Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received October 2, 2000

**Abstract**—By *ab initio* calculations, the molecular geometries of 1,10-phenanthroline and its 1 : 1 and 1 : 2 complexes with lithium and sodium ions were optimized, and the frequencies and intensities of normal modes of these species were evaluated. The experimentally observed bands were assigned on the basis of the calculation results. The concentration dependences of the IR spectra of the system 1,10-phenanthroline–LiClO<sub>4</sub> (NaClO<sub>4</sub>)–acetone-*d*<sub>6</sub> ( $C_{\text{phen}}$  0.05,  $C_{\text{salt}}$  from 0 to 1 M) were interpreted. The formation of the 1 : 1 and 1 : 2 complexes was confirmed spectroscopically.

Interest in complexes of 1,10-phenanthroline and its derivatives with Li<sup>+</sup> and Na<sup>+</sup> ions is due to the possibility of using such ligands in clinical lithium sensors, primarily potentiometric, applicable in media with a large excess of sodium ions [1]. To optimize the sensor selectivity, it is necessary to know the stoichiometry and constants of complexation of the sensor substance with ions in an ion-selective membrane [2, 3].

From the vibration spectra of solutions containing a ligand and a metal salt, it is possible to evaluate the concentration distribution of coexisting species and the step complexation constants, provided that the states of the ligand in complexes of different stoichiometries are spectroscopically discernible; if the spectral characteristics of complexes of different stoichiometries coincide, only the overall complexation constants can be determined. An IR study of complexation involves assignment of the vibration bands of the ligand in the free state and in complexes. With simple ligands like NH<sub>3</sub> or CN<sup>−</sup>, or with ligands in which the complexing groups have characteristic bands sensitive to complexation with a metal (e.g., β-diketones, carboxylic acids, primary amines [4]), interpretation of the vibration spectra involves no problems. However, the assignment becomes considerably more difficult when one or several ligand molecules coordinate with the metal in a polydentate mode to form chelates. Such a case is typical for the majority of compounds showing promise as analytical sensors: crown ethers, carboxamides, and aromatic heterocycles, including 1,10-phenanthroline derivatives [5, 6].

Assignment of normal modes in the spectra of multicentered chelates is often made using the isotope

shifts of the frequencies in the spectra of the deuterated complexes [7]; however, deuteration can be performed only with a limited set of compounds.

In this work we studied complexation in the system 1,10-phenanthroline–LiClO<sub>4</sub> (NaClO<sub>4</sub>)–acetone by IR spectroscopy. 1,10-Phenanthroline (phen) forms five-membered chelate rings with metal ions [8]. In organic solvents, lithium and sodium ions form 1 : 1 and 1 : 2 complexes with phenanthroline [9], which complicates interpretation of the experimental IR spectra. To analyze the concentration dependences of the IR spectra of solutions containing a free ligand and complexes of different stoichiometries, we used in this work the calculated frequencies and intensities of the spectrum components for the free ligand molecule and its complexes with cations. This approach can also be applied to other classes of organic ligands.

The phen molecule (point group  $C_{2v}$ ) has 60 normal modes:  $\Gamma = 21A_1 + 10A_2 + 20B_2 + 9B_1$ . Three types of vibrations are IR-active: in-plane vibrations  $A_1$  and  $B_2$ , and out-of-plane vibrations  $B_1$ . Out-of-plane vibrations  $A_2$  are forbidden in the IR spectrum (their calculated intensity is zero).

Hartree–Fock calculations of vibration frequencies usually give overestimated values. In this work, the calculated vibration frequencies of each type were correlated with the experimental vibration frequencies of the same type determined in [10] by IR and Raman spectroscopy (mulis of phen in Nujol and hexachlorobutadiene) and assigned using data for the deuterio derivatives. We found that, in the entire frequency range, the calculated and experimental frequencies were proportional, with the proportionality factor of 0.89. In what follows, as far as the calculated frequen-

**Fig. 1.** IR spectra of phen: (1) spectrum with the calculated frequencies and intensities, plotted assuming the Lorentz line shape with a half-width of  $5\text{ cm}^{-1}$ ; (2–4) experimental spectra taken in acetone- $d_6$ ,  $\text{CCl}_4$ , and  $\text{CDCl}_3$ , respectively.

cies are concerned, they are multiplied by this factor. However, absolute coincidence of the calculated and experimental frequencies cannot be expected, because, firstly, the experimental conditions in this work (acetone solutions) differ from those in [10]; secondly, in calculations, solvation of the ligand and complexes was not taken into account, whereas actually the spectra of compounds in a condensed medium, even incapable of specific interactions, can significantly differ from those in a vacuum [11].

Nevertheless, as seen from Fig. 1, agreement of the calculated frequencies and intensities for phen in a vacuum with the experimental IR spectra of phen in solution is quite satisfactory. Examples of bands exhibiting different sensitivity to the environment are shown in Fig. 1. The positions of in-plane vibrations  $A_1$  and  $B_2$  ( $1300\text{--}1700\text{ cm}^{-1}$ ) are weakly sensitive to the solvent polarity. Contrastingly, the  $B_1$  vibration of phen (calculated frequency  $836\text{ cm}^{-1}$ ) is observed at  $840\text{ cm}^{-1}$  in low-polar  $\text{CDCl}_3$  and at  $847\text{ cm}^{-1}$  in polar  $(\text{CD}_3)_2\text{CO}$ . Thus, agreement between the calculated and experimental frequencies is the best in low-polar solvents. This is quite natural, because in calculations there is no solvent field, in low-polar solvents this field is symmetrical, and in solvation of phen with polar solvent molecules their preferential orientations are different at different parts of the phen molecule, causing local asymmetry of the solvent field.

However, in the case of phen, the solvent effect is relatively weak, and, on the whole, the calculated spectrum (Fig. 1, 1) satisfactorily reproduces the experimental IR spectrum of phen in acetone (Fig. 1, 2). This fact allowed us to assign the experimental IR spectra of phen- $\text{LiClO}_4$  ( $\text{NaClO}_4$ ) solutions in deuterioacetone on the basis of the calculated spectra of the molecules and complexes in a vacuum.

The complexes  $\text{M}(\text{phen})^+$  ( $\text{M} = \text{Li}, \text{Na}$ ) belong to the  $C_{2v}$  point group and have the following normal modes:  $\Gamma = 22A_1 + 10A_2 + 21B_2 + 10B_1$ .

The structural parameters of the  $\text{M}(\text{phen})_2^+$  complexes were optimized for the  $D_{2d}$  symmetry, to which corresponds the following set of normal modes:  $\Gamma = 22A_1 + 10A_2 + 22B_2 + 11B_1 + 32E$ .

The frequencies and intensities of vibrations, taking into account correlations of irreducible representations of the  $D_{2d}$  group and its  $C_{2v}$  subgroup [12], are listed in Tables 1 and 2. As seen from these data, complexation with the lithium ion causes somewhat stronger changes in the calculated frequencies than complexation with the sodium ion. We can distinguish a set of normal modes of phen sensitive to formation of 2 : 1 and 1 : 1 complexes (i.e., changing by no less than  $5\text{ cm}^{-1}$  upon complexation) ( $\text{cm}^{-1}$ ):  $600 (B_2)$ ,  $682 (A_1)$ ,  $728 (B_1)$ ,  $763 (B_1)$ ,  $823 (A_1)$ ,  $836 (B_1)$ ,  $1042 (B_2)$ ,  $1076 (A_1)$ ,  $1505 (A_1)$ , and  $1602 (A_1)$ . Based on

<sup>a</sup> Calculated intensity 0.12, because of participation of the  $\text{Li}^+$  ion in the vibration.

the results of preliminary calculations, we chose the spectrum ranges from which the richest information on complexation can be derived, and also the solvent (acetone- $d_6$ ) transparent in these ranges. Some of the complexation-sensitive vibrations manifested in the spectrum ranges in which the solvent and anion have no absorption are shown in Fig. 2. The possibility of spectroscopically distinguishing the complexes  $\text{Li(phen)}_2^+$  and  $\text{Li(phen)}^+$  is illustrated by Fig. 3a, showing the calculated spectrum as a sum of Lorentzian functions with a half-width of  $5 \text{ cm}^{-1}$ .

In complexation, the shapes of the normal modes are, on the whole, preserved; this is seen from Fig. 2 for phen and its 1 : 2 and 1 : 1 complexes with  $\text{Li}^+$ . At the same time, the extent of participation of particular atoms in a vibration changes upon complexation, as demonstrated by the example of the two most intense  $B_1$  bands (Table 3) undergoing opposite shifts upon complexation.

Table 3 shows that complexation of phen with a metal ion is accompanied by an appreciable increase

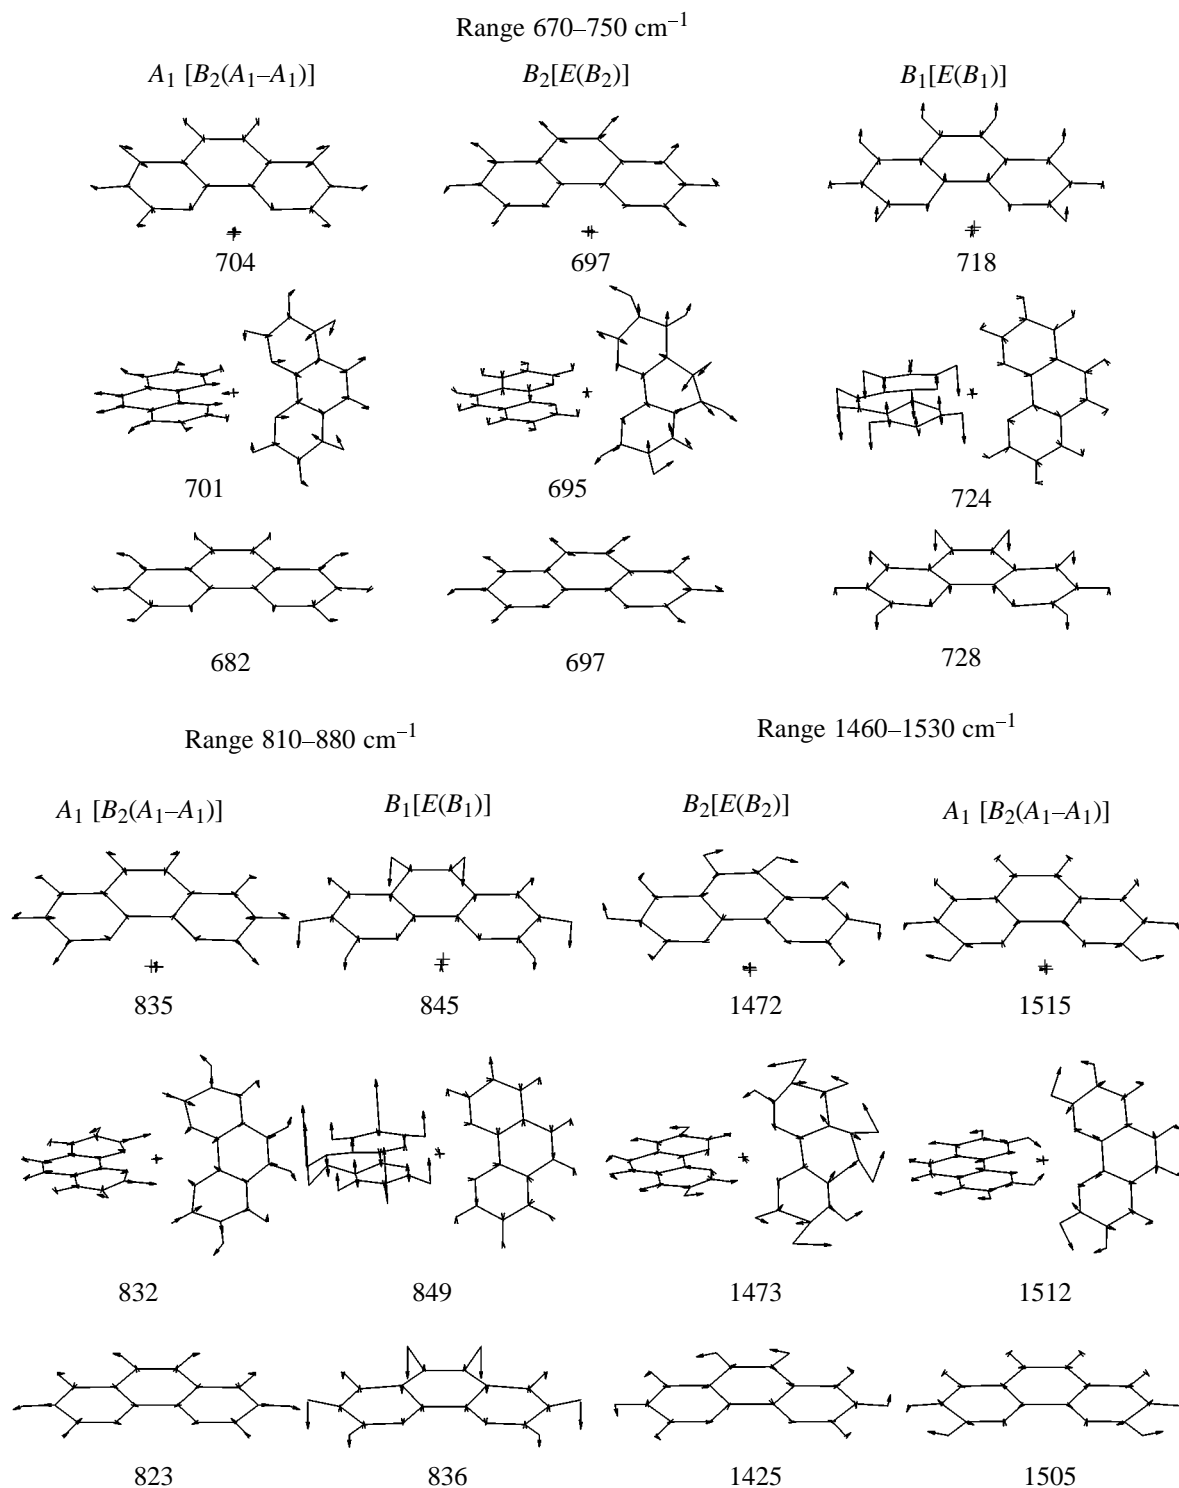

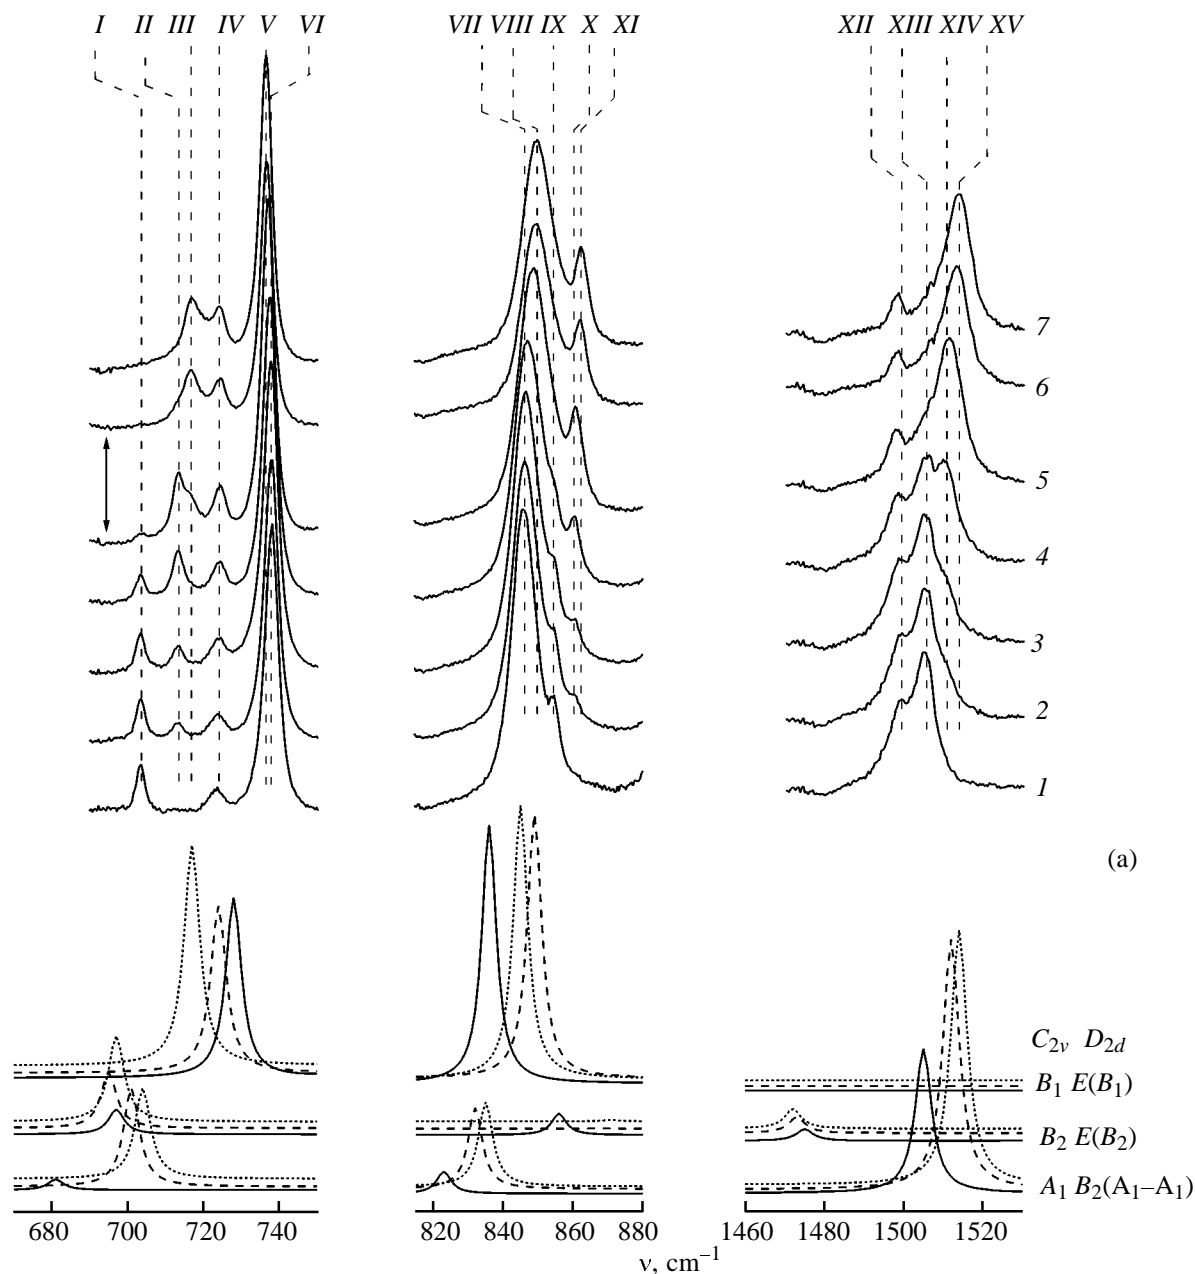

Fig. 2. Shapes of the normal modes of  $\text{Li}(\text{phen})^+$ ,  $\text{Li}(\text{phen})_2^+$ , and phen. Frequencies in  $\text{cm}^{-1}$ .

in the contribution of hydrogen atoms 13 and 14 [coordinate (3)] to the normal mode  $\nu_{49}$  ( $B_1$ ) and by a decrease in the contribution of torsional skeleton vibrations [coordinates (6)–(8)]. With the  $\nu_{51}$  mode

( $B_1$ ), the pattern is more complex: the contributions of the out-of-plane displacements of hydrogen atoms 21 and 22 [coordinate (1)], 15 and 16 [coordinate (2)], and 17 and 18 [coordinate (4)] decrease, that of hydro-

<sup>a</sup> Each of the natural coordinates given in the table has a mirror-symmetrical pair. <sup>b</sup> Assignment for phen [10]. <sup>c</sup> Deviation of the atom denoted by the first figure from the plane of atoms denoted by the next three figures. <sup>d</sup> Variation of the torsion angle formed by the atoms denoted by the given sequence of four figures. In parentheses is the number of the internal coordinate.

gen atoms 13 and 14 [coordinate (3)] increases, and the contributions of out-of-plane displacements of the carbon and nitrogen atoms [coordinates (7) and (8)] increase. Changes in the extent of participation of the light and heavy atoms in the vibrations may be one of the causes of different trends in shifts of vibration bands of the same class upon complexation; some other factors may also be operative, such as, e.g., changes in the force field upon complexation.

When assigning the bands in the experimental spectra (Fig. 3b, Roman figures), we primarily took into account the band intensities and the directions of their shifts, comparing these data with the calculated

spectra (Fig. 3a). In some cases, inversion of the relative arrangement of certain components as compared to the calculated spectrum was admitted. For example, the experimental band at 721–723  $\text{cm}^{-1}$  was assigned to a  $B_2$  vibration (calculated frequency 697  $\text{cm}^{-1}$ ) on the basis of the fact that its position and intensity vary only slightly upon complexation (Fig. 3b, IV). At the same time, the band observed at 701–717  $\text{cm}^{-1}$  was assigned to the  $A_1$  vibration (calculated frequency 682–704  $\text{cm}^{-1}$ ), as with increasing concentration of the salt, in compliance with the calculation results (Fig. 3a), it underwent a high-frequency shift with an increase in the intensity (Fig. 3b). Another example of inversion of the relative arrangement of the bands

**Fig. 4.** Results of joint treatment by the Löwenberg–Marraquard algorithm of the experimental spectra of 0.05 M solutions of phen in  $(\text{CD}_3)_2\text{CO}$ .  $\text{LiClO}_4$  concentration, M: (a) 0, (b) 0.014, and (c) 0.101. ( $\Delta$ ) Difference between the experimental spectrum and the spectrum fitted by the sum of the Lorentz functions.

is as follows: the component shifting upon complexation from 854 to 862  $\text{cm}^{-1}$  was assigned to the  $A_1$  vibration (Fig. 3b, IX–XI), whereas the component with a maximum at 845–854  $\text{cm}^{-1}$  was assigned to the  $B_1$  vibration (Fig. 3b, VII, VIII). This assignment was based on the fact that the  $B_1$  vibration band, according to calculations, should be stronger. The calculated shifts of some bands upon complexation [682–704 ( $A_1$ ), 728–718 ( $B_1$ ), 836–845 ( $B_1$ ), 1505–1515  $\text{cm}^{-1}$  ( $A_1$ ); Fig. 3a] agree with the experimentally observed shifts in the direction (701–717, 738–735, 845–851, 1505–1514  $\text{cm}^{-1}$ ; Fig. 3b), but in most cases are overestimated in the value.

By a similar procedure, we assigned the bands in the IR spectra of the system  $(\text{CD}_3)_2\text{CO}$ –phen– $\text{NaClO}_4$ .

Using the assignments made for the 1 : 1 and 1 : 2 complexes of  $\text{Li}^+$  and  $\text{Na}^+$  with phen, we resolved the experimental spectra into components belonging to the free ligand and to the ligand moiety in complexes of different stoichiometries.

The initial set of parameters for fitting the experimental spectrum by the sum of Lorentz functions included the required number of components and pre-

liminary values of their frequencies ( $\pm 2 \text{ cm}^{-1}$ ) and half-widths ( $3\text{--}7 \text{ cm}^{-1}$ ). The positions of the maxima and the half-widths were refined in the course of joint treatment by the Löwenberg–Marraquard algorithm [13] of the spectra of solutions with a constant (0.05 M) phen concentration and different (zero, “middle,” and maximal) concentrations of the salt. Apparently, when resolving a single spectrum, a better fitting can be attained, but only joint treatment of several spectra allows evaluation of common frequencies and half-widths of the components, optimized over the whole series. In this work, the component frequencies and half-widths optimized by joint treatment of four and more spectra virtually coincided with the results of treatment of three spectra.

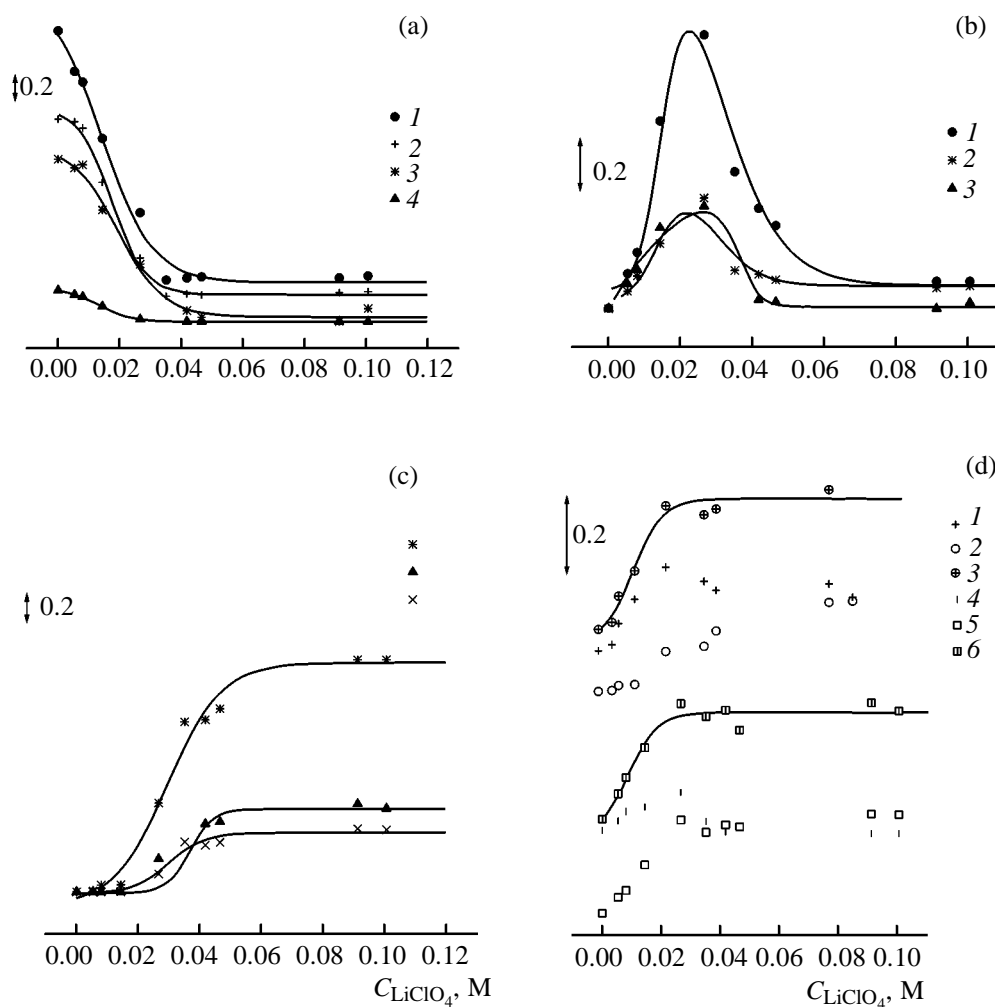

Let us consider resolution of the experimental spectrum for the system  $(\text{CD}_3)_2\text{CO}$ –phen– $\text{LiClO}_4$  in the range 670–750  $\text{cm}^{-1}$  as example.

As seen from Figs. 2 and 3a, there should be nine components in the range 670–750  $\text{cm}^{-1}$  and six components in each of the ranges 800–900 and 1450–1550  $\text{cm}^{-1}$ . However, for the first range, the number of functions fitting the experimental spectrum can be decreased to eight by describing the  $B_2$  components (belonging to different complexes but having close positions and intensities) by a single Lorentz function. The positions of the maxima and the half-widths, determined by joint treatment of three experimental spectra (Fig. 4), were used for resolving the other spectra of the series, with the component intensities being the only varied parameters.

By resolving the experimental spectra in the ranges 650–750, 800–900, and 1450–1550  $\text{cm}^{-1}$ , we obtained the dependences of the integral intensities of the spectrum components on the salt concentration. Figure 5 shows such dependences for the system with lithium perchlorate. The components belonging to the free ligand give monotonically descending curves (Fig. 5a); those belonging to the 2 : 1 complex give curves with a maximum (Fig. 5b); and those belonging to the 1 : 1 complex give ascending sigmoid (S-shaped) curves (Fig. 5c). When the bands belonging to different complexes strongly overlap (e.g., in the range of strong  $B_1$  bands), it appears impossible to reliably determine the intensities of separate components, although, on the whole, the shape of dependences 1 and 4 in Fig. 5d resembles the pattern in Fig. 5b, and the shape of dependences 2 and 5 resembles the pattern in Fig. 5c. For these cases, we plotted the dependences of the total intensities of the components corresponding to both components vs. the salt concentration (Fig. 5d, curves 3 and 6).

Figure 6 shows as an example the concentration

**Fig. 5.** Integral intensities of particular components of the IR spectra of the system phen–LiClO<sub>4</sub>–(CD<sub>3</sub>)<sub>2</sub>CO as functions of salt concentration (layer thickness 140 μm). (a) Components belonging to the free ligand: (1) 845, (2) 1505, (3) 738, and (4) 703 cm<sup>−1</sup>; (b) components belonging to the complex Li(phen)<sub>2</sub><sup>+</sup>: (1) 1511, (2) 861, and (3) 713 cm<sup>−1</sup>; (c) components belonging to the complex Li(phen)<sup>+</sup>: (1) 1514, (2) 717, and (3) 862 cm<sup>−1</sup>; and (d) components [(1) 735, (2) 737, (4) 848, (5) 851 cm<sup>−1</sup>] and curves (3, 6) corresponding to the sum of the complexes Li(phen)<sub>2</sub><sup>+</sup> and Li(phen)<sup>+</sup>.

dependences of the integral intensity of the A<sub>1</sub> component in the spectra of the systems of phen with LiClO<sub>4</sub> and NaClO<sub>4</sub>. The calculated frequency of this vibration is 682 cm<sup>−1</sup> for the free ligand, and upon complexation it increases (Tables 1 and 2; Fig. 3a).

To determine the step stability constants, it is appropriate to choose the concentration ranges in which all the absorbing species coexist in comparable amounts, despite the fact that, under these conditions, the spectrum is the most complex. From data in Figs. 5 and 6, it is possible to evaluate the stability constants of the complex species.

Calculation of the concentrations of particular species from the component intensities is a separate

problem whose solution requires determination of the integral absorption coefficients ( $D_{\infty}/l$ , where  $l$  is the absorbing layer thickness) of these species. For the system with LiClO<sub>4</sub>, the  $D_{\infty}/l$  values for components belonging to phen and Li(phen)<sup>+</sup> can readily be determined from the spectra of solutions of free phen (0.05 M) and of solutions in which the 1 : 1 complex prevails (0.05 M phen + 0.1 M LiClO<sub>4</sub>), respectively; for the system with NaClO<sub>4</sub>, the 1 : 1 complex prevails at  $C_{\text{salt}} > 0.15$  M. The system with NaClO<sub>4</sub> is a homogeneous solution in the entire examined concentration range, whereas in the system with LiClO<sub>4</sub> a solid phase is formed in the region of concentrations close to 2 : 1. In this case, to calculate the speciation and step complexation constants, it is necessary to determine the total ligand concentration in solution.

**Fig. 6.** Intensity of the  $A_1$  component (calculated frequency  $682\text{ cm}^{-1}$  for free phen) as a function of the (1, 3, 5)  $\text{LiClO}_4$  and (2, 4, 6)  $\text{NaClO}_4$  concentrations: (1, 2) component with a maximum at  $703\text{ cm}^{-1}$  corresponding to the free ligand; (3, 4) components corresponding to the complexes  $\text{M}(\text{phen})_2^+$ , maximum at (3)  $713$  and (4)  $711\text{ cm}^{-1}$ ; and (5, 6) components corresponding to the complexes  $\text{M}(\text{phen})^+$ , maximum at (5)  $717$  and (6)  $712\text{ cm}^{-1}$ .

Thus, we have suggested a procedure for interpreting the concentration dependences of the IR spectra of the systems phen– $\text{LiClO}_4$  ( $\text{NaClO}_4$ )–acetone, involving preliminary ab initio calculations of the vibration frequencies and intensities for the free ligand molecule and its complexes of the expected stoichiometry. Based on the results of quantum-chemical calculations for phen,  $\text{Li}(\text{phen})^+$ ,  $\text{Li}(\text{phen})_2^+$ ,  $\text{Na}(\text{phen})^+$ , and  $\text{Na}(\text{phen})_2^+$ , we chose the spectrum intervals in which the patterns given by different species are the best discernible. We suggested the parameters for resolving the experimental spectra, proved the formation of the 1 : 1 and 1 : 2 complexes in the systems, and obtained the concentration dependences of the intensities of the spectrum components belonging to the free ligand and its 1 : 1 and 1 : 2 complexes with  $\text{Li}^+$  and  $\text{Na}^+$ .

## EXPERIMENTAL

The optimized geometries and harmonic frequencies of the phen molecule and its 1 : 1 and 1 : 2 complexes with  $\text{Li}^+$  and  $\text{Na}^+$  in a vacuum were calculated

by the RHF method using the GAMESS program package [14, 15], assuming the  $C_{2v}$  symmetry for free phen and the 1 : 1 complex and the  $D_{2d}$  symmetry for the 2 : 1 complex. We used the DZV set of basis functions with one  $d$ -polarization function on the carbon and nitrogen atoms of the ligand, and for the lithium and sodium ions we used the TZV set with one  $d$ -polarization function. The displacements of atoms were visualized using the Molden 3.6 program [16]. The spectra were fitted by a sum of Lorentz components with a half-width of  $5\text{ cm}^{-1}$ .

Anhydrous  $\text{LiClO}_4$  and  $\text{NaClO}_4$  were prepared by a common procedure [17]. Anhydrous phenanthroline was prepared from phenanthroline monohydrate by vacuum sublimation ( $10^{-2}\text{ mm}$ ). Deuterated acetone was stored over 4 Å molecular sieves (Institute of Silicate Chemistry, Russian Academy of Sciences) in a hermetically sealed glove box. All manipulations (preparing solutions, filling cells and ampoules) were performed in a dry box using plastic and glass vessels. The quality of the chemicals used and the moisture content in solutions were monitored by IR (range of  $\text{H}_2\text{O}$  stretching vibrations,  $3800\text{--}3400\text{ cm}^{-1}$ ) and  $^1\text{H}$  NMR ( $\delta$  1–10 ppm) spectroscopy.

The IR spectra were recorded with a Specord M-80 diffraction spectrophotometer equipped with an IBM-compatible interface, in the ranges  $3800\text{--}3400$  (step  $0.8\text{ cm}^{-1}$ , slit  $2.5\text{ cm}^{-1}$ ),  $1660\text{--}1300$ , and  $950\text{--}570\text{ cm}^{-1}$  (step  $0.4\text{ cm}^{-1}$ , slit  $1.5\text{ cm}^{-1}$ ). A  $140\text{-}\mu\text{m}$  NaCl cell was used.
