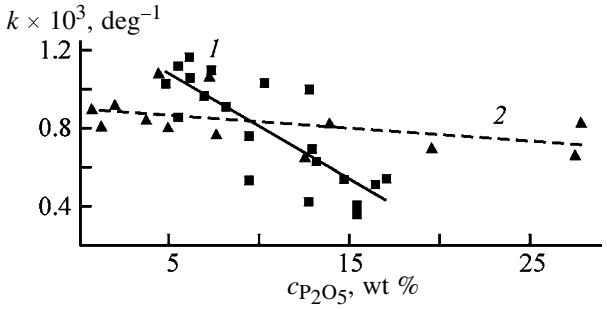
where ρ_t and ρ_{20} are the densities (g cm^{-3}) at a given temperature (°C) and 20°C; Δt is the temperature difference (t – 20) (°C); and k, expansion modulus of the liquid.

Tables 1 and 2 present the expansion modulus of phosphoric acid solutions in the extractant and TBP, estimated by Eq. (1). In fact, this is the mean cubic expansion coefficient α for the temperature ranges 10–20, 20–30, 20–40°C, etc. [6]. The graphical (see figure) and mathematic treatment of the k values revealed that the concentration dependence of k fits Eq. (2) for the solutions obtained by saturation of the process extractant and Eq. (3) for the solutions obtained by saturation of crude TBP with commercial phosphoric acid:

$$k \times 10^3 = 1.3444 - 0.054c_{P_2O_5}, \quad (2)$$

$$k \times 10^3 = 0.9046 - 0.0071c_{P_2O_5}, \quad (3)$$

where k is the expansion modulus and $c_{P_2O_5}$, phosphoric acid concentration in the solution, recalculated to P_2O_5 (wt %).



Previously [2], using data obtained in the course of

Expansion modulus k of phosphoric acid solutions in (*1*) commercial extractant and (*2*) crude TBP as a function of the acid concentration (wt %, recalculated to P_2O_5).

long-time service of the semicommercial plant, we have demonstrated that the phosphoric acid concentration in the extractant can be described by Eq. (4):

$$c_{P_2O_5} = 127\rho_{20} - 124.64, \quad (4)$$

For the solutions in crude TBP, we obtained relationship (5):

$$c_{P_2O_5} = 125\rho_{20} - 122.62, \quad (5)$$

where $c_{P_2O_5}$ is the phosphoric acid concentration in the organic solutions, recalculated to P_2O_5 (wt %).

From Eqs. (1)–(5), we obtain Eq. (6) for the density of process solutions of phosphoric acid in the extractant, and Eq. (7) for simulated solutions of phosphoric acid in TBP:

$$\rho_t = \frac{c_{P_2O_5} + 124.64}{127}[1 - (1.3444 - 0.054c_{P_2O_5})\Delta t \times 0.001], \quad (6)$$

$$\rho_t = \frac{c_{P_2O_5} + 122.62}{125}[1 - (0.9046 - 0.0071c_{P_2O_5})\Delta t \times 0.001]. \quad (7)$$

The results obtained using these equations are given in Tables 1 and 2, respectively. It should be pointed out that these equations are similar, having close coefficients. Table 1 shows that the difference between the densities estimated by Eqs. (6) and (7) is within 1%, being generally 0.3%. This fact suggests that the occurrence of the above-indicated amounts of impurities in the process solutions has no significant effect on the density of phosphoric acid solutions in TBP, and, therefore, the estimates can be made by both Eqs. (6) and (7).

CONCLUSION

Analytical expressions are derived for the dependences of the density of phosphoric acid solutions in tri-*n*-butyl phosphate on the temperature and composition of the organic phase over the temperature range 10–70°C and the range of the P_2O_5 concentration in the organic phase from 0.62 to 27.74 wt %.

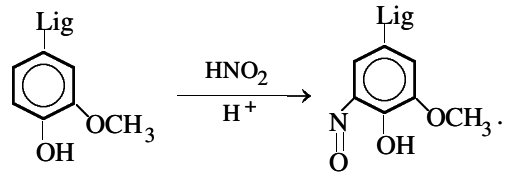
Received December 21, 2006; in the final form, April 2006

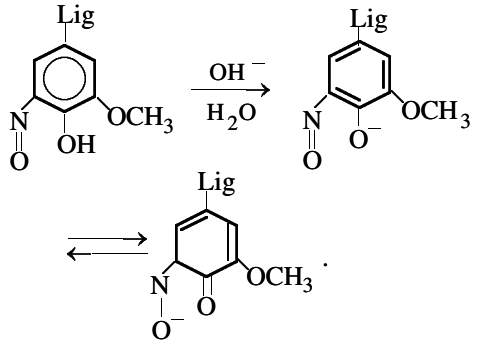
Abstract—The kinetics of lignosulfonic acid nitrosation in the presence of acetic and nitric acids used for generation of nitrous acid in combination with sodium nitrite was studied as applied to colorimetric determination of lignosulfonic acids.

DOI: 10.1134/S1070427206090333



Owing to high reactivity under mild conditions, nitrous acid is widely used in organic synthesis and analysis. Organic compounds of various types can be prepared using nitrous acid [1–3]. Certain organic reactions are catalyzed by nitrous acids [4, 5]. Vast material on the chemistry of nitroso and nitro compounds was summarized in monographs and reviews [6–9].

Numerous organic compounds can be identified by the reaction with nitrous acid: phenols (Liebermann's reaction), amines, amino acids and amino acridines, acid acylides, xylidines, naphthols, nitro compounds, alcohols, sulfanilamides, and thiols. These methods were summarized and considered in detail by Korenman in [10].



Nitrous acid and nitrites are widely used in lignin chemistry [11]. The possibility of using nitrous acid for cellulose bleaching was discussed in [12]. Nitrosated lignosulfonic acids (LSAs) are chelating agents for biogenic metal cations [13–15]. Nitrous acid is used for determining lignins in both solid and liquid media.

A method for determining wood pulp content in paper composites was developed by Gogotov et al. [16]. According to this technique, a paper composite is nitrosated at 60°C for 30 min at 6% sodium nitrite consumption and then the ratio of the reflection and scattering coefficients of the paper composite is measured at 430 nm.

Currently lignosulfonic acids are determined by the Pearl–Benson's method developed in the 1940s [17]. This method is widely used in many countries [18–23]. In this method, sulfite liquor or wastewater to be analyzed is treated with nitrous acid generated by acidification of aqueous sodium nitrite with acetic acid. The resulting solution is alkalized, kept for 15 min, and then the lignosulfonic acid content is determined from the optical density at 430 nm. The light absorption in this system is caused by the colored nitrosated sulfonic acid derivatives formed by the following reactions. In the first step, lignosulfonic acid is nitrosated by the S_E reaction

On alkalization, the phenolic groups of nitrosated lignosulfonic acid are ionized to form the anion stabilized by conjugation.

A method for quantitative determination of LSA based on its nitrosation was suggested in [24]. According to this method, the solution to be analyzed is

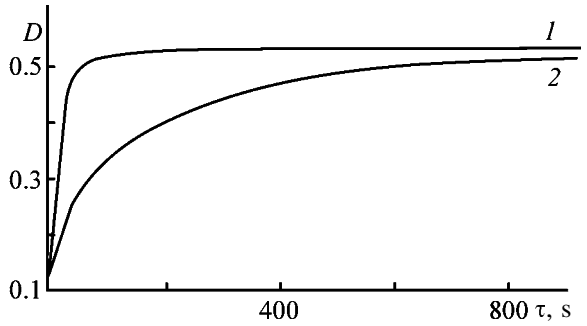


Fig. 1. Variation of the optical density of LST solution in the course of nitrosation with nitrous acid generated from sodium nitrite in combination with (*1*) nitric acid and (*2*) acetic acid. λ = 440 nm.

subjected to short treatment with hot nitric acid, and then the optical density is determined at 315–340 nm. It was found that, in LSA nitration at room temperature, the optical density of the solution changes with time, which is typical of catalytic reactions. The sigmoid-shape kinetic curve of this reaction consists of three separate portions. Within the first portion, the optical density remains virtually constant. The second portion of the kinetic curve is characterized by a sharp increase in the optical density. Within the third portion, the optical density reaches a maximum and then remains constant. We believe that this complicated kinetic pattern is caused by the fact that nitric acid is not only electrophilic but also oxidizing agent. The LSA oxidation with nitric acid yields nitrous acid which readily reacts with lignosulfonic acid. We found that, on adding sodium nitrite to the reaction mixture in the amount less than 1% of the total LSA content, the LSA nitrosation was accelerated and the kinetic curve lost its sigmoidal shape [25]. In this connection, it was of interest to elucidate how replacement of acetic acid used in the Pearl–Benson's method with nitric acid affects the LSA colorimetric determination.

EXPERIMENTAL

Aqueous sodium nitrite (10%), aqueous nitric acid (10%), aqueous acetic acid (10%), and aqueous ammonia (2 M) used in the experiments were prepared from chemically pure grade chemicals. The aqueous stock solution of lignosulfonate (LST) containing 10 mg ml^{-1} LST was prepared from powdered LST produced by the Kotlas Pulp and Paper Combine.

The colorimetric determination of LST was carried out as follows. Aqueous sodium nitrite (2 ml), distilled water (50 ml), and nitric acid (2 ml) were successively placed into a 100-ml volumetric flask. After keeping for a certain time, this mixtute was alkalized with aqueous ammonia, and the volume was brought to the mark with distilled water. The optical density of solutions was measured on a KFK 2MP photocolorimeter at 440 nm in 10-mm optical cells.

The kinetic of LST nitrosation was studied without alkalization of the reaction mixture. The electronic spectra were recorded on a Specord 200 spectrophotometer at 20-s intervals. The total electronic spectra were recorded on a Specord M 40 spectrophotometer.

First of all, we studied how LST nitrosation with nitrous acid generated from sodium nitrite in combination with nitric and acetic acid depends on the reaction time. In these experiments, the reagent concentrations were identical. The kinetic curves shown in Fig. 1 indicate that, in the presence of acetic acid, the optical density at 440 nm increases gradually with time, whereas in the case of nitric acid the optical density reaches a maximum within 1 min and then does not noticeably change.

The electronic spectra (Fig. 2) show that the nature of the acid used for the generation of nitrous acid affects not only the nitrosation kinetics but also the characteristics of the nitrosated products. The solution of LST nitrosated in the presence of nitric acid has a noticeably higher optical density than that nitrosated in the presence of acetic acid. At the same time,

	1.027	0.405	0.396	2.3
Mean determination error				5.0

with both acids the absorption maximum occurs near 23000 cm^{-1}.

It was found in special experiments that, for both nitric and acetic acids, the optical density of solutions in the course of LST nitrosation is described by the Bouguer–Lambert–Beer law within the entire concentration range.

The calibration plot of c vs. D [c is LST concentration and D, optical density] was constructred for a series of solutions with known LST concentration after nitrosation. As seen from Table 1, the slope b in our calibration plot is smaller than that in the calibration plot constructed using the Pearl–Benson's method. This fact means that our method is more sensitive with respect to LST.

The reproducibility of the LST determination by our method was evaluated from the results of three replicate experiments. The small values of the variation coefficients show that the reproducibility in the optical density determination is good (Table 2).

The LSA determination error was evaluated from the comparison of the LSA content in reference solutions prepared in advance and its value obtained photometrically after LSA nitrosation. Each determination was triply repeated. Table 3 shows that, as compared to the Pearl–Benson's method, our technique ensures more accurate LSA determination.

CONCLUSION

Use of nitric acid in combination with sodium nitrite ensures complete nitrosation of lignosulfonic acids within 1 min and increases both the sensitivity and accuracy of their colorimetric determination.

Sibirean State Technological University GOU VPO, Krasnoyarsk, Russia

Received March 10, 2006

Abstract—Thermal oxidative degradation of a composition based on a polyester resin modified with rosin and tetramethylammonium chloride and its use as a flux for low-temperature solder pastes were studied.

DOI: 10.1134/S1070427206090345

This work continues the studies [1–3] on the development of formulation of corrosion-inactive, low-temperature solder pastes based on polyester resin modified with rosin and quaternary ammonium salts.

Tetramethylammonium chloride (TMAC) was taken as a flux. 2 g of TMAC was added to 15 g of polyester resin modified with rosin and synthesized as described in [1]. The components were thoroughly mixed.

The characteristics of thermal oxidative degradation of both the composition and flux were determined by dynamic thermogravimetry [4]. To determine more precisely the temperature of the decomposition onset, along with TG curve, we recorded the DTG and DTA curves for both the substance studied and an inert reference (Figs. 1a and 1b). Measurements were performed with an MOM Q-1000 derivatograph (Hungary) in the programmed heating mode. A 0.03-g sample was heated in a platinum crucible in air, at a heating rate of 10 deg min^{-1}. The sensitivities were as follows: balance, 50 mg; DTA galvanometer, 1/3; and DTG galvanometer, 1/10.

We found that the polyester resin + TMAC composition decomposes in air within the 70–650°C

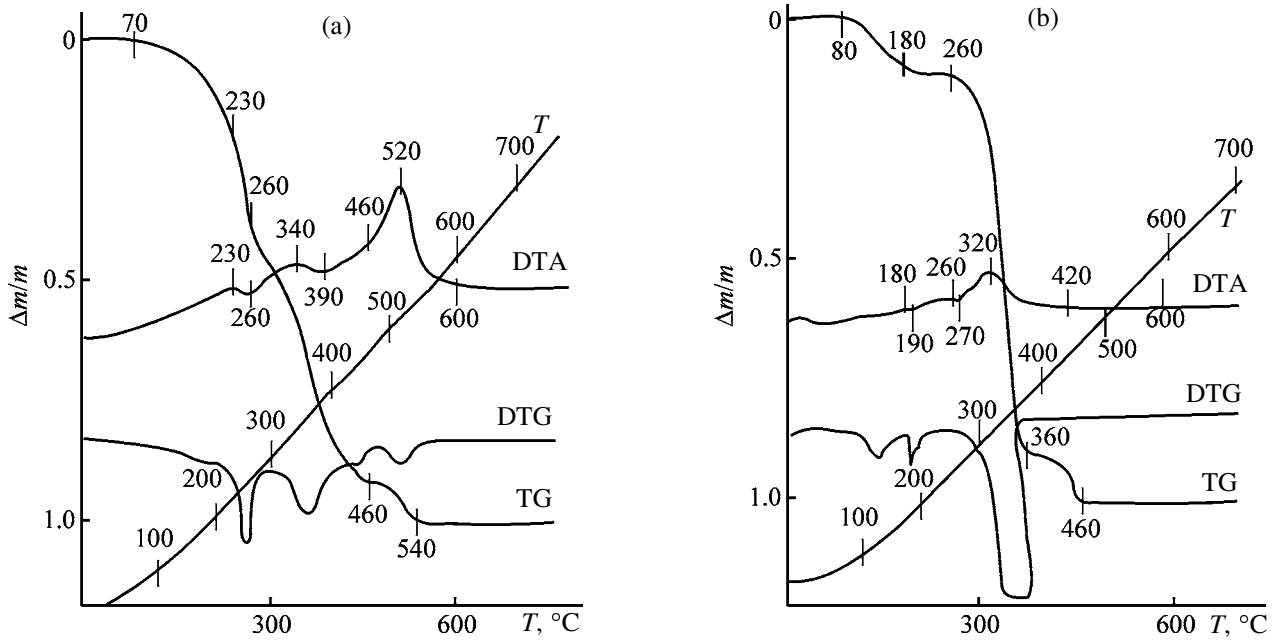

Fig. 1. Derivatogram of the (a) composition based on polyester resin and tetramethylammonium chloride and (b) tetramethylammonium chloride. ($\Delta m/m$) Relative weight loss and (T) temperature.

range in 3 steps (Fig. 1a). The first step at 70–230°C corresponds to elimination of the solvent and unbound water, residual alcohol, and unsaponifiable substances boiling in this temperature range. The second step at 260–340°C is caused by simultaneous endothermic decomposition of TMAC (Fig. 1b) and exothermic oxidation of the part of the products formed. The third step corresponds to a complex process with the characteristic temperature of 460 (temperature of the onset of the exothermic peak in the DTA curve corresponding to the onset of oxidation) and 520°C. The peak at 520°C reflects oxidation of gaseous products formed by thermal decomposition of the polyester resin [1].

The DTG and DTA curves of TMAC show that it decomposes within the 100–320°C range (Fig. 1b). This indicates that TMAS can be used as a flux of solder pastes with a fritting temperature of 320°C.

The study of solder pastes containing 15% polyester resin, 2% TMAC, and 83% solder powder showed that they correspond to GOST (State Standard) V 20.39.304–76 and OST (Branch Standard) 4GO 033000 [5].

CONCLUSIONS

(1) It was shown by dynamic thermogravimetry that the composition based on a polyester resin and tetramethylammonium chloride is stable with respect to thermal oxidative degradation.

(2) This composition meets the requirements to low-temperature solder pastes.

Abstract—The possibility of analysis of the shape of colloid particles in solutions of latex and French and Moldovan wines with a flow-type ultramicroscope and digital photo camera was studied. The micrographs taken can be used to determine distances between particles by comparison with particle radii found by an independent method. The concepts of Deryagin–Landau–Vervey–Overbeek's physical theory of stability of colloid systems were used to calculate the molecular force constants for wine particles.

DOI: 10.1134/S1070427206090357

Analysis of the shape of colloid particles is a topical problem of colloid science, because the stability, colloid characteristics, and other parameters of colloid systems depend on the particle shape. However, it has been impossible to determine the shape of particles in their natural environment because of the lack of appropriate equipment. Moreover, the light scattered by particles is, according to the known concepts, a result of its diffraction on particles when its wavelength is comparable with their radius. In this case, particles in the field of vision of an ultramicroscope are represented by diffraction rings and their shape is indeterminate.

In the study, the particle size and interparticle distances in finely dispersed structures were determined using micrographs taken with modern digital cameras.

The colloid particles in the field of vision of the ultramicroscope were photographed with a NIKON 5600 digital camera. As the object of photographing served calibrated colloid latex particles with radii of 600 and 1000 nm, obtained from the All-Russia Institute of Synthetic Rubbers (VNIISK) and particles from Cabernet wine produced in France and Moldova in 2004. All samples of latexes and wines were diluted 10^7-fold to make convenient observation of separate particles.

The ultramicroscope was equipped with a solid-state laser source of light with a power of 5 mW and wavelength λ = 630 nm.

Figure 1 shows micrographs of latex and wine particles in the field of vision of the microscope. Latex particles of size 600 and 1000 nm can be clearly seen. These particles have a regular spherical shape. Also seen are wine particles of irregular shape. Figure 2 shows a micrograph of a particle from French Cabernet wine, which is composed of several smaller particles. These particles are enveloped with a substance

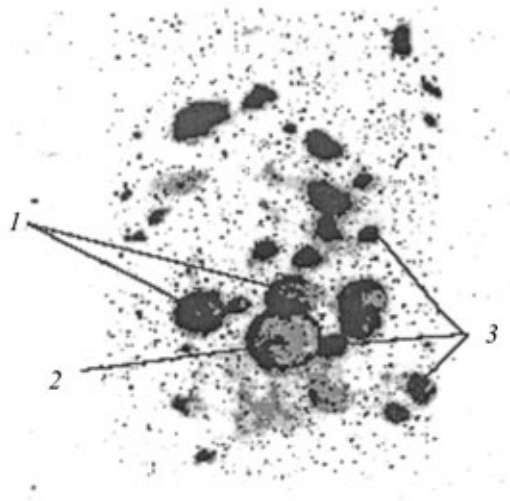

Fig. 1. Micrograph of colloid particles of a calibrated latex, with R = (*1*) 600 and (*2*) 1000 nm, and (*3*) of Cabernet wine.

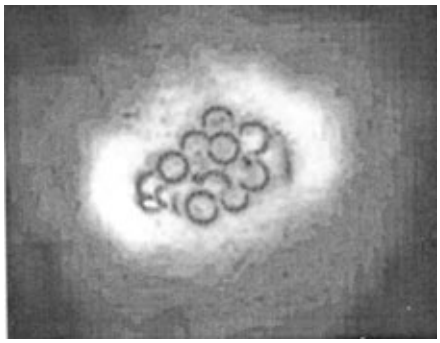

Fig. 2. Micrograph of a particle from French wine, composed of smaller particles, in the field of vision of the flow-type ultramicroscope.

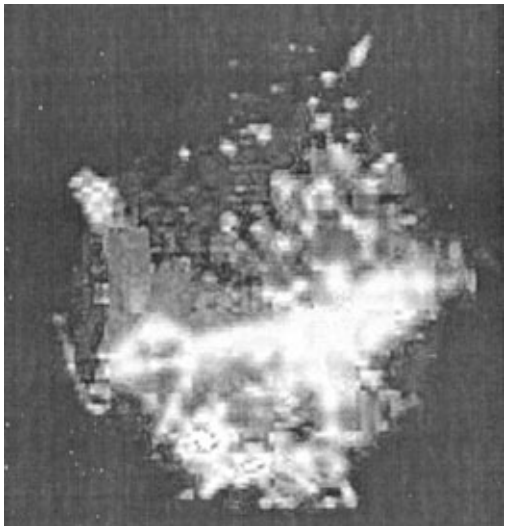

Fig. 3. Micrograph of an aggregate of particles from Cabernet wine (Moldova) after prolonged keeping at 55°C. Aggregate radius ~2000–2500 nm.

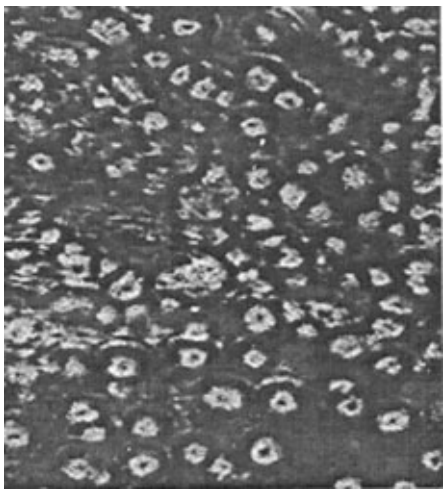

Fig. 4. Micrograph of latex particles of radius 1000 nm, taken with an MBI optical microscope (×20 objective, ×15 eyepiece).

that possibly serves as a surface layer stabilizing colloid particles in the wine. The fine particles in this aggregate are separated by spaces of width close to one tenth of the radius of these particles, whose most probable size is 120 nm [1]. This circumstance gives reason to state that, in accordance with Deryagin–Landau–Vervey–Overbeek's physical theory of stability of colloid systems (DLVO), particle aggregation occurs in the second, farther situated potential minimum in the curve of the interaction between particles vs. the interparticle distance.

Figure 3 shows a micrograph of a similar aggregate in Moldovan wine, composed of several tens of particles. The micrograph clearly shows the irregular shape of the aggregate, caused by the chaotic arrangement of the constituent particles. At the same time, chains of fine particles (~100–200 nm) are rather clearly seen in the micrograph. These chains have contacting lateral surfaces and form a primary aggregate of size smaller than that in Fig. 3.

In the micrographs presented, latex and wine particles have sizes close to the wavelength of the laser light sources. Despite the strong dilution, latex and wine particles still create a luminous background, which is superimposed on the coherent laser light and favors formation of particle images as in the ordinary optical photography. Probably, the optical image of particles is superimposed on the diffraction pattern formed by the same particles illuminated with coherent laser light. To verify this assumption, latex particles were photographed with an MBI microscope (×20 objective, ×15 eyepiece) (Fig. 4). Latex with a particle size of 1000 nm was sandwiched between a cover glass and a slide separated by a distance of 4–5 μm. The micrograph shows particles of virtually regular shape; however, their image was too small even at a high magnification of the object. Therefore, it was impossible to determine whether a surface layer was present.

Let us use the micrographs obtained to evaluate the molecular force constant (Hamaker constant A_{121}) from the potential energy of the farther potential minimum in the particle interaction curve, i.e., the overall constant determined by the interaction of a colloid particle of wine with water particles. In accordance with the DLVO theory, this energy can be found from the expression

$$U \approx -A_{121}R/12h, \quad (1)$$

where A_{121} is the Hamaker constant (J); R, particle radius (m); and h, interparticle distance (m).

Hence the Hamaker constant can be found as

$$A_{121} = 12Uh/R. \quad (2)$$

At $U = 3kT = 4.15 \times 10^{-23}$ J, a value characteristic of the second potential energy minimum, $h = 10 \times 10^{-9}$ m, and $R = 150 \times 10^{-9}$ m, the Hamaker constant $A_{121} \approx 1 \times 10^{-20}$ J. This value is in good agreement with the results of other studies [2].

The Hamaker constant directly related to the substance of a wine particle, A_{11}, can be calculated using Deryagin's concept [3], i.e.,

$$A_{121} = (A_{11}^{1/2} - A_{22}^{1/2})^2,$$

where A_{11} and A_{22} are the Hamaker constants for the substance of a particle and water, respectively: $A_{22} = 4.38 \times 10^{-20}$ J [3].

Hence follows that the Hamaker constant for the substance of a wine particle $A_{11} = 9.6 \times 10^{-20}$ J.

This value of the Hamaker constant is characteristic of colloid particles that contain oxides of metals [4], e.g., of iron and other metals, which find their way into wine from soil or wine-containing vessels.

CONCLUSIONS

Photographing of particles with a flow-type ultramicroscope gives a clearer notion of particle sizes in colloid systems, makes it possible to calculate some constants, and reveals structural features of particle aggregates and surface layers enveloping the particles.

Abstract—The composition and structure of titanium phosphate products formed in decomposition of titanite with phosphoric acid were studied. The sorption capacity of the products obtained for alkali and alkaline-earth elements was determined. The possibility of using phosphate products as titanium-containing pigment fillers was examined.

DOI: 10.1134/S1070427206100016

Titanium phosphates are widely known synthetic products used in manufacture of high-quality white paper and light-resistant plastics and serving as fillers for industrial rubber articles, building materials, and paints and as sorbents for radionuclides and ions of heavy and nonferrous metals. Each of the above-listed application fields of the product imposes certain requirements on its composition and structure, which are largely determined by the starting components and synthesis conditions [1–3]. In particular, three types of titanium phosphate with layered structure are known, which belong to ion-exchange materials. Titanium phosphate of the α-phase contains only HPO_4^{2-} groups and the formula of this compound can be represented as $Ti(HPO_4)_2 \cdot H_2O$ [4]. In the γ-phase, phosphorus(V) is present in $H_2PO_4^-$ and PO_4^{3-} groups and the composition of the phosphate corresponds to the formula $Ti(H_2PO_4)(PO_4) \cdot 2H_2O$ [5]. The third type of titanium phosphates belongs to oxo-hydroxo forms of general formula $TiO(OH)(H_2PO_4) \cdot 2H_2O$ [6]. Specific features of the layered structure of the phosphates are manifested in that protons that can be substituted by cations are situated between layers. Half of the protons form hydroxonium ions with water, and the other half, hydrogen bridges with atoms of the neighboring layer [7]. The different types of bonding of protons in the sorbent matrix predetermine their different abilities to be substituted.

As a rule, layered titanium phosphates are produced from sulfuric (hydrochloric) acid titanium-containing solutions by introduction of phosphoric acid and subsequent keeping of the reaction mass under boiling [8–10]. In the present study, we obtained titanium phosphate phases (TPP) by reacting the titanite mineral ($CaTiSiO_5$) with phosphoric acid [11, 12]. The aim of our study was to examine the composition and properties of TPP in relation to the conditions of their synthesis.

EXPERIMENTAL

Titanite $CaTiSiO_5$ was decomposed with 40–80% phosphoric acid, with the titanite-to-H_3PO_4 mass ratio in the starting mixture varied within s : l = 1 : (2–3) (in terms of 100% H_3PO_4) and the process performed in the boiling mode in the course of 12 h. The liquid and solid phases were separated by vacuum filtration of the reaction mass. Their substance composition was determined by chemical analysis. The specific surface area of the titanium phosphate solid phases (TPP) was determined by BET on a Flowsorb II 2300 electronic analyzer with degassing at 100°C for 2 h. An X-ray phase analysis (XPA) was performed with a DRON-3 instrument in Cu_{K_α} radiation. A thermogravimetric analysis of the samples was carried out in quartz test tubes at 20–980°C at a heating rate of 90 deg min^{-1}. Spectroscopic studies were performed on a UR-20 IR spectrometer.

We tested the sorption properties of the products under static conditions. For this purpose, we added to 20 ml of a solution containing 10^{-3} M of the metal ion a weighed portion of a modified sample in an amount corresponding to the mass ratio s : l = 1 : 200. We used a 0.1 N solution of NaCl as a sup-

Composition of precipitates formed in decomposition of titanite with phosphoric acid

40	27.7	31.95	5.13	20.36

porting electrolyte. The components were brought in contact for 2 h, after which the spent material was separated from the solution by filtration. The residual content of cations in the filtrate was determined and the extent of absorption of the element was calculated (in percent). The basic technical properties characteristic of the filler were determined by the techniques described in GOST (State Standard) 9808–84.

In the reaction of titanite with phosphoric acid, the crystal lattice of the mineral disintegrates and its components are converted to compounds having different solubilities in a phosphoric acid medium and in water. The precipitate formed is composed of several phases. One of these is an acid salt of composition corresponding to the formula $Ca(H_2PO_4)_2 \cdot H_2O$. Titanium(IV) forms a hydrophosphate $Ti(HPO_4)_2 \cdot H_2O$, and silicon, amorphous silica $SiO_2 \cdot nH_2O$. On treating the precipitate with water, $Ca(H_2PO_4)_2 \cdot H_2O$ completely passes into the aqueous phase. XPA data confirmed that calcium(II) is present in a washed precipitate is in particles of the undecomposed titanite. The table lists the compositions of washed precipitates (in terms of oxides) obtained in decomposition of titanite with H_3PO_4 of various concentrations.

Titanium(IV) present in the precipitate can be in the form of both TPP and particles of an undecomposed mineral. The degree of binding of titanium(IV) in TPP was calculated with account of the fact that the $TiO_2 : P_2O_5$ molar ratio in TPP is 1 : 1. The excess (not bound to P_2O_5) titanium(IV) is contained in particles of the undecomposed titanite. The extent to which titanium(IV) passes into the phosphate phase approaches 100% with a 80% H_3PO_4 and does not exceed 50% in the case of 40% H_3PO_4 (Fig. 1). Based on an analysis of structural bonds in the crystal lattice of titanite, we can conclude that, in acid treatment, bound titanium cannot dissolve faster than the calcium compound and silicon in silicon-oxygen tetrahedra cannot be activated before the Ti and Ca structural bonds are ruptured. Apparently, the Ti-cation is activated in the course of leaching-out of calcium(II), and this activation is accompanied by the formation of TPP, including that on the surface of grains of the mineral.

It was noticed that the degree of leaching-out of calcium(II) increases and, consequently, the diffusion drift of titanium(IV) to the mineral grain surface becomes faster as the acid concentration is raised. If diluted phosphoric acid is used in the decomposition process, the diffusion of titanium ions to the grain surface is hindered by the slow disintegration of calcium bonds in the structure (Fig. 2). The amount of phosphorus(V) bound to titanium(IV) increases with the content of phosphoric acid (Fig. 3). The amount of phosphoric acid did not exceed in all the experiments its stoichiometrically necessary consumption for formation of calcium and titanium(IV) phosphates. Therefore, it may be assumed that the initial content

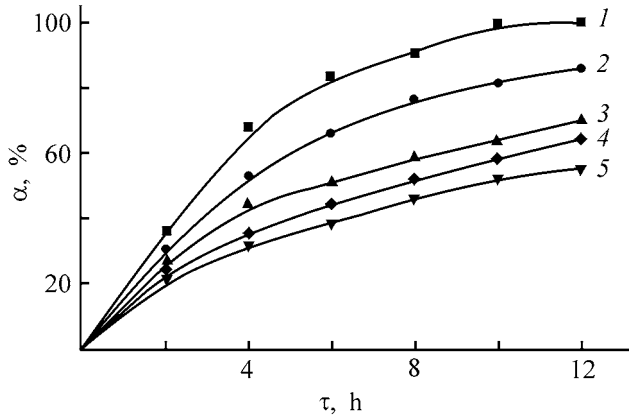

Fig. 1. Degree of binding of TiO_2 into TPP, α, vs. the process duration τ. H_3PO_4 content (wt %): (*1*) 80, (*2*) 70, (*3*) 60, (*4*) 50, and (*5*) 40.

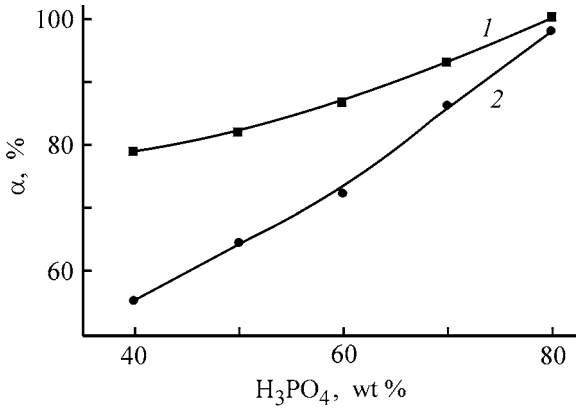

Fig. 2. Degree of binding of (*1*) CaO and (*2*) TiO_2 into TPP, α, vs. the H_3PO_4 content. Process duration 12 h.

of phosphoric acid predetermines the completeness of decomposition of the mineral.

The precipitates obtained were subjected to crystal-optic, thermogravimetric, and X-ray phase analyses and studied by IR spectroscopy.

Crystal-optical studies of TPP washed to remove calcium(II) demonstrated that, irrespective of the concentration of phosphoric acid, it is composed of $Ti(HPO_4)_2 \cdot H_2O$ and particles of undecomposed titanite and, in addition, contains amorphous silica.

The presence of two endothermic effects in the DTA curves in Fig. 4, which correspond to temperatures of 212–215 and 532–538°C and are accompanied by loss of mass, indicates that there occurs steplike dehydration of TPP. A calculation based on the TG and DTG curves demonstrated that 0.5 mol H_2O is removed below 215°C, and additional 0.5 mol H_2O, upon heating to 550–580°C. Apparently, the samples under study contain two kinds of water, which are retained in the product with different extents of firmness. The fact that the hydrogen ion is retained up to high temperatures may be only due to its presence in phosphate groups. The dehydration process presumably includes stages of removal of hydrate H_2O and water formed in condensation of acid phosphate groups. The exothermic effect at 864–873°C, which is not accompanied by any change in mass, is due to the formation of crystalline titanium diphosphate of composition TiP_2O_7. The titanium phosphate phases formed at initial H_3PO_4 contents of 50 and 40 wt % show a number of endothermic effects in the range 270–400°C. These effects are due to dehydration of hydroxy groups bound to silicon, which is formed in various modifications under the conditions specified.

The IR spectra of air-dry TPP in Fig. 5 contain high-intensity bands at 3600–3000 cm^{-1}, which are associated with stretching vibrations of water molecules and hydroxy groups, and also bands at 1600 cm^{-1}, which correspond to deformation vibrations of water molecules. To vibrations of the P–O bond of the tetrahedral PO_4^{3-} ion belong strong absorption bands at 1000 and 580 cm^{-1}. The broadening of the band at 1000 cm^{-1} is due to superposition of vibrations of SiO_4 tetrahedra. The weak band at 700 cm^{-1} can be attributed both to vibrations of the O–P–O bonds in the PO_4^{3-} ion and to active vibrations of O–Ti–O in the octahedral group of titanium. The absorption bands at 550–450 cm^{-1} are associated with deformation vibrations of P–O and Ti–O groups [13].

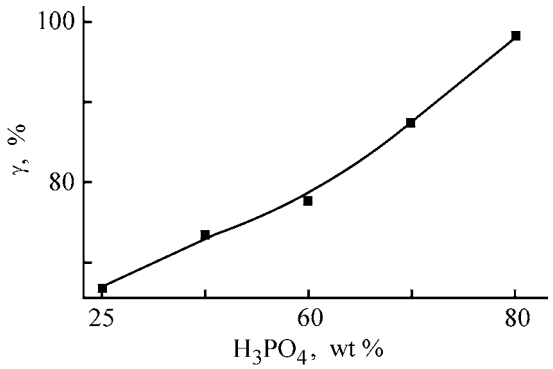

Fig. 3. Degree of P_2O_5 binding, γ, relative to the stoichiometry vs. the content of H_3PO_4.

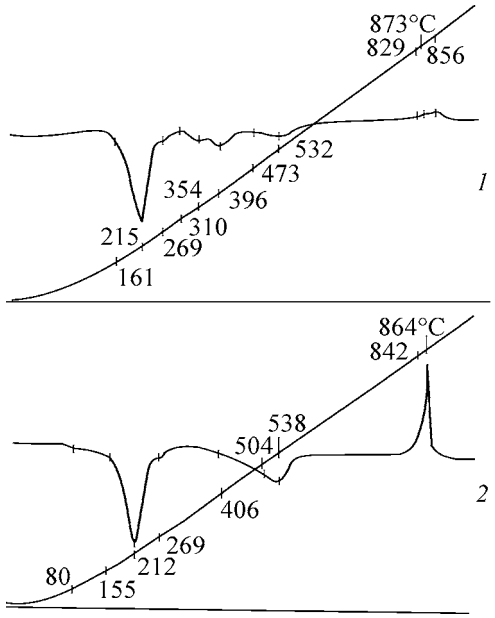

Fig. 4. Thermogram of the precipitate formed in decomposition of titanite with H_3PO_4. H_3PO_4 content (wt %): (*1*) 50 and (*2*) 80; the same for Fig. 5.

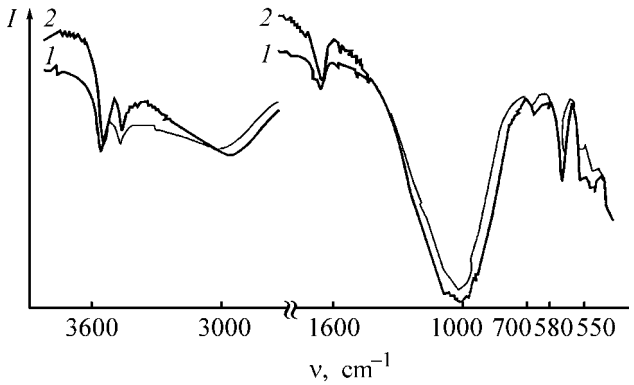

Fig. 5. IR spectra of products formed in decomposition of titanite with H_3PO_4. (*I*) Intensity and (ν) wavenumber.

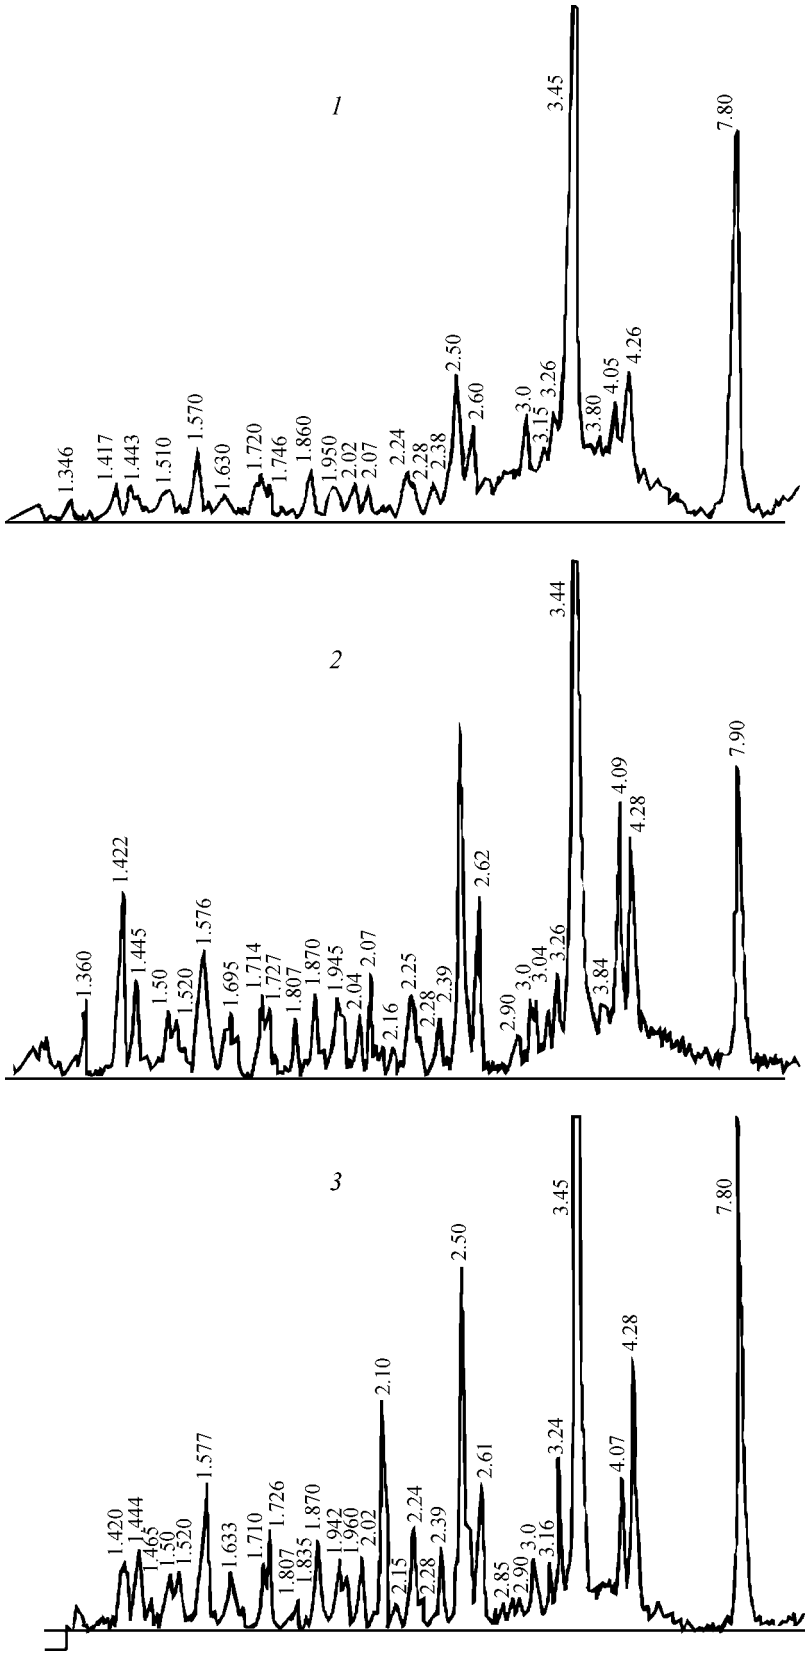

Fig. 6. X-ray diffraction patterns of the product formed in decomposition of titanite with H_3PO_4. H_3PO_4 content (wt %): (*1*) 40, (*2*) 60, and (*3*) 80.

According to XPA, all the TPP samples calcined at 850°C contain, in addition to the main crystalline phase (TiP_2O_7), an admixture of the titanite mineral, and its amount is the higher, the lower the H_3PO_4 concentration at which the product was synthesized. The air-dry product is a crystalline substance of composition $Ti(HPO_4)_2 \cdot H_2O$ (Fig. 6). Lowering the concentration of phosphoric acid in TPP synthesis results in that the intensities of the main reflections decrease and weak peaks disappear. On the whole, the diffraction pattern indicates that, irrespective of TPP synthesis conditions, the phase compositions remains virtually the same, but the packing order of layers and the type of internal bonds change. Presumably, the main phase $Ti(HPO_4)_2 \cdot H_2O$, contained in TPP, can be identified as the known layered α-phase of titanium phosphate. The hydrated silica phase is not involved in the formation of the structure of titanium phosphate and is an inert component in the precipitate formed in the reaction of titanite with H_3PO_4.

The specific surface area of TPP varies within the range 35–70 $m^2\ g^{-1}$, and the pore volume, within 0.1–0.2 $cm^3\ g^{-1}$. Lowering the H_3PO_4 content leads to an increase in the specific surface area of the product.

Figure 7 presents data on the sorption capacity of TPP for ions of alkali and alkaline-earth elements. It can be seen that the products obtained with 50–60 wt % H_3PO_4 effectively sorb cations. More severe synthesis conditions favor formation of compact precipitates, which impairs their sorption properties. The precipitates formed with dilute phosphoric acid contain up to 20–25% undecomposed mineral, which also makes lower their sorption capacity. It was noticed that the transfer of the sorbent to the sodium form by treatment with a NaOH solution and the subsequent grinding lead to an increase in the sorption capacity of the material. The maximum degree of sorption is 98% for Cs^+ ions and 79% for Sr^{2+}. The possible explanation of the lower degree of sorption for strontium(II) is that Cs^+ ions are sorbed in the whole volume of a sorbent particle, whereas sorption of Sr^{2+} probably occurs mainly on its surface.

To find out whether TPP can be used as pigment filler, we calcined it at 550–600°C and then ground the material in a vibration mill. These operations, successively, make the precipitate structure denser and raise the dispersity of its particles, which brings the values of such pigment parameters as oil (moisture) capacity and covering power to the required values. A sample of the pigment filler was successfully tested in a dry building mixture instead of the expensive titanium dioxide.

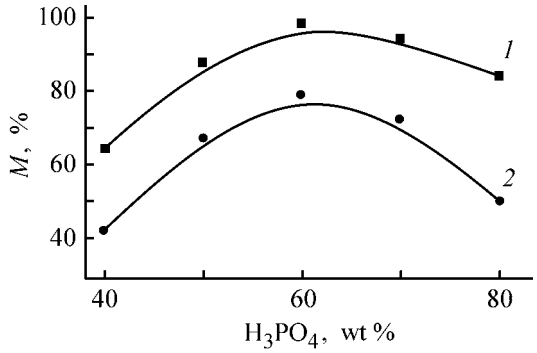

Fig. 7. Sorption capacity of TPP for (*1*) Cs^+ and (*2*) Sr^{2+} ions. (*M*) Degree of absorption of metal ions and ($[H_3PO_4]$) acid content.

CONCLUSIONS

(1) The reaction of titanite with phosphoric acid under boiling conditions leads to conversion of the components of the mineral to compounds with different types of behavior in an aqueous solvent, which enables effective separation of titanium(IV) and calcium(II).

(2) Titanium(IV) is formed as a layered titanium hydrophosphate, $Ti(HPO_4)_2 \cdot H_2O$. Hydrated silicon oxide remaining in the precipitate, together with titanium hydrophosphate, after separation of calcium(II) is not involved in the formation of the structure of the precipitate, being only its inert component.

(3) The formulation composed of titanium hydrophosphate and hydrated silicon dioxide has a rather high sorption capacity for cations of alkali and alkaline-earth elements and its thermal treatment yields a high-quality pigment filler.

(4) The data obtained can serve as a physicochemical substantiation of the choice of technological parameters in phosphoric acid processing of titanite, a waste product formed in integrated processing of apatite-nepheline ores.

SORPTION AND ION-EXCHANGE PROCESSES

Ion-Exchange Recovery of Nickel(II) from Wash Water Formed in Electroless Plating in Acid Hypophosphite Solutions

E. S. Plokhov, M. G. Mikhalenko, and S. V. Plokhov

Abstract—Kinetic aspects of extraction of Ni(II) ions with KU-2-8 cation-exchange resin in the Na^+ form from wash water produced in electroless nickel-plating were studied. The optimal conditions and parameters of ion-exchange purification and regeneration of the cation-exchanger were determined.

DOI: 10.1134/S1070427206100028

Despite the undeniable advantages of Ni–P coatings [1–3], a wider industrial application of processes for their deposition from acid hypophosphite solutions is hindered by the formation of large amounts of liquid nickel-containing waste [4], mostly constituted by spent plating solutions and wash water. The amount of this waste can be reduced to a minimum by integrated solution of the following problems: use of effective stabilizers in solutions for electroless nickel-plating, optimization of the plating and electrolyte adjustment conditions and of the composition of the adjusting solution used in plating, development of technologies for recovery and utilization of components from spent solutions and wash water [5]. The best technical and economic effect is achieved by purification of wash water to remove nickel(II) ions. It is known that joint use of ion exchange and electrolysis, with preliminary sorption treatment of wash water with activated carbon, is advisable for recovery of heavy metals ions from wash water [6–10].

The aim of this study was to determine the fundamental kinetic aspects and the optimal conditions and parameters of ion-exchange recovery of Ni(II) from wash water after electroless nickel-plating in acid hypophosphite solutions.

As objects of study served model solutions and industrial wash water of the following composition ($g\ l^{-1}$): $NiSO_4 \cdot 7H_2O$ 0.3–1.25 (in terms of nickel ions), sodium hypophosphite (NaH_2PO_2) 2.0, sodium phosphite (NaH_2PO_3) 0.4, sodium acetate 2.2, and CH_3COOH 3. The pH value was 4.5. The electrolyte temperature was $20 \pm 2°C$. The concentrations of impurity metal ions [Cu(II), Zn(II), Fe(III), and Sn(II)] in wash water were very low because of the short time of use of electroless nickel-plating solutions, which did not allow their quantitative determination. Removal of these ions was not considered in this study and they were not introduced into model solutions, because they had virtually no effect on the results of ion-exchange recovery of nickel(II). No stabilizer (thiourea, 0.0005 $g\ l^{-1}$) was introduced, either, into model solutions, because wash water is subjected to sorption treatment before ion exchange and this completely extracts the stabilizing agent from it.

The ion-exchange recovery of Ni(II) from wash water was studied on a laboratory setup comprising a glass column with an inner diameter of 0.019 m. The ratio of the inner diameter of the column to the height of a bed of the swollen ion exchanger was 1 : 9. The mass of the KU-2-8 cation exchanger in the Na^+ form in the column was 21.89 g. The concentration of nickel cations in wash water and in eluates was determined by spectrophotocolorimetry [11] and atomic-absorption spectroscopy [12] on SF-26 and SF-115 Saturn spectrophotometers, respectively. The relative determination error did not exceed ±2%.

Wash water produced in electroless nickel-plating in acid hypophosphite solutions contains nickel(II) in several cationic forms. Together with simple hydrated Ni^{2+} aqua-complex ions, $[Ni(H_2O)_n]^{2+}$ (n = 1–6) are present in the wash water, the most stable of which is the complex ion with octahedral structure [13].

The ion-exchange purification was performed to remove all kinds of nickel ions without separation. For this purpose, the cation exchanger was used in

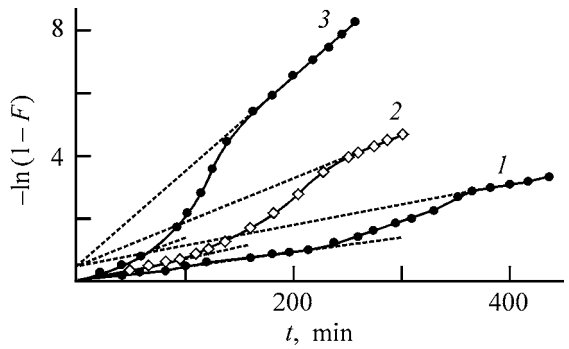

Fig. 1. Dynamic curves of nickel(II) sorption on KU-2-8 cation exchanger in the Na^+ form. (F) Degree of saturation of the ion exchanger and (t) time. Initial nickel(II) concentration in wash water ($g\ l^{-1}$): (*1*, *2*) 0.75 and (*3*) 1.25. Flow rate of wash water ($m^3\ m^{-2}\ h^{-1}$): (*1*) 0.5 and (*2*, *3*) 1.0.

the Na^+ form. The preferable use of the salt form of the ion exchanger, compared with the H^+ form, is due to the subsequent electrochemical treatment of eluates. The electroreduction of nickel(II) to metal from strongly acidic eluates requires a considerable expenditure of sodium hydroxide for bringing their pH to 2.0 [9]. This disadvantage can be avoided by using the cation exchanger in the salt form.

We studied the fundamental kinetic aspects of the ion-exchange recovery of nickel(II) from washing solutions with KU-2-8 cation exchanger in the Na^+ form by the dynamic method. For this purpose, we determined experimentally the dependences of the Ni(II) concentration after the ion exchanger on the time t during which the wash water was passed at various initial concentrations of metal ions in the liquid phase and various rates of its flow across the ion-exchanger bed (outlet ion exchange curves). From these dependences, we calculated dynamic curves of sorption of nickel(II) ions, plotted in the $-\ln(1 - F)$–t coordinates ($F = Q/Q_\infty$ is the degree of saturation of the ion exchanger, Q and Q_∞ are the running and limiting masses of the metal ions being recovered). The values of Q were determined by graphical integration of the outlet ion exchange curves, and the value of Q_∞, by extrapolation of the $Q = f(t)$ dependences to $t \to \infty$. Some of the dynamic sorption curves are shown in Fig. 1. Other sorption curves were of a similar shape. According to the ion-exchange theory, the presence of linear portions with different slopes in the dynamic sorption curves at low ($F \le 0.05$) and high ($F \ge 0.8$) degrees of saturation of the cation exchanger indicates that the process is outer- and inner-diffusion-controlled, respectively [14]. Hence, the ion exchange occurs, on the whole, under conditions of a mixed-diffusion kinetics. At low degrees of saturation of the cation exchanger, the ion-exchange recovery of Ni(II) is controlled by outer diffusion, i.e., by the mass transfer of metal ions from the bulk of the liquid phase to the surface of the ion exchanger. At high F values the inner diffusion (mass transfer of metal ions in the bulk of the ion exchanger) becomes the limiting stage.

The above conclusion about the nature of the limiting stage was additionally confirmed by calculation of the effective diffusion coefficient of nickel ions. For this purpose, we used the so-called basic equation of the inner-diffusion kinetics [15], which has for simple models of ion-exchanger particles (sphere, plate, and cylinder) the form

$$\ln(1 - F) = Bt - \ln A. \quad (1)$$

Here A and B are coefficients dependent on the diffusion mode.

Application of expression (1) is justified at $F \ge 0.8$. The extrapolation of linear portions of the sorption curves at high degrees of saturation of the ion exchanger to the ordinate axis (Fig. 1) gives 0.607 for coefficient A. This allows us to describe the ion-exchange process using the mathematical model of "a sphere with a shell" with $A = 0.61$ [15] and coefficient B given by

$$B = D\pi^2/R^2. \quad (2)$$

Here D is the effective diffusion coefficient of the ion being sorbed ($cm^2\ s^{-1}$), and R, the average grain radius of the ion exchanger, 0.125 cm.

The effective diffusion coefficient can be calculated by expression (2) if coefficient B is known.

We found coefficient B from expression (1) as the slope of linear portions of the experimental sorption curves (Fig. 1) at high degrees of saturation of the ion exchanger. The values of D, calculated by formula (2), were $(1.7–7.5) \times 10^{-7}$ $cm^2\ s^{-1}$, which corresponds in order of magnitude to the mixed-diffusion control over the ion-exchange process [14]. It is important to note that the theory of ion exchange under conditions of mixed-diffusion kinetics is not fully elaborated, and the equation of the inner-diffusion kinetics, which is used to describe the process, is exact only in static conditions. Therefore, the calculated values presented here should be regarded as qualitative.

The parameters of the ion-exchange recovery of Ni(II) from wash water can be improved under con-

ditions of mixed-diffusion kinetics and a cation exchanger of standard brand with known properties only by affecting the outer-diffusion stage, whose effectiveness depends mainly on the initial concentration of nickel ions in the liquid phase and on the rate at which they are passed across the ion-exchanger bed. As the parameters of the ion-exchange process serve the dynamic exchange capacity (DEC) and the breakthrough capacity (BC). The dynamic exchange capacity is the maximum mass of Ni(II) ions retained by 1 kg of a swollen ion exchanger in the given conditions of wash water flow, and BC, the maximum mass of Ni(II) ions retained by 1 kg of the swollen ion exchanger until nickel(II) appears after the cation exchanger [7].

The fact that the outer-diffusion stage contributes to the control over the process allows us to explain the dependences of DEC and BC on the flow rate U of wash water across the cation-exchanger bed (Fig. 2a), which were obtained by integrating the outlet ion exchange curves. An increase in the flow rate diminishes the time of contact of each elementary volume of wash water with the cation exchanger, which must make the ion-exchange parameters smaller. At the same time, the increase in the flow rate reduces the depth of the diffusion layer, which leads to a rise in the DEC and BC. Apparently, with U raised to 1.0 $m^3 m^{-2} h^{-1}$, the time of contact between the phases is sufficient and the key factor is the depth of the diffusion layer. Therefore, an increase in DEC and BC is observed. For flow rates higher than 1.0 $m^3 m^{-2} h^{-1}$, the key factor is the contact time, whose deficiency results in a decrease in the ion-exchange parameters. Consequently, the flow rate of 1.0 $m^3 m^{-2} h^{-1}$ corresponding to the maximum values of DEC and BC (33.0 and 19.7 g kg^{-1}, respectively) is the optimal for Ni(II) recovery.

The dependences of DEC and BC on the initial Ni(II) concentration in wash water, $c_{Ni\ (II)}$, obtained from outlet cation-exchange curves, also had maxima at 0.75 g l^{-1} (Fig. 2b). The constancy of the flow rates of wash water ensured that the diffusion layer depth and the time of contact between the phases were invariable. Under these conditions, the ion exchange parameters are affected by the contact time and by the gradient of Ni(II) concentration in the diffusion layer. An increase in $c_{Ni\ (II)}$ to 0.75 g l^{-1} makes the gradient of Ni(II) concentration in the diffusion layer higher and, at a sufficient contact time, causes a rise in DEC and BC. Further increase in the initial Ni(II) content of the liquid phase and in the concentration gradient occurs under the conditions of an insufficient contact time. Furthermore, the increase in

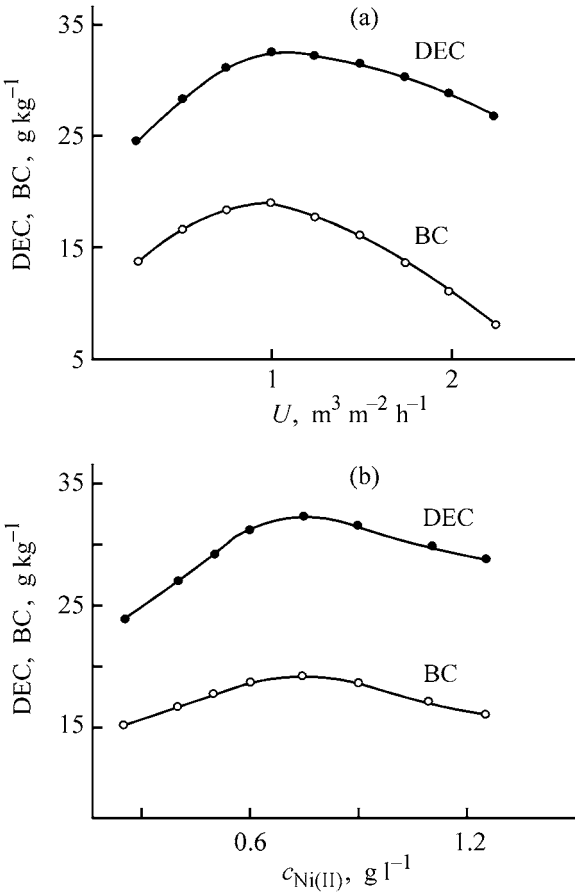

Fig. 2. Dependences of DEC and BC on (a) flow rate U of wash water and (b) concentration $c_{Ni(II)}$ of nickel ions in the water. KU-2-8 cation exchanger in the Na^+ form; Ni(II) concentration 0.75 g l^{-1}; (a) flow rate of wash water 1.0 $m^3 m^{-2} h^{-1}$.

the concentration enhances the ion–ion interaction (repulsion) of hydrated nickel-containing ions at the phase boundary. All these factors result in that DEC and BC decrease at Ni(II) concentrations higher than 0.75 g l^{-1}. Hence, the initial Ni(II) concentration of 0.75 g l^{-1} in wash water is the optimal value for ion-exchange recovery of metal ions.

The maxima in the dependences of DEC and BC on U and on the concentration have been observed previously [6–8, 10] when studying the ion-exchange recovery of heavy metal ions from wash water produced in various electrochemical processes (copper-, zinc-, nickel-, and chromium-plating). In [16], the basic equation of inner-diffusion kinetics (1) was transformed. A mathematical analysis of the resulting expression demonstrated that, under the conditions of mixed-diffusion kinetics, the dependences of DEC and BC on the flow rate and concentration must exhibit maxima because of the variation of the contact time,

Mass of nickel(II) recovered in regeneration

Na_2SO_4, g l^{-1}	Mass of nickel(II), g, recovered in indicated time, h				
	0.66	1.33	4.0	7.0	21.0
25	0.035	0.067	0.070	0.082	0.084
50	0.048	0.066	0.074	0.078	0.086
100	0.062	0.070	0.074	0.086	0.092
150	0.057	0.065	0.068	0.070	0.072

diffusion layer depth, and concentration gradient within this layer. Apparently, the same can be done with the basic equation of outer-diffusion kinetics. However, solution of this problem is beyond the scope of the present study.

The ion exchanger saturated in optimal conditions was regenerated with sodium sulfate solutions. By analogy with the saturation, the regeneration efficiency mainly depends on the concentration of the eluent and on its flow rate across the ion-exchanger bed.

The effect of eluent concentration on the regeneration efficiency was studied by the static method. For this purpose, equal weighed portions of the cation exchanger (4.0 g) were poured-over with Na_2SO_4 solutions of various concentrations, provided that the amount of anhydrous sodium sulfate was the same in all the experiments (12.5 g). The mass of Ni(II) removed from the cation exchanger by a certain instant of time was determined by chemical analysis of the liquid phase.

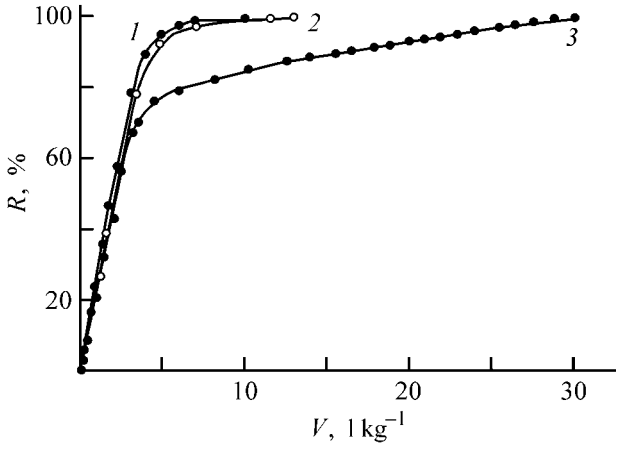

Fig. 3. Dependence of the degree of regeneration, *R*, of the cation exchanger on the volume *V* of the eluent solution passed. Na_2SO_4 concentration 100 g l^{-1}. Flow rate of the solution (m^3 m^{-2} h^{-1}): (*1*) 0.25, (*2*) 0.5, and (*3*) 1.0.

It is seen from the table that, at any instant of time, the largest mass of Ni(II) recovered from the cation exchanger corresponds to the Na_2SO_4 concentration of 100 g l^{-1}. Therefore, a solution containing 100 g l^{-1} of the eluent was considered the optimal for regeneration.

Experiments on regeneration in various hydrodynamic conditions allowed us to determine the optimal flow rate of the eluent across the cation-exchanger bed. It is 0.25 m^3 m^{-2} h^{-1} (Fig. 3), because at this flow rate the minimal volume of the eluent is expended for the complete regeneration, and the highest degree of regeneration degree is achieved. Use of flow rates lower than 0.25 m^3 m^{-2} h^{-1} is technologically inexpedient.

The ion exchange is a reversible process [14, 15], i.e., the regeneration can be regarded as saturation of the cation exchanger in the Ni^{2+} form with Na(I) ions. Therefore, the explanation of the extremal behavior of the dependences of regeneration parameters on the concentration of the eluent solution and on its flow rate is analogous to that in the case of nickel(II) recovery from wash water.

Analysis of curve *1* (Fig. 3) shows that, to save chemicals, reduce the regeneration time, and obtain eluates with a higher Ni(II) concentration (6.0 g l^{-1}), the regeneration should be carried out not completely, but to a 90% degree of regeneration, because this requires only a half of the eluent volume necessary for the complete regeneration. The reduction of the degree of regeneration of the ion exchanger will diminish DEC and BC by 10% in the case of a multiple use of the cation exchanger. This should be taken into account when designing ion-exchange equipment.

The results obtained in this study can be used to tackle with ecological problems of factories that employ processes of electroless nickel-plating and to design local systems for wash water purification with utilization of the metal recovered.

CONCLUSIONS

(1) It was found that the ion-exchange recovery of Ni(II) with the KU-2-8 cation exchanger in the Na^+ form from wash water produced in electroless metal plating in an acid hypophosphite electrolyte occurs under conditions of mixed-diffusion kinetics and is described by a mathematical model of "a sphere with a shell." At low degrees of saturation of the ion exchanger, the limiting stage is that of outer diffusion, whereas at high degrees of saturation, the process is controlled by the inner-diffusion stage.

(2) The optimal conditions and parameters of the ion-exchange recovery of metal ions from wash water produced in electroless nickel-plating were determined on a laboratory setup: initial Ni(II) concentration in the liquid phase 0.75 g l^{-1}; flow rate of the liquid phase across the cation-exchanger bed 1.0 $m^3 m^{-2} h^{-1}$; regeneration of the ion exchanger with a solution of 100 g l^{-1} Na_2SO_4, which flows at a rate of 0.25 $m^3 m^{-2} h^{-1}$ across the ion-exchanger bed, to a 90% degree of regeneration with a single use of the eluent to give eluates containing 6.0 g l^{-1} of nickel ions and 85 g l^{-1} of sodium sulfate.

(3) A physicochemical explanation was given for the experimental dependences of the dynamic exchange capacity and the breakthrough capacity on the flow rate of the solutions across the cation-exchanger bed and on the initial nickel(II) concentration in these solutions. The maximum values of the dynamic exchange capacity and the breakthrough capacity were found to be 33.0 and 19.7 g kg^{-1} of the ion exchanger, respectively.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Capacity of Acetylacetonated Humin-Like Compounds with Respect to Cations of Heavy Metals

Abstract—A method of synthesis of acetylacetonated humin-like compounds was developed. The effect of modification on the sorption capacity of humin-like compounds with respect to heavy metals was studied.

DOI: 10.1134/S107042720610003X

Humic substances (HS) have been studied for more than 200 years, and the number of papers devoted to the chemical structure, biological activity and practical applcation of HS and humin-like compounds (HLC) steadily grows, especially in the recent years. Economically developed countries, such as the United States, Germany, Canada, etc. make large investments in these studies. The interest of chemists and soil scientists in more complete and detailed studies of HS and HLC is caused by several reasons. Firstly, HS and HLC are of natural origin and positively affect the growth and evolution of plants. Therefore, these substances and complex fertilizers on their base find growing use in agriculture. Secondly, HS and HLC exhibit a pronounced pharmaceutical activity and can be used as highly active antioxidants, immunomodulators, biostimulants, bactericidal, antiviral, and antiumor preparations. Thirdly, due to their unique ability to bind heavy metals and radionuclides, HS and HLC can be used to solve environmental problems. In this conntext, growing attention is given to complexation HS and HLC with metal ions. For instance, it was found that small amounts of HS and HLC almost completely inhibit toxic influence of heavy metals on microorganisms and plants, even at high metal concentrations. HS and HLC similarly affect pesticides and transform them into inactive forms gradually decomposing into nontoxic compounds. Thus, due to high protecting activity with respect to the above pollutants and toxic substances, HS and HLC can be used for purification of subsoil water, soil, and atmosphere to remove heavy metals, radionuclides, and pesticides. In this context, studies aimed to enhance the complexing ability of HS and HLC with respect to heavy metal ions by chemical modification are of interest. A wide spectrum of synthetic macromolecular β-dicarbonyl compounds that can form stable polychelates with Cu, Fe, Co, Ni, Ca, Zn, Th, UO_2^{2+}, and rare-earth metal (REM) ions have been prepared [1]. However, introduction of β-dicarbonyl fragments, and, in particular, acetylacetone (AA) fragment into HS and HLC has not been described. At the same time, such a modification of HS and HLC would enhance the ability of HS and HLC to sorb metal ions.

The goal of our study was to develop a method for introduction of AA fragment into tea HLC structure and to examine the sorption capacity of the initial and modified HLC with respect to heavy metal ions.

The probable modification pathway is chloromethylation of HS and HLC, followed by nucleophilic substitution of chlorine by β-diketone fragments, in particular, AA. The choice of tea HLC as a subject of the study is firstly caused by the fact that they, in contrast to peat, coal, and sapropelic HS, have almost no mineral fraction that could affect the sorption activity of modified HLC. Secondly, tea HLC have a higher content of phenolic groups and lower average molecular weight, which suggests their higher reactivity as compared to the above HS in the stage of chloromethylation of the initial HLC and weaker steric hindrances in the stage of acetylacetonation of chloromethylated HLC.

EXPERIMENTAL

The objects of this study were HLC recovered from tea, chloromethylated HLC prepared by two methods (ChMHLC-1 and ChMHLC-2), and acetylacetonated HLC (AAHLC-1 and AAHLC-2) prepared from these intermediates.

To isolate HLC, a sample (~4 g) of black tea (preliminarily purified to remove bitumens by extraction with toluene for 8 h in a Soxhlet apparatus) was treated with 450 ml of 0.1 M KOH in a 1-l Erlenmeyer flask under stirring with a mechanical stirrer at 90°C (water bath) for 1 h. Then, the solution was allowed to stay for 2 h and then was centrifuged for 10–15 min (8000 rpm). The residue in the flask was treated with a fresh portion of 0.1 M KOH (450 ml), and the above procedure was repeated two times. All the centrifugates, which are brown-black solutions of HLC potassium salts, were combined and a 6 M HCl solution was added to pH ~2. In so doing, HLC was separated as a brown voluminous precipitate. It was centrifuged (8000 rpm), separated from the reddishbrown acidic solution of fulvic acid, washed with distilled water to pH ~5, and dried in a vacuum desiccator or a Fischer pistol in a vacuum at 60°C to constant weight. The HLC obtained (~2.5 g) were ground in an agate mortar and stored as a fine brown powder in a weighing bottle with a ground-glass stopper. A 19.9-g portion of tea HLC was prepared by this method.

Chloromethylation was performed by two methods: (1) without catalyst by heating a mixture of HLC with 40% formalin and concentrated hydrochloric acid, with bubbling gaseous HCl and (2) with $ZnCl_2$ as a catalyst. The reaction equations are as follows:

$$\text{HLC-H} + CH_2O + HCl \xrightarrow{H^+,\ \text{HCl solution}} \text{HLC}{-}CH_2Cl + H_2O,$$

$$\text{HLC-H} + CH_2O + HCl \xrightarrow{ZnCl_2,\ CCl_4} \text{HLC}{-}CH_2Cl + H_2O.$$

In the first case, to a mixture of the initial HLC (3 g) with $HCl_{(conc.)}$ (ρ = 1.19 g ml^{-1}, 12.6 ml) (weight ratio of HLC to HCl solution 1 : 5) in a 50-ml Erlenmeyer flask at stirring with a magnetic stirrer, we added 0.4 ml of 40% formalin (ρ = 1.071 g ml^{-1}) at a HLC to formalin weight ratio of 7 : 1. A strong flow of gaseous HCl (prepared by the reaction of concentrated sulfuric acid with dry NaCl) was bubbled for 2 h through this mixture at 60°C and continuous stirring. A precipitate of chloromethylated HLC (ChMHLC-1) was filtered through a fine-pore Schott filter no. 4 under vacuum, repeatedly washed with distilled water to pH 7, and dried to constant weight in a vacuum desiccator over anhydrous $CaCl_2$ at 20°C. As a result, 2.1303 g of ChMHLC-1 was prepared as a fine brown powder.

In the second case, to an HLC suspension (3 g) in dry CCl_4 (40 ml) in a 100-ml three-necked flask equipped with a reflux condenser with a $CaCl_2$ tube, a tube for supply of gaseous HCl, and a magnetic stirrer, we added with stirring paraformaldehyde (0.43 g) [weight ratio of HLC to $(CH_2O)_n$ = 7 : 1] and anhydrous $ZnCl_2$ (0.175 g) (weight ratio of HLC to $ZnCl_2$ = 40 : 1). A strong flow of gaseous HCl (prepared by the reaction of concentrated sulfuric acid with dry NaCl) was bubbled through this mixture with continuous stirring for 2 h. A precipitate of chloromethylated HLC (ChMHLC-2) was filtered through a fine-pore Schott filter no. 4 under vacuum, washed with dry CCl_4, and then repeatedly washed with distilled water to pH 7 and dried to constant weight in a vacuum desiccator over anhydrous $CaCl_2$ at 20°C. As a result, 2.4281 g of ChMHLC-2 was prepared as a fine brown powder.

The ChMHLC-1 and ChMHLC-2 intermediates were treated with Na-AA obtained by treatment of AA with sodium ethylate in dehydrated ethanol:

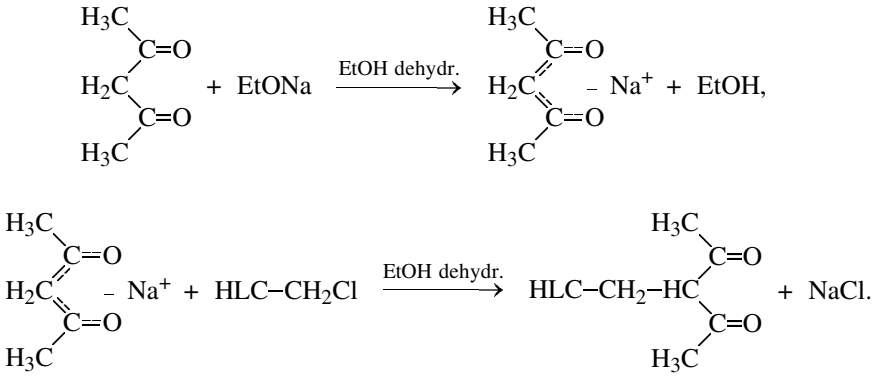

Table 1. Elemental analysis of the initial HLC, ChMHLC-1, 2, and AAHLC-1, 2

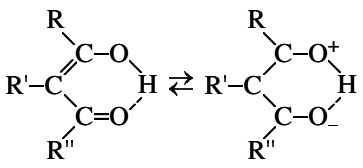
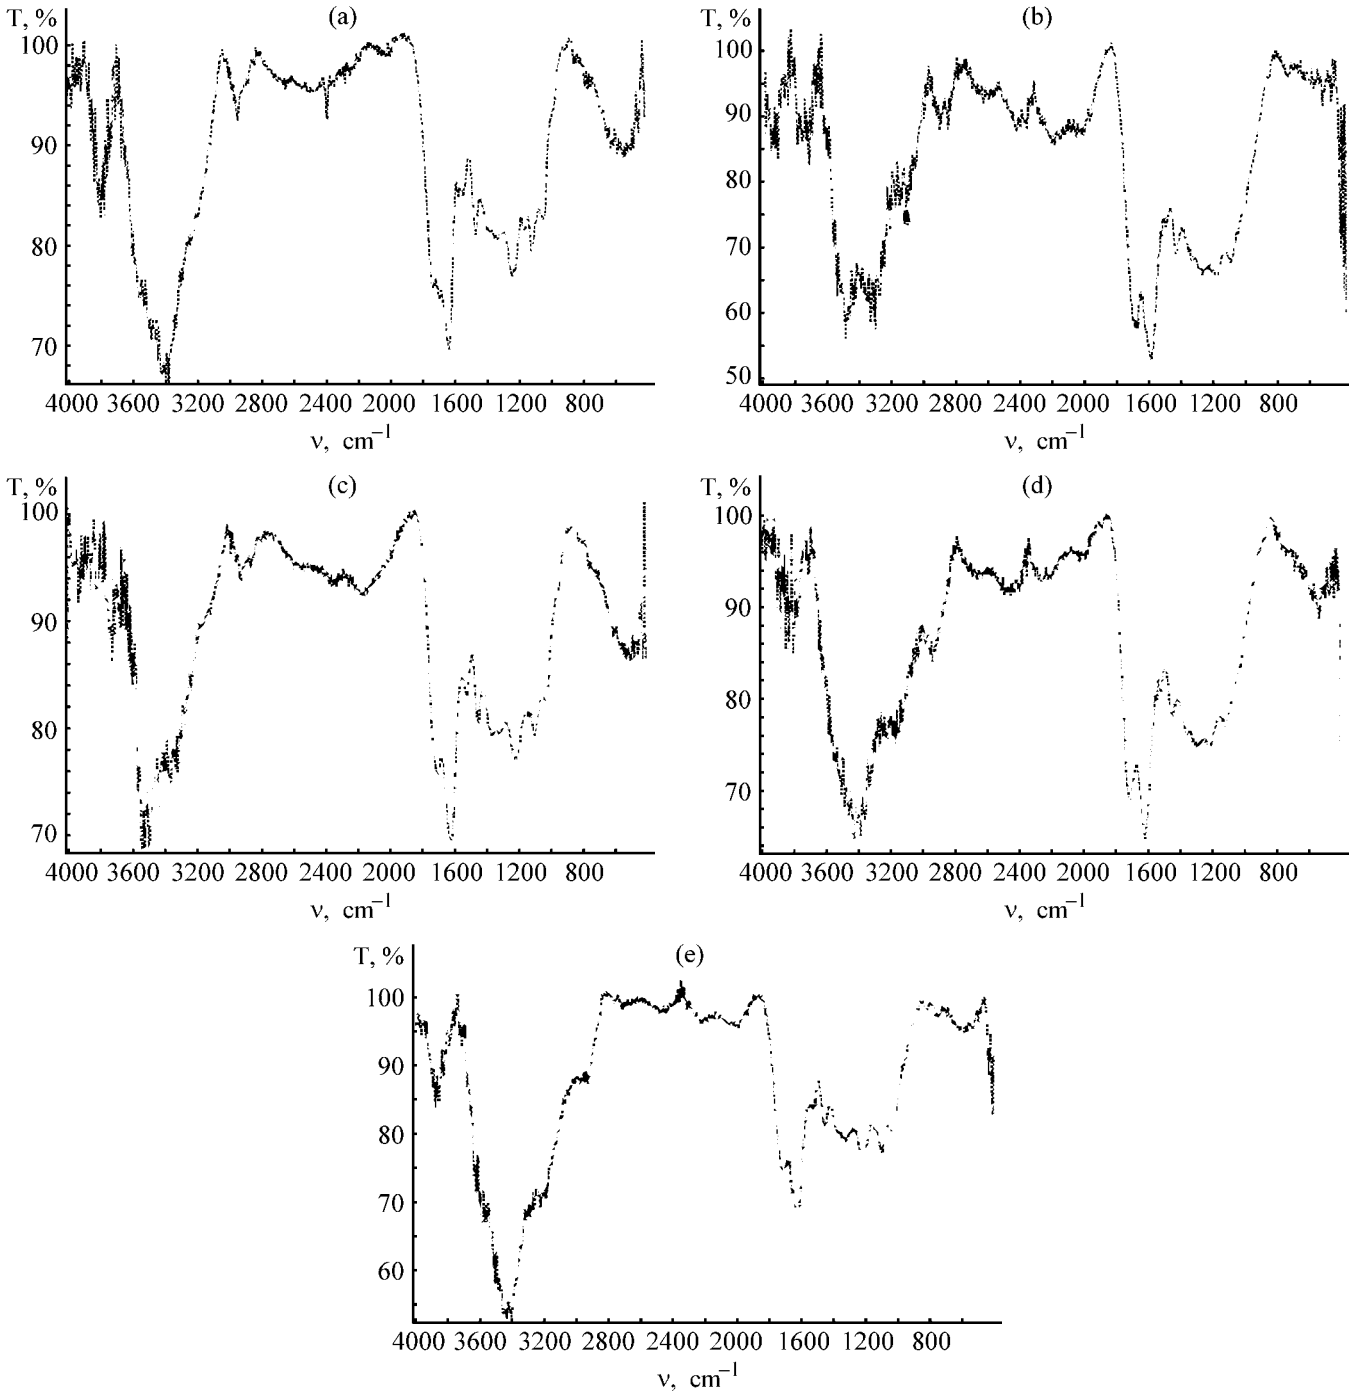
Sample	Content, wt %			
	C	H	N	O(+Cl)
Initial HLC	49.59	4.93	3.36	42.12
ChMHLC-1	47.61	4.76	3.14	44.49
ChMHLC-2	43.67	4.43	2.71	49.19
AAHLC-1	48.78	5.45	3.02	42.75
AAHLC-2	47.18	6.50	2.34	43.98

Table 2. Metal ion concentrations before and after treatment with initial and acetylacetonated HLC

Cations	Concentration, mg l^{-1}			
	initial solutions	initial HLC	AAHLC-1	AAHLC-2
Pb^{2+}	212.4	31.2	5.1	2.2
Cd^{2+}	104.3	104.2	52.2	21.2
Cu^{2+}	61.3	58.1	3.4	1.0
Mn^{2+}	60.5	59.2	56.4	52.5
Zn^{2+}	62.7	60.2	36.0	25.0



A solution of sodium ethylate in dehydrated ethanol was prepared by dissolving sodium (0.4242 g) in dehydrated ethanol (9.22 ml) in a 50-ml Erlenmeyer flask. To an EtONa solution, AA (1.89 ml) was added with stirring. The mixture appreciably warmed up, and after cooling, white NaAA crystals precipitated. The suspension obtained was heated to 60°C under stirring with a magnetic stirrer. The NaAA crystals dissolved to form a transparent solution containing about 30 wt % NaAA. To this solution, ChMHLC-1 or ChMHLC-2 (2 g; weight ratio of ChMHLC-1, 2 : NaAA = 8 : 9) was added with stirring. The reaction mixture was stirred at 60°C for 5 h, and then an AHLC-1, 2 precipitate was filtered through a fine-pore Schott filter no. 4 under vacuum and washed three times with dehydrated EtOH, three times with 10% HCl, and then with distilled water to pH 7. The resulting AAHLC-1 and AAHLC-2 samples were dried to constant weight in a vacuum desiccator over anhydrous $CaCl_2$. The weights of AAHLC-1 and AAHLC-2 samples, which are fine light brown powders, were 2.0066 and 1.7069 g, respectively.



The elemental analysis of the initial HLC, ChMHLC-1, 2, and AAHLC-1, 2 was performed on a Carlo Erba-1100 gas-chromatographic analyzer. The results obtained are listed in Table 1.

The complexing ability of AAHLC-1, 2 and initial HLC with respect to heavy metal ions was measured. 0.2-g samples of HLC, AHLC-1 and AHLC-2 were stirred with a magnetic stirrer for 2 h in a 50-ml Erlenmeyer flask with 8 ml of ~0.001 M $ZnSO_4$, $MnSO_4$, $CuSO_4$, $Pb(NO_3)_2$, and $CdCl_2$ solutions. Then the precipitates of HLC and AHLC-1, 2 were filtered through a Schott filter no. 4 under vacuum, and the filtrates and initial salt solutions were analyzed on a Saturn-1 atomic absorption spectrometer. The results obtained are listed in Table 2.

The IR Fourier spectra of ChMHLC-1 and ChMHLC-2 (Figs. 1b, 1c) show, as compared to the initial HLC (Fig. 1) an increase in the intensity of bands at 2916 and 2860 cm^{-1} for ChMHLC-1 and at ~2925 cm^{-1} for ChMHLC-2, belonging to C–H_2 stretching vibrations of methylene groups [2], which suggests that the content of $-CH_2-$ fragments in ChMHLC-1 and ChMHLC-2 becomes higher. For ChMHLC-2, the band at 2925 cm^{-1} overlaps with a broad band at 3650–3000 cm^{-1} belonging to stretching vibrations of –OH and –NH groups associated by H bonds [2]. In addition, the spectra of ChMHLC-2 and especially ChMHLC-1 contain a doublet at 420 and 440 cm^{-1} of C–Cl stretching vibrations. The IR data are confirmed by elemental analysis (Table 1), which shows that, compared to HLC, in ChMHLC-1 and especially ChMHLC-2, the content of C, H, and N decreases, whereas the total content of O and Cl increases. All the above facts confirm the incorporation of $-CH_2Cl$ groups into the HLC structure. The changes are more pronounced for ChMHLC-2 due to more rigorous chloromethylation conditions, since the aprotic Lewis acid $ZnCl_2$ in anhydrous CCl_4 is a stronger catalyst of the electrophilic chloromethylation reaction than H^+ in aqueous HCl.

In the IR spectra of AAHLC-1 and AAHLC-2 as compared to the initial HLC (Fig. 1), the band of the carbonyl group at 1717 cm^{-1} shifts to 1703 and 1691 cm^{-1}, respectively (Figs. 1d, 1e) and grows in intensity. The intensity of the band at 1616 cm^{-1} increases for AAHLC-1 and especially AAHLC-2. This band belongs to the enol form of β-dicarbonyl systems with an intramolecular hydrogen bond [3–5]:

IR Fourier spectra of humin-like compounds. (T) Transmission and (ν) wavenumber. Compound: (a) initial HLC, (b) ChMHLC-1, (c) ChMHLC-2, (d) AAHLC-1, and (e) AAHLC-1.

At the same time, as compared to ChMHLC-1 and ChMHLC-2 (Figs. 1b, 1c), for AAHLC-1 and AAHLC-2, the intensity of the broad band at 3600–3000 cm^{-1} grows, which corresponds to an increase in the content of OH groups associated by hydrogen bond in AAHLC-1 and AAHLC-2 as compared to ChMHLC-1 and ChMHLC-2. This is connected with an additional contribution into the total absorption of –OH and –NH– groups in ChMHLC-1 and ChMHLC-2, made by the OH group of the enol form of the β-dicarbonyl system introduced into HLC [3–5]. It should be noted that, in the IR spectra of AAHLC-1 and AAHLC-2, the doublet at 420, 440 cm^{-1} is preserved, suggesting an in-

complete substitution of chloromethyl groups in ChMHLC-1 and ChMHLC-2 by AA fragments. These IR data are confirmed by elemental analysis (Table 1), which shows that in AAHLC samples (especially, in AAHLC-2), the content of carbon and especially hydrogen increases, whereas the content of nitrogen and total content of oxygen and chlorine decrease as compared to ChMHLC. The above is the evidence of substitution (incomplete) of chloromethyl groups in ChMHLC-1 and ChMHLC-2 by AA fragments. The higher content of AA fragments in AAHLC-2 as compared to AAHLC-1 corresponds to higher content of chloromethyl groups in ChMHLC-2 as compared to ChMHLC-1.

The initial HLC (Table 2) sorb Pb^{2+} ions the most actively. The metal concentration in the solution decreases after sorption by a factor of 6.8. With respect to other ions, especially to Cd^{2+} and Mn^{2+}, HLC show a lower sorption capacity. AAHLC (especially AAHLC-2) exhibit substantially higher sorption capacity. After sorption with AAHLC-1, the Pb^{2+} concentration decreases by a factor of 41.6, and with AAHLC-2, by a factor of 96.6; concentration of Cd^{2+}, Cu^{2+}, Mn^{2+}, and Zn^{2+}, by factor of 2.0 and 4.9; 18.0 and 61.3; 1.1 and 1.2; and 1.7 and 2.5, respectively. These results show that AA fragments introduced into the initial HLC substantially enhance their complexing ability with respect to metal ions (except Mn^{2+}), especially in the case of AAHLC-2. Along with the IR data, this fact shows that the concentration of AA fragments in Aahlc-2 is higher than in AAHLC-1. As seen, the sorption capacity of AAHLC-2 is higher than that of AAHLC-1 by a factor 1.4–3.4.

The results obtained suggest that, to prepare AAHLC with the highest sorption capacity for heavy metal ions, it is preferable to use $ZnCl_2$ as a catalyst in anhydrous CCl_4 in the stage of synthesis of ChMHLC.

Because of the substantial increase in the sorption capacity of AAHLC in comparison with the initial HLC, the above-described method of the chemical modification can be recommended for obtaining sorbents based on HS and HLC with a high sorption capacity for heavy metal ions. Such preparations can be used for recovery of precious metals (REE, platinum metals, etc.) from solutions formed in processing of ores, fuel ashes, waste piles, wastewater, etc., and also as detoxicants.

CONCLUSIONS

(1) A new method of chemical modification of tea HLC was developed, based on introduction into the HLC structure of an acethylacetone fragment via chloromethylated intermediates.

(2) The IR and analytical data confirm the incorporation of chloromethyl fragments into the initial HLC structure, with their subsequent partial substitution by acetylacetone fragments.

(3) To achieve a more complete chloromethylation of HLC, followed by ChMHLC acetylacetonation, the use of paraformaldehyde in the stage of chloromethylation in the presence of Lewis acids, for e.g., $ZnCl_2$ is preferable over the use of formalin in aqueous HCl.

(4) Acetylacetonated HLC have a substantially higher sorption capacity for heavy metal ions as compared to the initial HLC.

(5) The method developed for chemical modification of HLC can be recommended for preparing acetylacetonated HLC with a high sorption capacity for heavy metal ions, which can be used in technology, ecology, and pharmacology.

Abstract—The organic matter of schungite rock from the Zazhogino Deposit of Karelian Transonega region was extracted in the sequential mode. The extract composition was determined by several modern physicochemical methods.

DOI: 10.1134/S1070427206100041

Schungite is a unique rock containing fullerenes [1, 2]. A wide number of diseases, including cancer, have been cured with schungite water and schungite preparations for a period of many years [3]. However, the cause of these unique biological properties is virtually not understood. One of the main explanations is the presence of fullerenes of the schungite composition. However, the fullerene content in the organic matter of schungite rock (OMSR) is low (up to 2 wt %), and the therapeutic action of schungite cannot be only due to the presence of fullerenes. All biologically active compounds of both OMSR and the mineral constituent of schungite rock (SR) should be taken into account.

One of the efficient methods for studying organic matter of caustobioliths, especially their low-molecular weight fraction containing components of different chemical nature, is extraction [4–8].

In this study, we examined for the first time the chemical composition of the extracts of OMSR (from Zazhogino Deposit of Karelian Transonega region) obtained by sequential extraction with organic solvents of gradually increasing polarity.

EXPERIMENTAL

Initial SR was ball-milled to 70–90 μm, placed in a Teflon vessel, and thoroughly stirred in 40% hydrofluoric acid at 20°C for 6 h. The solid was repeatedly washed with distilled water by decanting to pH ~7, filtered on a Buchner funnel under a reduced pressure, and dried at 100°C to constant weight. The OMSR content of the product enriched with organic matter (OM) was determined by thermal gravimetric analysis. Elemental analysis shows that the OMSR content in SR increases from 30.21 to 82.00 wt % after treatment with an HF solution. The elemental composition of OMSR (wt % daf) is as follows: C 95.45, H 0.30, N 0.60, O + S 3.65.

The organic fraction of the schungite rock was successively extracted form a weighed portion of the enriched schungite rock (100 g) in a Soxhlet apparatus with hot *n*-hexane, toluene, chloroform, acetone, ethanol, and acetic acid. The extraction was performed until the refractive index of the extract became equal to that of the initial solvent. The solvents were removed from the extracts. The residue was dried in a vacuum to constant weight and weighed to determine the yield. This procedure was used to prepare hexane, toluene, chloroform, and acetone extracts. The ethanol and acetic acid extracts were prepared by a different procedure described below. The elemental composition of each extract and the content of functional groups in the extracts were determined. The extracts were also analyzed by emission spectroscopy, atomic absorption analysis,

cryoscopy, and Fourier IR and UV-Vis spectroscopy. The toluene and chloroform extracts were methylated with an ether solution of diazomethane and then analyzed by gas chromatography-mass spectrometry (GC-MS) [9–13].

Ethanol was removed from the extract under a reduced pressure. Yellow oil with floating brown crystals was obtained. The extract yield was 1.44 wt % based on OMSR. Acetone was added to the extract. The oil fraction dissolved. The solvent was decanted, and the remaining crystals were washed with two portions of acetone. The brown crystals were dissolved in methanol. The solution was quantitatively transferred into a weighing bottle, and the solvent was removed in a vacuum. The yield of brown crystals (fraction no. 1) was 0.16 wt % based on OMSR. The combined acetone extracts were dried in a vacuum. A light yellow oil with a small amount of yellow crystals was obtained. The oil was separated from the crystals by decantation. The oil yield was 1.20 wt % based on OMSR (fraction no. 2). The remaining yellow crystals were dissolved in methanol. The solution was quantitatively transferred into a weighing bottle, and the solvent was removed in a vacuum. The yield of yellow crystals (fraction no. 3) was 0.08 wt % based on OMSR.

The yield of acetic acid extract was 1.90 wt % based on OMSR. To isolate the organic fraction from the extract, it was evaporated in a vacuum to ~50 mol and was diluted with distilled water to the total volume of 1 l. The resulting solution was extracted with chloroform (5x100 ml). The chloroform extracts were combined. Chloroform was distilled off, and then the small amount of AcOH was removed in a vacuum. The residue was dissolved in chloroform, and the solution was quantitatively transferred into a weighing bottle. The solvent was evaporated under a reduced pressure. The yield of the organic fraction of the acetic acid extract was 0.18 wt % based on OMSR. After the extraction, the aqueous phase was evaporated to dryness on a water bath. The weight of the brown residue was 1.41 g.

The yield of the hexane extract was 0.22 wt % based on OMSR. Absorption bands of the following structural fragments were identified in the IR Fourier spectrum (ν, cm^{-1}):

the absence of absorption in the range 900–650 suggests a nonaromatic structure of the hexane extract. The spectra of aromatic and heteroaromatic compounds contain in this range strong bands of out-of-plane bending vibrations of C–H bonds and bending vibrations of the rings, which usually correlate with the substitution type. The strong bands of carbon skeleton vibrations of aromatic and heteroaromatic compounds lie in the range 1600–1300;

naphthene structures containing probably aromatic rings (970–980, 980, 1950), and also cyclic hydrocarbons (3420–3140, 1110, 1060, 2966, 2931, 2854, 1464, 1377, 720) with short (C ≤ 4) alkyl substituents (720–740, 3030–3020, 1464–1590, 650–910) and substituents with unsaturated bonds (3050, 1642, 1600, 980, 880, 820);

aromatic rings (3000–3100, 1500–1600, a number of bands in the ranges 900–1200 and 650–900); isolated (650–900, 905–1200) and fused (3030–3080, 1500, 1600, 1500–1580, 1450–1500, 1125–1175, 1070–1100, 1000–1070) aromatic rings;

oxygen-containing heterocycles (3125–3165, 1565, 1015–1030, 845–870, 740–800); quinoid (1642, 1675, 1655–1622, 1642–1690), keto (1695, 1705, 1749, 1715, 1100), and carboxy (3500–3580, 1749–1800, 1280–1377, 1075–1190) groups;

pyrrole rings (3490–3400, 1565, 1500).

The yield of the toluene extract was 0.22 wt % based on OMSR.

The Fourier IR spectrum of the toluene extracts contains the following bands of structural fragments (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2880.0–2853.2), $\delta^{as}_{CH_3}$ (1462.2–1430.0 and 1385.0–1377.2); $\nu^{as}_{CH_2}$ (2940.0–2921.3), $\nu^{s}_{CH_2}$ (2870.0–2845.0), δ_{CH_2} (1491.5–1462.2); rocking vibrations (ρ) of $-(CH_2)_n-$ (742.8–720.0), ν_{CH} (2921.3–2880.0), δ_{CH} (1340.0); ν_{C-C} (1600.3–1515.0); alkenes R–CH=CH_2 (3095.0–3075.0; 1660.0–1645.0; 892.9–885.0); RR'C=CH_2 (3095.0–3075.0, 1660.0–1645.0, 892.9–885.0); R–CH=CH–R' (3045.0–3010.0; 1665.0–1635.0, 730.0–660.0); alkenes (3074.2, 1645.0, 720.0, 742.8, 660.0, 885.0, 892.9, 905.0, 985.0);

aromatic rings (3080.0–3030.0, 1625.0–1580.0, 1515.0–1462.2, 1462.2–1440.0);

alcohols and phenols (3552.5–3467.9, ν_{OH}, intermolecular hydrogen bonds in dimers; 3600.8–3420.0, ν_{OH}, intramolecular hydrogen bonds);

ketones R–CO–R' (1729.2–1700.0, $\nu_{C=O}$), esters R–COOR' (1750.0–1729.2), acid amides (3552.5–3200.0, 3467.9–3100.0); pyrrole, indole, pyridine, quinoline, piperidine heterocycles (3309.5–3367.5, 3367.5, 3325.0, 3347.5, 3467.9, 1491.9, 1285.2–1377.2, 742.8).

The yield of the chloroform extract was 0.04 wt % based on OMSR.

The Fourier IR spectrum of the chloroform extracts contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2880.0–2853.2), $\delta^{as}_{CH_3}$ (1461.1–1420.0, 1385.0–1377.2); $\nu^{as}_{CH_2}$ (2940.0–2923.3), $\nu^{s}_{CH_2}$ (2870.0–2853.5), δ_{CH_2} (1490.0–1461.1); rocking vibrations (ρ) of $-(CH_2)_n-$ (745.0–720.0); ν_{CH} (2923.3–2880.0); δ_{CH} (1340.0); ν_{C-C} (1600.0–1500.0); alkenes (3074.2, 1630.0, 720.0, 745.0, 660.0, 885.0, 905.0, 950.0);

aromatic rings (3074.2–3030.0; 1630.0–1580.0, 1512.2–1461.1; 1461.1–1440.0);

alcohols and phenols (3664.7–3572.9, ν_{OH}, free OH group; 3541.8–3455.8, ν_{OH}, intermolecular hydrogen bonds in dimers; 3411.9–3196.5, ν_{OH}, intermolecular hydrogen bonds in polyassociates; 3594.4–3411.9, ν_{OH}, intramolecular hydrogen bond); ν_{C-O} (phenol) (1220.0); primary (1060.0) and secondary (1207.9) hydroxy group of alcohols;

ketones, $\nu_{C=O}$ (1726.7–1700.0); acid amides (3541.8–3196.5; 3455.8–3102.0); pyrrole, indole, pyridine, quinoline, piperidine heterocycles (3313.8–3370.5, 3358.0, 3340.7, 3472.5, 1461.1, 1280.0–1377.5, 720.0–770.0); quinones (1635.0–1680.0); diketones (1729.2); carboxylic acids (3000.0–2500.0, 1600.3, 1630.0, 1462.2, 1491.5, 1300–1200).

The Fourier IR spectrum of the acetone extract contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2960.4), $\nu^{s}_{CH_3}$ (2868.4), $\delta^{as}_{CH_3}$ (1431.0), $\nu^{s}_{CH_3}$ (1381.1), $\nu^{as}_{CH_2}$ (2915.2), $\nu^{s}_{CH_2}$ (2852.7); CH_2 (1470.0, scissors vibrations); $-(CH_2)_n$ ($n \geq 4$) rocking vibrations (728.8);

aromatic rings (3037.4, 3046.0, 3072.4, 3088.0, 1537.5, 1520.0, 1580.0, 1600.0); fused aromatic systems (1650.0–1600.0, 1537.5–1431.0); 1,2,4-substituted (1284.9–1180.0, 1180.0–1120.0; 1071.5–1040.0, two bands);

alcohols and phenols [599.7–3516.5, ν_{OH}, intermolecular and intramolecular hydrogen bonds, e.g., for polyhydric alcohols (1,2–diols); π-hydrogen bond]; ν_{C-O} (phenol) (1200.0); secondary OH (1100.0–1071.5); primary OH (1040.0); δ_{OH} (1284.9): ketones (1727.2), quinones (1650.0–1680.0); diketones (1727.2), carboxylic acids (3013.8–2500.0, 1727.2, 1431.0, 1300–1200.0); acid amides (3046.0–3205.3, 1650.0, 3434.5, 3307.4, 1284.9); R–CO–SH (1727.2);

pyrrole, indole, pyridine, quinoline, piperidine heterocycles (3307.7–3368.8, 3360.9, 3339.9, 3338.9, 3461.4, 1431.0, 1381.1–1284.9, 728.8).

The Fourier IR spectrum of fraction 1 of the ethanol extract contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2978.3), $\nu^{s}_{CH_3}$ (2886.9), $\delta^{as}_{CH_3}$ (1402.1), $\delta^{s}_{CH_3}$ (2946.8), $\nu^{as}_{CH_2}$ (2850.0), $\nu^{s}_{CH_2}$ (1402.1, CH_2 scissors vibrations); 740.0, $-(CH_2)_n$ rocking vibrations);

aromatics rings (3007.7, 3040.1; 1515.0, 1550.0, 1580.0, 1635.4), mainly fused rings (1650.0–1635.4; 1550.0–1470.0), with short alkyl substituents (1280.0–1150.0; 1150.0–1109.3; 1060–1044.7); δ_{C-C} [out-of-plane, ring (685.0)]; δ_{OH} (out-of-plane, OH groups) (650.0); δ_{OH} (in-plane) (1340.0);

alcohols and phenols [3601.6–3509.1, ν_{OH}, intermolecular and intramolecular hydrogen bonds, e.g., for polyhydric alcohols (1,2-diols), π-hydrogen bond]; ν_{C-O} (phenol) (1229.1); secondary OH (1100.0–1080.0); primary OH (1044.7); δ_{OH} (1280.0), ketones (1734.7), quinones (1635.4–1680.0); diketones (1724.7), carboxylic acids (3007.7–2508.5; 1635.4; 3438.9; 3320.3; 1280.0; 1229.1); acid amides (3040.1–3235.9; 1635.4; 3438.9; 3320.3; 1280.0; 1229.1); R–CO–SH (1724.7);

pyrrole, indole, pyridine, quinoline, piperidine heterocycles (3320.3–3364.4; 3354.9; 3320.3, 3377.3, 3482.5; 1402.1, 1470.0, 1340.0, 1280.0, 740.0, 780.0).

The Fourier IR spectrum of fraction 2 of the ethanol extract contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2958.6), $\nu^{s}_{CH_3}$ (2885.1), $\delta^{as}_{CH_3}$ (1404.2), $\delta^{s}_{CH_3}$ (1368.1), $\nu^{as}_{CH_2}$ (2950.9), $\nu^{s}_{CH_2}$ (2850.0); CH_2 scissors vibrations (1404.2, 1460.0); $-(CH_2)_n$ ($n \geq 4$) rocking vibrations (745.6);

aromatic rings (3010.3, 3035.5; 3056.0, 3075.9, 1635.8, 1520.0, 1580.0) mainly fused rings (1650.0–1635.8, 1560.0–1480.0), with short alkyl substituents (1282.1–1113.5, 1150.0–1141.7; 1060.0–1041.7); δ_{C-C} (out-of-plane, rings) (680.1);

alcohols and phenols (3601.5–3505.0, ν_{OH}, intermolecular and intramolecular hydrogen bonds); ν_{C-O} (phenol) (1230.0); secondary OH (1230.0); primary alcoholic hydroxy group (1041.7); δ_{OH} (in-plane) (1368.1), δ_{OH} (out-of-plane) (680.1); ketones (1727.9), quinones (1635.4–1680.0); diketones (1727.9), carboxylic acids (3010.3–2500.0; 1635.8; 3441.0, 3320.3, 1282.1, 1230.0);

pyrrole, indole, pyridine, quinoline, piperidine heterocycles (3320.3–3377.1, 3334.3, 3377.1, 3492.0, 1404.2; 1460.0, 1480.0, 1282.1; 745.6); ν^{s}_{C-O-C} (aliphatic, 1109.3; aromatic, aryl alkyl ethers, 1080.0–1041.7); $\nu_{C=C}$ (in *cis*-vinyl ethers) (1635.8); ν_{C-O} (alicyclic 5- or 6-membered ring) (1041.7–1080.0).

The Fourier IR spectrum of fraction 3 of the ethanol extract contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2960.0), $\nu^{s}_{CH_3}$ (2885.5), $\delta^{as}_{CH_3}$ (1464.2), $\delta^{s}_{CH_3}$ (1367.6), $\nu^{as}_{CH_2}$ (2944.0), $\nu^{s}_{CH_2}$ (2872.5); CH_2 scissors vibrations (1464.2); $-(CH_2)_n$ rocking vibrations (745.5);

aromatic rings (3061.0, 3027.9, 3084.3, 1580.4, 1637.1, 1601.1), mainly fused rings (1680.0–1637.1, 1530.0–1580.4; 1530.0–1464.2), with short alkyl substituents (1287.0–1173.9; 1173.9–1123.7; 1040.8–1073.2); δ_{C-C} (out-of-plane ring vibrations) (651.8, 680.0);

alcohols and phenols (3606.0–3522.4, ν_{OH}, intermolecular and intramolecular hydrogen bond); ν_{C-O} (phenol) (1287.0, 1230.0); primary OH (1040.8) and secondary OH (1230.0, 1287.0) of alcohols; δ_{OH} (in-plane) (1367.6), δ_{OH} (out-of-plane) (651.3, 680.0); ketones (1727.7), quinones (1637.1–1680.0); diketones (1727.7), carboxylic acids (3010.3–2500.0; 1637.1, 1464.2, 1480.0, 1394.0, 1300.0–1200.0), acid amides (3027.9–3249.7, 1637.1, 3427.5, 3475.0, 3325.4, 1287.0, 1230.0);

pyrrole, indole, pyridine, quinoline, and piperidine heterocycles (3325.4–3365.5; 3352.9, 3392.8, 3497.7; 1447.3, 1464.2, 1287.0, 745.5); ν^{s}_{C-O-C} (aliphatic, 1123.7; aromatic, aryl alkyl ethers, 1073.2–1040.8); $\nu_{C=C}$ (in vinyl ethers) (1637.1); ν_{C-O} (alicyclic 5- or 6-membered ring) (1040.8–1073.2).

The Fourier IR spectrum of the organic fraction of the acetic acid extract contains the following bands (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2950.0), $\nu^{s}_{CH_3}$ (2880.0), $\delta^{as}_{CH_3}$ (1435.5), $\delta^{s}_{CH_3}$ (1371.9), $\nu^{as}_{CH_2}$ (2923.3), $\nu^{s}_{CH_2}$ (2851.4); CH_2 scissors vibrations (1435.5; 1460.0); $-(CH_2)_n$ rocking vibrations (720.0, 747.5);

aromatic rings (3021.5, 3046.7, 3060.0, 1530.0, 1560.0, 1580.0, 1638.0, 1659.9, 1600.0), mainly fused rings (1680.0–1638.0, 1530.0–1580.0, 1530.0–1435.0), with short alkyl substituents (1230.4, 1180.0, 1124.9, 1140.3); δ_{C-C} (out-of-plane ring vibrations) (603.9, 680.0);

alcohols and phenols (3602.3–3509.2, ν_{OH}, intermolecular and intramolecular hydrogen bonds); ν_{C-O} (phenol) (1230.4); primary OH (1044.3) and secondary OH (1230.4, 1280.0) of alcohols; δ_{OH} (in-plane) (1371.9), δ_{OH} (out-of-plane) (650.0, 680.0); ketones (1746.0), quinones (1638.0–1659.9, 1680.0); diketones (1746.0), carboxylic acids (3021.5–2522.0; 1638.0, 1435.5, 1371.9, 1300.0–1200.0); acid amides (3021.5–3257.4, 1638.0, 3423.3, 3408.6, 3465.4, 1230.4, 1280.0); aliphatic (1124.9), aromatic and aryl alkyl ethers (1080.0–1044.3, ν_{C-O-C}); vinyl ethers (1638.0, $\nu_{C=C}$); alycyclic 5- and 6-membered rings (1044.3–1080.0, ν_{C-O});

pyrrole, indole, pyridine, quinoline, and piperidine heterocycles (3304.2– 3372.9, 3353.2, 3388.5, 3483.0, 1435.5, 1230.4, 1280.0, 747.5).

The content of carboxylic acids in this extract is higher. Fractions 1 and 2 of the ethanol extract contain larger amounts of phenols, alcohols, and ketones.

The IR Fourier spectra of OMSR extracts are shown in Fig. 1.

As determined by gas chromatography-mass spectrometry (GC-MS), the methylated toluene extract contains the following compounds (Fig. 2):

alkanes: 2-methyldecane, tridecane, tetradecane, pentadecane, hexadecane, heptadecane, octadecane, 2,6,10-trimethylpentadecane, nonadecane, 2,6,10,14-

Fig. 1. (Contd.)

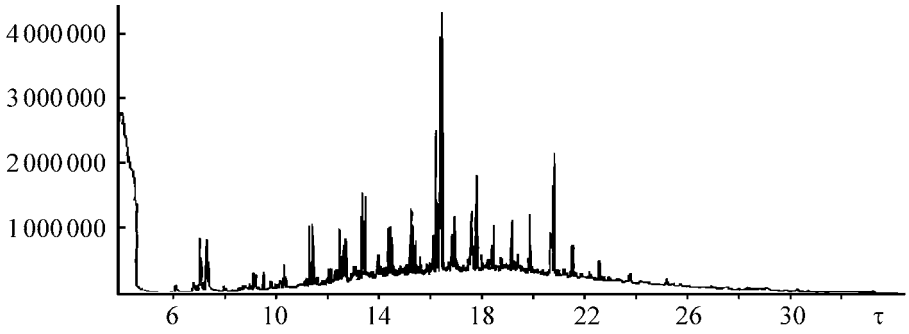

Fig. 2. Chromatogram of methylated toluene extract of OMSR.

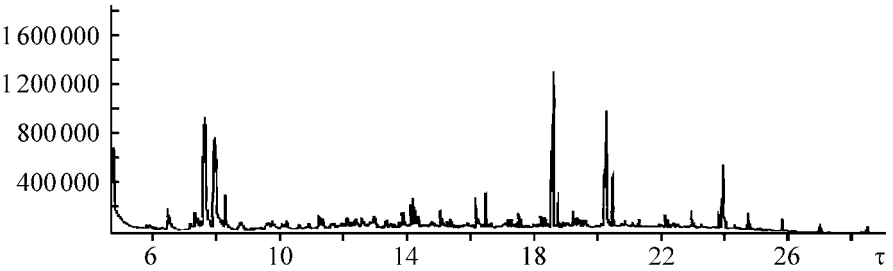

Fig. 3. Chromatogram of methylated chloroform extract of OMSR. The results of GCMS are consistent with the IR Fourier spectra of some extracts.

tetramethylpentadecane, eicosane, 2,6,10-14-tetramethylhexadecane, heneicosane, docosane, tricosane, tetracosane, pentacosane, heptacosane, and octacosane:

alkenes: 1-dodecene, 1-tetradecene, 1-hexadecane, 1-octadecene, and 1-nonadecene;

cycloalkanes: cyclododecane and cycloeicosane;

methyl esters of saturated carboxylic acids: octanoic, decanoic, dodecanoic, hexadecanoic, octadecanoic, and heptacosanoic acids;

methyl esters of unsaturated carboxylic acids: methyl octadec-8-enoate;

aromatic alcohols (benzyl alcohol), methyl ethers of phenols (2-methylphenol, 3-methylphenol, 4-methylphenol), fused aromatic compounds (1,2,3,4-tetrahydronaphthalene, 1-methylnaphthalene, 2-methylnaphthalene, and 2,6-dimethylnapthalene).

The GC-MS analysis of the methylated chloroform extract showed the presence of the following compounds (Fig. 3):

alkanes: hexadecane, docosane, tricosane, tetracosane, pentacosane, hexacosane, heptacosane, octacosane, and nonacosane;

methyl esters of saturated carboxylic acids: nonanoic, decanoic, undecanoic, dodecanoic, tridecanoic, tetradecanoic, pentadecanoic, hexadecanoic, octadecanoic, and eicosanoic acids;

methyl esters of unsaturated carboxylic acids: hexadec-7-enoic, hexadec-8-enoic, and octadec-8-enoic acids;

dimethyl esters of saturated dicarboxylic acids: octanedioic and nonanedioic acids;

esters of fused aromatic acids (methyl 1-phenanthrenecarboxylate).

Thus, OMSR from the Zazhogino Deposit of Karelian Transonega region is a complex multicomponent mixture of aliphatic, hydroaromatic, aromatic, and heterocyclic compounds. It consists of saturated, unsaturated, and aromatic acids, alcohols, ketones, ethers, esters, phenols, derivatives of pyrrole, indole, thiophene, and furan, alkaloids and steroids, and organometallic complexes.

CONCLUSIONS

(1) The structural features of the mobile phase of the organic matter of schungite rock form the Zazhogino Deposit of Karelian Transonega region were studied in detail for the first time by modern physicochemical methods including elemental analysis, emission spectral analysis, atomic absorption and X-ray

fluorescence spectroscopy, quantitative analysis of functional groups, cryoscopy, Fourier IR and UV-Vis spectroscopy, gas chromatography-mass spectrometry, and sequential extraction with solvents of different polarities.

(2) The mobile phase consists mainly of long-chain alkanes, alkenes, hydroaromatic, aromatic, and heterocyclic compounds. The main functional groups are carboxy, keto, and phenolic groups. The main heterocyclic compounds present in the organic fraction are derivatives of pyrrole, indole, and acridine.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Water-Soluble Polyelectrolytes of Varied Nature on Mineral Adsorbents

S. V. Krupin, E. S. Krivtsova, and V. P. Barabanov

Kazan State Technical University, Kazan, Tatarstan, Russia

Received March 29, 2006; in final form, May 16, 2006

Abstract—The adsorption behavior of water-soluble polyelectrolytes on mineral and synthetic adsorbents was analyzed. The effect of ionic strength, pH value, and hydrophobic interaction on the adsorption transfer of macrochains to the solid surface, determined by the conformation state of the macrochains and the electrokinetic potential of the adsorbent, was studied for model and industrial polyelectrolytes and adsorbents of varied acid-base nature.

DOI: 10.1134/S1070427206100053

The adsorption of macromolecular compounds from solutions on a solid surface underlies a number of technological processes (flocculation and purification of industrial wastewater, selective separation of disperse systems, structuring of soils, oil displacement, and restriction of water inflow in oil production) and plays an important role in the formation of properties of polymeric composite materials. In this context, the adsorption behavior of polyelectrolytes at a phase boundary is of independent scientific and practical interest [1].

The main goal of the present communication is to discuss the adsorption of industrial polyelectrolytes used in oil production to restrict the inflow of water and raise the extraction of oil from oil strata. Here, the principal factor is adsorption of polyelectrolytes from aqueous solutions by the porous bodies of a water-bearing stratum and an oil stratum strongly flooded in "secondary" extraction of oil by its displacement with water.

EXPERIMENTAL

As the closest models of industrial polyelectrolytes were used polyacids: polyacrylic, polymethacrylic, and polyfluoroacrylic.

Polyacid samples were obtained by preparative synthesis. Preparations of industrial copolymers (GIPAN, METASOL, and AMIFLOK) were produced from industrial samples reprecipitated from aqueous solutions with isopropanol and purified by dialysis. Selected parameters of the polyelectrolytes are listed in the table.

Parameters of the polyelectrolytes

Polyelectrolyte	pK_{char}	Hydrophobicity	$M \times 10^{-4}$, g mol^{-1}
Polyacrylic acid (PAA)	6.4	2	3.0
Polymethacrylic acid (PMAA)	7.0	3	4.2
Polyfluoroacrylic acid (PFAA)	3.2	0.5	4.2
Hydrolyzed polyacrylonitrile (GIPAN) MRTU (Interrepublican Technical Specifications) 6-01-166–67	6.5	2	5.3
Copolymer of methacrylamide with sodium methacrylate (METASOL) TU (Technical Specification) 6-01-1172–78	6.0	3	8.0
Copolymer of methacrylamide with diethylaminoethyl methacrylate (AMIFLOK) TU 6-01-1238–80	7.1	4.4	9.6

The adsorption behavior of the water-soluble polyelectrolytes mentioned above was analyzed using solid adsorbents of synthetic and mineral origin. The effect of the ionic strength of a solvent and hydrophobic interactions on the adsorption transfer of macrochains from aqueous solutions to a solid surface, determined by the conformation state of the macrochains, their surface activity, and the electric polarity of the adsorbent (dispersed phase of a complex colloid system), was studied for synthesized and industrial polyelectrolytes of varied acid-base nature.

As adsorbents served medium-dispersed and highly dispersed materials of varied colloid chemical nature: (1) quartz sand supplied to a glass-making plant, GOST (State Standard) 22551–77, composed of 98% silicon dioxide and 2% metal oxides (mostly iron and titanium), with a predominant particle size 0.25–0.075 mm (97%); (2) aerosil of A-175 brand, GOST 14022–77), specific surface area 175 ± 25 $m^2 g^{-1}$ (by BET); composition (%): silicon dioxide 99.9, titanium dioxide 0.03; average particle size 10–40 nm; electrokinetic potential at pH 3–8 in the range 0–70 mV; (3) pigments in the form of highly dispersed powders: TiO_2 (d = 0.2–0.80 μm), ZnS (d = 1–3 μm), $BaSO_4$ (d = 1–3 μm), and MgO; (4) microbiological cover glass degreased in solvents and steam-treated for 2 h.

The adsorption of polyelectrolytes was studied by interferometry [2]. The initial and equilibrium concentrations of dilute polyelectrolyte solutions were determined with an ITR-2 interferometer; the adsorption equilibrium was attained not later than in 72 h.

The free energy of adsorption of polyelectrolytes contains an electrostatic component (free energy of the electric double layer in adsorption of charged parts of a macrochain on a charged surface, dependent on polarization effects). Therefore, it has been shown [2–6] that the adsorption of water-soluble polyelectrolytes must depend on the charge density in the macrochain, surface charge density of the adsorbent, ionic strength and pH value of the solution, and acid-base nature of the polyelectrolyte and adsorbent.

A previous analysis of the adsorption isotherms of polybases, polyacids, and their copolymers [2, 7–10] has shown that, in a certain range of polyelectrolyte concentrations, the isotherms show "negative adsorption," which is due to competing adsorption of water and a polymer on the adsorbent surface. In this case, virtually no relaxation processes occur in water and it is capable of instantaneous orientation, with the appropriate end of its dipole facing the adsorbent surface. In addition, the adsorption of polybases on negatively charged surfaces obeys the Rebinder rule of polarity equalization and is described by a high affinity isotherm. At the same time, polymers with acid groups predominant in the macrochain diminish the adsorption from aqueous solutions. This occurs because the affinity of polyelectrolytes for water is enhanced as a result of an increase in the fraction of dissociated groups in macromolecules. The adsorption of polybases on silicon-containing adsorbents can be regarded as a reaction in which polymer-colloid complexes with the ionized surface of silicon dioxide are formed [11–14] or as chemisorption via formation of ionic bonds between the macromolecular coil and the matrix of silicon dioxide.

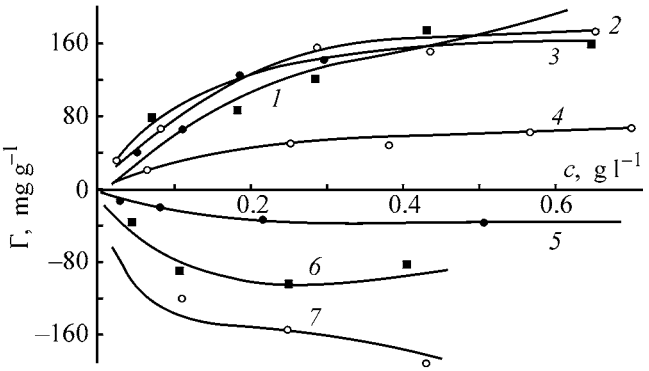

Fig. 1. Adsorption isotherms of (*1–3*) AMIFLOK and (*4–7*) GIPAN on adsorbents of varied nature. (Γ) Adsorption and (*c*) polyelectrolyte concentration; the same for Figs. 2–4. Adsorbent: (*1*) TiO_2, (*2*, *7*) MgO, (*3*, *5*) ZnS, (*6*) $BaSO_4$, and (*4*) anion-exchanger.

In view of the aforesaid, the adsorption of polyacids and polybases on various adsorbents of acid (oxides, sulfides) and basic (anion exchanger) nature was studied (Fig. 1). Here, the apparent factor is the leveling action of water on the nature of the "acid" adsorbents, which consists, in accordance with the Ken rule, in that a negative charge is imparted to the adsorbent. The role of ionic interactions is illustrated the most clearly by adsorption of hydrolyzed polyacrylonitrile on the anion exchanger, which has a basic nature in water.

In addition, it was found that the influence exerted by the electrostatic component on the interaction between a polyelectrolyte and an adsorbent is well manifested at various contents of carboxyl groups in the polyelectrolyte. Judging from the adsorption isotherms and from the wetting angles of polyelectrolyte

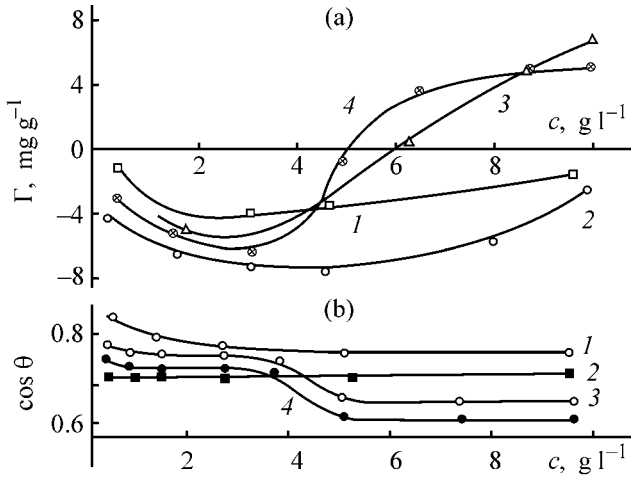

Fig. 2. Isotherms of (a) adsorption of GIPAN with varied content of carboxyl groups and (b) wetting of the glass surface. (cos θ) Cosine of the wetting angle of the polyelectrolyte on the surface. Adsorbent, quartz sand. Content of carboxyl groups (mol %): (*1*) 20, (*2*) 35, (*3*) 55, and (*4*) 67.

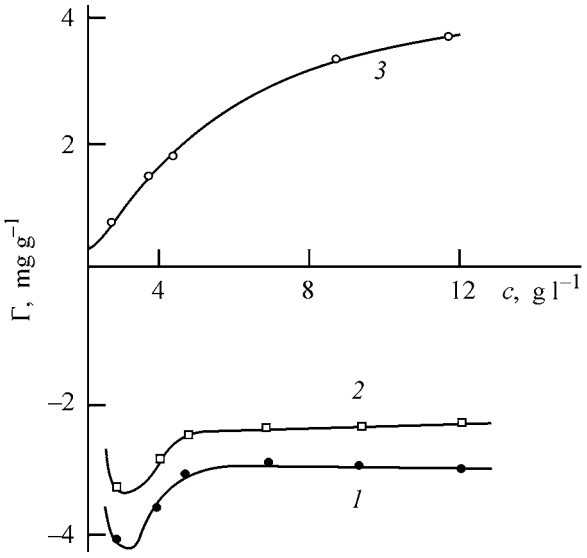

Fig. 3. Isotherms of adsorption of GIPAN with and without addition of iron(III) chloride on quartz sand. (*1*) In the absence of $FeCl_3$; in the presence of $FeCl_3$ at the following ratios with GIPAN: (*2*) 1 : 10 and (*3*) 1 : 2.

solutions on glass surfaces (Fig. 2), an increase in the number of carboxyl groups at a degree of hydrolysis exceeding 50% leads to the following: the ionic strength of the system grows, macrochains undergo coiling, and the adsorption becomes higher because of the counter-ionic binding, lower lyophylization of macrochains, and poorer wetting of the glass surface [16].

A study of the influence exerted by the concentration of triple-charged iron cations in solution on the adsorption of GIPAN from aqueous solutions on quartz sand demonstrated that the adsorption isotherm passes from negative to positive adsorption (Fig. 3). In order to assess the role of the structure of carboxyl-containing polyacids, the adsorption of polyacids was compared with that of industrial copolymers of acid type. In doing so, primary attention was focused on the relationship between the adsorption and the hydrophilic-hydrophobic balance in macromolecules, which is reflected in the value of the dissociation constant of acid groups and in the hydrophobicity of polychains [17]. The hydrophobicity is characterized by the ratio between the numbers of hydrophobic ($–CH_3$, $–CH_2–$, –CH=, –H–) and hydrophilic (–COOH, –COONa, $–CONH_2$) groups in a unit of the macromolecule. The necessary evidence is presented in the table.

The highest sensitivity to the hydrophilic-hydrophobic ratio was manifested in the adsorption azeotropy [2]. On passing from PAA to PMAA (Fig. 4) or to PFAA, the adsorption azeotropy in aqueous solutions disappears, but this occurs for different reasons: the isotherm of PFAA adsorption lies in the range of negative values, and that of PMAA adsorption, at positive values. Apparently, the large ionogenic capacity of PFAA, which can be judged from the characteristic dissociation constant pK_{char}, and the low hydrophobicity lead to a more pronounced repulsion of PFAA macroions and to negative charging of the surface of pyrogenic silicon dioxide (aerosil A-175). At the same concentration of adsorption centers on the adsorbent, this predetermines the considerably lower adsorption of PFAA, compared with PAA. In addition, the nature of the isotherm of PFAA adsorption can be accounted for by the increased energy of hydrogen bonding between the fluorine atoms of the polyacid and the hydrogen of water (about 42 kJ mol^{-1} [15]), which hinders adsorption of PFAA on aerosil.

The differences in the adsorption behavior of PMAA and PAA on aerosil cannot be accounted for by differences in the ionization of macromolecules at identical constants of electrolytic dissociation. However, the fact that the adsorption isotherm is of a high-affinity type for PMAA in the case of like charges of the adsorbate and adsorbent can be only due to the presence of a strong hydrophobic component in macromolecular coils of PMAA, which leads to a more compact conformation of macrocoils and to an increase in its adsorption. The similar relationship between the adsorption isotherms of GIPAN and METASOL also confirms the assumption made. The hydrophobic

nature of interaction in adsorbed layers of PMAA, MAA–MMA (copolymer of methacrylic acid with methyl methacrylate), and mixed adsorbed layers of polyacids with a surfactant is indicated by the relatively low activation energies of breakdown of these interactions, equal to several kilojoules per mole and comparable with the energy necessary for rupture of a small number of noncovalent bonds [16, 17].

The effect of hydrophobicity on the adsorption can also be judged from the amount of limiting adsorption and from the degree of filling of the adsorbent surface. The limiting adsorption of PAA on aerosil, equal to 63 mg g^{-1}, is reached at a concentration c_{eq} = 0.7 g/100 cm^3. The calculated value of the limiting adsorption in the case of formation of a monomolecular layer for PAA was 142 mg g^{-1}, whence follows that the degree of surface filling by PAA macromolecules is 0.45. A comparison of the experimental and calculated values of the limiting adsorption for PAA, equal to 82 and 168 mg g^{-1}, respectively, made it possible to evaluate the degree of surface filling to be 0.51. Comparison of the degrees of filling and values of the limiting adsorption of PAA and PMAA points to a higher surface activity of PMAA and higher density of filling of its surface, which is due to the hydrophobic interaction.

The calculated limiting adsorption was found using the formula

$$\Gamma_\infty = \frac{MS_{sp}}{\pi R_s^2 N_A},$$

where M is the molecular weight of the polymer (g mol^{-1}); S_{sp}, specific surface area of the adsorbent (175 m^2 g^{-1} for aerosil); R_s, macrocoil radius (m); and N_A, Avogadro number.

The macrocoil radius R_s was found from the root-mean-square distance between macrocoil ends $(h^{-2})^{1/2}$, using the relation $R_s = 0.36(h^{-2})^{1/2}$. In turn, the value of $(h^{-2})^{1/2}$ was calculated by the formula

$$(h^{-2})^{1/2} = (K_0/\Phi_0)^{1/2} M^{1/2},$$

where Φ_0 is the Flory coefficient equal to 2.84×10^{23} mol^{-1}. Because, according to published data [18], K_0 for PAA and PMAA is 1×10^{-3} and 0.6×10^{-3}, respectively, the macrocoil radius was found to be 4.4 and 4.8 nm.

CONCLUSIONS

(1) The enhancement of the ionization capacity of a polyacid results in the predominance of Coulomb repulsion forces, which hinders the adsorption of the polyacid on the like-charged surface, whereas the hydrophobic interaction in polyelectrolyte molecules favors a more compact conformation of macrochains, lessens the effectiveness of the Coulomb repulsion, and leads to an increase in the adsorption of polyelectrolytes on a like-charged surface.

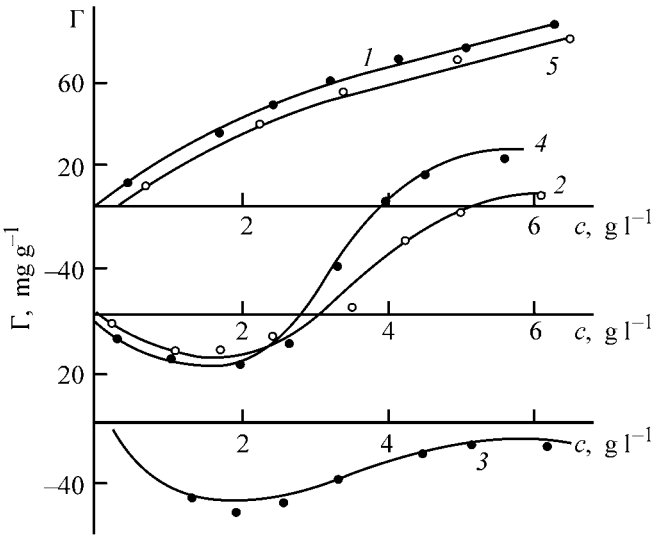

Fig. 4. Isotherms of adsorption of (*1*) PMAA, (*2*) PAA, (*3*) PFAA, (*4*) GIPAN, and (*5*) METASOL from aqueous solutions on aerosil.

(2) Analysis of experimental data on adsorption of industrial polyelectrolytes and of polymeric acids or polybases, which are, respectively, closely similar or antagonistic to the polyelectrolytes both in structure and acid-base properties and in principal characteristics, suggests that it is most advantageous to use copolymers with a sufficiently high hydrophobicity and basicity to restrict the inflow of water in oil wells.

(3) METASOL and AMFILOK should be recognized as best satisfying the requirements imposed, because they have the highest hydrophobicity; in addition, being a polybase salt, AMFILOK can compete for ionic bonding with the electrostatically negative matrix of oil-containing rock.

Abstract—Vinyl 2-hydroxyethyl sulfide (VHES) homopolymer and the homopolymer and vinyl 2-hydroxyethyl sulfide-acryl amide copolymer cross-linked by bisacrylamide were prepared by radical polymerization. The sorption of Au(III), Ag(I), Pd(II), Pt(IV), Hg(II), Pb(II), Fe(III), Ni(II), Cu(II) on these polymers under the static conditions was studied in relation to the solution pH. The polymers are highly selective and efficient sorbents for Au(III), Ag(I) and Hg(II).

DOI: 10.1134/S1070427206100065

Vinyl 2-hydroxyethyl sulfide (VHES), as well as alklyl vinyl sulfides [1], is a promising monomer for directed synthesis of functionalized polymers [2–4]. This monomer can be selectively prepared in high yield by the procedure described in [5, 6]. Radical copolymerization of VHES with acrylic monomers [2], *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride [3], and *N*-vinylpyrrolidone [4] in the presence of azobis(isobutyronitrile) (AIBN) has been studied. Simple procedures for preparing these copolymers have been developed. The copolymers consist of randomly distributed monomeric units and are soluble in water or acid aqueous solution.

It is known [7–11] that complexing sorbents containing dialkyl sulfide and alkyl 2-hydroxyethyl sulfide functional groups selectively sorb Au(III), Pd(II), and Pt(IV) from hydrochloric acid solutions Ag(I) and Pd(II) from nitric acid solutions and Hg(II) from nitric and hydrochloric acid solutions at room temperature. Hydrophilic sorbents with primary amide groups effectively and selectively sorb Hg(II) from hydrochloric and acetic acid solutions [12–14]. Therefore, preparation of VHES polymers insoluble in water and study of their sorption properties with respect to *d* metals are of interest.

The aim of this study was to prepare water-insoluble VHES homopolymer, VHES homopolymer cross-linked by *N*,*N*-methylenebisacrylamide, and VHES–acrylamide (AA) copolymer cross-linked by *N*,*N*-methylenebisacrylamide and to examine their sorption properties with respect to nonferrous, heavy, and noble metals.

EXPERIMENTAL

Vinyl 2-hydroxyethyl sulfide was prepared by vinylation of 2-mercaptoethanol with acetylene by the procedure described in [5]; bp 74–75°C (9 mm Hg), n_D^{20} 1.5220, d_4^{20} 1.0612. The purity of the monomer was determined by GLC, and by IR and NMR spectroscopy [2]. The properties of all the monomers, AIBN, and solvents purified by the conventional procedures were consistent with published data.

Our preliminary experiments showed that VHES readily polymerizes in the presence of AIBN both in the bulk and in a DMSO solution, with the polymerization being fast (up to 20% per hour) and proceeding to deep (about 70%) conversion.

VHES homopolymer (Table 1, polymer no. 1), VHES homopolymer cross-linked by *N*,*N*-methylenebisacrylamide (bis-AA) (no. 2), and VHES–acrylamide (AA) copolymer cross-linked by bis-AA (no. 3) were prepared by radical polymerization in the bulk (no. 1) or in solution (nos. 2, 3) under a reduced pressure in the presence of AIBN as an initiator. The total monomer concentration in the initial solu-

* Monomeric units:

** The limiting static sorption capacity (LSSC) of PVHES for Ag(I) was measured at $[HNO_3]$ = 1 M.

tions used to prepare polymers 2 and 3 was 50 and 35%, respectively. Polyvinyl 2-hydroxyethyl sulfide (PVHES) was precipitated three times from a methanol solution with acetone; the cross-linked polymers were washed three times with acetone and then with water and acetone. The purified polymers were dried in a vacuum at 50°C to constant weight. The weight yield of the polymers was determined (Table 1). The composition of the polymers and the content of sulfide groups ES (Table 2) were calculated from the results of elemental analysis.

The thermal stability of the polymers was studied in air by thermal analysis on an MOM Q-1500D derivatograph (Hungary) operating in the dynamic mode. The heating rate was 5 deg min^{-1}. Al_2O_3 was used as reference. The intrinsic viscosity [η] of the homopolymer was measured in DMSO on a Ubbelohde viscometer at 25°C. The IR spectra of the polymers were recorded on a Specord M 80 spectrometer (4000 – 400 cm^{-1}, Nujol).

The metal sorption was studied by the static procedure at the initial concentration of metal ions c_0^M = 0.0050 ± 0.0002 M, room temperature 20 ± 1°C, and vigorous agitation (WL-1 bench shaker). The sorption of Ag(I) was studied in the dark. The LSSC of the polymers for Ag(I) and Hg(II) was determined in 0.1 M HNO_3 at c_0^M = 0.49 and 0.10 M, respectively, at s : l = 1 : 100. The experiments were performed with intermittent agitation for τ = 10 days.

Solutions of metal salts were prepared by dissolution of weighed portions of $CuCl_2 \cdot 2H_2O$, $AgNO_3$, $Hg(NO_3)_2$ (analytically pure grade); $NiCl_2 \cdot 6H_2O$ (chemically pure grade); $FeCl_3 \cdot 6H_2O$, $Pb(NO_3)_2$, $PdCl_2$, $H_2PtCl_6 \cdot {}_6H_2O$ (pure grade) in HCl or HNO_3 solutions of required concentrations. Acetate solutions of Hg(II) were prepared by dilution of 0.10 M $Hg(NO_3)_2$ solution in 0.1 M HNO_3 in the presence of definite amounts of acetic acid and (or) sodium acetate. The pH of weakly acidic solutions was measured on a bench digital OP-211/1 pH meter with a combined glass electrode. The concentration of Ni(II), Cu(II), Pb(II), Pt(IV), and Ag(I) in the solutions was determined by atomic absorption spectroscopy on a Hitachi 506 spectrophotometer; the Pd(II) concen-

tration, by the spectrophotometic procedure using tin chloride [15]; Fe(III) concentration, by the spectrophotometric procedure using KCNS [16] on a Specord spectrophotometer; and the Hg(II) concentration, by the Volhard method [17]. The static sorption capacity was calculated as difference between the metal concentrations in the solution before and after sorption with an error no more than 5%.

The polymers consist of small (1) colorless or (2, 3) white irregular-shaped particles. The elemental analysis of the homopolymer is fairly consistent with the theoretical composition.

Found, %: C 45.91, H 7.76, S 30.04.
Calculated, %: C 46.11, H 7.76, S 30.77.

The atactic structure of the polymer follows from its ^{13}C NMR spectrum [2]. The intrinsic viscosity ($[\eta] = 0.3$ dl g^{-1}) of PVHES suggests its relatively high molecular weight. PVHES is soluble in DMSO, DMF, methanol, and also in concentrated HNO_3 (with decomposition) and HCl. The polymer is insoluble in acetone, ethanol, THF, chlorinated hydrocarbons, benzene, and water, and moderately concentrated HCl (≤5 M) and HNO_3. PVHES is a film-forming compound. It readily swells in aqueous solutions and exhibits a significant adhesion to glass. Its particles readily agglutinate owing to the high density of OH groups forming hydrogen bonds. The adhesion and film-forming properties of PVHES allow its application for preparing surface-layered sorbents with the silica gel or glass inert core.

We found that introduction of 10 wt % cross-linking agent (bis-AA) into the monomer mixture is sufficient for preparing a polymer free of the disadvantages of PVHES. Polymer nos. 2 and 3 (Table 1) exhibit no adhesion and cohesion properties and moderately swell in aqueous solutions.

The presence of the comonomeric units in the structure of the cross-linked polymers was confirmed by elemental analysis and IR spectroscopy. The IR spectra of the polymers were assigned according to [18]. A broad medium-intensity band with a complex shape at 3304 cm^{-1} in the spectrum of polymer no. 2 is due to stretching vibrations of the O–H bonds of ethanol and N–H bonds of secondary amide groups bound with hydrogen bonds. In the spectrum of polymer no. 3, this band is observed at 3320 cm^{-1} and is more intense owing to the contribution of ν_{as}(NH) vibration of the primary amide groups; the band at 3192 cm^{-1} is assigned to ν_s(NH) of the primary amide groups associated with hydrogen bonds. The moderate amide I band at 1650–1648 cm^{-1} and the less intense amide II band of the secondary amide groups of the cross-link at 1532–1520 cm^{-1} are observed in the spectra of polymer nos. 2 and 3. The strong amide I band at 1676 cm^{-1} and less intense amide II band as a shoulder at 1616 cm^{-1} are present in the spectrum of polymer no. 3. The weak amide III band of secondary amide groups at 1284 cm^{-1} and medium-intensity ν(C–O) band of primary alcoholic groups at 1048–1044 cm^{-1} are observed in the spectra of polymer nos. 2 and 3.

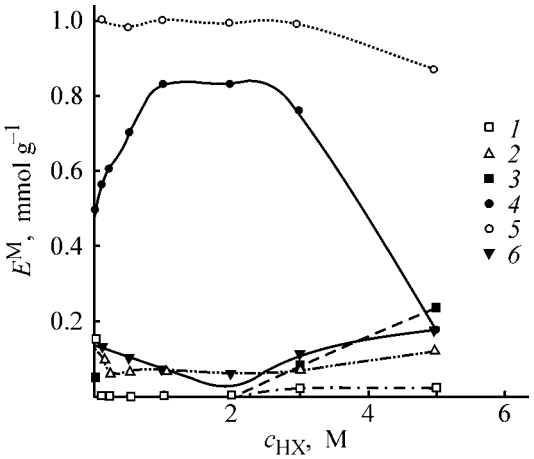

Fig. 1. Sorption capacity E^M of poly(vinyl 2-hydroxyethyl sulfide) for (*1*) Fe(III), (*2*) Pd(II), (*3*) Cu(II), (*4*) Ag(I), (*5*) Au(III), and (*6*) Pt(IV) vs. the concentration c_{HX} of nitric [Ag(I)] or hydrochloric acid.

The application field of the cross-linked polymers is restricted by the resistance of the bisacrylamide cross-link to hydrolysis (pH 1–11 [19]). The onset temperature of intense decomposition T_{do} of cross-linked polymers is somewhat lower than that of the homopolymer (Table 2).

Our preliminary experiments showed that the equilibrium sorption of Cu(II), Fe(III), Ni(II), and Pb(II) and pseudoequilibrium sorption of Pt(IV) on the homopolymer at pH ≥ 1 are attained within no more than 1–2 h. The equilibrium sorption of Pd(II) is reached in more than 24 h. We studied the sorption properties of PVHES with respect to metal ions in related to the acidity of the initial solution. At room temperature, Au(III) and Ag(I) are quantitatively sorbed with high distribution coefficients from solutions with acid concentrations lying in the range 0.1–5 M. However, Pd(II) and Pt(IV) are sorbed less effectively under these conditions. Base metals are sorbed with low distribution coefficients at pH 1, and Cu(II) and Fe(III) at $c_{HCl} \geq 3$ M (Fig. 1, Table 3). The negligible sorption of Cu(II) and Fe(III) in this range is probably due to anion exchange of anionic

complexes $[CuCl_4]^{2-}$ and $[FeCl_4]^-$ on partially protonated sulfide groups of the polymer [20]. The yellow color of the Cu(II) and Fe(III) complexes sorbed from strongly acidic solutions is typical of the anionic complexes of these metals [21]. The higher sorption of Cu(II), compared to that of Fe(III), is caused by electroselective anion exchange of differently charged anions $[CuCl_4]^{2-}$ and $[FeCl_4]^-$ in solutions dilute with respect to the metal ion [22].

The dependence of the sorption capacity of PVHES for Ag(I) on the HNO_3 concentration (Fig. 1) is typical of sorbents containing dialkyl sulfide functional groups reacting with Ag(I) by the following scheme:

$$-CH_2-CH- + Ag^+ + NO_3^- \rightleftarrows -CH_2-CH-$$
$$\quad\quad\quad

This assumption is indirectly confirmed by an increase in the pH of the solution to 2.64 after Ag(I) sorption from 0.05 M $AgNO_3$ at pH_0 4.65, s : l = 1 : 100 for τ = 6 days. It should be noted that pH of water (5.66) does not change after contact with the sorbent under the similar conditions.

The substantial decrease in E^{Ag} at the HNO_3 concentration exceeding 2 M (Fig. 1) is due to partial oxidation of the sulfide groups to the sulfoxide groups forming weaker complexes with Ag(I) [7]. The resistance of the sulfide groups of PVHES to oxidation with HNO_3 is somewhat higher than that of linear poly(methylene monosulfide) and styrene-divinylbenzene sorbent with grafted dialkyl sulfide groups ($c \le 1$ M HNO_3) [11, 23], which is probably due to steric hindrances caused by branching of the alkyl radical in the α-position with respect to the S atom [7].

The $LSSC^{Ag}$ of PVHES is significantly higher than that of known sorbents with lower content of sulfide groups, e.g. polyhydroxymacrothiacyclane (5.33 mmol g^{-1} [7]), and sorbents with grafted sulfide groups [23]. The $LSSC^{Ag}$ decreases in the order no. 1 > no. 2 > no. 3 in accordance with the decrease in the content of the sulfide groups E^S (Table 2).

The sorption of Pd(II) on the homopolymer and sorbent no. 3 is comparable with that of Pt(IV) (Fig. 1, Table 3). By contrast, the sorption capacity for Pd(II) of the known sorbents containing dialkyl sulfide groups and having no branching in the α-position with respect to the S atom [7, 9] and of nonbranched dialkyl sulfides [8, 20] at room temperature is significantly higher than that for Pt(IV). This is probably due to the steric effect of the α-branched hydrocarbon radical on the kinetics of Pd(II) sorption. The E^{Pt} of PVHES remains constant (0.14 mmol g^{-1}) and E^{Pd} increases from 0.11 to 0.42 mmol g^{-1} with the sorption time increasing from 2 to 6 h at c_0^M = 0.010 M, [HCl] = 0.1 M, and s : l = 1 : 200. It is known that square planar complexes $[PdCl_4]^{2-}$ react with low-molecular-weight dialkyl sulfides by the association mechanism of ligand exchange. The kinetics of association reactions is very sensitive to steric hindrances. The reaction of $[PdCl_4]^{2-}$ with α-branched dialkyl sulfides is substantially decelerated [7]. Reactions of ligand substitution in octahedral $[PtCl_6]^{2-}$ ions occur by the dissociation mechanism. In this case, the α-branching of the radical has virtually no effect on the complexation rate [7]. Hence, the time required for attainment of the equilibrium Pt(IV) sorption and E^{Pt} for this sorbent are comparable with those for Pt(IV) sorption on poly(ethylene monosulfide) from weakly acidic solutions with the same Pt(IV) concentration at low temperatures (E^{Pt} = 0.15 mmol g^{-1}, 30°C) [24]. Association of the alcoholic groups by interchain hydrogen bonds probably produces additional steric hindrance, since a decrease in the concentration of interchain hydrogen bonds owing to the cross-linking leads to increase in the efficiency of sorption recovery of Pd(II) and Pt(IV), with K_d remaining about the same (Table 3, polymer nos. 2, 3).

Table 4. Sorption properties of polymer nos. 2 and 3 with respect to Hg(II)

Polymer no.	$LSSC^{Hg}$, mmol g^{-1}	$LSSC^{Hg} : E^S$	E^{Hg}, mmol g^{-1}, in CH_3COONa solution, M	
			0.1	1.0
2	3.80	1 : 1.95	1.80	1.52
3	2.01	1 : 1.89	1.38	0.94

The distribution coefficients of Au(III), Pd(II), and Pt(IV) between polymer nos. 2 and 3 and hydrochloric acid solutions are high. These metals can be selectively separated from Cu(II) and Fe(III) which are sorbed insignificantly. The efficiency of Hg(II) recovery from nitric acid solutions by sorption on the cross-linked polymers is comparable with that of Pd(II) recovery from a hydrochloric acid solution (Table 3).

We studied Hg(II) sorption from nitrate and acetate solutions on the cross-linked polymers at s : l = 1 : 600, particle size of the sorbent d = 0.020–0.0315 cm (Fig. 2), agitation rate of 400 rockings/min, and sorption time of 24 h (Table 4, Figs. 3, 4).

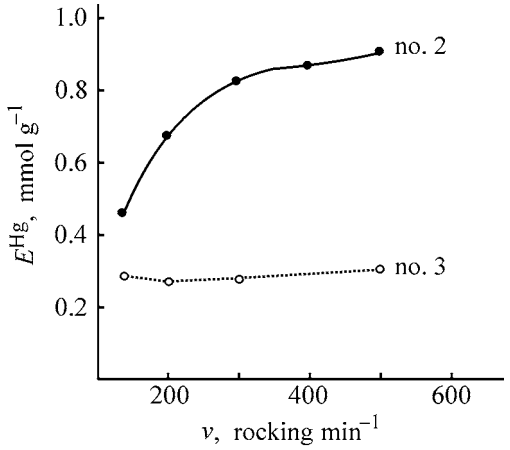

Fig. 2. Sorption capacity E^{Hg} of polymer nos. 2 and 3 at pH 1.52 (HNO_3) and τ = 30 min vs. the agitation rate ν.

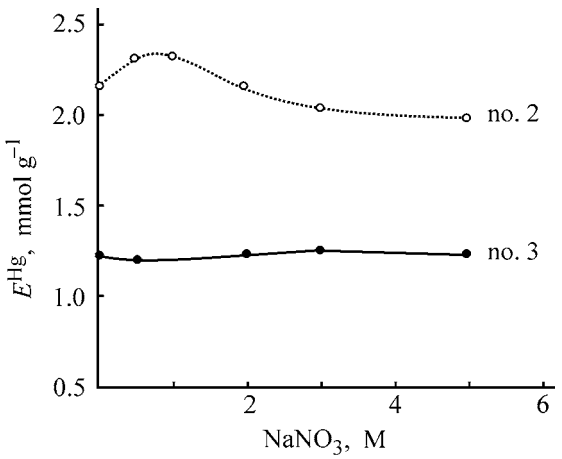

Fig. 3. Sorption capacity E^{Hg} of polymer nos. 2 and 3 in 0.01 M HNO_3 vs. the $NaNO_3$ concentration.

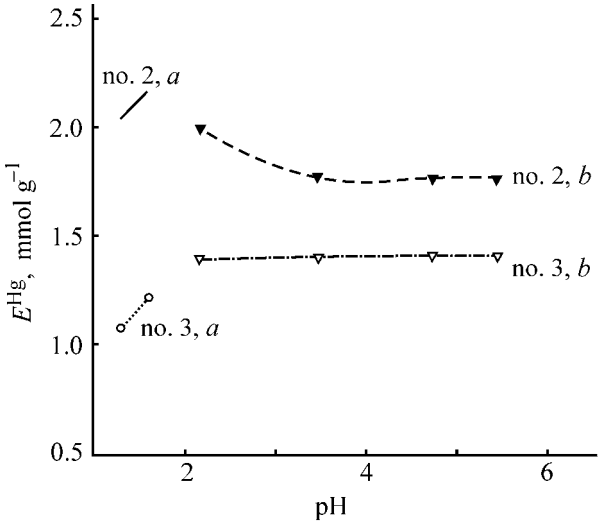

Fig. 4. Sorption capacity E^{Hg} of polymer nos. 2 and 3 in (*a*) nitrate and (*b*) 0.1 M acetate buffer vs. pH.

The rate of Hg(II) sorption from a nitrate solution on polymer no. 2 is controlled by internal diffusion even at high agitation rates (Fig. 2). The fact that the rate of Hg(II) sorption on polymer no. 3 is independent of the stirring rate (Fig. 2) suggests that the external diffusion has no effect on the rate of Hg(II) recovery. The time required for attainment of the equilibrium Hg(II) sorption from a nitrate solution at pH 1.52 on polymer nos. 2 and 3 is τ_e = 1.3 and 1.4 days, respectively; the half-time of the equilibrium sorption is $\tau_{0.5}$ = 1.5 and 5 h, respectively. The τ_e and $\tau_{0.5}$ for polymer no. 3 at s : l = 1 : 200 decrease to 24 and 2 h, respectively. This fact indirectly suggests high diffusion resistance of the polymer layer containing metal complexes.

The efficiency of Hg(II) recovery from nitrate and acetate solutions and the $LSSC^{Hg}$ are higher for polymer no. 2 (Tables 3, 4; Figs. 3, 4) with higher content of thioether groups E^S (Table 2). The $LSSC^{Hg} : E^S$ ratio for polymer nos. 2 and 3 (Table 4) suggests formation of sorption complexes with Hg : S = 1 : 2 under the saturation conditions. Based on this data, we suggested the following mechanism of sorption of cationic Hg(II) species prevailing in nitric acid solutions at pH 1–2 [25]:

$$2R_1SR_2 + Hg^{2+} + 2NO_3^- \rightarrow Hg(R_1SR_2)_2(NO_3)_2.$$

As in the case of Hg(II) extraction with thioethers [26], high concentrations of weakly coordinating anion NO_3^- insignificantly affect the efficiency of Hg(II) recovery with the cross-linked polymers from nitric acid solutions (Fig. 3). When the concentration of acetate ions forming relatively strong complexes with Hg(II) substantially increases, the efficiency of Hg(II) recovery decreases owing to the competing formation of anionic complexes $Hg(CH_3COO)_3^-$ and $Hg(CH_3COO)_4^{2-}$ in the solution. A similar trend was observed with the chloride concentration increasing in the course of Hg(II) extraction with thioethers from hydrochloric acid solutions [27]. This effect can be used, e.g., to desorb Hg(II) with a hot concentrated solution of CH_3COOH which does not induce hydrolysis of the amide bonds [12–14].

The fact that the efficiency of the Hg(II) sorption by cross-linked polymers at a constant ionic strength (0.1 M acetate buffer) is independent of pH in the range examined (Fig. 4, curves no. 2, *b*, no. 3, *b*) confirms the coordination of the sulfide groups to the metals. The slight decrease in the sorption capacity of polymer no. 2 for Hg(II) in going from nitrate to acetate solutions is due to the formation of acetate complexes of Hg(II) in the solution (Fig. 4, curves no. 2, *a*, no. 2, *b*). An increase in the sorption capacity of polymer no. 3 with increasing pH in going to the acetate solutions (curves no. 3, *a*, no. 3, *b*) suggests that the primary amide groups partially form Hg(II) complexes by the mechanism similar to that of Hg(II) sorption by cross-linked polyamide sorbents from acetate solutions at pH 2.6–6.2 [12, 13]:

$$n\mathrm{RC(O)NH_2} + \mathrm{Hg(CH_3COO)_2} \rightleftarrows (\mathrm{RC(O)NH})_n\mathrm{Hg(CH_3COO)_{2-n}} + n\mathrm{CH_3COOH},$$

where n = 1, 2.

CONCLUSIONS

(1) High-molecular-weight VHES homopolymer and the homopolymer and vinyl 2-hydroxyethyl sul-

fide–acryl amide copolymer cross-linked by bis-AA were prepared by radical polymerization. The polymers selectively sorb noble metal ions and Hg(II).

(2) The homopolymer is a highly efficient sorbent for Au(III) in hydrochloric acid solutions and for Ag(I) in nitric acid solutions. The low sorption capacity of the homopolymer for Pd(II) is probably due to the influence exerted on the kinetics of Pd(II) sorption by the steric hindrances caused by α-branching of the hydrocarbon radical and by the high concentration of the alcoholic groups associated by interchain hydrogen bonds. Silver(I) can be completely separated from Pb(II) at $c_{HNO_3} > 0.1$–5 M; Au(III), Pd(II), Pt(IV) can be selectively separated from Ni(II) at $c_{HCl} = 0.1$–5 M and from Cu(II) and Fe(III) at $c_{HCl} = 0.1$–3 M.

(3) In nitric acid solutions, Ag(I) reacts with the thioether groups of PVHES to form a sorption complex of the composition $Ag : S : NO_3^- = 1 : 1 : 1$ under the saturation conditions. Formation of Ag(I) chelates with alkyl 2-hydroxyethyl sulfide groups of polymer nos. 1–3 in 0.1 M HNO_3 is possible.

(4) The cross-linked polymers effectively sorb cationic Hg(II) species from nitric acid solutions with pH 1–1.6 to form the $Hg : S = 1 : 2$ sorption complexes with the thioether groups under the saturation conditions. A high $NaNO_3$ concentration and high acidity (pH 2.2–5.5) of 0.1 M acetate buffer have virtually no effect on the Hg(II) sorption. The efficiency of Hg(II) recovery decreases when the concentration of the acido ligands (acetate ions) forming strong anionic complexes with Hg(II) substantially increases. In 0.1 M acetate buffers, the reaction of Hg(II) with the primary amide groups of polymer no. 3 by the proton substitution mechanism is also possible.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of the Possibility of Anodic Oxidation of Suspensions Formed by Dispersed Graphite and Nitric Acid

Abstract—The dispersion stability of graphite–HNO_3 suspensions was studied in relation to the acid concentration, dispersity of the graphite powder, and solid-to-liquid phase ratio. The relative electrical resistivity was determined for the same system.

DOI: 10.1134/S1070427206100077

Chemical or electrochemical oxidation of graphite in nitric acid electrolytes is a necessary stage in synthesis of graphite intercalation compounds (GIC) processed into thermally expanded graphite. The main advantage of the electrochemical method is the possibility of obtaining a product with highly uniform composition and properties [1–3]. The continuous-operation equipment developed for electrochemical oxidation of dispersed graphite [4, 5] is based on pressing of the anode paste to the current lead to provide electronic conduction in the bulk of the electrode in motion of the paste in the interelectrode gap. Despite the sufficient reliability of the electrolyzer and the possibility of its automatic operation [5], the apparatus has low output capacity and is complicated in exploitation. A way to improve the output capacity of the apparatus and to simplify its design is to eliminate clamping, for which purpose it has been suggested to use electrically conducting graphite–HNO_3 mixtures with a sufficient electrical conductivity. Apparently, only paste-like mixtures with a predominant solid phase will exhibit electronic conduction. At the same time, anodic oxidation of graphite–acid suspensions to give graphite intercalation compounds by the reaction [6]

$$24nC + 3HNO_3 = C^+_{24n}NO^-_3 2HNO_3 + H^+ + e, \quad (1)$$

where n is the number of a GIC stage, requires a sufficient amount of the acid in the mixture for the maximum possible filling of the graphite matrix with the intercalate. In this study, graphite–HNO_3 mixtures will be named "suspensions" at any component ratio. Because the electrochemical oxidation of graphite in solutions with water content exceeding 20% yields graphite nitrate of second and higher stages [7], the mass ratio of graphite and HNO_3 in the suspension should be no less than 1 : 3. An excess of the liquid phase will lead to stratification of the suspension and to loss of the electric contact between graphite grains, and its deficiency, to nonuniform distribution of the components and to formation of electrolytically uncoupled graphite particles, which will eliminate regions of this kind from the electrochemical process. Therefore, the principal characteristics determining the possibility of anodic oxidation of graphite–acid suspensions will be the dispersion stability and electrical conductivity of a suspension.

This communication presents the results obtained in a study of the electrical conductivity and dispersion stability of graphite–HNO_3 suspensions in relation to the components ratio (s : l), graphite dispersity, and acid concentration.

EXPERIMENTAL

The suspensions studied were prepared from disperse graphite powders of GT OSCh brand [GOST (State Standard) 1891–78, special purity grade] with ash content of 0.1% and particle size in the range 200–250 μm and of Chinese manufacture (GB/T standard 3518–95, ash content 0.2%, particle size 250–300 μm). The choice of the graphite brands was due to their predominant use in modern techniques for synthesis of GIC. As electrolytes served 59 and 30% solutions of nitric acid of chemically pure grade [TU (Technical Specification) 701–89E].

The stratification of the suspensions was examined in a measuring cylinder of diameter 1.5 cm and height 10 cm (GOST 1770–74). The height of the liquid phase column and the total height of the mixture were measured at 10-min intervals until their constant ratio was attained. The instant of stratification of the suspension was judged from the appearance of the liquid phase on the surface of graphite particles after the keeping time specified above.

The degree of densification and the under-pressure electrical conductivity of dry graphite powders were studied in a special cell equipped with mobile punches bearing current leads (Fig. 1).

The electrical conductivity of graphite powders and suspensions was measured in a polymethyl methacrylate cell with two flat vertical platinum electrodes with a working surface area of 1 cm^2 and interelectrode spacing of 1.5 cm. To perform anodic polarization of the suspension electrode and suppress electronic conduction via graphite, the platinum cathode was embedded in a diaphragm material (polypropylene filtering cloth).

After the graphite powder or a graphite–HNO_3 suspension was charged into the cell, a direct current of 2.2 to 15 mA was passed (P-5848 potentiostat) with the ohmic voltage drop on the cell recorded with a Shch-1413 digital dc voltmeter. The voltage drop across the cell did not reach values at which Faraday reactions can occur. This was confirmed by the linear run of the dependences of the voltage across the cell on the current strength. The acid was introduced into the suspension with a microbatcher with an accuracy of 0.02 ml.

In the range currents at which Ohm's law was obeyed for the circuit, the electrical conductivity was calculated by the formula

$$\chi = Il/US,$$

where χ is the electrical conductivity (S cm^{-1}); I, current strength (A); U, voltage (V); S, electrode area (cm^2); and l, interelectrode spacing (cm).

A potentiostatic (P-5848 potentiostat) treatment of graphite–HNO_3 suspensions pressed at a load of 0.2 kg cm^{-2} was performed in a special three-electrode cell [1]. The current was recorded in the course of time with a KSP-4 recording potentiometer with an accuracy of 0.1 mA.

The standard silver chloride electrode of EVL-1M1 brand served as a reference electrode in all the electrochemical measurements, and, in what follows, all the potentials are given relative to this electrode.

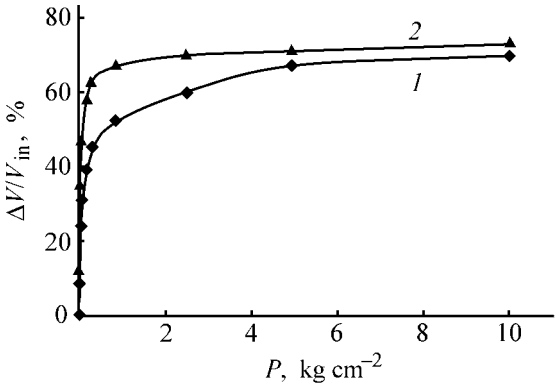

Fig. 2. Degree of densification of the graphite powder, $\Delta V/V_{in}$, under the action of the external pressure P. V_{in}, volume of the graphite powder in the absence of external pressure, $\Delta V = V_{in} - V$; V, volume of the graphite powder under an external pressure. Graphite: (*1*) Chinese and (*2*) GT.

All the experiments were carried out at a constant temperature of 298 ± 1 K.

The electrical conductivity of dry dispersed graphites is considerably lower than that of single crystals, which is due to the fact that the contact resistance between separate graphite particles is high because of their chaotic orientation in the volume. The electrical conductivity of graphite powders was determined under the action of an external pressure to provide contact between graphite particles. A considerable densification of the graphite powder is observed as the pressure is gradually raised to $P \approx 0.5$ kg cm^{-2} (Fig. 2). Further increase in the pressure on GT has virtually no effect on its bulk volume, whereas coarser

particles of the Chinese graphite continue to be densified, which is probably due to mechanical dispersion of particles oriented perpendicularly to the plane of action of the external load. The pressure clamping the graphite powder to the anode current lead, which should provide an electronic contact between separate particles and the anode, but, at the same time, should allow uniform distribution of the electrolyte throughout the electrode, was 0.2–0.5 kg cm^{-2} [1]. The electrical conductivity measured at this clamping pressure was 0.51 S cm^{-1} for GT-1 and 0.53 S cm^{-1} for Chinese graphite.

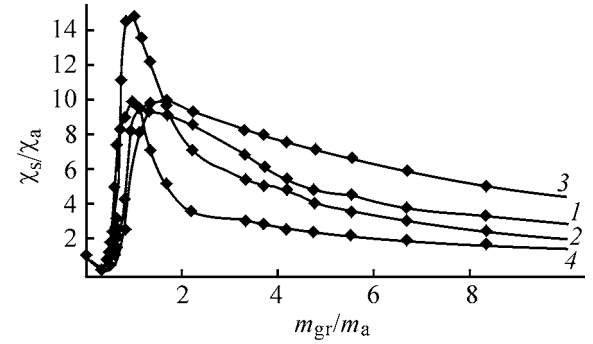

Fig. 4. Relative electrical conductivity of suspensions formed by graphite and HNO_3 solution, χ_s/χ_a, vs. the mass ratio of their components.

When graphite is wetted with the acid, the suspension volume remains, irrespective of the acid concentration, virtually unchanged until a mass ratio s : l = 1 : 0.5 is reached. As the amount of the liquid phase grows, the suspension volume considerably increases. It should be noted that complete wetting of coarser graphite particles (Chinese graphite) requires a substantially smaller amount of the acid, irrespective of its concentration, than wetting of GT graphite (Fig. 3). Measurements of the electrical conductivity of all the suspensions under study in conditions of dispersion stability at the maximum content of the liquid phase revealed an increase in its value by a factor of 3.2, compared with the corresponding acid solution (Table 1), which points to the existence of an electronic component in the electrical conductivity. However, the available data on the dispersion stability of suspensions are insufficient for making a final conclusion about the possibility of electrochemical synthesis of GIC with their use. This is because these data fail to provide a complete understanding of the electrochemical behavior of the suspensions (ionic and electronic components in a suspension) in relation to the solid-to-liquid phase ratio.

Measurements of the electrical conductivity of graphite–HNO_3 suspensions (Fig. 4) confirmed that the contact between particles of dispersed graphite is improved upon their wetting with HNO_3 solutions. In this case, the agglomeration of coarse particles of Chinese graphite, which improves the electronic contact between the particles, occurs considerably faster, which is indicated by the higher values of the electrical conductivity of the suspensions (Fig. 4, curves *1*, *3*). The maximum values of the electrical conductivity of the suspensions based on Chinese graphite are reached at a mass ratio s : l ≈ 1 : 0.66 (curves *1*, *3*), whereas in the suspensions based on GT, the maximum electrical conductivity is obtained at s : l ≈ 1 : 1

Table 2. Electric capacity in potentiostatic treatment of dispersed graphite electrodes

(curves *2*, *4*). The shift of the maximum values of electrical conductivity to a higher content of the liquid phase in the suspensions, observed for the finer particles of GT graphite, is presumably due to the more porous, compared with Chinese graphite, structure of the agglomerates and to larger specific surface area of graphite particles. The anomalously high values of electrical conductivity, observed for suspensions formed by GT graphite and 30% HNO_3 (curve *2*), are probably due to the largest area of contact between graphite particles, which leads to a more effective charge transfer. Such a favorable, for improvement of the electric contact, orientation may result both from a chemical interaction of the surface groups on GT graphite with the 30% solution of HNO_3 and from the action of the field generated by H_3O^+ and NO_3^- ions. The absence of an interaction of this kind in the 59% solution of HNO_3 can be attributed to a change in the structure of the acid. For example, according to the data of [8], the acid has a structure similar to that of NO_2OH esters and is characterized by a considerable decrease in the degree of dissociation, compared with less concentrated solutions.

Further dilution of the suspension with nitric acid leads to a decrease in the electrical conductivity because of the stratification of the suspension and increased share of the ionic component in charge transfer.

The kinetics of anodic processes was examined under potentiostatic polarization of suspension electrodes prepared in accordance with the results obtained (Table 1, Fig. 4) in a 59% solution of HNO_3. With account of the side processes involving the acid, the amount of acid molecules in the suspensions formed by graphite and 30% HNO_3 (Table 1) is insufficient for II-stage GIC to be formed by reaction (1), and, therefore, the kinetics of anodic reactions in this system was not analyzed. Previously, the potential of anodic polarization of a clamped graphite electrode in a 59% solution of HNO_3 and the electric capacity providing formation of a GIC with a high degree of thermal expansion have been found to be 2.1 V and 200–300 mA h g^{-1} [1]. Comparison of the results of a potentiostatic synthesis in a cell with a clamped electrode [1] (Fig. 5, curves *3*, *4*) with those of an electrochemical treatment of a suspension electrode (Fig. 5, curve *1*, *2*) shows that the currents are 1.5–4 times higher in the latter case (Table 2). This confirms the existence of an electronic contact between graphite particles, which is only formed when the content of liquid phase is optimized and graphite particles agglomerate under the action of surface tension forces. The fact revealed demonstrates that the true surface area of the carbon material, involved in the electrochemical process, is considerably larger in the suspension electrode. Graphite particles in the suspension remain mobile to a certain extent, which allows them to change their spatial orientation under the action of current. In the process, an electron can pass across the acid films adsorbed on the surface of carbon particles, i.e., the electron transfer is accompanied by a jump across the "liquid phase." The initial rise in current (Fig. 5) is presumably

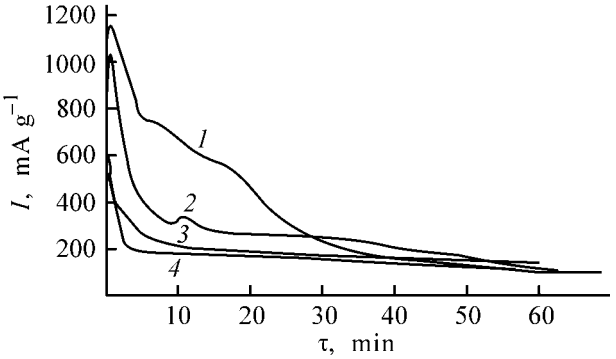

Fig. 5. Potentiostatic curves of anodic oxidation (E = 2.1 V) of dispersed graphite electrodes in a 59% solution of HNO_3. (*I*) Current strength and (τ) time. (*1*, *2*) Suspension electrode and (*3*, *4*) pressed electrode (P = 0.2 kg cm^{-2}). Graphite: (*1*, *3*) Chinese and (*2*, *4*) GT.

due to an increase in the electronic conductivity of the suspension electrode through reorientation and densification of graphite particles. The process of graphite intercalation after the completion of the induction period is accompanied by a steep decrease in current (Fig. 5). The volume expansion of graphite particles in GIC formation leads to densification of the suspension and, further, the currents for the suspension and pressed electrodes virtually coincide.

It can be seen from the results obtained (Fig. 5, Table 2) that the rate of anodic reactions is higher, on both suspension and pressed electrodes, for Chinese graphite, despite its smaller specific surface area. In this case, the kinetics of the electrochemical processes is determined by the contact resistance between graphite grains in the suspension bulk. This is confirmed by the fact that the difference in the anode currents during the first 20 min of anodic polarization is small (10%) for a clamped electrode (Fig. 5, curves *1*, *2*) and considerable (up to 200%) for the suspension electrode (curves *3*, *4*).

CONCLUSIONS

(1) It was shown that, in principle, anodic oxidation of dispersed graphite materials can be performed in suspensions with nitric acid and the suspension component ratio at which electrons are removed from graphite particles was determined.

(2) It was found that the rate of anodic processes in a 59% solution of HNO_3 is 1.5–4 times higher on a graphite suspension electrode, compared with the clamped electrode, and depends on the dispersity of the starting carbon powder.

(3) The experimental data were obtained, which create good prerequisites to improvement and simplification of the electrochemical technique for synthesis of graphite intercalation compounds.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Nature of a Reducing Agent on Properties of Ultradisperse Copper Powders

Abstract—Ultradisperse copper powders were produced by reduction of copper sulfate with glycerol, *L*-ascorbic acid, sodium hypophosphite, glucose, and hydrazine. The influence exerted by the nature of a reducing agent on the size-related parameters and physicochemical properties of the powders was studied.

DOI: 10.1134/S1070427206100089

One of the main current issues of modern science and technology is production of electrically conducting ultradisperse powders (UDPs) of copper. Numerous methods for synthesis of copper UDPs are known, which enable wide variation of their dispersity and properties. However, the problem of synthesis of copper UDPs with controlled particle size distribution, which can be used to create materials with nearly metallic electrical conductivity, remains topical. Composite materials of this kind find wide application in electronics for development of electrically conducting glues and pastes used in low-temperature soldering of device elements and in assembly of integrated circuits and flexible printed-circuit boards.

Previously, methods for synthesis of copper UDPs by reduction of copper sulfide with glycerol have been developed and patented [1, 2]. It was shown in [3] that chemical modification of copper UDPs makes it possible to obtain from these UDPs formulations possessing increased stability (of epoxy type, more than 10 years; of novolac type, more than 6 years) and low electrical resistivity (10^{-6}–10^{-7} Ω m).

It has been shown that it is preferable to carry out reduction of various copper salts with sodium hypophosphite and hypophosphorous acid in the water–hexanol system, rather than in an aqueous medium [4]. This is so because hexanol adsorbed on the surface of UDPs leads to an increase in their stability and electrical conductivity by blocking the surface of copper particles and thereby preventing their oxidation by atmospheric oxygen. It was also demonstrated that additional treatment of copper UDPs with formic acid makes them more stable and electrically conducting.

The present communication reports the results obtained in an experimental study of copper sulfide reduction with various reducing agents. The influence exerted by the nature of the reducing agent on the dispersity, stability, and electrical conductivity of copper powders is analyzed.

Five different reducing agents were chosen for copper by analysis of published data. These are glycerol, *L*-ascorbic acid, sodium hypophosphite, *D*-glucose, and hydrazine.

EXPERIMENTAL

The results obtained in reduction of copper salts with sodium hypophosphite have been described in sufficient detail [1–4]. The reduction with glycerol was carried out by the procedure described in [1]. The reaction of copper sulfate with sodium hypophosphite was performed by the method reported in [4]. The procedure used to reduce copper salts with ascorbic acid was described in [5].

The reduction with glucose was carried out in an alkaline medium by the technique reported in [6]. Copper sulfate and glucose were dissolved in separate vessels. A minor amount of an alkali (NaOH, KOH) was introduced into the glucose solution to bring the solution pH to 8–9. The copper sulfate solution was heated to 80–90°C. Then the glucose solution was gradually poured in the copper sulfate solution under permanent agitation and the mixture heated to 80–90°C. A red precipitate was formed in 40–50 min. The precipitate was separated from the solution, treated with formic acid to remove copper oxides, and stored in a 0.05% solution of stearic acid in ethanol.

Results obtained in reduction of copper sulfate with various reducing agents*

Sample no.	Reducing agent	t_r, °C	τ_r, min	S_{sp}, $m^2 g^{-1}$	D_{Cu_2O}	D_{Cu}	D_{max}	D_{av}
					nm			
1	Glycerol	180–185	180	0.51	–	85	1.29	1.46

5	Hydrazine sulfate	70–80	15	6.00	56	64	1.17	1.41

* t_r and τ_r, temperature and duration of the reduction reaction.

The reduction with hydrazine was performed by analogy with the procedure described in [7]. Copper sulfate and hydrazine sulfate solutions were prepared separately. A 1 M solution of an alkali (NaOH, KOH) was poured in a hydrazine sulfate solution to bring its pH to 8–9 and then the hydrazine solution was gradually poured in the copper sulfate solution under permanent agitation and heated to 70–80°C for 15–20 min. The copper powder was washed with water and treated with a 1% solution of hydroquinone and 0.05% solution of stearic acid in ethanol to improve its stability against oxidation and aggregation, as recommended previously [1].

In order to examine the influence exerted by the nature of a reducing agent on the properties of copper UDPs, both organic (glycerol, *L*-ascorbic acid, *D*-glucose) and inorganic (hypophosphorous acid, sodium hypophosphite, hydrazine sulfate) reagents were used. The interaction with these reducing agents occurs under various conditions (see table). As a result, the physicochemical and electrical properties of the ultradisperse copper powders obtained vary widely.

The physicochemical properties of the resulting ultradisperse copper powders were studied. The average sizes of copper(I) oxide crystallites, D_{Cu_2O} and metallic copper, D_{Cu}, were found from the spectra of X-ray phase analysis (XPA) in Fig. 1 by Scherrer formulas [8]. The specific surface area S_{sp} of the powders was determined by the BET technique from adsorption of argon. The most probable (D_{max}) and statistical-average (D_{av}) diameters of primary particles were calculated from the particle size distribution functions [9]. The results obtained are listed in the table.

Figure 2 shows the first maxima of mass particle-size distribution functions D_m, calculated from

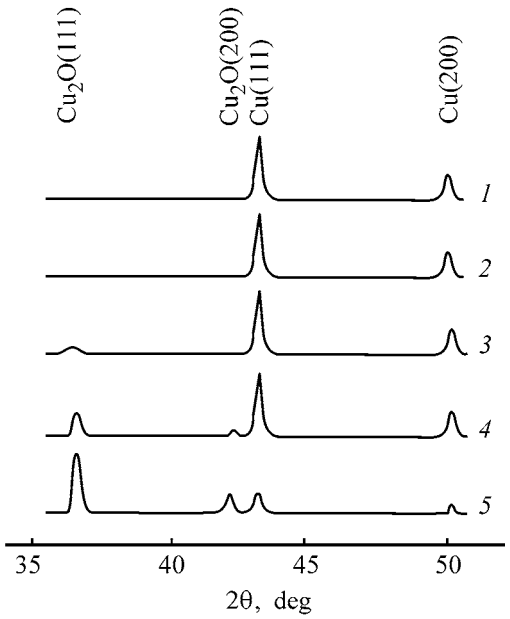

Fig. 1. Spectra obtained in X-ray phase analysis of ultradisperse copper powders (2θ) Bragg angle. (*1–5*) Sample numbers in the table; the same for Figs. 2, 3.

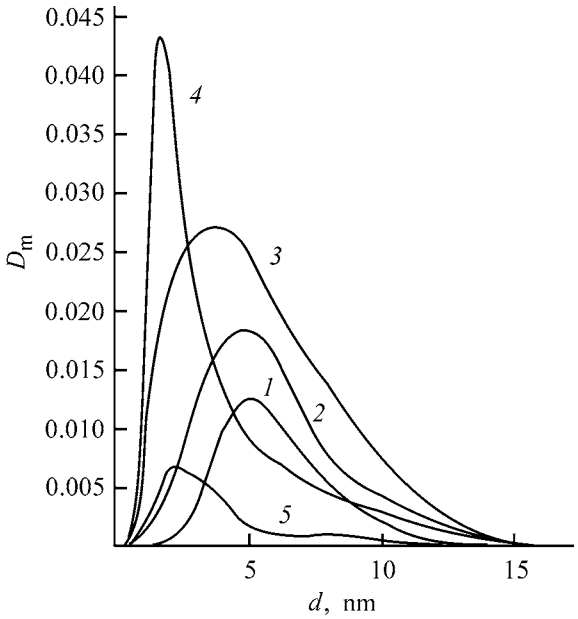

Fig. 2. First maxima of mass particle-size distribution functions $D_m(d)$, calculated from small-angle scattering curves. (d) Particle diameter.

small-angle scattering curves by special procedures [10].

It can be seen from the results presented above that copper powders produced by reduction with glycerol and *L*-ascorbic acid have the largest particle sizes according to small-angle scattering data and contain a virtually zero amount of Cu_2O.

It is apparent that, as the specific surface area of the powders grows, the content of copper(I) oxide in these powders increases. The only exception is sample no. 4, produced by reduction with *D*-glucose. This sample has a specific surface area smaller than that of copper powders synthesized by reduction with sodium hypophosphite and *L*-ascorbic acid, but contains a larger amount of copper(I) oxide. This is presumably due to the fact that the first peak in the particle size distribution curves (Fig. 2) is shifted for sample no. 4 to smaller sizes and has smaller values of D_{max} and D_{av} than sample nos. 2 and 3. Thus, a clearly pronounced correlation between the values of D_{maz} and D_{av}, on the one hand, and the content of copper(I) oxide, on the other, is observed for samples represented in the table.

The electrical conductivity σ and stability of copper powders were evaluated by changes in the electrical resistivity ρ (ρ = 1/σ) of formulations with SF-010 phenol-formaldehyde novolac resin (with 80% metallic phase). The electrical resistivity of the formulations was measured in the dc mode (12 V, 2.5 mA) at a temperature of 20–25°C. The results obtained are presented in Fig. 3.

It can be seen that the electrical conductivity and stability of the powders are in an agreement with the data on their dispersity: the larger the most probable (D_{max}) and statistical-average (D_{av}) particle diameters, the higher their stability and electrical conductivity. For example, the electrical conductivity was the highest for copper powders obtained by reduction of copper sulfate with glycerol (sample no. 1), which have the smallest specific surface area, largest D_{max} and D_{av}, and, according to XPA spectra, the lowest content of impurities, which is accounted for by the process conditions. Somewhat lower is the electrical conductivity of copper powders produced by reduction with *L*-ascorbic acid (sample no. 2). The electrical conductivity is the lowest for powders reduced with *D*-glucose and hydrazine (sample nos. 4 and 5), which have the smallest primary particles and the highest content of copper(I) oxide impurity.

It can also be seen from the table that the most probable and statistical-average diameters are close

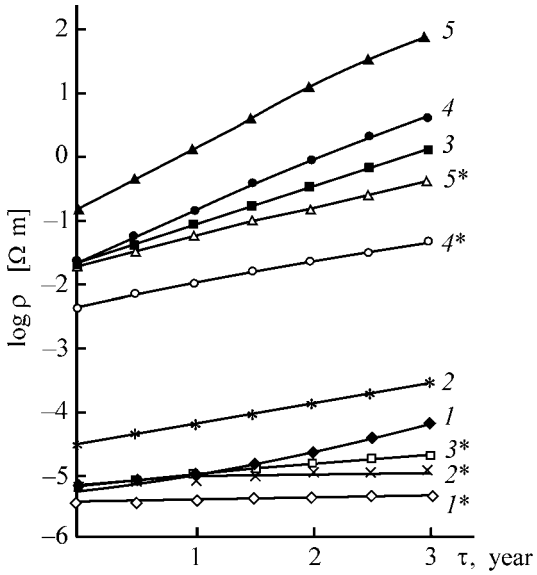

Fig. 3. Effect of the nature of a reducing agent on the variation of the electrical resistivity ρ of formulations composed of copper UDP and novolac resin with time τ. (*1–5*) Before treatment with HCOOH and (*1*–5**) after the treatment. (*1*, *1**) Glycerol, (*2*, *2**) *L*-ascorbic acid, (*3*, *3**) sodium hypophosphite, (*4*, *4**) *D*-glucose, and (*5*, *5**) hydrazine.

for copper UDPs produced by reduction with glycerol, *L*-ascorbic acid, and sodium hypophosphite. It is this circumstance that is, in all probability, responsible for the fact that UDPs reduced with sodium hypophosphite and *L*-ascorbic acid become comparable with the samples reduced with glycerol if appropriate stabilizing agents are used. The enhanced stability of UDPs produced by reduction with *L*-ascorbic acid and sodium hypophosphite may also be due to unreacted molecules of the reducing agent, which are adsorbed on the UDP surface. In the case of reduction with hydrazine, the electrical conductivity is several orders of magnitude lower, even if stabilizing agents are used, and the powders are unstable in the course of time. This is presumably due to their substantially larger specific surface area (see table, sample no. 5), which leads to enhanced oxidation of the copper powder in air.

It was found that additional treatment of copper UDPs with formic acid leads to a considerable increase in the electrical conductivity and stability of the ultradisperse powders produced by reduction of copper sulfate with glycerol (Fig. 3, curve *1**), *L*-ascorbic acid (*2**), and sodium hypophosphite (*3**). However, the electrical conductivity of the powders produced by reduction with *D*-glucose and hydrazine is several orders of magnitude lower even upon treat-

ment with formic acid (curves *4** and *5**, respectively) and they are unstable in the course of time.

CONCLUSIONS

(1) A comparison of the physicochemical properties of ultradisperse powders produced by reduction with various reducing agents revealed that glycerol, *L*-ascorbic acid, and sodium hydrophosphite are the most effective reducing agents for synthesis of stable copper powders with high electrical conductivity.

(2) It was shown that the nature of a reducing agent affects the size-related parameters and physicochemical properties of the powders obtained, which determines their stability and electrical properties.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Dispersity of Components of a Cathode Mixture on Discharge Characteristics of a Leclanché Cell

Abstract—The effect of dispersity of electrolytic manganese dioxide and of an electrically conducting additive to the cathode mixture on the discharge capacity of chemical power cells of the manganese–zinc system with a salt electrolyte was studied.

DOI: 10.1134/S1070427206100090

The most widely occurring type of chemical power cells (CPC) are primary cells of the manganese–zinc (MZ) system [1, 2]. By the end of the last century, the annual per capita consumption in the United States and Japan was 15 cells, and the present-day world production of cells of this system is 46 billion [3, 4] In view of the fact that utilization of worked-out primary CPC is still not carried out worldwide, a large amount of noxious substances contained in these cells find their way into the environment [2]. Thus, making the service life of CPC longer may aid in solving not only technical and economical, but also ecological problems.

At present, 140 years after it was developed, the Leclanché cell, a salt-type CPC of the MZ system $Zn/NH_4Cl/MnO_2$, retains its high practical importance. This is due to its low cost, high reliability and safety, convenient manufacturing technology, and wide application area. However, the electrical characteristics of the Leclanché cell are assessed as only acceptable or satisfactory [1, 2]. In the last decades, the rise in the specific energy capacity of CPC of the MZ system with a salt electrolyte lagged behind that for CPC with an alkaline electrolyte, which was, naturally, reflected on the production: during this time the number of manufactured alkaline cells exceeded that of saline cells [4]. It has been shown previously [5] that the Leclanché cell has not exhausted its potentialities in improvement of its electrotechnical characteristics.

The aim of this study was to demonstrate the possibility of a more effective use of the influence exerted by the dispersity of components of the cathode mixture on the discharge capacity of galvanic cells.

Experiments were performed with saline cells of the MZ system of R12 (336) standard size. The CPS were fabricated under laboratory conditions from materials and articles used in the industry, with all the technological conditions satisfied [1, 6]. Electrolytic manganese dioxide (EMD) of first grade [7], manufactured in Rustavi (Georgia), was used as the active cathode material. The composition of the dry cathode mixture was as follows (wt %): EMD 80, graphite 16.5, and carbon black 3.5. Each CPC batch comprised seven R12 galvanic cells. The CPC were discharged at room temperature in the continuous mode through a constant external resistance of 3.33 Ω to a final voltage of 0.67 V. The total internal resistance was calculated from discharge parameters [8].

EXPERIMENTAL

The mechanism of electrochemical reduction of MnO_2 in various electrolytes, associated with diffusion and concentration polarization in the solid phase, determines a dependence of the extent of utilization of the active substance on its particle size [1, 8]. It is known [9] that the particle size of the positive electrode of a CPC of the manganese–zinc system with an alkaline electrolyte strongly affects the electrochemical characteristics of the cells. Experiments demonstrating that the amount of electric energy produced by a cell is independent of the size of EMD particles in the salt electrolyte have been performed in a rather narrow range of dispersities of the active substance [10].

Table 1. Fraction composition of EMD and graphite powders

Sieve mesh, mm	EMD sample no.					Graphite sample no.	
	1	2	3	4	5	6	7
	under sieve, %						
0.200	100					86	97
0.160	96	100				72	94
0.100	83	87	100			39	89
0.063	65	66	80	100		16	82
0.050	30	40	42	52	100	7	74

Table 2. Discharge of R12 CPC through an external resistance of 3.33 Ω

Voltage, V		Discharge energy, W h	Coefficient of MnO_2 utilization, %
open-circuit	average over discharge		
1.69	0.867	0.902	32.8
1.68	0.873	0.981	35.5
1.68	0.890	1.125	39.9
1.69	0.852	0.915	33.9
1.68	0.845	0.814	30.0

Moreover, the composition of samples that have been tested in electrochemical cells did not correspond to the relative masses of components in the cathode mixture of the standard Leclanché cell [1, 6]. The electrochemical characteristics of CPC of the MZ system are strongly affected by the amount and quality of carbon materials added to the cathode mixture to raise its electrical conductivity [9, 11, 12]. Various types of carbon materials produced by modern techniques (carbon fiber, colloidal and thermally expanded graphite, etc.) are successfully used in technical electrochemistry and, in particular, in fabrication of certain types of CPC [13–16]. The macro- and microcharacteristics of these materials (structural defects, dispersity, porosity, and specific surface area) are important for their effective use.

The influence exerted by the EMD dispersity on the discharge capacity of Leclanché cells was studied with five samples of EMD powder with different fraction compositions. The elemental (flaky) graphite used in CPC manufacture or the low-ash graphite produced by processing of flaky graphite was added to the cathode mixture, together with acetylene black, as a conducting material [6].

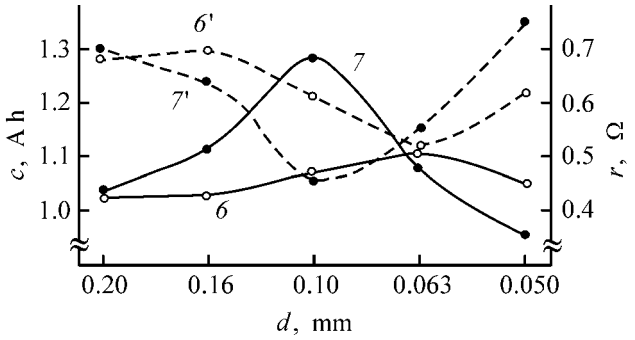

Fig. 1. (*6*, *7*) Discharge capacity and (*6*', *7*') internal resistance of R12 cells of the MZ system vs. the dispersity of the EMD powder. (*c*) Discharge capacity, (*r*) resistance, and (*d*) sieve mesh. Cells fabricated with the use of (*6*, *6*') elemental graphite and (*7*, *7*') low-ash graphite.

Table 1 lists results of a sieve analysis of EMD powder samples (nos. 1–5, no. 1 standard sample [7]) and the elemental (no. 6) and low-ash (no. 7) graphite. The EMD samples were obtained by sieving the starting product through the corresponding sieves.

According to the data of Table 1, the dispersity of the low-ash graphite is higher than that of the elemental graphite. This is particularly noticeable in comparison of fine fractions.

Table 2 lists some discharge characteristics of R12 galvanic cells fabricated from the above EMD samples and the low-ash graphite. The use of the latter as an electrically conducting additive to the cathode mixture, instead of the elemental graphite, raised by, on average, 13% the utilization coefficient of the active substance. The manner in which this coefficient varies is reflected in Table 2, which shows that the discharge capacity of the cells depends on the EMD dispersity (see Fig. 1, curves *6*, *7*). In both cases, the curve describing this dependence passes through a maximum. This is probably due to variation of the ohmic and diffusion characteristics inherent in porous electrodes [2, 17], of which type is the cathode of the CPC of the MZ system, fabricated by powder compaction. Presumably, the above characteristics of the porous electrode degrade, beginning with a certain degree of EMD dispersity, as the size of particles and pores in the electrode decreases. Another possible reason for the observed dependence of the electric capacity of the cells on the dispersity of the active substance is the tendency toward an increase in the con tact electrical resistance, caused by processes that occur at points of contact between EMD and graphite particles in operation of the cell [1]. This interpretation can be confirmed by the fact that the internal electrical resistance of the cell varies as the EMD

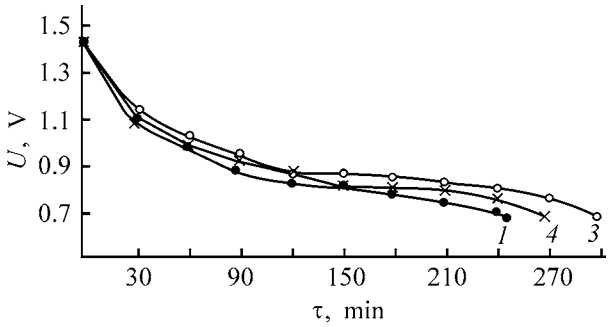

Fig. 2. Discharge curves of R12 cells of the MZ system, fabricated using (*1*, *4*) elemental and (*3*) low-ash graphite. (*U*) Voltage and (τ) time. Digits at the curves correspond to EMD sample nos. in Table 1.

dispersity increases. It can be seen from Fig. 1 that this resistance first decreases and then increases with both the elemental (curve *6*') and lowash (curve *7*') graphite used. The maximum discharge capacity of cells fabricated with the low-ash graphite exceeds by 16% that of cells fabricated using the elemental graphite. One more fact of importance is that the maximum capacity of the cell with the low-ash graphite was obtained for an EMD powder with particle size larger (Table 1, sample no. 3) than that in the case of the elemental graphite (sample no. 4). Thus, use of the low-ash graphite can lower the cost of EMD grinding by diminishing the energy expenditure.

Figure 2 shows discharge curves of the best R12 cells fabricated using the low-ash (curve 3) and elemental (curve *4*) graphite as additive to EMD samples (Table 1, sample nos. 3 and 4, respectively). The figure also shows curve *1*, which corresponds to cells based on the EMD powder of the standard fraction composition (Table 1, sample no. 1) and the elemental graphite. To the discharge curves *3* and *4* corresponds an increase in the discharge capacity of the cells by 24% for the low-ash graphite and by 8% for the elemental graphite, respectively. The results obtained may be due not only to the high dispersity of the low-ash graphite, but also to its other advantages: lower content of ash (by approximately a factor of 25) and impurities (on average, by a factor of 10), compared with the elemental graphite [6]. This circumstance determines the high content of carbon and, accordingly, the high electrical conductivity of the low-ash graphite, and just this was reflected in the data on the internal resistance of CPC (Fig. 1, curves *6*', *7*').

CONCLUSIONS

(1) The standard requirements to the fraction composition of EMD are not optimal for salt CPC of the MZ system and require adjustment toward a higher dispersity of the powder.

(2) Use of EMD with the optimal dispersity and the low-ash graphite as an additive to the cathode mixture improves the discharge capacity of Leclanché cell of R12 standard size by 22–25%.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Integrated Utilization of Spent Ion-Exchange Resins in Wastewater Treatment and in Polymer Composites

V. I. Korchagin and P. T. Poluektov

Voronezh State Technological Academy, Voronezh, Russia

Received May 25, 2006

Abstract—The possibility of recovery of contaminants (soaps of resin and fatty acids, Leukanol, and finely dispersed rubber) from spent synthetic ion-exchange resins in the stage of treatment of wastewater formed in production of synthetic rubbers and latexes, which polymer composites obtained, was studied.

DOI: 10.1134/S1070427206100107

The increasing volumes of industrial and household water consumption, deterioration of quality of natural water, organization of recycling water supply and local water treatment systems, and also the fact that the regulations concerning the water quality become more and more stringent, lead to higher consumption of ion-exchange resins. With this tendency preserved, the global demand for these materials will steadily increase; however, the problem of their utilization after repeated use remains unsolved.

Among widespread kinds of polymer wastes are spent synthetic cation exchangers having the form of a three-dimensional copolymer of styrene and divinylbenzene with grafted functional groups, which lose the ion-exchange power during operation. It is well known [1] that ion-exchange treatment of aqueous solutions involves various reactions yielding sparingly soluble, weakly dissociated, and complex compounds.

A no less important problem is treatment of wastewater formed in production of synthetic rubbers and latexes. This wastewater is a dilute colloidal system containing difficultly removable finely dispersed particles of quality standard rubber and concomitant organic components, such as potassium soaps of resin and fatty acids entering into the composition of rosin or tall oil, and also the nonbiodegradable Leukanol (Table 1).

The specific features of the polymer matrix and functional groups of spent ion exchangers, in combination with the properties of elastomers and surfactants present in wastewater, formed the basis for the development of an integrated process for reprocessing of waste cation-active resins and the efficient treatment of wastewater, with utilization of its valuable components.

As an object of study we used pure and spent cation exchangers: gel-like KU-2 × 8 and macroporous KU-23 with a specific surface area of 35 $m^2 g^{-1}$. The content of metal ions in the spent cation exchangers was 35–45 mg per gram of cation exchanger, predominantly in the form of iron ions (up to 25 mg per gram of cation exchanger). The ion-exchange resins were ground in a ball mill and also in a 1A27 disintegrator produced by the EKS (Riga, Latvia) with an efficiency of 2.0 kg h^{-1} and rotation rate of 8000 rpm, which allowed preparation of a filler with a particle size of up to 5 μm.

Table 1. Characteristics of wastewater formed in production of SKS-30ARK(M) rubber

Parameter	Parameter value	
	before treatment	after treatment
pH	4.9–6.5	7.0–8.5
COD, mg O_2 per 1 dm^3	1500–7500	80–200
BOD, mg O_2 per 1 dm^3	320–960	60–120
Polymer, mg dm^{-3}	35–1200	5–15
Suspended substances, mg dm^{-3}	90–300	5–20
Total content of salts of resin and fatty acids, mg dm^{-3}	175–280	10–20
Leukanol, mg dm^{-3}	90–350	Less than 2
Styrene, mg dm^{-3}	3–45	Absent

The content of Leukanol, oligomeric product of condensation of naphthalenesulfonic acid and formaldehyde with $n = 2–10$, in the solution was determined with an SF-46 spectrophotometer. The UV spectrum of Leukanol contains absorption bands peaked at 227 and 235 nm. The relative error of measurement of the Leukanol content was 5.0% [2].

The content of soaps of resin and fatty acids was determined by direct titration with alkali after the extraction of these acids from the acidified serum with diethyl ether [3].

The characteristic of the total contamination with organic substances, chemical oxygen demand (COD), was determined by the procedure [3] involving oxidation of organic compounds with an excess of potassium dichromate in a sulfuric acid solution, with heating in the presence of silver sulfate as a catalyst. The excess potassium dichromate was determined by titration with a solution of iron(II) sulfate, and the amount of potassium dichromate spent for the oxidation of organic substances was found from the difference.

The surface tension in the wastewater to be treated was determined tensimetrically on a Du Nouy device.

The physicochemical principles of wastewater treatment to remove polymer pollutants are presented in [4]. However, removal of concomitant components with the use of a finely dispersed waste formed in water treatment, spent KU-2 cation exchanger, was not considered [5].

The studies showed that addition of a finely dispersed spent cation exchanger in an amount of 0.1–1.5 g per gram of the polymer into rubber-containing wastes with vigorous stirring for 5–10 min ensures its uniform distribution over the wastewater volume. After the liquid-phase combination of the polymer phase with the finely dispersed cation exchanger, we performed their joint coagulation in a weakly acidic medium with the commonly used coagulant, aluminum sulfate or iron(III) chloride. The coagulation in an alkaline medium can be performed with a mineral powder, waste from production of building materials, whose major components are calcium oxide (70–95 wt %) and magnesium oxide (5–8%).

With the mineral powder, the filled latex system coagulates at pH 12.0 ± 0.5, and with aluminum sulfate or iron(III) chloride, at pH 3.5 ± 0.5, which is caused by the hydrolysis of the coagulants in the aqueous medium and release of OH^- and H^+ ions, respectively.

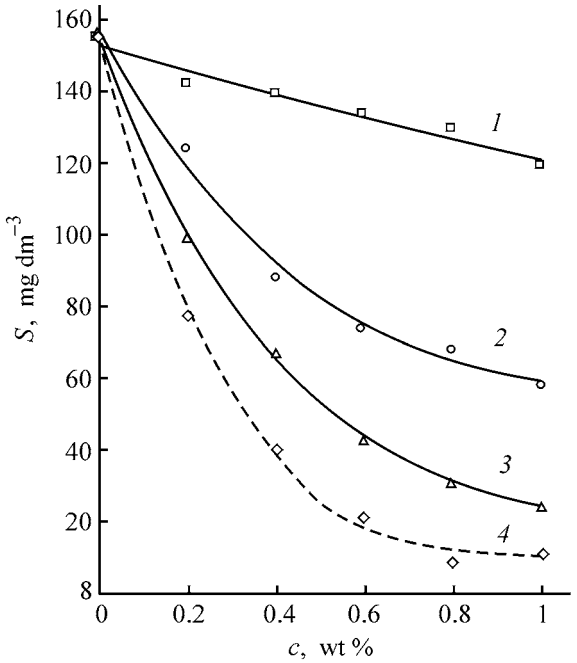

Fig. 1. Content of rosin soaps (surfactant) in the simulated waste vs. the concentration of the added cation exchanger with various structural characteristics. (*S*) Content of rosin soaps, and (*c*) concentration of cation exchanger. Gel cation exchanger KU-2 in the simulated wastes: (*1*) fresh and (*2*) spent. Spent macroporous cation exchanger KU-23: (*3*) simulated waste and (4) simulated waste containing 1.0 g dm^{-3} mineral powder.

It should be noted that a high degree of purification judget from COD, without using a spent cation exchanger is observed with aluminum sulfate or iron(III) sulfate as a coagulant, which is consistent with the Schulze–Hardy rule according to which the coagulating effect is exhibited by the counter-ion, and this effect increases with its charge.

Addition of milled ion-exchange resins to the latex wastewater causes a decrease in the COD upon coagulation, which is due to additional recovery of soaps of resin and fatty acids and also Leukanol. Figure 1 shows that the use of a spent ion-exchange resin, KU-2 cation exchanger belonging to the sorbents with a gel structure and high degree of neutralization of sulfo groups (more than 50%), allows the content of resin and fatty acids in the simulated waste to be decreased. The sorption power with respect to the surfactant significantly increases when using a spent macroporous cation-exchanger KU-23.

It is well known [6] that the volume of gel ion-exchange resins increases upon swelling, and coarse organic ions or uncharged molecules can penetrate into the space between the polymer chains of their network structure (matrix). In this case, coarse organic ions

can be not only absorbed with ion-exchange materials as a result of substitution for inorganic counter-ions of ion exchangers, but also firmly retained as a result of adsorption [1].

Therefore, the regeneration of ion-exchange resins used for treatment of water containing various types of surfactants and macromolecular compounds is severely complicated.

However, this factor, negative at first glance, can be useful in our case as providing irreversible recovery of ionized surfactant molecules and Leukanol from wastewater with likely charged particles of spent resins KU-2 and KU-23. This fact is of particular importance for removal of highly toxic nonbiodegradable detergent Leukanol, which is an oligomeric polyelectrolyte with the general formula

The presence of Leukanol in wastewater prevents its treatment at biological treatment facilities.

The studies showed that the sorption power of the cation exchanger with respect to Leukanol does not noticeably depend on the impurity content, i.e., on the extent of charge compensation in the cation exchanger, and is determined by its structure and degree of dispersion (Fig. 2).

The recovery of soaps of resin and fatty acids from wastes with a spent cation exchanger as a sorbent and a mineral powder or aluminum sulfate [or iron(III) chloride] as a coagulant, is due to the following factors. The first of these is conversion of soaps of resin and fatty acids to their Ca^{2+} and Mg^{2+} salts, which are poorly soluble in water, using the mineral powder, i.e., calcium and magnesium oxides, which favors the formation of macromolecular globules and, as a consequence, sorption interaction with the network structure of the KU-2 gel-like cation exchanger. Second, with iron(III) chloride or aluminum sulfate used in a medium with pH 3.5 ± 0.5 (Fig. 3), poorly soluble salts of resin and fatty acids with the ions of these metals can be formed and, the emulsifiers based on rosin and fatty acids transform into low-polarity acids, which are sorbed by the inner and outer surfaces of particles of the swollen cation exchanger.

The above facts suggest that resin and fatty acids are better sorbed by the cation-exchanger surface, which is confirmed by the decrease in the surface ten-

sion (Fig. 4) in conversion of soaps in wastewater. However, coagulation in an acidic medium can result in secondary contamination with metal ions present in the spent ion-exchange resin via partial regeneration of the ion-exchange resin, which complicates the use of spent cation exchangers as adsorbents of organic compounds from acidic medium.

The degree of compensation of the fixed charge affects the sorption power of the surfactant, i.e., the spent cation exchanger loses the ion-exchange power because of the formation of weakly dissociated compounds, which is accompanied by the loss of polarity by functional groups.

However, spent ion-exchangers do not completely lose the functional power. For example [1], the commonly used procedures of water treatment at heat and electric power plants allow utilization of, at most approximately 50% of the total exchange capacity of ion exchangers.

Milling of spent cation-exchangers allows partial regeneration of their functionality, which, in turn, causes a decrease in the adsorption power with respect to anionic surfactants. However, addition of a coagulant solution or suspension to a latex system filled with a cation exchanger is accompanied by ion exchange between the fixed ions and cations of the coagulant in alkaline medium, which allows neutralization of charges of fixed ions and increase in the sorption power (Fig. 1).

All the components of coagulated latex wastes, including Leukanol present in the form of separate molecules, interact with the surface of the finely dispersed adsorbent. As a result of adsorption, the total contamination with respect to COD and the surface tension decrease (Fig. 4).

In liquid-phase filling of latex wastes with spent cation exchangers, the concomitant components are recovered, i.e., the wastewater is purified (Table 1) and a filled polymer system is obtained. The filled rubber composition is separated from the waste using a vibrosieve with subsequent mechanical and thermomechanical dehydration. The resulting vulcanized rubbers based on the polymer composite have characteristics comparable with those of the elastomers filled with Kerogen-70, which is well known as organomineral filler of rubber stocks (Table 2).

Analysis of the physicomechanical characteristics shows that the impurities present in spent cation exchangers do not noticeably affect these characteristics.

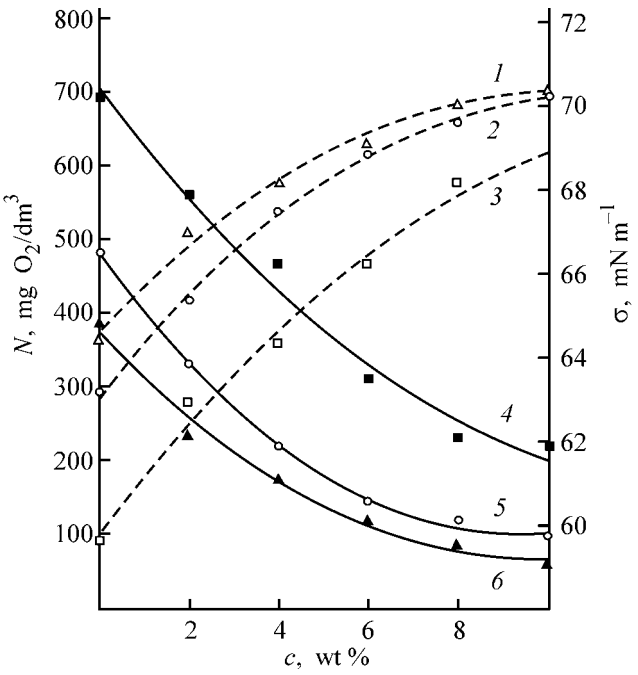

Fig. 4. COD N and surface tension σ vs. the concentration of spent KU-2 cation exchanger in the waste, c, with the initial content of the polymer of 10 g dm^{-3}, upon treatment with various coagulants. (*1–3*) Surface tension and (*4–6*) COD. Coagulant: (*1*, *6*) iron(III) chloride, (*2*, *5*) aluminum sulfate, and (*3*, *4*) mineral powder.

CONCLUSIONS

(1) Milled spent cation exchanger exhibits adsorption power with respect to anionic surfactants (soaps of resin acids and synthetic fatty acids) and also to oligomeric polyelectrolyte, Leukanol.

(2) In utilization of a spent cation exchanger, it is appropriate to recover soaps of resin and fatty acids in an alkaline medium.

Table 2. Influence of the filler type on the physicomechanical characteristics of vulcanized rubbers (composition of rubber stock, wt parts: rubber 100, filler 40, stearin 2, zinc white 5, Captax 3, and sulfur 2)

Filler type	Ultimate tensile stress, MPa	Tear resistance, kN m^{-1}	Shore hardness, *A*, arb. units
P-234 carbon black	8.3	56	64
Technical-grade chalk	2.3	12	42
Kerogen	6.1	42	46
Initial KU-2	5.4	36	52
Spent KU-2	5.9	38	54

(3) Preparation of polymer composites in waste treatment reduces the impact of wastes on the environment and expands the sources of raw materials.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Wastewater Purification To Remove Ammonium Ions by the Oxidation Method

S. A. Lobanov, V. Z. Poilov, and A. V. Sofronova

Perm State Technical University, Perm, Russia

Received March 10, 2006

Abstract—Wastewater purification to remove ammonium ions and carbamide by oxidation with hypochlorites of alkali and alkaline-earth metals was studied. The effect of various factors on the degree of purification was examined experimentally.

DOI: 10.1134/S1070427206100119

At present, the problem of wastewater purification to remove ammonium ions is encountered by numerous of industrial plants. The large amount of ammonium nitrogen in wastewater leads to oxygen starvation of plants and adversely affects the flora and fauna of the water basin.

Various methods [1] can be used in wastewater purification to remove ammonium ions. However, the majority of these methods have a number of drawbacks, which restricts their application. One of widely applied methods of purification of wastewater with low content of ammonium ions is the oxidative method. Ozone and chlorine can be used as oxidizing agents; however, their use involves gross expenditure and severe hazard. Hypochlorites of alkali and alkaline-earth metals can also be used [2]. In this case, a preliminary adjustment of wastewater pH to initial values of 8–10.5 with an alkaline agent or a buffer mixture is necessary. After that, a treatment with hypochlorite ions is carried out using hypochlorites of alkali or alkaline-earth metals (NaClO or $Ca(ClO)_2$) in amounts equivalent to, or exceeding by 5%, the equivalent content of ammonia or ammonium salts in wastewater. The oxidation proceeds in a liquid homogeneous medium to form a gaseous final product [3]:

$$2NH_4OH + 3NaClO = N_2 + 3NaCl + 5H_2O,$$

$$4NH_4OH + 3Ca(ClO)_2 = 2N_2 + 3CaCl_2 + 10H_2O.$$

As a result, toxic ammonium ions are replaced with sodium or calcium ions.

The method is simple in use, does not require development of special installations (necessary in ozonization), and provides a high degree of purification. Unlike chlorine and ozone, solutions of sodium or calcium hypochlorites are safe and less expensive, because they are formed as waste in catching of chlorine from discharge gases at soda and magnesium plants. Owing to such advantages, this method has found industrial application.

In the present study, we carried out a technological analysis in order to develop the optimal modes of wastewater purification to remove ammonium ions NH_4^+ by the oxidation method. The aim of the study was to determine the degree of wastewater purification to remove NH_4^+ under various chemical and technological conditions, such as temperature (for summer and winter conditions), pH of the medium, and amount of an oxidizing agent.

The following procedure was used in the experiments. A 100-ml portion of wastewater with a preliminarily determined content of ammonium ions was poured in a temperature-controlled reaction vessel. Then, using a separating funnel, we poured in a calculated amount of the solution of an oxidizing agent. The mixture was continuously agitated for a prescribed time. To determine the degree of water purification to remove ammonium ions, we sampled the reaction mixture to determine the content of NH_4^+ and ClO^- ions at certain intervals of time. We used wastewater from nitrogen-fertilizer plants, formed in the carbamide production. Sodium and calcium hypochlorites were used as oxidizing agents. Sodium hypochlorite was manufactured by Bereznikovo chemical combine under brand name Belizna (Whiteness) and contained 78 g l^{-1} of active chlorine ClO^-. As cal-

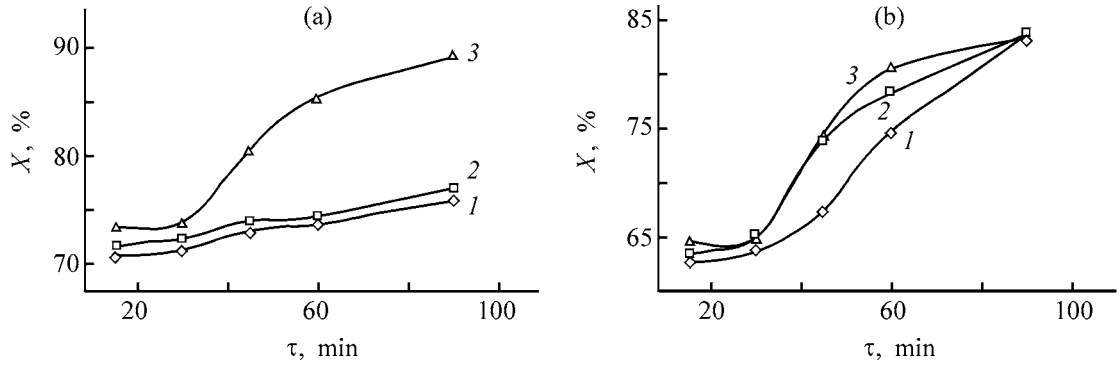

Fig. 1. Degree of wastewater purification, X, vs. time τ at various temperatures. Purification: (a) with sodium hypochlorite and (b) with calcium hypochlorite; the same for Figs. 2 and 3. Temperature (°C): (*1*) 0, (*2*) 20; (*3*) 30.

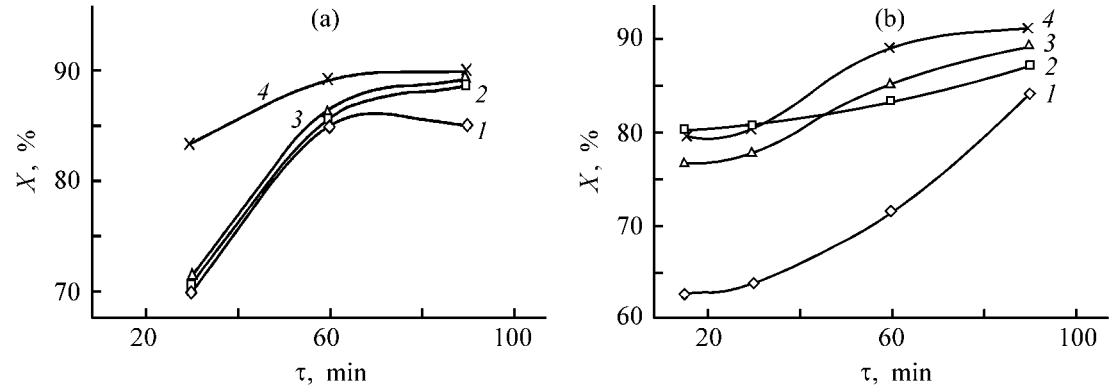

Fig. 2. Degree of wastewater purification, X, vs. time τ at various temperatures and an excess amount of the oxidizing agent. Temperature (°C): (*1*, *2*) 20 and (*3*, *4*) 30. Excess of the oxidizing agent (%): (*1*, *3*) 20 and (*2*, *4*) 40.

cium hypochlorite was used a clarified solution produced as a waste by the gas-purification station of Solikamsk magnesium plant. The content of active chlorine ClO^- was 66.48 g l^{-1}.

The dependences of the degree of purification of a wastewater containing 8.16 g l^{-1} of ammonium ions on time and temperature [stoichiometric consumption of NaClO and $Ca(ClO)_2$] at pH 8.5 are shown in Fig. 1. It can be seen that the effective purification time (T 20 and 30°C) is 60 min. After this time, the oxidation reaction continues, but its rate is low and the degree of purification varies only slightly. An increase in temperature results in that a higher degree of wastewater purification is achieved in a shorter time owing to the higher oxidation rate.

Comparing the action of oxidizing agents (Fig. 1), we can note that the degree of wastewater purification at 30°C is higher with sodium hypochlorite as compared with calcium hypochlorite, whereas at lower temperatures (0 and 20°C), the degree of wastewater purification with sodium hypochlorite is lower.

With $Ca(ClO)_2$, the final degree of purification, X (reached after 1.5 h), is virtually the same both at 30°C and at 0 and 20°C. Thus, calcium hypochlorite better oxidizes ammonium ions than sodium hypochlorite at low temperatures. Possibly, this is due to the presence of iron(III) impurity ions in the calcium hypochlorite solution, which accelerate the oxidation of ammonium ions.

We also found that the presence of an excess amount of the oxidizing agent also affects the completeness of wastewater purification to remove NH_4^+ ions (Fig. 2).

It can be seen from the time dependence of the degree of purification (Fig. 2) that the degree of purification increases with temperature and with the excess of hypochlorite. In the presence of an excess of hypochlorite, the reaction is more intensive even at the very beginning of the purification process and the degree of purification is higher, as demonstrated by the higher X values already after 30 min after the beginning of the process.

It is necessary to note that the maximum degree of wastewater purification to remove ammonium ions under the conditions specified in the experiments under discussion (Figs. 1 and 2) was 89–91%. At

Table 1. Results of wastewater purification with a calcium hypochlorite solution with preliminary neutralization of the wastewater with hydrochloric acid

τ, min	Wastewater without acidification (pH 8.5)		Fast neutralization (acidification to pH 5)		Neutralization within 1 h	
	$c_{NH_4^+}$, g l^{-1}	X, %	$c_{NH_4^+}$, g l^{-1}	X, %	$c_{NH_4^+}$, g l^{-1}	X, %
30	0.561	78.8	0.400	84.9	–	–
60	0.480	81.8	0.240	90.9	0	100
90	0.450	83.0	0.220	91.7	–	–

the same time, chemical analyses demonstrated that the efficiency of use of active chlorine in the oxidation process is higher and reaches 95–98%. This shows that a part of the oxidizing agent is consumed for oxidation of impurity components in wastewater. Carbamide is among such components. An analysis of the wastewater composition indicated that the content of carbamide considerably exceeds that of ammonium ions. In all probability, a part of hypochlorites enter into the following reactions with carbamide [4]

$$CO(NH_2)_2 + 3NaClO = 3NaCl + N_2 + CO_2 + 2H_2O,$$

$$2CO(NH_2)_2 + 3Ca(ClO)_2 = 3CaCl_2 + 2N_2 + 2CO_2 + 4H_2O.$$

For comparison purposes and for revealing the influence exerted by the presence of carbamide on the completeness of wastewater purification to remove ammonium ions, we carried out experiments with a model solution free of carbamide admixtures. The model solution was prepared by diluting a concentrated aqueous solution of ammonia. To compare the results, we prepared a solution containing 8.14 g l^{-1} of NH_4^+, which corresponds to the concentration of NH_4^+ in wastewater. The experiments were carried out at 20°C with a varied amount of the oxidizing agent introduced into wastewater. The results of these experiments are shown in Fig. 3.

It is seen from Fig. 3 that the degree of purification of the model solution to remove NH_4^+ ions is higher than that for the industrial wastewater. These data confirm that the oxidizing agent is partly consumed for side reactions in wastewater purification. Therefore, it is expedient to preliminarily decompose carbamide immediately before the subsequent purification with hypochlorites.

Carbamide is known [5] to be decomposed in acid media by the reaction

$$CO(NH_2)_2 + 2HCl + H_2O = 2NH_4Cl + CO_2.$$

In this context, we carried out experiments on treatment of wastewater containing 2.65 g·l^{-1} of NH_4^+ first with hydrochloric acid to pH 5 and then with calcium hypochlorite. In one experiment, the neutralization with hydrochloric acid was fast, and in the other, the neutralized solution was kept for 60 min. Then the wastewater was treated with a clarified solution of calcium hypochlorite. The volume ratio of the oxidizing agent solution to wastewater was 0.110. The results of the experiments are listed in Table 1. For com-

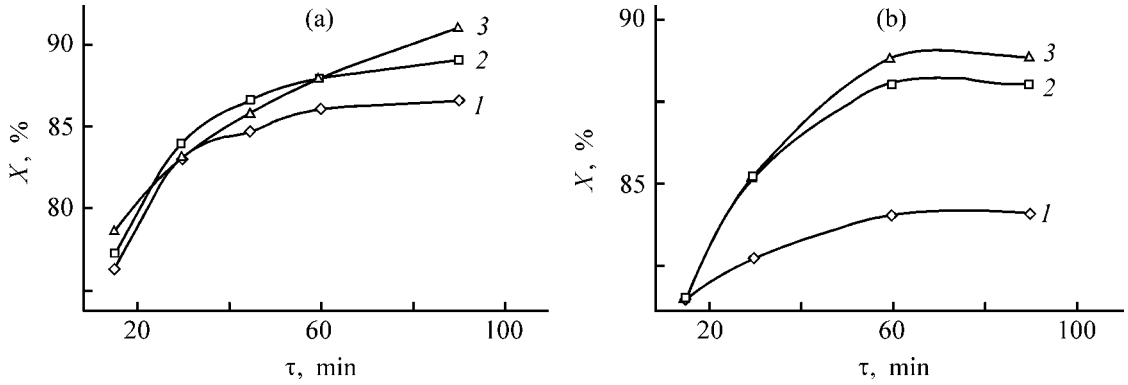

Fig. 3. Degree of purification of model wastewater, X, vs. time τ at varied excess of the oxidizing agent. Excess of the oxidizing agent (%): (*1*) 0, (*2*) 5, and (*3*) 20.

Table 2. Parameters of purification of water containing 0.530 g l^{-1} of ammonium ions at pH 5

Residual content, mg l^{-1}			Degree of wastewater purification, %	
NH_4^+	$CO(NH_2)_2$	ClO^-	to remove $CO(NH_2)_2$	to remove NH_4^+
1.1	320	0	98.93	99.79
1.7	341	0	98.86	99.68
0	36	0	99.88	100

parison, we carried out experiments on wastewater purification without preliminary neutralization (acidification with hydrochloric acid).

Analysis of the experimental data in Table 1 demonstrates that, with preliminarily neutralization of wastewater with hydrochloric acid for 60 min and the subsequent water treatment with calcium hypochlorite, 100% of ammonium ions are removed from wastewater. In the case of fast neutralization of wastewater with hydrochloric acid (for 30 min) and subsequent treatment of wastewater with calcium hypochlorite, carbamide contained in wastewater has not enough time to decompose, and the degree of wastewater purification to remove ammonium ions is 91.7%. Nevertheless, the degree of purification with calcium hypochlorite of wastewater acidified to pH 5 is higher than that at pH 8.5.

Similar experiments on neutralization with hydrochloric acid in wastewater purification were carried out with water containing 0.530 g l^{-1} of ammonium ions and 30 g l^{-1} of carbamide. The expenditure of the calcium hypochlorite solution was 0.25 m^3 per 1 m^{-3} of sewage. The duration of wastewater treatment with hydrochloric acid and calcium hypochlorite was 60 and 90 min, respectively. The results of these experiments on wastewater purification are listed in Table 2.

The data in Table 2 demonstrate that wastewater purification by the technique described above makes it possible to reduce the concentration of carbamide in wastewater to 36 mg l^{-1} (degree of purification 99.88%) and that of ammonium ions to 0–1.7 mg l^{-1} (degree of purification 99.68–100%). The residual concentration of hypochlorite ions in wastewater is zero.

CONCLUSIONS

(1) At high initial concentrations of ammonium ions in wastewater, an increased expenditure of NaClO and $Ca(OCl)_2$, which depends on the initial concentration of ammonium ions and carbamide, is required for achieving a high degree of purification by oxidation.

(2) Under winter conditions of purification (0°C), the rate of oxidation slightly decreases, which leads to a lower degree of purification or requires a longer duration of the process (up to 60–90 min).

(3) The carbamide impurity present in wastewater is oxidized by hypochlorites of alkali and alkaline-earth metals, which results in a decrease in the degree of water purification to remove ammonium ions by approximately 10%. Purification of water with high content of carbamide impurity requires that an excess amount of hypochlorites of alkali and alkaline-earth metals should be added, which enables purification of contaminated water to remove not only ammonium ions, but also carbamide.

(4) Preliminary adjustment of the pH of discharged solutions with high content of ammonium ions and carbamide makes it possible to raise the degree of water purification to remove ammonium ions by 10%. At a longer treatment duration, wastewater purification by this technique makes it possible to reduce the concentration of carbamide to 36 mg l^{-1} (degree of purification 99.88%) and that of ammonium ions to 0–1.7 mg l^{-1} (degree of purification 99.68–100%). In this case, the residual concentration of hypochlorite ions in wastewater is zero.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Asymmetric Diels-Alder Reaction between Acrylates and Cyclopentadiene in the Presence of Chiral Catalysts

E. G. Mamedov

Institute of Petrochemical Processes, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

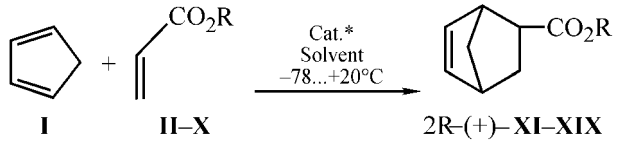
Received August 17, 2005; in final from, March 2006

Abstract—Asymmetric Diels-Alder reaction between cyclopentadiene and alkyl and cycloalkyl acrylates in the presence of new chiral catalysts, $BBr_3 \cdot MentOEt$, $AlCl_2OMent$, BBr_2OMent, and $BBr(OMent)_2$, was studied. Optically active bicyclo[2.2.1]hept-2-ene-5-carboxylates were synthesized. The influence of the reaction conditions on the total and optical yields and on the stereoselectivity of the adducts synthesized was examined.

DOI: 10.1134/S1070427206100120

The asymmetric catalysis is currently under rapid development. The number of publications on this subject and the finance assigned to development of this line tend to increase [1–3]. Organic reactions performed in the presence of chiral catalysts underlie modern asymmetric synthesis. A key issue for achievement of high results in this field is directed synthesis of new efficient optically active catalysts [4].

Norbornene and its saturated analogue norbornane are essential fragments of many important natural compounds [5]. Today, synthesis of new compounds containing these moieties attracts the researchers' attention [6–8]. Synthesis of representatives of this class of compounds in the optically active form is of certain theoretical and practical interest.



Among the promising lines of synthesis of optically active norbornene derivatives is the asymmetric Diels-Alder reaction (ADAR) in the presence of chiral catalysts. We described the first example of ADAR with $BF_3 \cdot MentOEt$ as chiral catalyst in [9]. That study laid the foundations of an efficient method of synthesis of optically active derivatives of norbornene by ADAR, which was further developed [10, 11] using optically active methyloxy- and bornyloxyaluminum dichlorides.

Here we report the results of examination of ADAR between acrylates and cyclopentadiene (CPD) in the presence of chiral catalysts, aimed at preparation of optically active norbornene derivatives.

Chiral B- and Al-containing complex catalysts were synthesized from natural *l*-(–)menthol; their characteristics are listed in Table 1.

All chiral catalysts are well soluble in organic solvents (CH_2Cl_2, CCl_4, $CHCl_3$, C_6H_6, C_5H_5Cl, $C_6H_5CH_3$) and can be used as homogenous catalysts.

Optically active norbornenecarboxylates **XI**–**XIX** are prepared by ADAR according to the scheme

I **II–X** 2R–(+)–**XI–XIX**

where R = Et (**II**, **XI**), *n*-Pr (**III**, **XII**), *i*-Pr (**IV**, **XIII**), *n*-Bu (**V**, **XIV**), *i*-Bu (**VI**, **XV**), *t*-Bu (**VII**, **XVI**),

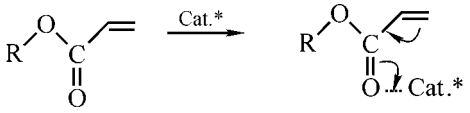
cyclopentyl (**VIII**, **XVII**), cyclohexyl (**IX**, **XVIII**), and cyclohex-3-enyl (**X**, **XIX**).

The reaction was run in a wide temperature range from –78 to 20°C in a CH_2Cl_2 or $C_6H_5CH_3$ solution. The catalyst-to-dienophile molar ratio was varied from 0.25 to 0.75. The physicochemical characteristics of adducts **XI**–**XIX** synthesized are listed in Table 2.

We examined how various reaction parameters affect the isomeric composition, as well as optical and chemical yields of the compounds synthesized. The results are summarized in Table 3.



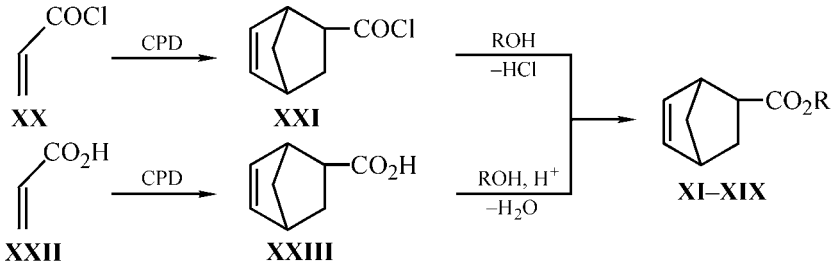
A mixture of *endo* and *exo* isomers of **XI**–**XIX** was separated by preparative chromatography. The amount of *exo* isomers was negligible; therefore, only *endo* isomers of the adducts were collected, and their optical activity was examined.

Table 3 shows that, in contrast to the noncatalyzed asymmetric Diels-Alder reaction of CPD with acrylic

diphenophiles, for which a temperature change insignificantly affects the optical yield of the adducts [12], the optical yield of **XI**–**XIX** significantly increases at lower temperatures in the presence of the chiral catalysts of interest. The optical yield of adduct **XII** with *endo* configuration, synthesized at –78°C, is as high as 94%.

On lowering the temperature, the stereoselectivity of the reaction increases, and the total yield of the adducts decreases. An increase in the content of chiral catalysts does not noticeably affect the optical yield of **XI**–**XIX**, but the total yield increases insignificantly. Table 3 also shows that the optical and total yields of the end products are virtually unaffected by the solvent.

At the reaction parameters within the limits examined, *endo* isomers of the adducts are preferentially formed. The isomeric composition of these adducts was determined by gas liquid chromatography. We found that all the Diels-Alder reactions between CPD and acrylates yield adducts with a positive rotation sign, as in the case of ADAR in the presence of Lewis acids [13]. The catalytic action of chiral catalysts can be attributed to formation of their complex with dienophiles **II**–**X**. The resulting electron deficiency on the multiple bond in dienophiles facilitates their reaction with CPD:

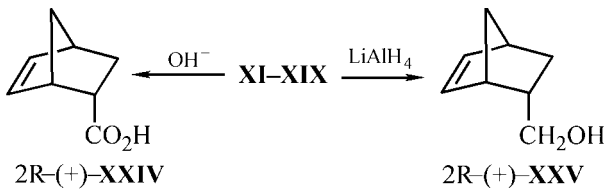


Here Cat.* is a chiral catalyst.

This is confirmed by a shift of the absorption band ν(C=O) from 1730 to 1640 cm^{-1} on passing from dienophiles to their complexes with chiral catalysts. These data are consistent with our observation that the absorption band of the C=O group of methacrylate is shifted from 1730 to 1630 cm^{-1} under the action of BBr_3, which suggests complexing between the catalysts and dienophiles.

All the physicochemical data for adducts **XI**–**XIX** synthesized by different procedures are identical.

The composition and structure of the compounds synthesized were confirmed by independent synthesis:



where R = Et, *n*-Pr, *i*-Pr, *n*-Bu, *i*-Bu, *t*-Bu, cyclopentyl, cyclohexyl, cyclohex-3-enyl.

The composition and structure of adducts **XI**–**XIX** were confirmed by their IR and ^1H NMR spectra.

In the IR spectra of the norbornenecarboxylates synthesized, the absorption bands of the ethylene moiety are observed at 1575–1550 and 3064–3040 cm^{-1} [ν(C=C), ν(C–H)]. The unusual position of the first absorption band is attributed to the strained state of the double bond [14]. The ν(C–H) absorption is characteristic of norbornenes, which distinguishes them both from alkenes with the terminal double bond (3080 cm^{-1}) and from cyclohexene (3024 cm^{-1}).

More information can be derived from the ^1H NMR spectra of nonbornenes derivatives. The spectra of the esters synthesized contain characteristic signals due to protons of the double bond of the norbornene moiety at 5.8–6.2 ppm. The signals from protons of the olefin moieties of the *exo* isomers are close because of the spatial remoteness from magnetically anisotropic groups of the substituent. The signals from *endo* isomers are significantly nonequivalent because of the shorter distance from the substituent situated on the rear side of the bicyclic moiety. The bridgehead protons appear at 2.6–2.9 ppm as a multiplet.

To determine the optical yield of the chiral compounds **XI**–**XIX**, they were converted either to **XXIV** by base hydrolysis or to **XXV** by reduction with $LiAlH_4$:

The optical yield of **XI**–**XIX** was determined by comparing the specific rotation of the *endo*-bicyclo[2.2.1]-hept-5-ene-2-carboxylic acid **XXIV** or 2-hydroxymethylbicyclo[2.2.1]hept-5-ene **XXV** synthesized with those of the corresponding enantiomerically pure sample described by Berson et al. [15]. Based on the correlation of the optical rotation sign of compounds with the known configuration [15], the relative configuration of **XI**–**XIX** was determined to be 2R–(+) for all the adducts with *endo* configuration.

EXPERIMENTAL

The IR spectra were measured on a UR-20 spectrophotometer at 4000–400 cm^{-1}, and the ^1H NMR spectra, on a Tesla BS-48 (80 MHz) spectrometer in CCl_4 with hexamethyldisiloxane as internal reference. The optical rotation was measured on a Perkin–Elmer-141 polarimeter and on a Spektropol-1 spectropolarimeter. Preparative separation was carried out on 900 × 0.8-cm columns packed with Porovina + 5% polyethylene glycol adipate; evaporator and column temperature, 240 and 170°C, respectively; carrier gas (nitrogen) flow rate 200 $cm^3\ min^{-1}$; flame-ionization detector; a Varian-Aerograph chromatograph. Chromatographic analysis of the compounds we synthesized was performed and their purity was determined with an LKhM-8MD chromatograph with a thermal-conductivity detector; 300 × 0.3-cm column with 5% Porovina on Dinokhrom II; carrier gas (helium) flow rate 40 $cm^3\ min^{-1}$; column and evaporator temperature, 145 and 240°C, respectively.

Acryloyl chloride **XX** was prepared by the known procedure [16].

The starting alkyl and cycloalkyl acrylates **II**–**X** were prepared by the reactions of acryloyl chloride with the corresponding alcohols [17].

The chiral catalysts were prepared by the known procedures: $BBr_3 \cdot$ MentOEt [16], $AlCl_2$OMent, BBr_2OMent, and BBr(OMent)$_2$ [18]. Alkyl and cycloalkylbicyclo[2.2.1]hept-2-ene-5-carboxylates **XI**–**XIX** were prepared by the reactions of CPD with the corresponding acrylates. To a 0.05 M solution of acrylate in 20 ml of CH_2Cl_2, 0.0125 mol of chiral catalyst in 10 mol of CH_2Cl_2 was added at a prescribed temperature. Next, 0.05 M of freshly distilled CPD in 10 ml CH_2Cl_2 was added dropwise with stirring.

After stirring for 0.5 h, the mixture was treated with a dilute HCl solution, washed with distilled water, and dried over $MgSO_4$. After the solvent was evaporated, the residue was vacuum-distilled (for conditions and results see Table 3).

Independent synthesis. Bicyclo[2.2.1]hept-2-ene-5-carboxylic acid chloride **XXI** [17] and bicyclo-[2.2.1]hept-2-ene-5-carboxylic acid **XXIII** [19] were prepared by known procedures. Independent synthesis of **XI**–**XIX** was carried out by the reactions of chloride **XXI** or acid **XXIII** with the corresponding alcohols. All the physicochemical characteristics of compounds **XI**–**XIX** prepared by independent synthesis are identical to those of the compounds prepared by condensation of CPD with acrylates **II**–**X** (Table 2).

CONCLUSIONS

(1) Asymmetric Diels-Alder reaction of alkyl and cycloalkyl acrylates with cyclopentadiene in the presence of chiral catalysts $BBr_3 \cdot$ MentOEt, $AlCl_2$OMent, BBr_2OMent, and BBr(OMent)$_2$ yields optically active norbornenecarboxylates with R–(+) configuration.

(2) As temperature is lowered, the optical yield of norbornenecarboxylates tends to grow and reaches 94% at –78°C; with increasing temperature, the total yield tends to grow, and the stereoselectivity, to fall.

(3) An increase in the content of the chiral catalyst does not noticeably affect the optical yield, but the total yield tends to increase; the solvent only slightly affects the optical and total yields of the adducts.

Abstract—The reaction of arabinogalactan and its oxidized forms with an antitubercular agent, *p*-aminosalicylic acid, was studied. The reaction conditions, chemical composition, and some physicochemical characteristics of the modified compounds were examined.

DOI: 10.1134/S1070427206100132

Arabinogalactan (AG) is a natural water-soluble polysaccharide whose macromolecules have a branched structure and a molecular weight of approximately 40 000. Arabinogalactan has a wide spectrum of biological activity and exhibits immunomodulating, antimutagenic, gastroprotective, and antimicrobial properties. Its specific types of biological activity, combined with a high membranotropism and dispersive power open wide avenues for using AG in medicine and other fields [1–3]. Arabinogalactan is readily subjected to various physical and chemical modifications allowing adjustment of its physicochemical characteristics. For example, modification of AG with medical products is one of the ways for production of more perfect forms of drugs [3–5]. Binding of drugs with AG provides prolonged effect and significantly reduces the toxicity of the initial drugs owing to a decrease in the total amount of a drug for a course of treatment [6].

In this study we examined modification of AG and its low-molecular-weight oxidized forms with an antitubercular agent, *p*-aminosalicylic acid (*p*-ASA) [7].

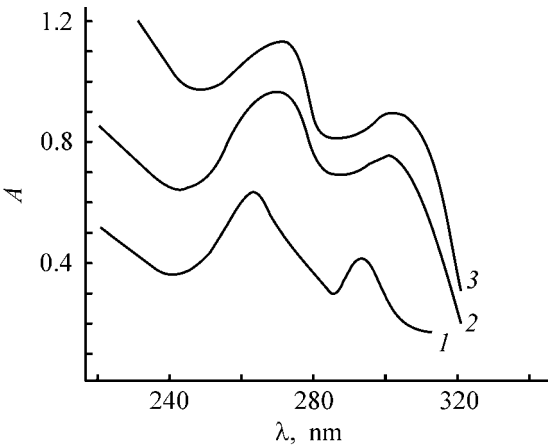
EXPERIMENTAL

We used AG with a molecular weight of 40 000, recovered by aqueous extraction from Siberian larch wood [8]. Extraction and purification of AG to remove water-soluble phenolic compounds was performed on a polyamide sorbent [8]. In so doing, an aqueous polysaccharide solution containing trace amounts of flavonoids was obtained. The ratio of the residues of galactose and arabinose in the polymer is 5.6 : 1 [9]. The oxidative functionalization of AG was performed by oxidation of its aqueous-peroxide solutions with molecular oxygen in a glass bubble-type reactor. The volume of the reaction mixture was 10 ml. After the reaction completion, the polymeric form of oxidized AG was separated from the oligomeric form by precipitation with acetone. The oligomeric form was recovered from the supernatant by distillation of acetone and water, which was followed by drying of the product in a vacuum. The analysis of the functional groups of AG and polymeric (AG_{pol}) and oligomeric (AG_{ol}) forms was described in [10, 11].

The IR spectra of the samples in mineral oil were recorded on a Specord M-80 spectrophotometer. The optical density was determined on a Specord M-40 spectrophotometer; pH of the solutions was measured on an ANION 4100 pH-meter and adjusted by adding 0.1 M NaOH. The specific rotation $[\alpha]_D^{25}$ was measured on a Perkin–Elmer polarimeter (model 141).

The modified compounds were synthesized by the reaction of *p*-ASA with AG and its oxidized

Table 1. Characteristics of AG, AG_{pol}, and AG_{ol} modified with *p*-ASA



Compound	α_D^{20}	IR spectrum ν, cm^{-1}	Appearance
AG	+11.9	3600–3150 (OH), 1740–1710 (COOH), 1152–1080 (C–O)	White powder
AG_{pol}	+8.4	3600–3050 (OH), 1750–1715 (COOH), 1150–1072 (C–O)	Yellowish powder
AG_{ol}	+5.3	3600–3150 (OH), 1760–1720 (COOH), 1130–1090 (C–O)	Brown amorphous substance
AG + *p*-ASA	+13	3450–3020 (OH), 1740–1710 (COOH), 1580 (Ph), 1150–1070 (C–O)	Gray-violet powder
AG_{pol} + *p*-ASA	+9	3550–3015 (OH), 1710–1740 (COOH), 1580 (Ph), 1140–1070 (C–O)	Light violet powder
AG_{ol} + *p*-ASA	+10	2950–2850 (OH), 1760–1720 (COOH), 1580 (Ph), 1040–950 (C–O)	Black amorphous substance

species in water at pH 7–8 [12, 13]. The synthesis procedure was as follows: 1 g of the polysaccharide or oligosaccharide (5.55 base-mmol) was dissolved in 20 ml of distilled water. *p*-ASA in an amount of 0.85 g (5.55 mmol) was suspended in 20 ml of water and pH was adjusted to 7–8. A *p*-ASA solution was added dropwise to a polysaccharide solution, with vigorous stirring at 25°C. The reaction was carried out for 3 h. After the reaction completion, the product was precipitated with ethanol and recrystallized from water into ethanol; the precipitate was separated and washed three times with ethanol and then with diethyl ether and dried in a vacuum. It was shown by thin-layer chromatography (TLC) that the products purified by the above procedure were individual compounds and contained no mechanical impurities of *p*-ASA. The TLC of the complexes was performed on Silufol plates in the systems of solvents *n*-butanol : pyridine : water 6 : 4 : 5; ninhydrin was used as a developer.

The resulting modified compounds of the initial AG (AG + *p*-ASA) and its oxidized species (AG_{pol} + *p*-ASA, AG_{ol} + *p*-ASA) were studied by IR and UV spectroscopy; the rotation angles were determined (Table 1). In the IR spectra of the compounds, there is a shift of the absorption peak in the range 3600–3100 cm^{-1} (OH stretching modes) by 20–50 cm^{-1} and a low-frequency shift of the absorption peaks of stretching modes of the ether C–O bond of pyranose and furanose rings in the range 1200–1100 cm^{-1} by 10–15 cm^{-1}, suggesting also the formation of intermolecular hydrogen bonds between *p*-ASA and polysaccharide molecules. In addition, in the range 1500–1750 cm^{-1}, the intensity of absorption band at 1750 cm^{-1} caused by vibrations of the carbonyl groups decreases, and an absorption band with a medium intensity, caused by vibrations of the benzene ring of *p*-ASA, appears at 1580 cm^{-1}.

In the electronic spectrum of *p*-ASA in aqueous solution at pH 7 and [*p*-ASA] = 10^{-4} M, there are two absorption peaks: at 266 and 298 nm (see figure). The electronic spectra of the reaction products are characterized by the bathochromic shift of the absorption peak to 270 and 303 nm. Solutions of polysaccharides do not absorb in this range.

The main functional groups of AG and its oxidized species are hydroxy and carboxy groups. The amino group in *p*-ASA can interact with carboxy groups of the polysaccharide. In an acidic medium, when dissociation of carboxy groups is suppressed, there is no interaction between polysaccharides and *p*-ASA. In alkaline medium at pH 7 and higher, when carboxy groups of polysaccharides are present in the solution in the form of carboxylate anions and amino groups in *p*-ASA, in the protonated form, modified compounds are formed. Therefore, it can be assumed that the reaction between AG, AG_{pol}, and AG_{ol} with *p*-ASA follows the scheme

Electronic spectra of aqueous solutions of (*1*) *p*-ASA, (*2*) AG + *p*-ASA, and (*3*) AG_{pol} + *p*-ASA. (*A*) Optical density and (λ) wavelength. Concentration (M): (*1*) 1×10^{-3} and (*2, 3*) 1×10^{-4}.

Table 2. Influence of conditions of AG, AG_{pol}, and AG_{ol} modification with *p*-ASA on the content of drug in the modified form

Molar ratio AG : *p*-ASA	τ, h	*T*, °C	Content of *p*-ASA, mol per mole of AG, AG_{pol}, and AG_{ol}
AG + *p*-ASA (mol COOH : mol AG = 0.047)			
1 : 1	0.5	20	0.01
1 : 1	1	20	0.01
1 : 1	2	20	0.02
1 : 1	4	20	0.02
1 : 0.5	24	20	0.01
1 : 1	24	20	0.02
1 : 1	3	25	0.02

1 : 1	4	20	0.21

$$AG\text{–}COOH + H_2N\text{–}C_7O_3H_5 \rightarrow AG\text{–}COO^{-+}H_3N\text{–}C_7O_3H_5,$$

where AG–COOH is AG, AG_{pol}, and AG_{ol}; H_2N–$C_7O_3H_5$ is *p*-ASA.

All the resulting modified compounds are readily soluble in water and DMSO, but insoluble in acetone, alcohols, and ether.

We studied the influence of the conditions of AG, AG_{pol}, and AG_{ol} modification with *p*-ASA on the content of the drug in the modified form (Table 2).

Table 2 shows that the keeping time and heating from 0 to 90°C do not affect significantly the *p*-ASA content of the resulting product. The *p*-ASA content in the compounds synthesized increased with the molar ratio [AG] : [*p*-ASA], and also does so an passing from AG to AG_{pol} and AG_{ol}. This is evidently caused by the higher content of carboxy groups in the oxidized samples of the biopolymer. In AG, there are 4.7 carboxy groups per 100 molecules of the polysaccharide, whereas in the polymer fraction their content is 12, and in the oligomer fraction, 76 per 100 molecules. Hence, the content of carboxy groups in the oligomer fraction is higher than that in the initial AG by approximately a factor of 15, and in the polymer fraction, by a factor of 3, which is in good agreement with data on the content of *p*-ASA in the compounds studied.

We found that, among the compounds studied, AG + *p*-ASA and AG_{ol} + *p*-ASA have high tuberculostatic activity in vitro against pathogenic mycobacteria, AG and AG_{pol} + *p*-ASA exhibit moderate activity, and under the action of AG_{pol} and AG_{ol} the growth of tuberculosis mycobacteria is partially suppressed.

CONCLUSIONS

A correlation between the concentration of carboxy groups in polysaccharides and the drug content in the modified compounds was elucidated. Depending on the polysaccharide fraction, we obtained modified compounds containing 1.4, 8.5, and 16.0% drug. In the course of modification, the protonated amino group of *p*-aminosalicylic acid reacts with carboxylate ions of AG.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Effect of Reactant Association on Addition of Tertiary Amines to Acrylic Acid in Aqueous Solutions

Received January 24, 2006

Abstract—The formation of betaines by the reaction of tertairy amines (*N*,*N*-dimethyl-*N*-2-hydroxyethylamine, *N*,*N*-dimethylaminoethyl methacrylate, *N*-methylmorpholine, *N*,*N*-dimethylaminopropionitrile, 1,4-diazabicyclo[2.2.2]octane) with acrylic acid in aqueous solutions in a wide concentration range was studied. The concentration effects observed were interpreted taking into account the association of the starting reagents.

DOI: 10.1134/S1070427206100144

Carboxy betaines are components of many cosmetics and pharmaceutical preparations [1]. In many cases, it is appropriate to prepare β-betains in a single step by nucleophilic addition of tertiary amines to the activated C=C bond in acrylic acid. Water is a convenient solvent for such reactions [2]. Previously, we have examined the reaction of a series of trialkylamines with acrylic acid in dilute and moderately concentrated aqueous solutions [3, 4]. From the practical viewpoint, it is appropriate to use as high concentrations of reactants as possible; however, specific features of betaine formation from amines and acrylic acid in concentrated aqueous solutions have not been studied yet.

Recent papers give more and more indications that (meth)acrylic monomers in aqueous soilutions tend to form stable molecular associates which can strongly affect the chemical properties of these compounds. In particular, studies of the hydrolysis of aminoalkyl and hydroxyalkyl methacrylates (*N*,*N*-dimethylaminoethyl and 2-hydroxyethyl methacrylates) have shown that the association of the monomers results in abnormal acceleration or inhibition of the reaction in concentrated solutions [5, 6]. Another consequence of the association of amine-containing (meth)acrylic esters or amides in water is the possibility of spontaneous radical polymerization under certain conditions [7, 8]. A study of the radical homopolymerization of acrylic acid (AA) in aqueous solutions also revealed a significant effect of the monomer self-association on the rate constant of chain propagation [9].

In this study, we examined the effect of reactant association on the nucleophilic addition of tertiary amines to AA to give betaines:

$$CH_2{=}CHCOOH + NRR'R'' \rightleftarrows RR'R''\overset{+}{N}CH_2CH_2COO^-,$$

where NRR'R" = $(CH_3)_2NCH_2CH_2OH$ (DMAE), $(CH_3)_2NCH_2CH_2OCOC(CH_3){=}CH_2$ (DMAEM), $H_3C{-}N\langle\rangle O$ (MeM), $(CH_3)_2N(CH_2)_3CN$ (DMAPN), $N(CH_2CH_2)_3N$ DABCO.

As amines we chose compounds containing, along with the reacting amino group, additional N- and O-containing functional groups: *N*,*N*-dimethyl-*N*-2-hydroxyethylamine (DMAE), *N*,*N*-dimethylaminoethyl methacrylate (DMAEM), *N*-methylmorpholine (MeM), *N*,*N*-dimethylaminopropionitrile (DMAPN), asnd 1,4-diazabicyclo[2.2.2]octane (DABCO). The additional functional groups considerably increase the solubility of amines and their salts in water, which allowed syntheses in aqueous solutions in a wide concentration range. Furthermore, according to [10], the energies of intermolecular associative interactions involving hydroxy, etser, ether, nitrile, and amino groups are essentially different. Therefore, we expected that comparison of the activities of polyfunctional amines in the betaine formation would furnish additional information on the effect of these interactions on the reaction in question.

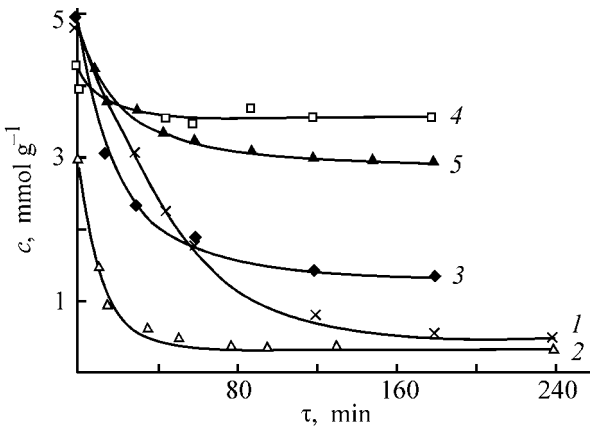

Fig. 1. Variation of the reactant concentration c with time τ. Amine: (*1*) DMAPN, (*2*) DABCO, (*3*) DMAE, (*4*) DMAEM, and (*5*) MeM; the same for Figs. 2, 3, and 5.

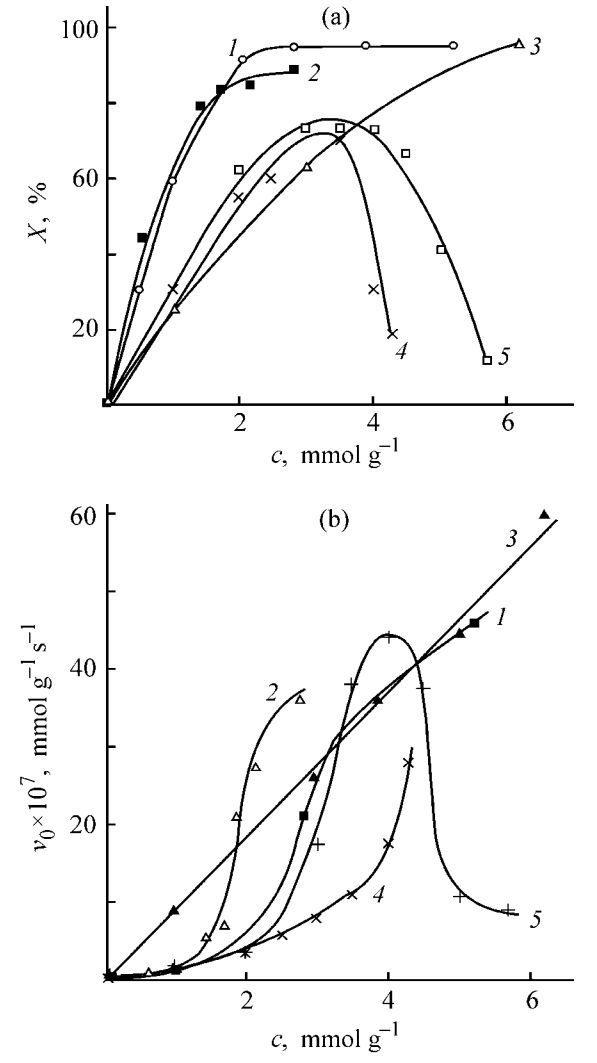

Fig. 2. (a) Equilibrium conversion X and (b) initial reaction rate v_0 vs. the reactant concentration c.

EXPERIMENTAL

The reaction of AA with tertiary amines was performed at 50°C and equimolar ratio of the reactants. Hydroquinone (0.5 wt % relative to AA) was added to the reaction mixtures to prevent radical polymerization. The reactant concentrations in aqueous solution were varied from 1 to 6 mmol g^{-1} (with DABCO, the maximal concentration was 3 mmol g^{-1}; at higher concentrations, the system became heterogeneous).

Addition of tertiary amines to AA was monitored by a decrease in the concentration of the C=C bonds determined by bromide–bromate titration. The specific viscosity of the reactants was measured with an Ubbelohde viscometer (d_c 0.34, 0.56, and 0.73 mm; 25°C). The ^{1}H NMR spectra were recorded on a Varian Gemini-300 Fourier spectrometer (300 MHz), solvent D_2O, reference DMSO.

3-(*N*,*N*-Dimethyl-*N*-hydroxyethylammonio)propionate. To 18.2 g of a 76% solution of AA in water, containing 0.07 g of hydroquinone, we added 17.1 g of DMAE. The resulting mixture was heated at 50°C for 5 h. After the reaction completion, water was distilled off in a vacuum, and the residue was washed with acetone. The product was vacuum-dried (20–40°C, 2 mm Hg) to constant weight. Yield 24.8 g (80.1%). The product contained no C=C bonds and no acid groups.

Found, %: N 8.58.
Calculated, %: N 8.70.

^{1}H NMR spectrum, δ, ppm: 3.34–3.39 ($-CH_2N^+$); 2.85 (CH_3N^+); 2.55–2.64 ($-C\underline{H}_2OH$, $-CH_2COO^-$).

The addition of amines to AA is an equilibrium reaction throughout the examined range of initial concentrations of the reactants. Figure 1 shows typical kinetic curves of consumption of the reactants at their high concentrations. Figures 2a and 2b show the dependences of the equilibrium conversion and initial reaction rate on the initial reactant concentration. The following trends can be revealed. As the initial concentrations are raised in the range 0–1.5 mmol g^{-1} for amines containing no oxygen (DMAPN, DABCO), the equilibrium conversion sharply increases, reaches a maximum (88–95%) at the initial concentration of about 2.5 mmol g^{-1}, and does not noticeably change with further increase in the concentration.

A different pattern is observed with the oxygen-containing amines. In the experiments with DMAE, the equilibrium conversion monotonically grows with

Inductive (σ^*) and steric (R_s) constants of substituents R, R', R" in the starting amines (N^* is the reaction center)

Amine	NRR'R"	$\Sigma\,\sigma^*$	$\Sigma\,-R_s$
DMAE	$(CH_3)_2N^*CH_2CH_2OH$	0.20	5.83
DMAEM	$(CH_3)_2N^*CH_2CH_2OCOC(CH_3)=CH_2$	0.5	6.33
MeM	$CH_3N^*(CH_2CH_2)_2O$	0.67	6.23
DABCO	$N^*(CH_2CH_2)_3N$	–	4.43
DMAPN	$(CH_3)_2N^*CH_2CH_2C\equiv N$	0.8	6.02

the initial solution concentration (with a minor deviation from linearity) and reaches almost 100% at the maximal concentration (actually, for neat reactants without solvent). With DMAEM and MEM, the equilibrium conversion first increases in the initial concentration, passes through a maximum, and then sharply decreases at concentrations exceeding 3.2 mmol g^{-1}.

The dependences of the initial rates on the reactant concentration also vary with the amine structure. This dependence is approximately linear with DMAE, passes through a pronounced maximum with MeM, is close to exponential with DMAEM, and is S-shaped with DMAPN and DABCO.

It has been shown previously [3, 4] that, in dilute solutions at approximately equimolar reactant ratio, the relative activity of various tertiary amines in reactions with AA is determined by the steric accessibility and nucleophilicity of the nitrogen atom. To evaluate these parameters for the amines examined in this study, we used the inductive (σ^*) and steric (R_s) constants of substituents, calculated according to [11, 12]. These procedures were developed for systems with a four-coordinate carbon atom as a reaction center. However, previous studies of *N*-alkylation of tertiary amines have shown that this approach also gives adequate results when applied to systems with a nitrogen atom as reaction center [13].

The constants listed in the table show that the amines chosen are similar in the steric accessibility and nucleophilicity of the reaction centers. Therefore, in accordance with the previously developed concepts, the amines should not essentially differ in the reactivity toward AA. Thus, the concentration effects observed cannot be interpreted in terms of the traditional concept of nucleophilic reactions of amines. We attribute the abnormal dependences of the initial rate of betaine formation and equilibrium conversion on the initial reactant concentration to intermolecular interactions of reactant molecules with the formation of various associates.

Therefore, the next step of our study was concerned with the association of amines in aqueous solutions in the presence of acids. In these experiments, AA was replaced with acetic acid to preclude betaine formation. We obtained the viscosity–concentration dependences (VCDs) for solutions of amine acetates (Fig. 3). It is known [14] that the occurrence and features of intermolecular interactions in solutions can be judged from the VCDs. Pronounced deviations of the VCDs from the linearity, observed with all the amines, suggest the occurrence of the association. Figure 3 shows that the VCDs of the salts of all the amines except DABCO exhibit pronounced maxima. According to [14, 15], maxima in the viscosity isotherms correspond to the formation of stable complexes in the system. To evaluate the relative capability of the amine salts for association, we cal-

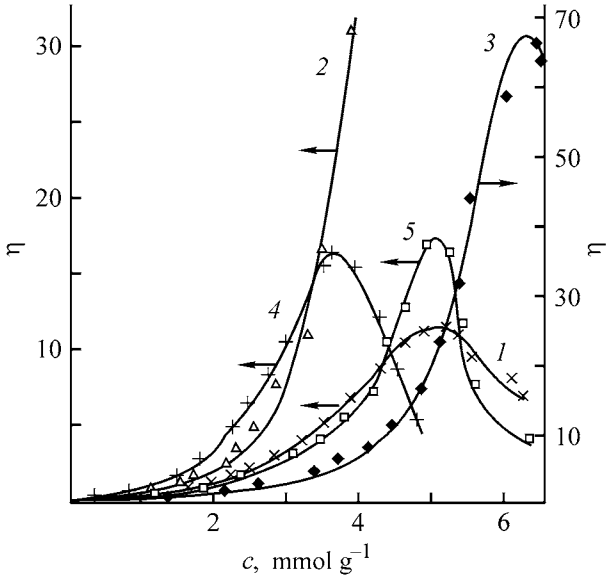

Fig. 3. Specific viscosity η of aqueous solutions of amine acetates at 25°C vs. the concentration *c*.

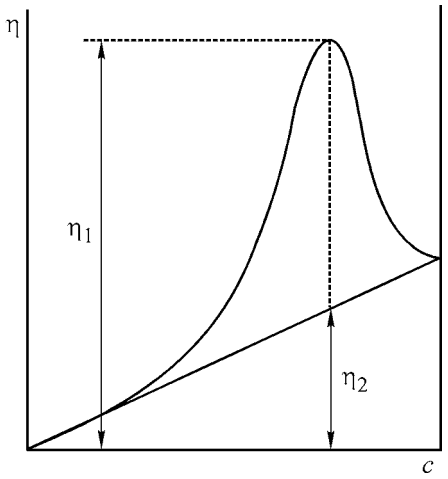

Fig. 4. Determination of η_1 and η_2 for calculating the association factor α.

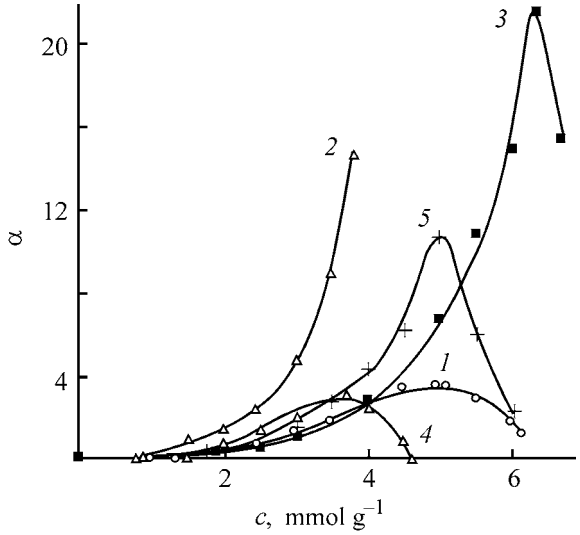

Fig. 5. Association factor α at 25°C vs. the concentration of amine acetates, *c*.

culated the association factor α reflecting the extent of deviation of the VCD from the linearity:

$$\alpha = (\eta_1 - \eta_2)/\eta_2,$$

where η_1 is the actual specific viscosity of an amine salt at a given concentration, and η_2 is the specific viscosity at the same concentration, estimated by extrapolation of the initial linear portion of the VCD (Fig. 4).

Figure 5 shows the dependences of α on the amine salt concentration. It is seen that DABCO and DMAE show the strongest tendency toward association, and DMAEM and DMAPN, the weakest tendency. Thus, the amines chosen are similar in the nucleophilicity and steric accessibility of reaction centers in the isolated molecules, but strongly differ in the tendency toward association in the presence of acids. In this context, it is reasonable to assume that the factor responsible for significant differences in the betaine formation kinetics is the effect of the association on the local concentration, accessibility, and reactivity of active centers of the reactants. Our results show that the association can both accelerate and inhibit the reaction.

In particular, it is known [16] that form linear aggregates alcohols in aqueous solutions. It is reasonable to assume that DMAE or its salt, containing a hydroxy group, also tend to form such associates. Apparently, the local concentration of the reactants in such associates increases, which facilitates their reaction. As a result, the concentration, initial rate, and equilibrium conversion proportionally increase.

Shibalovich et al. [17] measured the surface tension of aqueous solutions of DMAEM and its salts and showed that these compounds exhibit surface activity even in relatively dilute solutions. Hence, associates of micellar rather than linear type are more probable for DMAEM salts. It should be noted that, at concentrations less than 1.8 mmol g^{-1} (relatively dilute solutions), the dependences of the specific viscosity and reaction rate on the amino ester concentration are approximately linear. At concentrations exceeding 2 mmol g^{-1}, both the viscosity of the reaction mixtures and the initial reaction rate sharply increase, i.e., the association of the starting amine salts favorably affects the betaine formation. A sharp decrease in the equilibrium conversion in highly concentrated solutions (>3.5 mmol g^{-1}) is apparently due to formation in the course of the reaction of stable heteroassociates of the starting reactants and betaines, in which the mutual arrangement of the unchanged amino groups and C=C bonds is unfavorable for the reaction.

Data for the MeM–AA system show that, in this case, the reaction rate and viscosity of the system grow virtually linearly as the reactant concentration is raised to 2 mmol g^{-1}, and in the concentration range 2–4 mmol g^{-1} the growth accelerates. With a further increase in the concentration, the initial rate, equilibrium conversion, and viscosity sharply decrease. This fact may be due to the formation in highly concentrated solutions of stable homoassociates of the starting amine salts and heteroassociates of amine salts with the forming betaines, with the mutual arrangement of the amino group and C=C bond in these associates being unfavorable for the reaction.

With DABCO and DMAPN containing no oxygen atoms, the molecular "packing" in the homo- and

heteroassociates is favorable, according to the experimental data, for the betaine formation. Therefore, with an increase in the initial concentration to above 1.0 – 1.5 mmol g^{-1}, the initial reaction rate and viscosity of the mixture demonstrate virtually synchronous accelerated growth, without a decrease in the equilibrium conversion.

CONCLUSIONS

(1) The effect of the initial reactant concentration on the nucleophilic addition of tertiary amines to acrylic acid in aqueous solutions was examined.

(2) With an increase in the initial reactant concentration, the initial reaction rate grows linearly (*N*,*N*-dimethyl-*N*-2-hydroxyethylamine), exponentially (*N*,*N*-dimethylaminoethyl methacrylate), in the S-shaped mode (*N*,*N*-dimethylaminopropionitrile, 1,4-diazabicyclo[2.2.2]octane), or passes through a maximum followed by a sharp decrease (*N*-methylmorpholine).

(3) With an increase in the initial reactant concentration, the equilibrium conversion monotonically grows to reach maximal values (*N*,*N*-dimethyl-*N*-hydroxyethylamine, *N*,*N*-dimethylaminopropionitrile, 1,4-diazabicyclo[2.2.2]octane) or passes through a maximum followed by a sharp decrease (*N*,*N*-dimethylaminoethyl methacrylate, *N*-methylmorpholine).

(4) Salts of tertiary amines in aqueous solutions tend to form associates; their structure determines the course of the reaction of betaine formation.

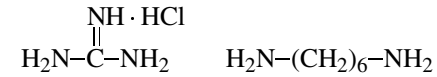
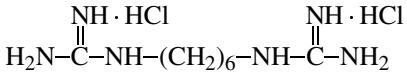
Abstract—Synthesis of polyhexamethyleneguanidine hydrochloride was studied by capillary electrophoresis. A procedure for determining the reaction components was developed.

DOI: 10.1134/S1070427206100156



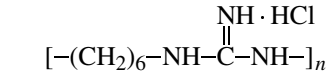
Presently, control of microbial pathogens (human and animal infectious agents) is a very topical problem. It has been demonstrated that water-soluble salts of the high-molecular-weight polycationic compound, polyhexamethyleneguanidine hydrochloride (PHMG), show high biocidal activity against pathogenic microorganisms and low toxicity [1, 2]. However, their application as biocidal agents, especially in medical practice, requires a high quality of the polymer, since admixtures of the initial monomers of guanidine hydrochloride (GHC) and hexamethylenediamine (HMDA) impart toxic and allergic properties to the product. It has also been demonstrated [1] that, in some cases, the biocidal characteristics of the product are dependent on the preparation procedure. Therefore, to control the course of the synthesis and to elucidate the sources of the biocidal activity loss, it was necessary to develop a procedure for prompt analysis of the product and to determine the reaction mechanism.

It is known that capillary electrophoresis (CE) is successfully used for separation and determination of such high-molecular-weight compounds as oligonucleotides, oligopeptides, and oligisaccharides [3, 4]. For example, CE has been used to separate polycationic dendrimers of polyaminoamides with various charge/molecular weight ratios [5].



The goals of this study included were to optimize the conditions of separation and determination of polymeric forms of PHMG (properties of the samples varied, depending on the synthetic conditions) and starting reagents used for its synthesis (GHC and HMDA), determine the reaction mechanism of synthesis, and searching for the ways to monitor the course of the synthesis.

EXPERIMENTAL



As samples for analysis we used PHMG, GHC, HMDA, and also 1,6-diguanidinohexane dihydrochloride (1,6-DGH):[1]

GHC HMDA

1,6-DGH

PHMG

Buffer solutions with pH 6.86 and 9.18 were prepared from NaH_2PO_4/Na_2HPO_4 and $Na_2B_4O_7 \cdot 10H_2O$ standard titrants, using double-distilled water.

For analysis we used a Kapel-105 capillary electrophoresis system (Lumex, St. Petersburg, Russia) equipped with a variable-wavelength UV detector (wavelength range 190–380 nm) and hydraulic sample injection system. We used a quartz capillary

[1] Samples were synthesized and purified at the Institute of Ecotechnological Problems, Moscow, Russia.

(inner diameter 75 μm, outer diameter 375 μm, total length 59 cm, distance to the detector 50 cm) with a polyimide outer protection coating (Composite Metal Services, Worcester, UK). The experiments were carried out at 25°C.

Based on analysis of the UV spectra of the compounds under study, we selected 200 nm as a working wavelength. The best peak resolution was obtained at a working voltage of 20 kV (current 20–50 μA). To refresh the active surface of the capillary, it was rinsed with 0.1 M NaOH, double-distilled water, and the buffer solution after each analysis. The electrophoregrams were recorded in the cathodic space of the capillary. Experimental data were processed using MultiChrom software package for Windows-95/98/NT. The concentration of the analyte in the injected sample was controlled by varying the injection time t and pressure in the injection system p. In making a calibration curve, the desired concentration of the analyte in reference samples was provided by varying the values of p and t (their product was proportional to the analyte concentration in the sample).

The CE method is based on the differentiated migration of components of the sample dissolved in a conducting buffer solution within a narrow capillary under the influence of the applied electric field. The separation is controlled by two factors [6]. First, the electrophoretic mobility of analytes, μ, depends on the size and charge of the ions to be separated. The electrophoretic velocity is written as

$$V = \mu E = zFE/6\pi\eta r N_a, \quad (1)$$

where E is the field strength; z, effective charge; r, Stokes radius of the ion; F, Faraday number; η, viscosity of the electrolyte solution; and N_a, Avogadro number.

Second is that, on applying an external electric field, the negatively charged inner surface of the quartz capillary attracts the counterions from the mobile layer, providing a driving force for a electroosmotic flow (EOF). Since, in our case, the analytes are positive ions, their migration velocity along the capillary is the sum of the EOF and electrophoretic velocities [Eq. (1)]. The electromigration velocity was controlled by varying pH and ionic strength of the buffer solution, i.e. the factors that govern the ζ potential of the surface of the quartz capillary and, therefore, the EOF velocity. In our experiments, it was demonstrated that, in analysis of PHMG and the starting reagents for its synthesis, the optimal conditions are the ionic strength from 0.02 to 0.05 M and pH 6–9.

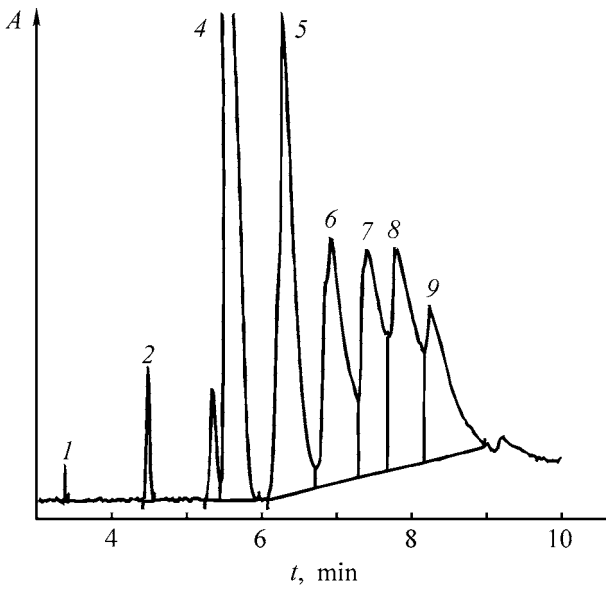


Fig. 1. Electrophoregrams of the mixture of PHMG and starting reagents for its synthesis. Hydrodynamic injection time of the sample 5 s at 30 mbar; 20 mM NaH_2PO_4/Na_2HPO_4 buffer (pH 6.86). Sample composition (mg ml^{-1}): GHC 0.1, HMDA 5.0, 1,6-DGH 1.0, and PHMG 2.0. (*A*) Peak intensity and (*t*) time; the same for Figs. 2, 3. Peak assignments: (*1*, *3*) HMDA, (*2*) GHC, (*4*) PHMD + 1,6-DGH + HMDA, and (*5*–*9*) PHMD oligomers.

A study of the kinetics of the polycondensation of GHC and HMDA [1] showed that, at the equimolar reagent ratio, water-soluble linear PHMG with MW of about 2500 is formed (mean number of units n = 13–14). At a slight molar excess of HMDA, MW increases, and branched or 3*D* polymers can be formed.

In developing a procedure for analysis of PHMG, an important criterion is the possibility of simultaneous determination of the initial reagents used in its synthesis. The typical electrophoregrams of individual GHC and HMDA, PHMG, and 1,6-DGH are shown in Fig. 1. The most difficult was to analyze HMDA, since it gives a weak peak in the electrophoregram, probably because of a low molar extinction coefficient at 200 nm (optimal wavelength selected for identification and determination of the other components). It is known [7] that HMDA, being a strong base, readily absorbs carbon dioxide from air and demonstrates a tendency toward association in solutions. Therefore, it may be suggested that, in the electrophoregram, HMDA will give three peaks corresponding to the cationic species (dicarbonate and carbonate) and dimers. This suggestion is supported by the electrophoregrams of commercial HMDA and HMDA di-

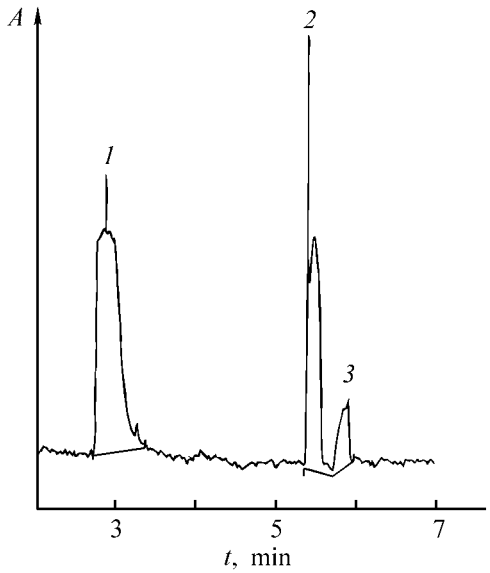

Fig. 2. Electrophoregram of HMDA. Hydrodynamic injection time of the sample 20 s; 20 mM $Na_2B_4O_7 \cdot 10H_2O$ buffer (pH 9.18); HMDA concentration in the sample 5.0 mg ml^{-1}. Peak assignments: (*1*) HMDA dihydrochloride, (*2*) HMDA hydrochloride, and (*3*) HMDA dimer.

hydrochloride specially prepared for this purpose (Fig. 2). Using the standard additive method, we assigned peak no. 2 in the electrophoregram to guanidine hydrochloride (Fig. 1).

In considering the reaction mechanism it was logical to suggest that, in synthesis of PHMG, 1,6-DGH is formed as one of the oligomers, i.e., that the polycondensation proceeds by two quite similar mechanisms *a* and *b*:

$$n\mathrm{H_2N{-}(CH_2)_6{-}NH_2} + n\mathrm{H_2N{-}\underset{\underset{\mathrm{NH\cdot HCl}}{\|}}{C}{-}NH_2} \rightarrow \mathrm{NH_2{-}[(CH_2)_6{-}NH{-}\underset{\underset{\mathrm{NH\cdot HCl}}{\|}}{C}{-}NH{-}]_n} + \mathrm{NH_3}, \quad a$$

$$n\mathrm{H_2N{-}(CH_2)_6{-}NH_2} + (n+1)\mathrm{H_2N{-}\underset{\underset{\mathrm{NH\cdot HCl}}{\|}}{C}{-}NH_2} \rightarrow \mathrm{NH_2{-}\underset{\underset{\mathrm{NH\cdot HCl}}{\|}}{C}{-}NH{-}[(CH_2)_6{-}NH{-}\underset{\underset{\mathrm{NH\cdot HCl}}{\|}}{C}{-}NH{-}]_n} + (n+1)\mathrm{NH_3}. \quad b$$

In the case with $n = 1$, 1,6-DGH is formed by mechanism *b*. To identify 1,6-DGH among the oligomers, this compound and PHMG were analyzed as individual components, and then their electrophoregrams were compared with those of the mixture of 1,6-DGH, DGC, HMDA, and PHMG (Fig. 1). The peaks were assigned using the standard additive method. For example, on addition of 1,6-DGH, the area of the first peak of PHMG increased by the value corresponding to the peak area of the additive, suggesting that it is 1,6-DGH that is responsible for the first peak in the electrophoregram of PHMG, which is consistent with mechanism *b*. As can be seen from the above scheme, the content of guanidine fragments in the oligomers is higher if they are formed by mechanism *b*, which can be considered among the possible explanations for the change in the biocidal activity of the resulting PHMG. It is known [1] that the biocidal activity of PHMG is caused by the presence of the guanidine groups, and the decrease in the biocidal activity of the product can be attributed to the fact that, in this case, the polycondensation proceeds preferentially by mechanism *a*.

In macromolecular chemistry, by oligomers are meant molecularly uniform substances, which are intermediate in molecular weight (from 500 to 5000) and chemical properties between polymers and monomers [8]. In their physical properties, oligomers differ significantly from each other, allowing their separation into individual compounds. Oligomers with higher MW, whose properties are closer to those of polymers, cannot be separated because of the similarity of their physical properties. In our case, the PHMG oligomers have different MW and, accordingly, different molecular sizes. However, only in the case of polycondensation by mechanism *b*, they will have different effective charges and, therefore, different migration rates in the electric field [see Eq. (1)].

In the case of mechanism *a*, the charge to MW ratio is a constant independent of the molecular size; all the oligomers will have the same electrophoretic mobility, and they can be separated only by, e.g., gel electrophoresis or through modification of the buffer solution by additon of appropriate solvents [3, 9, 10].

As mentioned above, the polycondensation product PHMG has a mean unit number of 13–14. Figure 1 shows the electrophoregram of oligomers formed by mechanism *b* as a series of five peaks corresponding to the first five oligomers with considerably different z/MW ratios (for 1,6-DGH z/MW = 2 at $n = 1$), which gradually decrease with increasing n. The other oligomers of this series are represented by a group of unresolved peaks. To increase the separation selectivity, we added solvents (methanol and acetonitrile) into the mobile phase. With acetonitrile, we

* (S) Peak area equal to the product of the optical density by the time, min; (c) concentration, mg ml^{-1}; (r) correlation coefficient; and (S_r) relative standard deviation.

obtained an electrophoregram containing resolved peaks of 16 oligomers (Fig. 3).

The sum of the peak areas (each being the function of the product of the optical density by the time) is the integral signal of the sum of PHMG oligomers. This sum and the signals of the first four oligomers are linear functions of the PHMG concentration (see table). The table also includes the linearity range of the calibration curves (CCs) and detection limits for the compounds studied, the latter being estimated from the peak area (signal/noise = 3).

To monitor the synthesis, samples were taken 20, 30, and 40 min after the beginning of the reaction. Figure 4 shows the evolution of the concentrations of the PHMG oligomers in the course of synthesis. The amounts of the lower oligomers formed by mechanism b initially decreases, reaching a constant value in about 30–40 min, i.e., by the end of the reaction, when the liberation of ammonia is virtually completed. Therefore, the course of the process and the quality of the resulting product can be monitored by the evolution of the concentration of the lower oligomers.

CONCLUSIONS

(1) The mixture of the starting toxic reagents (hexamethylenediamine and guanidine hydrochloride) and their polycondensation products (polyhexamethyleneguanidine hydrochloride and its oligomers) can be separated by capillary electrophoresis.

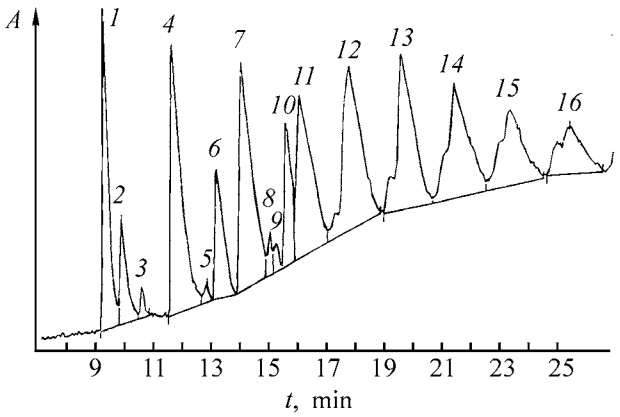

Fig. 3. Electrophoregram of PHMG. Hydrodynamic injection time of the sample 5 s at 30 mbar; 10 mM NaH_2PO_4/Na_2HPO_4 buffer (pH 6.86) + acetonitrile (1 : 1 v/v); PHMG concentration in the sample 1 mg ml^{-1}. For explanations, see text.

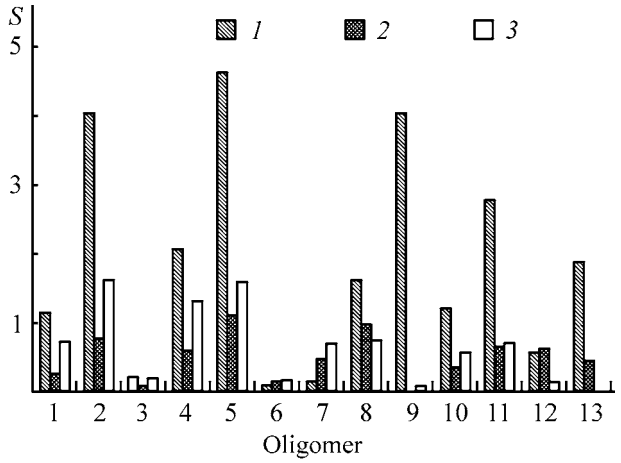

Fig. 4. Evolution of the concentrations of PHMG oligomer nos. 1–13 in the course of synthesis. (S) Peak area. Time (min): (*1*) 20, (*2*) 30, and (*3*) 40.

(2) A procedure is developed for quantitative analysis of polyhexamethyleneguanidine hydrochloride, its oligomers, and the starting reagents used in the synthesis.

(3) The course of the synthesis and the quality of the resulting polyhexamethyleneguanidine hydrochloride can be monitored by the decrease in the concentration of the lower oligomers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Composite Films with Silver Nanoparticles and Their Fractal Aggregates in a Polymeric Matrix

Abstract—Conditions were examined for preparation of film materials with polyacrylamide matrix, promising for optical applications and containing both single silver particles and their fractal aggregates.

DOI: 10.1134/S1070427206100168

Nanocomposite materials containing metal nanoparticles in polymeric matrices have unique optical properties [1–3] and open up new prospects for nanophotonics. This concerns both the fractal-structured nanocomposites or highly ordered colloid systems and composite media with random-uniform distribution of single metal nanoparticles in the matrix [1, 2]. In particular, nanocomposites containing fractal silver aggregates are regarded as one of the most promising types of photochromic media for polychrome recording of information with large storage times [1, 4].

One of the problems arising in preparation and application of metal nanocomposites is the rather low reproducibility of many synthesis methods [2]. In this context, development and improvement of methods for preparation of polymeric nanocomposites still remains an important applied task. Among the simplest methods ensuring uniform distribution of a metal in the matrix is preparation of metal sols by reduction of metal ions, followed by introduction of the sol into a monomer solution and its polymerization.

In this study, we prepared polymeric films, suitable for optical examinations and applications and containing both single silver nanoparticles and fractal aggregates of nanoparticles.

EXPERIMENTAL

Silver hydrosols were prepared from silver nitrate and sodium borohydride solutions. Low-concentration ion-stabilized sols were prepared by the procedure described in [5, 6] by mixing 10^{-3} M solution of $AgNO_3$ and 2×10^{-3} M solution of $NaBH_4$, precooled to 273 K, in a 1:3 (by volume) ratio. The initial temperature of the system was 283 K; next, the system was heated to 333 K and cooled to room temperature. The degree of silver reduction was estimated from the silver ion concentration determined by Folgard's method [7]; as references served standard solutions of silver nitrate, reducing agent, and deionized silver sols, obtained in the presence of a high-molecular-weight stabilizing agent poly-*N*-vinyl-pyrrolidone (PVP) and passed through columns packed with ion exchangers. Silver ions were reduced virtually completely upon heating the sol for 10 min at 333 K; the silver content was 0.003 wt %. The sols stabilized with PVP were prepared by a similar procedure, with a polymer solution preliminarily introduced ($M \approx 20 \times 10^5$) into a silver nitrate solution. The PVP content of the resulting system was 10^{-6} M.

Electron-microscopic examinations with a JEM-100 CX microscope showed that aggregated particles were virtually lacking in the sols. The reduction of silver ions in the presence of PVP decreased to a certain extent, from 18 [5] to 12 nm, the numeric-average particle diameter; the range of particle sizes changed from 5–33 [5] to 2–25 nm.

The electrophoretic mobility of the silver particles was measured by macroelectrophoresis in a Ken instrument at 293 K and a current source voltage of

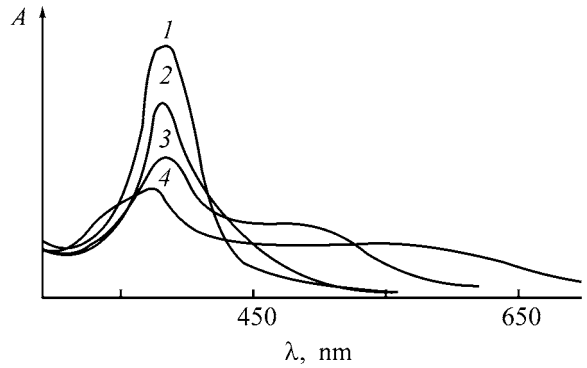

Fig. 1. Evolution of the absorption spectrum of the silver-borohydride hydrosol (*1*) freshly prepared and (*2–4*) with addition of pyridine responsible for the formation of fractal aggregates, at increasing periods of time elapsed after the addition [6]. (*A*) Absorption and (λ) wavelength.

100 V. The lateral liquid was a dispersion centrifugate or solution of potassium nitrate (10^{-3} M). The absorption spectra of the sols were determined on an SF-20 spectrophotometer. We used chemically pure-grade reagents and double-distilled water.

Uniform composition materials suitable for preparation of optical elements are obtained from polymer glasses with addition of nanoparticles of various chemical compositions. The concentration of the dispersed additives in the polymeric binder is typically no greater than 0.1 wt % [2]. Preparation of such nanocomposites requires stabilization of the available metal sols (since the electrostatic factor alone does not ensure the aggregation stability of the sols with such a metal concentration), as well as the controlled aggregate formation in the system. Linear polymers are widely used for stabilization of metal particles; the appropriate length of their chains, exceeding the range action of van der Waals attraction forces between the nanoparticles, is attained at the molecular weight of the polymer over 10^4 because the root-mean-square distance between the ends of a linear polymer chain $(r^2)^{1/2} \approx 0.06M^{1/2}$ [2, 8]. Ion-stabilized sols with a silver content of 0.003 wt %, prepared by Heard [5] and Creighton [6], have a yellow color both in the absence and presence of PVP. This corresponds to localization of the plasmon absorption peak at 400–430 nm; the appearance of the absorption spectra and the half-width of the peak are typical of sols containing single silver particles with a size of 5–30 nm [1, 5].

In the course of slow aggregation of the ion-stabilized silver sols by gradual neutralization of the surface charge (upon addition of pyridine replacing the potential-determining anions), the color of the silver sol successively changes from yellow to red and then to blue-gray [6]. In the absorption spectrum of the sol, the intensity of the absorption peak corresponding to single silver particles decreased, and a long-wave wing appeared covering the entire visible and a part of the IR spectral range (Fig. 1). We discussed the reasons for the evolution of the absorption spectra of the metal sols in [1, 9].

Our measurements revealed a fairly high electrophoretic rate for negatively charged silver particles obtained in the absence of polyvinylpyrrolidone (3.3×10^{-8} m^2 V^{-1} s^{-1}) and the lack of a charge for particles formed in the presence of a nonionic polymer. This suggests localization of the electric double layer within the adsorption layer of the stabilizer [10]. The thickness of the diffusion layer of counter ions, λ, on the surface of the particles in the sol was calculated by the expression

$$\lambda^{-1} = æ = (2F^2I/\varepsilon\varepsilon_0RT)^{1/2}.$$

Here, F is the Faraday constant; I, ionic strength of solution; ε, dielectric constant of the medium; ε_0, permittivity of free space; R, gas constant; and T, temperature.

The ionic strength of the solution $I = 1/2(\Sigma\, c_{0i}Z_i^2)$ (c_{0i} is the ion concentration, and Z_i, ion charge) was estimated taking into account the fact that, for sodium borohydride, the number of single-charged ions does not change as a result of hydrolysis and reduction reaction. The parameter λ for the sol was estimated at 7.6 nm; consequently, the thickness of the polymer layers does not exceed this value.

The sols stabilized with PVP, containing up to 0.15 wt % silver, were obtained at the same ratio of the reactants as in the case of low-concentration sols. The resulting dark brown sols were diluted to a silver concentration of 0.003 wt % for spectral and electrophoretic examinations. The electrophoretic measurements showed that the particles were not charged. The spectral characteristics of the diluted sols corresponded to those of low-concentration sols with single silver nanoparticles. The sols did not change their yellow color upon addition of 1 M KNO_3 or NaCl solution, upon heating and boiling. Even combined action of the electrolyte and boiling did not change the absorption spectra of the sols. Thus, under the actual conditions, stabilization with PVP of a high molecular weight yields highly stable sols with single silver nanoparticles.

Poly-*N*-vinylpyrrolidone is also used for stabilization of sols and simultaneous reduction of silver

ions in aqueous alcoholic solutions in preparation of the pharmacological agent Poviargol [11, 12]. Bogdanchikova et al. [13] showed that, in Poviargol, silver particles 1–2 nm in size are dominating; the second maximum in the particle-size distribution corresponds to the diameter of 70 nm. The electron-microscopic examinations by Panarin et al. [11] showed that Poviargol contains silver nanoparticle aggregates comprising from several to thousand grains each. Particle aggregation in the course of preparation of such systems (with the sedimentation stability of the sols preserved) is confirmed by their spectral characteristics [1]. The main distinctive features of the resulting systems are evidently due to the use of a strong reducing agent and a high-molecular-weight PVP: PVP with a molecular weight of 12.6×10^3 serves as the basic protective polymer in Poviargol [12].

Among the matrices used for development of new nanocomposites based on polymers with silver nanoparticles are polyacrylamide gels [2, 14]. Silver nanoparticles are obtained both in situ (with simultaneous photoreduction of Ag^+ ions and photocopolymerization of a monomer mixture) and by incorporation of cryochemically synthesized silver nanoparticles into polyacrylamide gels [2, 14]. For preparation of similar systems upon introducing polyvinylpyrrolidone-stabilized sol with silver nanoparticles, we used an aqueous solution of the 3 : 1 (by volume) monomer mixture of acrylamide and *N*,*N*'-methylene-bis-acrylamide. Copolymerization was initiated by introduction of the potassium persulfate–*N*,*N*,*N*',*N*'-tetramethylethylenediamine redox system. The silver concentration in the resulting composite medium based on polyacrylamide was 0.1 wt %. In the first stage of film preparation, the mixture was applied, in the initial phase of its viscosity growth, to a glass substrate and kept at room temperature. The optical characteristics of the films corresponded to those observed in absorption of single silver particles. However, prolonged removal of moisture in the course of slow drying of the films was responsible for the gradual appearance of local nonuniformities deteriorating the optical transparency. The reproducibility of the results virtually was not improved upon additional keeping of the films in a drying box at 330 K or in a desiccator with hygroscopic agents. Reproducible preparation of optically uniform films whose characteristics remain virtually unchanged for a long time can be achieved with semi-permeable membranes, used in dialysis, as substrates and by removing moisture with a water-jet pump. Such films can be stored without changes for over 2 years after preparation.

When introduced in an amount insufficient for total coverage of the surface of all the particles, the stabilizer can be nonuniformly distributed over particles [15]. Therefore, for preparation of a uniform system with fractal silver aggregates it is desirable to provide controlled formation of aggregates of particles with the surface entirely covered with the stabilizer. This fractal structure of the aggregates is manifested in the spectra by a significant long-wave broadening of the plasmon absorption band. The maximal broadening of the band in the spectrum corresponds to the minimal thickness of the polymer layers between the particles.

To obtain sols with optical characteristics corresponding to those of fractal silver aggregates, we used a protein-based stabilizer casein used for preparation of the pharmacological agent silver colloid (Collargol). Electron-microscopic examinations by Bogdanchikova et al. [13] showed that, in Collargol solutions, the particle size varies within 1–12 nm with d_{max} of 5 and 12 nm. Spectral examinations of the low-concentration silver sol with a casein stabilizer (c_{Ag} = 0.003 wt %) showed that the sol contains predominantly single silver particles and an insignificant fraction of microaggregates composed of several particles. The latter is indicated by a slightly increased width of the plasmon resonance, 100–120 nm, against 70–90 nm in silver sols with high electrostatic stabilization.

Partial astabilization of a sol based on Collargol is achieved by introducing an alkali. The negatively charged particles of the dispersed phase preserved the electrophoretic mobility in 0.2 M NaOH, while, at such ionic strengths, the particles with electric double layer (prepared in the absence of stabilizers) have a zero electrophoretic mobility. This suggests that the surface electrical characteristics of the particles are totally determined by the protein macromolecules: The isoelectric point of ampholytic casein corresponds to pH 4.7; with increasing pH, the negative charge tends to increase due to dissociation of the functional groups by the acid mechanism [16].

In the absence of light irradiation accelerating silver particle aggregation [1, 3], the spectral characteristics of the freshly prepared partially astabilized yellow sol remain unchanged for 1–2 weeks. Upon solar irradiation, the absorption spectra of the sol exhibit a slow evolution corresponding to thinning of the stabilizer layers between the neighboring particles of the aggregate. The precipitate formed 5 days after the light irradiation has a clear violet tint. This suggests that the adsorption layers preventing formation of dense silver particle aggregates of gray color are preserved [1, 5].

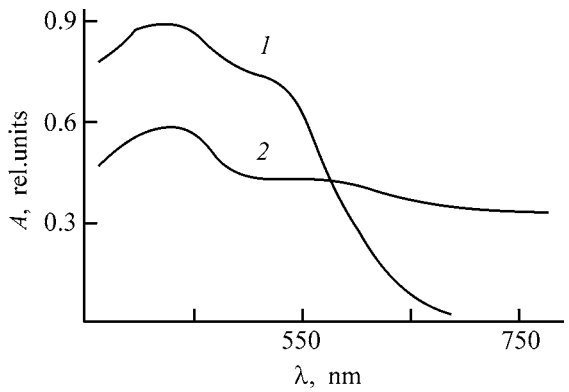

Fig. 2. Absorption spectrum of the silver sol prepared on the basis of Collargol. (*A*) Absorption and (λ) wavelength. Aggregation phase: (*1*) intermediate and (*2*) developed.

To accelerate the formation of fractal structures, the solution temperature was raised, which also decreased the relative amount of the alkali used for astabilization of the sols. The experimental conditions we selected for preparation of a sol with a silver concentration over 0.1 wt % and optical characteristics corresponding to the developed phase of the fractal aggregate formation were as follows. The sol with casein stabilizer (containing 0.07 wt % silver) was prepared by mixing on a magnetic stirrer at 330 K for 0.5 h, followed by the introduction of an alkali solution to the concentration of 0.03 M and evaporation on a water bath at 365 K till the system volume decreased by a factor of 1.5. The absorption spectra of such sols at tenfold dilution have an extended wing in the long-wavelength part of the visible spectral range (Fig. 2), which corresponds to the absorption spectra of sols with fractal silver aggregates [1].

The differential absorption spectra of the films based on polyacrylamide were, on the whole, close to those of the fractal silver aggregates. Prolonged storage of such films prepared on a substrate made of semi-permeable membranes with prompt removal of moisture results in a certain decrease/narrowing of the plasmon absorption band of the incorporated silver aggregates. This effect deserves special examination.

CONCLUSION

The methods for preparation of stable silver hydrosols stabilized with a high-molecular-weight nonionic polymer and silver hydrosols with fractal aggregates of nanoparticles and a protein stabilizer on the surface, as well as the methods for preparation of polymeric films containing fractal aggregates of nanoparticles, can be used for development of new photochromic materials.

Received April 28, 2006

Abstract—Chitosan/polyvinyl alcohol and chitosan/polyethylene oxide blend films were prepared by coagulation from solutions. The interaction energy density B and interaction parameter χ_{12} of the components were estimated from the change in the melting point of the synthetic component in the blends.

DOI: 10.1134/S107042720610017X

Because of its biological activity and polyelectrolyte behavior, chitosan finds wide application as powders, gels, films, and fibers [1]. Mechanical characteristics of chitosan-based materials can be improved by chemical modification of the polymer or blending with other polymers. Blends of chitosan with cellulose [2], polyelectrolytes [3–6], polyvinyl alcohol (PVA) [7, 8], and polyethylene oxide (PEO) [9] have been studied. It was demonstrated that addition of such flexible-chain polymers as PVA and PEO improves the mechanical characteristics of the films. The indicated polymers are biologically inert, which is important for medical applications of the polymer blends. In preparation of the blends, functional groups of chitosan interact with the hydroxy groups of PVA and the ether groups of PEO. Furthermore, an important factor is the increase in the packing density of the macromolecules in blends through filling of the cavities in the rigid structure of chitosan by flexible macromolecules.

It may be suggested that the hydroxy groups of PVA can form stronger hydrogen bonds with the OH and NH_2 groups of chitosan than the less polar ether groups of PEO. However, PEO, has a smaller size of the macromolecule and can provide a denser packing in filling the cavities of the chitosan structure. Therefore, we made a comparative study of the compatibility of chitosan with the indicated flexible-chain polymers under similar conditions. To eliminate the solvent effect on the interaction between the components having different solubilities and solution temperatures we used, in estimation of the interaction parameter the DSC data obtained for the blend films. This method is widely used to characterize the compatibility on the basis of data on the change in the glass transition and melting points of the components in the blends [10]. Evaluation of the compatibility from the glass transition point is complicated by the facts that the peak corresponding to glass transition of PVA in the blends is superimposed with the broad peak due to the evaporation of the bound water, and that the glass transition of PEO occurs below –50°C. Therefore, we selected as a parameter the melting point of the synthetic component in the blend. An additional argument in favor of this decision is that the effects of the conformation and H bonding of the synthetic component on the interaction with the chitosan molecules are insignificant at the melting point.

EXPERIMENTAL

In the experiments, we used chitosan purchased from Dalwoo-Chitosan Co. Ltd. (Korea) (degree of deacetylation 95%; moisture content 7.5%; viscosity at 25°C of 2% solution in 2% acetic acid 30.8 mPa s), polyvinyl alcohol (Merck) (mean MW 45000), and polyethylene oxide (Merck) with MW 35000.

The polymers were dissolved in 2% acetic acid at 80°C with stirring to obtain a clear solution of the desired concentration. The resulting solution was then vacuum-filtered (Buchner funnel) through a glass

filter no. 1. Stock polymer solutions were mixed in the required ratio for 1 h with continuous stirring.

Films were prepared by pouring the solutions onto a foil, which was followed by removing the solvent. The resulting films were 40–60 μm thick.

A thermal analysis of the films was carried out on a Netzsch-Geraetebau GmbH Thermal Analysis scanning calorimeter with heating from 30 to 500°C at a rate of 10 deg min^{-1} under nitrogen.

X-ray diffraction patterns were obtained on a Bruker D8 Advance diffractometer.

To characterize the interpolymer interaction, we used DSC data obtained for the blend films. The compatibility of the polymers was assessed with the melting point depression of the synthetic component serving as a parameter. The DSC curve of chitosan (Fig. 1) shows endothermic peaks associated with removal of adsorbed water (83°C) and glass transition (158.2°C).

The onset of thermal degradation of the chitosan film is observed at 251°C. The thermal degradation in nitrogen is exothermic, and the corresponding peak is observed at 280°C.

The observed broad endothermic glass transition peak and the lack of distinct peaks in the X-ray diffraction pattern of the chitosan film (Fig. 2) suggest an essentially amorphous supramolecular structure of the polymer obtained under the experimental conditions.

The DSC curves of PVA and PEO, obtained in this study, are typical of these polymers [11], so they are not presented here. The endothermic effects of melting were observed at 223.7 and 62°C for PVA and PEO, respectively. In the blends with chitosan, the melting points of the synthetic polymers steadily decreased with increasing chitosan content, and, at a chitosan : synthetic polymer ratio of 90 : 10, the thermal effects of melting were not detected at all. The change in the melting points of the synthetic polymers in the blends with chitosan is shown in Figs. 3a and 3b.

Table 1. Melting point of synthetic polymers in blends with chitosan

Polymer content, wt %	Melting point, °C		Polymer content, wt %	Melting point, °C	
	PVA	PEO		PVA	PEO
100	223.7	62.0	50	216.8	60.1
90	221.4	Not determined	30	208.7	59.4
70	218.0	60.3	10	Not determined	Not determined

Table 2. Thermodynamic parameters of interaction in blends of chitosan with synthetic polymers

Blend	B, cal cm^{-3}	χ_{12}
Chitosan–PVA	–3.3	–0.348 (T_m = 223.7°C)
Chitosan–PEO	–0.81	–0.13 (T_m = 62°C)

A similar effect of depression of the melting point has been reported for blends of well-compatible polymers [12–18]. The melting points of the synthetic components in the blends with chitosan are listed in Table 1.

Thermodynamically, the melting point depression is due to the exothermic effect of interpolymer interaction. Since chitosan occurs in our case essentially in the amorphous state, the interaction parameter was estimated from the dependence of the melting point depression ΔT_m in the amorphous polymer/crystalline polymer blend on the interpolymer interaction energy [19]:

$$\Delta T_m = T_m^0 - T_m = T_m^0(V_{2u}/\Delta H_{2u})B\nu_1^2, \qquad (1)$$

where the subscripts 1 and 2 refer to chitosan and synthetic polymers, respectively; T_m^0 is the melting point of the straight synthetic polymer; T_m, melting point of the synthetic polymer in the blend; ν, volume fraction; V_u, molar volume of the polymer unit; and B, interaction energy density of two polymers.

The interpolymer interaction energy density is related to the interaction parameter χ_{12} by

$$B = RT_m^0(\chi_{12}/V_{1u}). \qquad (2)$$

where R is the gas constant.

It follows from Eq. (2) that the dependence ΔT_m on χ_{12} should be linear, originating from the zero point. From the DSC data we obtained the concentration dependences of ΔT_m (Fig. 4) for the blends of chitosan with PVA and PEO. In estimating the volume fractions of the components, we used the density of amorphous chitosan of 1.5 g cm^{-3} [1], the density of PVA melt of 1.29 g cm^{-3} [16, 17], and that of PEA melt of 1.09 g cm^{-3} [18]. The densities of the polymer melts were taken because the interaction parameters were to be estimated at the melting point. The curves in Fig. 4 intersect the ordinate at 2.4 and 1.5°C for chitosan–PVA and chitosan–PEO blends. Such a deviation from the zero point is within the range typical of compatible polymers (0.5–2.5°C), and should be attributed to the residual entropy effect [12, 19]. In estimating parameter B, we used the $\Delta T_m/\nu_1^2$ ratio obtained from the plots in Fig. 4 (35 and 5.45 for PVA and PEO, respectively); V_u was estimated from the MW to density ratio; and the $\Delta H_{2u}/V_{2u}$ values were taken from [16–18] (45.4 and 49.7 cal cm^{-3}, for PVA and PEO, respectively). The estimated interaction energy densities B and interaction parameters χ_{12} are listed in Table 2.

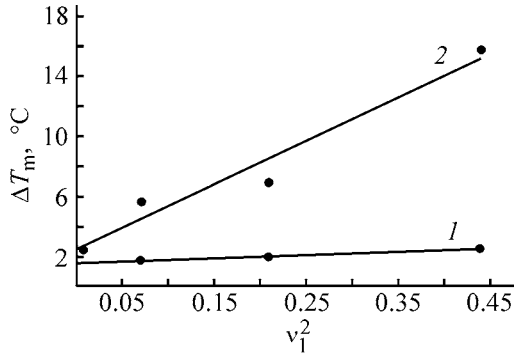

Fig. 4. ΔT_m of (*1*) PEO and (*2*) PVA vs. the volume fraction of chitosan in the blend, ν_1^2.

CONCLUSIONS

(1) Negative values of B and χ_{12} suggest that, in chitosan–polyvinyl alcohol and chitosan–polyethylene oxide blends, the interaction between dissimilar macromolecules is more preferable than that between similar ones. The compatibility of the polymers is provided by strong H bonding between the functional groups of their macromolecules.

(2) Comparison of the interaction parameters in chitosan–polyvinyl alcohol and chitosan–polyethylene oxide blends reveals that the functional groups of chitosan interact with the OH groups of polyvinyl alcohol more strongly than the ether groups of polyethylene oxide.

Abstract—Molecular characteristics of polyelectrolyte complexes of the ultrahigh-molecular-weight poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacryloyloxyethyl)ammonium chloride with oppositely charged surfactants in chloroform were studied by centrifugal sedimentation and viscometry. The effect of oil-soluble surfactants on the hydrodynamic properties of the complexes was examined.

DOI: 10.1134/S10704272061000181

The interaction of polyelectrolytes (PEs) with oppositely charged micelle-forming surfactants produces amphiphilic polymer–colloid complexes whose solubility in aqueous and organic solvents can be controlled by varying the hydrophilic-hydrophobic balance [1–4]. In this case, polyelectrolyte complexes (PECs) of various compositions and molecular organizations can be formed, depending on the initial reagent ratio [5]. At the equimolar PE/surfactant ratio, stoichiometric PECs (SPECs) are formed, which are insoluble in aqueous solvents. Bobrov et al. [6] have demonstrated that SPECs are amphiphilic because of the presence of polar and nonpolar fragments in their structure, namely ionic groups of PEs and surfactants, and hydrophobic aliphatic radicals of surfactants arranged into the lamellar micelles.

A study of the hydrodynamic behavior of SPECs based on amphiphilic anions and ultrahigh-molecular-weight poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacryloyloxyethyl)ammonium chloride (PDMBMAC) in chloroform and methanol showed an abnormal concentration dependence of the reduced viscosity η_r [7]. Such a behavior is typical of polyelectrolytes, suggesting the presence of an effective charge on the chains even in weakly polar solvents.

Additional hydrophobization of SPEC, caused by the presence of the benzyl radical in the polyelectrolyte unit and of hydrocarbon chains of a surfactant, is expected to provide preferential solubility of the complex in nonpolar solvents by virtue of solvation of the indicated fragments of SPEC. However, we have demonstrated previously [7] that the PDMBMAC-based complexes are insoluble in hydrocarbon solvents, and that an increasing fraction of hydrocarbons in mixtures with chloroform promotes compaction of the macromolecular globules.

It may be suggested that the effect of compaction is compensated by weakening of the ion–ion interactions as a result of association of polar groups of the complex with other amphiphilic compounds, e.g., oil-soluble surfactants (OSSs) characterized by low hydrophiliclipophilic balance. In this case, the shielding of the polar groups should make SPECs soluble in a wider spectrum of solvents, including hydrocarbon solvents, thus expanding the applicability range of SPECs.

In this study, we examined the effect of oil-soluble surfactants on the hydrodynamic properties of stoichiometric complexes of the ultrahigh-molecular-weight PDMBMAC in chloroform.

EXPERIMENTAL

Ultrahigh-molecular-weight PEs were synthesized by polymerization of quaternary salts of vinylpyridines and aminoalkyl esters of acrylic and methacrylic acids to form poly(1,2-dimethyl-5-vinyl)pyridinium methyl sulfate (P-1,2-DM-5-VPMS), poly(*N*,*N*,*N*-trimethyl-

PDMBMAC	5.67	1.9	13.6	162	13

N-methacryloyloxyethyl) ammonium methyl sulfate (PDMBMAMS) [8], and poly(*N*,*N*-dimethyl-*N*-methacryloyloxyethyl)ammonium chloride (PDMBMAC) [7].

Molecular properties of the complexes were characterized using static laser light scattering. The molecular weight MW of the PE samples and mean-square radius of gyration R_G were determined by Zimm's double extrapolation procedure [9]. The error of MW determination was within 10%. The Kuhn electrostatic segment was evaluated according to [10] on the suggestion that, in aqueous PE solutions, the contribution of the bulk interactions is negligible as compared to that caused by the electrostatic interactions:

$$l_k^{el} = 6R_g^2/L,$$

where L is the contour length of the chain.

Anionic surfactants, sodium dodecyl sulfate SDS (chemically pure grade, Merck) and Volgonat-emul'gator (VE) [mixture of sodium salts of alkylsulfonic acids RSO_3Na, R = C_{16}–C_{18}, Khimprom Joint-Stock Company, Volgograd, Russia; STP (Enterprise Standard) 2480-282-05 763 458 – 99], were recrystallized from ethanol.

The stoichiometric polyelectrolyte complexes were prepared by mixing components in aqueous solutions with vigorous stirring [7]. The composition of PECs, φ, was characterized by the ratio of the number of diphilic surfactant ions in PEC to the number of PE units in the polymeric complex (φ = $[surfactant]_{PEC}/[PE]_{PEC}$). This value was determined from the results of elemental analysis for sulfur and nitrogen.

Molecular characteristics of the resulting SPECs were determined by centrifugal sedimentation, using an MOM Model 3180 analytical ultracentrifuge (Hungary) at a rotation speed of 30 000 rpm. The sedimentation constants S_0 were determined by extrapolation to zero concentration. The molecular weight $M_{S\eta}$ was determined according to [9]. The M_{calc} value was estimated from MW of the initial PE and PEC composition.

Maleic and stearic acids (oil-soluble surfactants) were used without further purification.

The viscosity of the SPEC solutions in chloroform was measured with an Ubbelohde viscometer (capillary diameter 0.34 mm).

In addition to the solvent effect, the chemical structure of the PE elementary unit influences the solubility of SPECs in nonpolar solvents [2]. An increase in the hydrophobicity of the units of the initial PE makes higher the solubility of the complexes. In this connection, it was necessary to compare molecular and conformation characteristics of a series of ultrahigh-molecular-weight polyelectrolytes.

Table 1 shows that PDMBMAC has lower A_2, Kuhn electrostatic segment B, and radii of gyration R_G and equivalent hydrodynamic sphere R_H, compared to P-1,2-DM-5-VPMS and PDMBMAMS, which suggests the occurrence of intramolecular hydrophobic interactions caused by the presence of the benzyl radical, which is also reflected in the solubility and hydrodynamic behavior of this PE in various solvents [11]. Such a high molecular weight (13.6×10^6) and the presence of the bulky benzyl radical in the structure of PDMBMAC open the door for preparation of ultrahigh-molecular-weight SPECs soluble in low-polar organic solvents.

In all cases, the sedimentograms of the complexes in chloroform showed a single-peak profile. Since PDMBMAC is insoluble in chloroform in the absence of amphiphilic anions, the SPEC does not dissociate into the initial components, but occurs as an individual compound.

Table 2 shows that $M_{S\eta}$ of the PDMBMAC-based hydrophobic complexes in chloroform is $(3.0–4.4) \times 10^7$, and M_{calc}, $(2.7–3.2) \times 10^7$. Keeping in mind the polydispersity of the initial PE sample, one may suggest that the estimated $M_{S\eta}$ values are close to the M_{calc} obtained by taking into consideration MW of

the initial PE and the composition of PEC, φ, and also that SPEC does not form intermolecular associates in chloroform.

Table 2 shows that the radii of equivalent hydrodynamic spheres, R_H^S, of the SPECs obtained are about 100 nm, indicating that chloroform can solvate both the polar and nonpolar fragments of SPEC. As a result, the SPEC macromolecules in chloroform occur as loose swollen globules.

It may be suggested that the weakening of ion–ion interactions in the SPEC structure, as well as the solubility in hydrocarbon solvents, occur by virtue of association of the complexes with other amphiphilic compounds with clearly pronounced hydrophobic behavior. Such compounds can be oil-soluble surfactants (OSSs) having a low hydrophobic–lipophilic balance and a considerable solubility in organic solvents. Taking into consideration the presence of polar groups in the OSS structure, one may expect that its association with the ester groups of SPEC will weaken the intermolecular interactions.

Figure 1 shows how the concentration dependence of the reduced viscosity η_r of complex in chloroform is influenced by addition of oleic and stearic acids.

The concentration dependence of η_r of the complex without addition of OSS (Figs. 1a, 1b) shows that, over the SPEC concentration range 0.3–0.12 g dl^{-1}, SPEC behaves as an uncharged polymer (η_r decreases from 5.3 to 4.6 dl g^{-1}). Further decrease in the SPEC concentration initiates unfolding of the macromolecule as a result of electrostatic repulsion of the charges formed on the chain, which leads to an increase in the reduced viscosity to 4.7–4.9 dl g^{-1}.

Analysis of the concentration dependences of η_r of the solutions of the complex in the presence of OSSs reveals that, in all the systems investigated, the reduced viscosity increases with the OSS concentration (Fig. 1a, curves *2–4*; Fig. 1b, curves *2*, *3*). These curves are similar in shape to the concentration dependence of η_r, obtained without addition of OSS (Figs. 1a, 1b, curves *1*). However, the curves obtained in the presence of OSS are arranged above curve *1*, and η_r is higher by a factor of 1.3–1.5 than that obtained without OSS. Evidently, introduction of OSS weakens the ion–ion interactions in the complex by virtue of the solvation of the esteric fragments of SPEC. As a result, the intermolecular interaction between the solvent and the complex strengthens, providing further swelling of the SPEC globules.

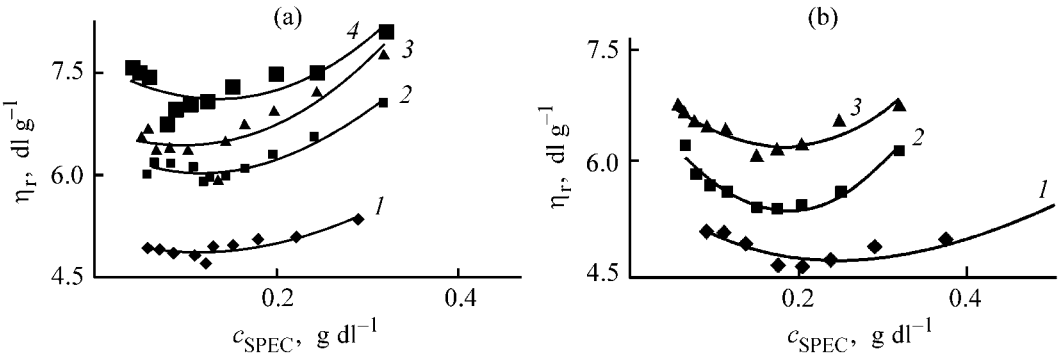

Fig. 1. Reduced viscosity η_r vs. the PDMBMAC–SDS concentration c_{SPEC} in chloroform in the presence of (a) oleic and (b) stearic acids. c_{OSS}/c_{SPEC}: (*1*) 0, (*2*) 5, (*3*) 10, and (*4*) 15.

* (η_r) Reduced viscosity in chloroform at c_{SPEC} = 0.1 g dl^{-1}.

A study of the effect of c_{OSS}/c_{SPEC} on η_r in chloroform (Table 3) showed that an increase in the OSS concentration also leads to a rise in the reduced viscosity of SPEC in chloroform by a factor of 1.6–1.8.

In modern engineering, polymers are widely used to raise the viscosity of aqueous and organic systems. High molecular weights and equivalent hydrodynamic sphere radii (about 100 nm) of the polyelectrolyte complexes obtained in this study suggest that they could be efficient agents to control rheological properties of nonpolar liquids.

CONCLUSIONS

(1) Molecular characteristics of stoichiometric polyelectrolyte complexes based on ultra-high-molecular-weight poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacryloyloxyethyl)ammonium chloride in chloroform are studied. The complexes are characterized by extremely large molecular weight [MW $(3.0-4.4) \times 10^7$], equivalent hydrodynamic sphere radius R_H^S of about 100 nm, and do not form intermolecular associates.

(2) Introduction of oil-soluble surfactants into chloroform solutions of the complexes promotes solvation of ion pairs and polar fragments and provides further swelling of the globules and high viscosity indices, thus expanding their applicability as modifiers of the rheological properties of process fluids.

Abstract—Specific features of the initiated oxidation of polyethylene and its low-molecular-weight analogue tridecane, associated with the occurrence of the process in the short-chain mode, were studied.

DOI: 10.1134/S1070427206100193

Action of aggressive factors and, primarily, atmospheric oxygen and temperature leads to degradation of polymers. Stabilizers are used to preserve the service characteristics of polymers. A search for new, more effective inhibitors of oxidative degradation of polymeric materials is an important theoretical and practical problem. Tentative evaluation of the antioxidation activity of substances is commonly performed on test systems, which simplifies solution of practical stabilization problems and makes it possible to abandon the inefficient empirical trial-and-error method of search for antioxidants (AO).

The aim of this study was to compare the fundamental kinetic aspects of initiated oxidation of polyethylene (PE) and its low-molecular-weight analogue, long-chain hydrocarbon tridecane (TD), in solutions of chlorobenzene (CB) and dichlorobenzene (DCB) to reveal the potentialities of the tridecane–chlorobenzene system as a test system in studies of the antioxidant stabilization of polyolefins.

EXPERIMENTAL

Industrial high-pressure polyethylene (M = 40000) was used in the study. The solvents were purified to remove impurities by the procedure described in [1], with subsequent distillation. The oxidation initiators (I), azodiisobutyronitrile (AIBN) for TD and dicumyl peroxide (DCP) for PE, were purified by recrystallization from ethanol and dried in a vacuum. The oxidation rate W_{O_2} was determined from the oxygen uptake in the initial stage of the reaction by gasometry, which can measure the oxygen absorption rate in the range 12×10^{-8}–1×10^{-4} mol l^{-1} s^{-1}. To provide the kinetic control, the oxidation was carried out at low concentrations of the substrates (PE, up to 8 wt %), partial oxygen pressure of 600 mm Hg, and vigorous agitation with a magnetic rabble at a rate of 200–250 rpm.

The AIBN-initiated oxidation of tridecane in a chlorobenzene solution was performed at 353 K, and PE was oxidized at 383 K. Experiments with neat chlorobenzene demonstrated that no oxygen absorption is observed at 353 K, whereas at 383 K, CB is oxidized at a rather fast rate ($W_{O_2} = 8 \times 10^{-7}$ mol l^{-1} s^{-1} [2]). Therefore, the more stable dichlorobenzene, which is not oxidized at these temperatures, was used to dissolve the polymer.

The influence exerted by the initiator concentration on the rate of oxygen uptake in oxidation of TD and PE was studied (see table). It has been shown previously [3] that, at low rates of initiation in an inert solvent, when rather long chains would be expected for establishing the polymer oxidation mechanism, the reaction rate is negligibly low. To reach noticeable oxidation rates, considerable initiator concentrations were used, with the initiation rates varying within the range $(1–6) \times 10^{-7}$ mol l^{-1} s^{-1}. Under these oxidation conditions, the length ν of the kinetic chain is ~6–7 units for TD and less than 4 units for PE, i.e., the oxidation involves short chains.

In the liquid-phase radical-chain oxidation of hydrocarbons [4], the process rate is first-order with respect to the substance and half-order with respect to the initiator, with the chain length varying from sev-

Oxygen uptake rate W_{O_2} and the kinetic chain length ν in initiated oxidation of tridecane and polyethylene in solutions ([TD] = 0.82 M, [PE] = 38 g l^{-1})

Oxidation substrate	T, K	Initiator	$[I] \times 10^{-2}$, M	$W_i \times 10^7$	$W_{O_2} \times 10^6$	ν
				mol l^{-1} s^{-1}		
TD	353	AIBN	0.61	1.32	0.9	6.8
			1.22	2.65	1.9	7.2
			1.82	3.95	2.7	6.8
			2.43	5.27	3.3	6.3
			3.04	6.60	4.1	6.2
PE	383	DCP	1.5	1.61	0.6	3.9
			2.7	2.88	1.1	3.8
			3.5	3.75	1.4	3.8
			4.5	4.82	1.6	3.4

eral tens to thousands of units. For short chains [4–7], more complex dependences are observed as a result of the involvement of low-molecular-weight radicals (of initiator or solvent) in chain termination. In this case, the kinetic equation of the chain process with short chains has the form

$$W_{O_2} = k_2[RH](W_i/k_6)^{1/2} + aW_i, \quad (1)$$

where a is a coefficient that accounts for release of oxygen in chain termination and its uptake in initiation reactions; [RH], concentration of the oxidation substrate; W_i, initiation rate; $W_i = 2ek_d[I]$; e, initiation efficiency; k_d, rate constant of thermal decomposition of the initiator [8, 9]; k_2, k_6, constants of further propagation and quadratic termination of chains, respectively.

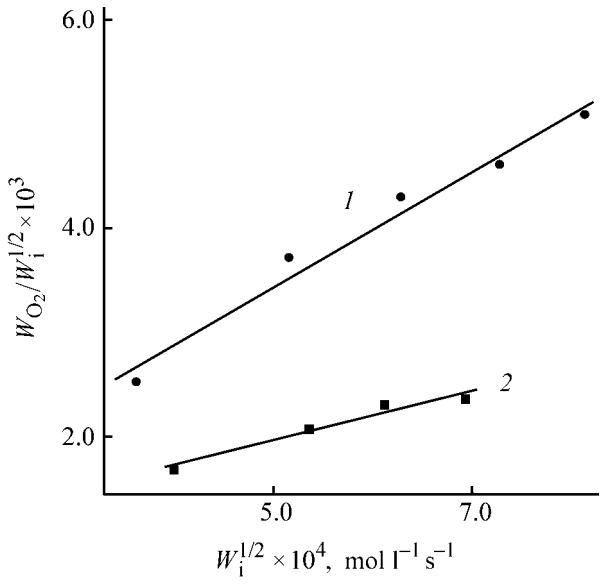

Fig. 1. Effect of the initiation rate W_i on the oxygen uptake rate W_{O_2} in oxidation of (*1*) tridecane and (*2*) polyethylene. (*1*) T = 355 K, [TD] = 0.82 M; (*2*) T = 383 K, [PE] = 38 g l^{-1}.

The data on the oxygen uptake rate at a varied initiation rate, obtained in the study (see table), are linearized in the coordinates of Eq. (1), $W_{O_2}/W_i^{1/2}$ vs. $W_i^{1/2}$ (Fig. 1). This behavior corresponds to oxidation of the long-chain hydrocarbon tridecane and polyethylene in the short-chain range, in contrast to [2], where a linear dependence of W_{O_2} on $W_i^{1/2}$ was observed in *n*-decane oxidation initiated with dicumyl peroxide.

The oxidizability parameter $k_2/k_6^{1/2}$ was found from Fig. 1 by extrapolation to the origin of coordinates: for TD at 353 K this parameter is 3.0×10^{-4} $(l\ s^{-1}\ mol^{-1})^{1/2}$. This value is an order of magnitude lower than those determined previously [3, 6] for benzene and cumene, in agreement with the lower oxidation reactivity of secondary C–H bonds, compared with those of tertiary type.

The fact that the fundamental aspects of initiation of TD and PE oxidation are identical shows that the kinetic schemes of oxidation of the polymer and its low-molecular-weight analogueare are similar.

The effect of raising the substrate concentration [RH] on the process kinetics is shown in Fig. 2. It can be seen that a nonlinear dependence of W_{O_2} on [RH] is observed at low TD and PE concentrations. The same curves were obtained for polymer solutions in [2, 5, 10–12], and this was attributed by the authors

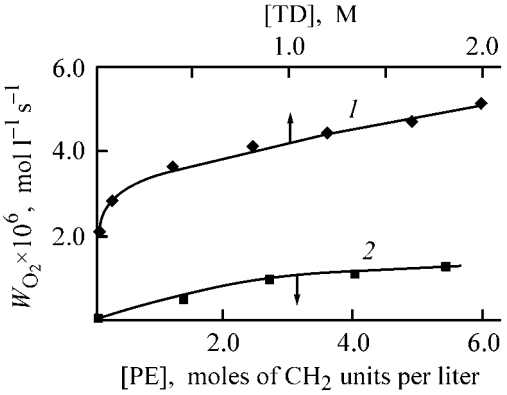

Fig. 2. Rate of initiated oxidation, W_{O_2}, of (*1*) tridecane and (*2*) polyethylene vs. the concentrations of the substrates, [TD] and [PE]. (*1*) T = 353 K, [AIBN] = 3.04×10^{-2} M; (*2*) T = 383 K, [DCP] = 2.7×10^{-2} M.

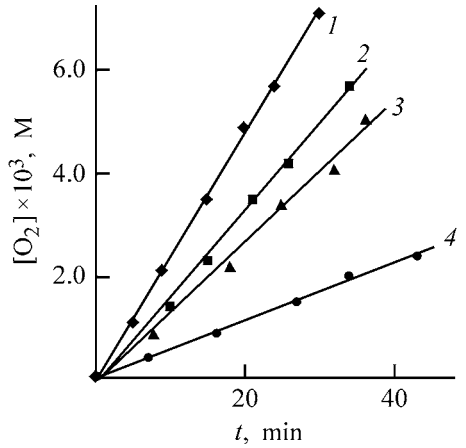

Fig. 3. Kinetic curves of oxygen uptake $[O_2]$ in oxidation of tridecane in a chlorobenzene solution in the presence of ionol. T = 353 K; [AIBN] = 3.04×10^{-2}, [TD] = 0.82 M. (*t*) Time; the same for Fig. 4. [AO] $\times 10^3$ (M): (*1*) 0, (*2*) 1.0, (*3*) 5.0, and (*4*) 10.0; the same for Fig. 4.

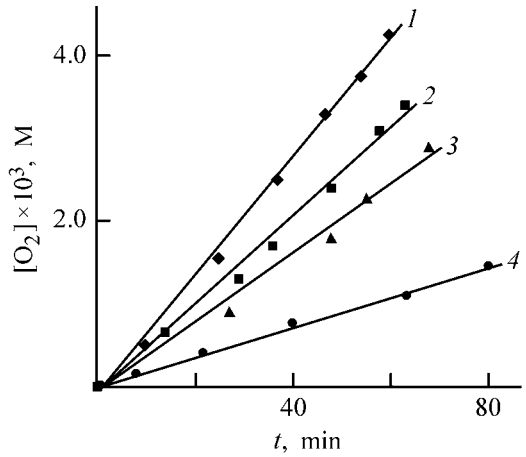

Fig. 4. Kinetic curves of oxygen uptake $[O_2]$ in oxidation of polyethylene in a dichlorobenzene solution in the presence of ionol. T = 383 K; [DCP] = 2.7×10^{-2} M, [PE] = 38 g l^{-1}.

of [11, 12] to solution structuring via aggregation processes that occur as the concentration of polymers increases. However, a similar behavior is observed in oxidation of tridecane (Fig. 2) and other low-molecular-weight hydrocarbons [2, 5, 6]. The nonlinear dependence of W_{O_2} on [RH] is attributed both to conjugated oxidation of the substrate and chlorobenzene [2], which occurs as a result of chain transfer to the solvent (neat CB is not oxidized at 353 K) and to specific oxidation at short chains with account of the intramolecular isomerization [7], i.e., of the relay mechanism of migration of a free valence along the polymer chain.

A comparison of the kinetics of TD and PE oxidation in solutions in the presence of ionol, a classical inhibitor of free-radical processes, also demonstrated that the results obtained in these two cases are identical. The kinetic curves of oxygen uptake by the substrates at varied antioxidant concentrations are shown in Figs. 3, 4. The run of the kinetic curves indicates that there is no induction period of oxidation. It should also be noted that ionol exerts an inhibiting action only at sufficiently high concentrations, which is characteristic of short-chain oxidation processes.

CONCLUSIONS

(1) The study demonstrated that, in initiated oxidation of tridecane in chlorobenzene and polyethylene in dichlorobenzene with molecular oxygen, similar kinetics of the processes are observed, including those in the presence of an inhibitor.

(2) It was shown that the tridecane–chlorobenzene system can serve as a test system adequately modeling the oxidation of polyethylene in solution and can be used in a search for new, more effective inhibitors of polyethylene oxidation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Sulfonation of Poly(Glycidyl Methacrylate) Chains Radiation-Chemically Grafted to Nonwoven Polypropylene

Yu. V. Bondar'

Institute of Environmental Geochemistry, Kiev, Ukraine

Received March 24, 2006

Abstract—Sulfonation of poly(glycidyl methacrylate) chains radiation-chemically grafted to nonwoven polypropylene was performed with sodium hydrosulfite in a water–dimethylformamide solution. Recommendations are given on optimization of the synthesis of a sorption-active hydrophilic polypropylene material bearing strongly acidic sulfo groups.

DOI: 10.1134/S107042720610020X

Nonwoven polypropylene materials are widely used in sorption processes as an adsorbing filtration material. In particular, polypropylene filters, are successfully used thanks to their fibrous structure and to the chemical resistance of the polypropylene base, for catching of microparticles from industrial gas discharges, for purification and separation of petroleum products, liquid chemicals, organic liquids, dyes, pigments, inks, pharmaceuticals, foodstuffs, etc. [1]. The range of possible applications of these materials can be extended by purposeful modification of the hydrophobic, chemically inert polypropylene base. Radiation-chemical technologies and, in particular, radiation-induced graft polymerization, find growing use for this purpose [2, 3]. This method allows introduction of polymer chains with the desired functional groups into an inert polymer matrix both by single-step grafting of appropriate monomers and by grafting of a precursor monomer followed by polymer-analogous transformations.

Because of the limited number of available vinyl monomers with functional groups, the second pathway seems extremely promising. An appropriate precursor monomer is glycidyl methacrylate (GMA), a vinyl monomer containing an epoxy ring which is readily opened under the action of acids, alcohols, and amines [4]. The following polymeric materials have been prepared under laboratory conditions by polymer-analogous reactions involving epoxy rings in grafted poly(glycidyl methacrylate) (PGMA) chains: those containing phosphoric acid groups [5], hydroxylamino and amino groups [6, 7], thiol groups [8], sulfonate groups [9–11], and iminodiacetic acid fragments [12]. However, none of these papers considered issues concerning the optimal density of grafted PGMA chains, efficiency of conversion of epoxy rings in GMA into functional groups, and stability of the functional groups in adsorption processes. The diversity of problems solved using polymeric adsorbents necessitates further search for the best synthesis procedures and a comprehensive study of the properties of the materials prepared.

The goal of this study was to perform a detailed analysis of the sulfonation of grafted PGMA chains and choose of the best conditions for preparing a sorption-active hydrophilic polypropylene material containing strongly acidic sulfo groups.

EXPERIMENTAL

Experiments were performed with a nonwoven material made of polypropylene fibers with radiation-chemically grafted PGMA chains; its preparation procedure is described elsewhere [13]. The PGMA chains were further modified with sodium hydrosulfite in a water–dimethylformamide solution at a weight ratio $NaHSO_3$: water : DMF = 2 : 7 : 3 at 70°C. The chemicals, sodium hydrosulfite (Aldrich) and dimethylformamide (DMF) (Merck, Germany), were used without additional purification.

The density S_{R-SO_3Na} (mmol g^{-1}) of sulfonate groups formed by conversion of the epoxy rings in PGMA was determned by gravimetric analysis (from the weight gain after the reaction):

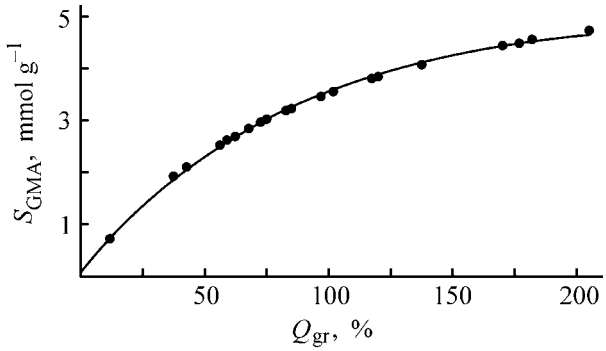

Fig. 1. Density S_{GMA} of grafted PGMA chains vs. the degree of GMA graft polymerization, Q_{gr}.

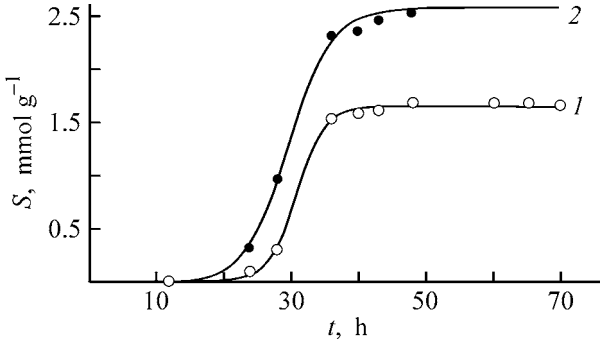

Fig. 2. Influence of the sulfonation time t on the density of the introduced sulfonate groups, S. Degree of GMA grafting, %: (*1*) 40 and (*2*) 180.

$$S_{R\text{–}SO_3Na} = \frac{m_2 - m_1}{m_2 M_{NaHSO_3}} \times 1000,$$

where m_1 is the weight of the grafted sample; m_2, weight of the sulfonated sample in the Na form; and M_{NaHSO_3}, molecular weight of $NaHSO_3$ (104).

The presence of functional groups was judged from the IR spectra recorded on a Perkin–Elmer Golden Gate Single Reflection ATR spectrometer.

The cation-exchange capacity $S_{R\text{–}SO_3Na_t}$ (mmol g^{-1}) reflecting the actual density of sulfonate groups formed by opening of epoxy rings in grafted PGMA chains was calculated from the back-titration results [14].

The adsorption properties of the sulfonated material were determined from the adsorption of Cu^{2+} ions from an aqueous solution of $CuCl_2 \cdot 2H_2O$ at pH 3.8. The content of Cu^{2+} ions in solution was determined with an atomic absorption spectrometer (UNICAM 989, UK).

The amount of metal ions adsorbed by unit weight of the dry modified material, S_m (mmol g^{-1}), was calculated by the formula

$$S_m = \frac{c_0 - c}{W} V,$$

where c_0 and c are the concentrations of metal ions in solution (mmol ml^{-1}) before and after adsorption, respectively; V, volume of the solution being analyzed (ml); and W, adsorbent weight (g).

The procedure for preparing a polymeric sulfonic cation exchanger by conversion of epoxy rings in grafted PGMA chains, considered in numerous papers [9–11], involved three steps: (1) GMA grafting, (2) sulfonation, and (3) hydrolysis. For example, Sasagawa et al. [10] performed sulfonation of porous polyethylene membranes with grafted PGMA chains (degree of grafting 200%, density of grafted chains 10 mmol g^{-1}) in a solution of the composition sodium sulfite : isopropanol : water = 10 : 15 : 75 at 80°C for 0.5–6 h. Since the maximal molar degree of conversion of epoxy rings in GMA into sulfonate groups did not exceed 28%, the unchanged epoxy rings were additionally subjected to hydrolysis in 0.5 M H_2SO_4 (80°C, 2 h). Similar conditions were used in [9, 11].

This sulfonation procedure has apparent advantages over other methods for sulfonation of polymeric materials: The process is fairly simple and easy to control; it allows preparation of a hydrophilic material with high density and prescribed localization of functional (sulfonate) groups.

In our study, the hydrophilic cation-exchange fabric bearing sulfonate groups was prepared in a two-step experiment involving radiation-induced graft polymerization of GMA onto a nonwoven polypropylene support, followed by sulfonation.

The specific features of radiation-induced graft polymerization of PGMA chains onto nonwoven polypropylene support were considered in [13]. By varying the absorbed dose, the temperature and time of grafting, the reaction medium, and the inhibitor concentration, we obtained a nonwoven polypropylene material with a widely varying density of grafted chains (Fig. 1).

The sulfonation with sodium hydrosulfite in aqueous-alcoholic solutions (water–methanol, ethanol, isopropanol) at 70°C failed, but water–dimethylformamide and water–dimethyl sulfoxide solutions appeared to be suitable for sulfonation at this temperature.

The kinetics of sulfonation of PGMA chains was monitored by the increase in the density of the sulfonate groups $S_{R\text{–}SO_3Na}$ (mmol g^{-1}), calculated from the sample weight gain after the reaction. The kinetic curves for two samples with degrees of grafting of 40 (curve *1*) and 180% (curve *2*) are shown in Fig. 2.

A specific feature of the sulfonation is a long induction period (about 20 h) followed by rapid sulfonation and then by flattening-out of the kinetic curve as the maximal conversion of the epoxy rings is attained. Figure 2 shows that the time in which the kinetic curve reaches a plateau depends on the degree of grafting: it is 48 h for the first sample (curve *1*) and 60 h for the second sample (curve *2*). The maximal densities of the sulfonate groups in these samples (plateau level) were 1.6 and 2.5 mmol g^{-1}, respectively.

To study in detail the correlation between the density of the sulfonate groups introduced and the degree of GMA grafting, we chose the reaction time of 70 h, in which the plateau is attained for all the samples.

At low degrees of grafting (Fig. 3, curve *2*), the densities of sulfonate groups, calculated by the gravimetric analysis, grow with the degree of grafting, but the curve slope noticeably decreases at degrees of grafting exceeding 50%. Such a pattern is attributable to the following: at low degrees of grafting, the major fraction of PGMA chains is grafted onto the surface of the polymeric matrix, whereas at high degrees of grafting, the amount of chains grafted onto internal layers increases. Apparently, surface epoxy rings are more accessible to conversion, whereas at high degrees of grafting, their primary conversion may hinder the conversion of the internal GMA epoxy rings.

The density of sulfonate groups, calculated from the back-titration data, is also plotted in Fig. 3 (curve *1*). As noted above, the density of sulfonate groups determined by back-titration, reflects the actual content of sulfonate groups in the sample. Figure 3 shows that, at low degrees of grafting, the curves of the density of the sulfonate groups, plotted on the basis of gravimetric and back-titration data, virtually coincide, whereas at higher degrees of grafting, the gravimetric method gives appreciably overestimated results. This fact suggests the occurrence of another reaction, along with the sulfonation, leading to weight gain. Such a side reaction can be only the hydrolysis of epoxy rings to give diols.

Figure 4 shows the IR spectra of the samples. The IR spectra of nonwoven polypropylene with grafted PGMA chains (Fig. 4, spectrum *2*) contain absorption bands at 1730 (C=O), 1300–1100 (C–O–C), and also 1260, 950–815, and 760 cm^{-1} (epoxy ring). After sulfonation for 70 h, the bands of the epoxy ring at 1260 and 950–815 cm^{-1} disappear irrespective of the degree of GMA grafting (Fig. 4, spectra *3*, *4*), and a new band, characteristic of OH vibrations, appears at 3400 cm^{-1} as well as the absorption bands

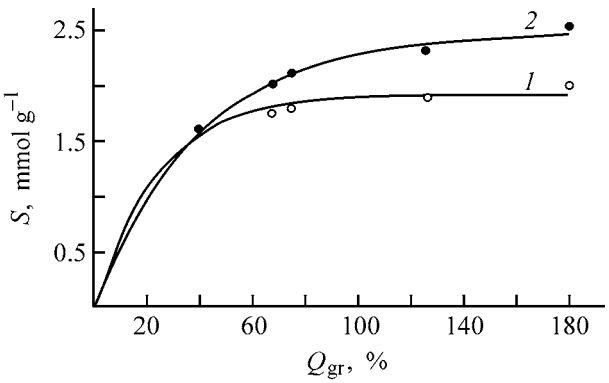

Fig. 3. Density of the introduced sulfonate groups *S*, calculated from (*1*) back-titration and (*2*) gravimetric data, vs. the degree of GMA grafting Q_{gr}.

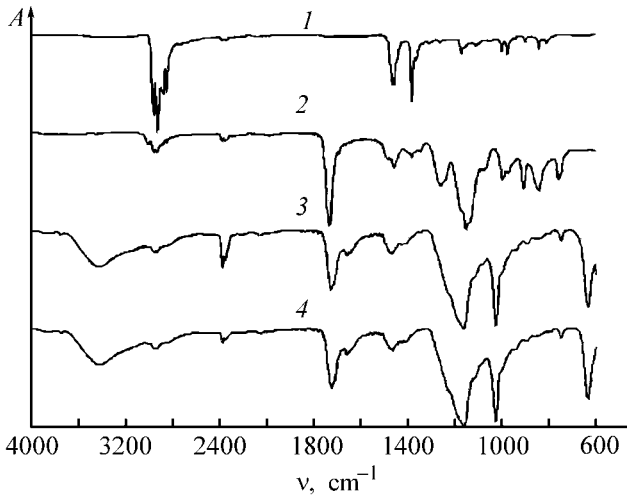

Fig. 4. IR spectra of the (*1*) initial nonwoven polypropylene, (*2*) nonwoven polypropylene with grafted PGMA chains, and (*3*, *4*) sulfonated samples with the degree of GMA grafting of 180 and 40%, respectively. (*A*) Transmission and (ν) wavenumber.

of sulfonate groups at 1150, 1030, and 670 cm^{-1}. The presence of an extremely weak peak of the epoxy ring at 760 cm^{-1} after sulfonation for 70 h can be accounted for by the possible, despite that the radiation grafting of GMA occurs at the acrylic group, also minor involvement of epoxy rings in the formation of cross-links [15]. The IR spectra of samples subjected to incomplete sulfonation (30–40 h) contained absorption bands assignable to vibrations of epoxy rings, hydroxy groups, and sulfonate groups.

Thus, the curves of the density of sulfonate groups vs. the degree of GMA grafting, plotted using the back-titration and gravimetric data, show that, in

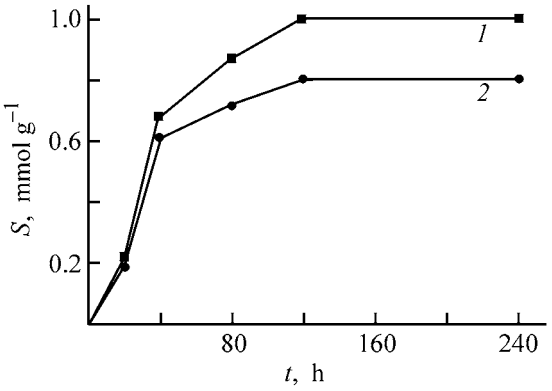

Fig. 5. Kinetic curves of adsorption of Cu^{2+} ions on the cation-exchange polypropylene material bearing sulfonate groups, synthesized in this study. (*S*) Amount of metal ions adsorbed per unit weight of the dry modified material and (*t*) time. Density of sulfonate groups, mmol g^{-1}: (*1*) 20 and (*2*) 1.67.

the course of sulfonation, the epoxy rings are opened not only in the desired reaction but also in a side reaction of diol formation (hydrolysis). The IR spectra of the samples, recorded at different stages of the reaction, confirm this conclusion. The sulfonation ends in complete conversion of the epoxy rings (plateau in the curve). Samples subjected to incomplete sulfonation (stopped before reaching the plateau) contained unchanged epoxy rings along with sulfonate and hydroxy groups; these samples were hydrophobic. After the plateau is reached, with the complete conversion of the epoxy rings into sulfonate and hydroxy groups, the samples become hydrophilic.

The results obtained are of practical significance. Apparently, to prepare an effective sorbent (cation exchanger), it is necessary to take samples with medium degrees of GMA grafting, since further increase in the degree of grafting does not lead to any appreciable increase in the density of sulfonate groups. For example, samples with a 70% degree of grafting will have the same ion-exchange capacity as those with a 170% degree of GMA grafting. This fact is particularly important in the case of synthesis of polymeric adsorbents, since high degrees of graft polymerization often lead to decreased strength of the polymeric support.

For two samples (ion-exchange capacity 2.0 and 1.67 mmol g^{-1}; degrees of grafting of 180 and 70%, respectively), taken in the H form, we determined the adsorption capacity for Cu^{2+} ions in adsorption from an aqueous salt solution. The results presented in Fig. 5 show that the equivalent adsorption capacity of the samples for Cu^{2+} ions is close to the ion-exchange capacity determined by back-titration. The exchange kinetics is fast, i.e., the cation-exchange material will be efficient in sorption processes.

CONCLUSIONS

(1) A cation-exchange material bearing sulfonate groups was prepared by radiation-induced graft polymerization of glycidyl methacrylate on a nonwoven polypropylene support, followed by the sulfonation with sodium hydrosulfite in a water–dimethyl sulfoxide solution at 70°C.

(2) The sulfonation kinetics was studied. The sulfonation ends in the plateau stage in complete conversion of the epoxy rings. The plateau is reached in 40–70 h, depending on the degree of glycidyl methacrylate grafting.

(3) The epoxy ring opening occurs along two pathways: introduction of sulfonate groups and formation of diols (hydrolysis of epoxy rings).

(4) Samples subjected to incomplete sulfonation (with the reaction was stopped before the plateau is reached) contain unchanged epoxy rings along with sulfonate and hydroxy groups. After the plateau is reached, all the epoxy rings are completely converted into the sulfonate and hydroxy groups, and only in this case, the samples become hydrophilic.

(5) To prepare an effective sulfonic cation exchanger, it is appropriate to take samples with medium degrees of glycidyl methacrylate grafting, because further increase in the degree of grafting does not lead to any appreciable increase in the density of sulfonate groups.

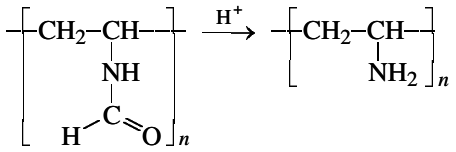
MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

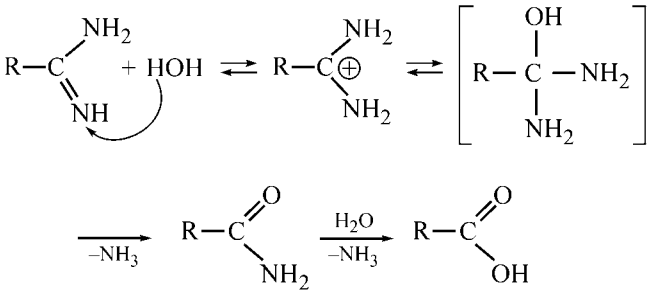
Bifunctional Monodisperse Microspheres of Copolymers of Methyl Methacrylate and *N*-Vinylformamide

A. I. Men'shikova, T. G. Evseeva, K. S. Inkin, Yu. O. Skurkis, and S. S. Ivanchev



Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 21, 2006



Abstract—Emulsion copolymerization of methyl methacrylate and *N*-vinylformamide in the presence of azo initiators and dextran as a polymeric stabilizer was analyzed with the aim to prepare monodisperse polymer microspheres with a polyfunctional surface. Hydrolysis of comonomer units and cationic groups of the initiator residues in the surface layer of the particles to give amphoteric surfaces containing carboxy and amino groups was studied. The optimal conditions of formation of monodisperse microspheres with diameter varied in the 340 – 660 nm range and the conditions of their hydrolysis, which allow direct control of the amount and nature of functional groups on their surface, were found.

DOI: 10.1134/S1070427206100211

At present, polystyrene particles with carboxy or aldehyde surface groups for covalent binding of bioligands are the most widely used corpuscular carriers in latex test-systems [1–4]. However, owing to the diversity of the chemical structures of biologically specific ligands and the necessity to preserve their biologically active conformation after linking, a search for new ways to introduce other functional groups in the surface layer is a topical task. The binding of amino groups to the particle surface by copolymerization of styrene with *N*-vinylformamide (VFA), initiated with 2-azobis(2-methylpropanamidine) (AMP) and followed by hydrolysis of the amide groups, was studied in [5]:

Due to protonation of the amino groups and also amidine groups of the initiator residues at the ends of the polymer chain, the surface of these particles was positively charged in a wide pH range. Moreover, the presence of carboxy groups on the particle surface, whose ionization provides inversion of the surface charge sign at pH ≥ 10, was observed. These carboxy groups can be formed by hydrolysis of the residues of AMP initiator [6, 7]:

Thus, the surface layer of the resulting particles contains both acid and base groups. This type of a polyfunctional surface provides multiple covalent, coordination, and ion-ion interactions with biological ligands; as a result, their structure and amphoteric properties become similar to those of corpuscular biological objects (cells and viruses). Addition of dextran and its derivatives, which provides formation of structures from the protein and polysaccharide fragments simulating the surface membranes of the cells and viruses, opens up additional opportunities for design of the carrier particle surface [8–11]. Biologically compatible polymers less hydrophobic than polystyrene are preferable as polymeric supports. This approach decreases the probability of nonspecific hydrophobic interactions proceeding simultaneously with immunochemical reactions and allows in vivo use of these supports for transportation of drugs and vaccines. As shown previously [9–11], particles of

* All the measurements were carried out in 0.001 M NaCl at pH 6.7.

poly(methyl methacrylate) (PMMA) with a carboxylated surface, prepared in the presence of dextran or its carboxylated derivatives, meet these requirements. In this study, we examined the emulsion copolymerization of methyl methacrylate (MMA) and VFA in the presence of dextran and cationic initiators with the aim to prepare monodisperse copolymer particles with a polyfunctional surface and to found conditions of their surface hydrolysis to obtain amphoteric surfaces containing carboxy and amino groups.

Methyl methacrylate (Ekros Joint-Stock Company, St. Petersburg, Russia) and VFA (98.5%, BASF Corp.) were purified by distillation by standard procedures. The cationic azo initiators, such as 2-azobis[2-(imidazolidinyl-2)propane] (AIP) and 2-azobis(2-methylpropanamidine), purchased from Waco Pure Chemical Industries Ltd. (Japan), and the fraction of dextran hydrolyzate produced by *Leuconostoc Mesnteroids* bacteria with molecular weight 60000 ± 10000, prepared at the Chemical-Pharmaceutical Academy (St. Petersburg, Russia) were used without additional purification. All the solutions were prepared using double-distilled water.

The emulsion copolymerization of MMA with VFA was carried out at 338 ± 1 K in the presence of dextran (0.2 wt % relative to water) in accordance with the procedure described elsewhere [2]. The VFA concentration in the monomer mixture was varied from 0 to 20 wt %, the ratio of the monomer mixture to the aqueous solution was 1 : 10, and the solution pH was varied within 4.8–6.7. The reaction was initiated with AIP or AMP (0.2 wt %).

The particle diameters in the resulting latexes were measured with a JEM 100 S electron microscope (JEOL, Japan). After triple washing to remove water-soluble fraction by centrifugation and intermediate dispersion, the total surface concentration of the carboxy and amino groups was determined by conductometric titration.

The electrophoretic mobility of the copolymer particles prepared under various conditions was determined by standard microphoresis in 10^{-3} M NaCl solutions in a wide pH range. Using experimental data, ζ potentials of the particles were calculated by the Smoluchowski equation.

The properties of particles formed by emulsion polymerization were studied in relation to the nature of the initiator, content of VFA in the monomer mixture, initial pH of the reaction mixture, and content of KH_2PO_4 additive (see table).

An electron microscopic examination of the latexes prepared showed a high monodispersity of the particles of PMMF and copolymers of MMA and VFA [P(MMA–VFA)] formed in the course of emulsifier-free emulsion polymerization in the presence of cationic azo initiators (Fig. 1). The particle size increases with the pH of the reaction mixture because the degree of protonation of the cationic groups of the initiator residues on the particle surface decreased and, consequently, so did the height of the electrostatic barrier preventing aggregation of the primary nuclei at the beginning of the synthesis (see table and Figs. 1a, 1b).

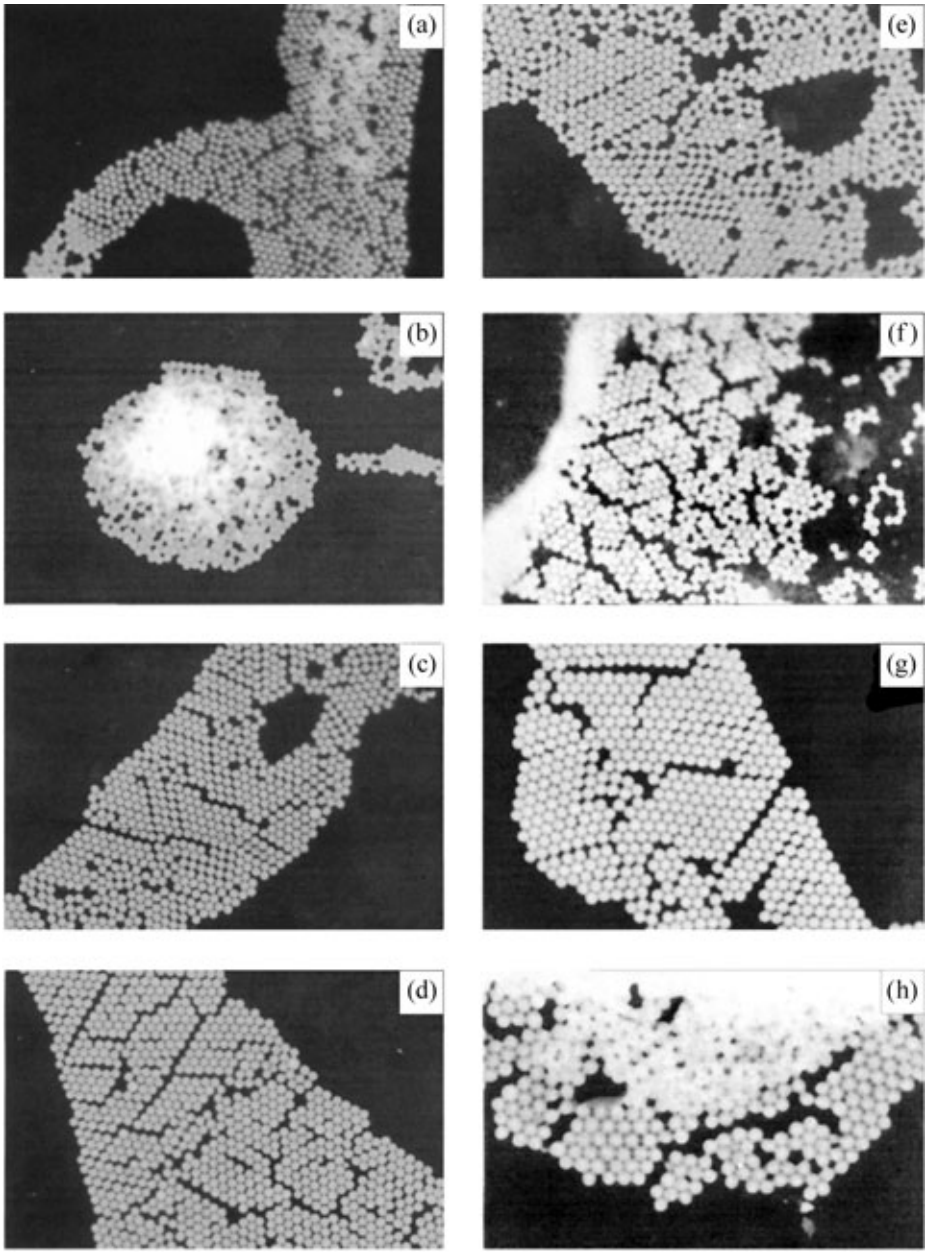

Fig. 1. Electron micrographs: (a–c) PMMA particles prepared in the presence of AMP initiator at pH (a, b) 5.5 and (c) 6.65 [(b) after hydrolysis]; (d–h) P(MMA–VFA) particles prepared in the presence (d) of AMP initiator and 5 wt % VFA and (e–h) of AIP initiator and (e) 5, (f, g) 10, and (h) 15 wt % VFA, (e, f, g) in the absence and (h) in the presence of KH_2PO_4 (0.01 M).

It should be noted that addition of VFA to the reaction mixture in the presence of AMP increases the diameter of the resulting P(MMA–VFA) particles as compared to PMMA particles (see table, run nos. 1–4, Fig. 1d). Moreover, on adding even 5 wt % VFA, the positive ζ potentials of the particles noticeably increase owing to the hydrolysis of this comonomer to form amino groups. However, with the VFA content of the monomer mixture increasing above 5 wt %, the resulting latex coagulated in the course of polymerization in the presence of AMP (run no. 5).

Immediately after the synthesis, the latexes of PMMA (sample no. 1) and of the copolymer of MMA with BFA (5 wt %) (sample no. 2) were hydrolyzed in the presence of 0.15 M HCl at 70–80°C for 24 h [5] to prepare amino groups in the surface layer of the styrene–VFA copolymer particles. However, this treatment led to coagulation of the latexes, which

is probably due to the hydrolysis of not only VFA units to form amino groups, but also initiator terminal groups to form carboxy groups. When weakly acidic and weakly basic groups are simultaneously present in the surface layer, the total surface charge of the particles and the electrostatic barrier of the latex stability both decrease.

Owing to the heterocyclic structure, the imidazole groups are more stable against hydrolysis than the amidine groups in AMP [6, 7]. Hence, we used in our further experiments the AIP initiator with imidazole groups to provide a positive charge of the latex particles. This allowed us to decrease the coagulum formation in the course of copolymerization. We found that the (co)polymerization in the presence of AMP decreased pH of the reaction mixture to 4.0–4.5, whereas in the case of AIP, the acidification was stronger and the pH of the final latex frequently reached 3.5. As a result, the positive ζ potential of the PMMA and P(MMA–VFA) particles prepared with AIP was significantly higher (see table, run nos. 6, 7), which provided their stronger electrostatic stabilization.

It should be noted that substitution of AIP for AMP in initiation of MMA copolymerization with VFA (5 wt %) causes an additional increase in the diameter of the particles formed (run nos. 2, 7), which is probably due to the difference in the rates of degradation of these initiators. The half-life of AMP is 10 h at 57°C, whereas for AIP, the same half-life is observed at about 61°C [12]. Thus, AIP causes a decrease in the rate of initiation and thus in the effective concentration of radicals in the reaction mixture, which, in turn, leads to an increase in the size of the resulting polymer–monomer particles (PMPs) as compared to the initiation of polymerization with AMP under the same conditions.

The AIP initiator increases the content of VFA in the monomer mixture from 5 to 20 wt % without any decrease in the latex stability. This allowed us to evaluate the effect of this hydrophilic comonomer on the particle size (see table, run nos. 7, 8, 10, 11; Figs. 1e, 1f, 1g). We found that, with the VFA content increasing to 10 wt %, the particle diameter slightly decreases. As, however, the VFA content increases to 15–20 wt %, the particle size strongly grows, with the narrow size distribution preserved (Fig. 2). The dependence observed is probably due to two opposite trends. On the one hand, a certain increase in the positive surface charge of a particle upon addition of small amounts of VFA decreases their size and, on the other, enrichment of the oligomer chains with VFA fragments at the beginning of the experiment decreases their surface activity and, thus, impairs their stabilizing performance. As a result, coarser particles are formed at high VFA concentrations, (Fig. 1h), with a simultaneous decrease in the positive ζ potential (see table). This is due to the enrichment of the surface layer of the resulting particles with polymeric chains containing predominantly VFA units. The conformation mobility of these chains at the water–polymer interface is high; as a result, the comparatively smooth and hydrophobic surface of PMMA particles is substituted by the "haired" hydrophilic surface of the copolymer particles. In this case, the ionic groups may be distributed and partially neutralized by counterions in the bulk of the lengthy hydrophilic surface layer; as a result, the charge at the phase sliding boundary and the ζ potential decrease.

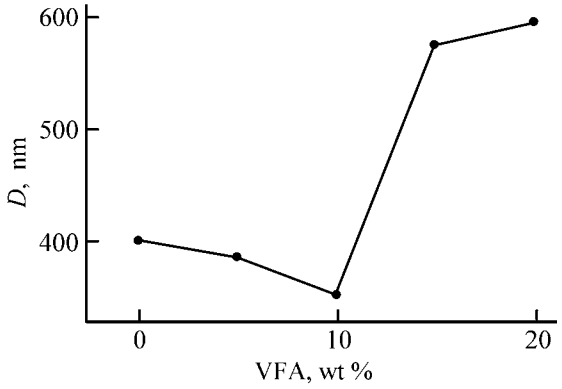

Fig. 2. Diameter of the P(MMA–VFA) particles D vs. the VFA content of the monomer mixture.

The size of the forming particles of a prescribed copolymer composition is usually controlled by varying the ionic strength of the reaction mixture. Indeed, raising the ionic strength of the reaction mixture by adding KH_2PO_4 (10^{-2} M) increases the particle diameter (see table, run nos. 8, 9, 11, 12). As, however, the content of the VFA units in the copolymer increases, this effect disappears owing to a rise in the hydrophilicity of the particle surface. It should be noted that the initial solution becomes more acidic in the presence of KH_2PO_4 and a larger amount of imidazole groups on the particle surface become protonated. This can exert an opposite effect on the size of the resulting particles by compensating for an increase in their diameter. When added to the reaction mixture, KH_2PO_4 also makes higher the content of the surface groups, because the shielding of the surface groups by counterions increases with the ionic strength of a dispersion medium and, in turn, their lateral repulsion decreases, which has been shown previously for a monofunctional carboxylated surface [10, 11].

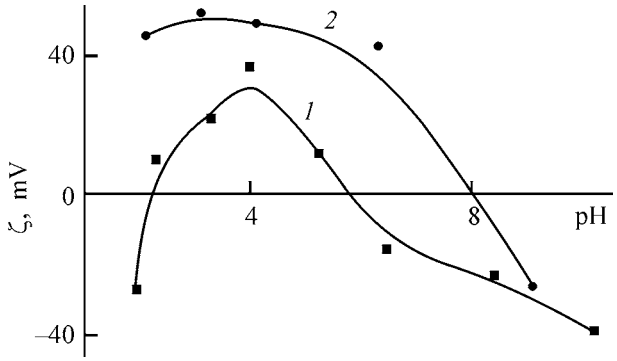

Fig. 3. ζ Potential of particles of PMMA latex prepared in the presence of initiators (*1*) AMP (run no. 1) and (*2*) AIP (run no. 6) vs. the solution pH; 10^{-3} M NaCl supporting electrolyte. Run nos. are the same as in the table; the same for Figs. 4, 5.

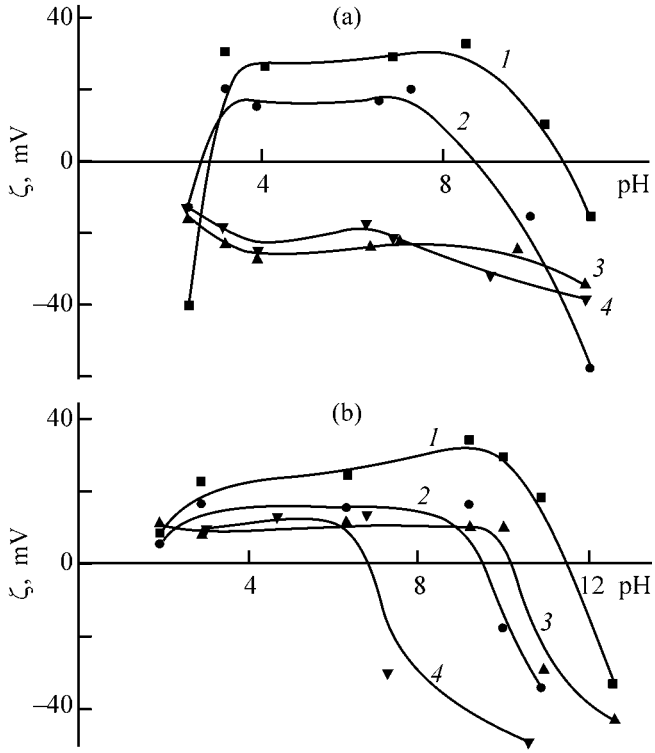

Fig. 4. ζ Potential of particles of (a) PMMA (run no. 3) and (b) P(MMA–VFA-5) latexes (run no. 4) prepared in the presence of AMP initiator (*1*) immediately after preparation and after storage for (*2*) 1, (*3*) 2, and (*4*) 3 days, vs. the solution pH.

Since certain differences were found in the products of polymerization of MMA and its copolymerization with VFA in the presence of AMP and AIP, we studied how the initiator we used affects the stability of the surface characteristics of PMMA and P(MMA–VFA) particles in their storage and subsequent treatment. We found that the surface charge of the resulting particles remained positive after storage for five months at 4°C for all the latexes prepared in the presence of any cationic azo initiator (see table). The ζ potential is more positive in the case of AIP, whose imidazole groups are more stable against hydrolysis.

However, as can be seen from the pH dependences of the ζ potential, an inversion of the potential sign is observed (Figs. 3–5). This suggests that the surface of PMMA and P(MMa–VFA) is enriched with carboxy groups owing to the hydrolysis of the terminal groups of the cationic azo initiators. In the case of the AIP initiator, the loss of the cationic groups upon hydrolysis was smaller than that with AMP (Fig. 3).

In keeping of latexes in acidic and alkaline solutions the PMMA particles retain positive charge for only 1 day (Fig. 4a), whereas addition of the VFA comonomer, whose units are hydrolyzed to form additional amino groups [13], expands the pH range in which the particle surface retains its charge for several days. For example, P(MMA–VFA-5) particles retain their positive charge for a week; the charge slightly decreases in neutral and weakly acidic solutions (Fig. 4b).

With increasing VFA content and upon addition of KH_2PO_4 buffer (10^{-2} M), the positive ζ potential of the resulting particles decreases (Fig. 5). Apparently, both factors favor synthesis of particles with more hydrophilic and, thus, more easily hydrolyzed surface, because the increase in the ionic strength leads to transfer of VFA from the reaction mixture into the polymer–monomer particles and to enrichment of the surface hydrophilic chains with the VFA fragments. In these chains, not only terminal groups of the initiator, but also MMA units can be hydrolyzed. A similar effect is observed as the VFA content in the monomer mixture increases from 15 to 20 wt %. As a result, inversion of the surface charge of the particles prepared under these conditions in acidic and alkaline solutions proceeds more rapidly.

Thus, we found that emulsifier-free emulsion copolymerization of MMA and VFA, initiated by cationic azo initiators in the presence of dextran, yields monodisperse particles 320–660 nm in diameter with a hydrophilic surface layer. The subsequent hydrolysis of the comonomer units and cationic groups of the initiator residues leads to the formation of the amphoteric surface containing both carboxy and amino groups. Taking into account the biocompatibility of the polymer matrix of these particles, structural similarity of their surface to that of cell membranes, and the possibility of their hydrolysis, we can expect that

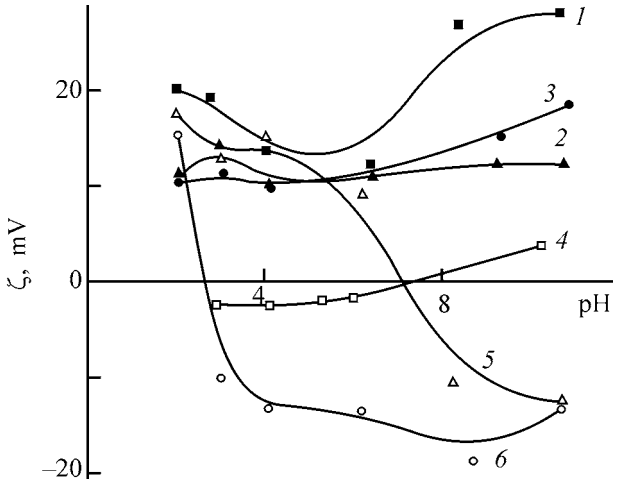

Fig. 5. ζ Potential of particles of (*1*, *4*) P(MMA–VFA-15) (run no. 10) and P(MMA–VFA-20) latexes [(*2*, *5*) run no. 11 and (*3*, *6*) run no. 12] prepared in the presence of AIP initiator (*1*, *2*, *4*, *5*) in the absence and (*3*, *6*) in the presence of KH_2PO_4, (*1*–*3*) immediately after preparation and (*4*–*6*) after storage for 1 day, vs. the solution pH.

these particles would be more efficient carriers of immunological reagents in vivo than the previously described PMMA particles modified with carboxymethyl dextran [10, 11].

CONCLUSIONS

(1) Emulsifier-free emulsion copolymerization of methyl methacrylate and N-vinylformamide in the presence of cationic azo initiators and dextran yields monodisperse microspheres 320–660 nm in diameter with positive surface charge in neutral and weakly acidic solutions.

(2) Comonomer ratio, nature of the cationic azo initiators, initial solution pH, and addition of the salt buffer significantly affect the diameter of the resulting particles, their ζ potential, and possibility of inversion of the surface charge sign.

(3) Hydrolysis in acidic and alkaline solutions of the *N*-vinylformamide units to form amino groups, which proceeds simultaneously with the hydrolysis of the amidine or imidazole groups of the initiator residues and of the ester groups of methyl methacrylate to form carboxy groups, leads to the formation of the hydrophilic amphoteric particle surface. Enrichment of the monomer mixture with *N*-vinylformamide and addition of sodium dihydrophosphate buffer enhance the hydrolysis of the resulting groups to form carboxy groups in the surface layer.

Received March 24, 2006

Abstract—Composition and rheological characteristics of aqueous solutions of acrylic acid/urea copolymers were studied, including the composition dependences of the equivalent conductivity and viscosity.

DOI: 10.1134/S1070427206100223

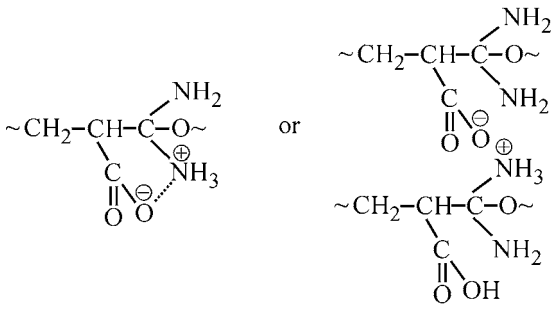
There is only limited information on copolymers of acrylic acid (AA) and urea (Ur) [1]. These branched copolymers are poorly soluble in common organic solvents. Srivastava and Majki [1] have demonstrated that AA/Ur copolymers are formed by the radical mechanism via addition of the vinyl radical of AA to the carbonyl group of urea. Together with the radical polymerization, some condensation reactions occur, resulting in branching of the copolymers.

To our knowledge, there is no information on the composition of AA/Ur copolymers and their characteristics, such as rheology of aqueous solutions, conductivity, etc. To characterize the composition of AA/Ur copolymers, we first determined their copolymerization constants. Then we examined the dependence of the molecular weight MW of the copolymers on the AA/Ur molar ratio in the monomer mixture, and also the rheology and conductivity of their aqueous solutions.

All the experiments on radical polymerization were carried out at a constant AA concentration of 2 M.

The copolymerization constants r_1 and r_2 were estimated using the classic Fineman–Ross equation for the case with no interaction between the urea-derived radical with the corresponding monomer (r_2) [2].

$$f = r_1 F + 1, \quad (1)$$



$$r_1 = K_{1,1}/K_{1,2}, \quad (2)$$

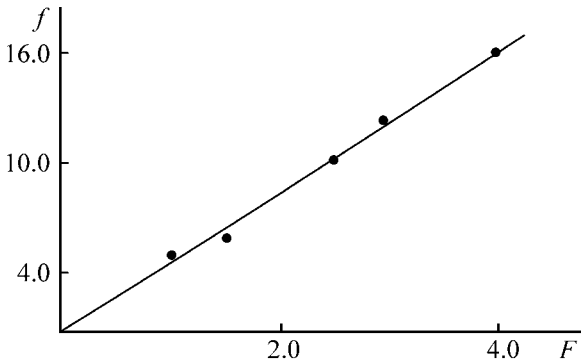
$$F = [\mathrm{AA}]/[\mathrm{Ur}], \quad (3)$$

where $f = a/b$; a and b are the AA and Ur units in the copolymer; $K_{1,1}$ and $K_{1,2}$, addition rate constants the AA radical to its monomer and Ur; and [AA] and [Ur], monomer concentrations.

The copolymerization constant r_1 was estimated from the Fineman–Ross plot (Fig. 1) to be 4 ± 0.1.

Results on r_1 and r_2 reveal that, in the copolymer, each Ur unit adjoins microblocks of the AA units. In synthesis of the copolymer of a given composition and structure, one may expect salt formation as a result of the interaction between the carboxy group of AA with the amino group of Ur. Such an interaction can be both intra- and intermolecular:

The resulting copolymer films were analyzed for ionic groups by IR spectroscopy. The spectra clearly



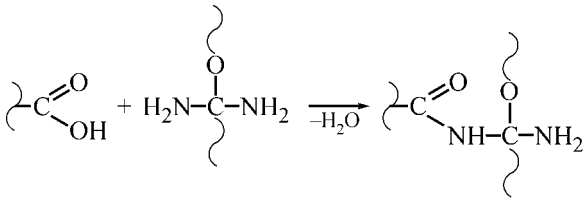


Fig. 1. Polymerization factor f from Eq. (1) vs. the AA/Ur molar ratio F.

show the bands at 1560–1640 cm^{-1} due to adsorption of the $\overset{+}{N}H_3$ and $H-C\overset{O}{\overset{//}{\underset{O^-}{\backslash}}}$ groups.

The bands at 1200–1280, 1710–1730, and 3400–3450 cm^{-1} are assigned to the –C–O–C–, $-C\overset{O}{\overset{//}{\underset{OH}{\backslash}}}$, and $-NH_2$ groups. The bands at 1695–1705 cm^{-1} suggest the presence of the $(-\underset{\underset{O}{\|}}{C}-NH-R-)$ group, which can be formed in the copolymer through the interaction between the –COOH and $-NH_2$ groups:

The presence of ionic groups will undoubted by provide higher conductivity of aqueous solutions of the copolymers, as compared to the polyacrylic acid reference. In this context, we studied the composition dependence of the equivalent conductivity of aqueous solutions of the copolymers. Figure 2 shows that the conductivity increases with the fraction of urea units in the copolymers, to reach a maximum at $F = 1$.

Then we studied the rheological properties of the copolymers prepared at $F = 2.5$, as influenced by temperature. We determined the concentration dependence of the reduced viscosity η_{sp}/c (c is the copolymer concentration in water) (Fig. 3).

The occurrence of a peak in the η_{sp}/c–c curves can be attributed to structural features of the polyelectrolytes under study, in which the degree of unfolding of the globules in water depends not only on the molecular weight of the copolymer, but also on the degree of dissociation of the ion pairs formed in the interaction of the carboxy and amino groups of the AA and Ur units, respectively. Such a viscosity anomaly is well documented [3, 4]. The clearly pronounced peaks in the curves (Fig. 3) suggest that the macromolecular chain, being in the maximally unfolded state, has an increased viscosity. Therefore, the unfolding threshold of such polyelectrolyte globules depends on both the temperature and copolymer concentration (Fig. 3).

The data on the molecular weights of the copolymers, as influenced by the initial AA/Ur molar ratios, are given in the table.

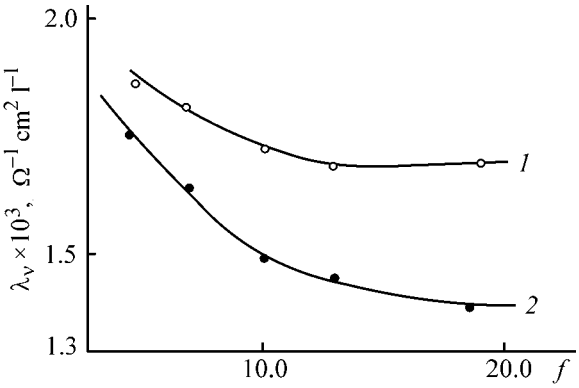

Fig. 2. Equivalent conductivity λ_v of aqueous copolymer solutions vs. their composition f. Solution concentration (wt %): (*1*) 0.5 and (*2*) 1. λ_v (PAA) (Ω^{-1} cm^2 l^{-1}): (*1*) 1.55×10^3 and (*2*) 1.28×10^3.

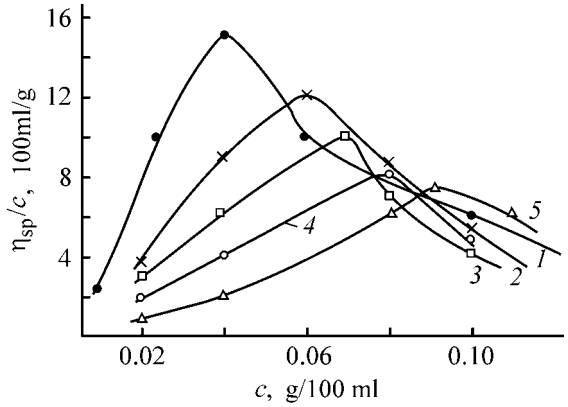

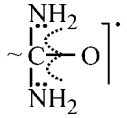

Fig. 3. Reduced viscosity η_{sp}/c of the copolymers in water vs. the concentration c. Temperature (°C): (*1*) 1.25, (*2*) 2.35, (*3*) 3.45, (*4*) 4.55, and (*5*) 5.65.

The results show that, at low F, i.e., with increasing Ur concentration in the initial mixture of the monomers, not only MW decreases, but also the copolymer yield. Therefore, in this case, urea serves as a polymer chain length regulator. The regulating capacity of urea is caused by the higher stability of its radicals (compared to the AA radical), which demonstrate lower rate of addition to the AA monomer. The sta-

Molecular weight of copolymers at various F

bility of the Ur radical is due to the mesomeric effect occurring between the unpaired electron of the oxygen atom and the free electron pair of the amine nitrogen:

EXPERIMENTAL

Acrylic acid was distilled, and the fraction with bp 141°C at 760 mm Hg (n_D^{20} = 1.4224) was taken. Urea was recrystallized from alcohol, washed with chloroform and ether several times, and dried to constant weight at 45–50°C in a vacuum oven, to obtain a product with mp 132.7°C. $(NH_4)_2S_2O_8$ was recrystallized from ethanol.

In copolymerization, the initiator concentration was maintained constant (1 wt % of the total molar content of the monomers). The copolymerization of AA and Ur was carried out in water at 70 ± 0.03°C in 50-ml reactors. After the completion of the reaction, the resulting copolymers were precipitated by adding ethanol (AA and Ur remain in solution). The precipitate was filtered off, washed several times with ethanol, and dried to constant weight.

The IR spectra of the copolymers (film obtained from 6% aqueous solution of the copolymer) were recorded on a Specord 75-IR spectrophotometer.

To characterize the composition of the copolymers, the concentration of the carboxy groups was determined by titration with 0.1 N aqueous NaOH, with phenolphthalein as an indicator. From these data, the amount of the carboxy groups m (g) was estimated as

$$m = \frac{V \times 0.1 \times 72}{10^3},$$

where V is the volume of NaOH (ml) consumed for titration.

The molecular weight of the copolymers was determined ebullioscopically [5]:

$$M = \frac{E \times 10^3}{\Delta T} \frac{g_2}{g_1},$$

where E is the ebullioscopic constant of water (0.52); g_2 and g_1, weight amounts of the copolymer and water (g); and ΔT, difference between the boiling points of the solution and solvent (water).

The viscosity of the aqueous copolymer solutions was determined using Ostwald and Ubbelohde capillary viscometers [4]. In this case, demineralized water was used.

CONCLUSIONS

(1) Acrylic acid/urea copolymers of various compositions were prepared and the copolymerization constants were determined.

(2) The rheological properties of acrylic acid/urea copolymers were studied. The concentration dependence of the reduced viscosity η_{sp}/c shows an anomalous behavior, which is probably due to structural and conformation features of the polyelectrolytes investigated.

(3) The dependence of the equivalent conductivity of the acrylic acid/urea copolymers on their composition is studied. The highest conductivity was observed for the copolymers with nearly equivalent proportion of the acrylic acid and urea units.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Mechanical and Thermal Properties of Cryogels and Foamed Cryogels Produced from Aqueous Solutions of Poly(vinyl alcohol)

L. K. Altunina, B. N. Manzhai, and M. S. Fufaeva

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received May 19, 2006

Abstract—The effect of sodium chloride and technical-grade carbon (carbon black) on the mechanical and thermal properties of cryogels and foamed cryogels produced from homogeneous and heterogeneous (foamed) solutions of poly(vinyl alcohol) was studied.

DOI: 10.1134/S1070427206100235

Aqueous solutions of poly(vinyl alcohol) (PVA) are transformed after a freeze-thaw cycle from their viscous-flow state to become elastic polymeric bodies capable of large reversible deformations. Cryogels formed under conditions of solvent crystallization are thermally reversible, but their melting point is several tens of degrees higher than the gelation point. The mechanical and thermal properties of the forming PVA cryogels depend on the composition and concentration of the components of the starting solution, on the molecular weight of the polymer and degree of its acetylation, and on modes and methods of cryogenic treatment of the starting solutions [1].

Cryogels have found wide use in biotechnologies, medicine, and technological processes for extraction and transportation of oil [2]. Recently, of increasing practical importance have been foamed cryogels (FCG) [3], which can be used, in particular, for thermal insulation of mouths of production oil wells in order to prevent precipitation of paraffin deposits. It seems that a promising way is to use cryogels and foamed cryogels to prevent degradation of the cryolite zone as a result of global warming-up and technologically induced processes in the northern climatic zone. Their application would be particularly important for improvement of the stability of antifiltration elements of water-retaining structures in water storage basins and for soil reinforcement.

EXPERIMENTAL

To develop the optimal method for production of cryogels and foamed cryogels, it is necessary to have full, to the maximum possible extent, information about molecular characteristics and specific rheological features of the behavior of starting PVA solutions. The methods of capillary and rotational viscometry were used to study the viscous properties of varied-concentration solutions of a PVA sample having an average molecular weight M = 74000 and containing in its structure residual acetate groups in an amount of 1%. The presence in the PVA chain of a certain amount of acetate groups hindering cryogelation is an inevitable result of the industrial manufacture of PVA from polyvinyl acetate [4]. It was found experimentally that solutions of the sample chosen for study, with the molecular parameters specified above, can form cryogels at a polymer concentration of no less than 5 g dl^{-1}. In starting solutions of this kind, a continuous fluctuation network of macromolecules is formed, and its presence is confirmed by the fact that the Weissenberg effect is observed in these solutions.

At concentrations higher than 5 g dl^{-1}, aqueous PVA solutions are typical non-Newtonian (pseudoplastic) fluids, whose viscosity depends on the shear rate. Making lower the temperature of polymer solutions to 0°C leads to a rise in their viscosity without loss of flowability. It should be noted that the viscosities of the starting solutions virtually coincide with

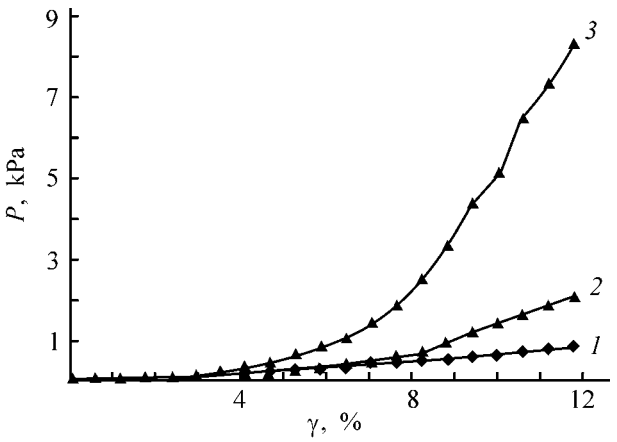

Fig. 1. Stress P vs. strain γ for cryogel samples with various PVA concentrations. c_{PVA} (g dl^{-1}): (*1*) 5, (*2*) 10, and (*3*) 16.

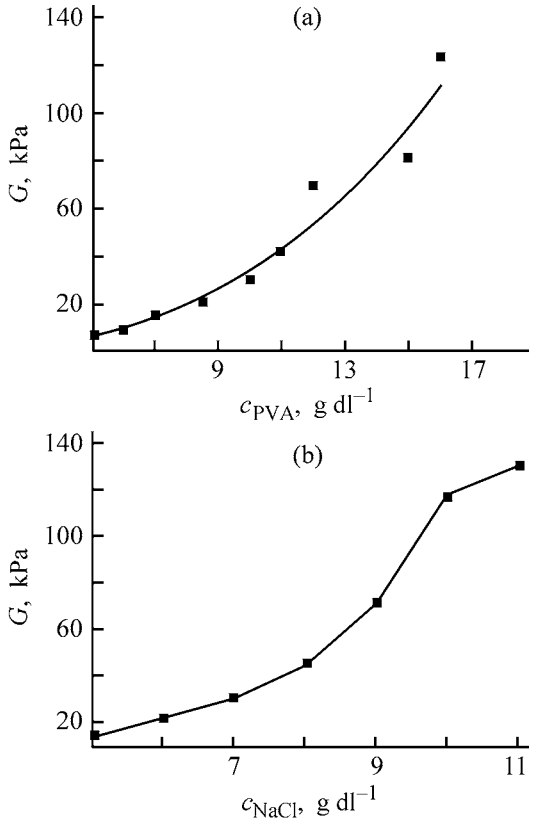

Fig. 2. Elastic modulus G of cryogels vs. concentrations of (a) PVA (c_{PVA}) and (b) sodium chloride (c_{NaCl}) at c_{PVA} = 5 g dl^{-1}.

the viscosities of solutions preliminarily subjected to low-temperature gelation and subsequent thermal melting. This feature emphasizes the total reversibility of the process of cryotropic gelation and the absence of irreversible structural changes in PVA molecules on performing a freeze-thaw cycle with the solutions.

To obtain cryogels, aqueous PVA solutions of various concentrations (5 to 16 g dl^{-1} with a step of 1 g dl^{-1}) were poured in cylindrical cells and frozen at T = –22°C for 20 h. Then they were thawed at T = 20°C in the course of 4 h and the resulting elastic cryogel samples were deformed to a strain γ and the stress P was measured. The results obtained are shown in Fig. 1.

It can be seen that the stress–strain curve clearly shows two different portions. The existence of these regions in the rheological curves is a consequence of the dual, with entropy- and energy-related components, nature of the elasticity of polymeric bodies. At small strains, which transfer the macromolecular coils of the polymer network of the cryogel from the more probable state to that with a lower probability, the dominant factor is the change in entropy. Upon further deformation of the sample, the chemical bond lengths and valence angles in polymer chains somewhat change, and, as a result, the elastic modulus (slope of the curve) noticeably increases. Figure 2a shows elasticity moduli of cryogels formed from polymer solutions of various concentrations and strained (compressed) by 10%.

It follows from Fig. 2a that, as the PVA concentration is raised from 5 to 16 g dl^{-1}, the elastic modulus strongly increases from 5 to 120 kPa. Of the highest practical value in use of cryogel as construction materials are samples with the lowest content of the structuring component, PVA. It is known from the literature that low-molecular-weight components adversely affect the mechanical properties of cryogels. However, presence of some of them, e.g., sodium chloride [5], in the starting polymer solutions favors strengthening of the cryogels obtained. The results of measurements of the elasticity moduli of PVA solutions with a concentration of 5 g dl^{-1} and varied content of sodium chloride are shown in Fig. 2b.

It can be seen that, as the NaCl concentration is raised from 5 to 11 g dl^{-1}, the elastic modulus of the cryogels increases from 15 to 130 kPa. It should be noted that the elastic modulus of the starting two-component cryogel produced from an aqueous PVA solution (c_{PVA} = 5 g dl^{-1}) is 5 kPa (Fig. 2a). It was found experimentally that further increase in the sodium chloride concentration is inadvisable because of the "salting-out" of the polymer from the solution and the corresponding decrease in the mechanical strength of the cryogels obtained.

In processes of cryotropic gel formation and use of the samples obtained, it is necessary to know the heat conductivity coefficients, whose values for the start-

ing solutions and the cryogels formed are listed in the table.

It follows from the table that the dissolution of the polymer in water leads to a considerable decrease in the heat conductivity coefficients λ_{PVA} of the polymer solutions, compared with the neat solvent (λ_W = 0.62 W K^{-1} m^{-1}), and the structuring of solutions into cryogels is accompanied by further decrease in the heat conductivity coefficient.

It is known that an effective way to reduce the heat conductivity coefficient of a material is to saturate it with a gas. Therefore, a gas phase was introduced into homogeneous PVA solutions to improve the thermal properties of cryogels, and, because of the foam formation, foamed cryogels were obtained after a freeze–thaw cycle. Gas-saturated formulations with a foam ratio of 2 were formed by bubbling air through a Schott filter into aqueous PVA solutions of various concentrations. The heat conductivity coefficient of the foam is substantially lower than that of the polymer solution [6]. As a result, the cooling and subsequent freezing of a gas-saturated formulation is considerably slower than that of the polymer solution. Therefore, starting foams stable in the course of time are necessary for synthesis of foamed cryogels. Measurements of the time of foam settling demonstrated that the foam stability increases with the polymer concentration in the solution (Fig. 3). However, even the polymer solution with the highest concentration (c_{PVA} = 10 g dl^{-1}) has a foam destruction time shorter than half an hour (1500 s), which is obviously insufficient for the process of full freezing of the foamed sample to be complete. Any further increase in the concentration of the polymer in the solution is inadvisable because it leads to a pronounced increase in the solution viscosity and makes impossible formation of a finely dispersed foam from this solution. Therefore, a powder of finely dispersed technical-grade carbon (carbon black) was introduced into the aqueous formulation containing PVA (c_{PVA} = 5 g dl^{-1}) and sodium chloride (c_{NaCl} = 11 g dl^{-1}) in order to make more stable the starting foam.

Introduction of a solid phase into the foam leads to localization of gas bubbles by the flotation mechanism on hydrophobic particles of carbon black, which results in a decrease in the surface energy of the three-phase system, compared with the starting two-phase system. As a result, stable foams are formed, which do not settle during 24 h. Raising the carbon black content of the foamed cryogels from 3 to 7% is accompanied by an increase in the elastic modulus from 4 to 50 kPa because of the structural-mechanical reinforcement of walls of gas cells with finely dispersed particles of carbon black (Fig. 4a).

The elastic properties of foamed cryogels that are produced from aqueous solutions upon a single freezing and contain PVA (c_{PVA} = 5 g dl^{-1}), sodium chloride (c_{NaCl} = 11 g dl^{-1}), and carbon black (c = 7%)

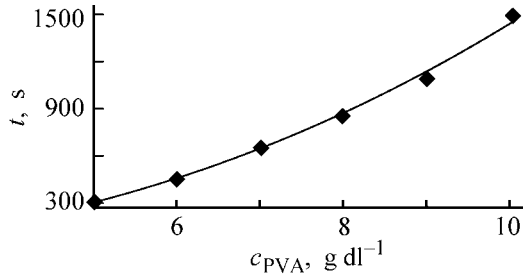

Fig. 3. Settling time t of a foam produced from aqueous PVA solutions with various concentrations c_{PVA}.

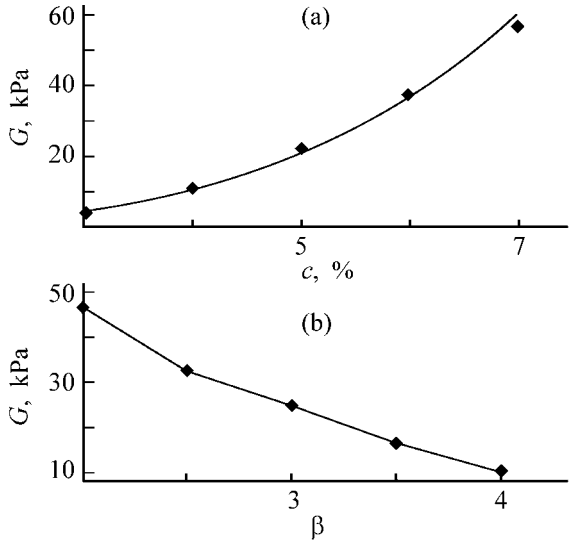

Fig. 4. Elastic modulus G of a foamed cryogel vs. (a) carbon black content c and (b) foam ratio β. (b) Solution composition: PVA 5 g dl^{-1}, NaCl 11 g dl^{-1}, carbon black 7%.

are strongly deteriorated as the foam ratio increases (Fig. 4b). As the ratio β of the starting foam increases from 2 to 4, the elastic modulus of the foamed cryogel decreases from 50 to 10 kPa. Presumably, foamed cryogels with low foam ratios (β = 2) can be used under practical conditions.

The heat conductivity coefficient was found experimentally for a foamed cryogel with a foam ratio β = 2 and the composition: PVA 5 g dl^{-1}, NaCl 11 g dl^{-1}, carbon black 7%, and water 77 g dl^{-1}. The following value was obtained: $\lambda_{FCG} = 0.25$ W K^{-1} m^{-1}, which is in a satisfactory agreement with the value calculated by the Manegold formula $\lambda_{FCG} = 2\lambda_W/3\beta + (\beta - 1/\beta)\lambda_G$. Thus, introduction of the gas phase into the continuous matrix of the cryogel improves the heat-insulating properties of the material.

Laboratory studies of the chemical stability of cryogels at a temperature of 20°C for 72 h demonstrated that they retain their stability when in contact with distilled and mineralized (Senoman) water, as well as with alkaline solutions and hydrocarbon liquids of different polarities (hexane, acetone, oil). Cryogel samples are also stable in acid media with pH > 1 and decompose only in concentrated sulfuric or hydrochloric acid. A gravimetric study of the stability of a foamed carbon-reinforced plastic in air revealed that it tends to be dehydrated. Removal (evaporation) of water leads to loss of elasticity by a cryogel sample, which is accompanied by its deformation and a decrease in its volume.

The mechanical properties of a foamed cryogel directly depend on the working temperature of articles made of this material, which should not exceed its melting point. Measurements of the melting points of cryogels and foamed cryogels of various compositions demonstrated that they are virtually independent of the content of PVA (5–16 g dl^{-1}) and carbon black (3–7%) and fall within the range $T \approx 73$°C, but presence of the salt has a strong effect. For example, the melting point increases from 97 to 110°C as the concentration of sodium chloride is raised from 5 to 11 g dl^{-1}.

CONCLUSIONS

(1) Introduction of technical-grade carbon (carbon black) into a polymer solution raises the stability of the foam produced from this solution and favors structural-mechanical reinforcement of the walls of gas cells in the resulting foamed cryogel.

(2) Sodium chloride makes higher the elastic modulus and the melting point of cryogels and foamed cryogels.

(3) Introduction of a gas phase into the polymer matrix leads to a decrease in the elastic modulus of the material, but its heat-insulating properties are markedly improved.

Abstract—The concentration dependences of the relative viscosity of epoxydiane resins (M_n = 400–650) in solutions of monoglycidyl esters, Cardura and Laproxide, and of the dynamic viscosity of filled epoxy formulations in a shear flow were studied. The optimal concentrations of the formulation components and structural parameters of the fractal aggregates of oligomers and clusters of pigment (filler) particles were calculated in the approximation of the cluster lattice model.

DOI: 10.1134/S1070427206100247

A study of the concentration dependences of the viscosity and structure of epoxydiane oligomers (EO) in solutions is of particular interest in view of the wide use of epoxy formulations for deposition of protective and anticorrosion coatings onto metals [1, 2]. To systems of this kind, in particular, belong formulations based on low-molecular-weight epoxydiane resins (M_n = 400–650), monoepoxy compound Cardura, and pigments and fillers [1].

As is known [3–5], the conditions under which a continuous fluctuation network of entanglements between macromolecules is formed in EO solutions are determined by the molecular weight M and concentration c of the oligomers and by the solvent polarity [6]. Such a network disintegrates at shear rates $g > 160$ s^{-1} [2]. It has been shown previously [3, 5] that the initial slope $[\eta]$ of concentration dependences of the relative viscosity $\eta_{rel}(c)$ of EO in solutions with chloroform, plotted in the $\ln \eta_{rel} - c$ coordinates, increases with the molecular weight M. The $\eta_{rel}(c)$ curves may be of two types. In the case when the size of EO molecules does not exceed the length of the statistical Kuhn segment (degree of polymerization DP ≈ 5) [2, 6], the condition $[\eta]_c/[\eta] \geq 1$, where $[\eta]_c = d\ln \eta_{rel}/dc$ ($c > 0$) is the current intrinsic viscosity, is valid for the $\eta_{rel}(c)$ curves. For $\eta_{rel}(c)$ curves of the second type, the condition $[\eta]_c/[\eta] < 1$ is satisfied. The hydrodynamic behavior of such EO (DP > 5) in solutions is similar to that of flexible-chain macromolecules with a large number of statistical Kuhn segments [5, 6].

Studies of the concentration dependences of the relative viscosity, $\eta_{rel}(c)$, and of the intensity of quasi-elastic scattering of light in EO solutions have shown [3–5] that discrete aggregates (associates) [7] and an infinite cluster of EO molecules [8] are formed in EO solutions. According to [4, 5], the minimum in the dependences of the Rayleigh scattering of light in solutions of ED-20 epoxydiane resin ($M_n \approx 400$) in Cardura is due to the formation of an infinite cluster of EO molecules at the critical concentration c^* = 52%. On introduction of epoxidized caoutchouc (EC, $M_n \approx 1000$), whose molecules can also be incorporated in the infinite cluster containing ED-20 and Cardura molecules, into a solution of the ED-20 resin in Cardura, such a cluster is formed at a threshold percolation probability $p_c \approx 0.69$, c^* (ED-20) = 48%, and c (EC) = 16% [4, 8].

As is known [9], the viscosity η of concentrated polymer solutions shows a power dependence on the concentration c and molecular weight M of macromolecules: $\eta \sim c^{\beta} M^{3.4}$, where β is a constant [10]. It would be expected [10] that, upon introduction of pigment (filler) particles into an oligomer solution, the infinite (fractal) cluster of such particles is formed at the critical particle concentration c_p, which corresponds to a threshold percolation probability $p_c \approx 0.31$ in a simple cubic lattice [8]. In accordance with the cluster lattice model [10], the viscosity η of a filled formulation will increase with the concentration c_p by the law: $\eta \sim c_p^{\beta}$ [9], and the exponent β will change jumpwise near the critical value c_p^*. In this case,

Table 1. Molecular parameters of epoxy oligomers* (298 K)

Sample no.	Oligomer	$M_n \pm 5\%$	E.n., %	[η], $cm^3\ g^{-1}$	η, Pa s	σ, $mN\ m^{-1}$
1	YD-128S	410	20.9	2.5/3.2	22.2	52.4
2	YD-136	630	13.6	4.5/4.8	6.2**	56.2
3	Cardura E-10P	250	17.2	–	0.035	30.6
4	Laproxide-702	520	8.4	–	0.101	34.6

* E.n., epoxide number; σ, surface tension at the liquid–air phase boundary. The values of [η] are given for solutions in Cardura (numerator) and Laproxide (denominator). For the mixture of YD-128S and YD-136 resins (mass ratio 2.9 : 1) dissolved in Cardura, [η] = 2.9 $cm^3\ g^{-1}$.

** Viscosity of a 80% solution of sample no. 2 in *o*-xylene.

the elastic modulus E of the filled epoxy formulation must also grow in accordance with the expression obtained for filled caoutchoucs: $E \sim \Delta c_p^t$, where $\Delta c_p = c_p - c_p^*$ ($c_p > c_p^*$) and $t = 1.8$ [8, 10].

The 3*D* structure of filled epoxy polymers [11] obtained by curing of epoxy formulations with amines [12] is characterized by alternation of regions with different densities of cross-link sites in the chemical network of a cross-linked polymer and different distributions of pigment (filler) particles [13]. The strength properties of polymers of this kind depend on the density of cross-link sites in the chemical network [2] and pigment (filler) concentration c_p [11]. According to the authors' data, the reduced relative elongation $\Delta l/lE$ (E is the elastic modulus) of films of a filled polymer produced by curing a formulation based on ED-20 epoxydiane resin, Cardura [4], and a mixture of pigments (fillers) shows an extremum near the critical concentration $c_p^* \approx 31$ vol % (Fig. 1).

It should be noted that development of the physicochemical principles of making up an epoxy formulation with an active solvent [1, 4], which are based on the cluster lattice model [8, 10], is topical for reliable substantiation of the prescribed composition of formulations of this kind [14] and promising for improvement of the strength and protective properties of epoxy polymers [11, 12].

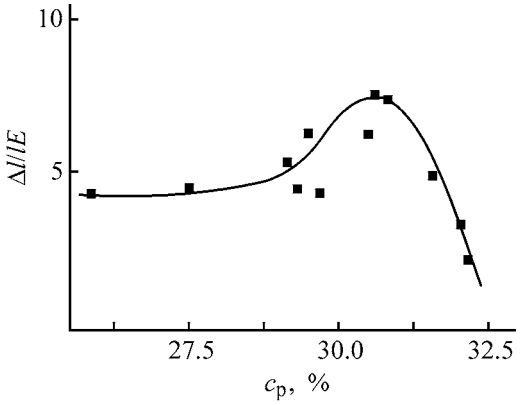

Fig. 1. Reduced relative elongation $\Delta l/lE$ of films of the epoxy polymer vs. volume concentration c_p of pigments and fillers. Film thickness 400 μm.

For this purpose, the concentration dependences of the relative viscosity of epoxydiane resins (M_n = 400–650) in solutions of monoglycidyl esters and the rheological behavior of filled epoxy formulations in shear flow were studied. The structural parameters of fractal aggregates of EO and clusters of pigment (filler) particles and the critical (prescribed) concentrations of the components of the epoxy formulation were calculated in terms of the cluster lattice model.

EXPERIMENTAL

As objects of study served the following commercial samples: YD-128S and YD-136 epoxydiane resins (Kykdo Chemicals); Cardura E-10P, monoglycidyl ester of Versatic acid, with the total number of carbon atoms equal to 10 (Shell Chemicals) [1]; and Laproxide, monoglycidyl ester of oligooxypropylene triol [4]. Some parameters of sample nos. 1–4 are listed in Table 1.

The concentration dependences of the relative viscosity $\eta_{rel}(c)$ of YD-128S and YD-136 epoxydiane resins (Table 1, sample nos. 1 and 2) and of their mixtures dissolved in Cadura and Laproxide were measured with an Ubbellohde capillary viscometer (shear rate $g = 100\ s^{-1}$) [6] at concentrations in the range c = 5–60 wt % and temperature of 298 K. The $\eta_{rel}(c)$ curves were plotted in the $\ln \eta_{rel}(c)$–$[\eta]c$ coordinates, where $[\eta]c$ is a dimensionless parameter

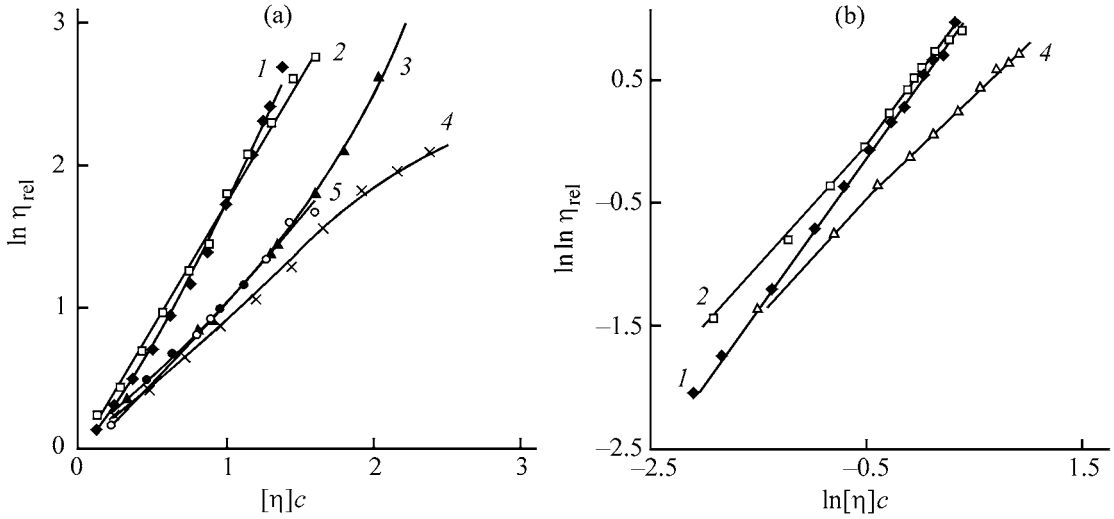

Fig. 2. Relative viscosity η_{rel} of epoxydiane resins (*1*, *5*) YD-128S and (*3*, *4*) YD-136 and (*2*) their mixture (mass ratio 2.9 : 1) in solutions in (*1–3*) Cardura and (*4*, *5*) Laproxide vs. the dimensionless parameter $[\eta]c$ in the coordinates (a) $\ln \eta_{rel}$–$[\eta]c$ and (b) $\ln\ln \eta_{rel}$–$\ln [\eta]c$, 298 K.

and c is concentration (g cm^{-3}) (Fig. 2). The intrinsic ($[\eta]$) and current intrinsic ($[\eta]_c$) viscosities were calculated from the $\eta_{rel}(c)$ curves by the expression $[\eta]_c = d\ln \eta_{rel}/dc$ at $c \to 0$ and $c > 0$, respectively [3, 6] (Table 1).

Filled epoxy formulations were prepared using an anticorrosive red iron oxide pigment (RIO, TR-303 brand, Czech Republic) [15] with a particle size of 5 μm and Microtalc filler (GShM, Tal'kon) [16] with a particle size $d \le 40$ μm. Samples of the formulations were prepared by mixing RIO pigment and Microtalc with YD-128S and YD-136 epoxydiane resins and Cardura. Into a paste composed of RIO pigment in Cardura, prepared in a bead mill, was introduced a mixture of YD-128S and YD-136 resins and Cardura (Table 3, sample no. 5), in which Microtalc was dispersed. The concentration c_{RIO} of RIO pigment in sample nos. 6–16 was 11%, and the concentration c_p of Microtalc was varied from 10 to 40%.

The flow curves $g(\tau)$ of filled epoxy formulations were measured on a Rheotest-2 rotational viscometer at shear rates g = 3–1312 s^{-1} and shear stresses τ = 3–2200 Pa in the temperature range 298–333 K (Fig. 3). When determining the viscosity η of epoxy formulations from flow curves $g(\tau)$, it was assumed that the dynamic viscosity $\eta(g)$ varies by the power law $\eta = Kg^{n-1}$, where K is a constant, and n, flow index [9]. The $\eta(g)$ curves are linear in log–log coordinates $\ln \eta$–$\ln g$ at g = 3–81 s^{-1} (Fig. 4), which makes it possible to calculate the flow index n from the slope of the linear portion of $\eta(g)$ curves and the initial viscosity η^0 of formulations at g = 1 s^{-1} and to obtain dependences of the initial viscosity η^0 and flow index n on the Microtalc concentration c_p (Table 3).

* YD-1236 resin was introduced into the formulation as a 80% solution in *o*-xylene (concentration of *o*-xylene is given in parentheses). c_p is the mass concentration of Microtalc.

The lattice density ρ of aggregates of EO molecules in solution and of clusters of solid particles was calculated by the expression $\rho = \omega^{\alpha}([\eta]/[\eta]_c)^{\alpha/(\alpha-1)}$, where ω = 0.637 is the coefficient of random packing of rigid spheres [8, 13], and α is the exponent similar to that in the expression for the intrinsic viscosity $[\eta] \sim M^{\alpha}$ [6] (Table 2). The lattice density ρ of clusters of pigment (filler) particles was calculated using the values $[\eta]_c = d\ln(\eta^0/\eta)/dc_p$, where η^0 and η are the initial viscosities of a filled formulation and of a mixture of resins in a solution in Cardura, respectively (Table 3).

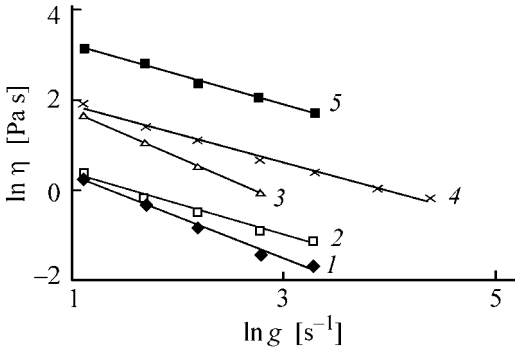

Fig. 4. Dynamic viscosity η vs. shear rate g in the ln η–ln g coordinates at 298 K. Sample no.: (*1*) 5, (*2*) 8, (*3*) 10, (*4*) 12, and (*5*) 15.

As can be seen from the data obtained (Fig. 2), the concentration dependences of the relative viscosity $\eta_{rel}(c)$ of epoxydiane resins in solutions in Cardura and Laproxide follow the expression $\ln\eta_{rel} = ([\eta]c)^{\alpha}$, where $\alpha = (3 - D)/D$, and D is the fractal dimension of aggregates of EO molecules [5, 13]. For the systems studied, with the exception of solutions of YD-136 resin in Laproxide, the $\eta_{rel}(c)$ curves plotted in the $\ln\eta_{rel}$–$[\eta]c$ coordinates lie above the bisector of the angle formed by the coordinate axes The point

of intersection of two linear portions of the $\eta_{rel}(c)$ curves plotted in the $\ln\ln\eta_{rel}$–$\ln[\eta]c$ coordinates corresponds to the critical concentration c^* of formation of an infinite cluster of EO molecules in solutions [5], and the values of the parameters α and D can be calculated from the slope of the linear portions of these curves [13] (Fig. 2b, Table 2).

Analysis of the values of the parameters α and D, obtained for solutions of YD-128S resin in Cardura and Laproxide (Table 2), shows that $\alpha > 1$ ($D < 1.5$) in two regions: $c < c^*$ and $c > c^*$. The corresponding $\eta_{rel}(c)$ curves belong to the case when EO molecules are smaller in size than the statistical Kuhn segment [2]. In the first portion of the $\eta_{rel}(c)$ curves for solutions of YD-136 resin in Cardura and Laproxide, $\alpha \le 1$ ($D \approx 1.5$) (Fig. 2a). These curves can be related to the case when the size of EO molecules only slightly exceeds the length of the statistical segment [2, 5]. For a mixture of YD-128S and YD-136 resins (mass ratio 2.9 : 1) dissolved in Cardura, $\alpha = 1.1$ ($D \approx 1.4$ (in the range $c < c^*$, and, therefore the average size of EO molecules in this mixture of resins is only slightly smaller than the length of the statistical segment [2].

Passing from dilute ($c < c^*$) to concentrated ($c > c^*$) solutions of epoxydiane resins leads to a change in the parameters α and D and in the density ρ of EO aggregates near the critical concentration c^* [3, 13]. In solutions of YD-128S resin and of a mixture of YD-128S and YD-136 resins in Cardura, the construction of an infinite cluster is complete at a lattice density of aggregates, $\rho_c \approx 0.69$, which is confirmed by the presence of absolute and local minima in the surface-tension curves $\sigma(c)$ at the liquid–air interface [8] (Fig. 5). The minima in the $\sigma(c)$ curves for solutions of these resins occur because the second derivative of the free Gibbs energy with respect to concentration, d^2F/dc^2, is zero [17]. They coincide on the concentration scale with the corresponding values of c^*.

The flow curves $g(\tau)$ of filled epoxy formulations can be conditionally divided into three groups differing in the rate at which the initial viscosity η^0 and yield stress τ_0 [9, 18] vary with the increasing concentration c_p of Microtalc (Fig. 3, Table 3). The first group of $g(\tau)$ curves are of pseudo-Newtonian type [9] and show a slight rise in η^0 and τ_0 at $c_p \le 15\%$ and ($c_{RIO} + c_p$) = 0–26% (Fig. 3a, sample nos. 5–8).

The flow curves of Bingham type [9], assigned to the second (Fig. 3b) and third (Fig. 3c) groups of formulation samples, have two portions, which are linear on the logarithmic scale. The first $g(\tau)$ portion at $g <$ 150 s^{-1} corresponds to a pseudoplastic flow of a viscous fluid, and the second at $g > 150$ s^{-1}, to a flow of cross-link sites of the fluctuating network of EO entanglements [9, 18]. The slope m_1 of the first portion of the $g(\tau)$ curves for the third group of samples steeply falls as the concentration c_p of Microtalc becomes higher, and the slope m_2 of the second portion in the curves of this group, increases jumpwise (Fig. 6). The bend in these curves at $g < 150$ s^{-1} indicates that strong hydrogen bonds are formed between EO molecules and filler particles [15].

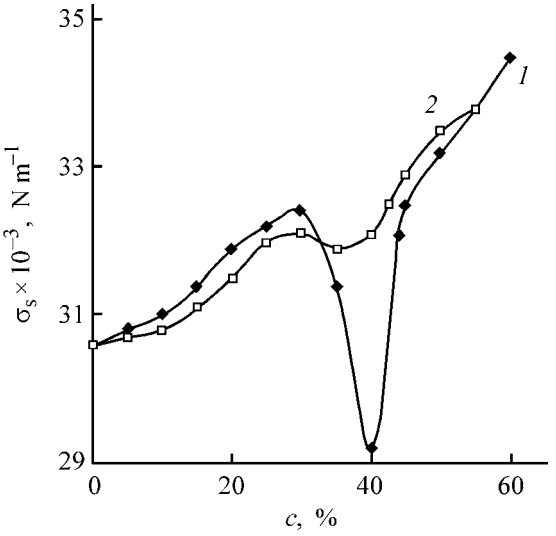

Fig. 5. Surface tension σ_s at the interface between a solution of an epoxydiane resin and air vs. the mass concentration c of (*1*) YD-128S resin and (*2*) mixture of YD-128S and YD-136 resins in Cardura at 298 K.

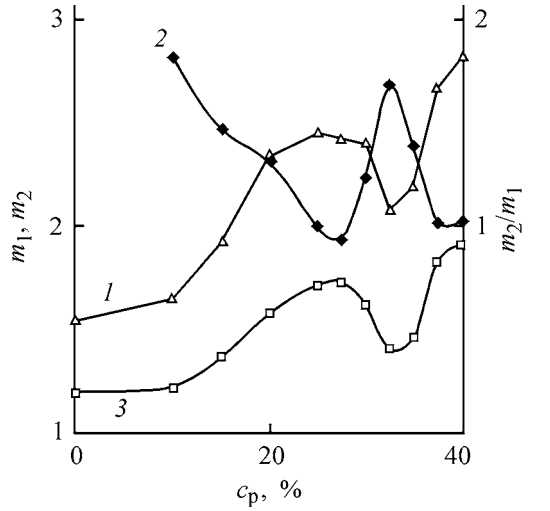

Fig. 6. Slopes of (*1*) first (m_1, $g < 150$ s^{-1}) and (*2*) second (m_2, $g > 150$ s^{-1}) linear portions of the flow curves $g(\tau)$ and (*3*) the ratio of these slopes, m_1/m_2, vs. the mass concentration c_p of Microtalc, 298 K.

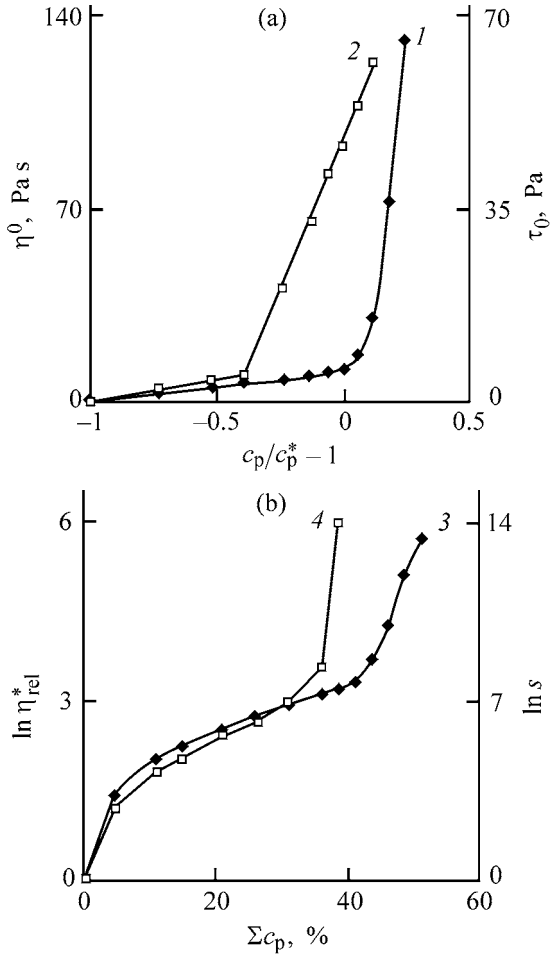

Fig. 7. (a) (*1*) Initial viscosity η^0 and (*2*) yield stress τ_0 vs. the parameter $(c_p/c_p^* - 1)$; (b) (*3*) reduced viscosity $\eta_{rel}^* = \eta^0/\eta$ and (*4*) degree of aggregation of pigment (filler) particles vs. the concentration Σc_p of the pigment and filler, at 298 K. c_p, critical Microtalc concentration, equal to 30%; η, viscosity of a mixture of resins in solution.

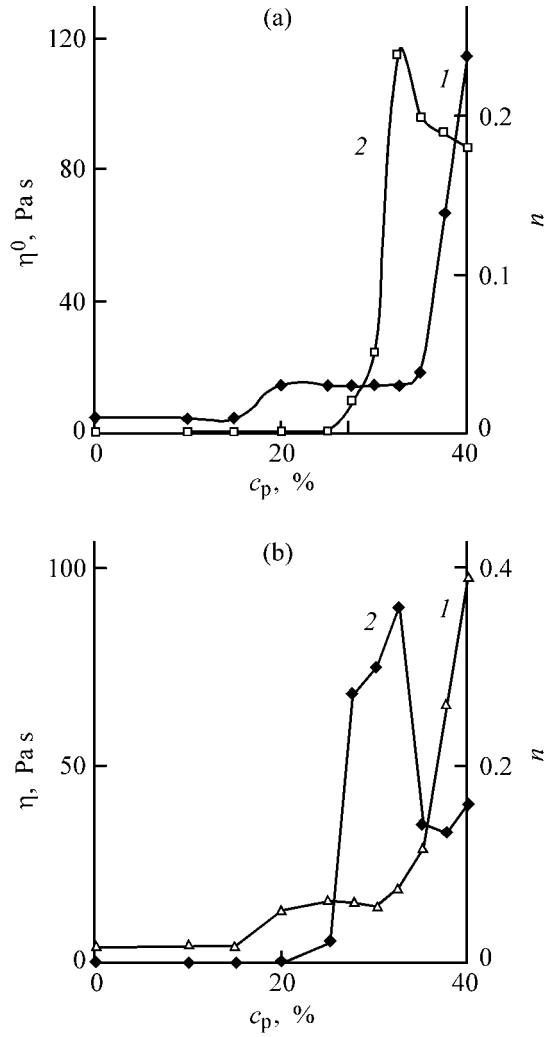

Fig. 8. (*1*) Initial viscosity η^0 and (*2*) flow index n of the formulations vs. the Microtalc concentration c_p. Temperature (K): (a) 323 and (b) 333.

The flow curves $g(\tau)$ show at $c_p = 20$–35% a steep rise in the yield stress τ_0 in accordance with the expression $\tau_0 \sim |c_p - c_p^*|^t$, where c_p^* is the critical Microtalc concentration, equal to 30% (Fig. 7, Table 3). Such a variation of the yield stress τ_0 near c_p^* is similar to the behavior of the elastic modulus E and the value of τ_0 in polymeric gels above the gelation threshold [10, 18], and the calculated value $t = 1.8$ coincides with the theoretical estimate of t [8].

As follows from the $\eta^0(c_p)$ curve, the initial viscosity η^0 of the formulations is virtually independent of temperature and Microtalc concentration c_p in the range $c_p = 20$–30%, but in the range $c_p = 32.5$–40%, the value of τ^0 increases jumpwise (Figs. 7, 8). The concentration dependence of the logarithm of the viscosity η^0 is of the power-law type: $\ln\eta^0 \sim c_p^{\alpha}$, where $\alpha = (3 - D)$ and D is the fractal dimension of clusters formed by pigment (filler) particles [8, 10]. As the critical concentration c_p^* of formation of an infinite cluster [8] of pigment (filler) particles can be taken a value of 30%, because the fractal dimension D of clusters is about 1.8 at $c_p = 15\%$ and reaches a value of approximately 2.5 in the range $c_p = 20$–30% (Table 3). The scaling of the dynamic viscosity η of the formulations at $c_p > c_p^*$ is due to relaxation of the irreversible deformation of an anomalously viscous fluid [9] and to disintegration of a continuous fluctuation network of entanglements of EO molecules [18]. The dynamic processes occurring in formulations of this kind ($c_p > c_p^*$) at low shear rates g lead to disintegration of the infinite cluster ($D \approx 2.5$) of filler particles into discrete clusters ($D \approx 1.1$) (Figs. 6, 7).

The concentration dependences of the flow index n of filled formulations have the form of delta functions [8]. The value of n is close to zero at $c_p \le 20\%$, increases jumpwise near the critical concentration $c_p^* = 30\%$, and falls as c_p grows in the range $c_p > 30\%$ (Table 3, Fig. 8). Such a run of the $n(c_p)$ curves is due to an unlimited increase in the degree of aggregation, s, of pigment (filler) particles near c_p^* (Fig. 7). The peak in the $n(c_p)$ curves corresponds to the threshold lattice density of clusters of pigment (filler) particles, $\rho \approx 0.69$, and the corresponding state of the formulation is similar to a dense solution of solid spheres at the percolation threshold [10, 14]. The disintegration of the infinite cluster of pigment (filler) particles into discrete clusters at $c_p > c_p^*$ leads to a sharp decrease in the lattice density ρ, fractal cluster dimension D, and flow index n of filled formulations (Table 3).

The volume concentration of the pigment and filler in the formulations was calculated by the expression $\Sigma c_p = (c_{RIO} + c_p)/\rho_c$ [1], where c_{RIO} and c_p are the mass concentrations of RIO and Microtalc, respectively; and ρ_c is the sample density. The volume density ρ_c of sample no. 12 (Table 3) is 1.34 g cm^{-3}, and $\Sigma c_p \approx 31$ vol %, which coincides with the critical particle concentration in the infinite cluster in the case of a simple cubic lattice [8].

Tests of the protective and anticorrosion properties of coatings obtained on metals by curing of filled epoxy formulations with amines [11] revealed that the best results are achieved at pigment and filler concentration in a formulation equal to 31 vol % (Table 3, sample no. 12). On introduction of a stoichiometric amount of tetrafunctional amine, Mannich base (M_n = 250) [14], into a formulation of this kind, the total mole fraction of YD-128S and YD-136 resins and Cardura in the organic phase of the formulation is $\Sigma m_i \approx 0.69$, and that of the amine curing agent, $m \approx 0.31$. The composition of sample no. 12 can be taken as a prescribed composition because the component concentrations satisfy the criterion of percolation in a simple cubic lattice [4, 8].

As is known [11, 12], the mechanical, protective, and thermal properties of an epoxyamine polymer depend on the density of cross-link sites in the chemical network [20]. Such a network is composed of quadruply and triply connected sites containing fragments of amine molecules [19], with fragments of molecules of epoxydiane resins and Cardura constituting intersite chains [2] and the coil part of the chemical network of the cross-linked polymer [12]. The concentration of epoxydiane resins, Cardura, and amine, as well as the formulation curing conditions, predetermine the structural parameters of the network [19, 20].

The most uniform chemical network is formed, according to the authors' data, in curing of sample no. 12. The cross-link sites of such a network and pigment (filler) particles constitute a continuous 3D network of the polymer [20], which can be represented as two embedded infinite clusters [8]. The lattice density of these clusters, which reflect the continuous small-scale chemical network of the polymer and the uniform large-scale physical network of pigment (filler) particles distributed within regions with lowered local density of cross-link sites of the chemical network [10, 20], is close to the critical values of 0.69 and 0.31, respectively [8].

It is this cluster structure of the chemical and physical networks that provides the high mechanical, protective, and anticorrosion parameters of a filled epoxy polymer (Fig. 1). In particular, 400-μm-thick films produced by curing of sample no. 12 (Table 3) have an ultimate tensile strength of about 30 MPa, elastic modulus $E \approx 900$ MPa, and maximum relative elongation $\Delta l/l = 7\%$.

Thus, the physicochemical principles to be used in making up epoxy formulations were developed with the help of the cluster lattice model. These principles make it possible to substantiate the prescribed composition of the formulations and to provide high strength and protection parameters of epoxy polymers and coatings [14].

CONCLUSIONS

(1) The optimal (prescribed) concentrations of formulation components and the structural parameters of molecule aggregates and pigment (filler) clusters were calculated in the approximation of the cluster lattice model for the example of a formulation containing low-molecular-weight epoxydiane resins, a monoepoxy compound Cardura, red iron oxide pigment and filler (Microtalc).

(2) It was shown that the yield stress τ_0 of the filled epoxy formulation varies in accordance with the expression $\tau_0 \sim |c_p - c_p^*|^t$, where c_p^* is the critical Microtalc concentration and $t = 1.8$. The initial viscosity η^0 of the formulation is a power function of the concentration c_p of pigment (filler) particles: $\ln \eta^0 \sim c_p^{(3-D)/D}$, where D is the fractal dimension of particle clusters. The scaling of the viscosity η^0 in a shear flow of the filled formulation in the range $c_p > c_p^*$ is due to the irreversible dynamic degradation of the continuous

fluctuation network of entanglements between oligomer molecules, which leads to disintegration of the infinite cluster ($D \approx 2.5$) of pigment (filler) particles into discrete clusters ($D \approx 1.1$).

(3) In the filled formulation, the degree of aggregation of pigment (filler) particles shows an unlimited rise near the threshold value c_p^* and the lattice density of particle clusters reaches the maximum value of ~0.69 and then sharply falls in the range $c_p > c_p^*$, which predetermines the extremal behavior of the flow index curves $n(c_p)$. The corresponding state of the formulation is close to that of a dense solution of solid spheres at the percolation threshold.

(4) Tests of the mechanical and protective properties of coatings produced by curing of the filled epoxy formulation with amines demonstrated that these properties are the best pronounced at a pigment (filler) concentration $c_p \approx 31$ vol %, which coincides with the threshold value c_p^*. These data make it possible to state the physicochemical principles to be used in making up these formulations and to substantiate their prescribed composition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Adhesion of Polyimide Films to Microelectonic Article Components

Abstract—Reactions between polypyromellitamido acid and component materials of microelectronic articles were examined by thermogravimetric analysis. Modes of modification of the surfaces of semiconductor structures to be used in formation of a system of interconnections with polyimide as interlayer insulator to obtain a high adhesion between the layers via their chemical reactions.

DOI: 10.1134/S1070427206100259

The miniaturization of the active elements of microelectronic articles and the ensuing increase in the degree of integration are responsible for the fact that a steadily growing area of the crystal (chip) is occupied by electric interconnections. An increase in the length of interconnections, with a simultaneous decrease in their cross section, leads to a pronounced rise in both the resistance and capacitance. This strongly limits the speed of response of devices.

A possible solution to this problem is to create multilevel interconnections, which, in, turn, give rise to many other problems. The most significant among them are breaks of the interconnecting paths and disturbance of the continuity of the insulator films at steps of the topological profile.

This problem can be tackled with by using films of organic insulators and, in particular, polyimides [1–4] ensuring the required planarity and continuity of the coatings. However, polyimides are chemically inert compounds and do not enter into chemical reactions with components of microelectronic articles (Si, SiO_2, Al, Al_2O_3, etc.), used for fabrication of interconnection systems. This results in an unsatisfactory adhesion of the films of the multilayer system and gives no way of obtaining the required parameters of the structures being manufactured.

Lee et al. [5] suggested to raise increasing the adhesion by forming an independent intermediate layer based on γ-aminopropyltriethoxysilane. Its hydrolysis yields silicon dioxide with attached amino groups, which react with the functional groups of polyamido acid to form a chemical bond between the film and the substrate. However, the method of preparation of such a film does not satisfy the requirements of microelectronics as regards the purity, defectiveness, carbon content, and other characteristics. Yih et al. [6] introduced various additives directly into the polyimide formulation, but this markedly affected the insulation quality. It should be noted that all the above-described options only partially, rather than cardinally, solve the problem.

Babaevskii et al. [7] found that physicochemical modification of thin polyimide films and coatings by plasmochemical treatment and treatment in hexamethyldisilasane vapor affects the nature of the bonds, surface and bulk properties, and nature of inter-phase interaction across the whole width of the films. We suggested that the grains in the films should be predominantly oriented in the (110) plane to improve the adhesion of aluminum films to other layers [8].

Today, the mostly used organic interlevel insulators are polypyromellitimide (PI) films. A characteristic feature of their preparation procedure is that a film of polypyromellitamido acid (PAA) is formed on the semiconductor substrate and is converted to polyimide by heat treatment. In contrast to PI, the PAA macromolecules contain chemically active functional groups –COOH and –NH–, which can, under certain conditions, react with the materials of the contacting layers and provide adhesion between them.

Diverse physicochemical processes are used to form the multilevel interconnection system for micro-

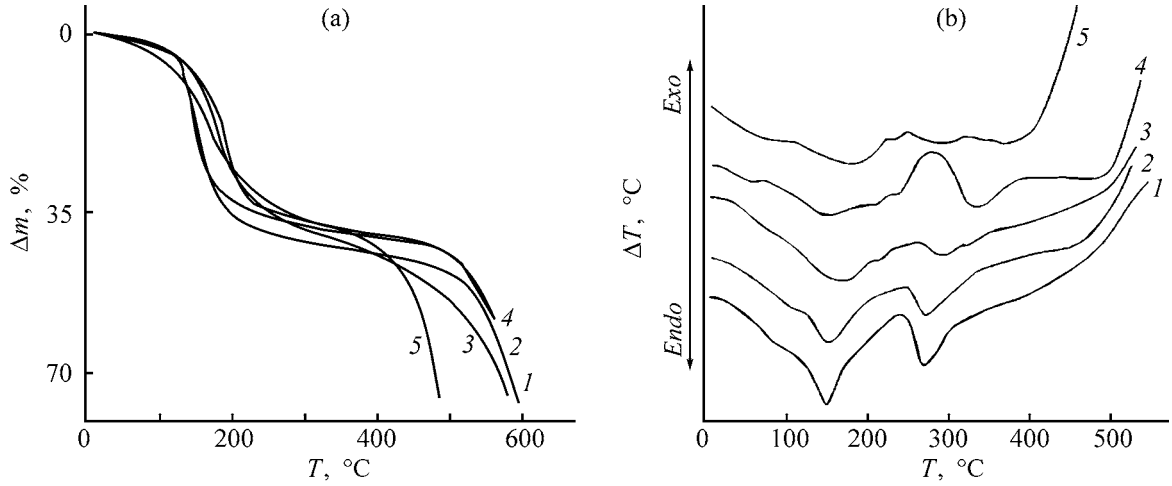

Fig 1. (a) TG and (b) DTA curves for PAA, PAA + silicon, PAA + silicon oxide, PAA + aluminum, PAA + aluminum oxide for different weighed portions. (Δm) Mass loss, and (T) temperature. Weighed portion, mg: (*1*) 62.7 PAA, (*2*) 53.1 PAA + 6.3 silicon, (*3*) 45.4 PAA + 5.8 silicon dioxide, (*4*) 39.5 PAA + 6.9 aluminum, and (*5*) 35.2 PAA + 4.7 aluminum oxide. Heating rate 10 deg min^{-1}.

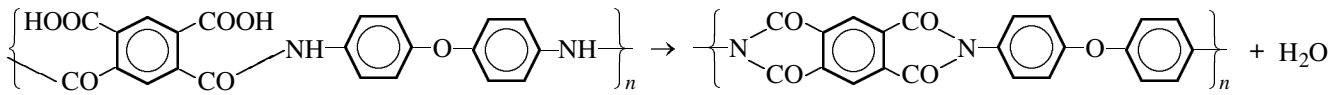
electronic articles, thus creating certain prerequisites for ensuring such conditions. High-temperature processes (>550°C) are absolutely unacceptable because of the possible degradation of the Al–Si contacts, and, in the case of shallow *p–n* junctions, to failures caused by short circuit of aluminum with the active region of the device.



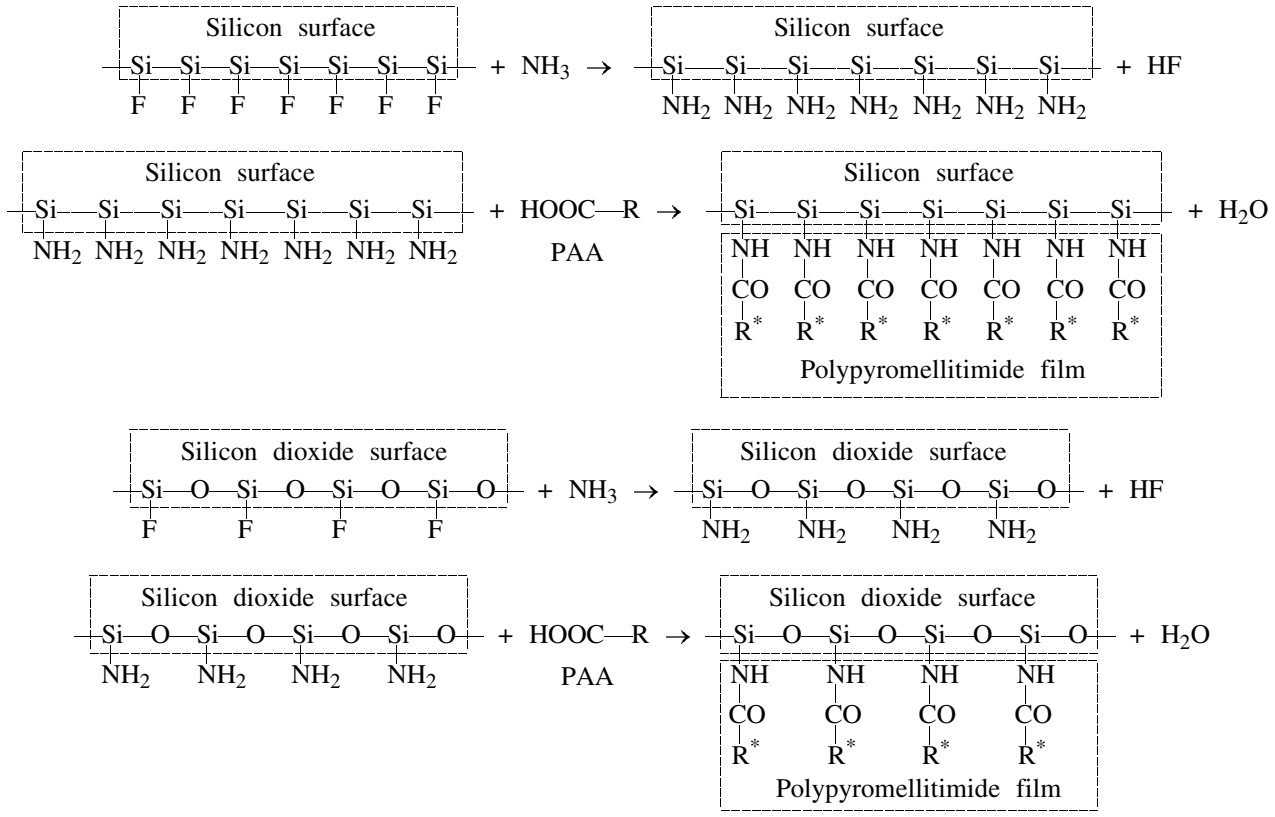
In this study, we examined chemical reactions of PAA with component materials of microelectronic articles and attempted to develop processes for modifying the surfaces of semiconductor structures and surface of polyimide films to provide a strong chemical bonding with the contacting layers and a high adhesion between them.

EXPERIMENTAL

In thermal analysis, we used a neat (without additives) solution of PAA in dimethylformamide (DMF) and its blends with powdered Si, SiO_2, Al, and Al_2O_3. The weighed portions were 62.7 mg of the PAA solution in DMF (henceforth, PAA), 53.1 mg of PAA with 6.3 mg of silicon, 45.4 mg of PAA with 5.8 mg of silicon dioxide, 39.5 mg of PAA with 6.9 mg of aluminum, and 35.2 mg of PAA with 4.7 mg of aluminum oxide.

A thermal analysis was carried out on an OD-102 derivatograph in the temperature range 20–600°C at a heating rate of 10 deg min^{-1} in a self-generated atmosphere. All the additives were finely ground powders; to prevent overlapping of curves we took different weighed portions of PAA. The adhesion of PI was monitored by the previously described procedure [9], as well as visually with an MMU-3 microscope.

Figure 1a demonstrates the TG, and Fig. 1b, the DTA curves for PAA, PAA + silicon, PAA + silicon dioxide, PAA + aluminum, and PAA + aluminum oxide blends. The thermogravimetric characteristics of PAA have been rather extensively examined and described [3]. The imidization proceeds by the scheme



In the first stage, at temperatures within the range 20–120°C (curve *1*), there is insignificant mass loss due, probably, to intermolecular interaction of the PAA macromolecules and partial release of the solvent and imidization water from the polyamido acid solution. In the second stage (120–160°C), the release of the solvent and water is accelerated, possibly due to superposition of the continuing growth of the molecular weight and the beginning intramolecular cyclization into imide rings. This agrees well with the boiling point of DMF (~153°C) and with the occurrence of an endothermic peak in the DTA curve. Since the onset of imidization coincides with the release of the solvent, there is no additional step in the mass loss curve.

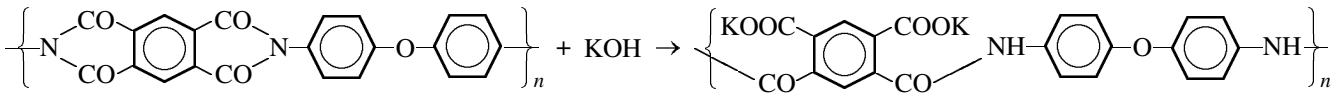
As the temperature increases, the release of volatile products is decelerated to a certain extent at 160–500°C and then accelerated at 500–600°C.

The peak in the DTA curve at 250–300°C is virtually not accompanied by any change in the sample mass. Bessonov et al. [1] attribute the improvement of the mechanical properties upon heating at 200–300°C to restoration of the molecular weight of polyamido acid (supposedly, via reactions at terminal groups). Also, cross-linking of the macromolecules is possible.

Silicon and silicon dioxide (curves *2* and *3*) virtually do not affect the thermogravimetric characteristics of PAA. A small shift of the solvent loss peak in the DTA curve to higher temperatures and smoothening of the corresponding step in the TG curve for the PAA + silicon dioxide blend is, most probably, due to sorption–desorption of the solvent released and imidization water by silicon dioxide. The TG and DTA curves suggest that PAA does not enter into chemical reactions with silicon or silicon dioxide, which gives no way of obtaining an acceptable adhesion of the PI film to these materials without taking additional measures.

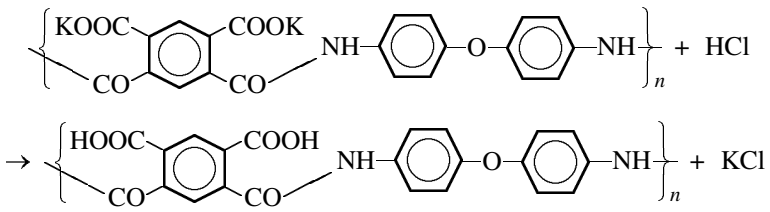
The process we developed for modification of the silicon dioxide and silicon surfaces ensures formation of a monolayer of amino groups on their surface. The process includes two stages. The first stage involves treatment of the surface in a fluorine-containing plasma and formation of a monolayer of fluorine atoms. The Si–F chemical bond is unstable; it is immediately hydrolyzed in the presence of trace amounts of moisture. Therefore, it is necessary to monitor the process and the purity of the reagents. Treatment of the surface with gaseous ammonia results in the replacement of fluorine atoms by amino groups. Modification does not require high temperatures, and the Si–NH_2 chemical bond is fairly stable. During the subsequent formation of the polyimide film, the –NH_2 functional groups on the substrate surface enter into a chemical reaction with –COOH groups in PAA macromolecules. Thus, the film being formed is "fastened" to the substrate surface by –CO–NH– bonds. The –CO– group belongs to the macromolecule of the film being formed, and the –NH– group, to the modified surface. A strong chemical bond is formed between the film and the substrate, which ensures their mutual adhesion. This method is suitable for a silicon substrate and a substrate coated with polycrystalline silicon, silicon dioxide, silicides, and similar silicon compounds. The process occurs at the film–substrate interface exclusively and does not deteriorate the electrical characteristics of the resulting insulation. Below given are the schemes of the occurring chemical reactions:

Formation of the adhesion bonds and intramolecular cyclization of PAA proceed simultaneously and compete with each other. The residual R of the polyamido acid macromolecule, the educt, is converted to a residual of the polyimide macromolecule in the reaction products and is designated as R^*.



As is known, the cyclization of PAA begins even at its drying temperature but does not go to completion. The reason is the growing rigidity of the macromolecules, which presents a spatial hindrance to approach of the reacting functional groups [1]. Therefore, a significant proportion of the functional groups and, in particular, –COOH, are not involved in the formation of imide rings in this stage and, despite the predominant occurrence of the processes considered, prtovides formation of the adhesion bonds.

In the presence of aluminum and aluminum oxide (curves *4* and *5*, respectively), the thermogravimetric characteristics of PAA are modified as follows. The solvent loss peaks are shifted to higher temperatures; this shift is more pronounced for the PAA + aluminum oxide blend, which can also be due to sorption–desorption of the solvent and water. The endothermic effect for the PAA + aluminum blend at 250–300°C is virtually completely compensated for by the exothermic effect in the same temperature range. This process does not affect the mass change, which suggests chemical reactions between the polymer and aluminum. Chemical reactions between PAA and metals were also noted by Bessonov et al. [1]. For the PAA + aluminum oxide blend, the steps in the TG curve are markedly smoothened, and the DTA peaks are rather weakly manifested, which suggests the predominant occurrence of adsorption processes. Intensive interaction in this blend begins only at 400°C, and the thermal stability of the polyimide being formed decreases by ca. 100°C. This is, probably, due to decomposition of the polymer under the action of aluminum oxide exhibiting amphoteric properties.



As is known, aluminum is immediately oxidized in air to form on its surface a thin oxide film. The thickness of this film depends on the storage time and conditions and can attain ca. 10 nm. Therefore, formation of a polyimide film on the surface of the aluminum-coated structure should be preceded by cleaning (a kind of "refreshing" of the surface) to remove the oxide immediately before application of PAA. The choice of the temperature modes for treatment of the polyamido acid film applied to the structure with aluminum in order to convert it into polyimide should also take into account the temperature range of interaction between PAA and the metallic substrate. Prolonged primary drying of the PAA film at a temperature below 250°C, leads not only to evaporation of the solvent, but also to a significant imidization without chemical reactions with the metallic base. Subsequent heat treatment of the structure at the temperature of the reaction between PAA and the metal (above 250°C) does not lead to formation of a sufficient number of adhesion bonds, since, by this moment, the concentration of the functional groups becomes too low.

Thus, polyamido acid actively reacts with aluminum at temperatures above 250°C, while polyimide is known to be inert toward aluminum [3]. Thus, an acceptable adhesion of metallized coatings to unmodified polyimide is unattainable in principle. At the same time, adhesion of polyimide films to metallized surfaces is typically fairly satisfactory. Therefore, it is reasonable to carry out surface modification of polyimide into polyamido acid in order to obtain good adhesion of the metal films to polyimide.

The process we developed for surface modification of the polyimide film into polyamido acid can include one or two stages. In the two-stage process, the polyimide film is initially treated with a dilute alkali solution (e.g., KOH). This results in opening of the imide rings to give salts of the polyamido acid and alkali by the scheme:

In this context, the most important aspect is termination of the process at a proper time, when it is complete on the surface and has not spread deep inside the polyimide film, as this will degrade the film. This termination is achieved by using dilute (to 1%) solutions of alkali and by maintaining the temperature within 15–30°C. The second stage consists in treatment of the resulting film in an acid solution, with the salts regenerated to the initial PAA by the scheme

Heat treatment after formation of the interconnection pattern leads to reaction of the resulting PAA with the metal film to form a strong –COO–Al chemical bond. PAA that does not react with aluminum (between the interconnecting paths) is converted back to polyimide.

In the one-stage process, the treatment was carried out in a solution of a weak base. Upon subsequent washing in water, the salts formed in the film are hydrolyzed to polyamido acid. The choice of the method for surface modification of polyimide into polyamido acid is dictated by the specific process conditions and the possibility of combining the treatment of polyimide with other operations, e.g., removal of the photoresist, opening of contact windows.

Monitoring of adhesion of the polyimide films prepared by the processes we developed showed that the film does not peel-off in peeling tests. Visual monitoring of opening of contact windows in hydrofluoric acid solutions also showed that the film does not peel-off at the contact window edges. Monitoring of adhesion of the metal film to polyimide did not reveal peeling-off for the aluminum interconnecting paths. The results we obtained were used for developing a process for fabrication of a multilevel system of interconnections in integrated circuits.

CONCLUSION

Processes were developed for modification of the surfaces of semiconductor structures, as well as of the surface of polyimide films, that provide chemical reactions between the polyimide films and the contacting layers to achieve a high mutual adhesion.

Abstract—Variation of the amount, composition, and structure of the residual lignin and resin in pulp samples from kraft cooking of birch and aspen woods and their blend with addition of distilled tall oil was studied by Fourier IR spectroscopy.

DOI: 10.1134/S1070427206100260

The use of deciduous wood, including birch and aspen wood, in production of kraft pulp involves so-called "resin problems," since the content of neutral substances (styrenes, waxes) in the extractive substances is 25–30%, and that of fats (mainly glycerides of unsaturated linoleic and oleic acids), 50–60%; these substances tend to readily transform in storage and production [1].

It is well known that, in cooking, the resin content in deciduous pulp can be decreased by adding various surfactants, among them products of wood chemistry [2].

We studied the possibility of using distilled tall oil (DTO) and its acidic components for this purpose. It has been shown previously [3, 4] that, in separate and combined kraft cooking of birch and aspen wood with addition of DTO, the content of resinous substances and residual lignin can be decreased by 30–40%.

To obtain fundamentally new data, we used in this study a noninvasive method, Fourier IR spectroscopy. This method is the most informative and allows determination of not only the content, but also structural transformations of the residual lignin in situ, without its recovery from fibers [5–7]. Here, we describe the results of using this method for studying changes in the composition and structure of residual lignin in pulp samples from kraft cooking of birch and aspen wood and their blends with DTO as an additive.

EXPERIMENTAL

The study was performed with samples of sound birch (Betula pubesceus) and aspen (Populus tremula) woods: age 25–35 years, stem diameter without bark 20 cm. For cooking we used hand-made chips of the following dimensions (mm): length 25–30, width 20–25, and thickness 2–3.

The content of extractive substances in birch and aspen sawdust was the same, 2.5%. The lignin content determined by the sulfuric acid method was 20.0% in birch wood and 20.4% in aspen wood; the pulp content determined by the nitric acid–alcohol method was 45.6 and 50.6%, respectively.

The kraft cookings were performed using white liquor (sulfide content 30%) in the same temperature–time mode (heating to 170°C over a period of 120 min, cooking at 170°C for 60 min) in a set of six pressure vessels. The prescribed expenditure of active alkali in the Na_2O units relative to absolutely dry wood charged into pressure vessels was 17 wt %. After the cooking was complete, the pulp was squeezed, washed on a filter with hot water, and dried in air; then the pulp yield and resin content were determined (the latter, by extraction with methylene chloride); the content of the residual lignin was determined by the sulfuric acid method, following the standard procedures [8].

Table 1. Yield and content of residual lignin and resin in pulp samples

Sample no.	Sample characteristics	Recovery from wood, %		Pulp yield, %	Content in pulp, %	
		lignin	resin		lignin	resin
	Pulp:					
1	from kraft cooking of birch wood without additives	93.4	81.0	47.2	2.7	0.43
2	extracted with methylene chloride	93.4	100.0	47.2	2.7	0.00
3	from cooking with addition of 3 wt % DTO	95.9	81.0	45.7	1.8	0.49
4	from kraft cooking of aspen wood without additives	97.6	95.4	51.6	0.95	0.37
5	extracted with methylene chloride	97.6	100.0	51.6	0.95	0.00
6	from cooking with addition of 3 wt % DTO	97.5	81.0	51.7	1.0	0.16
7	from kraft cooking of a blend (birch : aspen 50 : 50) without additives	95.3	89.2	52.0	1.8	0.52
8	extracted with methylene chloride	95.3	100.0	52.0	1.8	0.00
9	from cooking of the blend with addition of 3 wt % DTO	96.4	88.5	50.9	1.4	0.6

To obtain the Fourier IR absorption spectra, the pulp samples were prepared in the form of thin pellets of diameter 13 mm and weight 2–4 mg by direct pressing of fibers in a press mold without addition of KBr. Before recording the spectra on a Bruker IFS25IR Fourier spectrophotometer, the samples were purged for 5 h in the cell compartment of the spectrophotometer, which allowed improvement of the spectrum quality due to a decrease in the intensity of absorption bands of atmospheric water and water adsorbed on the fiber surface.

The characteristics of the pulp samples from separate kraft cookings of birch (sample nos. 1–3) and aspen (sample nos. 4–6) wood and from cooking of a blend of birch and aspen chips (sample nos. 7–9) are listed in Table 1.
