4.2. The big picture. Using the terminology of the previous subsection, we can now give an overview of our upper bound construction. (A formal description follows in subsection 4.4.) In $\mathbb{R}^d$, we build a subdivision $D_d(n)$ of the cube $[0, n]^d$. We use an auxiliary subdivision $B_d(m)$ of the cube $[0, m]^d$, for $m = \exp(\log^{(d-2)/(d-1)} n)$, such that all diagonal unit cubes of $[0, m]^d$ and all their 1-shadows are elements of $B_d(m)$. The remaining space in $[0, m]^d$ is filled with some subdivision of low stabbing number (which we discuss in more detail in the next paragraph). The construction of $D_d(n)$ is done recursively in $\log^{1/(d-1)} n$ steps. In each step, we scale up a copy of the subdivision $B_d(m)$ by a factor of m and subdivide its m diagonal cubes with copies of $B_d(m)$. After $\log^{1/(d-1)} n$ recursive steps, we obtain the subdivision $D_d(n)$ of $[0, n]^d$. Note that each diagonal unit cube of $[0, n]^d$ is an element of $D_d(n)$. Every axis-parallel line L that stabs a diagonal unit cube of $[0, n]^d$ can stab at most $1 + 2 \log^{1/(d-1)} n$ boxes of $D_d(n)$, since each recursive step adds at most two new boxes along L (namely, the 1-shadows of the diagonal unit cube of a copy of $B_d(m)$). We will show in subsection 4.4 that this argument carries over to any axis-parallel line, as well, if the axis-parallel stabbing number of $B_d(m)$ is $O(\log^{1/(d-2)} n)$.

For the construction of $B_d(m)$, we use the subdivision $D_{d-1}(m)$ (which exists by induction on the dimension). Recall that the 1-shadows of the diagonal unit cubes lie in the side buffers. By Lemma 11, it is enough to subdivide each side buffer F_j^σ such that the x_j^σ -shadows of all diagonal unit cubes are elements of this subdivision for every j and σ . Note, also, that the orthogonal projections of the diagonal unit cubes of $[0, m]^d$ to the face $f_j^\sigma = [0, m]^{d-1}$ are the diagonal unit cubes of f_j^σ . We subdivide f_j^σ with the $(d-1)$ -dimensional subdivision $D_{d-1}(m)$ (which contains all diagonal unit cubes) and “lift” each $(d-1)$ -dimensional box in f_j^σ to a full-dimensional box to fill the side buffer F_j^σ . Unfortunately, the side buffers are typically nonconvex, so the lift-up of a box in f_j^σ to F_j^σ may be a nonconvex axis-aligned polyhedron. We construct a subdivision of each such polyhedron (with very small stabbing number) to obtain an axis-aligned box subdivision of each side buffer F_j^σ .

4.3. Extending a subdivision from a side to the adjacent side buffer.

Lifting a $(d-1)$ -dimensional axis-aligned subdivision to fill a side buffer of $E_{d,\ell}$ raises a technical problem, which we resolve in this subsection (Lemma 18). Imagine that D' is a $(d-1)$ -dimensional axis-aligned subdivision of side f_d^- of $E_{d,\ell}$ with $|D'| \geq n$ boxes and $s_{d-1,1}(D') = O(\log^{1/(d-2)} n)$. The extension of a $(d-1)$ -dimensional box $b' \in D'$ to the adjacent side buffer F_d^- of $E_{d,\ell}$ is $b = (b' \times [0, 2^\ell]) \cap F_d^-$. Unfortunately, b is not necessarily an axis-aligned box, since F_d^- is nonconvex whenever $\ell \geq 2$. In this subsection, we subdivide each polyhedron $b = (b' \times [0, 2^\ell]) \cap F_d^-$ into axis-aligned boxes such that the axis-parallel stabbing number of the resulting subdivision of F_d^- is only $O(\log^{1/(d-2)} n)$.

We formulate all our results in this subsection for the side $f = f_d^-$ and side buffer $F = F_d^-$ of $E_{d,\ell}$. This allows us to define the above-below relations with respect to the x_d -axis. In particular, every box lies above its x_d -shadow. By symmetry, all our results hold for any side f_j^σ and corresponding side buffer F_j^σ for $j \in \{1, 2, \dots, d\}$ and $\sigma \in \{-, +\}$. Let us fix some notation for the $(d-1)$ -dimensional boxes and subdivisions of the side f . For a d -dimensional box $b \subseteq E_{d,\ell}$, let b' denote its orthogonal

projection to f . For example, we have $f = E'_{d,\ell}$. Similarly, let e' denote the orthogonal projection of the diagonal e . Clearly, e' is the diagonal of f incident to the origin. The side f has a hierarchical subdivision $\mathcal{C}'_i$, $i = 0, 1, 2, \dots, \ell$, with $\mathcal{C}' = \bigcup_{i=0}^{\ell} \mathcal{C}'_i$. Note that the orthogonal projection of every diagonal cube of $\mathcal{C}$ is a $(d-1)$ -dimensional diagonal cube of $\mathcal{C}'$.

Properties of side buffers and bricks. We first study the intersection of a side buffer with an axis-parallel line.

PROPOSITION 12. *The intersection of F with every axis-parallel line is connected (i.e., it is either empty or a line segment).*

Proof. Consider an axis-parallel line L . We may assume that $L \cap F \neq \emptyset$; otherwise there is nothing left to prove. Note that L stabs at most one diagonal cube in $\mathcal{C}_i$ for each $i = 0, 1, \dots, \ell$. The diagonal cubes stabbed by L form a chain $u_0 \supset u_2 \supset \dots \supset u_{\kappa}$, for some $\kappa \leq \ell$.

Assume first that L is parallel to the x_d -axis. L stabs a diagonal cube if and only if L intersects its x_d^- -shadow. The intersection $L \cap F$ is, therefore, the intersection of L with the x_d^- -shadow of the smallest cube u_{κ} . The intersection of L with the x_d^- -shadow of u_{κ} is a line segment.

Assume next that L is orthogonal to the x_d -axis. If L intersects the x_d^- -shadow of a diagonal cube $u \in \mathcal{C}$, then u lies above L . The diagonal cubes lying above L form a chain $u_{\kappa} \supset u_{\kappa+1} \supset \dots \supset u_{\ell}$ for some $\kappa > 0$. This chain is nonempty, since $L \cap F \neq \emptyset$. Any diagonal cube strictly containing u_{κ} already intersects L (so its x_d^- -shadow is disjoint from L). The intersection $L \cap F$ is, therefore, the intersection of L with the x_d^- -shadow of the largest cube u_{κ} . The intersection of L with the x_d^- -shadow of u_{κ} is a line segment. $\square$

Next we study the intersection of an x_d^- -brick of $E_{d,\ell}$ and the side buffer F .

PROPOSITION 13. *Let $u_1, u_2 \in \mathcal{C}$ be two diagonal cubes of $E_{d,\ell}$. If an x_d^- -brick of u_1 and the x_d^- -shadow of u_2 are not interior disjoint, then $u_1 \subseteq u_2$ or $u_2 \subseteq u_1$. Furthermore if $u_2 \subseteq u_1$, then this x_d^- -brick of u_1 must be the x_d^- -shadow of u_1 .*

Proof. Consider two diagonal cubes, u_1 and u_2 . Assume first that they have disjoint interiors. Since e is the diagonal of both u_1 and u_2 , the cube u_2 is contained in either the $(-, -, \dots, -)$ - or the $(+, +, \dots, +)$ -shadow of u_1 . If u_2 lies in the $(-, -, \dots, -)$ -shadow of u_1 , then the x_d^- -shadow of u_2 also lies in the $(-, -, \dots, -)$ -shadow of u_1 , whose interior is disjoint from any x_d^- -brick of u_1 (by the definition of bricks). If u_2 lies in the $(+, +, \dots, +)$ -shadow of u_1 , then the x_d^- -shadow of u_2 lies in the union of the $(+, +, \dots, +, +)$ -, $(+, +, \dots, +, 0)$ -, and $(+, +, \dots, +, -)$ -shadows of u_1 , whose interiors are all disjoint from any x_d^- -brick of u_1 . This confirms that if an x_d^- -brick of u_1 and the x_d^- -shadow of u_2 overlap, then u_1 and u_2 also overlap. If two diagonal cubes of $\mathcal{C}$ overlap, then one must contain the other.

Assume now that $u_2 \subseteq u_1$. Then the x_d^- -shadow of u_2 is contained in the union of u_1 and its x_d^- -shadow. Hence, the x_d^- -shadow of u_2 may intersect the $\mathbf{0}$ - and x_d^- -shadows of u_1 , but it has disjoint interior from any other shadow of u_1 . $\square$

PROPOSITION 14. *If a $(d-1)$ -dimensional box b' lies in a brick of $f = E_{d-1,\ell}$, then $(b' \times [0, 2^{\ell}]) \cap F$ lies in a brick of $E_{d,\ell}$.*

Proof. We may assume without loss of generality that b' is an entire brick of f . Assume that b' is a $\mathbf{v}'$ -shadow of a diagonal cube $u' \in \mathcal{C}'$ of the side f with $0 < |\mathbf{v}'| < d-1$. Let $u = \prod_{i=1}^d [a_i, c_i]$ denote the diagonal cube of $E_{d,\ell}$ whose orthogonal projection is u' . Let $\mathbf{v} = (\mathbf{v}', -)$ be the d -dimensional vector, whose first $(d-1)$ -coordinates are the coordinates of $\mathbf{v}'$ and the d th coordinate is negative. We show that the $\mathbf{v}$ -shadow of u contains $(b' \times [0, 2^{\ell}]) \cap F$. Note that $b' \times [0, 2^{\ell}]$ is the union

of the $(\mathbf{v}', -)$ -, $(\mathbf{v}', 0)$ -, and $(\mathbf{v}', +)$ -shadows of u . By Proposition 13, the $(\mathbf{v}', +)$ - or $(\mathbf{v}', 0)$ -shadow of u may overlap with the x_d^- -shadow of another diagonal cube u_1 only if $u \subset u_1$. The x_d^- -shadow of every diagonal cube u_1 , with $u \subset u_1$, lies below the hyperplane $x_d = a_d$, but the $(\mathbf{v}', +)$ - and $(\mathbf{v}', 0)$ -shadows of u lie above $x_d = a_d$. We have shown that the $(\mathbf{v}', +)$ - and $(\mathbf{v}', 0)$ -shadows of u are interior disjoint from F . It follows that $(b' \times [0, 2^\ell]) \cap F$ is contained in the $\mathbf{v}$ -shadow of u . $\square$

Staircase polyhedra. A d -dimensional *staircase polyhedron* of size m is a polyhedron in $\mathbb{R}^d$, which is the union of m disjoint boxes $b_1, b_2, \dots, b_m$ such that their d th extents are consecutive intervals along the x_d -axis, their first $d-1$ extents form $(d-1)$ -dimensional boxes $b'_1, b'_2, \dots, b'_m$ such that $b'_1 \supset b'_2 \supset \dots \supset b'_m$, and they all share at least one common vertex. For example, a staircase polyhedron of size m in the plane is a staircase polygon with $m-1$ reflex vertices (Figure 1(d)). See Figure 6(a) for an example in 3-space. If the $(d-1)$ -dimensional boxes $b'_1, b'_2, \dots, b'_m$ share a κ -dimensional face g , $0 < \kappa < d-1$, then we can “factor” the staircase polyhedra P with g , that is, P is the cross-product of the κ -dimensional box g and a $(d-\kappa)$ -dimensional staircase polyhedron of size m .

PROPOSITION 15. *If b is an x_d^- -brick of $E_{d,\ell}$, then $b \cap F$ is a staircase polyhedron of size at most ℓ .*

Proof. Let b be the $\mathbf{v}$ -shadow of a diagonal cube u of $E_{d,\ell}$ for some $\mathbf{v} \in \{-, 0, +\}^d$ such that $0 < |\mathbf{v}| < d$ and $v_d = -$. If $|\mathbf{v}| = 1$, then b is the x_d^- -shadow of u , and hence $b \subseteq F$.

Assume now that $|\mathbf{v}| > 1$. By Proposition 13, b can overlap with the x_d^- -shadow of a diagonal cube $\hat{u}$ only if $u \subset \hat{u}$. The diagonal cubes containing u form a chain $u_0 \supset u_1 \supset \dots \supset u_\kappa = u$ of some length $\kappa \leq \ell$. The intersection $b \cap F$ is the union of the intersections of the x_d^- -shadows of the cubes $u_0, u_1, \dots, u_\kappa$ with b . So $b \cap F$ can be represented as a union of at most κ interior-disjoint boxes $b_1, b_2, \dots, b_\kappa$, where b_i is the intersection of b with the difference set of the x_d^- -shadows of u_i and u_{i-1} for $i = 1, 2, \dots, \kappa$. Here, the d th extents of the boxes $b_1, b_2, \dots, b_\kappa$ form consecutive intervals along the x_d -axis, and their projections $b'_1, b'_2, \dots, b'_\kappa$ form a chain $b'_1 \supset b'_2 \supset \dots \supset b'_\kappa$. Since b has at least one common edge with the x_d^- -shadow of u , the $(d-1)$ -dimensional boxes $b' \cap b'_i$, $i = 1, 2, \dots, \kappa$, have at least one common vertex. Therefore, $b \cap F$ is a staircase polyhedron of size κ , $\kappa \leq \ell$. $\square$

PROPOSITION 16. *A staircase polyhedron P of size m in $\mathbb{R}^d$ can be subdivided into axis-aligned boxes such that the axis-parallel stabbing number of the subdivision is at most $1 + \log m$.*

Proof. We proceed by induction on d and m . Our claim is obvious in the boundary cases that $(d = 1 \text{ and } m \in \mathbb{N})$ or $(m = 1 \text{ and } d \in \mathbb{N})$, since in these cases P is already a d -dimensional box, and the trivial subdivision $\{P\}$ has stabbing number 1. We prove the claim for $d \in \mathbb{N}$ and $m \in \mathbb{N}$, assuming that it holds for every $d' < d$ and $m' \leq m$ and that it also holds for d and every $m' < m$. Let P be a d -dimensional staircase polyhedron defined as the union of interior-disjoint boxes $b_1, b_2, \dots, b_m$.

If the boxes $b'_1, b'_2, \dots, b'_m$ share a κ -dimensional face g for $0 < \kappa < d-1$, then (as we have mentioned earlier) P is the cross-product of g and a $(d-\kappa)$ -dimensional staircase polyhedron P'' of size m . By induction, P'' has a subdivision S'' of axis-parallel stabbing number $1 + \log m$. We can construct the subdivision of P as the cross-product $S = S'' \times \{g\}$, which has the same axis-aligned stabbing number as S'' . Moreover, any line orthogonal to g stabs at most one box of S .

Suppose now that $b'_1, b'_2, \dots, b'_m$ share exactly one vertex, which we may assume to be the origin. We may assume further that P lies in the positive “quadrant” of

FIG. 6. (a) A staircase polyhedron P of size 5 in $\mathbb{R}^3$. (b) Its dissection along d axis-aligned hyperplanes incident to point q into $2^{d-1} + 1 = 5$ pieces.

$\mathbb{R}^d$. Refer to Figure 6. Let q be the vertex antipodal to the closest vertex to the origin in the box $b_{\lceil m/2 \rceil}$. Partition P along the d axis-aligned hyperplanes incident to q and subdivide the resulting $2^{d-1} + 1$ polyhedra by induction. Let us bound the axis-parallel stabbing number of the resulting subdivision S . The d hyperplanes incident to q partition P into *pieces*, and every axis-parallel line stabs at most two pieces. The only piece lying above the hyperplane $x_d = q_d$ is a staircase polyhedra of size $\lfloor m/2 \rfloor$. There are 2^{d-1} pieces below $x_d = q_d$, each lying in a $(\mathbf{v}', -)$ -shadow of the point q for some $\mathbf{v}' \in \{-, +\}^{d-1}$. Denote by $P(\mathbf{v}')$ the piece lying in the $(\mathbf{v}', -)$ -shadow of q . If κ entries of the vector $\mathbf{v}'$ are negative (and the remaining $d - 1 - \kappa$ entries are positive), then $P(\mathbf{v}')$ is a cross-product of a κ -dimensional box (corresponding to the coordinates with negative entries) and a $(d - \kappa)$ -dimensional staircase polyhedra of size $\lfloor m/2 \rfloor$ (corresponding to the positive entries and x_d). By induction, each piece has an axis-aligned subdivision with axis-parallel stabbing number at most $\log m$. Furthermore, any line parallel to a coordinate axis that corresponds to a negative entry stabs at most one box. Altogether, any axis-parallel line stabs at most $1 + \log m$ boxes of the subdivision S . $\square$

LEMMA 17. Let b be a box contained in a brick of $E_{d,\ell}$. Then the polyhedron $b \cap F$ has a subdivision S into axis-aligned boxes such that

- every axis-parallel line stabs at most $O(\log \ell)$ boxes of S ;
- if an axis-parallel line L is orthogonal to the x_d -axis and the segment $L \cap b$ strictly contains segment $(L \cap b) \cap F$, then L stabs at most one box of S .

Proof. By Proposition 15, we may assume that $P = b \cap F$ is a d -dimensional staircase polyhedron of size at most ℓ . If we subdivide $b \cap F$ as described in Proposition 16, then the first assertion of Lemma 17 would immediately hold. In order to guarantee the second assertion, we first partition $b \cap F$ into several pieces along at most $d - 1$ hyperplanes orthogonal to the x_d -axis, and then we apply Proposition 16 for each piece independently.

Let $b = \prod_{i=1}^d [a_i, c_i]$. Let $b_1, b_2, \dots, b_m$, $m \leq \ell$, denote the boxes that define the staircase polyhedron $P = b \cap F$. We may assume $m \geq 2$; otherwise S consists of the single box b_1 . Recall that $b'_1 \supset b'_2 \supset \dots \supset b'_m$, where b'_j denotes the $(d-1)$ -dimensional box spanned by the first $d-1$ extents of b_j . Hence, the i th extents of $b'_1, b'_2, \dots, b'_m$ also form a nested sequence for $i = 1, 2, \dots, d-1$. Let H_i be the hyperplane orthogonal to the x_d -axis above all boxes b_j whose i th extents are $[a_i, c_i]$ and below all boxes $b_{j'}$ whose i th extents are strictly contained in $[a_i, c_i]$. Refer to Figure 7.

FIG. 7. (a) A box b and a staircase polyhedron P in $\mathbb{R}^3$. (b) The intersection $b \cap P$ and P . (c) The subdivision of $b \cap P$ into $d = 3$ pieces.

Partition P along all the hyperplanes H_i , $i = 1, 2, \dots, d-1$, into d pieces (some of which may be empty). Order the resulting pieces of P along the x_d -axis. The i th piece of P lies above $i-1$ hyperplanes. It is the cross-product of an i -dimensional staircase polyhedron P_i and a $(d-i)$ -dimensional box g_{d-i} , which is the cross-product of $d-i$ extents of b . Construct the subdivision of each piece, independently, as the cross-product of $\{g_{d-i}\}$ and the subdivision of P_i with stabbing number at most $1 + \log m \leq 1 + \log \ell$, as described in Proposition 16. Let S be the resulting subdivision of P .

Every line parallel to the x_d -axis stabs at most d pieces of P , and it stabs $O(\log \ell)$ boxes in the subdivision of each piece. If a line L is parallel to the x_i -axis, $1 \leq i \leq d-1$, and the segment $L \cap b$ strictly contains the segment $(L \cap b) \cap F$, then L must lie below the hyperplane H_i , and so L stabs at most one box of the subdivision S . $\square$

LEMMA 18. Let D' be an axis-aligned subdivision of side f of $E_{d,\ell}$ such that

- (a) D' contains every diagonal unit cube of C' , and
- (b) every box in D' either is a diagonal unit cube or lies in a brick of f .

Then there is an axis-aligned subdivision D of the side buffer F such that

- (a) D contains the x_d^- -shadow of every diagonal unit cube of $E_{d,\ell}$,
- (b) every box in D lies in a brick of $E_{d,\ell}$, and
- (c) the axis-aligned stabbing number of D is $s_{d,1}(D) = s_{d-1,1}(D') + O(\log \ell)$.

Proof. For every $(d-1)$ -dimensional diagonal unit cube $u' \in D'$, the lifting $(u' \times [0, 2^\ell]) \cap F$ is the x_d^- -shadow of a diagonal unit cube of C . Let the box $(u' \times [0, 2^\ell]) \cap F$ be an element of D for every diagonal unit cube $u' \in D'$. Next consider a box $b' \in D'$ which is a brick of $E_{d-1,\ell}$. By Proposition 14, the polyhedron $b = (b' \times [0, 2^\ell]) \cap F$ is contained in a brick of $E_{d,\ell}$. Subdivide b according to Lemma 17, and let all resulting boxes be elements of D . Then D is an axis-aligned subdivision of the side buffer F .

Every line parallel to the x_d -axis stabs at most one polyhedron $(b' \times [0, 2^\ell]) \cap F$, $b' \in D'$. By Lemma 17, it stabs at most $O(\log \ell)$ boxes of the subdivision D . Every line L orthogonal to the x_d -axis stabs at most $s_{d-1,1}(D')$ polyhedra $(b' \times [0, 2^\ell]) \cap F$. By Proposition 12, the intersection $L \cap F$ is a line segment, and so L intersects the boundary of F in at most two points, say p_1 and p_2 . Let b_1 and b_2 denote the polyhedra adjacent to p_1 and p_2 , respectively. By Lemma 17, b_1 and b_2 are subdivided so that $L \cap b_1$ and $L \cap b_2$ each stab $O(\log \ell)$ boxes. Any other polyhedron $(b' \times [0, 2^\ell]) \cap F$, $b' \in D'$, is subdivided so that L stabs only one resulting box. Altogether, L stabs at most $s_{d-1,1}(D') + 2O(\log \ell) = s_{d-1,1}(D') + O(\log \ell)$ boxes of D . $\square$

4.4. Upper bound construction. For every $d, n \in \mathbb{N}$, $d \geq 2$, we present an axis-aligned subdivision $D_d(n)$ that contains at least n boxes and has axis-parallel stabbing number $s_{d,1}(D_d(n)) = O(\log^{1/(d-1)} n)$. In the proof of Lemma 6 we have already described such a subdivision for $d = 2$. Here, we extend this construction for every $d \geq 3$. Along the way, we also define a family of auxiliary subdivisions $B_d(n)$ for every $d, n \in \mathbb{N}$, $d \geq 2$. We summarize the properties of the two families of subdivisions as follows.

LEMMA 19.

• For every $d \geq 3$ there is a constant $c_d > 0$ such that for every $n \in \mathbb{N}$ there is an axis-aligned subdivision $B_d(n)$ of the cube $[0, n]^d$ with the following properties:

- (i) $B_d(n)$ contains all n diagonal unit cube of $[0, n]^d$;
- (ii) every 1-shadow of every diagonal unit cube is an element of $B_d(n)$;
- (iii) every box of $B_d(n)$ either is a diagonal unit cube or lies in a brick of $[0, n]^d$;
- (iv) $s_{d,1}(B_d(n)) \leq c_d \log^{1/(d-2)} n$.

• For every $d \geq 2$ there is a constant $C_d > 0$ such that for every $n \in \mathbb{N}$ there is an axis-aligned subdivision $D_d(n)$ of the cube $[0, n]^d$ with the following properties:

- (a) $D_d(n)$ contains all n diagonal cubes of $[0, n]^d$;
- (b) every box of $D_d(n)$ is either a diagonal unit cube or lies in a brick of $[0, n]^d$;
- (c) $s_{d,1}(D_d(n)) \leq C_d \log^{1/(d-1)} n$.

Proof. We proceed by induction on d and n .

Base cases. For every $n \in \mathbb{N}$ and $d = 2$, Lemma 6 provides a construction $D_2(n)$. For every fixed $d \geq 3$, we proceed by induction on n . For an integer $d \geq 3$, let both $D_d(1)$ and $B_d(1)$ be the trivial subdivision $\{[0, 1]^d\}$. When we construct $B_d(n)$, we assume that we have already constructed the subdivision $D_{d-1}(n')$ for every $n' \in \mathbb{N}$. When we construct $D_d(n)$, we assume that we have already constructed the subdivision $B_d(n')$ for every $n' \in \mathbb{N}$.

Construction of $B_d(n)$. Let us assume first that $n = 2^\ell$ for some $\ell \in \mathbb{N}$. We construct the subdivision $B_d(n)$ of the cube $E_{d,\ell} = [0, 2^\ell]^d$. Let $B_d(n)$ contain all 2^ℓ diagonal unit cubes of $E_{d,\ell}$. Let $B_d(n)$ contain all cubes of the subdivision $S_{d,\ell}$ (which tile the complement of the diagonal unit cubes and all $2d$ side buffers, as described in Lemma 11). It remains to describe a subdivision of the $2d$ side buffers of $E_{d,\ell}$.

By symmetry, it suffices to describe the subdivision of a single side buffer $F = F_d^-$. Consider the $(d-1)$ -dimensional axis-aligned subdivision $D_{d-1}(2^\ell)$ of side $f = f_d^-$. By Lemma 18, it can be extended into an axis-aligned subdivision of F such that it contains all x_d^- -shadows of diagonal unit cubes of $E_{d,\ell}$, every box lies in a brick of $E_{d,\ell}$, and its axis-parallel stabbing number is $s_{d-1,1}(D_{d-1}(2^\ell)) + O(\log \ell) = O(\ell^{1/(d-2)} + \log \ell) = O(\log^{1/(d-2)} n + \log \log n) = O(\log^{1/(d-2)} n)$.

$B_d(2^\ell)$ clearly satisfies conditions (i), (ii), and (iii). For (iv), consider an axis-parallel line L . Line L stabs at most one diagonal cube, at most two boxes of $S_{d,\ell}$ by Lemma 11, and at most two side buffers. By the above argument, L stabs at most $O(\log^{1/(d-2)} n)$ boxes in the subdivision of each side buffer. This completes the construction of $B_d(2^\ell)$ for every $\ell \in \mathbb{N}$.

Finally, if n is not a power of 2, then take a subdivision $B_d(2^\ell)$ with $2^{\ell-1} < n < 2^\ell$, and clip it in the box $[0, n]^d \subset E_{d,\ell}$. Let $B_d(n)$ be the resulting subdivision. It contains all n diagonal unit cubes of $[0, n]^d$ and all their 1-shadows, and the stabbing number of $B_d(n)$ is at most that of $B_d(2^\ell)$, which is $O(\log^{1/(d-2)} n)$.

Construction of $D_d(n)$. First, let us assume that $n = \exp(\ell^{d-1})$ for some $\ell \in \mathbb{N}$ (and so $\log^{1/(d-1)} n$ is an integer). We obtain $D_d(n)$ in $\log^{1/(d-1)} n$ steps. Initially, let $\Delta(0) = \{[0, n]^d\}$ be the trivial subdivision. In step $i = 1, 2, \dots, \log^{1/(d-1)} n$, construct

$\Delta(i)$ by replacing each diagonal cube of $\Delta(i-1)$ with a scaled copy of the subdivision $B_d(\exp(\log^{(d-2)/(d-1)} n))$. Each step increases the number of diagonal cubes by a factor of $\exp(\log^{(d-2)/(d-1)} n)$. Let $D_d(n) = \Delta(\log^{1/(d-1)} n)$. It has

$$\begin{aligned} \left(\exp \left(\log^{(d-2)/(d-1)} n \right) \right)^{\log^{1/(d-1)} n} &= \exp \left(\log^{(d-2)/(d-1)} n \cdot \log^{1/(d-1)} n \right) \\ &= \exp(\log n) = n \end{aligned}$$

diagonal (unit) cubes.

Consider an axis-parallel line L . Assume that i , $1 \leq i \leq \log^{1/(d-1)} n$, is the largest integer such that L stabs some diagonal cube u of the subdivision $\Delta(i)$. Outside of u , the line L can stab at most $2(\log^{1/(d-1)} n - i)$ boxes, since each 1-shadow of every diagonal cube is an element of $B_d(\exp(\log^{(d-2)/(d-1)} n))$. Inside the cube u , the line L intersects $O(\log^{1/(d-2)} \exp(\log^{(d-2)/(d-1)} n)) = O(\log^{1/(d-1)} n)$ boxes by property (iv) of the subdivision $B_d(\log^{(d-2)/(d-1)} n)$. By construction and by property (iii), each box of $D_d(n)$ either is a cube of $Q_d(n)$ or lies in a brick of $[0, n]^d$.

Finally, if n is not of the form $\exp(\ell^{d-1})$, $\ell \in \mathbb{N}$, then take the subdivision $D_d(\exp(\ell^{d-1}))$ for $\exp((\ell-1)^{d-1}) < n < \exp(\ell^{d-1})$, and clip it in the box $[0, n]^d \subset E_{d, \ell^{d-1}}$. The resulting subdivision clearly contains n diagonal cubes, and its stabbing number is bounded by that of $D_d(\exp(\ell^{d-1}))$, which is $O(\log^{1/(d-1)}(\exp(\ell^{d-1}))) = O(\ell) = O(\log^{1/(d-1)} n)$. $\square$

THE VECTOR SPACE OVER $GF(2)$ GENERATED BY THE COMMON BASES OF TWO BINARY MATROIDS*

K. P. WEBB[†]

Abstract. A binary matroid pair consists of two binary matroids of the same rank defined on a common ground set. By excluding a particular binary matroid pair, we obtain a characterization of the vector space over $GF(2)$ generated by the incidence vectors for the common bases of a binary matroid pair.

Key words. binary matroid, matroid intersection

AMS subject classification. 05B35

DOI. 10.1137/050641417

1. Introduction. Let M and N be matroids with the same rank, defined on a common ground set S . We call the pair $P = (M, N)$ a *matroid pair*, and the common bases of M and N are called the *bases* of P . When M and N are both binary, P is said to be a *binary matroid pair*. The sets of bases of M, N , and P are denoted $\mathcal{B}(M)$, $\mathcal{B}(N)$, and $\mathcal{B}(P)$, respectively.

Given $S' \subseteq S$, the incidence vector $x \in \{0, 1\}^S$ for S' is defined by $x_e = 1$ if and only if $e \in S'$. We identify subsets of the ground set with their incidence vectors; for example, the convex hull generated by the incidence vectors for the elements of $\mathcal{B}(P)$ is referred to as the convex hull generated by $\mathcal{B}(P)$. Edmonds [3] proved that the convex hull generated by $\mathcal{B}(P)$ is the intersection of the convex hulls generated by $\mathcal{B}(M)$ and $\mathcal{B}(N)$. In this paper, we consider the incidence vectors to be defined over $GF(2) = \mathbb{Z}/2\mathbb{Z}$. We are interested in the vector space over $GF(2)$ generated by $\mathcal{B}(P)$, i.e., by the incidence vectors for the elements of $\mathcal{B}(P)$. This vector space is denoted $\text{Bin}(P)$. Similarly, $\text{Bin}(M)$ and $\text{Bin}(N)$ denote the vector spaces over $GF(2)$ generated by $\mathcal{B}(M)$ and $\mathcal{B}(N)$, respectively.

Edmonds' surprising result for the convex hull does not hold for the vector space over $GF(2)$: $\text{Bin}(P) \neq \text{Bin}(M) \cap \text{Bin}(N)$ in general. However, when M and N are binary matroids, by excluding a particular matroid pair we obtain a characterization of $\text{Bin}(P)$ in terms of $\text{Bin}(M)$ and $\text{Bin}(N)$. Some terminology is needed before stating our main result.

The rank of $S' \subseteq S$ in M is denoted $\text{rank}_M(S')$, and the matroid pair $P = (M, N)$ is *connected* if $\text{rank}_M(S') + \text{rank}_N(S \setminus S') > \text{rank}_M(S)$ whenever $\emptyset \neq S' \subsetneq S$. Recall that Edmonds' matroid intersection theorem [3] implies that if P is connected, then $\mathcal{B}(P) \neq \emptyset$. When $X, Y \subseteq S$ are such that there exists $B \in \mathcal{B}(P)$ with $X \subseteq B$ and $Y \subseteq S \setminus B$, then the matroid pair $(M/X \setminus Y, N/X \setminus Y)$ is called a *minor* of P and is denoted $P/X \setminus Y$.

Let $\mathcal{B}_M^0 \subseteq \text{Bin}(M)$ be the set of $x \in \text{Bin}(M)$ such that x is the sum of an *even* number of bases of M . As usual, we mean the sum of an even number of incidence vectors of bases of M . Similarly, let $\mathcal{B}_M^1$ contain all $x \in \text{Bin}(M)$ such that x is the

sum of an *odd* number of bases. For $x \in GF(2)^S$ and $S' \subseteq S$, let $x(S') = \sum_{s \in S'} x_s$. If $S_1, S_2, \dots, S_k$ are the connected components of M , then by a result of Rieder [6]

$$\mathcal{B}_M^0 = \{x \in GF(2)^S : x(S_i) = 0 \text{ for all } i \in \{1, \dots, k\}\},$$

$$\mathcal{B}_M^1 = \{x \in GF(2)^S : x(S_i) = \text{rank}_M(S_i) \pmod{2} \text{ for all } i \in \{1, \dots, k\}\}.$$

Since every element of $\text{Bin}(P)$ is the sum of either an even number or an odd number of bases of P , we have

$$(1.1) \quad \text{Bin}(P) \subseteq (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1).$$

Expanding the right-hand side of (1.1) gives

$$(1.2) \quad (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1) \subseteq \text{Bin}(M) \cap \text{Bin}(N).$$

We show in section 2 that $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ can be properly contained in $\text{Bin}(M) \cap \text{Bin}(N)$ for simple reasons regarding the parity of the rank of components of M and N . Furthermore, if P is a *twined K_4 pair*, as defined in section 4, then $\text{Bin}(P)$ is properly contained in $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. Our main theorem is the following.

THEOREM 1.1. *If M and N are binary matroids and $P = (M, N)$ is connected and does not have a twined K_4 pair as a minor, then*

$$\text{Bin}(P) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1).$$

The converse of Theorem 1.1 does not hold; a counterexample is given at the end of section 6. We use the matroid terminology and notation of Oxley [5] and assume that the reader is familiar with matroids and matroid representation.

2. Even or odd rank. By considering $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$, we show in this section that $\text{Bin}(P)$ can differ from $\text{Bin}(M) \cap \text{Bin}(N)$ due to rank parity. We first show that parity of the rank of the components of M and N affects the dimension of $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$.

PROPOSITION 2.1. *Let $P = (M, N)$ be a connected matroid pair on the ground set S . If c_M and c_N are the number of components of M and N , respectively, then $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$ has dimension $|S| - c_M - c_N + 1$. Furthermore, if every component of M and N has even rank, then $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ has dimension $|S| - c_M - c_N + 1$; otherwise, the dimension is $|S| - c_M - c_N + 2$.*

Proof. Let A_M and A_N be matrices over $GF(2)$ with columns indexed by S and rows given by the incidence vectors for the components of M and N , respectively. Let b_M and b_N be the column matrices such that $\mathcal{B}_M^1 = \{x \in GF(2)^S : A_M x = b_M\}$ and $\mathcal{B}_N^1 = \{x \in GF(2)^S : A_N x = b_N\}$. The existence of b_M and b_N follows from Rieder [6].

Note that $\mathcal{B}_M^0 \cap \mathcal{B}_N^0 = \{x \in GF(2)^S : A_M x = 0 \text{ and } A_N x = 0\}$. The rows of A_M and A_N together sum to zero, and the connectivity of P implies that no proper subset of these rows sums to zero. Since A_M and A_N together have $c_M + c_N$ rows, it follows that $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$ has dimension $|S| - c_M - c_N + 1$. If each component of M and N has even rank, then $\mathcal{B}_M^1 = \mathcal{B}_M^0$ and $\mathcal{B}_N^1 = \mathcal{B}_N^0$ and thus $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ has the same dimension as $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$. If a component of M or N has odd rank, then for all $x \in \mathcal{B}(P)$ we have $x \in \mathcal{B}_M^1 \cap \mathcal{B}_N^1$ but $x \notin \mathcal{B}_M^0 \cap \mathcal{B}_N^0$. However, the sum of any two elements in $\mathcal{B}_M^1 \cap \mathcal{B}_N^1$ belongs to $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$, and thus the dimension of $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ in this case is one greater than the dimension of $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$. $\square$

Next we show that the containment given in (1.2) can be strict.

PROPOSITION 2.2. *Let $P = (M, N)$ be a connected matroid pair on the ground set S , where M and N have even rank. If M and N both have a component of odd rank, then $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ is properly contained in $\text{Bin}(M) \cap \text{Bin}(N)$.*

Proof. The definition of $\mathcal{B}_M^0, \mathcal{B}_M^1, \mathcal{B}_N^0$, and $\mathcal{B}_N^1$ implies that

$$(2.1) \quad \text{Bin}(M) \cap \text{Bin}(N) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^0 \cap \mathcal{B}_N^1).$$

We claim that there exists $x \in \mathcal{B}_M^1 \cap \mathcal{B}_N^0$ with $x \notin (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. By (1.2), this implies the proposition.

As in the proof of Proposition 2.1, let $\mathcal{B}_M^1 = \{x \in GF(2)^S : A_M x = b_M\}$ and let $\mathcal{B}_N^1 = \{x \in GF(2)^S : A_N x = b_N\}$. Suppose y_M and y_N are row vectors over $GF(2)$ with $y_M A_M + y_N A_N = \mathbf{0}$. By the connectivity of P , the only nonzero solution to $y_M A_M + y_N A_N = \mathbf{0}$ is $y_M = y_N = \mathbf{1}$. Since M has even rank, $y_M = \mathbf{1}$ implies $y_M b_M = 0$. Therefore, there are no y_M, y_N satisfying both $y_M A_M + y_N A_N = \mathbf{0}$ and $y_M b_M = 1$. By Farkas' lemma, there exists $x \in GF(2)^S$ satisfying both $A_M x = b_M$ and $A_N x = 0$, and thus $\mathcal{B}_M^1 \cap \mathcal{B}_N^0 \neq \emptyset$, as claimed.

Since M and N both have a component of odd rank, $x \in \mathcal{B}_M^1 \cap \mathcal{B}_N^0$ implies $x \notin \mathcal{B}_M^0 \cup \mathcal{B}_N^1$, and thus $x \notin (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. The proposition follows. $\square$

Proposition 2.2 together with (1.1) and (1.2) implies that $\text{Bin}(P) \neq \mathcal{B}(M) \cap \mathcal{B}(N)$ whenever M and N have even rank but each has a component of odd rank. However, by assuming Theorem 1.1, we can show that $\text{Bin}(P) = \mathcal{B}(M) \cap \mathcal{B}(N)$ in some cases.

COROLLARY 2.3. *If M and N are binary matroids of odd rank and the matroid pair $P = (M, N)$ is connected and does not have a twined K_4 pair as a minor, then*

$$\text{Bin}(P) = \text{Bin}(M) \cap \text{Bin}(N).$$

Proof. Since M and N have odd rank, both $\mathcal{B}_M^1 \cap \mathcal{B}_N^0$ and $\mathcal{B}_M^0 \cap \mathcal{B}_N^1$ are empty. Thus (2.1) implies that $\text{Bin}(M) \cap \text{Bin}(N) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. The corollary now follows from Theorem 1.1. $\square$

3. Fundamental graphs. Let M be a matroid on the ground set S and let $B \in \mathcal{B}(M)$. For $X, Y \subseteq S$, the symmetric difference $(X \setminus Y) \cup (Y \setminus X)$ is denoted $X \Delta Y$. The *partial representation of M with respect to B* is the $\{0, 1\}$ matrix A with rows indexed by B and columns indexed by $S \setminus B$ such that $[A]_{u,v} = 1$ if and only if $B \Delta \{u, v\} \in \mathcal{B}(M)$. Note that when M is binary, the matrix $[I]A$ is a representation of M over $GF(2)$. The *fundamental graph for M with respect to B* is the labeled bipartite graph with vertex set S and edge set given by the adjacency matrix A . This graph is denoted $G(M, B)$, and abbreviated to $G(M)$ when the particular basis B is not significant.

The following proposition relates properties between a matroid and its fundamental graph. These properties can be proven by considering partial representations.

PROPOSITION 3.1. *Let M be a matroid on the ground set S with basis B .*

- (i) *The components of $G(M, B)$ correspond to the components of M .*
- (ii) *If $X \subseteq B$, $Y \subseteq S \setminus B$, then $G(M/X \setminus Y, B \setminus X)$ is the subgraph of $G(M, B)$ induced by $S \setminus (X \cup Y)$.*

Let $B, B' \in \mathcal{B}(M)$ have partial representations A and A' , respectively. If $B' = B \Delta \{u, v\}$, then A' is said to be obtained from A by *pivoting* on edge uv . If, in addition, M is binary, then $G(M, B')$ is said to be obtained from $G(M, B)$ by pivoting on edge uv .

For $u \in S$, let $N(u)$ be $\{v \in S : uv \in E(G(M, B))\}$. We recall that when M is binary, pivoting on uv in $G(M, B)$ results in swapping the labels on vertices u and v and

complementing the edges between $N(u) \setminus \{v\}$ and $N(v) \setminus \{u\}$. For $B, B' \in \mathcal{B}(M)$ with $|B \Delta B'| = 2k$, the basis exchange property of matroids guarantees a sequence of vertices $u_1, v_1, u_2, v_2, \dots, u_k, v_k$ such that B' is obtained from B by successively pivoting on edges $u_1v_1, u_2v_2, \dots, u_kv_k$. The fundamental graph $G(M, B')$ is similarly obtained from $G(M, B)$ by successively pivoting on each edge; this operation is referred to as pivoting on $B' \Delta B$ in $G(M, B)$.

PROPOSITION 3.2. *Let M be a binary matroid on the ground set S with basis B . If $B' \subseteq S$ with $B' \neq B$, then $B' \in \mathcal{B}(M)$ if and only if the subgraph of $G(M, B)$ induced by $B \Delta B'$ has an odd number of perfect matchings.*

Proof. Let A be the partial representation of M with respect to B , and let G' be the subgraph of $G(M, B)$ induced by $B \Delta B'$. Consider the matrix $X = [I|A]$, where the rows and columns of X are indexed by B and S , respectively, such that the indices correspond with the definition of A . Since M is binary, X is a representation over $GF(2)$ of M , and therefore B' is a basis of M if and only if the columns of X indexed by B' are a basis. By possibly permuting rows or columns, we may assume this column submatrix, X' , has the form

$$X' = \begin{matrix} & \begin{matrix} B' \cap B & B' \setminus B \end{matrix} \\ \begin{matrix} B' \cap B \\ B \setminus B' \end{matrix} & \begin{pmatrix} I & A'' \\ 0 & A' \end{pmatrix} \end{matrix}.$$

Note that A' is the incidence matrix for G' . If $|B'| \neq |B|$, then X' is not square and is therefore not a column basis of X . In this case, G' has a different number of vertices on each side of its vertex bipartition, and therefore G' has no perfect matchings. If $|B'| = |B|$, then X' is a column basis of X if and only if A' is nonsingular. Each nonzero term in the permutation expansion of the determinant of A' corresponds to a perfect matching in G' . Since we are working over $GF(2)$, a nonzero determinant occurs only in the case of an odd number of terms in this expansion. $\square$

If $P = (M, N)$ is a binary matroid pair on the ground set S with basis B , then the *fundamental graph for P with respect to B* is the labeled directed graph, denoted $G(P, B)$, with vertex set S and edge set $E(G(M, B)) \cup E(G(N, B))$, where the edges of $G(M, B)$ are directed into B and the edges of $G(N, B)$ are directed out of B . When the particular basis B is not significant, $G(P, B)$ is abbreviated to $G(P)$. By Proposition 3.1(ii), the induced subgraphs of $G(P)$ correspond to minors of P .

Let $P = (M, N)$ be a binary matroid pair with $B \in \mathcal{B}(P)$. If $B' \in \mathcal{B}(P)$, then $G(P, B')$ is obtained by pivoting on $B \Delta B'$ in $G(M, B)$ to obtain $G(M, B')$, pivoting on $B \Delta B'$ in $G(N, B)$ to obtain $G(N, B')$, and then identifying the vertices of $G(M, B')$ and $G(N, B')$. This operation is referred to as pivoting on $B \Delta B'$ in $G(P, B)$.

If G is a directed graph and $W \subseteq V(G)$, then $\delta^-(W)$ denotes the edges of G directed from $V(G) \setminus W$ to W . Similarly, $\delta^+(W)$ denotes the edges directed from W to $V(G) \setminus W$. When $\delta^+(W) \neq \emptyset$ for all $\emptyset \neq W \subsetneq V(G)$, then G is *strongly connected*. Stating that a graph is strongly connected will imply that it is directed. We close this section with an observation of Fonlupt and Zemirline [4] relating the connectivity of a matroid pair to the connectivity of the fundamental graph for the pair.

PROPOSITION 3.3. *Let P be a matroid pair. If $G(P, B')$ is strongly connected for some $B' \in \mathcal{B}(P)$, then $G(P, B)$ is strongly connected for all $B \in \mathcal{B}(P)$. Furthermore, P is connected if and only if $G(P)$ is strongly connected.*

4. Twined K_4 pairs. Let M and N be binary matroids on the ground set $S = \{1, 2, 3, 4, 5, 6\}$ and suppose that M and N have the following partial representations

FIG. 4.1. (a) $G(P, B)$, (b) a graph in $\mathcal{G}$.

A_M and A_N with respect to their common basis $B = \{1, 2, 3\}$:

$$(4.1) \quad A_M = \begin{matrix} & 4 & 5 & 6 \\ \begin{matrix} 1 \\ 2 \\ 3 \end{matrix} & \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \end{matrix}, \quad A_N = \begin{matrix} & 4 & 5 & 6 \\ \begin{matrix} 1 \\ 2 \\ 3 \end{matrix} & \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \end{matrix}.$$

If $P = (M, N)$, then $G(P, B)$ is the graph in Figure 4.1(a). Note that

$$\mathcal{B}(P) = \{\{1, 2, 3\}, \{1, 5, 6\}, \{2, 4, 6\}, \{3, 4, 5\}\},$$

and thus $|B' \cap \{4, 5, 6\}|$ is even for all $B' \in \mathcal{B}(P)$. Since $|S \cap \{4, 5, 6\}|$ is odd, we have $S \notin \text{Bin}(P)$. However, it can be verified that $S \in \mathcal{B}_M^0 \cap \mathcal{B}_N^0$, and thus $\text{Bin}(P) \neq (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$ for this matroid pair.

Let D be the arc set $\{(1, 4), (2, 5), (3, 6)\}$ of $G(P, B)$ in Figure 4.1. Note that $D = E(G(N, B))$. Let $\mathcal{G}$ be the set of graphs obtained from $G(P, B)$ by possibly subdividing arcs of D into directed paths of odd length, such that the orientation of the path is the same as the orientation of the original arc (see Figure 4.1(b)).

Let $G \in \mathcal{G}$ and let X, Y be the bipartition of $V(G)$. Note that the only induced subgraphs G' of G for which both $G'[\delta^+(X)]$ and $G'[\delta^+(Y)]$ have an odd number of perfect matchings are the three non-Hamiltonian directed cycles of G . Let C be such a cycle of G . It can be verified that pivoting on $V(C)$ in G , as described in section 3, results in a fundamental graph isomorphic to G . Thus, if P is a binary matroid pair with basis B such that $G(P, B) \in \mathcal{G}$, then by Proposition 3.2, $G(P, B') \in \mathcal{G}$ for all $B' \in \mathcal{B}(P)$.

DEFINITION 4.1. A binary matroid pair P with $G(P) \in \mathcal{G}$ is called a *twined K_4 pair*.

5. Vertex cycle space. Our proof of Theorem 1.1 uses the dimension of a vector space defined on the vertices of the fundamental graph for a matroid pair. In this section we define the required vector space and determine its dimension.

Let G be a directed graph, and for each circuit C in G , let $x_C \in GF(2)^{E(G)}$ and $y_C \in GF(2)^{V(G)}$ be the incidence vectors for $E(C)$ and $V(C)$, respectively. The (directed) *cycle space* of G is the vector space over $GF(2)$ generated by $\{x_C : C \text{ is a (directed) circuit in } G\}$. When G has c components, it is well known that the cycle space of G , denoted $\mathcal{C}(G)$, has dimension $|E(G)| - |V(G)| + c$. The cycle space and the directed cycle space are equal for strongly connected graphs (see Bondy and Murty [1]). We define the *vertex cycle space* of G , denoted $\mathcal{C}_V(G)$, as the vector space over $GF(2)$ generated by $\{y_C : C \text{ is a directed circuit in } G\}$.

THEOREM 5.1. Let G be a strongly connected bipartite graph with vertex bipartition $\{X, Y\}$. If c_X and c_Y are the number of connected components in $G[\delta^+(X)]$ and

$G[\delta^+(Y)]$, respectively, then the dimension of $\mathcal{C}_V(G)$ is

$$(5.1) \quad |X| + |Y| - c_X - c_Y + 1.$$

Proof. Let $f : \mathcal{C}(G) \rightarrow GF(2)^{X \cup Y}$ be the linear mapping with $f(x)_u = x(\delta^+(u))$ if $u \in X$, and $f(x)_u = x(\delta^-(u))$ if $u \in Y$. Then $f(x_C) = y_C$ for all directed circuits C in G , and therefore $\mathcal{C}_V(G)$ is the image of f . It follows that

$$(5.2) \quad \dim \mathcal{C}_V(G) = \dim \mathcal{C}(G) - \text{null} f = |E(G)| - |X| - |Y| + 1 - \text{null} f.$$

It remains to find $\text{null} f$.

For $Z \in \{X, Y\}$, let $G_Z = G[\delta^+(Z)]$. Note that

$$(5.3) \quad \begin{aligned} \mathcal{C}(G_Z) &= \{x \in GF(2)^{E(G_Z)} : x(\delta^+(u)) = 0 \text{ if } u \in Z, \\ &\quad x(\delta^-(u)) = 0 \text{ if } u \in V(G) \setminus Z\}. \end{aligned}$$

For $x \in GF(2)^{E(G)}$, let x^Z be x restricted to $E(G_Z)$. Conversely, given $x^X \in GF(2)^{E(G_X)}$ and $x^Y \in GF(2)^{E(G_Y)}$, let x be the associated vector in $GF(2)^{E(G)}$. We claim that the nullspace of f is

$$(5.4) \quad \{x \in GF(2)^{E(G)} : x^X \in \mathcal{C}(G_X) \text{ and } x^Y \in \mathcal{C}(G_Y)\}.$$

Certainly, if $x^X \in \mathcal{C}(G_X)$ and $x^Y \in \mathcal{C}(G_Y)$, then $x \in \mathcal{C}(G)$. By (5.3), $f(x) = 0$ in this case. Conversely, suppose $f(x) = 0$. Since $x \in \mathcal{C}(G)$, $x(\delta^+(u)) = x(\delta^-(u))$ for all $u \in X \cup Y$, and thus $x^X \in \mathcal{C}(G_X)$ and $x^Y \in \mathcal{C}(G_Y)$ by (5.3). Hence the nullspace of f is (5.4), as claimed. Thus

$$\text{null} f = \dim \mathcal{C}(G_X) + \dim \mathcal{C}(G_Y) = |E(G)| - 2(|X| + |Y|) + c_X + c_Y,$$

and the theorem now follows from (5.2). $\square$

6. Characterization by fundamental graphs. For a binary matroid pair P , we use Theorem 5.1 to characterize $\text{Bin}(P)$ in terms of $\mathcal{C}_V(G(P))$. This characterization will be the main tool in our proof of Theorem 1.1, and will also be used to show that the converse of Theorem 1.1 is false.

First note that $\mathcal{C}_V(G(P, B))$ does not depend on the particular basis B of P .

LEMMA 6.1. *Let $P = (M, N)$ be a connected binary matroid pair on the ground set S . If $B \in \mathcal{B}(P)$, then $\mathcal{C}_V(G(P, B)) = \mathcal{B}_M^0 \cap \mathcal{B}_N^0$.*

Proof. If C is a directed circuit in $G = G(P, B)$, then $E(C) \cap E(G(M, B))$ is a matching in $G(M, B)$, and thus $V(C)$ intersects each component in $G(M, B)$ with even parity. Rieder's characterization of $\mathcal{B}_M^0$ then implies that $V(C) \in \mathcal{B}_M^0$. Similarly, $V(C) \in \mathcal{B}_N^0$. Since C was arbitrary, $\mathcal{C}_V(G) \subseteq \mathcal{B}_M^0 \cap \mathcal{B}_N^0$.

By Proposition 3.1(i), $G[\delta^-(B)]$ and $G[\delta^+(B)]$ have c_M and c_N components, respectively, and by Proposition 3.3, G is strongly connected. Theorem 5.1 therefore implies that $\mathcal{C}_V(G)$ has dimension $|S| - c_M - c_N + 1$. Hence, by Proposition 2.1, $\mathcal{C}_V(G)$ and $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$ have the same dimension, and the lemma follows. $\square$

THEOREM 6.2. *If $P = (M, N)$ is a connected binary matroid pair, then*

$$(6.1) \quad \text{Bin}(P) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$$

if and only if $\mathcal{C}_V(G(P)) \subseteq \text{Bin}(P)$.

Proof. Recall that $\text{Bin}(P) \subseteq (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$, and let $G = G(P, B)$ for some $B \in \mathcal{B}(P)$. If (6.1) holds, then $\mathcal{C}_V(G) \subseteq \text{Bin}(P)$ by Lemma 6.1. Conversely, suppose

that $\mathcal{C}_V(G) \subseteq \text{Bin}(P)$. If every component of M and every component of N has even rank, then $\mathcal{B}_M^1 \cap \mathcal{B}_N^1 = \mathcal{B}_M^0 \cap \mathcal{B}_N^0$ and (6.1) holds by Lemma 6.1. If a component of M or N has odd rank, then $B \notin \mathcal{B}_M^0 \cap \mathcal{B}_N^0$, and thus by Lemma 6.1, the dimension of $\text{Bin}(P)$ is at least one greater than the dimension of $\mathcal{B}_M^0 \cap \mathcal{B}_N^0$. By Proposition 2.1, the dimension of $\text{Bin}(P)$ is then at least the dimension of $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. This yields (6.1). $\square$

When $P = (M, N)$ is a connected matroid pair on the ground set S , and M and N are simple matroids with c_M and c_N components, respectively, Fonlupt and Zemirline [4] show that the convex hull generated by $\mathcal{B}(P)$, over $\mathbb{R}$, has dimension $|S| - c_M - c_N + 1$. Theorem 6.2 together with Proposition 2.1 implies the following corollary about the dimension of $\text{Bin}(P)$.

COROLLARY 6.3. *Let $P = (M, N)$ be a connected binary matroid pair on the ground set S with $\mathcal{C}_V(G(P)) \subseteq \text{Bin}(P)$. If M and N have c_M and c_N components, respectively, then $\text{Bin}(P)$ has dimension $|S| - c_M - c_N + 1$ when every component of M and N has even rank, and dimension $|S| - c_M - c_N + 2$ otherwise.*

While Theorem 1.1 provides sufficient conditions for the equality of $\text{Bin}(P)$ and $(\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$, the converse of the theorem is false. For example, let $P = (M, N)$ be the binary matroid pair on the ground set $S = \{1, 2, \dots, 8\}$ with basis $B = \{1, 2, 3, 4\}$ and fundamental graph $G(P, B)$ as shown in Figure 6.1.

FIG. 6.1. $G(P, B)$ has a twined K_4 pair as a minor.

There are exactly seven directed circuits in $G(P, B)$, and it can be verified that the vertex set for each circuit is contained in $\text{Bin}(P)$. Thus, by Theorem 6.2, $\text{Bin}(P) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. However, $G(P, B) \setminus \{4, 8\} \in \mathcal{G}$, and thus $P/\{4\} \setminus \{8\}$ is a twined K_4 pair.

7. Proof of the main theorem. In this section, Theorem 6.2 is used to prove the main theorem, Theorem 1.1. We first require some terminology. Given subgraphs G_1 and G_2 of a graph G , let $G_1 \cup G_2$ denote the subgraph with vertices $V(G_1) \cup V(G_2)$ and edges $E(G_1) \cup E(G_2)$. If C and C' are directed circuits in the directed graph G , then the components of the subgraph with vertices $V(C) \cap V(C')$ and edges $E(C) \cap E(C')$ are called the *intersection paths* between C and C' . Note that an intersection path may be an isolated vertex. If there are at least two intersection paths between C and C' , and the order of the paths traveling on C is the reverse of the order of the paths traveling on C' , then we say that C and C' are *twined* circuits. For example, the two Hamilton circuits in the graph of Figure 4.1(b) are twined and have three intersection paths. We require one lemma about twined circuits.

LEMMA 7.1. *Let C and C' be directed circuits in the directed graph G . If there are at least two intersection paths between C and C' , then there exists a directed circuit in $C \cup C'$ that is twined with C .*

Proof. Let C and C' have k intersection paths $P_1, P_2, \dots, P_k$. Assume that the order of the paths traveling on C is $P_1, P_2, \dots, P_k$. Let α be the permutation of

$\{1, 2, \dots, k\}$ such that $\alpha(1) = 1$ and $P_{\alpha(k)}, P_{\alpha(k-1)}, \dots, P_{\alpha(1)}$ is the order of the paths on C' . If $\alpha(i) = i$ for all i , then C and C' are twined. Otherwise, let n be minimum such that $\alpha(n) > \alpha(n+1)$ and let $m < n$ be maximum such that $\alpha(m) < \alpha(n+1)$. The directed path in C from the first vertex of $P_{\alpha(m)}$ to the first vertex of $P_{\alpha(n+1)}$, followed by the directed path in C' from the first vertex of $P_{\alpha(n+1)}$ to the first vertex of $P_{\alpha(m)}$, forms a directed circuit C'' in $C \cup C'$ that is twined with C . The number of intersection paths between C'' and C is $n+1-m \geq 2$. $\square$

We now prove our main theorem, which we restate here.

THEOREM 1.1. *If M and N are binary matroids and the matroid pair $P = (M, N)$ is connected and does not have a twined K_4 pair as a minor, then*

$$\text{Bin}(P) = (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1).$$

Proof. Suppose that $\text{Bin}(P) \neq (\mathcal{B}_M^0 \cap \mathcal{B}_N^0) \cup (\mathcal{B}_M^1 \cap \mathcal{B}_N^1)$. By Theorem 6.2, there is a directed circuit C in $G(P)$ with $V(C) \notin \text{Bin}(P)$. Over all $B \in \mathcal{B}(P)$ and all directed circuits C in $G(P, B)$ with $V(C) \notin \text{Bin}(P)$, choose B and C to minimize the length of C , denoted $|C|$. Let G be the subgraph of $G(P, B)$ induced by $V(C)$, and let G_M and G_N be the subgraphs of G induced by the edges of $G(M, B)$ and $G(N, B)$, respectively. Given a directed circuit C' in G with chord e , let C'_e denote the unique directed circuit in $C' \cup \{e\}$ with $e \in E(C'_e)$.

CLAIM 7.1.1. *If C' is a directed circuit in G and C' is twined with C , then C' is a Hamilton circuit of G and $|E(C') \setminus E(C)|$ is odd.*

Subproof. Suppose that the directed circuit C' in G is twined with C and let $E(C') \setminus E(C) = \{e_1, \dots, e_k\}$, where the edges are labeled to respect their cyclic order on C' . Since C and C' are twined,

$$(7.1) \quad V(C') = V(C) \Delta V(C_{e_1}) \Delta V(C_{e_2}) \Delta \dots \Delta V(C_{e_k}).$$

Since G does not have parallel edges, $|C_e| < |C|$ for all $e \in E(G) \setminus E(C)$. In particular, $|C_{e_i}| < |C|$ for all $i \in \{1, \dots, k\}$, and thus the minimality of $|C|$ implies

$$(7.2) \quad V(C_{e_i}) \in \text{Bin}(P) \quad \text{for all } i \in \{1, \dots, k\}.$$

Since $V(C) \notin \text{Bin}(P)$, (7.1) and (7.2) imply that $V(C') \notin \text{Bin}(P)$. The minimality of $|C|$ implies that $|C'| = |C|$ and therefore C' is a Hamilton circuit of G . If k is even, say $k = 2l$, then since C' is a Hamilton circuit,

$$(7.3) \quad V(C) = \bigtriangleup_{i=1}^l V(C_{e_{2i}}).$$

Together with (7.2), equation (7.3) contradicts the assumption that $V(C) \notin \text{Bin}(P)$. Thus k is odd and the claim follows. $\square$

CLAIM 7.1.2. *There exists a directed circuit in G that is twined with C .*

Subproof. Consider the perfect matching $T_M = E(G_M) \cap E(C)$ of G_M and the perfect matching $T_N = E(G_N) \cap E(C)$ of G_N . Since $V(C) \notin \text{Bin}(P)$ and $B \in \mathcal{B}(P)$, $V(C) \Delta B$ is not a basis of P . Without loss of generality, we may assume that $V(C) \Delta B \notin \mathcal{B}(N)$. By Proposition 3.2, G_N has a perfect matching T'_N with $T'_N \neq T_N$. Since T_M and T'_N are both perfect matchings of G , the union of T_M and T'_N is a set of disjoint directed circuits which spans $V(G)$. Assume that $T_M \cup T'_N$ is the disjoint union of m directed circuits $C^1, \dots, C^m$. Since $V(C) = V(C^1) \Delta \dots \Delta V(C^m)$ and $V(C) \notin \text{Bin}(N)$, there exists $i \in \{1, \dots, m\}$ with $V(C^i) \notin \text{Bin}(N)$. If $m > 1$, then $|C^i| < |C|$, and thus C^i contradicts the choice of C . It follows that $m = 1$, and

$T_M \cup T'_N$ is therefore a directed circuit C' with $V(C') = V(C)$. Since $T_N \neq T'_N$, the circuits C' and C are distinct and therefore have at least two intersection paths. By Lemma 7.1, G has a directed circuit that is twined with C . $\square$

Over all directed circuits in G that are twined with C , choose the circuit C' to minimize $|E(C') \setminus E(C)|$. Let $k = |E(C') \setminus E(C)|$ and let $P_1, P_2, \dots, P_k$ be the intersection paths between C and C' , where the indices respect the cyclic order of the paths on C . For $i \in \{1, \dots, k\}$, let $x_i, y_i \in V(G)$ be the first and last vertices, respectively, of P_i . Then

$$E(C) \setminus E(C') = \{y_1 x_2, y_2 x_3, \dots, y_k x_1\},$$

$$E(C') \setminus E(C) = \{y_1 x_k, y_2 x_1, \dots, y_k x_{k-1}\}.$$

Without loss of generality we may assume that $x_1 \in B$. Since k is odd (Claim 7.1.1), it follows that $x_i \in B$ for all i . The intersection paths between C and C' therefore have odd length, and to prove that the matroid pair minor corresponding to G is a twined K_4 pair, it remains to show that $G = C \cup C'$ and $k = 3$.

Given a directed path Q in G and $x, y \in V(Q)$ with $xy \in E(G) \setminus E(Q)$, call xy a *forward arc* of Q if x precedes y along Q , and call xy a *backward arc* of Q otherwise.

CLAIM 7.1.3. *If $e \in E(G) \setminus E(C \cup C')$, then e is a backward arc of an intersection path between C and C' .*

Subproof. Let $x, y \in V(G)$ be such that $xy \in E(G) \setminus E(C \cup C')$. Since C and C' are Hamiltonian in G , there exist $i, j \in \{1, \dots, k\}$ such that $x \in V(P_i)$ and $y \in V(P_j)$. Without loss of generality we may assume that $i = 1$.

If $j \neq 1$, let $C'' = C'_{xy}$. Then C'' is not a Hamilton circuit of G , but C and C'' are twined with $j \geq 2$ intersection paths. This contradicts Claim 7.1.1; hence we may assume that $x, y \in V(P_1)$.

Suppose that xy is a forward arc of P_1 . Let C'' be the directed circuit formed by the union of xy , the path from y to y_2 in C , the arc $y_2 x_1$ in C' , and the path from x_1 to x in P_1 . Then C'' is not a Hamilton circuit of G , but C and C'' are twined with two intersection paths. This again contradicts Claim 7.1.1, and thus xy is a backward arc of P_1 . $\square$

CLAIM 7.1.4. *Let $xy \in E(G) \setminus E(C)$ be such that C_{xy} is induced, and let $x', y' \in V(G)$ be such that $x'y, xy' \in E(C)$. Furthermore, assume that $k > 3$ if $xy \in E(C')$. Then $B' = B \Delta V(C_{xy})$ is a basis of P , and $C_{x'y'}$ is a directed circuit in $G(P, B')$.*

Subproof. Since C_{xy} is induced, $B' \in \mathcal{B}(P)$ by Proposition 3.2. We consider how successively pivoting on each edge of C_{xy} affects G . Recall that pivoting in G implies separate pivoting in $G(M, B)$ and in $G(N, B)$. Recall also that if $uv \in E(G(M, B))$, then pivoting on uv deletes the edge $u'v'$ if and only if $u'v' \in E(G(M, B))$, $u' \neq u, v' \neq v$, and both $u'v \in E(G(M, B))$ and $uv' \in E(G(M, B))$. Similarly, pivoting on uv adds the edge $u'v'$ if and only if $u'v' \notin E(G(M, B))$, $u' \neq u, v' \neq v$, and both $u'v \in E(G(M, B))$ and $uv' \in E(G(M, B))$.

Let $uv \in E(C_{xy})$, and let Q be the path in C from y' to x' . Let $u'v' \in E(Q)$ be such that the two edges $u'v'$ and uv are either both in $G(M, B)$ or both in $G(N, B)$. By Claim 7.1.3, either $u'v \notin E(G)$ or $uv' \notin E(G)$. Thus, by the properties of pivoting in G , the edge $u'v'$ remains after pivoting on uv . Since C_{xy} is induced, if $z \in V(C_{xy}) \setminus \{u, v\}$, then $zv \notin E(G)$ and $uz \notin E(G)$. Thus pivoting on uv does not change $N(z)$. Hence, after successively pivoting on each edge of C_{xy} , all edges of Q remain.

Note that by Claim 7.1.3, $x'y' \notin E(G)$. Let $uv \in E(C_{xy})$ with $uv \neq xy$. If $xy \notin E(C')$, then neither $x'v$ nor uy' is an edge of G by Claim 7.1.3, so pivoting on

uv does not add edge $x'y'$. If $xy \in E(C')$, then since $k > 3$, either $x'v \notin E(G)$ or $uy' \notin E(G)$ by Claim 7.1.3, and again pivoting on uv does not add edge $x'y'$. However, since $x'y, xy', xy \in E(G)$, pivoting on xy adds edge $x'y'$. It follows that after pivoting on each edge of C_{xy} , the edge $x'y'$ has been added. Since $C_{x'y'} = Q \cup x'y'$, we conclude that the directed circuit $C_{x'y'}$ is a subgraph of $G(P, B')$. $\square$

CLAIM 7.1.5. $G = C \cup C'$.

Subproof. Suppose instead that $xy \in E(G) \setminus E(C \cup C')$. By Claim 7.1.3, xy is a backward arc of an intersection path P_j between C and C' . Choose xy such that $|C_{xy}|$ is minimum and let $x', y' \in V(G)$ be such that $x'y, xy' \in E(C)$.

The minimality of $|C_{xy}|$ together with Claim 7.1.3 implies that C_{xy} is an induced subgraph of G . Let $B' = B \Delta V(C_{xy})$. By Claim 7.1.4, $B' \in \mathcal{B}(P)$ and $C_{x'y'}$ is a directed circuit in $G(P, B')$.

By the minimality of $|C|$, both $V(C_{x'y'})$ and $V(C_{xy})$ are contained in $\text{Bin}(P)$. Since $V(C) = V(C_{x'y'}) \Delta V(C_{xy})$, this contradicts the assumption that $V(C) \notin \text{Bin}(P)$. Thus $E(G) \setminus E(C \cup C') = \emptyset$ and $G = C \cup C'$. $\square$

CLAIM 7.1.6. *There are exactly three intersection paths between C and C' .*

Subproof. Suppose instead that $k > 3$ and consider $C_{y_2x_1}$. By Claim 7.1.5, $C_{y_2x_1}$ is induced in G , and therefore, by Proposition 3.2, $B' = B \Delta V(C_{y_2x_1})$ is a basis of P . Since $y_2x_3, y_kx_1 \in E(C)$, Claim 7.1.4 implies that $C_{y_kx_3}$ is a directed circuit in $G(P, B')$. By the minimality of $|C|$, both $V(C_{y_kx_3})$ and $V(C_{y_2x_1})$ are contained in $\text{Bin}(P)$. Since $V(C) = V(C_{y_kx_3}) \Delta V(C_{y_2x_1})$, this contradicts the assumption that $V(C) \notin \text{Bin}(P)$. Thus $k = 3$. $\square$

Claims 7.1.5 and 7.1.6 imply that the minor of P corresponding to G is a twined K_4 pair, thus completing the proof of Theorem 1.1. $\square$

We close by noting that Theorem 1.1 can be applied to binary matroid pairs that are not connected. For example, let $P = (M, N)$ be a binary matroid pair on the ground set S where M and N have rank r , and suppose that P is not connected. If there exists a partition $\{S_1, S_2\}$ of S such that $\text{rank}_M(S_1) + \text{rank}_N(S_2) < r$, then $\mathcal{B}(P)$ is empty and thus $\text{Bin}(P)$ is trivial. If there exists a partition $\{S_1, S_2\}$ of S such that $\text{rank}_M(S_1) + \text{rank}_N(S_2) = r$, then $B \in \mathcal{B}(P)$ if and only if $B \cap S_1$ is a basis of $(M \setminus S_2, N \setminus S_2)$ and $B \cap S_2$ is a basis of $(M/S_1, N/S_1)$ (see Fonlupt and Zemirline [4]). Determining $\text{Bin}(P)$ in this case thus reduces to determining the vector space over $GF(2)$ generated by the common bases of two smaller pairs of matroids.

Acknowledgments. I thank Jim Geelen for many helpful discussions, and thank the referees for many helpful suggestions.

DETERMINANTS AND LONGEST CYCLES OF GRAPHS*

VLADIMIR EJOV[†], JERZY A. FILAR[†], WALTER MURRAY[‡], AND GIANG T. NGUYEN[†]

Abstract. We consider the Hamiltonian cycle problem on a given graph G . With such a graph we can associate a family $\mathcal{F}$ of probability transition matrices of Markov chains whose entries represent the probabilities of traversing corresponding arcs of the graph. When the underlying graph is Hamiltonian, we show the transition probability matrix induced by a Hamiltonian cycle maximizes—over $\mathcal{F}$ —the determinant of a matrix that is a rank-one correction of the generator matrix of a Markov chain. In the case when the graph does not possess a Hamiltonian cycle, the above maximization yields a transition matrix of a chain with a longest simple cycle (in G) comprising that chain’s unique ergodic class. These problems also have analogous eigenvalue interpretations.

1. Introduction. Briefly stated, the Hamiltonian cycle problem (HCP) is as follows: *Given a graph, find a simple cycle that contains all vertices of the graph (Hamiltonian cycle) or prove that a Hamiltonian cycle does not exist.* With respect to this property—*Hamiltonicity*—graphs possessing one or more Hamiltonian cycles are called Hamiltonian.¹ By a *graph* of order N we will mean a simple N -vertex graph (without self-loops and multiple edges) that can be both symmetric (every edge admits the two-way traffic) or directed (*digraph*, with one-way traffic along each edge).

This paper evolved from a line of research [6], [4], [1], [2] (surveyed in [5]) that exploits Markov chains to study properties of the HCP. More specifically, we consider the HCP as an optimization problem over the space $\mathcal{F}$ of probability transition matrices of Markov chains whose entries represent the probabilities of traversing corresponding arcs of a graph. We prove that when the underlying graph is Hamiltonian the transition probability matrix induced by a Hamiltonian cycle maximizes, over $\mathcal{F}$, the determinant of a matrix that is a rank-one correction of the (negative) generator matrix of the corresponding Markov chain. In the case when the graph does not possess a Hamiltonian cycle, the above maximization yields a transition matrix of a chain with a longest simple cycle (in G) comprising that chain’s single, nonexhaustive, ergodic class. These problems also have analogous eigenvalue interpretations.

In notation made precise later, the main result states that for all possible transition probability matrices $\mathbf{P} \in \mathcal{F}$ generated by the given graph G

$$\det[\mathbf{I} - \mathbf{P} + \alpha\mathbf{J}] \leq \alpha kN,$$

¹The name of the problem is due to Sir William Hamilton’s investigations of the existence of such cycles on the dodecahedron graph [7].

where $\alpha > 0$ is a fixed parameter, k is the length of the longest simple cycle in G , N is the number of nodes, and $\mathbf{J}$ is an $N \times N$ matrix of 1's. If $\mathbf{e}$ denotes the column vector of 1's, then $\mathbf{J}$ is a rank-one matrix $\mathbf{e}\mathbf{e}^T$. Furthermore, the above upper bound is attained at some $\mathbf{P} \in \mathcal{F}$.

The paper is organized as follows. In section 2 we introduce some basic concepts and the necessary notation. In section 3 we discuss a numerical example that motivates the theoretical results derived in section 4. Conclusions are supplied in section 5.

2. Preliminaries and notation. Consider a connected graph G of size N . Let $V(G)$ and $E(G)$ be the set of nodes and the set of arcs in G , respectively, where $|V(G)| = N$. Let $\mathcal{F}$ be the set of all probability transition matrices $\mathbf{P}$ of Markov chains whose entries represent the probabilities of traversing corresponding arcs of the graphs. Naturally, every element in $\mathbf{P}$ is nonnegative and $\mathbf{P}$ is stochastic, which means every row sums to 1. That is,

$$\mathcal{F} := \left\{ \mathbf{P} \mid p_{ij} \geq 0; \sum_j p_{ij} = 1 \forall i; p_{ij} = 0 \forall (i, j) \notin E(G) \right\}.$$

Let $\mathcal{D} \subset \mathcal{F}$ be the set of all probability transition matrices $\mathbf{P}$ of deterministic Markov chains,

$$\mathcal{D} := \{ \mathbf{P} \in \mathcal{F} \mid p_{ij} \in \{0, 1\} \},$$

and let $\mathcal{DS} \subset \mathcal{F}$ be the set of all probability transition matrices $\mathbf{P}$ of doubly stochastic Markov chains,

$$\mathcal{DS} := \left\{ \mathbf{P} \in \mathcal{F} \mid \sum_i p_{ij} = 1 \forall j \right\}.$$

Remark 2.1. Note that all Hamiltonian cycles (if any) of a given graph G correspond to probability transition matrices of Markov chains that are both irreducible² and doubly stochastic. These probability transition matrices are also called Hamiltonian cycles.

3. Determinant of rank-one corrected generator matrix. Define

$$(3.1) \quad \mathbf{A}(\mathbf{P}) := \mathbf{I} - \mathbf{P} + \frac{1}{N}\mathbf{J},$$

where $\mathbf{J} = \mathbf{e}\mathbf{e}^T$. Recall that in the literature on Markov chains, the matrix $\mathbf{P} - \mathbf{I}$ is often called the *generator matrix* of the chain whose probability transition matrix is $\mathbf{P}$.

Example 3.1. Consider a complete graph G_4 on 4 nodes (without self-loops). Take three deterministic Markov chains with probability transition matrices $\mathbf{P}_1$, $\mathbf{P}_2$, and $\mathbf{P}_3$:

$$\mathbf{P}_1 = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{P}_2 = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \quad \text{and} \quad \mathbf{P}_3 = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}.$$

²A Markov chain is irreducible if all states belong to a single ergodic class.

It is easy to verify that

$$\mathbf{A}(\mathbf{P}_1) = \mathbf{I} - \mathbf{P}_1 + \frac{1}{4}\mathbf{J} = \frac{1}{4} \begin{bmatrix} 5 & -3 & 1 & 1 \\ 1 & 5 & -3 & 1 \\ 1 & 1 & 5 & -3 \\ -3 & 1 & 1 & 5 \end{bmatrix},$$

$$\mathbf{A}(\mathbf{P}_2) = \mathbf{I} - \mathbf{P}_2 + \frac{1}{4}\mathbf{J} = \frac{1}{4} \begin{bmatrix} 5 & -3 & 1 & 1 \\ -3 & 5 & 1 & 1 \\ 1 & 1 & 5 & -3 \\ 1 & 1 & -3 & 5 \end{bmatrix},$$

and

$$\mathbf{A}(\mathbf{P}_3) = \mathbf{I} - \mathbf{P}_3 + \frac{1}{4}\mathbf{J} = \frac{1}{4} \begin{bmatrix} 5 & -3 & 1 & 1 \\ 1 & 5 & -3 & 1 \\ -3 & 1 & 5 & 1 \\ 1 & -3 & 1 & 5 \end{bmatrix}.$$

Calculating the corresponding determinants yields

$$\det \mathbf{A}(\mathbf{P}_1) = 4, \quad \det \mathbf{A}(\mathbf{P}_2) = 0, \quad \text{and} \quad \det \mathbf{A}(\mathbf{P}_3) = 3.$$

Incidentally, the easiest way to verify that $\det \mathbf{A}(\mathbf{P}_2) = 0$ is to multiply $\mathbf{A}(\mathbf{P}_2)$ by the column vector $(1, 1, -1, -1)^T$.

It will be shown later that it is not a coincidence that $\mathbf{P}_1$ corresponds to a Hamiltonian cycle and the determinant of $\mathbf{A}(\mathbf{P}_1)$ is exactly equal to the number of nodes in that longest of all possible simple cycles. Analogously, $\mathbf{P}_3$ corresponds to a Markov chain that traces out a 3-cycle and a transient state and $\det \mathbf{A}(\mathbf{P}_2)$ is again equal to the number of nodes in the cycle containing the home node. While $\mathbf{P}_2$ may appear to be a counterexample to this pattern, it can be excluded because it contains more than one ergodic class.

4. Results. When a Markov chain traces out a Hamiltonian cycle, its probability transition matrix $\mathbf{P}$ will be denoted by $\mathbf{P}_H$. Our results will be proved under a little more generality by replacing the coefficient $\frac{1}{N}$ of the matrix $\mathbf{J}$ by a parameter $\alpha > 0$. Thus, for $\mathbf{P} \in \mathcal{F}$, define

$$\mathbf{A}_\alpha(\mathbf{P}) = \mathbf{I} - \mathbf{P} + \alpha\mathbf{J}, \quad \alpha > 0.$$

For the special value $\alpha = \frac{1}{N}$, we write

$$\mathbf{A}(\mathbf{P}) := \mathbf{A}_{\frac{1}{N}}(\mathbf{P}) = \mathbf{I} - \mathbf{P} + \frac{1}{N}\mathbf{J},$$

as in (3.1).

THEOREM 4.1. *For any graph G*

$$\det_{\mathbf{P} \in \mathcal{F}} \mathbf{A}_\alpha(\mathbf{P}) \leq \alpha kN,$$

where k is the size of the longest cycle in the graph.

In order to prove Theorem 4.1, we will require several results. Lemma 4.2 states the relationship between $\det \mathbf{A}_\alpha(\mathbf{P})$ and the eigenvalues of $\mathbf{P}$. Propositions 4.3, 4.4, and 4.5 prove Theorem 4.1 for three disjoint exhaustive classes of deterministic Markov chains: Hamiltonian cycles, Markov chains with two or more independent cycles (corresponding to two or more ergodic classes), and Markov chains with only a single cycle of length $k < N$, respectively. Proposition 4.6 shows that for any $\mathbf{P} \in \mathcal{F}$, the determinant of $\mathbf{A}_\alpha(\mathbf{P})$ is bounded above by the corresponding determinant of some deterministic Markov chain.

LEMMA 4.2. *Consider any graph G and $\mathbf{P} \in \mathcal{F}$ that has eigenvalues $\lambda_1, \lambda_2, \dots, \lambda_{N-1}$ and $\lambda_N = 1$. Then*

$$\det_{\mathbf{P} \in \mathcal{F}} \mathbf{A}_\alpha(\mathbf{P}) = \alpha N \prod_{i=1}^{N-1} (1 - \lambda_i).$$

Proof. Let μ_i 's be the eigenvalues of $\mathbf{A}_\alpha(\mathbf{P})$. Then

$$\det_{\mathbf{P} \in \mathcal{F}} \mathbf{A}_\alpha(\mathbf{P}) = \prod_{i=1}^N \mu_i.$$

We shall show that

$$\prod_{i=1}^N \mu_i = \alpha N \prod_{i=1}^{N-1} (1 - \lambda_i).$$

We start with the case $\mathbf{P} \in \mathcal{DS}$. For any $\mathbf{P} \in \mathcal{DS}$, $\ker(\mathbf{J})$ is $\mathbf{P}$ -invariant. This follows from the fact that $\mathbf{JP} = \mathbf{PJ} = \mathbf{J}$. If $\mathbf{v} \in \ker(\mathbf{J})$, then $\mathbf{A}_\alpha(\mathbf{P})\mathbf{v} = \mathbf{v} - \mathbf{Pv} + \mathbf{0} \in \ker(\mathbf{J})$. Therefore, the eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_N$ for $\mathbf{A}_\alpha(\mathbf{P})$ can be chosen so that $\mathbf{u}_N = \mathbf{e} = [1, 1, \dots, 1]$ and the remaining eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_{N-1}$ span $\ker(\mathbf{J})$. We observe that $\mathbf{e}$ is an eigenvector of $\mathbf{P}$ with eigenvalue 1 and $\mu_N = \alpha N$ since $\mathbf{A}_\alpha(\mathbf{P})\mathbf{e} = \alpha N\mathbf{e}$. As $\mathbf{u}_1, \dots, \mathbf{u}_{N-1}$ span the $\ker(\mathbf{J})$, then $\mu_i = 1 - \lambda_i$, $i = 1, \dots, N-1$, where $\lambda_1, \dots, \lambda_{N-1}$ are the remaining eigenvalues of $\mathbf{P}$.

Hence,

$$\det \mathbf{A}_\alpha(\mathbf{P}) = \alpha N \prod_{i=1}^{N-1} (1 - \lambda_i).$$

Consider now the general case $\mathbf{P} \in \mathcal{F}$. We recall that $\mathbf{e}$ is an eigenvector of $-\mathbf{P}$ with eigenvalue -1 . Let $\mathbf{u}$ be an eigenvector of $-\mathbf{P} + \alpha\mathbf{J}$ with eigenvalue $-\lambda$, $\lambda \neq 1$. Then $\mathbf{u} = \mathbf{v} + \mu\mathbf{e}$ for some $\mathbf{v} \in \ker(\mathbf{J})$. We can then show that there exists vector $\mathbf{w} = \mathbf{v} + \beta\mathbf{e}$ such that $\mathbf{Pw} = \lambda\mathbf{w}$. Indeed, take $\beta = \frac{\mu(1-\alpha N-\lambda)}{1-\lambda}$. Then

$$\begin{aligned} \mathbf{Pw} &= \mathbf{P}(\mathbf{v} + \mu\mathbf{e} - \mu\mathbf{e} + \beta\mathbf{e}) = (\mathbf{P} - \alpha\mathbf{J} + \alpha\mathbf{J})(\mathbf{v} + \mu\mathbf{e} - \mu\mathbf{e}) + \mathbf{P}\beta\mathbf{e} \\ &= \lambda\mathbf{v} + \mu(\lambda + \alpha N - 1)\mathbf{e} + \beta\mathbf{e} = \lambda\mathbf{w}. \end{aligned}$$

Thus, every eigenvalue $\lambda \neq 1$ of $\mathbf{P}$ is also an eigenvalue of $\mathbf{P} - \alpha\mathbf{J}$, and vice versa, which completes the proof. $\square$

PROPOSITION 4.3. *For any Hamiltonian cycle $\mathbf{P}_H \in \mathcal{D}$*

$$\det \mathbf{A}_\alpha(\mathbf{P}_H) = \alpha N^2, \quad \alpha > 0.$$

Proof. Because the arguments used are not the same, we will present the proof for Proposition 4.3 for two separate cases: (i) $\alpha = \frac{1}{N}$ and (ii) $\alpha \neq \frac{1}{N}$.

(i) Consider $\alpha = \frac{1}{N}$. From Lemma 4.2,

$$\begin{aligned} \det \mathbf{A}(\mathbf{P}_H) &= \prod_{i=1}^N \mu_i = \prod_{i=1}^{N-1} (1 - \lambda_i) \\ &= 1 - \sum_{i=1}^{N-1} \lambda_i + \sum_{\substack{i > j \\ i, j=1}}^{N-1} \lambda_i \lambda_j + \cdots + (-1)^{N-1} \prod_{i=1}^{N-1} \lambda_i \\ &= 1 - q_1(\lambda) + q_2(\lambda) + \cdots + (-1)^{N-1} q_{N-1}(\lambda), \end{aligned}$$

where q_i is the i th elementary symmetric polynomial in $\lambda_1, \dots, \lambda_{N-1}$, $i = 1, \dots, N-1$.

Let $Q_1(\lambda), \dots, Q_{N-1}(\lambda), Q_N(\lambda)$ be elementary symmetric polynomials in all of $\mathbf{P}_H$'s eigenvalues $\lambda_1, \dots, \lambda_N$. Define $q_0 = Q_0 = 1$. Hence, $q_1 = Q_1 - q_0$, $q_2 = Q_2 - q_1, \dots, q_{N-1} = Q_{N-1} - q_{N-2}$. Since the characteristic polynomial $c_x(\mathbf{P}_H) = 1 - x^N$ (e.g., see [3]), it implies that $Q_1 = Q_2 = \cdots = Q_{N-1} = 0$. Therefore, $q_1 = Q_1 - q_0 = -1$; $q_2 = Q_2 - q_1 = 1, \dots, q_{N-1} = Q_{N-1} - q_{N-2} = (-1)^{N-1}$. Hence,

$$\det \mathbf{A}(\mathbf{P}_H) = 1 + 1 + \cdots + 1 = N.$$

In particular,

$$\prod_{i=1}^{N-1} (1 - \lambda_i) = N.$$

(ii) Consider $\alpha \neq \frac{1}{N}$. As in the proof of Lemma 4.2, we can choose first $N-1$ eigenvectors $\mathbf{u}_1, \dots, \mathbf{u}_{N-1}$ of $\mathbf{A}_\alpha(\mathbf{P}_H)$ spanning $\ker(\mathbf{J})$ with eigenvalues $1 - \lambda_i$, $i = 1, \dots, N-1$, and the last eigenvector $\mathbf{u}_N = \mathbf{e}$ with corresponding eigenvalue αN . Therefore,

$$\det \mathbf{A}_\alpha(\mathbf{P}_H) = \alpha N \prod_{i=1}^{N-1} (1 - \lambda_i) = \alpha N^2. \quad \square$$

Remark 4.1. Since $\mathbf{P}\mathbf{e} = \mathbf{e}$, then $\mathbf{P}$ has an eigenvalue with value 1. Let $\lambda_1, \dots, \lambda_{N-1}$ denote the remaining eigenvalues of $\mathbf{P}$ and note that the corresponding eigenvectors may be chosen to be orthogonal to $\mathbf{e}$. Without loss of generality, we can assume that a Hamiltonian cycle is the cycle $1 \rightarrow 2 \rightarrow 3 \rightarrow \cdots \rightarrow N \rightarrow 1$. It follows that $\mathbf{I} - \mathbf{P}_H$ is a nonsingular upper-Hessenberg matrix plus a rank-one modification. Consequently, it can have at most one zero eigenvalue, and it follows that $\mathbf{P}_H$ has only one unit eigenvalue.³

PROPOSITION 4.4. *Let $\mathbf{P} \in \mathcal{D}$ be a Markov chain that contains two or more independent cycles. Then*

$$\det \mathbf{A}_\alpha(\mathbf{P}) = 0, \quad \alpha > 0.$$

Proof. Without loss of generality, assume that the first cycle is $1 \rightarrow 2 \rightarrow \cdots \rightarrow k_1 \rightarrow 1$ and the second is $k_1 + 1 \rightarrow k_1 + 2 \rightarrow \cdots \rightarrow k_1 + k_2 \rightarrow k_1 + 1$. Note that the size of the first cycle is k_1 and that of the second is k_2 .

³This argument avoids the appeal to the celebrated Perron–Frobenius theorem.

Consider the column vector

$$\mathbf{v} = [1, \dots, 1, -\frac{k_1}{k_2}, \dots, -\frac{k_1}{k_2}, 0, \dots, 0],$$

where the first k_1 elements are unity, the next k_2 elements are $-k_1/k_2$, and the last $N - k_1 - k_2$ elements are zeros. Then $\mathbf{I}\mathbf{v} = \mathbf{v}$, $\mathbf{P}\mathbf{v} = \mathbf{v}$, $\mathbf{J}\mathbf{v} = \mathbf{0}$, so $(\mathbf{I} - \mathbf{P} + \alpha\mathbf{J})\mathbf{v} = \mathbf{0}$, and hence

$$\det \mathbf{A}_\alpha(\mathbf{P}) = \det [\mathbf{I} - \mathbf{P} + \alpha\mathbf{J}] = 0. \quad \square$$

PROPOSITION 4.5. *Let $\mathbf{P} \in \mathcal{D}$ be a Markov chain that contains just a single cycle of length $k < N$. Then*

$$\det \mathbf{A}_\alpha(\mathbf{P}) = \alpha k N, \quad \alpha > 0.$$

Proof. Without loss of generality, assume that $\mathbf{P}$ contains the cycle $1 \rightarrow 2 \rightarrow \dots \rightarrow k \rightarrow 1$, and for $i \geq k+1$, $\mathbf{P}_{i,j} = 1$ for one value of j from the set $\{i+1\} \cup \{1, \dots, k\}$, and $\mathbf{P}_{i,l} = 0$ for all $l \neq j$.

Hence $\mathbf{P}$ is a matrix of the generic form

$$(4.1) \quad \left[\begin{array}{ccc|ccc} 0 & 1 & & & & \\ & & \ddots & & & \\ & & & \ddots & & \\ & & & & 1 & \\ 1 & & & & & 0 \\ \hline & & & 1 & & \\ & & & & 0 & 0 \\ & & & & 0 & 1 \\ & & & & & \ddots \\ 1 & & & & & & 0 \end{array} \right].$$

We will present the proof for Proposition 4.5 for two separate cases: $\alpha = \frac{1}{N}$ and $\alpha \neq \frac{1}{N}$.

(i) Consider $\alpha = \frac{1}{N}$. Let $\mathbf{E} = \{\mathbf{e}_i\}$ be the standard basis of $\mathbb{R}^N$ where for each $\mathbf{e}_i$, the i th entry is unity and all other elements are zeros. Consider a new basis $\mathbf{V}$ of $\mathbb{R}^N$ that consists of $\mathbf{v}_1 = \mathbf{e}_2 - \mathbf{e}_1, \dots, \mathbf{v}_{k-1} = \mathbf{e}_k - \mathbf{e}_1$; $\mathbf{v}_k = \mathbf{e}$; $\mathbf{v}_{k+1} = \mathbf{e}_{k+1}, \dots, \mathbf{v}_N = \mathbf{e}_N$.

Let $\mathbf{B} = -\mathbf{P} + \frac{1}{N}\mathbf{J}$. First, we show that vectors $\mathbf{v}_k, \mathbf{v}_{k+1}, \dots, \mathbf{v}_N$ form a basis of $\ker(\mathbf{B}^{N-k+1})$. It is clear that $\mathbf{v}_k = \mathbf{e} \in \ker \mathbf{B}$, and $\mathbf{J}\mathbf{u} = \mu\mathbf{e}$ for any $\mathbf{u} \in \mathbb{R}^N$ and some $\mu \in \mathbb{R}$, since $\text{rank } \mathbf{J} = 1$ and $\mathbf{J}\mathbf{e} = \mathbf{e}$. Therefore, by (4.1)

$$\mathbf{B}\mathbf{v}_{k+1} = -\mathbf{P}\mathbf{e}_{k+1} + \frac{1}{N}\mathbf{J}\mathbf{e}_{k+1} = \frac{1}{N}\mathbf{e},$$

and similarly for $k+2 \leq i \leq N$

$$\mathbf{B}\mathbf{v}_i = \gamma_i \mathbf{v}_{i-1} + \frac{1}{N}\mathbf{e} \quad \text{for } \gamma_i \in \{-1, 0\}.$$

If now we consider $\mathbf{B}^m \mathbf{v}_i$, then (modulo multiple of $\mathbf{e}$) the longest possible chain could be $\mathbf{v}_N \xrightarrow{\mathbf{B}} \mathbf{v}_{N-1} \xrightarrow{\mathbf{B}} \mathbf{v}_{N-2} \xrightarrow{\mathbf{B}} \dots \xrightarrow{\mathbf{B}} \mathbf{v}_{k+1} \xrightarrow{\mathbf{B}} \mathbf{0}$. At the last step any multiple of $\mathbf{e}$ also vanishes. Thus $\mathbf{B}$, restricted to the span of basic vectors $\{\mathbf{v}_k, \dots, \mathbf{v}_N\}$, is a nilpotent

linear operator $\tilde{\mathbf{B}}$, with $\tilde{\mathbf{B}}^{N-k+1} = 0$. Hence, 0 is an eigenvalue of $\mathbf{B}$ of multiplicity at least $N - k + 1$.

Since every $\mathbf{v}_i$, $i = k, \dots, N$, is obviously an eigenvector of $\mathbf{I}$ with eigenvalue 1,

$$\det \mathbf{A}(\mathbf{P}) = \prod_{i=1}^{k-1} (1 - \lambda_i),$$

where λ_i 's are the eigenvalues of the $(k-1) \times (k-1)$ leading principal minor of $\mathbf{B}$ in the $\mathbf{V}$ basis.

It remains to show that $\lambda_1, \dots, \lambda_{k-1}$ coincide with eigenvalues of a $\mathbf{P}_{H_k}$ of the simple cycle of size k with eigenvalue 1 excluded.

Indeed,

$$\mathbf{J}\mathbf{v}_i = 0 \quad \text{for } i = 1, \dots, k-1.$$

Hence,

$$\mathbf{B}\mathbf{v}_1 = -\mathbf{P}(\mathbf{e}_2 - \mathbf{e}_1) = -\mathbf{e}_1 + \mathbf{e}_k + \mathbf{v}_1^*,$$

where $\mathbf{v}_1^* \in \text{span}\{\mathbf{v}_k, \dots, \mathbf{v}_N\}$.

Analogously,

$$\mathbf{B}\mathbf{v}_i = -\mathbf{P}(\mathbf{e}_{i+1} - \mathbf{e}_1) = -\mathbf{e}_i + \mathbf{e}_k + \mathbf{v}_i^*,$$

where $\mathbf{v}_i^* \in \text{span}\{\mathbf{v}_k, \dots, \mathbf{v}_N\}$, $i = 2, \dots, k-1$.

Therefore, we observe that the $(k-1) \times (k-1)$ leading principal minor for $\mathbf{B}$, namely, $[\mathbf{B}]_{k-1}$, is the same as the principal leading minor $[\mathbf{M}]_{k-1}$ of $-\mathbf{P}_{H_k} + \frac{1}{k}\mathbf{J}_k$ if we choose bases $\mathbf{V}$ and $\{\mathbf{e}_1^{(k)} - \mathbf{e}_1, \dots, \mathbf{e}_{k-1}^{(k)} - \mathbf{e}_1, \mathbf{e}_k\}$, respectively, where $\mathbf{J}_k$ is the $k \times k$ matrix of units; $\mathbf{e}_j^{(k)}$ is the j th vector of the standard unit basis of $\mathbb{R}^k$ and $\mathbf{e}^{(k)} = (1, 1, \dots, 1)^T \in \mathbb{R}^k$.

Hence, for $r > 0$, principal minors of powers of $\mathbf{B}^r$ and $\mathbf{M}^r$ coincide and so the eigenvalues $\lambda_1, \dots, \lambda_{k-1}$ of $[\mathbf{B}]_{k-1}$ and of $\mathbf{P}_{H_k}$ (excluding eigenvalue 1) also coincide. For $\mathbf{P}_{H_k}$, according to Proposition 4.3, with $N = k$,

$$\prod_{i=1}^{k-1} (1 - \lambda_i) = k.$$

Therefore,

$$\det \mathbf{A}(\mathbf{P}) = \prod_{i=1}^{k-1} (1 - \lambda_i) = k.$$

(ii) Consider $\alpha \neq \frac{1}{N}$. Let $\mathbf{V}$ be a new basis in $\mathbb{R}^N$ that consists of $\mathbf{v}_1 = \mathbf{e}_2 - \mathbf{e}_1, \dots, \mathbf{v}_{k-1} = \mathbf{e}_k - \mathbf{e}_1$; $\mathbf{v}_k = \mathbf{e}$, $\mathbf{v}_{k+1} = \mathbf{e}_{k+1} + \mu_{k+1}\mathbf{e}, \dots, \mathbf{v}_N = \mathbf{e}_N + \mu_N\mathbf{e}$, where for $1 \leq j \leq N - k$,

$$(4.2) \quad \mu_{k+j} = \begin{cases} \frac{\alpha}{1 - \alpha N} & \text{if } \mathbf{P}_{k+j-1, k+j} = 0, \\ \frac{\alpha + \mu_{k+j-1}}{1 - \alpha N} & \text{if } \mathbf{P}_{k+j-1, k+j} = 1. \end{cases}$$

It follows that $\mathbf{B}_\alpha \mathbf{v}_k = (-1 + \alpha N) \mathbf{v}_k$ and that vectors $\mathbf{v}_{k+1}, \dots, \mathbf{v}_N$ form a basis of $\ker(\mathbf{B}_\alpha^{N-k})$, where $\mathbf{B}_\alpha = -\mathbf{P} + \alpha \mathbf{J}$.

Indeed,

$$\mathbf{B}_\alpha \mathbf{v}_k = (-\mathbf{P} + \alpha \mathbf{J}) \mathbf{e} = -\mathbf{e} + \alpha N \mathbf{e} = (-1 + \alpha N) \mathbf{v}_k.$$

By (4.1) and (4.2)

$$\mathbf{B}_\alpha \mathbf{v}_{k+1} = (-\mathbf{P} + \alpha \mathbf{J}) \left(\mathbf{e}_{k+1} + \frac{\alpha}{1 - \alpha N} \mathbf{e} \right) = \alpha \mathbf{e} - \frac{\alpha}{1 - \alpha N} \mathbf{e} + \frac{\alpha^2 N}{1 - \alpha N} \mathbf{e} = 0,$$

and for $k + 2 \leq i < N$

$$\mathbf{B}_\alpha \mathbf{v}_i = \gamma_i \mathbf{v}_{i-1} \quad \text{for } \gamma_i \in \{-1, 0\}.$$

Thus $\mathbf{B}_\alpha$, restricted to the span of basic vectors $\{\mathbf{v}_{k+1}, \dots, \mathbf{v}_N\}$, is a nilpotent linear operator $\tilde{\mathbf{B}}_\alpha$, with $\tilde{\mathbf{B}}_\alpha^{N-k} = 0$. Hence, 0 is an eigenvalue of $\mathbf{B}_\alpha$ of multiplicity $N - k$. We note that $\mathbf{e}$ is an eigenvector of $\mathbf{A}_\alpha(\mathbf{P})$ with eigenvalue αN and $\mathbf{v}_1, \dots, \mathbf{v}_{k-1} \in \ker(\mathbf{J})$. Hence,

$$\det \mathbf{A}_\alpha(\mathbf{P}) = \alpha N \prod_{i=1}^{k-1} (1 - \lambda_i),$$

where λ_i 's are the eigenvalues of the $(k-1) \times (k-1)$ leading principal minor of $\mathbf{B}_\alpha$.

By an argument completely analogous to that used to establish part (i),

$$\prod_{i=1}^{k-1} (1 - \lambda_i) = k. \quad \square$$

Given a probabilistic solution we show how to obtain a deterministic solution that is at least as good.

PROPOSITION 4.6. *For any $\mathbf{P} \in \mathcal{F}$, there exists $\mathbf{D} \in \mathcal{D}$ such that $\det \mathbf{A}_\alpha(\mathbf{D}) \geq \det \mathbf{A}_\alpha(\mathbf{P})$.*

Proof. Let $\hat{\mathbf{P}} \in \{\arg \max_{\mathbf{P} \in \mathcal{F}} \det \mathbf{A}_\alpha(\mathbf{P})\}$ with minimal total number of randomizations in its rows compared to the other Markov chains in $\{\arg \max_{\mathbf{P} \in \mathcal{F}} \det \mathbf{A}_\alpha(\mathbf{P})\}$. If $\hat{\mathbf{P}} \in \mathcal{D}$, there is nothing to prove.

Suppose $\hat{\mathbf{P}} \notin \mathcal{D}$. Then $\hat{\mathbf{P}}$ contains a row, say row 1, where a randomization occurs. Let this row be $[\dots \ a \ \dots \ b \ \dots \ c \ \dots]$, $0 < a, b, \dots < 1$. Consider a Markov chain $\hat{\mathbf{D}}_\nu \in \mathcal{F}$ that coincides with $\hat{\mathbf{P}}$ in rows $2, \dots, N$ and whose first row is

$$[\dots \ \nu \ \dots \ \frac{(1-\nu)b}{1-a} \ \dots \ \frac{(1-\nu)c}{1-a} \ \dots], \quad 0 \leq \nu \leq 1.$$

Note that $\hat{\mathbf{D}}_{\nu=a} = \hat{\mathbf{P}}$. As $\det \mathbf{A}(\hat{\mathbf{D}}_\nu)$ is a linear function in ν , $\max_{\nu \in [0,1]} \det \mathbf{A}(\hat{\mathbf{D}}_\nu)$ occurs either at $\nu = 0$ or $\nu = 1$, or else $\det \mathbf{A}(\hat{\mathbf{D}}_\nu) = \det \mathbf{A}(\hat{\mathbf{P}})$ for all $\nu \in [0,1]$. In each of these situations, the Markov chain $\hat{\mathbf{D}} = \hat{\mathbf{D}}_{\nu=0}$ or $\hat{\mathbf{D}}_{\nu=1}$ has at least one more zero than $\hat{\mathbf{P}}$, and $\det \mathbf{A}(\hat{\mathbf{D}}) \geq \det \mathbf{A}(\hat{\mathbf{P}})$ so $\hat{\mathbf{D}} \in \{\arg \max_{\mathbf{P} \in \mathcal{F}} \det \mathbf{A}(\mathbf{P})\}$. Thus, by induction on the number of randomizations, the problem is reduced to $\mathbf{P} \in \mathcal{D}$. $\square$

Proof of Theorem 4.1. Propositions 4.3, 4.4, 4.5, and 4.6 complete the proof for Theorem 4.1, which gives an upper bound for $\det \mathbf{A}_\alpha(\mathbf{P})$, $\alpha > 0$. $\square$

Corollary 4.7 states the results specifically for $\alpha = \frac{1}{N}$, showing that for Hamiltonian graphs, this upper bound can only be achieved at Hamiltonian cycles and is larger than the upper bound for non-Hamiltonian graphs.

COROLLARY 4.7.

(i) For any graph G

$$\det_{\mathbf{P} \in \mathcal{F}} \mathbf{A}(\mathbf{P}) \leq N.$$

(ii) If G is a Hamiltonian graph, then

$$(a) \max_{\mathbf{P} \in \mathcal{F}} \det \mathbf{A}(\mathbf{P}) = N,$$

$$(b) \det \mathbf{A}(\mathbf{P}) = N \Leftrightarrow \mathbf{P} = \mathbf{P}_H.$$

(iii) If G is a non-Hamiltonian graph, then $\det_{\mathbf{P} \in \mathcal{F}} \mathbf{A}(\mathbf{P}) \leq N - 1$.

Proof. (i) and (ii.a) These statements follow directly from Theorem 4.1 for $\alpha = \frac{1}{N}$.

(ii.b) Suppose there exists $\mathbf{P} \in \mathcal{F}$ such that $\det \mathbf{A}(\mathbf{P}) = N$ and $\mathbf{P}$ is not a $\mathbf{P}_H$. Then there exists a reduction $\mathbf{P} \rightarrow \mathbf{P}_1 \rightarrow \cdots \rightarrow \mathbf{P}_r \rightarrow \mathbf{D}$ as in Proposition 4.6. Now, because $\det \mathbf{A}(\mathbf{D}) = N$, it follows from Propositions 4.3–4.5 that $\mathbf{D} = \mathbf{P}_H$. In the preceding sequence, at every step, $\det \mathbf{A}(\mathbf{P}_i) = N$, $i = 1, \dots, r$. Consider $\mathbf{P}_r$. Since it is the last step of the reduction, there is exactly one row where a randomization occurs. Let this row be $[\dots \ a \ \dots \ b \ \dots \ c \ \dots]$, $0 < a, b, \dots < 1$, and $\mathbf{P}_H$ has a unity in the place of a .

If we replace the above row with

$$[\dots \ \nu \ \dots \ \frac{(1-\nu)b}{1-a} \ \dots \ \frac{(1-\nu)c}{1-a} \ \dots], \quad 0 \leq \nu \leq 1,$$

$\det \mathbf{A}(\mathbf{P}_r) = N$ for all ν . Set $\nu = 0$. Then the above row becomes

$$[\dots \ 0 \ \dots \ \frac{b}{1-a} \ \dots \ \frac{c}{1-a} \ \dots],$$

and we can further apply the reduction procedure as in Proposition 4.6. This procedure will terminate with a deterministic Markov chain with the same value of $\det \mathbf{A}$, but it is not of the above Hamiltonian form $\mathbf{P}_H$. Since it is a deterministic Markov chain whose $\det \mathbf{A} = N$, it is also a Hamiltonian cycle. So we now have two Hamiltonian cycles sharing exactly $N - 1$ arcs, and this is a contradiction.

(iii) In a non-Hamiltonian graph, the length of the longest possible cycle is $N - 1$. It follows directly from Theorem 4.1 that for any $\mathbf{P} \in \mathcal{F}$, $\det \mathbf{A}(\mathbf{P}) \leq N - 1$. $\square$

To emphasize that the preceding results provide an interesting upper bound for a function of eigenvalues λ_i 's of a stochastic matrix $\mathbf{P} \in \mathcal{F}$, we restate Corollary 4.7 above. Of course, if the graph G is complete, it follows that this upper bound applies to any stochastic matrix.

COROLLARY 4.8. Consider any graph G , and let $\lambda_1, \dots, \lambda_{N-1}, \lambda_N = 1$ be the eigenvalues of $\mathbf{P}$. Then the following hold:

(i) For $\mathbf{P} \in \mathcal{F}$,

$$\prod_{i=1}^{N-1} (1 - \lambda_i) \leq N.$$

(ii) For a Hamiltonian graph G ,

$$\max_{\mathbf{P} \in \mathcal{F}} \prod_{i=1}^{N-1} (1 - \lambda_i) = \max_{\mathbf{P} \in \mathcal{DS}} \prod_{i=1}^{N-1} (1 - \lambda_i) = N.$$

(iii) For a non-Hamiltonian graph G ,

$$\max_{\mathbf{P} \in \mathcal{F}} \prod_{i=1}^{N-1} (1 - \lambda_i) \leq N - 1.$$

Remark 4.2. In [1] and [2], Remark 2.1 was exploited by perturbing probability transition matrices in $\mathcal{F}$ by a small parameter $\varepsilon > 0$ to ensure that all Markov chains are irreducible. Then it was shown that for ε sufficiently small, any Hamiltonian Markov chain $\mathbf{P}_H$ is a global minimizer of the following optimization problem, namely,

$$g_{11}^\varepsilon(\mathbf{P}_H) = \min_{\mathbf{P} \in \mathcal{DS}} [g_{11}^\varepsilon(\mathbf{P})],$$

where $g_{11}^\varepsilon(\mathbf{P})$ is the $(1, 1)$ -element of the fundamental matrix $\mathbf{G}(\mathbf{P})$.

The observation that led to the present paper is that for $\mathbf{P} \in \mathcal{DS}$ the objective function $g_{11}^\varepsilon(\mathbf{P})$ of the above minimization problem is, of course, a ratio of two determinants,

$$(4.3) \quad g_{11}^\varepsilon(\mathbf{P}) = \frac{\text{cof}([\mathbf{A}_\varepsilon(\mathbf{P})]_{11})}{\det \mathbf{A}_\varepsilon(\mathbf{P})},$$

where $\mathbf{A}_\varepsilon(\mathbf{P}) = (\mathbf{I} - \mathbf{P} + \frac{1}{N}\mathbf{J}) = [\mathbf{G}_\varepsilon(\mathbf{P})]^{-1}$, and where $\text{cof}([\mathbf{A}_\varepsilon(\mathbf{P})]_{11})$ is the cofactor of the $(1, 1)$ -element of $\mathbf{A}_\varepsilon(\mathbf{P})$ and $\det \mathbf{A}_\varepsilon(\mathbf{P})$ is its determinant.

Apart from no longer having the need for the ε perturbation, the global minimum of the new problem has a better separation from the next best minimum.

5. Conclusions. We note that the matrix

$$\mathbf{A}_\alpha(\mathbf{P}) = \mathbf{I} - \mathbf{P} + \alpha\mathbf{J}, \quad \alpha > 0,$$

is merely a “rank-one modification” of the generator $\mathbf{P} - \mathbf{I}$ of the Markov chain $\mathbf{P}$. Of course, the case $\alpha = 0$ was considered before but did not yield useful results as $\det[\mathbf{I} - \mathbf{P}] \equiv 0$ for all $\mathbf{P} \in \mathcal{F}$.

Clearly, the preceding results suggest an interesting optimization problem,

$$\max_{\mathbf{P} \in \mathcal{DS}} \det \mathbf{A}_\alpha(\mathbf{P}),$$

the solution of which solves the original Hamiltonian cycle problem. Of course, in the above, the smaller feasible region of doubly stochastic Markov chains $\mathcal{DS}$ was taken instead of $\mathcal{F}$ as all Hamiltonian cycles (if any) induce probability transition matrices in Γ that are doubly stochastic. The numerical tractability of the above nonlinear programming problem is currently being investigated.

Acknowledgment. The authors would like to thank N. Litvak, M. Haythorpe, and A. Eshragh for numerous useful discussions.

ISOMETRIC EMBEDDINGS OF SUBDIVIDED COMPLETE GRAPHS IN THE HYPERCUBE*

LAURENT BEAUDOU[†], SYLVAIN GRAVIER[†], AND KAHINA MESLEM[‡]

Abstract. Isometric subgraphs of hypercubes are known as partial cubes. These graphs have first been investigated by Graham and Pollak [*Bell System Tech. J.*, 50 (1971), pp. 2495–2519] and Djoković [*J. Combinatorial Theory Ser. B*, 14 (1973), pp. 263–267]. Several papers followed with various characterizations of partial cubes. In this paper, it is proven that a subdivision of a complete graph of order n ($n \geq 4$) is a partial cube if and only if it is isomorphic to $S(K_n)$ or there exist $n - 1$ nonsubdivided edges of K_n adjacent to a common vertex in the subdivision and the other edges of K_n are subdivided an odd number of times. As a corollary, we build partial cubes with arbitrary graph as a minor.

Key words. isometric embedding, partial cube, subdivision of a graph

Introduction. Isometric subgraphs of hypercubes are called *partial cubes*. They were first investigated by Graham and Pollak [11] and Djoković [7] in the early 1970s. Later, several algorithmic characterizations were shown, most of them using a relation defined on the set of edges (the Θ relation introduced by Djoković [7] and Winkler [17]). This relation easily led to a recognition algorithm for partial cubes running in $O(mn)$ (m is the number of edges and n the number of vertices). This complexity was then improved for specific classes of graphs by Brešar, Imrich, and Klavžar [2], and recently the general complexity was pulled down to $O(n^2)$ by Eppstein [8].

The search for structural characterizations was motivated by the work of Brešar and Klavžar [3] using subdivided wheels to answer in negative a question of Chepoi and Tardif [6] whether partial cubes are precisely bipartite graphs with convex intervals. Then Gravier, Klavžar, and Mollard [12] characterized the partial cubes that are subdivided wheels (see Theorem 1.1). Until now, only low-density graphs have been considered, so that we decided to study the other side of the problem, namely, high-density graphs, and their best known representatives: complete graphs. This is the starting point of this paper. For more information on partial cubes, see the book [13]. We also mention recent relevant works in [9, 10, 15].

In this paper we prove a conjecture due to Aïder, Gravier, and Meslem [1] which characterizes all the subdivisions of a complete graph K_n that are a partial cube. Either all its edges are subdivided exactly once, or one of the vertices has no incident subdivided edge and all other edges are subdivided an odd number of times. First, using the characterization of partial cubes through expansions over proper covers, it is shown that these graphs are partial cubes. Then, through a case study, it is shown

that there is always a vertex of the complete graph that can be isometrically removed. Thus the result is proven by induction.

1. Preliminary definitions and main result. We consider only finite, simple, loopless, connected, and undirected graphs $G = (V, E)$ where V is the set of vertices and E is the set of edges.

For a graph G , the *distance* $d_G(u, v)$ between vertices u and v is defined as the number of edges on a shortest uv -path (or uv -geodesic). A subgraph H of G is called *isometric* in G if $d_G(u, v) = d_H(u, v)$ for all distinct vertices u and v in $V(H)$.

The vertex set of the n -cube (or *hypercube*) Q_n consists of n -tuples $(b_1, b_2, \dots, b_n)$ with $b_i \in \{0, 1\}$. Two vertices are adjacent in Q_n if the corresponding tuples differ precisely in one place. Q_n is a bipartite graph. A *partial cube* is an isometric subgraph of Q_n . A graph G admits an *isometric embedding* in the hypercube if it is isomorphic to a partial cube and by extension is called partial cube.

By replacing edges of a graph G by paths, we obtain a *subdivided graph* of G . The *subdivision* of a graph G , denoted $S(G)$, is the subdivided graph obtained from G by adding exactly one vertex to each edge of G (see Figure 1.1(b)). A *principal vertex* is a vertex of a subdivided graph of G that was not added during the subdivision (it was already in G). Given S a set of principal vertices of G , we denote by $\langle S \rangle$ the subgraph induced in G by the vertices of S and all the subdivision vertices added between each pair of vertices in S . A vertex v in a subdivided graph of G which is adjacent to all the principal vertices that are its neighbors in G is called *universal* in the subdivided graph of G . It means that all the edges of G incident to v have not been subdivided.

W_k denotes the k -wheel, that is, the graph obtained as a combination of the one vertex graph K_1 and the cycle C_k . We denote the central vertex of W_k by u and the remaining vertices by $w_1, \dots, w_k$. $W_k(m_1, \dots, m_k; n_1, \dots, n_k)$ is the graph obtained by subdividing edges of W_k , where m_i is the number of vertices added on the edge $w_i w_{i+1}$, and n_i the number of vertices added on the inner edge uw_i (see Figure 1.1(a)). Gravier, Klavžar, and Mollard proved the following theorem.

THEOREM 1.1 (see [12]). *Let $k \geq 3$. Then a subdivided k -wheel W is a partial cube if and only if W is isomorphic to $W_k(m_1, \dots, m_k; 0, \dots, 0)$, where m_i is odd for $i = 1, \dots, k$, or $W = W_3(1, 1, 1; 1, 1, 1)$.*

FIG. 1.1.

Let G' be a connected graph. A *proper cover* G'_1, G'_2 consists of two isometric subgraphs G'_1, G'_2 of G' such that $G' = G'_1 \cup G'_2$ and $G'_0 = G'_1 \cap G'_2$ is a nonempty subgraph, called the *intersection* of the cover. Additionally, there are no edges between $G'_1 \setminus G'_2$ and $G'_2 \setminus G'_1$. The *expansion* of G' with respect to the proper cover G'_1, G'_2 is the graph G constructed as follows. Let G_i be an isomorphic copy of G'_i for $i = 1, 2$,

and, for any vertex u' in G'_0 , let u_i be the corresponding vertex in G_i for $i = 1, 2$. Then G is obtained from the disjoint union $G_1 \cup G_2$, where for each u' in G'_0 the vertices u_1 and u_2 are joined by an edge. See Figure 1.2 for a visual explanation.

FIG. 1.2. Expansion through a proper cover.

Chepoi [4] proved that a graph is a partial cube if and only if it can be obtained from K_1 by a sequence of such expansions.

Our aim is to demonstrate the following theorem conjectured in [1].

THEOREM 1.2. *Let G be a subdivided graph of a complete graph K_n ($n \geq 4$). G is a partial cube if and only if G is isomorphic to $S(K_n)$ or G contains a universal vertex u and the number of added vertices to each edge not incident to u in K_n is odd.*

2. Proof of the main result. In this section, we provide the validity of Theorem 1.2. We will use some specific terminology. Let G be a subdivided K_n . We have to note that in our proof, we use only principal vertices. The proof is mostly based on paths joining principal vertices in G . The subdivided edge between x and y , principal vertices of G , is denoted $P(x, y)$. An edge joining two principal vertices in G , x and y , is said to be *plain* (it has not been subdivided). For u a principal vertex of G , we denote by $G \setminus u$ the subdivided graph of K_{n-1} induced by $V(G) \setminus U$, where U consists of vertex u and all nonprincipal vertices lying on subdivided edges between u and other principal vertices. For each x and y principal vertices in G , we say that x sees y , and we denote $x \rightarrow y$ if the subdivided edge joining these vertices in G is geodesic.

Notice that in our figures, a line (resp., a dotted line) represents a geodesic (resp., nonisometric) path between two principal vertices in G . A bold line represents a plain edge. A dashed line represents a subdivided edge with undetermined status.

We first recall several former results.

PROPOSITION 2.1 (see [14]). *For any $n \geq 1$, $S(K_n)$ is a partial cube.*

LEMMA 2.2 (see [1]). *Let G be a subdivided graph of K_n ($n \geq 4$), where each edge in K_n is an isometric path in G . G is a partial cube if and only if G contains a universal vertex and the other edges of K_n have exactly one added vertex or G is isomorphic to $S(K_n)$.*

2.1. Proof of the sufficient condition. With these two results, we are now able to complete the proof of the sufficient condition.

Let $n \geq 4$ and let G be a subdivided graph of K_n isomorphic to $S(K_n)$, or with a universal vertex and all its other edges subdivided an odd number of times. Let us show it is a partial cube.

According to Proposition 2.1, if G is isomorphic to $S(K_n)$, then it is a partial cube. Thus, we just have to prove that if G has a universal vertex u and an odd number of added vertices to each edge of K_n not incident to u , then it is a partial cube.

Let us suppose that G is such a graph. Considering only principal vertices, we can enumerate them from w_1 to w_n and assume that w_n is the universal vertex. For $1 \leq i < j \leq n-1$, let us denote by m_{ij} the number of subdivision vertices added between vertices w_i and w_j . The m_{ij} 's are odd and define all of the graph G . We show that G is a partial cube by induction on $\sum_{1 \leq i < j \leq n-1} m_{ij}$. If $m_{ij} = 1$ for all $1 \leq i < j \leq n-1$, then by Lemma 2.2, G is a partial cube. We can thus assume that $m_{12} \geq 3$. By the induction hypothesis the graph G' which has the same values for the m_{ij} 's but $m'_{12} = m_{12} - 2$ is a partial cube. Let us denote by $w'_1, w'_{1,1}, w'_{1,2}, \dots, w'_{1,m'_{12}}, w'_2$ the vertices (not only principal ones) along the subdivided edge $w'_1 w'_2$ (if $m_{12} = 3$, set $w'_{1,2} = w'_2$). Then G can be obtained from G' by an expansion with respect to the proper cover $G'_1 = \{w'_1, w'_{1,1}, \dots, w'_{1,(m'_{12}+1)/2+1}\}$ and $G'_2 = G' \setminus G'_1 \cup \{w'_1, w'_{1,(m'_{12}+1)/2+1}\}$. Both subgraphs are isometric in G and there is no edge from $G'_1 \setminus G'_2$ to $G'_2 \setminus G'_1$. Hence the sufficient condition is proven.

See Figure 1.2 for an example when $n = 5$ and $m_{12} = 7$.

Remark 2.3. Each expansion adds one dimension to the hypercube of the embedding. As the graph with m_{ij} 's equal to 1 is embedded in Q_{n-1} (see [1]), the graph G can be embedded in the hypercube of dimension $n-1 + (\sum_{1 \leq i < j \leq n-1} (m_{ij} - 1))/2$.

2.2. Proof of the necessary condition. We will proceed by induction. Subdivided graphs of K_4 and K_5 have already been studied in other articles: the theorem holds for K_4 since it is contained in Theorem 1.1 (a 3-wheel is isomorphic to K_4); and for K_5 , we have the following proposition.

PROPOSITION 2.4 (see [1]). *Let G be a subdivided graph of K_5 . G is a partial cube if and only if G is isomorphic to $S(K_5)$ or G contains a universal vertex u and the number of the added vertices to each edge not incident to u in K_5 is odd.*

2.2.1. Useful results. We now demonstrate results to be used for the later proof.

PROPOSITION 2.5. *A geodesic between two principal vertices in G goes through at most 3 principal vertices.*

Proof. For a contradiction, assume that a geodesic path between x and y principal vertices of G goes through at least four principal vertices (x and y included). We now consider the first four principal vertices of this xy -geodesic: x, x_1, x_2 , and x_3 . They induce in G an isometric subgraph (for each pair of vertices in this subgraph, a geodesic is contained in the subgraph) $\langle x, x_1, x_2, x_3 \rangle$ which is a subdivided graph of K_4 (see Figure 2.1(a)). Thus, this subgraph $\langle x, x_1, x_2, x_3 \rangle$ is a partial cube as an isometric subgraph of a partial cube. Then, by Theorem 1.1, either $\langle x, x_1, x_2, x_3 \rangle$ is isomorphic to $S(K_4)$ (impossible since the edge between x and x_3 is subdivided strictly more than once, or the considered path would not be a geodesic) or there is a universal vertex in it. But $P(x, x_2)$ cannot be a plain edge because $d_G(x, x_2) = d_G(x, x_1) + d_G(x_1, x_2) \geq 2$. In addition, $P(x_1, x_3)$ cannot be a plain edge for the same reason, so that there is no universal vertex in this subgraph which is in contradiction with Theorem 1.1. $\square$

From now on, for any x, y , and v principal vertices of G , we will denote $x \xrightarrow{v} y$ if the path along x, v , and y is an xy -geodesic. Therefore, given x and y principal vertices of G , either $x \rightarrow y$ or there exists v principal vertex of G such that $x \xrightarrow{v} y$.

LEMMA 2.6. *If $P(x, y)$ is plain and $y \rightarrow v$, then an xv -geodesic is contained in $\langle x, y, v \rangle$.*

FIG. 2.1.

Proof. For a contradiction let us suppose that $x \xrightarrow{w} v$ for some w principal vertex distinct from x , y , and v , with $x \not\xrightarrow{y} v$ and $x \not\xrightarrow{y} v$. We denote by a the distance between y and v , and by b the distance between x and v (see Figure 2.1(b)). Then we must have $b < a + 1$ (else, $x \xrightarrow{y} v$). Moreover, if $b \leq a - 1$, the sequence y, x, w, v would be a yv -geodesic going through 4 principal vertices, which is impossible by Proposition 2.5. Finally, we have $b = a$ and thus an odd cycle of length $2a + 1$, which is also impossible (partial cubes are bipartite). $\square$

FIG. 2.2.

For any principal vertex u of G , we define two sets K_u and L_u partitioning the remaining principal vertices of G : K_u contains principal vertices x such that $u \rightarrow x$ and L_u contains other principal vertices a (there exists $x \in K_u$ such that $u \xrightarrow{x} a$). We will denote them by K and L when there is no doubt (see Figure 2.2).

DEFINITION 2.7. We define types related to u for the vertices of K_u as follows (see also Figure 2.3):

- x has type $\mathcal{L}$ if there exists y in K_u such that $u \xrightarrow{x} y$.
- x has type $\mathcal{I}$ if there exists y in L_u such that $u \xrightarrow{x} y$.
- x has type $\mathcal{C}$ if there exist y, z in K_u such that $y \xrightarrow{x} z$.
- x has type Λ if there exist y, z in L_u such that $y \xrightarrow{x} z$.
- x has type $\mathcal{R}$ if there exist y in K_u and z in L_u such that $y \xrightarrow{x} z$.

FIG. 2.3.

Remark 2.8. If there is no principal vertex v in G such that $G \setminus v$ is isometric, then for any principal vertex u in G , every vertex of K_u has at least one of these types. Moreover, there is no principal vertex x with only type $\mathcal{L}$ ($u \xrightarrow{x} y$) because $u \rightarrow y$, and $G \setminus x$ would be isometric.

LEMMA 2.9. *If there is no vertex v in G such that $G \setminus v$ is isometric, then for any u in G , no vertex of K_u has type $\mathcal{C}$.*

Proof. Let u be a principal vertex of G . Let us suppose that there exists a vertex x in K with type $\mathcal{C}$: $y \xrightarrow{x} z$, where y and z are in K . The subdivided $K_4 - \langle u, x, y, z \rangle$ —is isometric in G , and thus a partial cube. It is not isomorphic to $S(K_4)$ since $y \xrightarrow{x} z$, so there must be a universal vertex. Neither z nor y is a universal vertex in this subdivided K_4 since $d_G(y, z) \geq 2$. The vertex u is not universal either, otherwise $y \xrightarrow{u} z$. Consequently x is the universal vertex in $\langle u, x, y, z \rangle$, and $P(u, z)$ and $P(u, y)$ are subdivided exactly once.

CLAIM 2.10. *For each vertex t in K distinct from x , y , and z , if y sees t , then $P(x, t)$ is plain.*

Let $t \in K$ be a vertex seen by y , and let us denote $a = d_G(y, t)$. On the one hand, $a - 2 < d_G(u, t) < a + 2$, otherwise a ut -geodesic or a yt -geodesic would go through four principal vertices (forbidden by Proposition 2.5). On the other hand, $d_G(u, t) \notin \{a - 1, a + 1\}$, otherwise $\langle u, y, t, x \rangle$ would contain an odd cycle, and G would not be a partial cube. Then $d_G(u, t) = a$ (see Figure 2.4).

FIG. 2.4.

Consider now an xt -geodesic. It does not go through y , otherwise y would have type $\mathcal{C}$ and thus $P(u, y)$ would be plain, and $\langle y, u, x \rangle$ would be an odd cycle (more precisely a triangle). Consequently, $d_G(x, t) \leq a$. Furthermore, an xt -geodesic has a length at least $a - 1$, otherwise $y \not\rightarrow t$ (a shorter path would exist through x). $d_G(x, t) \neq a$, otherwise $\langle x, t, y \rangle$ would be an odd cycle in G , which is a contradiction. Consequently, $d_G(x, t) = a - 1$. Moreover, we can assume that $x \rightarrow t$, otherwise there would be a yt -geodesic going through four principal vertices of G , which is forbidden by Proposition 2.5. $\langle x, y, t, u \rangle$ is an isometric subdivision of K_4 , which is not isomorphic to $S(K_4)$ ($P(x, y)$ is plain). There must be a universal vertex which can only be x (else, it would lead to triangles). Thus $P(x, t)$ is plain and $a = 2$. Claim 2.10 is proven.

Now, let us consider a type of vertex y in K .

- The vertex y is not of type $\mathcal{C}$, otherwise we would have $P(u, y)$ plain that would lead to a triangle which is forbidden.
- If the vertex y has type $\mathcal{I}$, then there exists a vertex v in L such that $u \xrightarrow{y} v$. An xv -geodesic is contained in $\langle x, y, v \rangle$ by Lemma 2.6. Then the subdivided K_4 , $\langle u, y, x, v \rangle$, is isometric in G and different from $S(K_4)$. The vertices u and v are not universal since $P(u, v)$ is not isometric. The same holds for x , otherwise we would not have $u \xrightarrow{y} v$. y is not universal since $P(u, y)$ is subdivided once; this is a contradiction. Consequently, y is not a vertex of type $\mathcal{I}$.

• Let us show that the vertex y is not of type Λ . If there exist two vertices v and w in L , such that $v \xrightarrow{y} w$, then an xv -geodesic (resp., xw -geodesic) is contained in $\langle x, v, y \rangle$ (resp., $\langle x, w, y \rangle$) thanks to Lemma 2.6. Consequently, the subdivided K_4 , $\langle x, y, v, w \rangle$, is isometric in G and is not isomorphic to $S(K_4)$ (because $v \xrightarrow{y} w$). The vertex v (resp., w) is not universal, otherwise (x, y, v) (resp., (x, y, w)) is a triangle in G . The vertex x is not universal, otherwise $P(v, y)$ and $P(w, y)$ must be subdivided and $v \xrightarrow{y} w$. If y is a universal vertex in $\langle x, y, v, w \rangle$, then the distance between u and v is less than or equal to 3. If it is 3, we would have a uv -geodesic going through u, x, y, v principal vertices, which is forbidden. If it is 2, an odd cycle will arise, which is also forbidden. If it is 1, v would not be in L , which contradicts our hypothesis. Finally, we conclude that y has not the type Λ .

• The vertex y is not of type $\mathcal{R}$. If y has type $\mathcal{R}$, then either $t \xrightarrow{y} v$ or $x \xrightarrow{y} v$, where t is a vertex in K different from x, y , and z (it would give rise to a zv -geodesic going through four principal vertices z, x, y , and v), and v is a vertex in L . In the first case, using Claim 2.10 a tv -geodesic would go through t, x, y, v principal vertices (see Figure 2.5(a)). This is a contradiction. In the second case, we cannot have $u \xrightarrow{y} v$, otherwise y would have type $\mathcal{I}$ treated above. Neither can we have $u \xrightarrow{x} v$ (else, the sequence u, x, y, v would be a geodesic going through four principal vertices). Then there exists t in K such that $u \xrightarrow{t} v$ (see Figure 2.5(b)). Let a be the distance between v and y . We denote by b the distance between u and v . Then $b \leq a + 1$, else we would have $u \xrightarrow{y} v$, which contradicts precedent conclusions (y would have type $\mathcal{I}$). Moreover, $a - 1 \leq b$, else we would have a yv -geodesic going through y, u, t, v principal vertices, which is forbidden. Finally, to avoid an odd cycle, we must have $b = a$. But $d(x, v) = a + 1$, and thus an xv -geodesic goes through x, u, t, v principal vertices. This is forbidden by Proposition 2.5. Therefore, y cannot have type $\mathcal{R}$.

FIG. 2.5.

We conclude that the vertex y has none of the types $\mathcal{C}, \mathcal{I}, \Lambda, \mathcal{R}$. This contradicts Remark 2.8. Consequently, there is no vertex with type $\mathcal{C}$. $\square$

2.2.2. Proof of the induction step. We can now suppose that the partial cube G is a subdivision of K_n with $n \geq 6$. Moreover, by Lemma 2.2 we can assume that G is not isomorphic to $S(K_n)$ and that the theorem holds for any $m < n$.

Case 1. There exists u a principal vertex in G such that $G \setminus u$ is isometric. As $G \setminus u$ is isometric in G which is a partial cube, $G \setminus u$ is also a partial cube. With the induction hypothesis, there exists $x \in G \setminus u$ a universal vertex in $G \setminus u$, or $G \setminus u$ is isomorphic to $S(K_{n-1})$.

We first consider the case when $G \setminus u$ is isomorphic to $S(K_{n-1})$.

• If $u \rightarrow v$ for all $v \in G \setminus u$: As G is not isomorphic to $S(K_n)$ there exists $v \in G \setminus u$ such that $P(u, v)$ is not subdivided exactly once. Let y, z be vertices in $G \setminus \{u, v\}$. Then $\langle u, v, y, z \rangle$ is clearly isometric in G (there are no shorter paths outside from $\langle u, v, y, z \rangle$). Therefore, it is a partial cube, and a subdivided K_4 not isomorphic to $S(K_4)$ since $P(u, v)$ is not subdivided exactly once. Then, by Theorem 1.1, u is the only possible universal vertex in $\langle u, v, y, z \rangle$, and $P(u, v)$, $P(u, y)$, and $P(u, z)$ are plain edges. This is true for any pair of vertices y, z . Therefore, u is a universal vertex in G (see Figure 2.6(a)). Hence, the theorem is proven in this case.

FIG. 2.6.

• If there exists a principal vertex $a \in G$ such that $u \not\rightarrow a$: Let x be a principal vertex of $G \setminus u$ that minimizes $d_G(u, x)$. There exists a principal vertex b such that $b \in G \setminus \{u, a, x\}$ ($n \geq 6$). We can assume that $u \xrightarrow{x} a$, and either $u \rightarrow b$ or $u \xrightarrow{x} b$. These four vertices induce an isometric subgraph of G which is a subdivided graph of K_4 . But $P(u, a)$ is subdivided at least three times (or it would be isometric). Therefore, it neither is isomorphic to $S(K_4)$ nor has a universal vertex (see Figure 2.6(b)). Hence, there is no such case.

We then consider the case when $G \setminus u$ has a universal vertex x .

CLAIM 2.11. x is universal in G .

For this, we consider y and z two principal vertices of G closest to u (distinct from x). Therefore, a uy -geodesic and a uz -geodesic are contained in $\langle x, u, y, z \rangle$. Moreover, as $P(x, y)$ and $P(x, z)$ are plain, a yz -geodesic is contained in $\langle x, y, z \rangle$. In addition, we have either $u \rightarrow x$, or $u \xrightarrow{y} x$. Finally $\langle u, x, y, z \rangle$ is an isometric subdivision of K_4 which is not $S(K_4)$ (there is a plain edge). The only possible universal vertex is x , otherwise there would be odd cycles (more precisely triangles), so that $P(u, x)$ is plain and x is universal in G .

Case 2. For every principal vertex u in G , $G \setminus u$ is not isometric. In this case, we know that there exist three principal vertices u, v_K, v_L such that $u \xrightarrow{v_K} v_L$. We will now denote K for K_u and L for L_u . These are clearly two nonempty sets since $v_K \in K$ and $v_L \in L$.

By Lemma 2.9 there is no vertex with type $\mathcal{C}$ in K .

LEMMA 2.12. There are no vertices x and y in K such that $P(x, u)$ and $P(x, y)$ are both plain.

Proof. Suppose on the contrary that it is possible. Thus, we consider a type of y , which cannot be $\mathcal{C}$ by Lemma 2.9.

y has type $\mathcal{I}$: Then there exists $b \in L$ such that $u \xrightarrow{y} b$. The distance between u and b is then $d(y, b) + 2$. Then the sequence u, x, y, b would also be a ub -geodesic going through four principal vertices. This is forbidden by Proposition 2.5. Thus y cannot be of type $\mathcal{I}$.

FIG. 2.7.

y has type Λ : Then there exist b and c in L such that $b \xrightarrow{y} c$. By Lemma 2.6, we know that an xb -geodesic and an xc -geodesic are contained in $\langle x, y, b, c \rangle$. Then the subdivision of K_4 induced by $\langle x, y, b, c \rangle$ is isometric and distinct from $S(K_4)$ so it has a universal vertex which can either be x or y (else it would lead to a triangle). If x is universal, then $P(b, y)$ and $P(c, y)$ are both subdivided once because they are geodesics (they cannot be plain to avoid triangles; see Figure 2.7(a)). This contradicts $b \xrightarrow{y} c$; there is a shorter path through x . If y is universal (see Figure 2.7(b)), let us suppose $d_G(u, c) = 3$; then u, x, y, c is a uc -geodesic going through four principal vertices, which is impossible by Proposition 2.5; therefore, $d_G(u, c) = 2$ (it cannot be equal to 1 because $c \in L$). The geodesic of length 2 and the walk of length 3 between u and c induce an odd cycle of length 5. We conclude that there is no y with type Λ .

y has type $\mathcal{R}$: Then there exists $b \in L$ and $t \in K$ such that $t \xrightarrow{y} b$.

- If $t = x$, we denote by l the distance between y and b . Then $d_G(x, b) = l + 1$. A ub -geodesic cannot go through x (it would go through four principal vertices, which is forbidden by Proposition 2.5) or y (it would have type $\mathcal{I}$). Therefore, there exists a vertex z in K such that $u \xrightarrow{z} b$; we denote by p the distance between u and b . Then $p > l$, else the sequence x, u, z, b would be a geodesic going through four principal vertices. In addition, $p \leq l + 1$, else we would have $u \xrightarrow{y} b$ and y would have type $\mathcal{I}$. Therefore $p = l + 1$, which is also impossible because it induces an odd cycle going through b, y, u, z of length $2l + 3$ (see Figure 2.8).

FIG. 2.8.

- If $t \neq x$, let l be the distance between y and t . We then consider $d_G(x, t)$, denoted by p (see Figure 2.9). On the one hand, $p \leq l$, else we would have a geodesic path of length $l + 1$ between x and t , going through y , and thus it would have type $\mathcal{C}$, which is forbidden by Lemma 2.9. Furthermore, p is not equal to l since there would be an odd cycle (x, t, y) of length $2l + 1$. On the other hand we know that $p > l - 2$ since $t \rightarrow y$. Hence, $p = l - 1$, which implies that $l \geq 2$ (and hence $P(y, t)$ is not plain). From this we can also conclude that $x \rightarrow t$, because if we had $x \xrightarrow{y} t$,

FIG. 2.9.

the path (y, x, v, t) of length l would then be a geodesic going through four principal vertices, which is impossible (by Proposition 2.5). Finally, $\langle y, x, b, t \rangle$ is isometric in G . It cannot be $S(K_4)$ because $P(x, y)$ is plain, and, as $P(y, t)$ is not plain, x must be the universal vertex in this subgraph. Then x would have type $\mathcal{C}$, which is impossible (by Lemma 2.9).

This means y cannot not have any of the required types. This ends the proof of Lemma 2.12. $\square$

PROPOSITION 2.13. *Each vertex v of L sees exactly one vertex of K .*

Proof. Existence: We just have to consider a uv -geodesic: it goes through K by visiting a vertex x which is seen by v .

Uniqueness: Suppose on the contrary that v sees two distinct vertices x and y of K . We can assume that $u \xrightarrow{x} v$. Furthermore, as it exists we can consider a 4-tuple (a, u, x, y) that realizes the following: $u \xrightarrow{x} a$, $a \rightarrow y$, and $d_G(u, x) + d_G(x, a) + d_G(a, y)$ is minimum for G and u .

CLAIM 2.14. $\langle u, a, x, y \rangle$ is an isometric subdivision of K_4 in G .

FIG. 2.10.

Suppose on the contrary that it is not isometric. There exists a' principal vertex of G distinct from u and a such that $x \xrightarrow{a'} y$. By Lemma 2.9, we can assume that $a' \in L$ (otherwise it would have type $\mathcal{C}$). Moreover, $d_G(u, x) + d_G(x, a') + d_G(a', y) < d_G(u, x) + d_G(x, a) + d_G(a, y)$. As (a, u, x, y) is a minimum for this quantity, it means that ua' -geodesics do not go through x or y . There exists a vertex x' in K distinct from x and y , such that $u \xrightarrow{x'} a'$ (see Figure 2.10). We then have the following: $u \xrightarrow{x'} a'$, $a' \rightarrow y$, and $d_G(u, x') + d_G(x', a') + d_G(a', y) < d_G(u, x) + d_G(x, a) + d_G(a, y)$. This is a contradiction with the assumption that proves our Claim 2.14.

Theorem 1.1 implies that x or y is universal in $\langle x, y, a, u \rangle$ (it cannot be isomorphic to $S(K_4)$ since $u \neq a$). Let us assume x is this universal vertex. Then $P(u, x)$ and $P(x, y)$ are both plain, which is impossible by Lemma 2.12.

We then have proven Proposition 2.13: each vertex v of L sees exactly one vertex x of K . In addition, we have $u \xrightarrow{x} v$, which is the only ua -geodesic. $\square$

We will now prove that $|K| = 1$.

Suppose on the contrary that there exist x and y distinct vertices of K . Both must have a type $\mathcal{R}$, $\mathcal{I}$, or Λ (by Remark 2.8 and Lemma 2.9). Each one of these types implies that both x and y see at least one vertex in L . Let a be a vertex of L such that x sees a . Then we consider a shortest path from a to y . It is not the subdivided edge $P(y, a)$ because of Proposition 2.13. It does not go through x , else $\langle a, y, u, x \rangle$ would induce an isometric subdivision of K_4 and x would be universal: $P(x, u)$ and $P(x, y)$ would then be plain, which is forbidden by Lemma 2.12. So there exists b in L such that $a \xrightarrow{b} y$. As b sees y we can assume that $u \xrightarrow{y} b$ (by Proposition 2.13). We then consider that (x, a, y, b) are the vertices such that $x, y \in K$, $a, b \in L$, $u \xrightarrow{x} a$, $u \xrightarrow{y} b$, and $a \xrightarrow{b} y$, which minimize the quantity $d_G(x, a) + d_G(a, b) + d_G(b, y)$.

CLAIM 2.15. $\langle u, x, y, a, b \rangle$ is isometric.

The only pairs of vertices that could have their geodesics out of the subdivided K_5 , $\langle u, x, y, a, b \rangle$, are (x, y) and (x, b) . Let us consider (x, y) and suppose that $x \xrightarrow{t} y$. Then $t \notin K$, else it would have type $\mathcal{C}$, and $t \notin L$, else it would see two vertices of K (forbidden by Proposition 2.13). Therefore, $t = u$, which is in the subdivided K_5 considered. Consequently, if $\langle u, x, y, a, b \rangle$ is not isometric, then any shortest xb -path does not belong to it. According to Proposition 2.13, the vertex b does not see any other vertex in K than y . Then there exists a vertex a' in L such that $b \xrightarrow{a'} x$. Since x is the unique vertex of K that a' sees (Proposition 2.13), $u \xrightarrow{x} a'$ (see Figure 2.11). Therefore, $u \xrightarrow{x} a'$, $u \xrightarrow{y} b$, and $b \xrightarrow{a'} x$. Furthermore, $d_G(x, a') + d_G(a', b) + d_G(b, y) < d_G(x, a) + d_G(a, b) + d_G(b, y)$, which contradicts the assumption $(d_G(x, a) + d_G(a, b) + d_G(b, y))$ is minimum). Hence, our claim is proven.

FIG. 2.11.

Hence, this subdivision of K_5 is a partial cube, and by Proposition 2.4 it either is isomorphic to $S(K_5)$ or has a universal vertex. It cannot be isomorphic to $S(K_5)$ because $P(u, a)$ would then be a ua -geodesic, and it is not since $a \in L_u$. Hence, it must have a universal vertex which can neither be u (it does not see a), nor a or b (they do not see u), nor x or y (then we would have $P(x, u)$ and $P(x, y)$ plain, which is forbidden by Lemma 2.12). Thus, this subgraph is not a partial cube, which contradicts our hypotheses.

We conclude $|K| = 1$, and then u sees only one vertex in G , which means that no geodesic goes through it. It implies that $G \setminus u$ is isometric. This is in contradiction with the assumption that for every principal vertex u in G , $G \setminus u$ is not isometric.

Hence Theorem 1.2 is proven.

2.3. A corollary. With this theorem we can construct many partial cubes starting from an arbitrary graph.

COROLLARY 2.16. *Let G be a subdivision of a graph of order n such that each edge contains an odd number of added vertices. K is a graph obtained from G by joining a vertex u adjacent to each principal vertex of G . Then K is a partial cube.*

Proof. Let D be the maximum number of subdivision of an edge in G . Then we add edges to obtain a subdivision of K_n . Each added edge is subdivided $2Dn + 1$ times so that the distances between vertices are unchanged. Then, by Theorem 1.2, the graph K' obtained by adding a vertex u adjacent to each principal vertex of G is a partial cube. Consequently we can remove the added edges without changing distances between principal vertices. We obtain that K is a partial cube. $\square$

Remark 2.17. This corollary shows that any minor can be found in a partial cube. Thus there cannot be a characterization of partial cube based upon forbidden minors.

Conclusion. A brief summary of the proof could be the following. We first prove that if a vertex can be removed isometrically, we then have a universal vertex thanks to the induction hypothesis. Then we still have to prove that we can always remove a vertex. We consider that if every vertex is needed, they can be split into two sets L and K such that all the vertices of K have a type among $\mathcal{C}, \Lambda, \mathcal{R}, \mathcal{I}$. We prove that none can have type $\mathcal{C}$. After that, we exhibit an isometric subdivision of K_4 to show that any vertex of L cannot see two vertices of K . We conclude by finding an isometric subdivision of K_5 that cannot have any universal vertex and is distinct from $S(K_5)$.

In the end, we have a structural characterization of every subdivision of complete graphs that are partial cubes.

At this point, one could ask questions with respect to two distinct directions. On the one hand, we could wonder what kind of graphs are isometrically embeddable in powers of K_3 and more generally in Hamming graphs. Our thought is that most of these graphs are also embeddable in hypercubes.

On the other hand, the study of subdivided graphs is a first step toward studying ℓ_1 -graphs (graphs which admit a λ -scale embedding in hypercubes; see [16, 5] for more information about ℓ_1 -graphs).

Acknowledgment. The authors wish to thank the anonymous referee for his precious advise and comments.

OPTIMAL DISTANCE LABELING FOR INTERVAL GRAPHS AND RELATED GRAPH FAMILIES*

CYRIL GAVOILLE[†] AND CHRISTOPHE PAUL[‡]

Abstract. A distance labeling scheme is a distributed graph representation that assigns labels to the vertices and enables answering distance queries between any pair (x, y) of vertices by using only the labels of x and y . This paper presents an optimal distance labeling scheme with labels of $\mathcal{O}(\log n)$ bits for the n -vertex interval graphs family. It improves by $\log n$ factor the best known upper bound of [M. Katz, N. A. Katz, and D. Peleg, *Distance labeling schemes for well-separated graph classes*, in Proceedings of the 17th Annual Symposium on Theoretical Aspects of Computer Science, Lecture Notes in Comput. Sci. 1770, Springer-Verlag, Berlin, 2000, pp. 516–528]. Moreover, the scheme supports constant time distance queries, and if the interval representation of the input graph is given and the intervals are sorted, then the set of labels can be computed in $\mathcal{O}(n)$ time. Our result is tight as we show that the length of any label is at least $3 \log n - \mathcal{O}(\log \log n)$ bits. This lower bound derives from a new estimator of the number of unlabeled n -vertex interval graphs, that is, $2^{\Omega(n \log n)}$. To our knowledge, interval graphs are thereby the first known nontrivial hereditary family with $2^{\Omega(n f(n))}$ unlabeled elements and with a distance labeling scheme with $f(n)$ bit labels.

Key words. graph representation, distance in graphs, distributed data-structure

AMS subject classifications. 05C62, 05C12, 68P30

DOI. 10.1137/050635006

1. Introduction. From an efficient graph representation, we could expect a small amount of memory space and fast elementary routines to answer queries like adjacency (see, e.g., [30] for an overview). Among the classical type of queries, let us mention those arising from the field of communication networks and distributed computing, like routing, connectivity, and distance queries. Peleg [26] introduced the concept of *informative labeling schemes* which generalizes the *implicit graph representation* proposed in [19]. Like classical graph representations, informative labeling schemes have the property of being a distributed data-structure: labels are assigned to the vertices and queries can be answered using only the labels of the involved vertices. Schemes providing compact labels play an important role for localized distributed data-structures (see [14] for a survey).

This paper focuses on the *distance labeling scheme* [27], which, for a graph family $\mathcal{F}$, is a pair $\langle L, f \rangle$ of functions such that for any graph $G = (V, E) \in \mathcal{F}$:

- $L(v, G)$ is a binary label associated with the vertex v in the graph G , and
- for all $x, y \in V$, $f(L(x, G), L(y, G)) = \text{dist}_G(x, y)$, the distance in G between x and y .

A scheme is an $\ell(n)$ -distance labeling if, for every n -vertex graph $G \in \mathcal{F}$, the length of the labels is at most $\ell(n)$ bits. The first results on the distance labeling

scheme [15] show that the family of n -vertex graphs requires $\Theta(n)$ bit labels while n -vertex trees need only $\Theta(\log^2 n)$ bit labels.¹ The case of dynamic tree networks has been studied in [23, 22, 24, 21]. The variant of approximated distance labeling schemes has been considered in [12, 32, 33, 34, 35, 29, 16, 25, 31]. Efficient distance labeling schemes are known for a number of restricted graph families. $\mathcal{O}(\sqrt{n} \log n)$ bit labels are enough for planar graphs, which is not tight with respect to the $\Omega(n^{1/3})$ lower bound [15]. For bounded degree graphs, $\Omega(\sqrt{n})$ is a lower bound on the label length. Finally, $\mathcal{O}(\log^2 n)$ -distance labeling schemes are known for interval and permutation graphs [20], for distance hereditary graphs [13], for bounded tree-width graphs, and, more generally, for bounded clique-width graphs [9].

A trivial observation is that a distance labeling scheme for a family $\mathcal{F}$ requires labels at least as large as labels of an adjacency labeling scheme for $\mathcal{F}$. A first natural question is: (1) *Could it be the same size for a large enough graph family?* As shown in [19], an information-theoretic lower bound coming from the number of n -vertex graphs in the family plays an important role for the label length. The unsolved *implicit graph representation conjecture* of [19] asks whether any hereditary family with $2^{nf(n)}$ graphs of n vertices enjoys an $\mathcal{O}(f(n))$ -adjacency labeling; $\Omega(f(n))$ is a lower bound. Moreover, up to now, none of the hereditary graph families is known to support an $o(\log^2 n)$ -distance labeling scheme.² It should be noticed that among the graph families listed above, the $\Omega(\log^2 n)$ lower bound on label length for n -vertex trees applies to neither interval nor permutation graphs. So the second question is: (2) *Can we improve the $\mathcal{O}(\log^2 n)$ upper bound [20] for either interval or permutation graphs?* This paper positively answers the above questions by considering the family of interval graphs. Interestingly, using some ideas from this paper, [2] positively answers the case of permutation graphs.

A graph $G = (V, E)$ is an *interval graph* (see, e.g., [4]) iff it is the intersection graph of a family $\mathcal{I}$ of intervals on the real line: vertices of V are in bijection with the intervals of $\mathcal{I}$ and two vertices x and y are adjacent iff their intervals $\mathcal{I}(x)$ and $\mathcal{I}(y)$ intersect. $\mathcal{I}$ is a *realizer* of the interval graph G . Obviously storing the bounds of each interval defines an $\mathcal{O}(\log n)$ -adjacency labeling scheme, as it can be shown that all the interval boundaries of $\mathcal{I}$ can be chosen in $\{1, \dots, 2n\}$. A graph is a *proper interval graph* iff it is the intersection graph of an inclusion-free realizer; i.e., none of the intervals of the realizer is contained in another interval.

We show that any $\ell(n)$ -distance labeling on the n -vertex interval graph family requires labels of length $\ell(n) \geq 3 \log n - \mathcal{O}(\log \log n)$ bits. This lower bound derives from a new estimator on the number of interval graphs. We also obtain an asymptotically tight upper bound of $5 \log n + 3$ bits for the label length. To that aim, we reduce any interval graph G to a proper interval graph G' such that the distance in G between any two vertices x, y can be retrieved from the distance in G' and the adjacency in G between x and y . It surprisingly follows that the core of the distance labeling problem of interval graphs consists in the design of a $2 \lceil \log n \rceil$ -distance labeling scheme for proper interval graphs. We also prove that the bound for proper interval graphs is asymptotically tight. Moreover, once the labels have been assigned, the distance computation from the labels takes a constant number of additions and comparisons on $\mathcal{O}(\log n)$ -bit integers. Even more interestingly, if the list of intervals of the graph is

¹In this paper all the logarithms are in base two.

²It is not difficult to construct a family of diameter two graphs whose adjacency can be decided with $\mathcal{O}(\log n)$ bit labels (some bipartite graphs, for instance), so supporting an $\mathcal{O}(\log n)$ distance labeling scheme. However, “diameter two” is not a hereditary property.

given sorted, then the preprocessing step to set all the labels runs optimally in $\mathcal{O}(n)$ time. Our scheme extends to circular-arc graphs.

At this step, it is worth remarking that any $\ell(n)$ -distance labeling scheme on a family $\mathcal{F}$ converts trivially to a nondistributed data-structure for $\mathcal{F}$ of $\mathcal{O}(\ell(n)n/\log n)$ space. The time complexity of distance queries remains unchanged, assuming that a cell of space can store $\Omega(\log n)$ bits of data. Therefore, as a byproduct we can compute in $\mathcal{O}(n)$ time an $\mathcal{O}(n)$ space data-structure for interval graphs supporting constant time distance queries. This latter formulation implies the result of [5]. However, both approaches differ in essence. The technique of [5] consists in building a one-to-one mapping from the vertices of the input graph to the nodes of a rooted tree, say, T . Then, distances are computed as follows. Let $l(v)$ be the level of v in T (i.e., the distance from the root), and let $A(i, v)$ be the i th ancestor of v (i.e., the i th node on the path from v to the root). If $l(x) > l(y) + 1$, then $\text{dist}(x, y) = l(x) - l(y) - 1 + d_1(z, x)$, where $z = A(l(x) - l(y) - 1, x)$, and where $d_1(z, x)$ is the distance between two nodes whose levels differ by at most 1. The distance d_1 is 1, 2, or 3 depending on the interval representation of the involved vertices. Answering a query is mainly based on the efficient parallel implementation of *level ancestor queries* on trees (to compute z) of [3]. However, this clever scheme cannot be converted into a distributed data-structure as ours can be for the following reason. As the tree has to support level ancestor queries, it implies that any node, if represented with a local label, can extract any of its ancestors with its label. In particular, x and y can extract from their label their nearest common ancestor and its level, so x and y can compute their distance in T . By the lower bound of [15], this cannot be done in less than $\Omega(\log^2 n)$ bit labels. So, access to a global data-structure is inherent in the approach of [5].

Section 2 deals with lower bounds. We first show that the number $I(n)$ of n -vertex labeled interval graphs is at least $2^{2n \log n - o(n \log n)}$, which is asymptotically tight. This first bound is then used to prove the lower bound on the length label for any distance labeling scheme of n -vertex interval graphs. A lower bound for proper interval graphs is also given. Section 3 describes a $(5 \log n + 3)$ -distance labeling scheme for interval graphs and its extension to circular-arc graphs. Section 4 deals with the relationship between distance labeling schemes and the notion of universal distance matrix.

2. Lower bounds. This section establishes lower bounds on the label length required to get an exact distance labeling scheme for interval graphs and proper interval graphs. We first prove a lower bound on the number of interval graphs from which, using the technical composition tool of an α -linkable subfamily (introduced in subsection 2.2), we derive the announced lower bounds on distance labeling schemes.

2.1. On the number of interval graphs. Let $I(n)$ be the number of labeled interval graphs with n vertices. Computing $I(n)$ is an unsolved graph-enumeration problem. Cohen, Komlós, and Muller [7] gave the probability $p(n, m)$ that a labeled n -vertex m -edge random graph is an interval graph under conditions on m . They computed $p(n, m)$ for $m < 4$ and showed, more generally, that

$$p(n, m) = \exp\left(-\frac{32c^6}{3}\right), \quad \text{where } \lim_{n \rightarrow +\infty} \frac{m}{n^{5/6}} = c.$$

As the total number of labeled n -vertex m -edge graphs is $\binom{\binom{n}{2}}{m}$, a formula of $p(n, m) \cdot \binom{\binom{n}{2}}{m}$ follows for the number of labeled interval graphs with $m = \Theta(n^{5/6})$ edges. Unfortunately, using this formula results in $I(n) \geq 2^{\Omega(n^{5/6} \log n)} = 2^{o(n)}$, which is a

lower bound too weak for our needs. The exact number of interval graphs is given up to 30 vertices in [17]. Actually, the generating functions for interval and proper interval graphs (labeled and unlabeled) are known [17], but only an asymptotic of $2^{2n+o(n)}$ for unlabeled n -vertex proper interval graphs can be estimated from these equations. In conclusion, Hanlon [17] left open whether the asymptotic on the number of unlabeled interval graphs is $2^{\mathcal{O}(n)}$ or $2^{\Omega(n \log n)}$.

As the number of labeled interval graphs is clearly at least $n! = 2^{(1-o(1))n \log n}$ (just consider a labeled path), the open question of Hanlon is whether $I(n) = 2^{(c-o(1))n \log n}$ for some constant $c > 1$. Hereafter we show that $c = 2$, which is optimal.

THEOREM 1. *The number $I(n)$ of labeled n -vertex interval graphs satisfies $\frac{1}{n} \log I(n) \geq 2 \log n - \log \log n - \mathcal{O}(1)$. It follows that there are $2^{\Omega(n \log n)}$ unlabeled n -vertex interval graphs.*

Proof. There are at least $I(n)/n!$ unlabeled interval graphs. First let us show that the lower bound on $\frac{1}{n} \log I(n)$ stated in Theorem 1 implies that there are $2^{\Omega(n \log n)}$ unlabeled n -vertex interval graphs. Indeed, using the fact that $\log(n!) = n \log n - \Theta(n)$, we have

$$\begin{aligned} \frac{1}{n} \log I(n) &\geq 2 \log n - \log \log n - \mathcal{O}(1) \\ \Rightarrow \log I(n) &\geq 2n \log n - n \log \log n - \mathcal{O}(n) \\ \Rightarrow \log I(n) - \log(n!) &\geq 2n \log n - \log(n!) - n \log \log n - \mathcal{O}(n) \\ \Rightarrow \log(I(n)/n!) &\geq n \log n - n \log \log n - \mathcal{O}(n) \\ \Rightarrow I(n)/n! &\geq 2^{n \log n - o(n \log n)}. \end{aligned}$$

So there are $2^{\Omega(n \log n)}$ unlabeled interval graphs. Let us now prove the lower bound on $I(n)$.

Let $\mathcal{S}_{p,k}$ denote the set of all the sequences $(S_1, \dots, S_p)$ of integer sets such that, for every $i \in \{1, \dots, p\}$, it holds that $|S_i| = k$ and $S_i \subset \{0, \dots, (p-i)(k+1) + k\}$. As there are $\binom{(p-i)(k+1)+k+1}{k}$ ways to choose S_i , it follows that $|\mathcal{S}_{p,k}| = \prod_{i=1}^p \binom{(p-i)(k+1)+k+1}{k} = \prod_{i=1}^p \binom{(p-i+1)(k+1)}{k} = \prod_{i=1}^p \binom{i(k+1)}{k}$.

From every $S = (S_1, \dots, S_p) \in \mathcal{S}_{p,k}$ we construct an interval graph G_S of vertex set $V(G_S) = A \cup B \cup C$ with $A = \{a_{i,j} \mid 1 \leq i \leq p, 1 \leq j \leq k\}$, $B = \{b_0, \dots, b_p\}$, and $C = \{c_1, \dots, c_k\}$. The edge set is defined by the intersection of the intervals associated to each vertex of G_S . For every $v \in V(G_S)$, the interval of v is $\mathcal{I}(v)$ and is defined as follows: for $i \in \{1, \dots, p\}$ and $j \in \{1, \dots, k\}$ (in the following, we denote by $s_{i,j}$ the j th smallest integer of S_i)

- $\mathcal{I}(a_{i,j}) = [(i-1)(k+1) + j, i(k+1) + s_{i,j}]$;
- $\mathcal{I}(b_i) = [i(k+1), i(k+1) + k]$ and $\mathcal{I}(b_0) = [0, k]$; and
- $\mathcal{I}(c_j) = [p(k+1) + j, p(k+1) + j + k]$.

As depicted in Figure 1 (where $p = k = 3$), for each fixed i , the right boundaries of the $a_{i,j}$'s must differ and must fall into the area delimited by the two vertical dotted lines. The intervals associated with the b_i 's and c_j 's are all of length k .

We consider the set $\mathcal{F}_{p,k}$ composed of all labeled graphs G_S obtained for $S \in \mathcal{S}_{p,k}$ and such that b_0 is labeled 1 and c_j is labeled $j+1$ for every $j \in \{1, \dots, k\}$. Clearly, $\mathcal{F}_{p,k}$ is composed of labeled connected interval graphs on $n = (p+1)(k+1)$ vertices. Thus, $I((p+1)(k+1)) \geq |\mathcal{F}_{p,k}|$. We will first show that

$$(1) \quad \forall p, k \geq 1, \quad |\mathcal{F}_{p,k}| = (p(k+1))! \cdot |\mathcal{S}_{p,k}|$$

and then show how to fix $p = p(n)$ and $k = k(n)$ to get the desired lower bound on $I(n)$.

FIG. 1. The interval representation of G_S for $S = (S_1, S_2, S_3)$.

By construction $\mathcal{F}_{p,k}$ contains at most $|\mathcal{S}_{p,k}|$ unlabeled graphs, and each one has at most $(|A| + |B \setminus \{b_0\}|)! = (p(k+1))!$ ways of labeling, since $b_0, c_1, \dots, c_k$ are labeled $1, \dots, k+1$. Hence $|\mathcal{F}_{p,k}| \leq (p(k+1))! |\mathcal{S}_{p,k}|$. To prove equality, we describe hereafter a two-step procedure that from any $G \in \mathcal{F}_{p,k}$ (1) retrieves in a unique way a sequence S such that G is isomorphic to G_S and (2) gives the label sequence of the vertices of G in a given order (for instance, in the increasing order of their left boundary in the interval representation of G_S). These two steps ensure that $|\mathcal{F}_{p,k}| \geq (|A| + |B \setminus \{b_0\}|)! |\mathcal{S}_{p,k}|$.

For that, let us consider any labeled graph $G \in \mathcal{F}_{p,k}$. Let S be a sequence such that G is isomorphic to G_S . (Obviously, at this step, S and the interval representation of G_S are unknown.) We say that a vertex v of G is *identified* if one can decide whether $v = a_{i,j}$ or $v = b_i$ or $v = c_j$ (and then give for each case the corresponding indices i and j). So identifying all the vertices of G completes step (2). As we will see later, identifying a vertex v also allows the recovery of its interval representation and eventually its associated integer $s_{i,j}$, completing step (1) as well.

For every $i \in \{0, \dots, p\}$, let L_i denote the set of vertices of G_S whose left boundary is $\leq i(k+1)$, i.e., at most equal to the left boundary of b_i . To show that all the vertices of G can be identified, it suffices to show that all the vertices of L_p can be identified in G . Indeed, $G_S \setminus L_p$ consists of the vertices of C , and each $c_j \in C$ can be identified in G as its label is $j+1$. So, let us show by induction that all the vertices of L_p can be identified in G .

$L_0 = \{b_0\}$ can be identified in G as its label is 1. Assume that L_{i-1} can be identified, $i > 0$, and let us show how to identify the vertices of L_i . As $L_{i-1} \subset L_i$, we just have to identify $L_i \setminus L_{i-1} = \{a_{i,1}, \dots, a_{i,k}\} \cup \{b_i\}$.

Let $G_i = (G_S \setminus L_{i-1}) \cup \{b_{i-1}\}$. In the graph G_i , we have the following properties that come trivially from the interval definition of G_S :

1. the neighbors of b_{i-1} are $a_{i,1}, \dots, a_{i,k}$;
2. every vertex of $V(G_i) \setminus \{b_{i-1}\} \setminus C$ is of degree $> k$; and
3. the degree of $a_{i,j}$ is $k + j + s_{i,j}$.

Note that by assumption b_{i-1} and L_{i-1} are identified, so the above properties also hold for the graph $(G \setminus L_{i-1}) \cup \{b_{i-1}\}$. Combining properties 1 and 3, the $a_{i,j}$'s can be identified as the degree of $a_{i,j}$'s are distinct and increasing with j . Moreover, as the graph G_{i+1} can be obtained from G_i by removing the identified vertices $b_{i-1}, a_{i,1}, \dots, a_{i,k}$,

it follows (applying properties 1 and 2 to G_{i+1}) that b_i can be identified: it is the only degree k vertex of $G_{i+1} \setminus C$. Thus L_i 's vertices can be identified in G . Therefore, all the vertices of L_p , and thus all the vertices of G , can be identified. This completes step (2).

Recovering the sequence S is easy once $a_{i,j}$'s have been identified in G : it suffices to compute G_i and, by Property 3, to recover $s_{i,j}$ from the degree of $a_{i,j}$. This completes step (1) of the procedure and thus proves equation (1).

Using the fact that $\binom{a}{b} \geq (a/b)^b$, we have

$$|\mathcal{S}_{p,k}| \geq \prod_{i=1}^p \left(\frac{i(k+1)}{k} \right)^k = \left(1 + \frac{1}{k} \right)^{pk} (p!)^k \geq (p!)^k.$$

Thanks to (1) and using the fact that $x! \geq (x/e)^x$, we have

$$|\mathcal{F}_{p,k}| \geq \left(\frac{p(k+1)}{e} \right)^{p(k+1)} \left(\frac{p}{e} \right)^{pk} \geq \left(\frac{p^2 k}{e^2} \right)^{pk}.$$

As $I(n)$ is increasing, for every $n \geq (p+1)(k+1)$ we therefore have

$$\log I(n) \geq \log |\mathcal{F}_{p,k}| \geq 2pk \log p + pk \log k - \mathcal{O}(pk).$$

Let us choose $k = \lfloor \log n \rfloor - 1$ and $p = \lfloor n/\log n \rfloor - 1$ so that $n \geq (p+1)(k+1)$. Observe that $pk \geq n(1 - 4/\log n)$. We have

$$\begin{aligned} \log I(n) &\geq 2pk \log(n/\log n) + pk \log \log n - \mathcal{O}(n) \\ &\geq 2pk \log n - pk \log \log n - \mathcal{O}(n) \\ &\geq 2n(1 - 4/\log n) \log n - n(1 - 4/\log n) \log \log n - \mathcal{O}(n) \\ &\geq 2n \log n - n \log \log n - \mathcal{O}(n). \end{aligned}$$

This ends the proof of Theorem 1. $\square$

Each vertex can be described by its interval representation, and since there are at most $2n$ interval boundaries ranging in $[1, 2n]$, adjacency labels of length $\lceil 2 \log(2n) \rceil$ suffice. Concatenating such labels according to the vertex ordering of the graph yields an upper bound on the number of labeled n -vertex graphs, i.e., $I(n) \leq \lceil 2 \log(2n) \rceil^n \leq 2n \log n + \mathcal{O}(n)$. It follows that $\frac{1}{n} \log I(n) \leq 2 \log n + \mathcal{O}(1)$, and so the lower bound of Theorem 1 on $\frac{1}{n} \log I(n)$ is tight up to an additive factor of $\log \log n$.

2.2. Lower bounds on distance labeling schemes. The *eccentricity* of a vertex x in a graph G is the maximum of the distances between x and any vertex of G . An α -graph, for integer $\alpha \geq 1$, is a graph G having a pair of vertices (l, r) , possibly with $l = r$, each one of eccentricity at most α . Let $\mathcal{S} = (H_0, H_1, \dots, H_k)$ be a sequence of α -graphs, and let (l_i, r_i) denote the pair of vertices that defines the α -graph H_i for $i \in \{0, \dots, k\}$. For each nonnull integer sequence $W = (w_1, \dots, w_k)$, we denote by $\mathcal{S}^W$ the graph obtained by attaching a path of length w_i between the vertices r_{i-1} and l_i for every $i \in \{1, \dots, k\}$ (see Figure 2).

A subfamily $\mathcal{H} \subset \mathcal{F}$ of graphs is α -linkable if $\mathcal{H}$ consists only of α -graphs and if $\mathcal{S}^W \in \mathcal{F}$ for every sequence $\mathcal{S}$ of graphs of $\mathcal{H}$ and for every nonnull integer sequence W .

The following lemma shows a lower bound on the length of the labels required by a distance labeling scheme on any graph family having an α -linkable subfamily. The bound is related to the number of labeled graphs contained in the subfamily. As we

FIG. 2. Linking a sequence of α -graphs.

shall see, interval graphs support a large 1-linkable subfamily (we mean large with respect to n), whereas proper interval graphs support a large 2-linkable subfamily.

LEMMA 1. Let $\mathcal{H}$ be an α -linkable subfamily of a graph family $\mathcal{F}$. Let $H(\nu)$ denote the number of labeled ν -vertex graphs of $\mathcal{H}$. Then, every distance labeling scheme on the family of n -vertex graphs of $\mathcal{F}$ requires a label of length at least $\frac{1}{\nu} \log H(\nu) + \log \nu - 9$, where $\nu = \lfloor n/(\alpha \log n) \rfloor$.

Let us first sketch the proof. It uses a sequence $\mathcal{S}$ of $k = \Theta(\log n)$ graphs H_i taken from an arbitrary α -linkable subfamily $\mathcal{H}$. Each graph H_i has $\nu = \Theta(n/\log n)$ vertices, and consecutive H_i 's from $\mathcal{S}$ are spaced with paths of length $\Theta(n/\log n)$. Intuitively, the term $\frac{1}{\nu} \log H(\nu)$ measures the minimum label length required to compute the distance between any two vertices within the same H_i 's (i.e., whether they are adjacent or at distance at least two). The $\log \nu$ term is required to compute the distance between vertices of distinct H_i 's. The difficulty is to show that some vertices require both pieces of information, observing that one can distribute information on the vertices in a nontrivial way. For instance, the two extreme vertices of a path of length w_i do not require $\log w_i$ bit labels, but only $\frac{1}{2} \log w_i$ bits: each extremity can store one half of the binary word representing w_i and merge their labels for a distance query.

Proof of Lemma 1. Let p, q, k be nonnull integers. Let $\mathcal{W}$ be the set of all the integer sequences $(w_1, \dots, w_k)$ such that $w_i \in \{1 + (j-1)(2\alpha+1) \mid 1 \leq j \leq q\}$. Since a sequence may contain repeated elements, $|\mathcal{W}| = q^k$. Let $\mathcal{H}$ be an arbitrary α -linkable subfamily of $\mathcal{F}$. Let $H(p)$ be the number of labeled p -vertex graphs of $\mathcal{H}$. For every $W \in \mathcal{W}$, we denote by $\mathcal{H}_p(W)$ the set of all graphs $\mathcal{S}^W$ where $\mathcal{S}$ is a sequence of $k+1$ graphs of $\mathcal{H}$, each with exactly p vertices (see Figure 2).

The number of vertices of any graph of $\mathcal{H}_p(W)$ is $(k+1)p + (\sum_{i=1}^k (w_i - 1)) \leq (k+1)p + k(q-1)(2\alpha+1) + 1 \leq (k+1)(p+3\alpha q)$ as $\alpha \geq 1$. Since $\mathcal{H}$ is an α -linkable subfamily of $\mathcal{F}$, any graph $\mathcal{S}^W$ belongs to $\mathcal{F}$, and thus, for every $n \geq (k+1)(p+3\alpha q)$, we get $\bigcup_{W \in \mathcal{W}} \mathcal{H}_p(W) \subseteq \mathcal{F}_n$, where $\mathcal{F}_n$ denotes the family of all n -vertex graphs of $\mathcal{F}$.

Let $\langle L, f \rangle$ be any distance labeling scheme on $\mathcal{F}_n$. We consider the set $\mathcal{L}_W$ of all the $(k+1)$ -tuples of labels for all the graphs $\mathcal{S}^W \in \mathcal{H}_p(W)$, each tuple being formed by taking a vertex label successively in $H_0, H_1, \dots, H_k$. More formally,

$$\begin{aligned} \mathcal{L}_W = & \bigcup_{\substack{\mathcal{S}^W \in \mathcal{H}_p(W) \\ \text{with } H=(H_0, \dots, H_k)}} \{ (L(u_0, H_0), \dots, L(u_k, H_k)) \mid (u_0, \dots, u_k) \\ & \in V(H_0) \times \dots \times V(H_k) \}. \end{aligned}$$

Finally, let $\mathcal{L} = \bigcup_{W \in \mathcal{W}} \mathcal{L}_W$.

CLAIM 1. L assigns on a graph of $\mathcal{F}_n$ a label of length at least $\frac{1}{k+1} \log |\mathcal{L}| - 1$.

Indeed, assume that the length of any label assigned by L on some graph of $\mathcal{F}_n$ is at most t bits. Then, as there are $2^{t+1} - 1$ binary strings of length at most t , there are $(2^{t+1} - 1)^{k+1}$ distinct $(k+1)$ -tuples of such labels. Since $\mathcal{L}$ is a set of $(k+1)$ -tuples, thus $|\mathcal{L}| \leq (2^{t+1} - 1)^{k+1}$, implying that $t \geq \log(|\mathcal{L}|^{1/(k+1)} + 1) - 1 \geq \frac{1}{k+1} \log |\mathcal{L}| - 1$.

CLAIM 2. $|\mathcal{L}_W|^p \geq H(p)^{k+1}$. We can assume each graph $H_j \in \mathcal{S}$ of any $\mathcal{S}^W \in \mathcal{H}_p(W)$ is defined on a copy of the same sorted set of vertices. Therefore, a set L_S of $(k+1)$ -tuples can be associated with each $\mathcal{S}^W$,

$$L_S = \{(L(v_j, H_0), \dots, L(v_j, H_k)) \mid j \in [1, p]\},$$

each $(k+1)$ -tuple being composed by the labels of an arbitrary vertex in each H_i . We have $\bigcup_{\mathcal{S}^W \in \mathcal{H}_p(W)} L_S \subseteq (\mathcal{L}_W)^p$. Let us show that $L_S \neq L_{S'}$ for all $\mathcal{S} \neq \mathcal{S}'$. Indeed, if $\mathcal{S} \neq \mathcal{S}'$, there exist two vertices, say, v_{j_1} and v_{j_2} , adjacent in the i th graph H_i of $\mathcal{S}$ but not adjacent in $H'_i \in \mathcal{S}'$ ($\text{dist}_{\mathcal{S}^W}(v_{j_1}, v_{j_2}) \geq 2$). The distance decoder f must therefore return different values for the corresponding pair of labels, i.e., $f(L(v_{j_1}, H_i), L(v_{j_2}, H_i)) \neq f(L(v_{j_1}, H'_i), L(v_{j_2}, H'_i))$. As both labels, $L(v_{j_1}, H_i)$ and $L(v_{j_1}, H'_i)$ ($L(v_{j_2}, H_i)$ and $L(v_{j_2}, H'_i)$, respectively), are located in the same respective $(k+1)$ -tuple of L_S and $L_{S'}$, $L_S \neq L_{S'}$ follows. It implies that

$$\left| \bigcup_{\mathcal{S}^W \in \mathcal{H}_p(W)} L_S \right| \geq |\mathcal{H}_p(W)|.$$

Since $\mathcal{H}_p(W)$ contains any sequence of $(k+1)$ p -vertex graphs of $\mathcal{H}$, $|\mathcal{H}_p(W)| = H(p)^{k+1}$ ($H(p)$ counting the p -vertex graphs of $\mathcal{H}$). Combining the previous inequalities and inclusions, Claim 2 follows: we have $|\mathcal{L}_W|^p \geq H(p)^{k+1}$.

CLAIM 3. For all distinct $W, W' \in \mathcal{W}$, $\mathcal{L}_W \cap \mathcal{L}_{W'} = \emptyset$.

First observe that if W and W' differ at the i th entry, with $w_i \neq w'_i$, then $[w_i, w_i + 2\alpha] \cap [w'_i, w'_i + 2\alpha] = \emptyset$. Indeed, by construction of the integers of $\mathcal{W}$, $|w_i - w'_i| \geq 2\alpha + 1$. We observe that $f(L(u, H_{i-1}), L(v, H_i)) \in [w_i, w_i + 2\alpha]$ for every $i \in \{1, \dots, k\}$ and for all $(u, v) \in V(H_{i-1}) \times V(H_i)$. Note also that every tuple of labels $T \in \mathcal{L}_W$ contains a label taken from H_{i-1} and a label from H_i . So, as the ranges of distances are disjoint, if W and W' differ by the i th entry, then every element $T \in \mathcal{L}_W$ and every element $T' \in \mathcal{L}_{W'}$ must differ by the $(i-1)$ th or the i th entry, proving the last claim.

From the last two claims and since $|\mathcal{W}| = q^k$, $|\mathcal{L}| \geq \sum_{W \in \mathcal{W}} |\mathcal{L}_W| \geq H(p)^{(k+1)/p} q^k$ holds. From Claim 1, the label length is at least (note that $k/(k+1) \geq 1 - 2/(k+2)$ for $k \geq 1$)

$$t \geq \frac{1}{p} \log H(p) + \frac{k}{k+1} (\log q) - 1 > \frac{1}{p} \log H(p) + \left(1 - \frac{2}{k+2}\right) (\log q) - 1.$$

Let $\nu = \lfloor n/(\alpha \log n) \rfloor$, $p = q = \nu$, and $k = \lfloor \alpha \log n/(1+3\alpha) \rfloor - 1$. We have $n \geq (k+1)(p+3\alpha q)$, as required. So,

$$\begin{aligned} t+1 &\geq \frac{1}{\nu} \log H(\nu) + \left(1 - \frac{2}{\alpha \log n/(1+3\alpha)}\right) \log \nu \\ &\geq \frac{1}{\nu} \log H(\nu) + \log \nu - \frac{2(1+3\alpha)}{\alpha} \frac{\log \nu}{\log n} \\ &\geq \frac{1}{\nu} \log H(\nu) + \log \nu - 8, \quad \text{as } n \geq \nu \text{ and } \alpha \geq 1, \text{ completing the proof.} \quad \square \end{aligned}$$

Let us now show that interval graphs and proper interval graphs both enjoy a large enough α -linkable subfamily of labeled graphs. The lower bounds on distance labeling schemes for these two graph families therefore follow from Lemma 1 and Theorem 1.

THEOREM 2. *Any distance labeling scheme on the family of n -vertex interval graphs requires a label of length at least $3 \log n - 4 \log \log n$.*

Proof. Let $I(\nu)$ be the number of labeled interval graphs with ν vertices. Let $\mathcal{H}$ be that family of labeled ν -vertex interval graphs enjoying a universal vertex (adjacent to any other vertex) where the universal vertex is labeled ν . Any graph of $\mathcal{H}$ is a 1-graph (set the universal vertex as $l = r$). And note that $\mathcal{H}$ is a 1-linkable subfamily of the family of interval graphs (see Figure 3). Moreover, it is straightforward to see that any $(\nu - 1)$ -vertex labeled interval graph is an induced subgraph of some $H \in \mathcal{H}$. It follows that the number $H(\nu)$ of ν -vertex labeled graphs of $\mathcal{H}$ is precisely $I(\nu - 1)$.

FIG. 3. Each H_i is a 1-linkable ν -interval graph with a universal vertex $l_i = r_i$.

By Lemma 1 applied to $\mathcal{H}$ and the interval graph family, the maximum length t of a label of length is at least

$$t \geq \frac{1}{\nu} \log H(\nu) + \log \nu - \mathcal{O}(1) \geq \frac{1}{\nu} \log I(\nu - 1) + \log \nu - \mathcal{O}(1).$$

From Theorem 1, we have

$$\begin{aligned} \frac{1}{\nu} \log I(\nu - 1) &= \frac{\nu - 1}{\nu} (2 \log(\nu - 1) - \log \log(\nu - 1) - \mathcal{O}(1)) \\ &\geq 2 \log(\nu - 1) - \log \log \nu - \mathcal{O}(1). \end{aligned}$$

Since $\mathcal{H}$ is a 1-graph family, we have $\alpha = 1$. Therefore, Lemma 1 sets $\nu = \lfloor n / \log n \rfloor$. This implies that $\nu - 1 \geq \frac{n}{2 \log n}$.

$$\begin{aligned} \frac{1}{\nu} \log I(\nu - 1) &\geq 2 \log \left(\frac{n}{2 \log n} \right) - \log \log \lfloor n / \log n \rfloor - \mathcal{O}(1) \\ &\geq 2 \log n - 3 \log \log n + \log \log \log n - \mathcal{O}(1). \end{aligned}$$

Gathering everything together, we obtain

$$\begin{aligned} t &\geq 2 \log n - 3 \log \log n + \log \log \log n + \log \lfloor n / \log n \rfloor - \mathcal{O}(1) \\ &\geq 3 \log n - 4 \log \log n, \end{aligned}$$

completing the proof. $\square$

THEOREM 3. *Any distance labeling scheme on the family of n -vertex proper interval graphs requires a label of length at least $2 \log n - 2 \log \log n - \mathcal{O}(1)$.*

Proof. Let Q_p be the intersection graph of the interval family $\{\mathcal{I}(x_i) = [i, i + p], \mathcal{I}(y_i) = [i + p, i + 2p - 1], 1 \leq i \leq p\}$. (See Figure 4.) Since any interval is of length p , Q_p is a proper interval graph with $2p$ vertices.

Let $\mathcal{H}$ be the family of labeled graphs isomorphic to Q_p such that the vertices x_1 and y_1 are labeled 1 and 2, respectively. Let $Q \in \mathcal{H}$. It is not difficult to see by

FIG. 4. The graph Q_4 and its interval representation.

induction that once x_i and y_i have been identified in Q , then x_{i+1} and y_{i+1} can be identified, too. It suffices to remove all the vertices $x_1, \dots, x_{i-1}$ and $y_1, \dots, y_{i-1}$ from H (and so to form a graph isomorphic to $Q_{p-(i-1)}$), and observe that in this latter graph (1) x_{i+1} is the neighbor of x_i , distinct from y_i , with minimum degree; and (2) y_{i+1} is the only nonneighbor of x_i that is adjacent to x_{i+1} . Therefore, the cardinality of $\mathcal{H}$ is $(2p-2)!$.

Now, setting $l = x_1$ and $r = y_p$, l and r are both of eccentricity 2, as the vertex x_p is a universal vertex. So $\mathcal{H}$ is a family of 2-graphs. Moreover $\mathcal{H}$ is a 2-linkable subfamily of the proper interval graphs.

Let $\nu = 2p$. The cardinality $H(\nu)$ of $\mathcal{H}$ is $(\nu-2)!$. We note that $\frac{1}{\nu} \log(\nu-2)! \geq \log \nu - \mathcal{O}(1)$. By Lemma 1, for $\alpha = 2$ and $\nu = \lfloor n/(2 \log n) \rfloor$, the length of the maximum label for n -vertex proper interval graphs is at least

$$\frac{1}{\nu} \log H(\nu) + \log \nu - \mathcal{O}(1) \geq \log \nu + \log \nu - \mathcal{O}(1) \geq 2 \log n - 2 \log \log n - \mathcal{O}(1),$$

ending the proof. $\square$

3. Upper bounds on distance labeling schemes. This section deals with optimal distance labeling schemes for proper interval graphs, interval graphs, and circular-arc graphs. We first show how to complete any interval graph G into a proper interval graph G' so that the distance between two vertices x and y in G can be retrieved from the distance in G' and the adjacency in G between x and y . Then, we present a distance labeling scheme for proper interval graphs. This scheme is based on an adjacency labeling scheme of an auxiliary graph. It turns out that the auxiliary graph of any proper interval graph enjoys an optimal adjacency labeling scheme. The $\mathcal{O}(\log n)$ -distance labeling scheme for interval graphs follows. Finally, an extension of this scheme is proposed for the family of circular-arc graphs.

From now on, the input interval graph G is supposed to be an n -vertex connected graph, and $\mathcal{I}$ is given as a realizer. We then denote by $\mathcal{I}(x)$ the interval associated with vertex x and by $L(x)$ and $R(x)$, respectively, the left and the right boundaries of $\mathcal{I}(x)$. As in [5], the intervals of $\mathcal{I}$ are assumed to be sorted according to the left boundaries. We will also assume w.l.o.g. that the left boundaries are pairwise distinct and range in $\{1, \dots, 2n\}$. These hypotheses are not restrictive since in $\mathcal{O}(n)$ time one can scan all the intervals and their boundaries from $\min_x L(x)$ to $\max_x L(x)$ and compute another realizer for G with sorted and distinct boundaries in $\{1, \dots, 2n\}$.

3.1. Reduction to proper interval graphs. Proper interval graphs are interval graphs having an inclusion-free realizer. There are several recognition algorithms that run in linear time, that is, $\mathcal{O}(n + m)$ time, where n is the number of vertices and m the number of edges; cf. [8, 10, 18]. Moreover, these algorithms output an inclusion-free realizer.

It is well known that the family of proper interval graphs can be characterized as the family of $K_{1,3}$ -free³ interval graphs [37] (see Figure 5) or as the family of intersection graphs of a family of unit length intervals [28].

FIG. 5. The $K_{1,3}$ is an interval graph but not a proper interval graph.

Reducing the interval graph to a proper interval graph, the interval realizer we obtain yields a slightly different characterization of proper interval graphs. Such a realizer is called a *proper realizer*.

DEFINITION 1. A realizer $\mathcal{I}$ of an interval graph is proper if for every pair of intervals $\mathcal{I}(x)$ and $\mathcal{I}(y)$ such that $\mathcal{I}(x) \subseteq \mathcal{I}(y)$, $R(x) = R(y)$.

Let us notice that an inclusion-free realizer of intervals is a proper realizer; indeed, only special inclusions are allowed in a proper realizer. The reverse is also true: any interval graph having a proper realizer is $K_{1,3}$, i.e., is a proper interval graph. Let $\mathcal{I}$ be a proper realizer of an interval graph G . Assume by contradiction that G contains a set of four vertices that induces a $K_{1,3}$; say, a, b, c are three independent vertices adjacent to a common neighbor x . W.l.o.g. assume that $L(a) < R(a) < L(b) < R(b) < L(c) < R(c)$. It follows that $L(x) \leq R(a)$ and $L(c) \leq R(x)$. Thereby we have $\mathcal{I}(b) \subset \mathcal{I}(x)$ and $R(b) \neq R(x)$, which is a contradiction; the realizer $\mathcal{I}$ is supposed to be proper.

Our reduction is based on the notion of an *enclosing neighbor*.

DEFINITION 2. Let $\mathcal{I}$ be a nonproper realizer of an interval graph $G = (V, E)$. Let $x \in V$ such that $\mathcal{I}(x) \subset \mathcal{I}(y)$ and $R(x) < R(y)$ for some vertex y . The enclosing neighbor of x , denoted by $N_e(x)$, is a neighbor of x for which $\mathcal{I}(x) \subset \mathcal{I}(N_e(x))$ such that the following conditions are satisfied:

- $R(N_e(x))$ is maximal, and
- $\mathcal{I}(N_e(x))$ is maximal for the inclusion.

As the left boundaries of $\mathcal{I}$ are pairwise disjoint, the enclosing neighbor, if it exists, is unique for every vertex. From a realizer $\mathcal{I}$, we can construct a proper realizer $\mathcal{I}'$ as follows: if x has an enclosing neighbor, then we set $\mathcal{I}'(x) = [L'(x) = L(x), R'(x) = R(N_e(x))]$, and we set $\mathcal{I}'(x) = \mathcal{I}(x)$ otherwise.

Let us remark that

1. $R'(x) \geq R(x)$;
2. by maximality of its right boundary $\mathcal{I}(N_e(x)) = \mathcal{I}'(N_e(x))$; and
3. G is a subgraph of $G' = (V, E' \subseteq E)$, the graph realized by $\mathcal{I}'$.

We say that a vertex x has been *extended* in G' if $R'(x) > R(x)$.

LEMMA 2. The realizer $\mathcal{I}'$ is proper. It can be computed from $\mathcal{I}$ in $\mathcal{O}(n)$ time.

³That is, the graph does not contain a $K_{1,3}$ graph as an induced subgraph.

Proof. Assume there is a pair of vertices u and v such that $\mathcal{I}'(u) \subset \mathcal{I}'(v)$ and $R'(u) < R'(v)$. W.l.o.g. assume that $\mathcal{I}'(v)$ is maximal for inclusion. Notice that $R(v) = R'(v)$; otherwise v would have an enclosing neighbor w that would imply $\mathcal{I}'(v) \subset \mathcal{I}'(w)$, contradicting the maximality of v . As $R(u) \leq R'(u)$, we have $L(v) < L(u) < R(u) < R'(v)$. Now, $R(v) = R'(v)$ implies $\mathcal{I}(u) \subset \mathcal{I}(v)$, meaning that u has an enclosing neighbor. It follows that $R'(u) \geq R(v) = R'(v)$, contradicting $R'(u) < R'(v)$. So we proved that for any pair of vertices u and v such that $\mathcal{I}'(u) \subset \mathcal{I}'(v)$, we have $R'(u) = R'(v)$; thereby $\mathcal{I}'$ is proper.

The realizer $\mathcal{I}'$ can be computed as follows: scan the intervals of $\mathcal{I}$ according to their left boundary ordering and output the ordered set of vertices $S = \{x_1, \dots, x_i, \dots\}$ so that x_{i+1} has minimum left boundary among $\{x \mid L(x_i) < L(x) \text{ and } R(x_i) < R(x)\}$. Now for any vertex $v \notin S$, its enclosed neighbor is the maximum $x_i \in S$ such that $L(x_i) < L(v)$. Two scans of the vertices suffice to compute those enclosed neighbors. As by construction the vertices of S are maximal for the inclusion, they do not have enclosed neighbors. It follows that computing $\mathcal{I}'$ requires only $\mathcal{O}(n)$ time. $\square$

The main result of this subsection shows that distances in G can be retrieved from the distances in G' whose realizer $\mathcal{I}'$ is proper. To prove Theorem 4, the lemma below is required.

LEMMA 3. *If x and y are two vertices such that $R(x) = R'(x) \leq R(y)$, then $\text{dist}_G(x, y) = \text{dist}_{G'}(x, y)$.*

Proof. Let us first remark that since G is a subgraph of G' , then $\text{dist}_G(x, y) \geq \text{dist}_{G'}(x, y)$. So assume that $\text{dist}_G(x, y) = k > 1$. Let us first remark that any path of G' that does not use any extended vertex is also a path of G . Let $P = [x = u_0, u_1, \dots, u_j, \dots, u_k = y]$ be a shortest x, y -path in G' using a minimum number of extended vertices. Assume there exists some $j > 0$ such that u_j has been extended (i.e., $\mathcal{I}(u_j) \neq \mathcal{I}'(u_j)$) and choose j minimum. By assumption $\mathcal{I}(u_{j-1}) = \mathcal{I}'(u_{j-1})$ holds and implies that u_{j-1} and u_j are adjacent in G . Since $\mathcal{I}(u_j) \subset \mathcal{I}(N_e(u_j))$, substituting in P vertex u_j by vertex $N_e(u_j)$ yields a shortest x, y -path P' in G' using fewer extended vertices than P , which is a contradiction; P does not contain any extended vertex. $\square$

DEFINITION 3. *For any vertex x , the maximum neighbor of x , denoted by $N_m(x)$, is a neighbor of x such that $R(N_m(x))$ is maximum.*

Like enclosing neighbors, maximum neighbors are not extended in G' ; i.e., for any x , $R'(N_m(x)) = R(N_m(x))$. Otherwise we would have $\mathcal{I}(N_m(x)) \subset \mathcal{I}(v)$ for some vertex v and $R(N_m(x)) < R(v)$. Since $\mathcal{I}(x) \cap \mathcal{I}(N_m(x)) \neq \emptyset$, we also have $\mathcal{I}(x) \cap \mathcal{I}(v) \neq \emptyset$. Since $R(N_m(x)) < R(v)$, by definition, we should have $v = N_m(x)$, which is a contradiction.

Let us define $\text{adj}_G(x, y)$ as 1 if x and y are adjacent in G and as 0 otherwise.

THEOREM 4. *Let x and y be two vertices such that $R(x) \leq R(y)$. Then,*

$$(2) \quad \text{dist}_G(x, y) = \text{dist}_{G'}(N_m(x), y) + 1 - \text{adj}_G(x, y).$$

Proof. If x and y are adjacent, then $N_m(x)$ and y are also adjacent in both G and G' ; therefore, the result holds. So assume that x and y are not adjacent. Since $N_m(x)$ has not been extended in G' , by Lemma 3, $\text{dist}_{G'}(N_m(x), y) = \text{dist}_G(N_m(x), y)$. So we have to prove that $\text{dist}_G(x, y) = 1 + \text{dist}_G(N_m(x), y)$.

Let us first remark that $\text{dist}_G(N_m(x), y) \leq \text{dist}_G(x, y)$ since $R(x) < L(y)$ and $R(x) < R(N_m(x))$. The only case to be considered is $\text{dist}_G(N_m(x), y) = k > 1$. Let $P = [N_m(x), v_1, \dots, v_{k-1}, y]$ be a shortest $N_m(x), y$ -path. Let us assume that

$\text{dist}_G(x, y) = k$, then there exists a path $Q = [x, u_1, u_2, \dots, u_{k-1}, y]$ of length k . By definition of $N_m(x)$, we have $R(u_1) < R(N_m(x))$. It implies that $N_m(x)$ is adjacent to u_2 ; therefore, $[N_m(x), u_2, \dots, u_{k-1}, y]$ is a path of length $k - 1$, which is a contradiction. $\square$

Given a distance labeling scheme of a proper interval graph, (2) directly describes the decoder function of a distance labeling scheme for the family of interval graphs. The label $L(x, G)$ of each vertex should contain

- $R(x)$ and $L(x)$, the boundaries of $\mathcal{I}(x)$ that enable us to test $\text{adj}_G(x, y)$; and
- $L'(x, G')$ and $L'(N_m(x), G')$, the labels of x and $N_m(x)$ in the distance labeling scheme of the proper interval graph G' that enable us to compute $\text{dist}_{G'}(x, y)$.

COROLLARY 1. *If there exists a distance labeling scheme for n -vertex proper interval graphs using labels of length $s(n)$, then the n -vertex interval graph family enjoys a distance labeling scheme using labels of length $2 \lceil \log(2n) \rceil + 2s(n)$.*

3.2. Distance labeling scheme of proper interval graphs. Let us now assume that a proper realizer $\mathcal{I}$ for a graph $G = (V, E)$ is given (so G is a proper interval graph). Let x_0 be the vertex with the minimum left boundary. Notice that x_0 also has a minimum right boundary. We define the *layer partition* $V_0, V_1, \dots, V_k$ (see Figure 6) as the partition of vertices into distance layers from x_0 :

$$\forall i \geq 0, \quad V_i = \{v \mid \text{dist}_G(x_0, v) = i\}.$$

FIG. 6. A proper interval graph with an interval representation and the associated layer partition.

Given the sorted list of intervals, the layer partition can be computed in $\mathcal{O}(n)$ time. Let $\lambda(x)$ denote the unique index i such that $x \in V_i$. Let H be the digraph on the vertex set V composed of all the arcs xy such that $\lambda(x) < \lambda(y)$ and $(x, y) \in E$. Note that H is acyclic.

CLAIM 4. *The transitive closure H^t of H is a poset (partially ordered set).*

Let $\text{adj}_{H^t}(x, y)$ be the boolean function such that

$$\text{adj}_{H^t}(x, y) = 1 \text{ iff } xy \text{ is an arc of } H^t.$$

Notice that since H^t is a digraph, $\text{adj}_{H^t}(x, y) = 1$ implies that $\text{adj}_{H^t}(y, x) = 0$. Also by definition of H^t , if $\text{adj}_{H^t}(x, y) = 1$, then $\lambda(x) < \lambda(y)$ holds.

THEOREM 5. *For all distinct vertices x and y such that $\lambda(x) \leq \lambda(y)$,*

$$(3) \quad \text{dist}_G(x, y) = \lambda(y) - \lambda(x) + 1 - \text{adj}_{H^t}(x, y).$$

To prove Theorem 5, we need the following preliminary result.

LEMMA 4. *For all $i \geq 1$, let x_{i-1} be the vertex of V_{i-1} having maximum right boundary.⁴ Then $\{x_{i-1}\} \cup V_i$ is a clique of G .*

Proof. Let us first show that x_{i-1} dominates V_i . It holds for $i = 1$ by definition of the layer partition. Let us consider the case for larger i . First any vertex $v \in V_i$ has a neighbor in V_{i-1} and x_{i-1} has a maximum right boundary among V_{i-1} 's vertices. This implies that $L(x_{i-1}) < L(v) < R(x_{i-1})$; in other words, v neighbors x_{i-1} .

Let us show now that V_i induces a clique. Since $V_0 = \{x_0\}$, for any vertex $v \in V_1$, $\mathcal{I}(v)$ contains $R(x_0)$; both V_0 and V_1 are cliques. For larger i , we already proved that any $v \in V_i$ satisfies $L(x_{i-1}) < L(v) < R(x_{i-1})$. Since the realizer of G is assumed to be proper, we also have $L(v) < R(x_{i-1}) \leq R(v)$. Therefore, for any $v \in V_i$, $\mathcal{I}(v)$ contains $R(x_{i-1})$. This implies that V_i is a clique. $\square$

Proof of Theorem 5. Let x and y be two vertices such that $\lambda(x) = i$ and $\lambda(y) = i + h$ with $h \geq 0$. It is obvious that $h \leq \text{dist}_G(x, y)$. Note that by definition of the layer partition, the statement holds for $i = 0$.

Let us consider $i > 0$. Lemma 4 implies the result in cases $h = 0$ and $h = 1$. So assume the statement holds for $h - 1 \geq 0$, and let us prove it for h . By Lemma 4, x is adjacent to x_i and x_{i+h-1} is adjacent to y . Therefore, $[x, x_i, \dots, x_{i+h-1}, y]$ is a path of length $h + 1$ and $\text{dist}_G(x, y) \leq \lambda(y) - \lambda(x) + 1$. Inequality holds iff x is adjacent to some vertex $z \in V_{i+1}$ such that $\text{dist}_G(z, y) = h - 1$. In that case, we have $\text{adj}_{H^t}(x, z) = 1$, and, by induction, hypothesis $\text{adj}_{H^t}(z, y) = 1$ holds. Since H^t is transitive, $\text{dist}_G(x, y) = h$ iff $\text{adj}_{H^t}(x, y) = 1$. This ends the proof. $\square$

Therefore, to compute the distance between any pair of vertices, we have to test whether $\text{adj}_{H^t}(x, y) = 1$. For this reason H^t can be considered as the *graph of errors* associated with the layer partition. Let us now prove that in H^t the adjacency can be encoded using short labels (namely, $2 \log n$ bits labels).

THEOREM 6. *There exists a total ordering π of the vertices such that*

$$(4) \quad \text{adj}_{H^t}(x, y) = 1 \text{ iff } \lambda(x) < \lambda(y) \text{ and } \pi(y) < \pi(x).$$

Moreover, given H^t and $\mathcal{I}$, the ordering π can be computed in $\mathcal{O}(n)$ time.

Proof. We first claim that such an ordering π is obtained by an elimination ordering of the vertices such that at each step, the sink of the subgraph of H induced by the noneliminated vertices that has a minimum left bound is removed. This can be implemented by using a depth-first search of H : the ordering π is the postorder traversal of the search (i.e., the order in which the vertices have been removed from the LIFO-stack).

In the example in Figure 6, we obtain the following ordering:

$$\pi = 9, 6, 4, 2, 10, 7, 11, 8, 5, 3, 1.$$

It is easy to check that if $\text{adj}_{H^t}(x, y) = 1$, then $\lambda(x) < \lambda(y)$ and $\pi(y) < \pi(x)$. So assume that $\text{adj}_{H^t}(x, y) = 0$ and $\lambda(x) < \lambda(y)$ (which implies $L(x) < L(y)$).

⁴For $i > 0$, x_i is the maximum neighbor of x_{i-1} and $x_0 \in V_0$.

CLAIM 5. *Let z be a vertex such that $\lambda(y) < \lambda(z)$. If $\text{adj}_{H^t}(x, z) = 1$, then $\text{adj}_{H^t}(y, z) = 1$.*

Since $\text{adj}_{H^t}(x, z) = 1$, the graph G contains a x, z -shortest path of length $\lambda(z) - \lambda(x)$. Let $P = [x, \dots, v_{\lambda(y)-1}, v_{\lambda(y)}, v_{\lambda(y)+1}, \dots, z]$ be such a path with $v_i \in V_i$ for $i \in \{\lambda(y) - 1, \lambda(y), \lambda(y) + 1\}$ and possibly $x = v_{\lambda(y)-1}$ and $z = v_{\lambda(y)+1}$. Note that $\text{adj}_{H^t}(x, y) = 0$ implies that $\text{adj}_{H^t}(v_{\lambda(y)-1}, y) = 0$. It follows that $v_{\lambda(y)-1}$ and y are nonadjacent in G . Now if $\text{adj}_{H^t}(y, z) = 0$, it similarly implies that $\text{adj}_{H^t}(y, v_{\lambda(y)+1}) = 0$, and thus y and $v_{\lambda(y)+1}$ are also nonadjacent vertices of G . As P is a shortest path, $v_{\lambda(y)-1}$ and $v_{\lambda(y)+1}$ are nonadjacent in G . As by construction $\lambda(v_{\lambda(y)}) = \lambda(y)$, y is adjacent in G to $\lambda(v_{\lambda(y)})$. It follows that in G the set of vertices $\{y, v_{\lambda(y)-1}, v_{\lambda(y)}, v_{\lambda(y)+1}\}$ induce a $K_{1,3}$, which is a contradiction; G is a proper interval graph. Claim 5 follows: if $\text{adj}_{H^t}(x, z) = 1$, then $\text{adj}_{H^t}(y, z) = 1$.

Note also that at the step when y becomes a sink, there remains no vertex z such that $\lambda(y) < \lambda(z)$ and $\text{adj}_{H^t}(x, z) = 1$. If x is also a sink, since $L(x) < L(y)$, the priority rule implies $\pi(x) < \pi(y)$, and we are done. So assume x is not a sink. Therefore, there exists z such that $\text{adj}_{H^t}(x, z) = 1$. By Claim 5, z satisfies $\lambda(z) \leq \lambda(y)$. Moreover, we show that $L(z) < L(y)$. Otherwise z and y would both belong to $V_{\lambda(y)}$, and a shortest path of length $\lambda(y) - \lambda(x)$ between x and z would imply a shortest path of the same length between x and y , contradicting $\text{adj}_{H^t}(x, y) = 0$. Finally, both z and y are sinks, but $L(z) < L(y)$ implies that z is eliminated before y . Recursively applying this argument enables us to prove that x will be eliminated before y by the algorithm, and so $\pi(x) < \pi(y)$.

Let us now analyze the time complexity of the computation of the π ordering. Notice that the digraph H can be stored in $\mathcal{O}(n)$ space. The set of vertices is sorted in an array with respect to the left boundary of their interval. Since the layers and also the neighborhood in H of any vertex appear consecutively in this array, each vertex can be associated with its first and last neighbor in the array. The priority rule implies that when a vertex v is popped by the algorithm, any vertex $u \in V_{\lambda(v)}$ such that $L(u) < L(v)$ has already been popped. Assuming that the layer of any vertex is stored and that for each layer, the index of the last popped vertex is maintained, the next vertex to be pushed can be found in $\mathcal{O}(1)$. Therefore, π can be computed in $\mathcal{O}(n)$ time. $\square$

In passing, let us point out an interesting combinatorial property of poset H^t . The *dimension* of a poset P on a set V is the minimum number d of total orders $\rho_1, \dots, \rho_d$ on V such that $x <_P y$ iff $x <_{\rho_i} y$ for every i [11, 36]. By choosing $\rho_1 = \pi$ and ρ_2 as any linear extension of λ , Theorem 6 immediately implies the following corollary.

COROLLARY 2. *H^t is a poset of dimension two.*

We now have the material to define the distance labeling scheme for proper interval graphs. To each vertex x of G , we assign the label $L(x, G) = \langle \lambda(x), \pi(x) \rangle$. The distance decoder is given by (3) and (4). Clearly, $\lambda(x), \pi(x) \in \{1, \dots, n\}$, so the main result follows.

THEOREM 7. *The family of n -vertex proper interval graphs enjoys a distance labeling scheme using labels of length $2 \lceil \log n \rceil$, and the distance decoder has constant time complexity. Moreover, given the sorted list of intervals, all the labels can be computed in $\mathcal{O}(n)$ time.*

3.3. Optimized distance labeling scheme for interval graphs. According to Corollary 1 and Theorem 7, the family of interval graphs enjoys a $(6 \log n + \mathcal{O}(1))$ -distance labeling scheme with constant time decoder. We shall see that these labels can be compacted to $5 \log n + \mathcal{O}(1)$ bits. Let us recall that for any vertex x of an

interval graph G , we have to know $R(x)$ and $L(x)$, the boundaries of the interval $\mathcal{I}(x)$, plus the labels of x and $N_m(x)$ in the extended proper interval graph G' .

The improvement is based on the observation that $\lambda(x)$ and $\lambda(N_m(x))$ differ at most by one ($\lambda(N_m(x)) - \lambda(x) \in \{0, 1\}$). Indeed, there is no edge in G between a pair of vertices that does not belong to the same distance layer or consecutive distance layers. Therefore, a single bit, say, $b(x)$, suffices to recover $\lambda(N_m(x))$ from $\lambda(x)$. Therefore, the label of a vertex x can be defined as follows:

$$L(x, G) = \langle L(x), R(x), \lambda(x), \pi(x), b(x), \pi(N_m(x)) \rangle.$$

As $1 \leq L(x) < R(x) \leq 2n$, so $2 \lceil \log n \rceil + 2$ bits suffice to store the first two integers. The next four components can be stored with $3 \lceil \log n \rceil + 1$ bits, summing up to $5 \lceil \log n \rceil + 3$. Thus, we have the following theorem.

THEOREM 8. *The family of n -vertex interval graphs enjoys a distance labeling scheme using labels of length $5 \lceil \log n \rceil + 3$, and the distance decoder has constant time complexity. Moreover, given the sorted list of intervals, all the labels can be computed in $\mathcal{O}(n)$ time.*

Proof. We have already discussed the length of the labels. The distance decoder takes a constant time. Concerning the time complexity of constructing all the labels, let us first observe that in $\mathcal{O}(n)$ time one can compute $N_m(x)$ for each x as follows: Since $\mathcal{I}'$ is proper, a maximum neighbor of a given vertex x is precisely the vertex y with maximum left boundary satisfying $L(y) \leq R(x)$. Since we made the assumption that the intervals have been given sorted with respect to their left boundaries, a single scan enables us to compute the maximum neighbor of each vertex.

Since the distance labels in proper interval graphs can be computed in $\mathcal{O}(n)$ time, and since G' can be obtained within the same complexity, all the labels of G can be computed in $\mathcal{O}(n)$ time. $\square$

3.4. A scheme for circular-arc graphs. Circular-arc graphs are a natural generalization of interval graphs in which vertices are mapped to arcs of a circle rather than intervals on the real line. This section shows that the distance labeling scheme problem for circular-arc graphs reduces to the interval graphs case. Consider a circular-arc graph G . We can associate with every vertex x of G a range $I(x) = [\theta_l(x), \theta_r(x)]$ of angles where $\theta_l(x)$ and $\theta_r(x)$ are taken clockwise in $[0, 2\pi)$. The range $I(x)$ can be seen as a “cyclic” interval in which $[\theta_l(x), \theta_r(x)]$ for $\theta_l(x) > \theta_r(x)$ stands for $[\theta_l(x), 2\pi) \cup [0, \theta_r(x)]$. The vertices x and y are adjacent if $I(x) \cap I(y) \neq \emptyset$. See an example in Figure 7.

A neighbor y of x is a *right neighbor* (resp., *left neighbor*) iff $\theta_l(y) \in I(x)$ and $\theta_r(y) \notin I(x)$ (resp., $\theta_l(y) \notin I(x)$ and $\theta_r(y) \in I(x)$). Notice that some neighbor of x may be neither a right nor a left neighbor. A path $x_0, x_1, \dots, x_k$ is a *right-path* from x_0 to x_k if, for every $i \in \{0, \dots, k-1\}$, x_{i+1} is a right neighbor of x_i . Intuitively, a right-path is obtained starting from x_0 and successively clockwise encountering the vertices $x_1, \dots, x_k$.

LEMMA 5. *Every shortest path between nonadjacent vertices x and y is either a right-path from x to y or a right-path from y to x .*

Proof. Assume that $P = [x = x_0, x_1, \dots, x_k = y]$ is a shortest path from x to y but is neither a right-path from x_0 to x_k nor a right-path from x_k to x_0 .

W.l.o.g. assume that x_1 is a right neighbor of x_0 . The case that x_1 is not a right neighbor of x_0 can be treated similarly by exchanging the roles of θ_r and θ_l boundaries. Since the path from x_0 to x_k is not a right-path, there is an integer i , $1 \leq i < k$, such

FIG. 7. A circular-arc graph with its arc representation. Vertices are labeled from 1 to 18 according to their value θ_l .

that x_{i+1} is not a right neighbor of x_i and such that the subpath from x_0 to x_i is a right-path.

- If x_{i+1} is not a left neighbor of x_i , then either $I(x_i)$ is included in $I(x_{i+1})$ or vice-versa. In both cases, the vertex with the smallest range can be removed from the path, henceforth proving the existence of a shorter path, which is a contradiction.
- If x_{i+1} is a left neighbor of x_i , then $\theta_l(x_i) \in I(x_{i-1}) \cap I(x_{i+1})$, proving that x_{i-1} and x_{i+1} are adjacent. By the way, the path P can be shortened to $[x = x_0, \dots, x_{i-1}, x_{i+1}, \dots, x_k = y]$, which is a contradiction. $\square$

Let $x_1, \dots, x_n$ be the vertices of G ordered such that $\theta_l(x_i) \leq \theta_l(x_{i+1})$ for every $i \in \{1, \dots, n-1\}$. We associate with G a new intersection graph $\tilde{G}$ with vertex set $V(\tilde{G}) = \bigcup_{1 \leq i \leq n} \{I(x_i^1), I(x_i^2)\}$, where, for every $1 \leq i \leq n$,

$$I(x_i^1) = \begin{cases} [\theta_l(x_i), \theta_r(x_i)] & \text{if } \theta_l(x_i) \leq \theta_r(x_i), \\ [\theta_l(x_i), \theta_r(x_i) + 2\pi] & \text{if } \theta_l(x_i) > \theta_r(x_i), \end{cases}$$

$$I(x_i^2) = \begin{cases} [\theta_l(x_i) + 2\pi, \theta_r(x_i) + 2\pi] & \text{if } \theta_l(x_i) \leq \theta_r(x_i), \\ [\theta_l(x_i) + 2\pi, \theta_r(x_i) + 4\pi] & \text{if } \theta_l(x_i) > \theta_r(x_i). \end{cases}$$

Intuitively, $\tilde{G}$ is obtained from G by listing all the intervals according to increasing angle θ_l , starting from the arc of x_1 , and turning clockwise around twice. So, each vertex x_i in G appears twice in $\tilde{G}$ as x_i^1 and x_i^2 . It is straightforward to check that $\tilde{G}$ is an interval graph.

LEMMA 6. For every $i < j$, $\text{dist}_G(x_i, x_j) = \min \{ \text{dist}_{\tilde{G}}(x_i^1, x_j^1), \text{dist}_{\tilde{G}}(x_j^1, x_i^2) \}$.

Proof. Let $P = [x_i, x_{t_1}, \dots, x_{t_k}, x_j]$ be a shortest path between x_i and x_j in G . From Lemma 5 P is a right-path from x_i to x_j or a right-path from x_j to x_i .

In the former case, we have $i \leq t_1 \leq \dots \leq t_k \leq j$. Consider the path $P' = [x_i^1, x_{t_1}^1, \dots, x_{t_k}^1, x_j^1]$ of $\tilde{G}$. Because P' can be constructed from P by turning clockwise from x_i to x_j in G , P' is isomorphic to P , showing that $\text{dist}_G(x_i, x_j) \leq \text{dist}_{\tilde{G}}(x_i^1, x_j^1)$. We observe that any shortest path from x_i^1 to x_j^1 in $\tilde{G}$ must be a right-path. By construction, every right-path of length l between a given pair of vertices in $\tilde{G}$ is isomorphic to some right-path of same length between the corresponding vertices

in G . So a shorter path between x_i^1 and x_j^1 would provide a shorter path between x_i and x_j in G . Therefore, P' is a shortest path in $\tilde{G}$ and $\text{dist}_G(x_i, x_j) = \text{dist}_{\tilde{G}}(x_i^1, x_j^1)$.

Assume now that P is a right-path from x_j to x_i . P is obtained by turning clockwise from x_j to x_i . P is isomorphic to a right-path P'' in $\tilde{G}$ between x_j^1 and x_i^2 . Indeed, since $i < j$, $\theta_l(x_i) \leq \theta_l(x_j) < \theta_l(x_i) + 2\pi$. Similarly to the previous case, P'' is a shortest path, proving that, in this case, $\text{dist}_G(x_i, x_j) = \text{dist}_{\tilde{G}}(x_j^1, x_i^2)$ and completing the proof of the lemma. $\square$

Therefore, a distance labeling scheme for interval graphs can be transformed into a scheme for a circular-arc graph family by doubling the number of vertices and the label length.

THEOREM 9. *The family of n -vertex circular-arc graphs enjoys a distance labeling scheme using labels of length $\mathcal{O}(\log n)$, and the distance decoder has constant time complexity. Moreover, given the sorted list of intervals, all the labels can be computed in $\mathcal{O}(n)$ time.*

4. Universal distance matrix. Given a family $\mathcal{F}$ of graphs, [6, 1] considered the size of the smallest *induced universal graph* to give a measure of the density of $\mathcal{F}$. A graph $\mathcal{G}$ is an induced universal graph with respect to $\mathcal{F}$ if any graph of $\mathcal{F}$ is an induced subgraph of $\mathcal{G}$. In this section, we similarly define the *universal distance matrix* of a family $\mathcal{F}$, which is a square matrix $\mathcal{U}_n$ containing the distance matrix of every (unweighted) n -vertex graph of $\mathcal{F}$ as an *induced submatrix*. A matrix $B = (B_{i,j})_{1 \leq i,j \leq p}$ is an induced submatrix of a matrix $A = (A_{i,j})_{1 \leq i,j \leq q}$ if there exists a sequence $(s_1, \dots, s_p)$ of indices such that $B_{i,j} = A_{s_i, s_j}$ for all $i, j \in \{1, \dots, p\}$. Intuitively, a small universal distance matrix for $\mathcal{F}$ indicates that many distance patterns repeat in many different graphs of $\mathcal{F}$.

Proposition 1 will be a tool for proving lower and upper bounds on the dimension of universal distance matrix. The proof technique is similar to the proof given by [19] for the relationship between adjacency schemes and induced universal graphs [1, 6].

PROPOSITION 1. *If $\mathcal{F}$ enjoys an ℓ -distance labeling scheme, then $\mathcal{F}$ has a universal distance matrix of dimension $2^{\ell+1} - 1$. If $\mathcal{F}$ has a universal distance matrix of dimension d , then $\mathcal{F}$ enjoys a $\lfloor \log d \rfloor$ -distance labeling scheme.*

Proof. For every integer $i \geq 1$, let $\phi(i)$ denote the i th binary string in the lexicographic order $\phi(1) = \epsilon$, $\phi(2) = 0$, $\phi(3) = 1$, $\phi(4) = 00$, $\phi(5) = 01$, $\phi(6) = 10$, $\phi(7) = 11$, $\phi(8) = 000, \dots$. We note that the length of $\phi(i)$ is $\lfloor \log i \rfloor$. We denote by ϕ^{-1} the inverse function of ϕ .

A universal distance matrix M for $\mathcal{F}$ can be defined from any distance labeling scheme $\langle L, f \rangle$ for $\mathcal{F}$ as follows: $M_{i,j} = f(\phi(i), \phi(j))$ if there exists a graph $G \in \mathcal{F}$ with two vertices u and v such that $L(u, G) = \phi(i)$ and $L(v, G) = \phi(j)$, and $M_{i,j} = \infty$ otherwise.

With every $G \in \mathcal{F}$, one can associate the subset $I_G = \{\phi^{-1}(L(u, G)) \mid u \in V(G)\}$ of indices. By construction, for all $i, j \in I_G$, $M_{i,j} = f(\phi(i), \phi(j))$, which is the distance in G between the vertices labeled $\phi(i)$ and $\phi(j)$. So M contains as an induced submatrix the distance matrix of every $G \in \mathcal{F}$: M is universal. Moreover, its dimension is smaller than the largest integer contained in a subset I_G , which cannot exceed the number of binary strings of length at most ℓ , i.e., $2^{\ell+1} - 1$.

Now, assume M is a universal distance matrix of dimension d for $\mathcal{F}$. Then a distance labeling scheme $\langle L, f \rangle$ can be constructed as follows: if the distance matrix of G is the induced submatrix of M with a sequence of indices I_G , then we label the vertex corresponding to the index $i \in I_G$ by the binary string $\phi(i)$. The length of

this label is the length of $\phi(i)$. The length is therefore bounded by the length of $\phi(d)$, that is, $\lfloor \log d \rfloor$ bits. Now, given two binary labels λ and λ' , extracted from the same graph, one can compute the distance by searching in M (which depends only on $\mathcal{F}$) the entry $M_{\phi^{-1}(\lambda), \phi^{-1}(\lambda')}$. As the two labels are extracted from the same graph, this value is the distance between the corresponding vertices. $\square$

From Proposition 1 and previously known bounds on the distance labeling scheme [15], trees have a universal distance matrix of dimension $2^{\Theta(\log^2 n)}$, whereas any universal distance matrix for cubic graphs must be of dimension at least $2^{\Omega(\sqrt{n})}$. By the way, the dimension of the smallest universal distance matrix can be considered as a complexity measure of a graph family. From Proposition 1 and Theorems 3 and 2 we obtain the following corollaries.

COROLLARY 3. *The dimension of the smallest universal distance matrix of n -vertex proper interval graphs is at most $\mathcal{O}(n^2)$ and at least $\Omega(n^2/\log^2 n)$.*

COROLLARY 4. *The dimension of the smallest universal distance matrix of n -vertex interval graphs is at most $\mathcal{O}(n^5)$ and at least $\Omega(n^3/\log^4 n)$.*

A UNIFIED VIEW OF GRAPH SEARCHING*

DEREK G. CORNEIL[†] AND RICHARD M. KRUEGER[†]

Abstract. Graph searching is perhaps one of the simplest and most widely used tools in graph algorithms. Despite this, few theoretical results are known about the vertex orderings that can be produced by a specific search algorithm. A simple characterizing property, such as is known for LexBFS, can aid greatly in devising algorithms, writing proofs of correctness, and showing impossibility results. This paper unifies our view of graph search algorithms by showing simple, closely related characterizations of various well-known search paradigms, including BFS and DFS. Furthermore, these characterizations naturally lead to other search paradigms, namely, maximal neighborhood search and LexDFS.

Key words. graph searching, graph traversal, depth-first search, breadth-first search, LexBFS

AMS subject classifications. 05C85, 68R10, 68W05

DOI. 10.1137/050623498

1. Introduction. Graph searching is fundamental. Most graph algorithms employ some mechanism for systematically visiting all vertices and edges in the given graph. After choosing an initial vertex, a search of a connected graph visits each of the vertices and edges of the graph such that a new vertex is visited only if it is adjacent to some previously visited vertex. At any point there may be several vertices that may possibly be visited next; this generic graph search does not specify which vertex to choose. The *breadth-first search* (BFS) and *depth-first search* (DFS) algorithms are the traditional strategies for determining the next vertex to visit (see [7] for a recent overview of these searches). BFS traverses an untraversed edge incident with the least recently visited vertex, whereas DFS traverses an untraversed edge incident with the most recently visited vertex. Both searches were used in the 19th century to solve maze traversals. More recently, DFS, as popularized by Tarjan [14], has been used for such problems as graph connectivity, planarity, topological ordering, and strong connectivity of digraphs. Applications of BFS include shortest path problems, network flows, and recognition of various graph classes.

In the mid 1970s, Rose, Tarjan, and Lueker [11] introduced a variant of BFS for determining perfect elimination orderings in chordal graphs. Their *lexicographic breadth-first search* (LexBFS) has garnered much attention recently and has become an important search algorithm used for recognition of various graph families, diameter approximation, and finding key structures in certain graph classes [3]. One of the key points regarding LexBFS, and one of the reasons for its usefulness, is that there is a very simple characterization of LexBFS orderings. This characterization is critical to the proofs of correctness of various algorithms. In light of the power of such a tool, it is somewhat surprising that the traditional searches of BFS and DFS are not known to have similar characterizations. Other than LexBFS, only the *maximum cardinality search* (MCS) of Tarjan and Yannakakis [15] has a known characterization [1].

To provide a common underpinning for viewing graph searches, we examine what is meant by a “generic graph search.” We describe a graph search similarly to Tarjan [14]. Given a possibly disconnected graph G whose vertices are initially unexplored, we start from some vertex s of G and choose one of its edges to follow. Traversing this edge leads to a new vertex. We continue, at each step selecting an untraversed edge leading from a vertex already reached. Traversing this edge leads either to a new vertex or to one previously reached. Whenever we run out of edges leading from old vertices, we choose some new unreached vertex and begin again from there. Each edge is traversed exactly once, and we eventually reach all vertices in the graph. How we choose amongst all the edges we may next traverse determines the type of search we perform (i.e., whether it is a BFS or a DFS). The order in which we reach the vertices exhibits very different properties depending on this selection rule.

From a characterization point of view, we concentrate on the following situation. Suppose in the ordering of vertices we have three vertices, a , b , and c , where a was reached before b , which was reached before c , and we have an edge ac present in our graph, but the edge ab is absent (see Figure 1.1). The question is, “how could vertex b have been chosen before vertex c by our search?” With what we know so far about this situation, it seems that c should have been chosen before b . What can we infer about the graph such that the search could have chosen b before c ?

FIG. 1.1. A curious triple of vertices in a search ordering.

In the case of LexBFS, the answer is known. There must exist another vertex d chosen earlier than a such that db is an edge, but dc is not an edge of G [11, 8]. In fact, Brandstädt, Dragan, and Nicolai [1] showed that this condition is a characterization of a vertex ordering being generated by LexBFS.

Experience with LexBFS has shown that such a characterizing property is instrumental in the applicability of the search to various problems. For example, the LexBFS characterization is fundamental in proving that the reverse of a LexBFS ordering of a chordal graph is a perfect elimination ordering [11]. Furthermore, many of the recent LexBFS-based algorithms use multiple sweeps of LexBFS to reveal structure of the given graph (see [3] for several examples). Each subsequent search uses information from the previous sweep(s) to break ties of which vertex to visit next. The related proofs of correctness rely heavily on the LexBFS characterization. The characterization can also be used to show that there is some LexBFS ordering that certifies a graph as being cocomparability, even though we don’t know how to find it efficiently [4].

In light of this simple characterization result for LexBFS (and similar results for MCS) and recognizing its usefulness, it is somewhat surprising that it appears that this question has never been asked regarding the more traditional search paradigms of BFS and DFS. In section 2 we further explore the question “how could b have been chosen before c by a graph search?” We present answers to this question for each of the known search paradigms and show that those answers in fact characterize the vertex orderings realizable by the graph search. We will also introduce two new search paradigms, a depth-first version of LexBFS we call LexDFS, and a generalization we

call maximal neighborhood search (MNS). To illustrate the usefulness of these new characterizations, we examine in section 3 which searches of a given graph G are valid searches of powers of G . In particular, we would like to obtain a search ordering of G^k without the necessity of computing G^k (i.e., in time linear in the size of G). We conclude with some remarks about the impact of these new characterizations and their extension to other areas.

1.1. Notation and definitions. We now define some notation to facilitate our discussion. We let $G = (V, E)$ be a graph on vertex set V and edge set E . We will assume, for simplicity, that all graphs in this paper are connected and undirected; extension of our results to disconnected graphs is straightforward. Let $n = |V|$. We define $\sigma = (v_1, \dots, v_n)$ to be a linear ordering of V , which will typically be the left-to-right order in which we number the vertices in a search. We let $\sigma_i = (v_1, \dots, v_i)$ be a prefix of the ordering σ for $1 \leq i \leq n$. We use the notation $\sigma(i) = v_i$ and $\sigma^{-1}(v_i) = i$ to refer to a specific vertex in σ . The ordering σ implicitly imposes a total order on V ; we say $v_1 <_\sigma v_2 <_\sigma \dots <_\sigma v_n$ and omit the subscript σ when the ordering is clear. We let $G_i = G[v_1, \dots, v_i]$ be the subgraph of G induced on a prefix of σ , and let $N_H(v)$ be the neighborhood of v in a subgraph H of G . When referring to searches, $s = v_1$ is the start vertex.

A graph is said to be *chordal* if every cycle of length at least 4 has at least one chord. A vertex is *simplicial* in a graph G if its neighborhood is a clique in G . An ordering $(v_1, \dots, v_n)$ of V is a *perfect elimination ordering* of G if v_i is simplicial in G_i . A graph is chordal if and only if it has a perfect elimination ordering [6]. A graph is *bipartite* if its vertex set can be partitioned into two disjoint sets X, Y such that all edges are of the form xy for some $x \in X$ and $y \in Y$. A graph is *chordal bipartite* if it is bipartite and every cycle of length at least 6 has a chord. The *complement* of a graph $G = (V, E)$, written $\overline{G} = (V, \overline{E})$, is defined by $\overline{E} = \{xy : x, y \in V \text{ with } x \neq y \text{ and } xy \notin E\}$. The k th *power* of a graph G , written $G^k = (V, E^k)$, for some positive integer k , is obtained from G by including an edge between every pair of vertices that are of distance at most k in G (hence G^1 is precisely G itself).

We draw particular attention to the fact that the search algorithms in this paper generate vertex orderings from left to right. In many applications it may be useful to reverse the ordering generated by search, and some of the LexBFS literature considers this reversal as part of the search algorithm.

2. Characterizing graph search.

2.1. Generic search. We begin by formalizing the generic search idea, similar to Tarjan's description in [14], and present it as Algorithm 1. We use a generic "set" data structure S to store the candidate vertices we may next visit during our search. We note that we impose no selection criteria on which member of S we choose in line 3 beyond that it must be in S .

We call any ordering of V that can be generated by Algorithm 1 a *search ordering* of the graph G . As an example, we notice that $(1, 6, 2, 3, 4, 5)$ is not a valid search ordering of the 3-sun in Figure 2.1, whereas $(1, 2, 4, 3, 5, 6)$ is a valid search ordering of this graph. The reader will notice that this search ordering is neither a BFS nor a DFS, which is permissible by the generic selection criterion in line 3. We may opt to use a more restrictive data structure to obtain other properties for our search, such as replacing set S with a queue to obtain BFS. Note also that, as stated, a given vertex may be added to S multiple times as each of its neighbors is numbered. How S deals with this can change the nature of the search. For example, using a variant of a stack

ALGORITHM 1: Generic search.

input : a graph $G = (V, E)$ and start vertex $s \in V$
output: an ordering σ of V

```

1  $S \leftarrow \{s\}$ 
2 for  $i \leftarrow 1$  to  $n$  do
3   pick and remove an unnumbered vertex  $v$  from  $S$ 
4    $\sigma(i) \leftarrow v$  // This assigns to  $v$  the number  $i$ 
5   foreach unnumbered vertex  $w$  adjacent to  $v$  do
6      $\mid$  add  $w$  to  $S$ 

```

FIG. 2.1. The 3-sun, used as an example for our graph searches.

where the add operation moves a vertex to the top of the stack if that vertex was added previously will yield DFS.

We now proceed to answer the fundamental question raised above about our search orderings: how could b have been chosen before c ? We give a simple answer, which turns out to be the characterizing property of search orderings.

(S): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex $d < b$ such that $db \in E$.

We note that (S) makes no statement to the relative order of a and d in σ . It simply says that there must be a vertex adjacent to b visited sometime earlier than b in σ . We will now show that (S) characterizes search orderings. That is to say that any ordering that the generic search algorithm can produce has this property, and that any vertex ordering with this property can be produced by the generic search algorithm when we break ties suitably.

THEOREM 2.1. *For an arbitrary graph G , an ordering σ of V is a search ordering of G if and only if σ has property (S).*

Proof. For the forward direction, suppose σ is an ordering generated by Algorithm 1. Let $a < b < c$ be a triple of vertices in σ with $ac \in E$ and $ab \notin E$. At the point when b is chosen, both b and c must be in S . Since b is in S , some neighbor of b must have already been chosen; call this neighbor d . Thus $d < b$ and $db \in E$. Since the triple $a < b < c$ was arbitrary, property (S) holds on σ .

For the converse, suppose $\sigma = (v_1, \dots, v_n)$ is an ordering respecting property (S). Suppose for contradiction that $(v_1, \dots, v_{i-1})$ can be obtained by Algorithm 1, but $(v_1, \dots, v_i)$ cannot, for some i , $1 < i \leq n$. That is, v_i is the first vertex in σ that cannot be chosen next by the algorithm. Consider the next iteration of the algorithm after choosing v_{i-1} . Since v_i cannot be chosen next, $v_i \notin S$. Let u be a vertex that the algorithm may choose next. Then u must be in S . Let w be the neighbor of u which caused u to be added to S . Since $v_i \notin S$, we know that $wv_i \notin E$. By applying property (S) to the vertex triple $w < v_i < u$, we know there exists a vertex $d < v_i$ with $dv_i \in E$. Hence $v_i \in S$, contradicting our assumption that v_i could not be chosen by Algorithm 1. $\square$

In fact, the perceptive reader will note that vertex c is irrelevant when restricting our attention to connected graphs. However, the presence of c is required when extending to more general settings.

2.2. BFS. We now proceed to the familiar BFS algorithm. BFS is a restriction of generic search in that we use a queue to determine which vertex we may choose next at our selection step. BFS does not, however, determine which order to push the neighbors of a numbered vertex onto the queue (see LexBFS in section 2.3 for a search that does). Algorithm 2 should be familiar to most readers.

ALGORITHM 2: Breadth-first search (BFS).

input : a graph $G = (V, E)$ and start vertex $s \in V$
output: an ordering σ of V

```

1 initialize queue to  $\{s\}$ 
2 for  $i \leftarrow 1$  to  $n$  do
3   dequeue  $v$  from beginning of queue
4    $\sigma(i) \leftarrow v$  // This assigns to  $v$  the number  $i$ 
5   foreach unnumbered vertex  $w$  adjacent to  $v$  do
6     if  $w$  is not already in queue then
7       enqueue  $w$  to end of queue

```

We mention that $(1, 2, 3, 4, 5, 6)$ is a valid BFS ordering of the 3-sun in Figure 2.1. Note that $(1, 2, 3, 6, 5, 4)$ is not a BFS ordering of this graph, though it does give a distance layering of the graph with respect to vertex 1.

We key in on our central question: How could b have been chosen before c in a BFS? The answer is a simple restriction to the answer we found for generic search.

(B): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex $d < a$ such that $db \in E$.

This property is merely property (S) with the added restriction that $d < a$. Interestingly, we find that this is sufficient to characterize all BFS orderings.

THEOREM 2.2. *For an arbitrary graph G , an ordering σ of V is a BFS ordering of G if and only if σ has property (B).*

Proof. For the forward direction, suppose σ is a BFS ordering. Let $a < b < c$ be a triple of vertices in σ with $ac \in E$ and $ab \notin E$. If b was removed from (and thus placed on) the queue before c , it must have a neighbor d that was numbered at least as early as a . Since a does not have b as a neighbor, d must be earlier than a .

For the reverse direction, suppose for contradiction that $\sigma = (v_1, \dots, v_n)$ is an ordering satisfying property (B) such that $(v_1, \dots, v_{i-1})$ can be produced by BFS, but $(v_1, \dots, v_i)$ cannot, for some i , $1 < i \leq n$. That is, v_i cannot be chosen next by any valid execution of BFS on G . Let u be a vertex that may be chosen next by some execution of BFS. Since u is dequeued in this extension, it must have been enqueued when some neighbor v_j with $j < i$ was previously numbered. Then $v_j v_i \notin E$; otherwise some valid execution of BFS can enqueue v_i before u . Applying (B) to the triple $v_j < v_i < u$, there must exist a vertex $d < v_j$ with $dv_i \in E$. Thus v_i is enqueued before, and dequeued before, u , contradicting our assumption above. $\square$

To illustrate an application of this property, we now prove the correctness of a generalization of a well-known technique for extracting a shortest s, w -path (for arbitrary w) given an ordering with property (B) starting with s . For notation, when given a vertex ordering σ of V and a subset $T \subseteq V$, we say $\sigma|_T$ is the restriction of σ to T .

COROLLARY 2.3. *Let σ be an arbitrary ordering of the vertices of a graph G , and let $H = G[T]$ be a connected induced subgraph of G such that $\sigma|_T$ satisfies (B). Suppose s is the first vertex in $\sigma|_T$, and let $w = w_0$ be an arbitrary vertex in T . For $i > 0$, define w_i to be the leftmost (in $\sigma|_T$) neighbor of w_{i-1} , until s is reached. Then $(s = w_k, \dots, w_1, w_0 = w)$ is a shortest s, w -path in H .*

Proof. Suppose, for contradiction, that $(s = w_k, \dots, w_1, w_0 = w)$ is not a shortest s, w -path in H . Let $(s = x_{k'}, \dots, x_1, x_0 = w)$ be a shorter s, w -path, with $k' < k$. Note that $x_{k'} < w_{k'}$. Choose the smallest $i > 0$ such that $x_i < w_i$. Then $w_{i-1} \leq x_{i-1}$. Since $x_i x_{i-1} \in E$ and w_i is the leftmost neighbor of w_{i-1} , we know that $x_i w_{i-1} \notin E$ (and thus $w_{i-1} \neq x_{i-1}$). Consider the triple $x_i < w_{i-1} < x_{i-1}$. Since $x_i x_{i-1} \in E$ but $x_i w_{i-1} \notin E$, property (B) applied to $\sigma|_T$ says there is a vertex d in T such that $d < x_i$ with $dw_{i-1} \in E$. This contradicts w_i being the leftmost neighbor of w_{i-1} , and hence our original path was in fact shortest. $\square$

2.3. LexBFS. In the studies of LexBFS, the answer to our key question, property (LB) below, has long been exploited as a useful characterization of LexBFS orderings. For completeness, we present the traditional LexBFS labeling algorithm as Algorithm 3.

As an example, consider Algorithm 3 on the graph in Figure 2.1 from the start vertex 1. The ordering $(1, 2, 3, 5, 4, 6)$ is a valid LexBFS ordering of the 3-sun. Note that once 1, 2, 3 are picked, 5 must be chosen over 4 since $label(5) = \{4, 3\}$ while

ALGORITHM 3: Lexicographic breadth-first search (LexBFS).

input : a graph $G = (V, E)$ and start vertex $s \in V$

output: an ordering σ of V

```

1 assign the label  $\epsilon$  to all vertices
2  $label(s) \leftarrow \{n+1\}$ 
3 for  $i \leftarrow 1$  to  $n$  do
4   pick an unnumbered vertex  $v$  with lexicographically largest label
5    $\sigma(i) \leftarrow v$  // This assigns to  $v$  the number  $i$ 
6   foreach unnumbered vertex  $w$  adjacent to  $v$  do
7     append  $(n-i)$  to  $label(w)$ 
```

$label(4) = \{4\}$. This ordering is also a BFS ordering of the 3-sun, but the BFS ordering $(1, 2, 3, 4, 5, 6)$ is not a LexBFS ordering.

We now restate the answer to our key question for LexBFS.

(LB): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex $d < a$ such that $db \in E$ and $dc \notin E$.

This property says that if we choose b before c , but there is an earlier vertex a that would normally pull c before b , then there must be an even earlier vertex d that caused b to be pulled ahead of c . Though this has long been known to be a property of LexBFS orderings [11, 8], the reverse direction showing (LB) characterizes LexBFS orderings has only recently been shown [1].

THEOREM 2.4 (see [11, 8, 1]). *For an arbitrary graph G , a vertex ordering σ is a LexBFS ordering of G if and only if σ has property (LB).*

Remarkably, the requirement of dc not being an edge is the only difference between lexicographic and traditional BFS. We obtain the immediate corollary, without any mention of the respective algorithms, that a LexBFS ordering is a BFS ordering, since (B) subsumes (LB).

2.4. DFS. We now turn our attention to DFS. DFS is very different from BFS in that it progresses forward through the graph as much as possible, backtracking only when necessary, whereas BFS first systematically explores close vertices before venturing out to the far reaches of the graph. One also notes that DFS produces two vertex orderings: a discovery ordering, which is the order vertices are first visited, and a finishing ordering, indicating the order in which each vertex's neighborhood is fully explored with all incident edges traversed and causing a backtracking step. In this paper we concentrate on the discovery orderings of DFSs, though we note an interesting relationship between the two orderings in section 4.

We start by presenting a DFS algorithm exploiting a stack data structure to store candidate vertices to visit next. We present DFS as Algorithm 4 in a style similar to our generic search algorithm in section 2.1. We note that line 6 would typically be included in the push operation of a suitable stack-type data structure, but we include the step here in our algorithm for clarity.

We again concentrate on our key question: If given a DFS ordering with $a < b < c$ with ac an edge but ab not an edge, how could DFS have chosen b over c ? The answer is property (D), which we will show characterizes DFS orderings.

(D): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex d with $a < d < b$ such that $db \in E$.

ALGORITHM 4: Depth-first search (DFS).

input : a graph $G = (V, E)$ and start vertex $s \in V$
output: an ordering σ of V

```

1 initialize stack to  $\{s\}$ 
2 for  $i \leftarrow 1$  to  $n$  do
3   pop  $v$  from top of stack
4    $\sigma(i) \leftarrow v$  // This assigns to  $v$  the number  $i$ 
5   foreach unnumbered vertex  $w$  adjacent to  $v$  do
6     if  $w$  already in stack then remove  $w$  from stack
7     push  $w$  on top of stack

```

Notice that this property restricts (S) only in that d must also appear to the right of a . We contrast this with BFS property (B), where d was to the left of a . In this sense, DFS is the opposite search paradigm to BFS.

THEOREM 2.5. *For an arbitrary graph G , an ordering σ of V is a DFS ordering of G if and only if σ has property (D).*

Proof. For the forward direction, suppose σ is an ordering produced by DFS. Suppose we have a triple of vertices $a < b < c$ in σ with $ac \in E$ and $ab \notin E$. Since b is numbered (and $b \neq s$, the initial vertex), b must have been pushed on the *stack* when one of its neighbors was previously numbered. Let d be the rightmost neighbor of b appearing before b in σ . Then $d < b$ and $d \neq a$. Suppose $d < a$. Since a was numbered after d , c is pushed on the stack above b . As there are no other neighbors of b before b is numbered, c is higher on the stack than b and must be numbered before b , a contradiction. Thus we must have $a < d$, and property (D) holds.

Now for the reverse direction, suppose $\sigma = (v_1, \dots, v_n)$ is an ordering respecting property (D). Suppose $(v_1, \dots, v_{i-1})$ can be obtained by DFS, but $(v_1, \dots, v_i)$ cannot. That is, v_i is the first vertex in σ that cannot be chosen next by DFS. Let u be a vertex that DFS may choose next. Then $v_i < u$. Let v_j be the rightmost vertex in σ_{i-1} such that $v_j u \in E$ (that is, v_j is the parent vertex of u in the DFS-tree). Then $v_j v_i \notin E$ (otherwise v_i could be chosen next) and, more generally, $v_k v_i \notin E$ for all k , $j \leq k < i$. By applying property (D) to the triple $v_j < v_i < u$, we know there exists a vertex d between v_j and v_i such that $dv_i \in E$, a contradiction to v_i being ineligible to be chosen next. $\square$

We can apply (D) repeatedly to obtain the following simple corollary.

COROLLARY 2.6. *Given a graph G and an arbitrary DFS ordering σ of V , if $a < b < c$ and $ac \in E$, then there exists a path P from a to b whose vertices increase in σ . That is, there exists an a, b -path $P = (a = d_k, \dots, d_1, d_0 = b)$ in G with $\sigma^{-1}(d_i) < \sigma^{-1}(d_{i-1})$ for each $d_i \in P \setminus \{b\}$.*

Most previous results regarding DFS rely on properties of the DFS-tree. The *DFS-tree* T is defined on the vertices of G and includes exactly those edges traversed to number a new vertex. Formally, $v_i v_j \in E(T)$ with $i < j$ if and only if $i = \max\{k \mid v_k v_j \in E(G) \text{ and } k < j\}$. We say u is the *parent* of v in T if $uv \in E(T)$ and $\sigma^{-1}(u) < \sigma^{-1}(v)$. The *nontree edges* (or *back edges*) are the remaining edges in G . In T , u is an *ancestor* of v if there is a path from u to v all of whose edges go from parent to child. We say two vertices are *related* if one is an ancestor of the other.

Many data structure textbooks (for example, [2]) mention the following fundamental property of DFS (which follows from Corollary 2.6).

(D2): In a DFS-tree of an undirected graph, the two endpoints of each back (non-tree) edge are related.

Consider a back edge uv in a DFS-tree. The four-vertex condition (D) is stronger than (D2) in that it says all vertices between u and v (inclusive) are related to u .

2.5. LexDFS. Looking at the relationship between BFS and LexBFS, one naturally asks whether there is a “lexicographic analogue” for DFS. We have noted that LexBFS enforces the requirement of “ $dc \notin E$ ” on top of BFS. It is natural to question whether a similar requirement makes sense for DFS. We state this restriction of property (D) below.

(LD): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex d with $a < d < b$ such that $db \in E$ and $dc \notin E$.

We turn to the task of devising an algorithm that realizes this property. Considering our 3-sun example in Figure 2.1, once vertices 1 and 2 are chosen, the only way to avoid violating (LD), and hence the only valid ordering, is $(1, 2, 3, 5, 6, 4)$. Clearly this is a DFS ordering, and we observe that the DFS ordering $(1, 2, 4, 5, 6, 3)$ violates (LD). The LexBFS ordering $(1, 2, 3, 5, 4, 6)$ is also disallowed.

These examples suggest that our algorithm should choose vertices that are adjacent to as many vertices we have more recently numbered as possible. As it is to be related to LexBFS, our algorithm should also be in some sense similar to our LexBFS algorithm. (We discuss the property that actually relates LexBFS and LexDFS in section 2.6.) We present Algorithm 5 as our LexDFS algorithm.

ALGORITHM 5: Lexicographic depth-first search (LexDFS).

input : a graph $G = (V, E)$ and start vertex $s \in V$

output: an ordering σ of V

```

1 assign the label  $\epsilon$  to all vertices
2  $label(s) \leftarrow \{0\}$ 
3 for  $i \leftarrow 1$  to  $n$  do
4   pick an unnumbered vertex  $v$  with lexicographically largest label
5    $\sigma(i) \leftarrow v$  // This assigns to  $v$  the number  $i$ 
6   foreach unnumbered vertex  $w$  adjacent to  $v$  do
7     prepend  $i$  to  $label(w)$ 
```

Examining Algorithm 5, our answer to the “what is LexDFS?” question becomes quite convincing. There is just one difference between this algorithm and the LexBFS algorithm. For LexDFS, we *prepend* the new digit i to $label(w)$ at line 7, whereas, for LexBFS, we *append* the new label digit $n - i$. This elementary change converts the algorithm from a BFS into a DFS. We now show that our algorithm correctly defines LexDFS.

THEOREM 2.7. *For an arbitrary graph G , an ordering σ of V is a LexDFS ordering of G if and only if σ has property (LD).*

Proof. For the forward direction, suppose σ is an ordering computed by some execution of LexDFS. We define $label_u(v)$ to represent the label assigned to vertex v in this execution immediately before vertex u was numbered. Let $a < b < c$ be a triple of vertices in σ with $ac \in E$ and $ab \notin E$. Since b was numbered before c , $label_b(b) \geq label_b(c)$. We note that the digits in each label appear in decreasing order. Since $\sigma^{-1}(a)$ appears in $label_b(c)$ and does not appear in $label_b(b)$, $label_b(b)$ must include some digit $j > \sigma^{-1}(a)$ which does not appear in $label_b(c)$. Let $d = \sigma(j)$. Then $d < b$, $db \in E$, and $dc \notin E$. Since $j > \sigma^{-1}(a)$, $a < d$, and thus property (LD) is satisfied.

Now for the reverse direction, suppose $\sigma = (v_1, \dots, v_n)$ is an ordering respecting property (LD). Suppose $(v_1, \dots, v_{i-1})$ can be obtained by LexDFS, but $(v_1, \dots, v_i)$ cannot. That is, v_i is the first vertex in σ that cannot be chosen next by LexDFS. Let u be a vertex that LexDFS may choose next. Since u must be chosen over v_i , at this point of execution $label(u)$ must be lexicographically larger than $label(v_i)$: let j be the largest digit in $label(u)$ that is not in $label(v_i)$ (i.e., v_j is the rightmost vertex in σ_{i-1} with $v_j u \in E$ and $v_j v_i \notin E$). By applying property (LD) to the vertex triple $v_j < v_i < u$, we know there exists a vertex d between v_j and v_i such that $dv_i \in E$ and $du \notin E$. Then $\sigma^{-1}(d)$ is in $label(v_i)$ but not in $label(u)$. Since $v_j < d$, $label(v_i)$ is in fact larger than $label(u)$, a contradiction to v_i being ineligible to be chosen next. $\square$

When examining a new search algorithm, we should concern ourselves with its implementation. Algorithm 5 does not immediately have a linear-time implementation using those ideas used for LexBFS. The partitioning idea exploited for LexBFS cannot efficiently be applied to LexDFS (leading to an $O(m \log n)$ time bound), as its depth-first properties can pull in an arbitrary vertex to be the next to be numbered. We refer to [10] for an $O(\min\{n^2, m \log n\})$ implementation; recently an $O(m \log \log n)$ implementation has been discovered [13] employing van Emde Boas trees to keep track of the relative lexicographic order of unnumbered vertices. It is an open question whether there is a linear-time implementation of LexDFS.

2.6. Maximal neighborhood search. We now consider the question of “what fact relates LexBFS and LexDFS?” What useful property does this nonedge dc give us? Equivalently, we ask what type of search we get when adding the restriction $dc \notin E$ to the generic search property (S). We formalize our discussion around this property.

(M): Given an ordering σ of V , if $a < b < c$ and $ac \in E$ and $ab \notin E$, then there exists a vertex d with $d < b$ and $db \in E$ and $dc \notin E$.

Surprisingly, this property has already been used in the literature. Tarjan and Yannakakis [15] mentioned that both MCS (where at each step we choose a vertex that is adjacent to the maximum number of vertices previously numbered) and LexBFS respect our property (M) (which [15] calls “P”), and they showed that any ordering

with property (M) is the reverse of a perfect elimination ordering of a chordal graph. But the paper does not consider whether there is a natural search algorithm that is characterized by this property. We answer that question here by introducing *maximal neighborhood search* (MNS) as Algorithm 6.

The idea behind MNS is simple: at each step, pick a vertex whose neighborhood in the part of the graph already explored is maximal (with respect to set inclusion). This is a straightforward generalization of the LexBFS, LexDFS, and MCS algorithms. We obtain each of these searches from Algorithm 6 by further specifying how to order incomparable neighborhoods. For LexBFS, we choose a vertex adjacent to as many *earliest* chosen vertices as possible. For LexDFS, we choose a vertex adjacent to as many *most recently* chosen vertices as possible. For MCS, we choose a vertex whose neighborhood has *maximum* cardinality.

ALGORITHM 6: Maximal neighborhood search (MNS).

input : a graph $G = (V, E)$ and start vertex $s \in V$
output: an ordering σ of V

- 1 assign the label $\emptyset$ to all vertices
- 2 $label(s) \leftarrow \{n + 1\}$
- 3 **for** $i \leftarrow 1$ **to** n **do**
- 4 pick an unnumbered vertex v with maximal label (under set inclusion)
- 5 $\sigma(i) \leftarrow v$ // This assigns to v the number i
- 6 **foreach** *unnumbered vertex* w *adjacent to* v **do**
- 7 add i to $label(w)$

We now show that the vertex orderings produced by Algorithm 6 are characterized by property (M).

THEOREM 2.8. *For an arbitrary graph G , an ordering σ of V is an MNS ordering if and only if σ has property (M).*

Proof. For the forward direction, suppose σ is an MNS ordering. Suppose $a < b < c$ is a triple in σ that violates (M). That is, $ac \in E$ and $ab \notin E$, yet there is no vertex $d < b$ with $db \in E$ and $dc \notin E$. Consider the point in the execution when $b = v_i$ is chosen. Then $N_{G_{i-1}}(b) \subsetneq N_{G_{i-1}}(c)$, so b could not have been chosen next by MNS, a contradiction. Hence (M) must hold for σ .

For the converse, suppose $\sigma = (v_1, \dots, v_n)$ is an ordering respecting property (M). Suppose $(v_1, \dots, v_{i-1})$ can be obtained by MNS, but $(v_1, \dots, v_i)$ cannot; that is, v_i is the first vertex in σ that cannot be chosen next by MNS. Then there must be another vertex u with $N_{G_{i-1}}(u) \supsetneq N_{G_{i-1}}(v_i)$. Let $x \in N_{G_{i-1}}(u) - N_{G_{i-1}}(v_i)$ (such an x must exist). We apply (M) to the triple $x < v_i < u$, giving a vertex $d < v_i$ with $dv_i \in E$ and $du \notin E$. This contradicts $N_{G_{i-1}}(u) \supsetneq N_{G_{i-1}}(v_i)$, and hence our assumption that v_i could not be chosen by MNS was incorrect. $\square$

Thus, for chordal graphs, every MNS ordering is the reverse of a perfect elimination ordering. A natural question is whether every perfect elimination ordering of a chordal graph is the reverse of an MNS ordering. This question is studied by Shier [12] and answered in the negative: the reverse of many perfect elimination orderings are not search orderings, and thus cannot be found by MNS. However, [12] shows how to generalize search orderings by considering connected components in the unvisited portion of the graph to capture the entire family of perfect elimination orderings.

3. Application to powers of graphs. All searches give a certain amount of insight into a graph's structure, including the insight gained from our four-vertex characterizations. At times we wish to use this insight to gain information about some graph arising from a given graph via some function. Examples of such functions include the graph's complement, some power of the graph, the line graph, or the product or join of the graph. Often, we want to obtain insight into the structure of a derived graph without incurring the possibly large cost of computing the function.

Search is often a convenient and efficient way to do this. For example, it has been previously noted that a LexBFS ordering (and thus a BFS ordering) of the complement of a graph can be found without computing the complement, given a slight modification of the standard LexBFS algorithm [9]. Dahlhaus, Gustedt, and McConnell [5] have shown how to find a DFS ordering of the complement of a graph in time linear in the original graph. We can use such results to obtain information about the derived graph (such as whether the graph's complement is chordal) more efficiently than actually computing the derived graph.

In this section, we consider the problem of computing some type of search ordering of some power of the graph, but without resorting to computing that power. One possibility is to compute a search ordering of the original graph, and ask whether it is a search ordering of the power. We will show that the aforementioned search characterizations are invaluable in obtaining straightforward proofs of both positive and negative results for this problem.

We start with the simple question of whether a BFS ordering of a graph remains a BFS ordering for all powers of a graph.

THEOREM 3.1. *For any graph G , every BFS ordering of G is a BFS ordering of G^k for all $k \geq 1$.*

Proof. Let σ be a BFS ordering of G . The theorem is trivially satisfied when $k = 1$. For $k > 1$, we assume for induction that σ is a BFS ordering for all powers of G strictly less than k and consider σ on G^k . Suppose $a < b < c$ is a triple in σ on G^k with $ac \in E^k$ and $ab \notin E^k$.

If $a < b < c$ is such a triple in σ on G^{k-1} , then by (B) and our induction hypothesis, there exists a vertex $d < a$ with $db \in E^{k-1} \subseteq E^k$, hence satisfying (B) on G^k .

Suppose instead that $a < b < c$ is not such a triple in σ on G^{k-1} . Then $ac \notin E^{k-1}$. But then there must be a vertex e with $ae \in E^{k-1}$ and $ec \in E$. Since $ab \notin E^k$ but $ae \in E^{k-1}$, we must have $eb \notin E$. We have 3 cases for the position of e in σ relative to a and b .

Case 1. $e < a$. In σ on G , since $ec \in E$ and $eb \notin E$, we apply (B) to the triple $e < b < c$, giving us a vertex $d < e < a$ such that $db \in E \subseteq E^k$, satisfying (B) on G^k .

Case 2. $a < e < b$. We first consider σ on G . We know that $ec \in E$ and $eb \notin E$, so by applying (B) to the triple $e < b < c$, we get a vertex $d < e$ such that $db \in E$. If $d < a$, we're done; otherwise, we have $a < d$. Since $db \in E$ but $ab \notin E^k$, we must have $ad \notin E^{k-1}$. We apply (B) and our inductive hypothesis to the triple $a < d < e$ in σ on G^{k-1} , giving us a vertex $d_2 < a$ such that $d_2d \in E^{k-1}$. Since $d_2d \in E^{k-1}$ and $db \in E$, d_2 and b are of distance at most k in G . Thus $d_2b \in E^k$, satisfying (B) on G^k .

Case 3. $b < e$. In σ on G^{k-1} , since $ae \in E^{k-1}$ and $ab \notin E^{k-1}$, we apply (B) and our inductive hypothesis to the triple $a < b < e$, giving us a vertex $d < a$ with $db \in E^{k-1} \subseteq E^k$, satisfying (B) on G^k .

In each case, we show the existence of a vertex $d < a$ with $db \in E^k$, and hence (B) is satisfied by σ on G^k . Thus σ is a BFS ordering of G^k . $\square$

While a BFS ordering survives through the powers of a graph, and clearly generic search orderings also survive, one naturally wonders about DFS. We now show that a DFS ordering of G is not necessarily a DFS ordering in a given power of G . Again, the characterizing property of DFS will play an crucial role in our proof.

THEOREM 3.2. *For every $k \geq 2$, there exists a graph G such that no DFS ordering of G is a DFS ordering of G^k .*

Proof. Fix $k \geq 2$. We first show the existence of a graph G such that no DFS ordering starting from a distinguished start vertex s is a DFS ordering of G^k .

Let G be the graph consisting of two vertices s and r connected by three paths of length $k + 1$. This graph is diagrammed in Figure 3.1.

FIG. 3.1. Given k , a graph G where no DFS from s is a DFS of G^k . The possible DFS path through G is shown in gray.

Let σ be an arbitrary DFS ordering of G starting from s . The DFS will proceed from s along one of the three paths to reach r . From r , the DFS will follow a second path towards s to reach a adjacent to s . As s is already discovered, the DFS will recurse back to r and travel the third path towards s . Let b be the first vertex visited on this third path, and let c be the next vertex on the path.

Thus, in σ , we have $s < r < a < b < c$. Moreover, b appears in σ immediately following a (when a is reached, all neighbors of a are already numbered, so DFS recurses to r , where b must be the next vertex to be numbered).

Now consider σ in G^k . One easily verifies that a and c are of distance k in G , and a and b are of distance $k + 1$ in G . Hence $ac \in E^k$ and $ab \notin E^k$. But since a and b are next to each other in σ , there can be no vertex between a and b . Therefore, the triple $a < b < c$ violates the condition (D). Hence σ cannot be a DFS ordering of G^k .

To prove the theorem, we consider two copies of G joined at s by an edge: call this graph G' . Consider any DFS ordering σ' of G' : it may start in either copy of G , possibly at s itself. We observe that if σ' starts in one copy of G , σ' restricted to the other copy of G appears as a DFS ordering of G starting at s . Following the argument above, we can identify three vertices $a < b < c$ in the second copy of G .

We note that no vertex from the other copy of G is within distance k of b , and thus there can be no edge ab in $(G')^k$. The triple $a < b < c$ violates (D) as above, so σ' is not a DFS of $(G')^k$. Since σ' was chosen arbitrarily, no DFS ordering of G' can be a DFS ordering of $(G')^k$. $\square$

Failing for DFS, one may wonder about LexBFS. Brandstädt, Dragan, and Nicolai [1] have shown that the reverse of a LexBFS ordering of a chordal graph G is a common

perfect elimination ordering of all odd powers of G . One may be tempted to think that a LexBFS ordering of a chordal graph is a LexBFS ordering of the odd powers, but we show this is not the case.

THEOREM 3.3. *For each $k \geq 2$, there exists a chordal graph G such that no LexBFS ordering of G is a LexBFS ordering of G^k .*

Proof. Let $k \geq 2$ be fixed. If k is even, we consider the graph G_k in Figure 3.2(a); otherwise, if k is odd, we consider the graph H_k in Figure 3.2(b). We note that each of these graphs is chordal. We will show that no LexBFS ordering of the graph starting from vertex 1 will be a LexBFS ordering of the k th power, then join two copies of the graph at vertex 1 to prove the theorem for a LexBFS ordering starting from an arbitrary vertex.

FIG. 3.2. Constructions for (a) k even and (b) k odd, where no LexBFS ordering starting from 1 is a LexBFS ordering of G^k .

Suppose k is even. We note that any LexBFS ordering σ of the graph G_k which starts at 1 must have $7 < a' < b' < c'$. Then $a < b < c$ in σ . We examine the triple $a < b < c$ in G_k^k . We note that $ac \in E(G_k^k)$ since $d_{G_k}(a, c) = 2(k/2 - 1) + 2 = k$, and $ab \notin E(G_k^k)$ since $d_{G_k}(a, b) = 2(k/2 - 1) + 3 = k + 1$. It is easy to check that there is no vertex $d < a$ with $db \in E(G_k^k)$ and $dc \notin E(G_k^k)$: any vertex left of a within distance k of b in G_k must be within distance k of c . Thus property (LB) is violated in G_k^k , showing σ is not a LexBFS ordering of G_k^k .

Now suppose k is odd. Considering the graph in Figure 3.2(b), we note that any LexBFS ordering σ of H_k that starts at 1 must have $a' < b' < c'$. Then $a < b < c$ in σ . We note that $d_{H_k}(b', 3) = 2$ and $d_{H_k}(c', 3) = 3$, and $d_{H_k}(b', 6) = 1$ and $d_{H_k}(c', 6) = 3$, but for all other vertices $x < a'$ in σ , $d_{H_k}(b', x) \geq d_{H_k}(c', x)$. We examine the triple $a < b < c$ in H_k^k . We have $ac \in E(H_k^k)$, since $d_{H_k}(a, c) = 2(\frac{k-1}{2} - 1) + 3 = k$, and $ab \notin E(H_k^k)$, since $d_{H_k}(a, b) = 2(\frac{k-1}{2} - 1) + 4 = k + 1$. But since all vertices $d < a$ in σ within distance k of b are also within distance k of c , there is no candidate vertex d to satisfy property (LB) for a, b, c . Thus σ is not a LexBFS ordering of H_k^k .

To complete the proof, we construct a graph G consisting of two copies of G_k if k is even (respectively, two copies of H_k if k is odd), with the vertices labeled 1 in each copy joined by an edge. Any LexBFS ordering of G when restricted to at least one of the copies of G_k (or H_k) will appear as a LexBFS ordering with start

vertex 1. Applying the argument above will identify vertices $a < b < c$ that violate property (LB) in G^k , completing our proof. $\square$

We note that the graph in Figure 3.2(b) is in fact strongly chordal. A graph is *strongly chordal* if it is chordal and every cycle $C = (x_1, \dots, x_{2k})$ of even length has a chord $x_i x_j$ where the distance between the endpoints x_i and x_j in C is odd. An immediate corollary of Theorem 3.4 is that for each $k \geq 1$, there exists a strongly chordal graph G such that no LexBFS ordering of G is a LexBFS ordering of G^{2k+1} .

LexBFS does, however, work for a particular class of graphs, as shown by the next theorem.

THEOREM 3.4. *Let G be a chordal bipartite graph. If σ is a LexBFS ordering of G , then σ is a LexBFS ordering of the graph G^2 .*

Proof. Let σ be a LexBFS ordering of a chordal bipartite graph $G = B(X, Y, E)$. Let $l(x)$ denote the BFS layer of x in σ ; $l(x) = 0$ if x is the first vertex of σ . We first state a few simple facts.

FACT 1. *If $x \in X$ and $xy \in E$, then $y \in Y$.*

FACT 2. *If $x \in X$ and $xy \in E^2 - E$, then $y \in X$.*

FACT 3. *If $x \in X$, $y \in Y$, and $z \in X$, then $l(x) = l(y) + 2i - 1 = l(z) + 2j$ for some (possibly negative) integers i, j .*

FACT 4. *If there is some induced P_5 a, b, c, d, e with $l(a) = l(e) = l(b) - 1 = l(d) - 1 = l(c) - 2$, then there exists an induced C_{2k} , $k \geq 3$, in G .*

To prove our theorem, suppose we have $a < b < c$ with $ac \in E^2$ and $ab \notin E^2$. We will show the existence of a vertex $z < a$ with $zb \in E^2$ and $zc \notin E^2$.

Case 1. $ac \in E$. By (LB) on $a < b < c$, there is a $d < a$ with $db \in E$ and $dc \notin E$. If $dc \notin E^2$, d satisfies the theorem. So assume $dc \in E^2 - E$. Since $ab \notin E^2$, we must have $da \notin E$. By Facts 2 and 3, and since $l(d) \leq l(a) = l(c) - 1$, we have $l(d) = l(c) - 2$. By (LB) on $d < a < b$, there is an $e < d$ with $ea \in E$ and $eb \notin E$. Since $l(e) = l(d)$, $ed \notin E$. By (LB) on $e < d < a$, there must be some $f < e$ with $fd \in E$, $fa \notin E$ and $l(f) = l(d) - 1 = l(c) - 3$. Thus $fb \in E^2$ and $fc \notin E^2$, satisfying our requirement.

Case 2. $ac \notin E$. Then there is some d with $da, dc \in E$; choose the leftmost (in σ) such d . Since $ab \notin E^2$, $db \notin E$. We have 4 cases for the position of d relative to a, b , and c .

Case 2.1. $c < d$. By (LB) on $a < c < d$, there is an $e < a$ with $ec \in E$ and $ed \notin E$. Since d is leftmost, $ea \notin E$. By (LB) on $e < a < c$, there is an $f < e$ with $fa \in E$ and $fc \notin E$. Then f, a, d, c, e is an induced P_5 such that Fact 4 gives us an induced cycle of length at least 6, contradicting G being chordal bipartite.

Case 2.2. $b < d < c$. By (LB) on $a < b < d$, there is an $e < a$ with $eb \in E$ and $ed \notin E$. Since $ab \notin E^2$, $ea \notin E$. For generality, we discard our assumptions that $b < d$ and $ed \notin E$. Now, by (LB) on $e < a < b$, there is some $f < e$ with $fa \in E$ and $fb \notin E$, which means $l(f) = l(a) - 1 = l(c) - 3$. If $fe \in E$, then $fb \in E^2$ and since $fc \notin E^2$, f satisfies the theorem. Otherwise $fe \notin E$, so applying (LB) to $f < e < a$ gives us a $g < f$ with $ge \in E$, $ga \notin E$. Since $l(g) \leq l(f) = l(c) - 3$, we know $gc \notin E^2$, so g fulfills the theorem since $gb \in E^2$.

Case 2.3. $a < d < b$. By (LB) on $d < b < c$, there is some $e < d$ with $eb \in E$ and $ec \notin E$. Since $ab \notin E^2$, $ea \notin E$. If $e < a$, we are in the generalized Case 2.2 above, and can find a vertex g to satisfy the theorem. When $a < e$, we can apply (LB) to $a < e < d$ to give an $f < a$ with $fe \in E$, $fd \notin E$. Thus $fb \in E^2$ and f satisfies the theorem unless there exists some g with $fg, gc \in E$. Suppose such a g exists. Then $l(f) = l(g) - 1 = l(c) - 2$ and $dg \notin E$. If $ag \notin E$, then a, d, c, g, f forms a P_5 and

Fact 4 gives us an induced cycle of length at least 6, contradicting G being chordal bipartite. Thus $ag \in E$ and $d < g$ (since d is leftmost). By (LB) on $f < d < g$, there is an $h < f$ with $hd \in E$ and $hg \notin E$. Then $l(h) = l(f)$ and $hf \notin E$. But then f, g, c, d, h is a P_5 such that Fact 4 gives us an induced cycle of length at least 6, contradicting G being chordal bipartite. Thus no such g can exist, and f satisfies the theorem.

Case 2.4. $d < a$. By (LB) on $d < b < c$, there is an $e < d$ with $eb \in E$, $ec \notin E$. Then $l(e) = l(b) - 1 = l(c) - 1$, so $ec \notin E^2$, thus completing the proof. $\square$

FIG. 3.3. A bipartite graph with a LexBFS ordering that is not a LexBFS ordering of the square.

Note that this theorem cannot be strengthened to bipartite graphs, as shown by the graph in Figure 3.3. Call this graph B . The ordering $\sigma = (a, b, c, d, e, f, g)$ is clearly a LexBFS ordering of B ; however, the triple of vertices $d < e < f$ violates property (LB) in B^2 . We have $df \in E^2$ and $de \notin E^2$, but every vertex in σ left of d that is adjacent to e in B^2 is also adjacent to f in B^2 . Attaching a second copy of B via an edge at a ensures no LexBFS ordering of the graph is a LexBFS ordering of its square.

4. Concluding remarks. We have examined six different search algorithms from the perspective of our key question: If a search visits a vertex a before b before c , and there is an edge ac but no edge ab , how could the search have visited b before c ? In this examination, we have discovered characterizing properties for the classic breadth-first and depth-first searches, and introduced a new class of maximal neighborhood searches. We summarize the characterizations of the six search paradigms and the hierarchy they form in Figure 4.1.

From this picture, one might be tempted to conjecture that the set of LexBFS orderings of a graph might be exactly the intersection of the set of MNS orderings and the set of BFS orderings. Clearly any LexBFS ordering must be both a BFS ordering and an MNS ordering, but the converse does not hold. For example, the ordering $(3, 1, 2, 5, 4)$ is both a BFS ordering and an MNS ordering of the gem in Figure 4.2, but is not a LexBFS ordering of this graph. Similarly for DFS, $(1, 2, 3, 4, 5)$ is both a DFS ordering and an MNS ordering of this graph, but not a LexDFS ordering.

We mentioned that the DFS algorithm produces two different orderings of the vertices of a graph: the discovery ordering and the finishing ordering. The following proposition relates these two orderings in the case of undirected graphs.

PROPOSITION 4.1. *For an arbitrary undirected graph G , an ordering σ of V is the reverse of a DFS finishing ordering if and only if σ has property (D).*

In other words, for undirected graphs, every ordering is the reverse of a finishing

FIG. 4.1. Summary of search characterizations. For example, vertex ordering σ is a LexDFS ordering if and only if σ satisfies the condition for generic search together with $dc \notin E$ and $a < d$.

FIG. 4.2. The gem, used as an example to distinguish sets of orderings.

ordering if and only if it is a discovery ordering. Note that a similar proposition does not hold for LexDFS.

Though we have concentrated on simple graphs in this paper, these ideas can easily be extended to more general environments. Our characterizations make no mention of multiple edges, but are equally applicable to searches on multigraphs. A search ordering implicitly imposes an orientation on the edges of a simple graph: it is straightforward to apply the same ideas to directed graphs to obtain similar characterizations. We can also extend such characterizations beyond graphs: these ideas also hold for searches on hypergraphs. We refer to [10] for details.

Such characterizing properties can be a very powerful and useful tool for studying graphs. Beyond giving us a better understanding of how a search reveals the structure

of a graph, it allows us to employ (and analyze) multiple sweeps of a search to gather additional information about a graph. Multisweep LexBFS has recently been applied to a variety of problems [3], resulting in very simple, and in many cases intuitive, algorithms. Will the results presented in this paper lead to multisweep algorithms involving other searches or combinations of different searches?

Acknowledgments. We wish to thank the anonymous referees for their valuable comments on the paper; in particular, one referee noticed Proposition 4.1 and kindly allowed us to include it in the paper. We also thank Marty Golumbic for his careful reading of an earlier draft of the paper.

A SIMPLE LINEAR TIME LexBFS COGRAPH RECOGNITION ALGORITHM*

ANNA BRETSCHER[†], DEREK CORNEIL[†], MICHEL HABIB[‡], AND CHRISTOPHE PAUL[§]

Abstract. Recently lexicographic breadth first search (LexBFS) has been shown to be a very powerful tool for the development of linear time, easily implementable recognition algorithms for various families of graphs. In this paper, we add to this work by producing a simple two LexBFS sweep algorithm to recognize the family of cographs. This algorithm extends to other related graph families such as P_4 -reducible, P_4 -sparse, and distance hereditary. It is an open question whether our cograph recognition algorithm can be extended to a similarly easy algorithm for modular decomposition.

Key words. graph algorithms, cograph recognition, linear time algorithms, LexBFS, P_4 -free graphs, modular decomposition

1. Introduction. We introduce a new¹ linear time algorithm to recognize *cographs*, namely, graphs with no induced path on four vertices (P_4). Although several optimal cograph recognition algorithms already exist, our algorithm is of interest for several reasons: it is conceptually and practically simpler than previous algorithms; it returns both positive and negative certificates; it is *lexicographic breadth first search* (LexBFS) based, introducing a new variant LexBFS[−]; it is the foundation of recognition algorithms for other related families of graphs; and finally, it could potentially be generalized to a simple linear time graph modular decomposition algorithm.

Cographs or *complement reducible* graphs have the property of being defined both recursively and by a simple forbidden induced subgraph characterization, namely, no induced P_4 [9]. Cographs are the family of graphs constructed from a single vertex under the closure of the operations of union and complementation or, equivalently, union and join. As shown in [9] these operations uniquely define a tree representation referred to as a *cotree*. The certificate returned by our algorithm is either a cotree representation if the graph is a cograph or an induced P_4 .

Cographs arise in applications such as examination scheduling problems [26], automatic clustering of index terms [17], and recently in the recognition of read-once functions [16]. Surprisingly, despite the structural simplicity of cographs, constructing linear time recognition algorithms has been challenging. The first linear time algorithm to recognize cographs and construct the cotree was achieved by Corneil, Perl, and Stewart [10] in 1985. The algorithm examines each vertex in turn, inserts it into the cotree if the graph is a cograph, and returns an induced P_4 otherwise. A

¹A variation of our algorithm, using three LexBFS sweeps instead of two, was outlined in [4].

parallel cograph recognition algorithm appeared in [13]. Recently, Habib and Paul [19] have used vertex splitting to produce a new linear time recognition algorithm for cographs. Despite being optimal, each of these algorithms requires more complex data structures or algorithmic techniques than our new algorithm.

The motivation for studying cographs lies not only in their simplicity but also in their extension to other families and to *modular decomposition*. In fact, our cograph algorithm has already been extended to recognize *distance hereditary*, *P_4 -reducible*, and *P_4 -sparse* graphs [3]. *Distance hereditary* graphs are characterized by the property that the distance between any two connected vertices of an induced subgraph equals their distance in the original graph. Their relationship to cographs stems from the fact that for any vertex v and integer k , the set of vertices at distance k from v induces a cograph. The family of *P_4 -reducible* graphs requires that each vertex belongs to at most one induced P_4 , and the *P_4 -sparse* graphs are defined by the restriction that any set of five vertices induces at most one P_4 . These two graph families belong to the *P_4 -heirarchy*, which is a set of graph families defined by various restrictions on the number or types of allowed induced P_4 s. Additional families in the *P_4 -heirarchy*, parity graphs and house, hole, domino (HHD)-free graphs, are related to cographs and may also be recognizable by similar algorithms.

There are several methods for *decomposing* or revealing the structure of a graph. A graph is decomposed by splitting the graph into smaller subgraphs in a well-defined manner. The ultimate goal is to decompose a graph into its most basic building blocks or *prime subgraphs*. An important consequence of the decomposition process is the construction of a tree representation of the graph (see, for example, [22]). Such a tree representation of a graph can lead to the simplification of difficult graph related problems, such as transitive orientation [24] and NP-hard problems such as maximum size clique, maximum size stable set, minimum coloring, and minimum clique covering, for restricted families of graphs.

Modular decomposition is one such decomposition scheme. Unfortunately, algorithms for modular decomposition are notorious for being either linear time and impractical or less efficient. The optimal *theoretical* algorithms (see [23, 14, 24, 12]) are linear in time; however, the best *practical* algorithms are only $\mathcal{O}(|V| + |E| \log |V|)$ [14, 20] and $\mathcal{O}(|V| + |E| \cdot \alpha(|V|, |E|))$ [14], where $\alpha(|V|, |E|)$ is the inverse Ackermann function. Recent results are proving hopeful that a simple linear time algorithm may exist for finding the modular decomposition of a graph. The motivation for this discussion lies in the relationship between cographs and modular decomposition.

Cographs are exactly those graphs that are completely decomposable with respect to modular decomposition; i.e., they are the graphs whose prime subgraphs are single vertices. Additionally, the cotree is exactly the modular decomposition tree for cographs. The cotree is algorithmically significant as a tool for dynamic programming algorithms, thereby reducing NP-hard problems such as coloring, clique detection, hamiltonicity, etc., on arbitrary graphs to fast polynomial time problems on cographs [9]. As we will show, our results provide a very natural cotree construction algorithm from two LexBFS orderings of the vertices. Since the algorithm was easily extended to construct tree representations of distance hereditary, *P_4 -reducible*, and *P_4 -sparse* graphs, a natural question is whether there exists a generalized algorithm to construct the modular decomposition tree for any graph. Note that any linear time modular decomposition algorithm, such as [23, 14, 24, 12], immediately yields a somewhat complicated, linear time cograph recognition algorithm.

As previously noted, our algorithm is based on two LexBFS orderings of the ver-

tex set. The real beauty of LexBFS lies in its straightforward implementation and linear running time. Not only can it be implemented in linear time for an input graph G , but using only the edges of G one can also do a LexBFS of the complement of G in time linear in the size of G . Furthermore, more sophisticated vertex selection methods can be easily implemented with minor modifications to the original LexBFS implementation. We will define one of these variations (LexBFS⁻) in section 3. LexBFS based recognition algorithms fall into a simple algorithmic paradigm of “*order*” the vertex set and “*check*” for a graph characterizing property. The following algorithm overview for our cograph recognition algorithm illustrates the paradigm.

Algorithm sketch RECOGNIZE_COGRAPH(G)

Input: Graph G .

end RECOGNIZE_COGRAPH

This technique of using LexBFS to construct a vertex ordering that has a graph characterizing property was first introduced by Rose, Tarjan, and Lueker [25] in 1976 for chordal graph recognition. Their algorithm produces a vertex ordering that is then tested for a property specific to chordal graphs, namely, a perfect elimination ordering [25]. More recently, this paradigm has been used to recognize interval graphs [11, 18], unit interval graphs [7, 21], and bipartite permutation graphs [5, 21]. See [6] for a survey of these algorithms as well as other applications of LexBFS.

The remainder of this paper is organized as follows. We begin by defining cograph and cotree specific notation and theory, followed by a discussion of LexBFS and the newly defined variant LexBFS⁻. The remaining sections discuss the algorithm and prove its correctness. The first of these sections proves the *neighborhood subset property* (NSP), a relationship between the neighborhoods of two sets drawn from the neighborhood and nonneighborhood with respect to a given vertex. This property leads naturally to the recognition algorithm, which is followed by an overview of the implementation details. We conclude by summarizing our results and indicating possible directions for future work.

2. Background. We will assume standard graph theoretic notation and definitions as in [28]; however, here we will highlight those of particular importance to this paper.

All graphs in this paper are undirected. Let U be a subset of V . Then $V - U$ or $V \setminus U$ is the set of vertices belonging to V and not U . The *cardinality* of U is denoted by $|U|$ and $G[U]$ is the subgraph of G , induced by U . We will denote the complement graph of $G = (V, E)$ by $\bar{G} = (V, \bar{E})$, where $\bar{E} = \{uv | u, v \in V, u \neq v, \text{ and } (u, v) \notin E\}$. The neighborhood $N(v)$, of vertex v , is the set of vertices adjacent to v , and the complement neighborhood $\bar{N}(v)$ is the set of vertices not adjacent to v in G .

We refer to a chordless path on k vertices by P_k . Suppose that $x_1x_2 \dots x_{k-1}x_k$ is a P_k . We say that x_1 and x_k are the endpoints of P_k and that $x_2, \dots, x_{k-1}$ are

the midpoints. Given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, the *union* of G_1 and G_2 is the graph $G = (V_1 \cup V_2, E_1 \cup E_2)$. The *join* of G_1 and G_2 is the graph $G = (V_1 \cup V_2, E_1 \cup E_2 \cup E)$, where $E = \{u_1 u_2 | u_1 \in V_1 \text{ and } u_2 \in V_2\}$.

Given a rooted tree T and two vertices x and y in T , we say that x is an *ancestor* of y , and y is a *descendant* of x , if x lies on the path from y to the root of T . For a set of leaves S of T , we say that the *lowest common ancestor* (lca) of S is the internal node v of T such that v is the root of the smallest rooted subtree of T containing S . We say that the children of a node are *siblings*. A subset $M \subseteq V$ is a *module* of $G = (V, E)$ if for all vertices $x, y \in M$ and $v \in V - M$, $xv \in E$ if and only if $yv \in E$.

2.1. Cographs and cotrees. Figure 1 illustrates a cograph G and an embedding of the corresponding cotree T_G . Leaves of T_G represent the vertex set V , and each internal node signifies the union (0) or join (1) operations on the children. The significance of the 0(1) nodes is captured by the fact that $xy \in E$ if and only if the $\text{lca}(x, y)$ is a 1 node, as depicted in Figure 1. For the remainder of this section, assume that G refers to a cograph and T_G to its cotree.

FIG. 1. (Left) A cograph G . (Right) An embedding of the cotree T_G of G .

The algorithm relies on the following properties of cographs:

1. *Complement property.* $\overline{G}$ is a cograph; i.e., cographs are closed under complementation.
2. *Complement cotree property.* The cotree $\overline{T}$ of $\overline{G}$ is exactly T with 0 and 1 nodes interchanged.
3. *Hereditary property.* Cographs are hereditary in the sense that any induced subgraph is also a cograph.
4. *Induced subtree property.* An induced rooted subtree t of T is the cotree of an induced subgraph of G .

Generally, given an internal 0 or 1 node u , we let T^u refer to the induced subtree rooted at u . However, we will need to be able to refer to more specific subtrees of a cotree. Consider the root R of T . Let x be a leaf of T . Then P_{xR} will denote the directed path of T from x to R . Note that with the exception of x , the path alternates between 0 and 1 nodes. Let $(0_1^x, \dots, 0_k^x)$ (resp., $(1_1^x, \dots, 1_{k'}^x)$) refer to the 0 nodes (resp.,

the 1 nodes) from x to R on P_{xR} . Notice that each node 0_i^x or 1_i^x has one child on P_{xR} and at least one child not on P_{xR} .

We now define the subtrees rooted on a path P_{yR} for each y . Consider 0_i^y on P_{yR} and only the children of 0_i^y that do *not* lie on P_{yR} . We can define the set of subtrees T_{0i}^y to be the induced subtrees rooted at these children of 0_i^y . The analogous definition holds for T_{1j}^y and 1_j^y . Figure 2 highlights four such sets, namely, $T_{01}^x, T_{02}^x, T_{11}^x$, and T_{12}^x , for the cotree presented in Figure 1.

FIG. 2. Each shaded subtree indicates a different subtree T_{0i}^x or T_{1j}^x rooted on the path P_{xR} .

We conclude this section with an observation about the induced subtrees T_{0i}^y and T_{1i}^y of a cotree.

OBSERVATION 1. *For any vertex y of a cograph, the leaves of T_{0i}^y (or T_{1i}^y) define a module. More generally, a set M of vertices is a module if and only if there exists a set U of sibling nodes of the cotree such that $M = \cup_{u \in U} \{x \mid x \text{ is a leaf of } T^u\}$.*

3. LexBFS and LexBFS⁻. We begin by describing a lexicographic breadth first search (LexBFS) and then develop the new variant, LexBFS⁻.

3.1. LexBFS. For a graph $G = (V, E)$, a *LexBFS* of G , denoted $\text{LexBFS}(G)$, is a breadth first search in which preference is given to vertices whose neighbors have been visited *earliest* in the search [25]. We denote this ordering by the function $\sigma : V \rightarrow \mathbb{N}$, where $\sigma(y) = i$ indicates that y is the i th vertex of σ and inversely, $\sigma^{-1}(i) = y$. We use $u <_\sigma v$ to indicate that $\sigma(u) < \sigma(v)$.

There are several different paradigms for implementing LexBFS. The term *lexicographic* stems from the original *labeling* paradigm in which vertices pass a label to each unnumbered neighbor. The next vertex is chosen such that it has the lexicographically largest label. Another conceptualization of LexBFS involves pivots and partitioning [18]. The partitioning paradigm will prove more useful for illustrating the variant LexBFS⁻. Algorithm LEXBFS below is a variation of the version appearing in [18].

The partitioning paradigm considers a pivot (the current vertex) and all unnumbered vertices. A vertex is considered to be visited if it has been a pivot, i.e., numbered. The algorithm begins with a list L of cells initialized to a single cell containing the vertex set. Each step consists of choosing a pivot α in the leftmost (first) cell of L . The pivot is removed from its cell and the unnumbered neighborhood of α is defined to be $N'(\alpha) = \{v \mid v \in N(\alpha) \text{ and } v \text{ unnumbered}\}$. For each cell $P \in L$, all

Algorithm LEXBFS(G, τ)

Input: A graph $G = (V, E)$ and an initial ordering τ of the vertices.

Output: An ordering σ of the vertices of G .

```

1.  $L \leftarrow (V)$ 
2.  $i \leftarrow 1$ 
3. while  $\exists P_i \neq \emptyset$  in  $L = (P_1, \dots, P_k)$  do
4.   Let  $P_l$  be the leftmost nonempty cell
5.   Remove the first vertex  $x$  (smallest with respect to  $\tau$ ) from  $P_l$ 
6.    $\sigma(x) \leftarrow i$ 
7.    $i \leftarrow i + 1$ 
8.   for each cell  $P_j, j \geq l$  do
9.     Let  $P' = \{v \mid v \in N(x) \cap P_j\}$ ;
10.    if  $P'$  is nonempty and  $P' \neq P_j$ , then
11.      Remove  $P'$  from  $P_j$ 
12.      Insert  $P'$  to the left of  $P_j$  in  $L$ 
13.    end for
14. end while
15. return  $(\sigma)$ 
end LEXBFS

```

members of $N'(\alpha)$ belonging to P are removed from P and inserted into a new cell P' positioned in L immediately to the left of P .

For example, if x is the first vertex selected by a LexBFS on G (see Figure 1 and Table 3.1), then the vertex set is split into two cells $\boxed{y \ u \ v \ w \ z}$ and $\boxed{d \ e \ c \ a \ b}$, where $\boxed{y \ u \ v \ w \ z}$ is moved ahead of $\boxed{d \ e \ c \ a \ b}$ since each vertex in $\{y, u, v, w, z\}$ is adjacent to x , whereas each vertex in $\{d, e, c, a, b\}$ is not adjacent to x .

The LexBFS terminates when all vertices have been visited. It outputs an ordering σ of the vertices. The numbering convention in this paper follows that of [11], where the ordering σ is the order in which vertices are visited during the LexBFS. Throughout the paper, when we refer to the “leftmost vertex” or “first” vertex in a set, the ordering is with respect to σ . Table 3.1 walks through a LexBFS of the cograph of Figure 1.

The following lemma is a very useful characterization of LexBFS orderings.

LEMMA 3.1 (see [15, 1]). Four point condition. *An ordering σ is a LexBFS of G if and only if for any $x <_\sigma y <_\sigma z$ such that $xz \in E$ but $xy \notin E$, there exists v such that $v <_\sigma x$, $vy \in E$, and $vz \notin E$.*

In addition, when restricted to cographs, LexBFS orderings can be shown to be *umbrella-free*. An *umbrella* of an ordering σ is a triple of vertices x, y, z such that $x <_\sigma y <_\sigma z$, where $xz \in E$, $xy \notin E$, and $yz \notin E$.

LEMMA 3.2. *Any LexBFS σ of a cograph G is umbrella-free (there does not exist $x <_\sigma y <_\sigma z$ such that $xz \in E$, $xy \notin E$, and $yz \notin E$).*

Proof. Let x, y, z be an umbrella such that x is leftmost in σ . By the four-point condition, there exist $u <_\sigma x$ such that $uy \in E$ but $uz \notin E$. Note that $ux \notin E$; otherwise, $\{u, x, y, z\}$ would induce a P_4 . But then u, x, y is also an umbrella, contradicting the choice of x . $\square$

We now introduce the notion of *slices*. Notice that when a pivot is selected from the leftmost cell, *any* vertex in the cell could be the pivot as each vertex in the cell

TABLE 3.1

Step by step LexBFS of G from Figure 1. The resulting ordering is $\sigma : x y w z u v a d c b e$.

$\sigma(\alpha)$	α	$N'(\alpha)$	Cells
			x d y u e v w c a z b
1	x	{y u v w z}	y u v w z d e c a b
2	y	{w z d e c a b}	w z u v d e c a b
3	w	{z d e c a b}	z u v d e c a b
4	z	{u v a}	u v a d e c b
5	u	{v a d e c b}	v a d e c b
6	v	{a d e c b}	a d e c b
7	a	{ }	d e c b
8	d	{c b}	c b e
9	c	{ }	b e
10	b	{ }	e
11	e	{ }	

has the same set of numbered neighbors. We say that these vertices form a *slice*. The following definitions formalize this notion.

Given an ordering σ of the vertices, for each vertex x , we can define subsets of the neighborhood of x ,

$$N_i(x) = \{u \mid u \in N(x) \text{ and } \sigma(u) < i\},$$

which contain the neighbors of x appearing before the i th vertex in the ordering σ . When the i th pivot of a LexBFS is selected, $N_i(x)$ is the same for each vertex x in the leftmost cell P_i (the following definition establishes that these vertices form a slice).

DEFINITION 3.3. A slice (or set of tied vertices) of a LexBFS ordering σ is a set of consecutive vertices $S = \{u \mid i \leq \sigma(u) \leq j\}$ such that for any $u \in S$, $N_i(u) = N_i(\sigma^{-1}(i))$, and for any v , $j < \sigma(v)$, or $\sigma(u) < i$, $N_i(v) \neq N_i(\sigma^{-1}(i))$.

Examples of slices of a LexBFS are the whole set V and the neighborhood of the first vertex visited by the search. Notice that there are exactly $|V|$ slices, one for each vertex of the search, or one for each occurrence of a “leftmost” cell in the LexBFS procedure. Consider the LexBFS obtained in Table 3.1. The different bracket styles indicate the slices constructed during the sweep and highlight those at a common nesting depth:

$$(3.1) \quad \sigma : [x(y\{w\langle z \rangle\}\{u\langle v \rangle\})(a)(d\{c\langle b \rangle\}\{e\})].$$

As shown by the following lemma, slices of a LexBFS ordering exhibit nice structural properties.

LEMMA 3.4. Let S be a slice of a LexBFS σ of a graph G . Then σ restricted to the vertices of S is a LexBFS of the subgraph induced by those vertices.

Since slices form the foundation of the recognition algorithm, we will need notation to refer to any slice of a LexBFS. The slice starting at vertex x will be denoted by $S(x)$. A *subslice* is a slice nested within a slice. In the following, some of the identified subslices may be empty. Notice that $S(x) \cap N(x)$ is a subslice of $S(x)$ which we denote by $S^A(x)$. Once the final vertex of $S^A(x)$ has been used as a pivot, the remaining vertices of $S(x)$ are grouped into cells $S(x) \cap \overline{N}(x) = S_1(x), S_2(x), \dots$, where all vertices in $S_i(x)$ have the same neighborhood in $S^A(x)$. The $S_i(x)$ are called x -cells. We let x_i be the first vertex, as chosen by σ , in $S_i(x)$. Note that $S_1(x)$ is a slice in

σ , whereas $S_j(x), j \geq 2$, could be the union of slices since there may be some edges from vertices in some $S_i(x), i < j$, to vertices in S_j . Since x_i is identified by σ , the four-point condition immediately establishes the following observation.

OBSERVATION 2. *Consider v -cell $S_j(v)$ as identified by σ . If some vertex in $S_j(v)$ other than v_j has a neighbor in $S_i(v)$ for $i < j$, then v_j also has a neighbor in $S_h(v), h \leq i$. Thus to find the leftmost vertex in $\overline{N}(v)$ that is adjacent to some vertex in $S_j(v)$, we have only to look at v_j 's neighbors.*

For cographs, each $S_i(x)$ is a maximal slice of $S(x)$, since, as shown in Lemma 3.6 below, any edge between two x -cells in $S(x) \cap \overline{N}(x)$ implies the existence of a P_4 . Equation (3.2) illustrates the subslices of $S(x)$ as defined by the LexBFS ordering of Table 3.1. (The $S_i(x)$ are slices since G is a cograph.) In particular, $S^A(x) = \{y, w, z, u, v\}$ and $S^N(x) = \langle S_1(x), S_2(x) \rangle$, where $S_1(x) = \{a\}$ and $S_2(x) = \{d, c, b, e\}$:

$$(3.2) \quad \mathbf{x} \ [\mathbf{y} \ \mathbf{w} \ \mathbf{z} \ \mathbf{u} \ \mathbf{v}] \ [\mathbf{a}] \ [\mathbf{d} \ \mathbf{c} \ \mathbf{b} \ \mathbf{e}].$$

Again it is noted that in a LexBFS ordering, the slice $S(x)$ is defined for each vertex x and that the sets $S^A(x)$ and $S^N(x)$ may be empty sets. Consider a, u , and c in (3.1); $S(a) = \{a\}$, so $S^A(a) = \emptyset$ and $S^N(a) = \emptyset$; $S^N(u)$ is empty in $S(u)$, while for vertex c the set $S^A(c)$ is empty.

DEFINITION 3.5. *If S is a consecutive set of vertices in a LexBFS ordering σ and x is the first vertex of S , then the left neighborhood of S is*

$$N_{<}(S) = \{y | y <_{\sigma} x \text{ and } y \in N(z) \ \forall z \in S\}.$$

LEMMA 3.6. *Let $G = (V, E)$ be a cograph and σ a LexBFS sweep of G . Then for any vertex v and $i < j$*

$$(3.3) \quad \forall x \in S_i(v), \forall y \in S_j(v), xy \notin E \text{ and}$$

$$(3.4) \quad N_{<}(S_i(v)) \supset N_{<}(S_j(v)).$$

Proof. We begin by showing that for any $x \in S_i(v)$ and $y \in S_j(v)$, $xy \notin E$. Assume that $xy \in E$ and i is the smallest index such that there exist $j > i$, $y \in S_j(v)$, and $xy \in E$. As $y \notin S_i(v)$ there exists $u \in S^A(v)$ such that $ux \in E$ and $uy \notin E$. As both x and y are nonadjacent to v , $\{v, u, x, y\}$ induces a P_4 , contradicting that G is a cograph, and thus (3.3) holds. Finally, Lemma 3.2 and (3.3) show that there does not exist $u <_{\sigma} x$ such that $uy \in E$ but $ux \notin E$, thereby proving (3.4). $\square$

A property similar to Lemma 3.6, stated differently, has been observed in [13].

3.2. LexBFS⁻. In the above implementation of LexBFS, Algorithm LEXBFS selects the pivot x from the leftmost cell, and for each cell P_j , the vertices in $N(x) \cap P_j$ are removed from P_j and inserted into a new cell P' that is inserted to the *left* of P_j . Notice that inserting P' to the *right* of P_j is equivalent to inserting the *nonneighbors* in P_j , $\overline{N}(x) \cap P_j$, to the left of the neighbors of x in P_j , i.e., equivalent to performing a LexBFS of the complement of G . Thus, a LexBFS of $\overline{G}$ can be accomplished in linear time *without* computing $\overline{G}$, i.e., using only the edge set of G and Algorithm LEXBFS with a small modification to line 12, namely,

$$12^- \text{Insert } P' \text{ to be the right of } P_j \text{ in } L.$$

A *LexBFS minus*, or LexBFS⁻, of a graph G is a modified version of a LexBFS of $\overline{G}$. The modification arises in how the pivots are selected. The idea is to have an initial LexBFS ordering τ of G . LexBFS⁻(G, τ) does a LexBFS of $\overline{G}$ and selects the

next pivot to be the vertex in the leftmost cell that was numbered earliest in τ . To implement this “*tie-breaking mechanism*,” simply pass τ as the initial ordering of the vertex set. Notice that the leftmost vertex in the leftmost cell *is* the vertex that was numbered earliest in τ . Therefore, a $\text{LexBFS}^-(G, \tau)$ can easily be implemented in linear time with minor modifications to Algorithm LEXBFS. It follows that a minus sweep on $\overline{G}$ can also be accomplished in linear time. Such an ordering resulting from $\text{LexBFS}^-(G, \sigma)$ will be denoted $\overline{\sigma}^-$.

The slice-cell notation for a LexBFS ordering $\overline{\sigma}$ of $\overline{G}$ follows that of a LexBFS of G . We will denote the slice starting at vertex x and its subslice of adjacent vertices by $\overline{S}(x)$, $\overline{S}^A(x)$, respectively. The remaining x -cells are $\overline{S}^N(x) = \langle \overline{S}_1(x), \dots, \overline{S}_k(x) \rangle$. For example, given the graph G in Figure 1 and $\sigma : xyzwzuvadcbe$, LexBFS^- yields

$$\overline{\sigma}^- : \mathbf{x} [\mathbf{a} \mathbf{d} \mathbf{e} \mathbf{c} \mathbf{b}] [\mathbf{z}] [\mathbf{y} \mathbf{u} \mathbf{v} \mathbf{w}],$$

where $\overline{S}^A(x) = \{a, d, e, c, b\}$ and $\overline{S}_1(x) = \{z\}$, $\overline{S}_2(x) = \{y, u, v, w\}$.

The next lemma highlights an important observation about modules and LexBFS^- sweeps.

LEMMA 3.7. *Let M be a module of a graph G , let σ be a LexBFS of G , and let $\overline{\sigma}^-$ be the ordering resulting from $\text{LexBFS}^-(G, \sigma)$. The first vertex of M in σ is v if and only if v is the first vertex of M in $\overline{\sigma}^-$. Furthermore, $S(v)$ and $\overline{S}(v)$ are the inclusion minimal slices of σ , respectively, $\overline{\sigma}^-$, containing M .*

Proof. Let v be the first vertex of M visited by $\overline{\sigma}^-$. At the stage v is selected in $\overline{\sigma}^-$, M is contained in the slice $\overline{S}(v)$. Since v breaks the tie, v must be the first vertex of $\overline{S}(v)$ to appear in σ and therefore the first vertex of M to appear in σ .

Assume v is the first vertex of M in σ . Let $\overline{S}$ be the inclusion minimal slice of $\overline{\sigma}^-$ containing M , and let u be the first vertex of $\overline{S}$. If $u \neq v$, then $u \in \overline{S} \setminus M$. But this implies that there exists a slice $\overline{S}' \subseteq \overline{S} \setminus \{u\}$ containing M , contradicting the minimality of $\overline{S}$. $\square$

Motivated by Lemma 3.6, we wish to have a property appearing in σ or $\overline{\sigma}^-$ that indicates the presence of a P_4 in G . To set the stage for this, we are interested in whether the first vertex of a specific P_4 in a given LexBFS is an endpoint or a midpoint of the P_4 . In particular, note that a LexBFS of a P_4 starting at a midpoint of the P_4 satisfies the conditions of Lemma 3.6, whereas a LexBFS starting at an endpoint does not. First, we prove a result about the presence of P_4 s in an arbitrary LexBFS.

LEMMA 3.8. *Let $S(v)$ be the minimal slice of LexBFS σ that contains $P_4 p$. If v does not belong to any P_4 s in G , then $p \cap S^A(v)$ consists of the midpoints of p .*

Proof. By the minimality of $S(v)$, we know that v is not universal to p , since $S^A(v)$ is a slice of $S(v)$. If v is not adjacent to any vertices in p , then, again by the minimality of $S(v)$, there is some vertex $x \in S^A(v)$ that is adjacent to some, but not all, vertices in p . Thus there is an edge $yz \in p$ such that $xy \in E$, $xz \notin E$; but now we have a P_4 on v, x, y, z , contradicting v not belonging to a P_4 . Thus v is adjacent to some, but not all, vertices of p . Now it is easy to check that for v to avoid being in a P_4 , v must be adjacent to the midpoints of p , as required. $\square$

We now use this lemma to study the relative starting points of a $P_4 p$ in σ and of $\overline{p}$ in $\overline{\sigma}^-$.

COROLLARY 3.9. *Let σ be an arbitrary LexBFS of graph G , and let vertex w be the first vertex of σ that is in a P_4 . Let p be an arbitrary P_4 that contains w . If w is an endpoint of p , then in $\overline{\sigma}^-$, the first vertex of $\overline{p}$ is a midpoint of $\overline{p}$.*

Proof. Let $\overline{S}(v)$ be the minimal slice of $\overline{\sigma}^-$ containing $\overline{p}$. If $v \in \overline{p}$, then $v = w$ and the corollary clearly holds. Otherwise, since w is the leftmost vertex in σ that

belongs to a P_4 , and $w \in \overline{S}(v)$, we know that $v <_\sigma w$ and thus v does not belong to a P_4 . The result now follows by applying Lemma 3.8 to $\overline{\sigma}^-$. In particular, all such P_4 s $\overline{p}$ in $\overline{S}(v)$, regardless of whether w is an endpoint of p , have a midpoint as their first vertex is $\overline{\sigma}^-$. $\square$

The previous results deal only with the “first” P_4 s. We now show that these results cannot be generalized to all P_4 s. For example, not all P_4 s with an endpoint as the first vertex in σ have a midpoint as the first vertex of the complement P_4 in $\overline{\sigma}^-$, as demonstrated by C_5 123451, $\sigma : 1\ 2\ 5\ 3\ 4$, and $\overline{\sigma}^- : 1\ 3\ 4\ 5\ 2$. The $P_4 : 2345$ in G and the $P_4 : 3524$ in $\overline{G}$ have endpoints 2 and 3, respectively, as the first vertex in σ and $\overline{\sigma}^-$, respectively. Furthermore, it is possible for a P_4 to have both endpoints as midpoints of p and $\overline{p}$, respectively. To see this, consider a “bull” (a vertex v adjacent to the midpoints of a P_4) and a LexBFS starting at v . Note that the “bull” is self-complimentary.

4. Correctness of the algorithm. Recall that in the cograph recognition algorithm overview given previously, the algorithm consists of a LexBFS sweep σ , followed by a LexBFS $^-$ of G using σ as the input vertex ordering. A certificate in the form of a cotree or an induced P_4 is returned. This section first presents a characterization of cographs in terms of a property of σ and $\overline{\sigma}^-$. We then consider the case when the input graph G does not satisfy this property and a P_4 is returned, followed by the case where G does satisfy the property and a cotree is constructed. We show how LexBFS orderings can be used to characterize the family of cographs.

4.1. The neighborhood subset property. Motivated by Lemma 3.6, this section introduces the neighborhood subset property (NSP) and a related theorem characterizing cographs.

DEFINITION 4.1. *The local neighborhood of a v -cell $S_i(v)$, denoted by $N^l(S_i(v))$, of a slice $S(v)$ for a LexBFS σ is the set of vertices in $S(v)$ before v_i adjacent to at least one vertex in $S_i(v)$.*

Notice that in the case of cographs, it directly follows from Lemma 3.6, (3.3), that the above definition can be restricted.

OBSERVATION 3. *If σ is a LexBFS of a cograph, then $N^l(S_i(v)) = N_{<}(S_i(v)) \cap S^A(v)$.*

DEFINITION 4.2. *A LexBFS sweep satisfies the NSP if and only if*

$$\forall v \in V, \forall i < j, \text{ such that } S_j(v) \neq \emptyset, N^l(S_i(v)) \supset N^l(S_j(v)).$$

As pointed out in the previous section, a LexBFS of a P_4 starting at a midpoint of the P_4 does not violate the NSP. However, as shown in the following theorem, by looking at both σ and $\overline{\sigma}^-$ we are guaranteed to find a P_4 that does violate the property.

THEOREM 4.3 (neighborhood subset theorem). *Let σ be a LexBFS ordering of a graph $G = (V, E)$, and let $\overline{\sigma}^-$ be the sweep LexBFS $^-(G, \sigma)$. Then G is a cograph if and only if σ and $\overline{\sigma}^-$ satisfy the NSP.*

Proof. ($\Rightarrow$) Assume that G is a cograph. Lemma 3.6 and Observation 3 prove that σ satisfies the NSP. As $\overline{G}$ is a cograph, applying Lemma 3.6 and Observation 3 on $\overline{G}$ and $\overline{\sigma}^-$ proves that the NSP holds for $\overline{\sigma}^-$.

($\Leftarrow$) Assume that G is not a cograph; i.e., there exists an induced P_4 . First notice that the complement $\overline{p}$ of a P_4 p is a P_4 and that the midpoints of p are precisely the endpoints of $\overline{p}$. The following properties are the core arguments of the proof.

CLAIM 1. Let $p = abcd$ be an induced P_4 of G . Notice that the endpoints are a and d . If $S(a)$ contains p , then there exists a pair of integers i, j such that $S_i(a)$ and $S_j(a)$ fail the NSP.

Proof. Since a is adjacent to b but not adjacent to c or d , $b \in S^A(a)$ and there exists a pair of integers i, j such that $c \in S_i(a)$ and $d \in S_j(a)$. Since b is adjacent to c but not to d , i and j are distinct integers. If $c <_\sigma d$ (i.e., $i < j$) as $cd \in E$, $bc \in E$, and $bd \notin E$, $N^l(S_i(a)) \not\supseteq N^l(S_j(a))$. Otherwise, $d <_\sigma c$ (i.e., $j < i$), and the four-point condition applied on $b <_\sigma d <_\sigma c$ implies the existence of a vertex $x \in S^A(a)$, $x <_\sigma b$, such that $xd \in E$ and $xc \notin E$. Thereby $N^l(S_j(a)) \not\supseteq N^l(S_i(a))$, failing the NSP. $\square$

CLAIM 2. Let $p = abcd$ be an induced P_4 of G . If $S(v)$ with v not in any P_4 is the inclusion-minimal slice of LexBFS σ containing p , then there exists a pair of integers i, j such that $S_i(v)$ and $S_j(v)$ fail the NSP.

Proof. By Lemma 3.8, $p \cap S^A(v) = \{b, c\}$; thus $a \in S_i(v)$ and $d \in S_j(v)$. Finally, since $b \in N(a) \setminus N(d)$ and $c \in N(d) \setminus N(a)$, the local neighborhoods $N^l(S_i(v))$ and $N^l(S_j(v))$ fail the NSP. $\square$

We now return to the proof that if G is not a cograph, then the NSP fails. Since G is not a cograph, there exists a P_4 p in G or, equivalently, $\bar{p}$ in $\bar{G}$. We let w be the leftmost vertex in σ that is in some P_4 and let $p = abcd$ be any P_4 containing w . Examine $\bar{p}$ in $\bar{G}$ and let $\bar{S}(v)$ be the inclusion-minimal slice containing $\bar{p}$. Three distinct cases have to be considered:

1. Vertex v is an endpoint of $\bar{p}$. Then Claim 1 applies.
2. Vertex v is a midpoint, say, a , of $\bar{p}$. Thus a is the leftmost vertex of p in σ and is an endpoint of p . Let $S(u)$ be the inclusion minimal slice of σ containing p . If $u = w = a$, Claim 1 applies; otherwise, by the choice of w , u is not in any P_4 , and Claim 2 applies.
3. Vertex v does not belong to $\bar{p}$. By the LexBFS⁻ rule, v is to the left of $\{a, b, c, d\}$ in σ and thus is not in any P_4 , by our choice of p . Thus Claim 2 applies. $\square$

We now show that the NSP for σ can be tested in linear time.

LEMMA 4.4. Given the list of local neighborhoods, $N^l(S_i(v))$, $i > 0$, for each vertex v , sorted with respect to the same ordering (say, σ), the NSP of σ can be tested in $\mathcal{O}(n + m)$.

Proof. For each vertex v and for each i , first check that $|N^l(S_{i+1}(v))| < |N^l(S_i(v))|$; if not, report failure. Otherwise, simultaneously walk the lists $N^l(S_i(v))$ and $N^l(S_{i+1}(v))$. If the current vertex x of $N^l(S_{i+1}(v))$ is not the current vertex of $N^l(S_i(v))$, then walk $N^l(S_i(v))$ until x is reached. If x is not reached, then the inclusion $N^l(S_{i+1}(v)) \subset N^l(S_i(v))$ is not satisfied and failure is reported. If $N^l(S_{i+1}(v))$ is walked without reporting failure, then report success.

Since each local neighborhood is searched at most twice, the above algorithm runs in time linear in the total size of the local neighborhoods. Since there are at most n slices, there are at most n local neighborhoods. The size of each local neighborhood of a v -cell $S_i(v)$ is bounded by the number of “left” edges from vertices in $S_i(v)$. Therefore, summing the sizes of all the neighborhood sets results in $\mathcal{O}(n + m)$ complexity. $\square$

4.2. Reporting a P_4 from σ or $\bar{\sigma}^-$ (when G fails the NSP). We now consider the certificate returned by the algorithm, an induced P_4 , when the input graph is not a cograph.

LEMMA 4.5. Let σ be a LexBFS ordering failing the NSP for v -cells of $S^N(v)$. If j is the smallest integer such that $S_j(v)$ and $S_{j+1}(v)$ fail the NSP, then one of the

following induced P_4 s is in G :

$$vw y v_{j+1} \quad \text{or} \quad v_j w y v_{j+1} \quad \text{or} \quad y v w v_j,$$

where v_i is the first vertex chosen by σ in $S_i(v)$, $w <_\sigma v_j$, $w \in (N(v_j) \setminus N(v_{j+1})) \cap S^A(v)$, and $y <_\sigma v_{j+1}$, $y \in (N^l(v_{j+1}) \setminus N^l(v_j))$.

Proof. By the definition of v -cells, there exists $w \in S^A(v)$ such that $w \in N(v_j) \setminus N(v_{j+1})$. We now show that there exists $y <_\sigma v_{j+1}$ such that $y \in N^l(v_{j+1}) \setminus N^l(v_j)$. Since $S_j(v), S_{j+1}(v)$ fail the NSP, there exists $x \in S_{j+1}(v)$ adjacent to $z \in N^l(v_{j+1}) \setminus N^l(v_j)$. If $v_{j+1}z \in E$, then set $y = z$. Otherwise, by the four-point condition on z, v_{j+1}, x , there exists $z' <_\sigma z$ such that $z'v_{j+1} \in E, z'x \notin E$. Thus by the definition of $S_{j+1}(v)$, $z' \in \bar{N}(v)$. If $z' \in S_j(v)$, then set $y = z'$. If $z' \in N^l(v_j)$ and thus $z' <_\sigma v_j$, we have contradicted the choice of $j, j+1$. Without loss of generality, we assume y is the *rightmost* such vertex. There are two cases; y is either a neighbor of v or a nonneighbor.

FIG. 3.

1. y is a nonneighbor of v . There exists $i < j+1$ such that $y \in S_i(v)$ (see Figure 3). Since j is minimum, w adjacent to v_j implies that w is also adjacent to y . Note that v is a neighbor of w ; v is not a neighbor of y or v_{j+1} ; w is a neighbor of y but not v_{j+1} ; and y is a neighbor of v_{j+1} . Hence, $\{v, w, y, v_{j+1}\}$ is an induced P_4 .
2. y is a neighbor of v . Then $y \in S^A(v)$, and since y is rightmost, v_j and v_{j+1} are not adjacent (see Figure 4). It follows that the subgraph induced by the set of vertices $\{v, w, y, v_j, v_{j+1}\}$ contains an induced P_4 . More precisely, if w and y are adjacent, $v_j w y v_{j+1}$ is an induced P_4 ; otherwise $v_j w v y v_{j+1}$ is an induced P_5 , containing the induced P_4 $y v w v_j$, thereby completing the proof. $\square$

FIG. 4.

We now have the following simple algorithm $\text{Report\_}P_4$ to output an induced P_4 once the neighborhood subset test returns a vertex v and an index $j \geq 1$ such that the first pair of v -cells failing the NSP are $S_j(v)$ and $S_{j+1}(v)$. Note that our description is for σ only; see the comments at the end of section 5 for the minor modifications needed to produce a P_4 , if the NSP failure is in $\bar{\sigma}^-$.

Algorithm REPORT- $P_4(\sigma, \bar{\sigma}^-)$

Input: Vertex v and smallest index j such that $S_j(v), S_{j+1}(v)$ fail the NSP in σ

Output: An induced P_4 .

Choose $w \in (N^l(v_j) \setminus N^l(v_{j+1})) \cap S^A(v)$

Choose y to be the rightmost vertex such that $y \in N^l(v_{j+1}) \setminus N^l(v_j)$

if $yv \notin E$

return ($vw y v_{j+1}$)

else if $wy \in E$

return ($v_j w y v_{j+1}$)

else

return ($y v w v_j$)

end REPORT- P_4

LEMMA 4.6. *Reporting a P_4 , given a pair of v -cells $S_j(v)$ and $S_{j+1}(v)$ of σ failing the NSP, takes at most $\mathcal{O}(\Delta)$ time, where Δ is the maximum degree of the graph.*

Proof. Assume that the local neighborhoods are sorted according to the LexBFS ordering σ . To locate vertices $w \in (N^l(v_j) \setminus N^l(v_{j+1})) \cap S^A(v)$ and $y \in N^l(v_{j+1}) \setminus N^l(v_j)$, simply walk the local neighborhoods $N^l(v_j)$ and $N^l(v_{j+1})$, each of which are no larger than Δ . The adjacency test between y and w takes Δ time simply by walking the adjacency list of w or of y . $\square$

4.3. Constructing the cotree from $\sigma, \bar{\sigma}^-$ (when G satisfies the NSP).

We now assume that the graphs we are operating on are cographs. We will refer to an arbitrary cograph as G and its cotree as T with root R . We begin by relating slices $S_i(x)$ to modules of G and subtrees T_{0i}^x of G . This relationship results in a simple cotree construction algorithm.

Let x be an arbitrary vertex of G and consider the LexBFS(G) starting at x , resulting in σ , and the ordering $\bar{\sigma}^-$ produced by LexBFS $^-(G, \sigma)$. The following observation follows directly from the neighborhood subset theorem.

OBSERVATION 4. *Each $S_i(x)$ and $\bar{S}_j(x)$ induces a module in G .*

Furthermore, there is a well-defined relationship between the leaves of an induced subtree in T and the vertices in each $S_i(x)$ or $\bar{S}_j(x)$.

LEMMA 4.7. *Let x be the first vertex of a LexBFS σ of G . For any i , the slice $S_i(x)$ contains exactly the leaves of T_{0i}^x .*

Proof. Consider σ and the stage of the sweep where x and each vertex of $S^A(x)$ have been numbered. Since x is the first vertex of σ , only nodes adjacent to x have been numbered. If a vertex in $S^A(x)$ is adjacent to the leaves of T_{0i}^x , then by the neighborhood subset theorem, the vertex is adjacent to all leaves in T_{0j}^x , where $j < i$; see Figure 2. Therefore, the leaves of T_{01}^x must belong to the slice $S_1(x)$. By the neighborhood subset theorem, no leaf in T_{0i}^x is adjacent to any leaf in $T_{0j}^x, j \neq i$. Consequently, we can use the same argument to show that the next slice $S_2(x)$ contains exactly the leaves of T_{02}^x and, inductively, that the i th slice $S_i(x)$ contains the leaves of the subtree T_{0i}^x . $\square$

COROLLARY 4.8. *Let x be the first vertex of a LexBFS σ of a cograph G , and let τ be any LexBFS of $\bar{G}$ that starts at x (for example, $\bar{\sigma}^-$). Then, in τ , for any j , $\bar{S}_j(x)$ contains exactly the leaves of T_{1j}^x .*

Proof. Since the cotree of $\bar{G}$ is exactly the cotree of G with 1 and 0 nodes interchanged, Lemma 4.7 applied to τ implies that $v \in \bar{S}_i(x)$ if and only if $v \in$

T_{1i}^x . $\square$

Lemma 4.7 and Figure 2 motivate the following corollary.

COROLLARY 4.9. *Given σ and $\bar{\sigma}^-$ of a cograph G , if x is the first vertex of σ , then the path P_{xR} can be reconstructed from the sequences $S^N(x)$ and $\bar{S}^N(x)$.*

Proof. Lemma 4.7 applied to σ and to $\bar{\sigma}^-$ shows that each $S_i(x)$ and $\bar{S}_i(x)$ slice defines the set of leaves of each T_{0i}^x and T_{1i}^x subtree. To embed P_{xR} , it remains only to determine which of 0_1^x and 1_1^x is the parent of the leaf x in the cotree. Let u (resp., v) be the first vertex of $S_1(x)$ (resp., $\bar{S}_1(x)$). It is straightforward to see that 0_1^x is the parent of leaf x if and only if u is adjacent to v . $\square$

These results, along with the hereditary property of cographs, motivate the following preliminary recursive cotree construction algorithm.

Algorithm TREE (module M , G)

Input: A module M of cograph G .

Output: A Cotree T of M .

```

if  $M = \{v\}$ 
    return ( $\{v\}$ )
for any  $v \in M$ , compute:
    [ $v, S^A(v), S_1(v), \dots, S_k(v)$ ] with respect to  $\sigma$ , an arbitrary LexBFS of  $G[M]$ 
    [ $v, \bar{S}^A(v), \bar{S}_1(v), \dots, \bar{S}_h(v)$ ] with respect to  $\bar{\sigma}^-$ , the LexBFS $^-$  of  $\bar{G}[M]$ 
    with respect to  $\sigma$ 
    if  $S^A(v) = \emptyset$  ( $\bar{S}^A(v)$ , resp.),
        return ( $v \textcircled{0} \text{ TREE}(S_1(v), G)$ ) (resp., ( $v \textcircled{1} \text{ TREE}(\bar{S}_1(v), G)$ ))
    else for any  $a \in S_1(v)$  and  $b \in \bar{S}_1(v)$ 
        if  $ab \in E$ , then
            ( $\star$ ) return ( $v \textcircled{0} \text{ TREE}(S_1(v), G) \textcircled{1} \text{ TREE}(\bar{S}_1(v), G) \textcircled{0} \text{ TREE}(S_2(v), G) \dots$ )
        else
            ( $\star\star$ ) return ( $v \textcircled{1} \text{ TREE}(\bar{S}_1(v), G) \textcircled{0} \text{ TREE}(S_1(v), G) \textcircled{1} \text{ TREE}(\bar{S}_2(v), G) \dots$ )

```

Note that the notation “ $x \textcircled{1} T_1 \textcircled{0} T_2 \dots$ ” is parsed as “ $((x \textcircled{1} T_1) \textcircled{0} T_2) \dots$ ” and means that x and T_1 are children of a 1 node, this 1 node and T_2 are the children of a 0 node, etc. In addition, we point out that if T_1 is rooted at a 1 node, the $\textcircled{1}$ operation will *merge* the two 1 nodes together and likewise for the 0 node case. The correctness of the algorithm follows directly from Lemma 4.7, Observation 4, Corollary 4.9, and the properties of cographs.

LEMMA 4.10. *If G is a cograph, Algorithm TREE($V(G)$, G) returns T , the cotree of G .*

Proof. The proof is a simple induction argument. Certainly, a single leaf is the cotree of the graph on one vertex. So now consider when M is the entire vertex set $V(G)$. Corollary 4.9 proves that v and the $\textcircled{1}$ and $\textcircled{0}$ nodes in line ($\star$) or ($\star\star$) construct the path P_{vR} for the cotree of the cograph G . The remainder of the cotree consists of the subtrees whose parent nodes lie on P_{vR} . Since each slice $S_i(v)$ or $\bar{S}_i(v)$ is a module and furthermore, by the hereditary property of cographs, induces a cograph, by the inductive assumption, TREE($S_i(v)$, G) will return the cotree representing $G[S_i(v)]$. In addition, by Lemma 4.7, the cotree returned by TREE($S_i(v)$, G) is exactly the subtree T_{0i}^v of T . An analogous argument using Corollary 4.8 holds for $\bar{S}_j(v)$, completing the proof. $\square$

For complexity reasons, it is impractical to compute LexBFS and LexBFS⁻ orderings of each module in G . To meet the linear time bound, TREE(V(G), G) needs to be altered to use only the two orderings σ and $\bar{\sigma}^-$, a LexBFS of G and a LexBFS⁻ of G using σ . Lemma 4.11 and Corollary 4.12 show that in certain situations, the two sweeps are sufficient.

LEMMA 4.11. *Given σ and $\bar{\sigma}^-$ of G and $S_i(v)$, for arbitrary v and i , if $S_i(v) = S(y)$ contains exactly the leaves of T_{0i}^v , then $S_j(y)$ contains exactly the leaves of T_{0j}^y for all j .*

Proof. Since $S(y) = S_i(v) = T_{0i}^v$, $S_i(v)$ induces a module and a cograph. Therefore, applying Lemma 4.7 to $S(y)$ implies that $S_j(y)$ contains exactly the leaves of T_{0j}^y for all j . $\square$

Complementing Lemma 4.11 results in Corollary 4.12.

COROLLARY 4.12. *Given σ and $\bar{\sigma}^-$ of G and $\bar{S}_i(v)$ for arbitrary v and i , if $\bar{S}_i(v) = \bar{S}(y)$ contains exactly the leaves of T_{1i}^v , then $\bar{S}_j(y)$ contains exactly the leaves of T_{1j}^y for all j .*

This raises the following questions: If $S(y) = S_i(v) = T_{0i}^v$, does $\bar{S}_j(y)$ contain exactly the leaves of T_{1j}^y for each j ? Or, if $\bar{S}(y) = \bar{S}_i(v) = T_{1i}^v$, does $S_j(y)$ contain exactly the leaves of T_{0j}^y for each j ? We now answer these questions with the following observation and lemmas.

Since the leaves of an induced subtree of a cotree induce a module, the next observation follows immediately from Lemma 3.7.

OBSERVATION 5. *Given σ and $\bar{\sigma}^-$ of G , if z is the leftmost vertex with respect to σ in T_{0i}^y then $T_{0i}^y \subseteq S(z)$ and $T_{0i}^y \subseteq \bar{S}(z)$. The same is true for z , the leftmost vertex with respect to σ in T_{1j}^y .*

Lemma 4.13 claims that if $S_i(v)$ contains the leaves of a subtree T_{0i}^v , then in $\bar{\sigma}^-$, the only vertices in the inclusion minimal slice containing $S_i(v)$ either belong to $S_i(v)$ or are independent of $S_i(v)$.

LEMMA 4.13. *Consider σ and $\bar{\sigma}^-$ of G and any vertex v such that $S(v)$ is a module and any index i such that $S_i(v)$ contains exactly the leaves of T_{0i}^v . Let $\bar{S}(u)$ be the inclusion-minimal slice containing $S_i(v)$; then $\bar{S}(u) - S_i(v)$ is a subset of $\bar{S}^A(u)$ and for all $z \in \bar{S}(u) - S_i(v)$, z is independent of the vertices in $S_i(v)$.*

Proof. By Lemma 3.7 and the fact that $S(v)$ induces a module, $S(v) \subseteq \bar{S}(v)$. Since each vertex in $S_i(v)$ is not adjacent to v and $S_i(v) \subseteq \bar{S}(u) \subseteq \bar{S}(v)$, every vertex in $\bar{S}(u)$ must be uniform with respect to v . Therefore, for all $y \in \bar{S}(u)$, y and v cannot be adjacent, implying that $\text{lca}(y, v) = 0$. Now consider any vertex $z \in \bar{S}(u) - S_i(v)$. Since $\text{lca}(z, v) = 0$, then $z \in T$, where T is rooted at the child of a 0 node (not 0_i^v) on P_{vR} . Hence, the lca of z with any leaf in T_{0i}^v is a 0 node. Since $u \in S_i(v)$ and every vertex in $\bar{S}(u) - S_i(v)$ is not adjacent to u , it must be the case that $\bar{S}(u) - S_i(v) \in \bar{S}^A(u)$ and for all $z \in \bar{S}(u) - S_i(v)$, z is independent of the vertices in $S_i(v) = T_{0i}^v$. $\square$

Lemma 4.13 indicates that we can recurse on $\bar{S}(u)$ to construct the 1-rooted subtrees of T_{0i}^v . Similarly, Corollary 4.14 shows that the complement case holds as well, i.e., that if $\bar{S}_j(v)$ contains exactly the leaves of T_{1j}^v , then we can recurse on the inclusion-minimum slice containing $\bar{S}_j(v)$ in σ to construct the 0 rooted subtrees of T_{1j}^v . The proof of the corollary is very similar to that of the lemma.

COROLLARY 4.14. *Consider σ and $\bar{\sigma}^-$ of G and any vertex v such that $\bar{S}(v)$ is a module and any index j such that $\bar{S}_j(v)$ contains exactly the leaves of T_{1j}^v . Let $S(u)$ be the inclusion-minimal slice containing $\bar{S}_j(v)$; then $S(u) - \bar{S}_j(v)$ is a subset of $S^A(u)$ and for all $y \in S(u) - \bar{S}_j(v)$, y is universal to the vertices in $\bar{S}_j(v)$.*

LEMMA 4.15. *Consider σ and $\bar{\sigma}^-$ of G . For any vertex v in V , $S_i(v)$ contains exactly the leaves of T_{0i}^v and $\bar{S}_j(v)$ contains exactly the leaves of T_{1j}^v .*

Proof. Throughout this proof we will apply Observation 4 to conclude that the various $S_j(v), \bar{S}_j(v)$ are modules. By Lemma 4.7 and Corollary 4.8, if v is the first vertex of σ , the claim holds. The proof will be by induction on the nested depth of the subslices. Assume that $S(y)$ is a module and that $S_i(y)$ contains exactly the leaves of T_{0i}^y and $\bar{S}_j(y)$ contains exactly the leaves of T_{1j}^y . We will consider each case separately.

Let v be the first vertex of $S_i(y)$, so $S(v) = S_i(y)$. By Lemma 4.11, each $S_k(v)$ contains exactly the vertices of the subtrees T_{0k}^v of T_{0i}^y . We now consider the 1-rooted subtrees of T_{0i}^y . Since v is the first vertex in $S_i(y)$, Observation 5 implies that $S_i(y) \subseteq \bar{S}(v)$. Let the set of vertices in $\bar{S}(v)$ but *not* in $S_i(y)$ be denoted by X . Lemma 4.13 applied to $S(y)$ and $S_i(y)$ implies that $X \in \bar{S}^A(v)$ and, furthermore, that every vertex in X is independent of the vertices in $\bar{S}(v) \cap S_i(y)$. Therefore, we can use an argument similar to that in the proof of Corollary 4.8 to show that each $\bar{S}_j(v)$ contains exactly the leaves of the 1-rooted subtrees T_{1j}^v of T_{1j}^y .

Similarly, if v is the first vertex of $\bar{S}_j(y)$, then by Corollary 4.12, each $\bar{S}_k(v)$ contains exactly the leaves of the subtrees T_{1k}^v of T_{1j}^y . Observation 5 implies that given $\bar{S}_j(y) = T_{1j}^y$ and that v is the first vertex of $\bar{S}_j(y)$, $\bar{S}_j(y) \subseteq S(v)$. Corollary 4.14 requires that every vertex in $S(v) - \bar{S}_j(y)$ belongs to $S^A(v)$ and is universal to the vertices in $\bar{S}_j(y)$. Therefore, we can use an argument analogous to that in the proof of Lemma 4.7 to show that each $S_m(v)$ contains exactly the leaves of the 0-rooted subtrees T_{0m}^v of T_{1j}^y . $\square$

We now have the tools to prove that a recursive cotree construction algorithm can be achieved using only σ and $\bar{\sigma}^-$.

LEMMA 4.16. *Given σ and $\bar{\sigma}^-$ of a cograph G , the cotree T of G can be constructed.*

Proof. Certainly the claim holds for the trivial case of a single vertex. We will argue inductively by considering the largest slice possible and showing that the recursion holds.

Let x be the first vertex of σ and therefore of $\bar{\sigma}^-$ as well, and consider each $S_i(x)$. By Lemma 4.7, $S_i(x)$ contains exactly the leaves of T_{0i}^x . In addition, since $S(x) = V$, $S(x)$ induces a module. Let u be the first vertex of $S_i(x)$. By Lemmas 4.11 and 4.15, each $S_j(u)$ contains the leaves of the subtree T_{0j}^u , and each $\bar{S}_h(u)$ contains exactly the leaves of T_{1h}^u . Therefore, we can build the path P_u , from u to the root of T_{0i}^x as in the proof of Corollary 4.9 and by induction, build each subtree T_{0j}^u and T_{1h}^u rooted on P_u .

The argument for the complement is nearly identical. By Corollary 4.8, $\bar{S}_m(x)$ contains exactly the leaves of T_{1m}^x . If u is the first vertex of $\bar{S}_m(x)$, then by Corollary 4.12 and Lemma 4.15, each $\bar{S}_j(u)$ contains the leaves of the subtree T_{1j}^u and each $S_h(u)$ contains exactly the leaves of T_{0h}^u . Therefore, again, we can build the path from u to the root of T_{1m}^x as in the proof of Corollary 4.9 and by induction, build each subtree T_{1j}^u and T_{0h}^u . $\square$

Notice that at each stage of building a path in the cotree and recursing on the subtrees, for each vertex v , we need only to know the first vertex of each of the $S_i(v)$ and $\bar{S}_j(v)$ subslices. We will denote the first vertex of the i th subslice by $v[i]$ and the first vertex of the j th subslice in the complement by $\bar{v}[j]$. Each list of first vertices is generated during the appropriate LexBFS sweep at no extra cost to LexBFS complexity. COTREE illustrates the algorithm.

Algorithm COTREE (vertex v)

Input: Vertex v of a slice $S(v)$ of cograph G with respect to σ .

Output: A Cotree T of $v \bigcup_{\forall i} S_i(v) \bigcup_{\forall j} \bar{S}_j(v)$.

```

  if ( $v[1] = \text{nil}$  and  $\bar{v}[1] = \text{nil}$ ),
    return (  $\{v\}$  )
  if ( $v[1] = \text{nil}$ ),
    return (  $v \textcircled{1}$  COTREE( $\bar{v}[1]$ ) )
  if ( $\bar{v}[1] = \text{nil}$ ),
    return (  $v \textcircled{0}$  COTREE( $v[1]$ ) )
  if  $v[1]\bar{v}[1] \in E$ , then
    (★) return (  $v \textcircled{0}$  COTREE( $v[1]$ )  $\textcircled{1}$  COTREE( $\bar{v}[1]$ )  $\textcircled{0}$  COTREE( $v[2]$ )  $\dots$  )
  else
    (★★) return (  $v \textcircled{1}$  COTREE( $\bar{v}[1]$ )  $\textcircled{0}$  COTREE( $v[1]$ )  $\textcircled{1}$  COTREE( $\bar{v}[2]$ )  $\dots$  )

```

LEMMA 4.17. *Given $v[i]$ and $\bar{v}[j]$ for each vertex v and for all i, j , Algorithm COTREE(v) belongs to $\mathcal{O}(n + m)$.*

Proof. Notice that each vertex v is passed to COTREE at most once and that for each v , the size of the lists $v[i]$ and $\bar{v}[i]$ is bounded by the degree of v . Further, one iteration of the algorithm requires $\mathcal{O}(\deg(v))$ time to execute line (★) or (★★). The test that $v[1]\bar{v}[1] \in E$ can be completed in constant time. To see this, note that $v[1]$ must belong to $\bar{S}^A(v)$ and, further, by the LexBFS⁻ tie breaking mechanism, must be the first vertex in $\bar{S}^A(v)$. This implies that $v[1]$ will be the first vertex of $N^l(\bar{S}_1(v))$ (with respect to the adjacencies of G) if and only if $v[1]\bar{v}[1] \in E$. The local neighborhood for each $\bar{S}_i(v)$ with respect to the adjacencies of G can be generated during the LexBFS⁻ at no extra cost.

Therefore, summing for all v , the complexity is $\mathcal{O}(n + m)$. $\square$

COROLLARY 4.18. *Let x be the first vertex of a pair of LexBFS $\sigma, \bar{\sigma}^-$ of a cograph G . Then Algorithm COTREE(x) produces a cotree of G in $\mathcal{O}(n + m)$ time.*

5. Putting things together. Theorem 4.3 ensures the correctness of Algorithm RECOGNIZE_COGRAPH. The subroutines Algorithm COTREE and Algorithm REPORT_P₄ have already been described.

Algorithm RECOGNIZE_COGRAPH(G)

Input: Graph G .

Output: Cotree T if G is a cograph, an induced P_4 otherwise.

Let τ be an arbitrary ordering of V

Compute LexBFS(G, τ) resulting in σ of G , with first vertex x

Given σ , compute LexBFS⁻(G, σ), a LexBFS of $\bar{G}$, resulting in $\bar{\sigma}^-$

if $\sigma, \bar{\sigma}^-$ satisfy the NSP on $G, \bar{G}$, respectively,

 return (COTREE(x))

else

 return (REPORT_P₄($\sigma, \bar{\sigma}^-$))

end RECOGNIZE_COGRAPH

To show the linearity of the above algorithm, it remains to explain how the NSP can be checked in linear time. Although it can be done during the LexBFS search itself as explained in [3], it is simpler to do the test as a postprocessing. This test is

divided into two steps.

Step 1

Sort the adjacency list of every vertex in G with respect to σ

Step 2

for each $v \in V$ (following σ increasing) where $v_2 \neq NIL$ **do**

$A \leftarrow N_{<}(v_1) \cap S^A(v)$

$i \leftarrow 1$

while $v_{i+1} \neq NIL$ **do**

$B \leftarrow N_{<}(v_{i+1}) \cap S(v)$

if B not included in A , **then**

return (NSP fails on σ, v, i)

else $A \leftarrow B; i \leftarrow i + 1$

end while

end for

return (NSP succeeds on σ)

5.1. Complexity analysis. First we note, by Observation 2, that it suffices to consider $N_{<}(v_{i+1})$ instead of $N^l(S_{i+1}(v))$. Sorting the adjacency lists according to σ as specified in step 1 takes $\mathcal{O}(|E|)$ time; simply create a new set of adjacency lists, walk through the ordering, and for each vertex v , append v to the end of the adjacency list of each vertex $y \in N(v)$, i.e., for each y in the original adjacency list of v .

Each time the neighborhood of a vertex is used in the previous procedure, the edges to visit are at the beginning of its adjacency list and can be deleted from this list after having been processed. The computations of the sets A and B can be done easily using standard partition refinement techniques as developed in [20, 18]. Hence the overall complexity of this procedure is $\mathcal{O}(m)$.

Therefore, testing the NSP on σ can be done in $\mathcal{O}(n + m)$ time complexity. Observing that the NSP of a LexBFS ordering $\bar{\sigma}^-$ on $\bar{G}$ can be checked on G by reversing the order inclusion to be tested, it is straightforward to check the NSP of $\bar{\sigma}^-$ on $\bar{G}$ in linear time $\mathcal{O}(n + m)$. Similar arguments hold for finding a P_4 in G when $\bar{\sigma}^-$ on $\bar{G}$ does not fulfill the NSP. It can be done in $\mathcal{O}(\Delta)$ time, where Δ is the maximum degree of the graph G .

6. Concluding remarks. We conclude by first stating the major result of this paper followed by a discussion of future research directions directly related to these results.

MAIN RESULT. *There exists a simple, linear time, LexBFS based recognition algorithm for the family of cographs that returns a certificate in the form of a cotree or an induced P_4 .*

While optimal cograph recognition algorithms already exist, we feel our new LexBFS based recognition algorithm improves upon previous algorithms for several reasons. It follows a simple paradigm: *order* the vertices, *check* for a characterizing property, and *return* an appropriate certificate. In addition, the algorithm is easily implemented and returns a certificate in both the positive and negative cases. Finally we feel that the algorithm has potential to be generalized and extended to other families and, possibly, modular decomposition. We realize that our new algorithm does not have one very nice feature of the original linear time cograph recognition algorithm [10], in that it is not incremental. Unfortunately, LexBFS does not lend itself

to incremental algorithms, and, as such, our algorithm cannot be used in dynamic situations.

Concerning the algorithm itself, it is natural to wonder if LexBFS is the only sweep that can be used in this way to recognize cographs. First we note that BFS is too weak since it does not guarantee the nesting of the local neighborhoods of the $\{S_i(v)\}$, and thus with such an algorithm, a cograph might not satisfy the NSP. If we try to generalize LexBFS to other maximal neighborhood searches (MNS) such as LexDFS (see [8]) and maximum cardinality search (MCS), we risk having some vertex of $S^N(v)$ before a vertex of $S^A(v)$. Note that using the 4-vertex condition of MNS [8] (namely, an ordering σ is an MNS of G if and only if, for any $x <_\sigma y <_\sigma z$ such that $xz \in E$ but $xy \notin E$, there exists v such that $v <_\sigma y$, $vy \in E$, and $vz \notin E$), it is easy to show that Lemma 3.1 holds, namely, every MNS of a cograph is umbrella-free.

Similar to P_4 -reducible and P_4 -sparse graphs, other families in the P_4 -hierarchy such as P_4 -lite, P_4 -extendible, and P_4 -tidy (see [2] for definitions) may be well suited to a recognition algorithm that is an extension of our cograph recognition algorithm. In addition, distance hereditary graphs have a simple recognition algorithm that is again based on this cograph algorithm, motivating the question of whether families of graphs related to distance hereditary graphs, such as parity graphs, $(k, +)$ -distance hereditary graphs, or HHD-free graphs, have similar recognition algorithms.

Finally, the most interesting and most challenging question is whether there exists a modular decomposition algorithm that generalizes our cograph recognition algorithm. This is a natural question to ask since cographs are the family of completely decomposable graphs with respect to modular decomposition.

Note added in proof. The cograph recognition algorithm presented in this paper does extend to a simple, linear time algorithm for modular decomposition; however, an even easier linear time modular decomposition algorithm has recently appeared (see [27]).

ON COMPUTING THE DISTINGUISHING NUMBERS OF PLANAR GRAPHS AND BEYOND: A COUNTING APPROACH*

V. ARVIND[†], CHRISTINE T. CHENG[‡], AND NIKHIL R. DEVANUR[§]

Abstract. A vertex k -labeling of graph G is *distinguishing* if the only automorphism that preserves the labels of G is the identity map. The *distinguishing number* of G , $D(G)$, is the smallest integer k for which G has a distinguishing k -labeling. In this paper, we apply the principle of inclusion-exclusion and develop recursive formulas to count the number of inequivalent distinguishing k -labelings of a graph. Along the way, we prove that the distinguishing number of a planar graph can be computed in time polynomial in the size of the graph.

Key words. distinguishing numbers, distinguishing labelings, planar graphs, efficient counting algorithms

DOI. 10.1137/07068686X

1. Introduction. A vertex k -labeling of graph G is a mapping $\phi : V(G) \rightarrow \{1, 2, \dots, k\}$. It is said to be *distinguishing* if the only automorphism that preserves the labels of G is the identity map. The *distinguishing number* of G , $D(G)$, is the minimum number of labels needed so that G has a distinguishing labeling. The notion of distinguishing numbers for graphs was first introduced and developed by Albertson and Collins [2]. Their focus was on determining the relationships between a graph's automorphism group and its distinguishing number. Their work has since been extended in many directions by researchers for graphs and groups (e.g., [3, 5, 8, 6, 7, 10, 12, 16, 17, 20, 21]).

Let (G, ϕ) denote the labeled version of G under the labeling ϕ . Given two distinguishing k -labelings ϕ and ϕ' of G , we say that ϕ and ϕ' are *equivalent* if there is some automorphism of G that maps (G, ϕ) to (G, ϕ') . We are interested in computing $D(G, k)$ —the number of inequivalent k -distinguishing labelings of G —which was first considered by Arvind and Devanur [4] and Cheng [9] to determine the distinguishing numbers of trees. Our motivations for studying this parameter are as follows. First, $D(G) = \min\{k : D(G, k) > 0\}$, so if we can compute $D(G, k)$ efficiently, then we can also determine $D(G)$ efficiently. The usual way of proving that $D(G) = k^*$ is to present a distinguishing k^* -labeling of G and then argue that G has no distinguishing labelings that use $k < k^*$ labels. Counting the number of inequivalent distinguishing k -labelings of G provides us with an altogether different method for solving $D(G)$. Second, when G is connected, solving for $D(G, k)$ allows us to determine the distinguishing number of H , where $H = \alpha G$ (i.e., H consists of α copies of G). To distinguish H , each copy of G must be assigned a distinguishing labeling. Additionally, no two copies of G can be assigned equivalent distinguishing labelings. Hence, $D(H) =$

FIG. 1. An example of two graphs with the same number of vertices, isomorphic automorphism groups, and identical distinguishing numbers but a different number of inequivalent k -labelings: $D(G_1, k) = k^4(k^4 - 1)/2$, but $D(G_2, k) = k^7(k - 1)/2$.

$\min\{k : D(G, k) \geq \alpha\}$. Finally, researchers have noted that two labels are sufficient for distinguishing many nonrigid graphs (e.g., [3, 12, 16]). The number of inequivalent distinguishing k -labelings of graphs provides one more level of granularity that enables us to differentiate between graphs with the same distinguishing numbers. For example, consider the two graphs shown in Figure 1. They have the same number of vertices, their automorphism groups are isomorphic, and they can be distinguished with two labels. Yet, $D(G_1, k) = k^4(k^4 - 1)/2$, but $D(G_2, k) = k^7(k - 1)/2$, so with two labels at most 120 copies of G_1 can be distinguished compared to 64 copies for G_2 . In this sense, G_1 is less symmetric than G_2 because k labels can distinguish more copies of G_1 than G_2 for any $k \geq 2$.

To solve for $D(G, k)$, we apply two of the most common techniques for counting—the principle of inclusion-exclusion (PIE) and recursion. We show that when G 's automorphisms are known and the size of its automorphism group $\text{Aut}(G)$ is $O(\log n)$, where n is the number of vertices in G , then a straightforward application of PIE can determine $D(G, k)$ efficiently. We then modify the technique so that when $\text{Aut}(G)$ is isomorphic to Z_t (the cyclic group of order t), D_t (the dihedral group of order $2t$), $Z_t \times Z_2$, or $D_t \times Z_2$, the value of $D(G, k)$ can be computed in time polynomial in n, t , and $\log k$. Consequently, we are able to prove that if G is a triconnected planar graph, then $D(G, k)$ and $D(G)$ can be determined efficiently. Next, by viewing G via a tree decomposition T_G that is made up of G 's cut vertices, separating pairs, and triconnected components, we show that $D(G, k)$ can be determined recursively. To implement this technique efficiently for a family of graphs, several ingredients are necessary including efficient algorithms for testing graph isomorphism and finding the automorphisms of a graph's triconnected components. Since these algorithms exist for planar graphs, we arrive at the main result of the paper—that when G is a planar graph, then $D(G, k)$ and $D(G)$ can be computed efficiently.

In their introductory paper, Alberston and Collins [2] raised the issue of determining the computational complexity of $\text{DIST} = \{(G, k) | G \text{ has a distinguishing } k\text{-labeling}\}$. Currently, the best known result about DIST , which is due to Russell and Sundaram [19], is that it belongs to AM, the set of languages for which there are Arthur and Merlin games. This result essentially follows from the fact that testing graph rigidity is in AM. When G is restricted to certain graph families, however, DIST can belong to P . For example, distinguishing numbers of cycles, hypercubes [5, 8], and acyclic graphs [4, 9] can be computed efficiently. Our main result extends this further— DIST belongs to P when G is a planar graph. Our work complements that of Fukuda, Negami, and Tucker [12] on triconnected planar graphs where they show that, except for seven graphs, all graphs in this family have a distinguishing number of at most 2.

In the next section, we give basic results that will be used throughout the paper. In section 3, we show how the PIE can be used to determine $D(G, k)$. In section 4, we develop recursive formulas for a tree decomposition of G that eventually lead to the

computation of $D(G, k)$. We conclude in section 5. We note that our algorithms for computing $D(G, k)$ have G and k as input; hence, when we say that they are efficient, we mean that they run in time polynomial in the size of G and $\log k$. Additionally, these algorithms involve addition and multiplication. In cases where the numbers used are functions of k , their values never exceed k^n , where n is the number of nodes in graph G ; i.e., the numbers have at most $n \log k$ bits. Thus, in our analysis, we assume that each addition takes $O(n \log k)$ time and each multiplication takes $O(n^2 \log^2 k)$ time in the worst case.

2. Basic notions. Suppose that ϕ and ϕ' are two distinguishing labelings of G . Since (labeled) graph isomorphism is an equivalence relation, we shall say that ϕ and ϕ' are *equivalent* if $(G, \phi) \cong (G, \phi')$; that is, there is an automorphism of G that maps (G, ϕ) to (G, ϕ') . Let $\mathcal{L}(G, k)$ denote the set of all distinguishing k -labelings of G , $L(G, k)$ the size of $\mathcal{L}(G, k)$, and $D(G, k)$ the number of equivalence classes of $\mathcal{L}(G, k)$. Below, we establish the relationships between $D(G)$, $D(G, k)$, and $L(G, k)$.

LEMMA 2.1. *Let G be a graph and $\text{Aut}(G)$ its automorphism group.*

- i. $D(G) = \min\{k : L(G, k) > 0\} = \min\{k : D(G, k) > 0\}$.
- ii. $D(G, k) = L(G, k)/|\text{Aut}(G)|$.

Proof. If there is a distinguishing k -labeling of G , then the set $\mathcal{L}(G, k)$ must have at least one labeling and one equivalence class. It follows that the smallest k for which this is true must be the distinguishing number of G , proving the first part of the lemma.

To prove the second part, note that $\text{Aut}(G)$ is a group that acts on $\mathcal{L}(G, k)$. By definition, each $\phi \in \mathcal{L}(G, k)$ is preserved by only one automorphism in $\text{Aut}(G)$ —the identity automorphism. Hence, according to the orbit-stabilizer lemma, the size of the equivalence class of $\mathcal{L}(G, k)$ that contains ϕ (i.e., the orbit of ϕ) is $|\text{Aut}(G)|$. Consequently, the number of equivalence classes of $\mathcal{L}(G, k)$ is $L(G, k)/|\text{Aut}(G)|$. $\square$

Throughout this paper, we shall make use of Lemma 2.1 by viewing the problem of finding a graph's distinguishing number as a counting problem. While it may seem that computing $D(G, k)$ to find $D(G)$ requires more work than needed, the lemma below (first proved in [9]) shows that it does not if we need to distinguish multiple copies of G .

LEMMA 2.2. *Let G be a graph whose g connected components are $G_1, G_2, \dots, G_g$. Let ϕ be a labeling of G . Then ϕ is distinguishing if and only if the following two conditions hold:*

- i. ϕ when restricted to G_i is distinguishing for $i = 1, \dots, g$.
- ii. If $G_i \cong G_j$, $i \neq j$, then $(G_i, \phi|_{G_i}) \not\cong (G_j, \phi|_{G_j})$ for every pair of $i, j \in \{1, \dots, g\}$.

The following is immediate.

LEMMA 2.3. *Let G be a connected graph. If H consists of α copies of G (i.e., $H = \alpha G$), then $D(H) = \min\{k : D(G, k) \geq \alpha\}$.*

2.1. Blocks, cut vertices, separating pairs, and triconnected components. Let $G = (V, E)$ be a connected graph. Recall that G is r -connected if $|V| > r$ and, for any $X \subseteq V$ such that $|X| < r$, removing the vertices in X from G does not disconnect G ; i.e., $G - X$ remains connected. Suppose that we are interested in determining if G has some property (e.g., if it is planar). A common technique is to first decompose G into its blocks—which are either edges or 2-connected (or biconnected) subgraphs of G —and then decompose the blocks into its “triconnected components” [14]—which are parallel edges (or bonds), cycles, or 3-connected graphs.¹ It is then the

¹Unlike blocks, however, the triconnected components of a graph need not be one of its subgraphs.

triconnected components which are initially studied; the results are then assembled to infer the properties of the blocks, which in turn infer the property of G . We shall apply this technique in section 4 to determine $D(G, k)$. In particular, we shall make use of a tree T_G that captures the relationships among the cut vertices, separating pairs, and triconnected components of G to assemble the information for computing $D(G, k)$.

A *block* of G is a maximally connected subgraph of G that does not contain a cut vertex. Thus, a block of G is either an edge or a maximal biconnected subgraph of G . Furthermore, any two blocks of G have at most one vertex in common, and this vertex is a cut vertex of G . The *block-cut vertex graph* of G is a bipartite graph where one partite set consists of *b-vertices*, which correspond to the blocks of G , and the other partite set consists of *c-vertices*, which correspond to the cut vertices of G . A *b-vertex* is adjacent to a *c-vertex* if and only if the block associated with the *b-vertex* contains the cut vertex associated with the *c-vertex*. It is well known that the block-cut vertex graph of G is a tree whose leaves are *b-vertices*, and so it has a unique center. Moreover, it can be constructed in time linear in the size of G [1].

Every block of G that is biconnected can similarly be represented by a tree via its triconnected components and separating pairs. To do so, the definitions of 3-connectedness and separating pairs have to be extended to multigraphs. Our discussion closely follows the paper of Hopcroft and Tarjan [14]. Let B be a biconnected multigraph and $\{x, y\}$ be a pair of vertices in B . The set $\{x, y\}$ partitions the edge set of B in the following way: Two edges belong to the same class if and only if they lie in a path that contains neither x nor y except possibly as endpoints. The classes are called the *separation classes of B with respect to $\{x, y\}$* . If there are at least two separation classes, then the pair $\{x, y\}$ is a *separating pair of B* except when (i) there are exactly two separation classes, and one class consists of a single edge, or (ii) there are exactly three classes, each consisting of a single edge. If B is a biconnected multigraph and has no separating pairs, then B is said to be *triconnected*.

Let $\{x, y\}$ be a separating pair of B , and let the separation classes of B with respect to $\{x, y\}$ be $E_1, \dots, E_m$. An immediate consequence of the definition of separating pairs is that the classes can be divided into two groups $E' = \cup_{i=1}^k E_i$ and $E'' = \cup_{i=k+1}^m E_i$ so that both E' and E'' have at least two edges. Let $B' = (V(E'), E' \cup \{(x, y)\})$ and $B'' = (V(E''), E'' \cup \{(x, y)\})$. The graphs B' and B'' are called *split graphs of B with respect to (x, y)* , and the edges (x, y) added to both graphs are called *virtual edges*. To *split B* is to replace B by two of its split graphs. Hopcroft and Tarjan suggested denoting the i th splitting operation via the pair $\{x, y\}$ by $s(x, y, i)$ and labeling the (x, y) edges added to B' and B'' by i to differentiate this split from other splits.

Suppose that B is split, its split graphs are split, and so on until there are no more splits possible. The remaining graphs are called the *split components of B* . Clearly, they all must be triconnected; they can be grouped together as follows: the triple bonds $\mathcal{B}_{b3}$, the (simple) triangles $\mathcal{B}_t$, and the rest of the triconnected (simple) graphs $\mathcal{B}_{tg}$. Since there are many ways of splitting B , the split components of B are not necessarily unique (e.g., consider a 4-cycle). Nonetheless, this lack of uniqueness can be fixed by an operation called *merge*, which is the reverse of split. Let $B_1 = (V_1, E_1)$ and $B_2 = (V_2, E_2)$ be two split components of B that contain virtual edge $e = (x, y)$ labeled i . The graph $(V_1 \cup V_2, E_1 - \{e\} \cup E_2 - \{e\})$ is called the *merge graph of B_1 and B_2* . To *merge B_1 and B_2* is to create their merge graph. As before, the operation is denoted by $m(x, y, i)$ to differentiate it from other merge operations. So suppose that the split components of B are contained in $\mathcal{B}_{b3} \cup \mathcal{B}_t \cup \mathcal{B}_{tg}$. Merge the triple bonds in $\mathcal{B}_{b3}$ as much as possible to obtain a set of bonds $\mathcal{B}_b$. Merge the triangles in $\mathcal{B}_t$ as much as possible to obtain a set of cycles $\mathcal{B}_p$. The set of graphs in

FIG. 2. A graph and its block-cut vertex graph.

$\mathcal{B}_b \cup \mathcal{B}_p \cup \mathcal{B}_{tg}$ is called the *triconnected components* of B . For example, a cycle has only one triconnected component—itsself—because the triangles obtained by splitting the cycle can be merged. The following has been proven in [14].

LEMMA 2.4. *Let B be a biconnected multigraph with $m_B \geq 3$ edges. The total number of edges in the split components of B is at most $3m_B - 6$. Additionally, the triconnected components of B are unique and can be found in time linear in the size of B .*

Lemma 2.4 implies that the order in which the split and merge operations are applied to decompose B to its triconnected components is not important—the same components are obtained.

The biconnected multigraph B can now be represented by its *triconnected component-separating pair graph*, which is a bipartite graph where one partite set consists of *t*-vertices that correspond to the triconnected components of B and the other partite set consists of *s*-vertices that correspond to B 's separating pairs which exist as virtual edges in B 's triconnected components. A *t*-vertex is adjacent to an *s*-vertex if and only if the triconnected component associated with the *t*-vertex contains the separating pair associated with the *s*-vertex. It is easy to verify that this bipartite graph must again be a tree, all of its leaves are *t*-vertices, and consequently it has a unique center. Moreover, because the triconnected components of B can be found in linear time, the tree can also be constructed in linear time.

Building a tree decomposition of G . Let G be a (simple) connected graph. Let us now build a tree decomposition of G , T_G , that incorporates the triconnected component-separating pair graph of each block of G into the block-cut vertex graph of G . Initially set T_G to be the block-cut vertex graph of G . Then, for each *b*-vertex z whose associated block is B , replace z with B 's triconnected component-separating pair graph T_B . Attach T_B to each neighbor y of z in the following manner. Let a be the cut vertex associated with y . Node a is part of one or more triconnected components and separating pairs of B . It is straightforward to check that the vertices in T_B associated with these components and pairs form a subtree which has a unique center because all of the leaves of the subtree are *t*-vertices. Connect the center of this subtree in T_B to y . For example, in Figure 2, the center of the block-cut vertex graph is a *b*-vertex which has two *c*-vertices as neighbors: One is associated with e and the other with j . When this *b*-vertex is replaced with its associated triconnected component-

From here onwards, we shall treat T_G as a rooted tree. For each node v in T_G , let T_v denote the subtree of T_G rooted at v . We define $G(T_v)$ recursively as follows: When v is a leaf node of T_G and, hence, a t -vertex, let $G(T_v)$ be the triconnected component of G associated with v . Otherwise, v is a c -, s -, or a t -vertex and has at least one child. When v is a c -vertex, construct $G(T_v)$ by taking the union of the graphs in $\{G(T_w) : w \text{ a child of } v\}$. When v is an s -vertex whose associated separating pair is $\{x, y\}$, let w_x and w_y denote the children of v whose associated cut vertices are x and y , respectively. (Note that they may not exist.) Construct $G(T_v)$ by first merging the graphs in $\{G(T_w) : w \text{ is a child of } v \text{ and is a } t\text{-vertex}\}$ via $\{x, y\}$ and then appending $G(T_{w_x})$ and $G(T_{w_y})$ (if they exist) to x and y , respectively. Finally, when v is a t -vertex whose associated triconnected component is H , construct $G(T_v)$ by first merging the graphs in $\{G(T_w) : w \text{ is a child of } v \text{ and is an } s\text{-vertex}\}$ to H and then taking the union of the resulting graph with the graphs in $\{G(T_w) : w \text{ is a child of } v \text{ and is a } c\text{-vertex}\}$.

We make a few observations about $G(T_v)$. First, if w_1 and w_2 are children of v in T_G , the vertices and edges that $G(T_{w_1})$ and $G(T_{w_2})$ have in common belong to $G(T_v)$. Thus, $G(T_v)$ consists of the structure associated with v together with connected graphs “hanging” from it; these connected graphs are exactly from the set $\{G(T_w) : w \text{ is a child of } v\}$. Second, when $v = r(T_G)$, then $G(T_v) = G$. Finally, some of the $G(T_v)$ ’s may not be subgraphs of G since some of them may contain one or more copies of the edge (x, y) , where $\{x, y\}$ is a separating pair of G but (x, y) is not an edge of G .³

In our later discussions, we will mostly be interested in the automorphisms of $G(T_v)$ that fix a cut vertex, a separating pair, or a triconnected component, and so we use $\text{Aut}(G(T_v); *)$ to denote the set of automorphisms of $G(T_v)$ that fix the structures in $*$. For example, let $\{x, y\}$ be a separating pair in $G(T_v)$. The automorphisms of $G(T_v)$ in $\text{Aut}(G(T_v); x, y)$ fix the vertices x and y , while those in $\text{Aut}(G(T_v); xy)$ fix the edge (x, y) . When H is a triconnected component in $G(T_v)$, the automorphisms of $G(T_v)$ in $\text{Aut}(G(T_v); H)$ map H to itself (i.e., the set $V(H)$ to itself), and the automorphisms in $\text{Aut}(G(T_v); H, x, y)$ map H to itself and, additionally, vertices x and y to themselves. From Lemma 2.5, we have the next lemma.

LEMMA 2.6. *Let G be a connected graph and T_G its tree decomposition. Then $\text{Aut}(G) = \text{Aut}(G; A)$, where A is the structure associated with $r(T_G)$.*

From the construction of T_G , we also have the next two lemmas.

LEMMA 2.7. *Let v be a c -vertex in T_G and a be its associated cut vertex. Let w be a child of v in T_G . The following are true:*

- (i) *If w is an s -vertex, then it is associated with some separating pair $\{a, b\}$ and $\text{Aut}(G(T_w); a) = \text{Aut}(G(T_w); a, b)$;*
- (ii) *if w is a t -vertex and its associated triconnected component is H , then H contains a and $\text{Aut}(G(T_w); a) = \text{Aut}(G(T_w); H, a)$.*

Proof. Since v and w are adjacent in T_G and v is a c -vertex while w is an s - or a t -vertex, there is a block B that contains cut vertex a and the structure associated with w . As we noted in the construction of T_B , a must be part of one or more separating pairs and triconnected components in B , and the vertices associated with these pairs and components form a subtree in T_B . Let us call this subtree $T_{B,a}$. Since w was chosen so that it is the center of $T_{B,a}$, the structure associated with w contains a .

By the way the block-cut vertex graph of G is constructed, B must be the only block in $G(T_w)$ that contains a . Hence, every automorphism of $G(T_w)$ that fixes a

³We note, though, that, in computing for $D(G, k)$, we can ignore the “other” copies of (x, y) as their multiplicity does not affect any of our computations.

must map the separating pairs and triconnected components of B that contain a to similar separating pairs and triconnected components. That is, the actions of every automorphism in $\text{Aut}(G(T_w); a)$ induces an automorphism on $T_{B,a}$. But $T_{B,a}$ has a unique center— w —which means that every automorphism in $\text{Aut}(G(T_w); a)$ must map the structure associated with w to itself. The lemma follows. $\square$

LEMMA 2.8. *Let v be an s -vertex in T_G and $\{x, y\}$ be its associated separating pair. Let w be a child of v in T_G . If w is a t -vertex whose associated triconnected component is H , then $\text{Aut}(G(T_w); x, y) = \text{Aut}(G(T_w); H, x, y)$ and $\text{Aut}(G(T_w); xy) = \text{Aut}(G(T_w); H, xy)$.*

Proof. Since v and w are adjacent in T_G and v is an s -vertex while w is a t -vertex, there is again a block B that contains the structures associated with both vertices. By the way the triconnected component-separating pair graph of B is constructed, it must be the case that H is the only triconnected component in $G(T_w)$ that contains $\{x, y\}$. Hence, every automorphism in $\text{Aut}(G(T_w); x, y)$ must map H to itself, and so $\text{Aut}(G(T_w); x, y) = \text{Aut}(G(T_w); H, x, y)$. By the same reasoning, $\text{Aut}(G(T_w); xy) = \text{Aut}(G(T_w); H, xy)$. $\square$

The following lemmas will also be useful later.

LEMMA 2.9. *The tree T_G can be constructed in $O(n^2 + nm)$ time, where n is the number of vertices and m the number of edges in G .*

Proof. Constructing G 's block-cut vertex graph and rooting it at its center takes $O(n + m)$ time. Creating the separating pairs-triconnected components graph T_B of block B takes $O(n_B + m_B)$ time, where n_B and m_B are the number of nodes and edges, respectively, in block B . Connecting T_B to T_G takes $O(c_B(n_B + m_B))$, where c_B is the number of cut vertices in block B . Thus, doing this for all blocks B takes $O(n^2 + nm)$ time since $\sum_B n_B \leq n + m$ and $\sum_B m_B = m$. $\square$

LEMMA 2.10. *Let B be a block of G with n_B vertices and $m_B \geq 3$ edges. Let $\mathcal{H}$ be the set that contains all of the triconnected components of B . For each $H \in \mathcal{H}$, let $\mathcal{S}_H$ denote the set containing the separating pairs of G in H used in the construction of T_G . Then $\sum_{H \in \mathcal{H}} |\mathcal{S}_H| = O(m_B)$ and $\sum_{H \in \mathcal{H}} |V(H)| = O(m_B)$.*

Proof. Suppose that the split operation was applied g times to B until no more splits are possible. Let $\mathcal{H}'$ contain the resulting split components. For each $H' \in \mathcal{H}'$, define $\mathcal{S}_{H'}$ as in the lemma. We note that, when B is split into two components, the separating pair used to create the split becomes part of both components. That is, each split operation contributes a value of 2 to $\sum_{H' \in \mathcal{H}'} |\mathcal{S}_{H'}|$. Hence, $\sum_{H' \in \mathcal{H}'} |\mathcal{S}_{H'}| = 2g$. Now, according to Lemma 2.4, the total number of edges in the split components in $\mathcal{H}'$ is at most $3m_B - 6$. Since a split component in $\mathcal{H}'$ has at least three edges, $g \leq m_B - 2$ and so $\sum_{H' \in \mathcal{H}'} |\mathcal{S}_{H'}| = O(m_B)$. Next, notice that $|V(H')| \leq |E(H')|$ for each $H' \in \mathcal{H}'$ so $\sum_{H' \in \mathcal{H}'} |V(H')| \leq 3m_B - 6$. Finally, because $\sum_{H \in \mathcal{H}} |\mathcal{S}_H| \leq \sum_{H' \in \mathcal{H}'} |\mathcal{S}_{H'}|$ and $\sum_{H \in \mathcal{H}} |V(H)| \leq \sum_{H' \in \mathcal{H}'} |V(H')|$, the lemma follows. $\square$

Finally, we note that we call T_G a tree decomposition of G because it really is a tree decomposition as defined by Robertson and Seymour (see Chapter 12 in [11] for an introduction). That is, if v is a node of T_G and V_v contains the vertices of the structure in G associated with v , it should be clear from our construction that the following are true: (i) $V_v \subseteq V(G)$ for each v , (ii) $\cup_v V_v = V(G)$, (iii) every edge of G has two of its endpoints in some V_v , and (iv) whenever y and z are neighbors of v , then $V_y \cap V_z \subseteq V_v$. In our discussion, however, it is important that we keep track of the actual structure associated with v and not just the vertices in V_v .

3. Counting the distinguishing k -labelings of graphs via PIE. Given a graph G and its automorphisms, we begin by applying the PIE to count its distinguish-

ing k -labelings. Unfortunately, the technique requires the computation of $\Omega(2^{|Aut(G)|})$ terms and so becomes impractical when G has many automorphisms. We show how the method can be modified when $Aut(G)$ is isomorphic to certain groups. In particular, we prove that, when G is a triconnected planar graph, $L(G, k)$, $D(G, k)$, and $D(G)$ can be computed in time polynomial in $\log k$ and the size of G .

Suppose that $Aut(G) = \{\pi_0, \pi_1, \dots, \pi_{g-1}\}$, where π_0 is the identity automorphism. Let ϕ be some k -labeling of G . We say that an automorphism π_i of G *preserves* ϕ if $\phi(v) = \phi(\pi_i(v))$ for each v of G . Clearly, π_0 preserves ϕ , and if no other automorphism of G preserves ϕ , then ϕ is a distinguishing k -labeling of G . Let $P \subseteq Aut(G)$ and $N_{\geq}(P)$ denote the number of k -labelings of G that are preserved by all of the automorphisms in P . Let $N_{=}(P)$ equal the number of k -labelings of G that are preserved by all of the automorphisms in P but no others. Thus, $L(G, k) = N_{=}(\{\pi_0\})$. According to the PIE,

$$(1) \quad N_{=}(\{\pi_0\}) = \sum_{\{\pi_0\} \subseteq P \subseteq Aut(G)} (-1)^{|P|-1} N_{\geq}(P).$$

Next, we describe a method for computing $N_{\geq}(P)$ for each $P \subseteq Aut(G)$. Suppose that $\pi_i \in P$. A k -labeling ϕ is preserved by π_i if and only if ϕ assigns the same label to v and to $\pi_i(v)$ for each vertex v in G . In fact, if there is a sequence of vertices $v_1, v_2, \dots, v_r$ such that $v_j = \pi_i(v_{j-1})$ for $j = 2, \dots, r$, then ϕ must assign all of these r vertices the same label. By extending this idea further, we arrive at the following lemma.

LEMMA 3.1. *Let $\pi_i \in Aut(G)$ and ϕ be a k -labeling of G . Let G_{π_i} be the graph whose node set is $V(G)$ and whose edge set consists of the pairs $(v, \pi_i(v)), v \in V(G)$. The automorphism π_i preserves ϕ if and only if, for each connected component in G_{π_i} , ϕ assigns the same label to all of the vertices in that component. Consequently, when $P \subseteq Aut(G)$, the automorphisms in P preserve ϕ if and only if, for each connected component in $\cup_{\pi_i \in P} G_{\pi_i}$, ϕ assigns the same label to all of the vertices in that component.*

An immediate implication of the lemma is if $\cup_{\pi_i \in P} G_{\pi_i}$ has t connected components and there are k labels available, then $N_{\geq}(P) = k^t$. We are now ready to prove the next result.

THEOREM 3.2. *Let G be a graph on n vertices and k be a positive integer. Suppose that all of the automorphisms of G are given. Then $L(G, k)$ can be computed in $O(n^3 \log^2 k + 2^{|Aut(G)|}(n \times |Aut(G)| + n \log k))$ time.*

Proof. Begin by computing and storing the values $k, k^2, k^3, \dots, k^n$. Set $L(G, k)$ to 0. For each subset P such that $\{\pi_0\} \subseteq P \subseteq Aut(G)$, (i) construct $\cup_{\pi_i \in P} G_{\pi_i}$ and find the number of its connected components t by using a breadth-first search and (ii) add $(-1)^{|P|-1} k^t$ to $L(G, k)$. According to (1), at the end of this algorithm the value of $L(G, k)$ is the number of distinguishing k -labelings of G . Computing the powers of k can be done in $O(n^3 \log^2 k)$ steps. Each iteration of the for loop takes at most $O(n \times |Aut(G)| + n \log k)$ time, where the first term in the sum accounts for the time it takes to construct $\cup_{\pi_i \in P} G_{\pi_i}$ and find its connected components and the latter term accounts for adding k^t to $L(G, k)$. Since there are $2^{|Aut(G)|-1}$ subsets P to consider, computing $L(G, k)$ takes $O(n^3 \log^2 k + 2^{|Aut(G)|}(n \times |Aut(G)| + n \log k))$ time. $\square$

COROLLARY 3.3. *Let G be a graph with n vertices and k be a positive integer. Suppose that all of the automorphisms of G are given. If $|Aut(G)| = O(\log n)$, then $L(G, k)$ can be computed in time polynomial in n and $\log k$.*

The reason why implementing the PIE formula for $L(G, k)$ can take exponential time is because there are $\Omega(2^{|Aut(G)|}) N_{\geq}(P)$ terms in the formula. Below, we demonstrate that the technique can be modified when $Aut(G)$ is isomorphic to certain groups. We consider the case when $Aut(G) \cong \Gamma$, where (i) $\Gamma = Z_t$, the cyclic group of order t , (ii) $\Gamma = D_t$, the dihedral group of order $2t$, and (iii) $\Gamma = Z_t \times Z_2$ or $D_t \times Z_2$. All will be useful when we discuss triconnected planar graphs in the next subsection. A key feature of these results is that $|Aut(G)| = O(t)$, and yet the number of $N_{\geq}(P)$ terms that must be computed to derive $L(G, k)$ is polynomial in t and not exponential in t . Before we proceed, we first prove the following lemma.

LEMMA 3.4. *Let $P \subseteq Aut(G)$ and $\langle P \rangle$ be the subgroup generated by P . Every k -labeling of G preserved by all of the automorphisms in P is also preserved by all of the automorphisms in $\langle P \rangle$.*

Proof. Let ϕ be a k -labeling of G preserved by all of the automorphisms in P . Let $\pi \in \langle P \rangle$. Since $Aut(G)$ is finite, we can write π as $\sigma_r * \sigma_{r-1} * \cdots * \sigma_1$, where $r \in \mathbf{Z}^+$ and each $\sigma_i \in P$. Since each σ_i preserves ϕ , for each vertex u of G ,

$$\phi(u) = \phi(\sigma_1(u)) = \phi(\sigma_2(\sigma_1(u))) = \cdots = \phi(\sigma_r(\cdots(\sigma_2(\sigma_1(u))))).$$

That is, $\pi = \sigma_r * \sigma_{r-1} * \cdots * \sigma_1$ preserves ϕ as well. $\square$

In the subsequent discussion, when $Aut(G) \cong \Gamma$, we shall denote the automorphisms of G as π_σ , where $\sigma \in \Gamma$, and let $\pi_\sigma * \pi_{\sigma'} = \pi_{\sigma * \sigma'}$.

When $Aut(G) \cong Z_t$. Let Z_t be the cyclic group of order t and ρ be one of its generators. Its elements are ρ^0 (the identity), $\rho, \rho^2, \dots, \rho^{t-1}$, where $\rho^i * \rho^j = \rho^{i+j \bmod t}$.

THEOREM 3.5. *Let $Aut(G) \cong Z_t$, where the prime factorization of t is $\prod_{i=1}^s p_i^{r_i}$. Suppose that a generator π_ρ of $Aut(G)$ is given. Let $P^* = \{\pi_{\rho^i} : i \in \{t/p_1, t/p_2, \dots, t/p_s\}\}$. Then*

$$L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P).$$

Proof. To prove the theorem, we will show that a k -labeling ϕ of G is distinguishing if and only if no automorphism in P^* preserves ϕ . One direction is obvious: If ϕ is distinguishing, all nontrivial automorphisms of G do not preserve ϕ . Since P^* contains only nontrivial automorphisms of G , the result follows. So suppose that ϕ is not distinguishing. It must be preserved by some π_{ρ^j} , $j \neq 0$. Let $g = \gcd(t, j) = \prod_{i=1}^s p_i^{t_i}$, where $0 \leq t_i \leq r_i$. We know that $\rho^g \in \langle \rho^j \rangle$. Since $j < t$, we also know that g must divide one of the numbers in $\{t/p_1, t/p_2, \dots, t/p_s\}$, say, t/p_1 ; i.e., $\rho^{t/p_1} \in \langle \rho^g \rangle$. By Lemma 3.4, it follows that if π_{ρ^j} preserves ϕ , then π_{ρ^g} also preserves ϕ , which implies that $\pi_{\rho^{t/p_1}}$ does so as well. That is, some automorphism in P^* preserves ϕ . By applying the PIE, $L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P)$. $\square$

When $Aut(G) \cong D_t$. Let D_t be the dihedral group of order $2t$. If we let the generators of D_t be the rotation ρ and reflection τ , then the elements of D_t are ρ^0 (the identity), $\rho^1, \dots, \rho^{t-1}$, $\tau\rho^0, \tau\rho^1, \dots, \tau\rho^{t-1}$, where $\tau^2 = \rho^0$, $\tau\rho^i = \rho^{-i}\tau$, and $\rho^i * \rho^j = \rho^{i+j \bmod t}$.

THEOREM 3.6. *Let $Aut(G) \cong D_t$, where the prime factorization of t is $\prod_{i=1}^s p_i^{r_i}$. Suppose that generators π_ρ and π_τ of $Aut(G)$ are given. Let $P^* = \{\pi_{\rho^i} : i \in \{t/p_1, t/p_2, \dots, t/p_s\}\}$. Then*

$$N_{=}(\{\pi_{\rho^0}, \pi_{\tau\rho^i}\}) = \sum_{\{\pi_{\rho^i}\} \subseteq P \subseteq \{\pi_{\tau\rho^i}\} \cup P^*} (-1)^{|P|-1} N_{\geq}(P)$$

and

$$(2) \quad L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P) - \sum_{i=0}^{t-1} N_{=}(\{ \pi_{\rho^0}, \pi_{\tau \rho^i} \}).$$

Proof. We shall first prove that a k -labeling ϕ of G that is preserved by at least two nontrivial automorphisms of G is also preserved by some automorphism in the set $P^* = \{ \pi_{\rho^i} : i \in \{t/p_1, t/p_2, \dots, t/p_s\} \}$. If one of the automorphisms that preserves ϕ is preserved by π_{ρ^j} , $j \neq 0$, then by the proof of Theorem 3.5 it must also be preserved by some automorphism in P^* . If the two automorphisms that preserve ϕ are $\pi_{\tau \rho^i}$ and $\pi_{\tau \rho^j}$, where $i < j$, then $\pi_{\tau \rho^i} * \pi_{\tau \rho^j} = \pi_{\rho^{j-i}}$ also preserves ϕ . Once again, some automorphism in P^* must preserve ϕ .

To prove (2), we now consider the set of all k -labelings of G . Let sets A , B , and C consist of all k -labelings of G preserved by π_{ρ^0} only, by π_{ρ^0} and $\pi_{\tau \rho^i}$ for some $i \in \{0, 1, \dots, t-1\}$ only, and by some automorphism in P^* , respectively. Any k -labeling of G must belong to exactly one of the three sets because: (i) if it is distinguishing, it belongs to set A and if not to $B \cup C$; (ii) if it is preserved by exactly one nontrivial automorphism of G , and it is of the form $\pi_{\tau \rho^i}$, it belongs to set B ; otherwise, it belongs to set C ; (iii) finally, if it is preserved by at least two nontrivial automorphisms of G , then it belongs to set C . That is, $A \cup B \cup C$ contains all of the k -labelings of G , and no two of them have a k -labeling of G in common. Thus, $L(G, k) = |A| = k^n - |B| - |C|$.

By the way we defined set B , $|B| = \sum_{i=0}^{t-1} N_{=}(\{ \pi_{\rho^0}, \pi_{\tau \rho^i} \})$. Consider a k -labeling of G that is preserved by $\pi_{\tau \rho^i}$. From our earlier argument, we can assume that such a k -labeling is preserved by $\pi_{\tau \rho^i}$ only or by $\pi_{\tau \rho^i}$ and some other automorphism in P^* , in addition to being preserved by π_{ρ^0} . According to the PIE, this means that $N_{=}(\{ \pi_{\rho^0}, \pi_{\tau \rho^i} \}) = \sum_{\{ \pi_{\tau \rho^i} \} \subseteq P \subseteq \{ \pi_{\tau \rho^i} \} \cup P^*} (-1)^{|P|-1} N_{\geq}(P)$. Finally, C consists of all of the k -labelings of G preserved by at least one of the automorphisms in P^* . So, according to the PIE, $k^n - |C| = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P)$. Hence, $L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P) - \sum_{i=0}^{t-1} N_{=}(\{ \pi_{\rho^0}, \pi_{\tau \rho^i} \})$, which proves (2). $\square$

Example. Consider the cycle on n vertices C_n , where n is a prime number. Then $\text{Aut}(C_n) = D_n$ and $P^* = \{ \pi_{\rho} \}$. To solve for $L(C_n, k)$, we need the following values: $N_{\geq}(\emptyset)$, $N_{\geq}(\pi_{\rho})$, $N_{\geq}(\{ \pi_{\tau \rho^i}, \pi_{\rho} \})$, and $N_{\geq}(\{ \pi_{\tau \rho^i} \})$. Every k -labeling of C_n should be counted in $N_{\geq}(\emptyset)$ so $N_{\geq}(\emptyset) = k^n$. To solve for $N_{\geq}(\pi_{\rho})$, recall that we considered $G_{\pi_{\rho}}$, which is a graph that has only one component. Hence, $N_{\geq}(\pi_{\rho}) = k$. Similarly, $N_{\geq}(\{ \pi_{\tau \rho^i}, \pi_{\rho} \}) = k$. Finally, $G_{\pi_{\tau \rho^i}}$ consists of $(n+1)/2$ components, since any reflection of C_n fixes one vertex v and maps the equidistant vertices from v to each other. Thus, $N_{\geq}(\{ \pi_{\tau \rho^i} \}) = k^{(n+1)/2}$. From (2),

$$\begin{aligned} L(C_n, k) &= N_{\geq}(\emptyset) - N_{\geq}(\{ \pi_{\rho} \}) - \sum_{i=0}^{n-1} (N_{\geq}(\{ \pi_{\tau \rho^i} \}) - N_{\geq}(\{ \pi_{\tau \rho^i}, \pi_{\rho} \})) \\ &= k^n - k - nk^{(n+1)/2} + nk \\ &= k^n - nk^{(n+1)/2} + (n-1)k \\ &= k(k^{(n-1)/2} - 1)(k^{(n-1)/2} - (n-1)). \end{aligned}$$

Consequently, $D(C_n, k) = k(k^{(n-1)/2} - 1)(k^{(n-1)/2} - (n-1))/2n$. When $n = 5$, for example, $D(C_5, 1) = D(C_5, 2) = 0$, but $D(C_5, 3) = 12$, so $D(C_5) = 3$.

When $\text{Aut}(G) \cong Z_t \times Z_2$ or $D_t \times Z_2$. We state the following theorem without proof because the arguments are just extensions of those in Theorems 3.5 and 3.6.

THEOREM 3.7. *Suppose that the prime factorization of t is $\prod_{i=1}^s p_i^{r_i}$, the group $Z_t \times Z_2 = \{(\rho^i, \sigma^j), i \in \{0, 1, \dots, t-1\}, j \in \{0, 1\}\}$, and the group $D_t \times Z_2 = \{(\rho^i, \sigma^j), (\tau \rho^i, \sigma^j), i \in \{0, 1, \dots, m-1\}, j \in \{0, 1\}\}$. When t is odd, set $P_0^* = \{\pi_{(\rho^0, \sigma)}\}$; otherwise, set $P_0^* = \{\pi_{(\rho^0, \sigma)}, \pi_{(\rho^{t/2}, \sigma)}\}$. Let $P^* = P_0^* \cup \{\pi_{(\rho^i, \sigma^0)} : i \in \{t/p_1, t/p_2, \dots, t/p_s\}\}$.*

(i) *When $\text{Aut}(G) \cong Z_t \times Z_2$,*

$$L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P).$$

(ii) *When $\text{Aut}(G) \cong D_t \times Z_2$, and for $b = 0$ or 1 ,*

$$N_{=}(\{\pi_{(\rho^0, \sigma^0)}, \pi_{(\tau \rho^i, \sigma^b)}\}) = \sum_{\{\pi_{(\tau \rho^i, \sigma^b)}\} \subseteq P \subseteq \{\pi_{(\tau \rho^i, \sigma^b)}\} \cup P^*} (-1)^{|P|-1} N_{\geq}(P)$$

and

$$L(G, k) = \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P) - \sum_{b=0}^1 \sum_{i=0}^{t-1} N_{=}(\{\pi_{(\rho^0, \sigma^0)}, \pi_{(\tau \rho^i, \sigma^b)}\}).$$

Remark. Since the number of prime factors of t is $O(\log t)$, the number of $N_{\geq}(P)$ terms in the formula for computing $L(G, k)$ is $O(t)$ when $\text{Aut}(G) \cong Z_t$ or $Z_t \times Z_2$ and $O(t^2)$ when $\text{Aut}(G) \cong D_t$ or $D_t \times Z_2$.

3.1. When G is a triconnected planar graph. What is interesting about the family of triconnected planar graphs is that the automorphism groups of the graphs are only of limited kinds.

LEMMA 3.8 (see [18]). *Let G be a triconnected planar graph. The automorphism group of G is isomorphic to a subgroup of one of the following groups: A_4 , A_5 , S_4 , $A_4 \times Z_2$, $A_5 \times Z_2$, $S_4 \times Z_2$, Z_t , D_t , $Z_t \times Z_2$, or $D_t \times Z_2$, for some integer t .*

Since a subgroup of a dihedral group is a cyclic group or a dihedral group, clearly the subgroups of $D_t \times Z_2$ are cyclic, dihedral, or isomorphic to $Z_{t'} \times Z_2$ or $D_{t'} \times Z_2$, where $t' \leq t$. In other words, the automorphism group of a triconnected planar graph is either bounded by a constant or is isomorphic to one of four groups only.

Additionally, because triconnected planar graphs have only unique embeddings on the plane up to equivalence,⁴ finding all of their automorphisms can also be done efficiently. We sketch one such method next. Let G be a triconnected planar graph with n vertices and m edges. Let $e = (u, v)$ be an edge of G . Let us designate its direction as being from u to v and one of the faces F that it borders as its right face. Create a copy of G , $G_{e,F}$, which specially marks e and its direction—and face F . For any edge $e' = (u', v')$ whose direction and right face F' are fixed, create an analogous graph $G_{e',F'}$, and by using a planar graph isomorphism testing algorithm determine if $G_{e,F}$ and $G_{e',F'}$ are isomorphic (where the marked edge and face of $G_{e,F}$ are mapped to the marked edge and face of $G_{e',F'}$). If so, then there is an automorphism of G that maps e to e' and F to F' ; moreover, by visiting the faces of $G_{e,F}$ and $G_{e',F'}$ in the same order, the rest of π can be determined in time linear in the size of G . Since there is a linear time isomorphism testing algorithm for planar graphs [15], each iteration of the for loop takes $O(n)$ time. Since there are $O(m)$ iterations, then in

⁴A triconnected planar graph can have two planar embeddings, one of which is a mirror image of the other.

$O(nm) = O(n^2)$ time all of the automorphisms of G can be determined. Furthermore, because each edge has two directions and two faces bordering it, the algorithm above also shows that $|Aut(G)| \leq 4m = O(n)$ when G is a triconnected planar graph.

To solve for $L(G, k)$ for triconnected planar graphs, we do the following: If $|Aut(G)| \leq 5!$, use Theorem 3.2. Otherwise, determine if $Aut(G)$ is cyclic, dihedral, or isomorphic to a direct product of a cyclic group and Z_2 or to a direct product of a dihedral group and Z_2 . If $Aut(G)$ is cyclic or dihedral, apply Theorem 3.5 or 3.6, respectively; otherwise, apply Theorem 3.7.

THEOREM 3.9. *Let G be an n -vertex triconnected planar graph. Computing $L(G, k)$ and $D(G, k)$ can be done in $O(n^3 \log^2 k + n^3 \log n + n^3 \log k)$ time. Therefore, computing $D(G)$ takes $O(n^3 \log^3 n)$ time.*

Proof. As we stated earlier, if G has at most $5!$ automorphisms, we use Theorem 3.2 to solve for $L(G, k)$ and $D(G, k)$. Otherwise, we need to determine to which of the four groups $Aut(G)$ is isomorphic. In particular, $Aut(G)$ falls into case i , where $i = 1$ if the group is cyclic, $i = 2$ if the group is isomorphic to $Z_t \times Z_2$ for some t , $i = 3$ if the group is dihedral, and $i = 4$ if the group is isomorphic to $D_t \times Z_2$ for some t . We note that there is some overlap in the four cases because, if t is odd, $Z_t \times Z_2 \cong Z_{2t}$ and $D_{2t} \times Z_2 \cong D_{4t}$. Thus, when we say that $Aut(G)$ belongs to case 2 or 4, we shall assume that t is even. We describe our algorithm $TriconnectCount(G, k)$ in Figure 4.

In the first part of our algorithm, we determine the case to which $Aut(G)$ belongs by considering the order of each element in $Aut(G)$. It is easy to verify the following facts: (i) If $Aut(G)$ has an element with order $|Aut(G)|$, it must be cyclic; (ii) if $Aut(G)$ has only three elements with order 2 (and $3 < |Aut(G)|/2$), then it belongs to case 2; (iii) if $Aut(G)$ has between $|Aut(G)|/2$ and $|Aut(G)|/2 + 1$ of its elements with order 2, it belongs to case 3. Once the appropriate case for $Aut(G)$ is determined, we set the value of t .

The second part of the algorithm begins by computing the prime factors of t , finding an element $\pi \in Aut(G)$ such that the order of π is t , and then computing $P^* = \{\pi^i : i \in \{t/p_1, t/p_2, \dots, t/p_s\}\}$. If $Aut(G)$ is cyclic or dihedral, P^* is indeed the one needed in Theorems 3.5 and 3.6, respectively, to compute $L(G, k)$. In cases 2 and 4, two more elements are missing in P^* . To understand what they are, we note that since t is even π would be of the form $\pi_{(\rho, \sigma^b)}$, where $b = 0$ or 1 and ρ and σ are generators of Z_t and Z_2 , respectively. If we set $p_1 = 2$, then $(\pi_{(\rho, \sigma^b)})^{t/2} = \pi_{(\rho^{t/2}, \sigma^0)}$, or $\pi_{(\rho^{t/2}, \sigma^1)}$, and $(\pi_{(\rho, \sigma^b)})^{t/p_i} = \pi_{(\rho^{t/p_i}, \sigma^0)}$ for $i = 2, \dots, s$. At this point, the two missing elements in P^* have order 2; they can be distinguished from the other elements of $Aut(G)$ with order 2 because they commute with every other element of $Aut(G)$ (i.e., they belong to the center of $Aut(G)$), whereas the others do not. By updating P^* , we now obtain the appropriate P^* in Theorem 3.7. Finally, for cases 3 and 4, we place all elements of $Aut(G)$ with order 2 not in P^* into set T . It is easy to check that the rest of the algorithm computes $L(G, k)$ correctly since they follow directly from the theorems we have established.

Computing and storing the powers of k take $O(n^3 \log^2 k)$ time. Finding all of the automorphisms of G takes $O(n^2)$ time. It is easy to verify that, in the rest of the algorithm, the bottleneck is in computing the value of $L(G, k)$ when $|Aut(G)| > 5!$. By applying the same analysis we used in Theorem 3.2 and noting that $|P^*| = O(\log t)$ and $|T| = O(t)$, computing $L(G, k)$ takes $O(t^2(n \log t + n \log k))$ time. Finally, because G is a triconnected graph, $|Aut(G)| = O(n)$, and so $t = O(n)$. Hence, the total run time of $TriconnectCount(G, k)$ is $O(n^3 \log^2 k + n^3 \log n + n^3 \log k)$. Once we have the value for $L(G, k)$, we simply divide it by $|Aut(G)|$ to determine $D(G, k)$. To find $D(G)$, do a binary search over the range $[1, n]$ to determine the smallest k for which $D(G, k) >$

TriconnectCount(G, k)

Input: A triconnected planar graph G with n vertices, a positive integer k .

Output: The value of $L(G, k)$.

Compute and store the values $k, k^2, k^3, \dots, k^n$.

Find all the automorphisms of G .

If $|Aut(G)| \leq 5!$

$L(G, k) \leftarrow \sum_{\{\pi_0\} \subseteq P \subseteq Aut(G)} (-1)^{|P|-1} N_{\geq}(P)$
return($L(G, k)$)

else

compute the order of each automorphism $\pi \in Aut(G)$

if there is an automorphism whose order is $|Aut(G)|$

CASE $\leftarrow 1$, $t \leftarrow |Aut(G)|$,

else

if there are only 3 automorphisms with order 2

CASE $\leftarrow 2$, $t \leftarrow |Aut(G)|/2$,

else

if there are between $|Aut(G)|/2$ and $|Aut(G)|/2 + 1$ elements with order 2

CASE $\leftarrow 3$, $t \leftarrow |Aut(G)|/2$,

else

CASE $\leftarrow 4$, $t \leftarrow |Aut(G)|/4$.

Compute the prime factors of t : $p_1, p_2, \dots, p_s$.

Find an automorphism $\pi \in Aut(G)$ whose order is t .

Compute $P^* = \{\pi^i : i \in \{t/p_1, t/p_2, \dots, t/p_s\}\}$.

If CASE = 2 or 4

add to P^* the two other automorphisms of G which belong to the center of $Aut(G)$.

If CASE = 3 or 4

let T consist of all automorphisms in $Aut(G)$ that is not in P^* whose order is 2.

$L(G, k) \leftarrow \sum_{P \subseteq P^*} (-1)^{|P|} N_{\geq}(P)$.

If CASE = 1 or 2

return($L(G, k)$)

else

while $T \neq \emptyset$

pick $\pi' \in T$ and delete π' from T

$L(G, k) \leftarrow L(G, k) - \sum_{\{\pi'\} \subseteq P \subseteq \{\pi'\} \cup P^*} (-1)^{|P|-1} N_{\geq}(P)$

return ($L(G, k)$).

FIG. 4. The algorithm for computing the number of distinguishing k -labelings of a triconnected planar graph.

0 to find $D(G)$. This adds an extra $\log n$ factor to the run time of *TriconnectCount*(G, k). $\square$

4. Computing $D(G, k)$ via recursion. In this section, we shall generalize the recursive technique (discovered independently by Arvind and Devanur [4] and by Cheng [9]) that was used to compute the distinguishing numbers of trees. The main idea behind the technique is quite simple. Let T be a tree rooted at r . Let T_v denote the subtree of T rooted at vertex v . Start by setting $D(T_v, k) = k$ for each leaf v since a single node has k distinguishing k -labelings. Then, for $i = \text{height}(T) - 1$ to 0, do the following: For all nodes v at depth i , compute $D(T_v, k)$ based on the values computed for $D(T_w, k)$, w a child of v in T . Thus, at the end of the algorithm

$D(T_v, k)$, which equals $D(T, k)$, is determined. To apply the above technique to a connected graph G , we will view G as a rooted tree using the tree decomposition T_G described in section 2.1. Additionally, we will also consider a generalized version of the distinguishing k -labelings of a graph which we shall define shortly. Finally, we will develop recursive formulas that relate the number of (generalized) inequivalent distinguishing k -labelings of $G(T_v)$ with those of $G(T_w)$, w a child of v in T_G .

Let Γ be a subgroup of $\text{Aut}(G)$. We say that a labeling ϕ of G is Γ -distinguishing if no nontrivial automorphism in Γ preserves ϕ and that two labelings ϕ and ϕ' of G are *equivalent with respect to Γ* if some automorphism in Γ maps (G, ϕ) to (G, ϕ') . Let $\mathcal{L}(G, k; \Gamma)$ be the set consisting of the Γ -distinguishing k -labelings of G , $L(G, k; \Gamma)$ be the size of $\mathcal{L}(G, k; \Gamma)$, and $D(G, k; \Gamma)$ be the number of equivalence classes of $\mathcal{L}(G, k; \Gamma)$ with respect to Γ . When $\Gamma = \text{Aut}(G; *)$ as defined in section 2.1, we shall refer to $\mathcal{L}(G, k; \Gamma)$, $L(G, k; \Gamma)$, and $D(G, k; \Gamma)$ as $\mathcal{L}(G, k; *)$, $L(G, k; *)$, and $D(G, k; *)$, respectively. Finally, when (x, y) is an edge of G , we will at times differentiate between the cases when a k -labeling of G assigns x and y the same or different colors. When we do so, we will place a subscript next to $\mathcal{L}$, L , and D ; the subscript is 1 if x and y are assigned the same color and is 2 otherwise. Thus, $\mathcal{L}_1(G, k; xy)$ consists of all k -labelings of G in $\mathcal{L}(G, k; xy)$ that assigned x and y the same color, etc. It is easy to verify that the following version of Lemma 2.1 remains true.

LEMMA 4.1. *Let G be a graph and Γ be a subgroup of $\text{Aut}(G)$. Then $D(G, k; \Gamma) = L(G, k; \Gamma)/|\Gamma|$.*

Given a connected graph G , we showed in section 2.1 how to construct a tree decomposition of G , T_G . The construction started with G 's block-cut vertex graph. Each b -vertex whose associated block is B is then replaced with B 's triconnected component-separating pair graph T_B and then connected to the rest of the block-cut vertex graph. Thus, T_G is made up of c -, s -, and t -vertices which represent the cut vertices, separating pairs, and triconnected components, respectively, of G . We shall now describe recursive formulas for $D(G(T_v), k; *)$ based on the type of vertex v in T_G .

THEOREM 4.2. *Let v be a c -vertex in T_G and a be the cut vertex in G associated with v . Suppose that, when all of the graphs in $\mathcal{G} = \{G(T_w) : w \text{ is a child of } v \text{ in } T_G\}$ are fixed at a , there are g isomorphic classes and the i th isomorphic class contains m_i copies of the connected graph G_i ; i.e., $\mathcal{G} = m_1 G_1 \cup m_2 G_2 \cup \dots \cup m_g G_g$. Then*

$$D(G(T_v), k; a) = k \prod_{i=1}^g \binom{D(G_i, k; a)/k}{m_i}.$$

Proof. By the way T_G was constructed, if $\mathcal{G} = m_1 G_1 \cup m_2 G_2 \cup \dots \cup m_g G_g$, then $G(T_v)$ is made up of $\sum_{i=1}^g m_i$ connected components all hanging from vertex a . It is easy to verify that ϕ is a labeling in $\mathcal{L}(G(T_v), k; a)$ if and only if ϕ assigns inequivalent labelings from $\mathcal{L}(G_i, k; a)$ to the m_i copies of G_i , $i = 1, \dots, g$, and the labels assigned to vertex a by all of the labelings are the same. This means that an equivalence class of $\mathcal{L}(G(T_v), k; a)$ is defined by (i) the label assigned to a and (ii) the set of m_i equivalence classes from $\mathcal{L}(G_i, k; a)$ that contain the labelings of the m_i copies of G_i , $i = 1, \dots, g$. There are k possible labels for a . Once the label for a is chosen, say, l , there are $D(G_i, k; a)/k$ different equivalence classes of $\mathcal{L}(G_i, k; a)$ which assign vertex a the same label. This is so because the number of equivalence classes of $\mathcal{L}(G_i, k; a)$ where a is assigned the label l must be the same for every possible value of l . It follows that there are $\binom{D(G_i, k; a)/k}{m_i}$ different sets of m_i equivalence classes that can contain the labelings assigned to the m_i copies of G_i for $i = 1, \dots, g$. By the product rule of counting, the theorem is established. $\square$

FIG. 5. In this graph, (x, y) is a separating pair. Notice that the labeling of the 5-cycle on the left does not destroy the automorphism of the 5-cycle that flips the graph along the edge (x, y) , but the labeling for the entire graph is distinguishing.

The next two theorems deal with the case when v is an s -vertex.

THEOREM 4.3. *Let v be an s -vertex in T_G and $\{x, y\}$ be the separating pair associated with v . If it exists, let w_x denote the child of v that is a c -vertex associated with x . Similarly, if it exists, let w_y denote the child of v that is a c -vertex associated with y . Suppose that, when all of the graphs in $\mathcal{G} = \{G(T_w) : w \text{ is a } t\text{-vertex and a child of } v \text{ in } T_G\}$ are fixed at x and y , there are g isomorphic classes and the i th isomorphic class has m_i copies of the connected graph G_i ; i.e., $\mathcal{G} = m_1 G_1 \cup m_2 G_2 \cup \dots \cup m_g G_g$. Then $D(G(T_v), k; x, y)$ equals*

$$k^2 \max\{D(G(T_{w_x}), k; x)/k, 1\} \max\{D(G(T_{w_y}), k; y)/k, 1\} \prod_{i=1}^g \binom{D(G_i, k; x, y)/k^2}{m_i}.$$

Proof. Once again, it is easy to verify that $\phi \in \mathcal{L}(G(T_v), k; x, y)$ if and only if ϕ assigns inequivalent labelings from $\mathcal{L}(G_i, k; x, y)$ to the m_i copies of G_i , $i = 1, \dots, g$, and the labels assigned to x and to y by all of the labelings are the same. Thus, an equivalence class of $\mathcal{L}(G(T_v), k; x, y)$ is defined by (i) the labels assigned to x and y , (ii) the equivalence classes of $\mathcal{L}(G(T_{w_x}), k; x)$ and $\mathcal{L}(G(T_{w_y}), k; y)$ that contain the labelings of $G(T_{w_x})$ and $G(T_{w_y})$, respectively, and (iii) the set of m_i equivalence classes of $\mathcal{L}(G_i, k; x, y)$ that contain the labelings of the m_i copies of G_i , $i = 1, \dots, g$. There are k^2 labels available for x and y . Once the labels are chosen, say, l_x and l_y , the number of equivalence classes of $\mathcal{L}(G_i, k; x, y)$ where x and y are assigned the said labels is $D(G_i, k; x, y)/k^2$. This is so because, in any labeling in $\mathcal{L}(G_i, k; x, y)$, the labels of the vertices in G_i other than x and y are the ones that actually destroy the nontrivial automorphisms of $\text{Aut}(G_i; x, y)$. Consequently, the number of labelings and the number of equivalence classes of $\mathcal{L}(G_i, k; x, y)$ with x and y assigned l_x and l_y must be the same regardless of the pair (l_x, l_y) . Of the $D(G_i, k; x, y)/k^2$ equivalence classes of $\mathcal{L}(G_i, k; x, y)$ that are being considered, m_i must be chosen to contain the labelings of the m_i copies of G_i . Similarly, the number of equivalence classes of $\mathcal{L}(G(T_{w_x}), k; x)$ where x is assigned the label l_x and the number of equivalence classes of $\mathcal{L}(G(T_{w_y}), k; y)$ where y is assigned the label l_y are $D(G(T_{w_x}), k; x)/k$ and $D(G(T_{w_y}), k; y)/k$, respectively. By the product rule of counting, the theorem is established. $\square$

We will also need to compute $D(G(T_v), k; xy)$. Unlike our previous characterizations, however, it is not necessarily the case that when $\phi \in \mathcal{L}(G(T_v), k; xy)$, then ϕ assigns inequivalent labelings from $\mathcal{L}(G_i, k; xy)$ to each copy of G_i . Figure 5 shows one such exception. Our approach this time is to consider the equivalence classes of $\mathcal{L}(G(T_v), k; x, y)$ and count those that *do not* belong to $\mathcal{L}(G(T_v), k; xy)$.

Consider an arbitrary graph H with an edge (x, y) , and suppose that $\text{Aut}(H; xy) \neq \text{Aut}(H; x, y)$. Let $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ denote the set of automorphisms of H that

map x to y and y to x . Notice that $\text{Aut}(H; xy)$ is the disjoint union of $\text{Aut}(H; x, y)$ and $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$. Moreover, $\text{Aut}(H; x, y)$ is a subgroup of $\text{Aut}(H; xy)$, and $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ is a coset of $\text{Aut}(H; x, y)$.

Suppose that ϕ_1 and ϕ_2 belong to the same equivalence class in $\mathcal{L}(H, k; x, y)$. If some automorphism in $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ preserves ϕ_1 , then it is easy to verify that another automorphism in $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ also preserves ϕ_2 . That is, for each equivalence class in $\mathcal{L}(H, k; x, y)$, either all of the labelings do not destroy some automorphism of $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ (and so do not belong to $\mathcal{L}(H, k; xy)$) or all do (and so belong to $\mathcal{L}(H, k; xy)$). Let $\mathcal{B}(H, k; x, y)$ be the set that contains all equivalence classes of $\mathcal{L}(H, k; x, y)$ whose labelings do not belong to $\mathcal{L}(H, k; xy)$, and denote its size as $B(H, k; x, y)$. Our discussion will focus on computing $B(H, k; x, y)$ because this is the number of “bad” equivalence classes of $\mathcal{L}(H, k; x, y)$ in that they do not carry over as equivalence classes of $\mathcal{L}(H, k; xy)$.

Suppose that $\pi \in \text{Aut}(H; x \rightarrow y, y \rightarrow x)$. It is easy to verify that (i) when all of the labelings in an equivalence class of $\mathcal{L}(H, k; x, y)$ destroy all of the automorphisms in $\text{Aut}(H; xy)$, then π maps these labelings to the labelings of another equivalence class of $\mathcal{L}(H, k; x, y)$; (ii) on the other hand, when all of the labelings in an equivalence class of $\mathcal{L}(H, k; x, y)$ do not destroy the automorphisms in $\text{Aut}(H; xy)$, then π maps these labelings to themselves. In other words, under the action of $\text{Aut}(H; xy)$ the equivalence classes of $\mathcal{L}(H, k; x, y)$ either get paired up or stay singleton. The ones that get paired up are precisely the equivalence classes of $\mathcal{L}(H, k; xy)$; i.e., each equivalence class of $\mathcal{L}(H, k; xy)$ is made up of two equivalence classes of $\mathcal{L}(H, k; x, y)$. We shall say that such a pair of equivalence classes are *partners* in $\mathcal{L}(H, k; x, y)$. The ones that stay single are the equivalence classes in $\mathcal{B}(H, k; x, y)$. We have proved the following lemma.

LEMMA 4.4. *Let H be a graph with edge (x, y) and $\text{Aut}(H; xy) \neq \text{Aut}(H; x, y)$. Then $D(H, k; x, y) = 2D(H, k; xy) + B(H, k; x, y)$.*

We also need the following lemma.

LEMMA 4.5. *Let H be a graph with edge (x, y) and $\text{Aut}(H; xy) \neq \text{Aut}(H; x, y)$. Then $D_2(H, k; xy) = \binom{k}{2} D(H, k; x, y) / k^2$, so $D_1(H, k; xy) = D(H, k; xy) - \binom{k}{2} D(H, k; x, y) / k^2$.*

Proof. Consider the labelings in $\mathcal{L}_2(H, k; xy)$. Since x and y are assigned different labels, they immediately destroy all of the automorphisms in $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$. Thus, we can construct a labeling in $\mathcal{L}_2(H, k; xy)$ by first choosing distinct labels for x and y , then choosing the equivalence classes of $\mathcal{L}(H, k; x, y)$ that will contain the labeling of H , and finally picking the labeling of H from the equivalence class. Hence, $L_2(H, k; xy) = k(k-1) \times D(H, k; x, y) / k^2 \times |\text{Aut}(H, k; x, y)|$, so

$$\begin{aligned} D_2(H, k; xy) &= L_2(H, k; xy) / |\text{Aut}(H, k; xy)| \\ &= k(k-1) D(H, k; x, y) / k^2 \frac{|\text{Aut}(H, k; x, y)|}{|\text{Aut}(H, k; xy)|} \\ &= k(k-1) D(H, k; x, y) / 2k^2, \end{aligned}$$

where the last equation follows from the fact that $|\text{Aut}(H; x, y)| = |\text{Aut}(H; x \rightarrow y, y \rightarrow x)|$ because $\text{Aut}(H; x \rightarrow y, y \rightarrow x)$ is a coset of $\text{Aut}(H; x, y)$ and so $|\text{Aut}(H; xy)| = 2|\text{Aut}(H; x, y)|$. Finally, since $D(H, k; xy) = D_1(H, k; xy) + D_2(H, k; xy)$, the formula for $D_1(H, k; xy)$ in the lemma follows. $\square$

THEOREM 4.6. *Let v be an s -vertex in T_G and $\{x, y\}$ be the separating pair associated with v . If it exists, let w_x denote the child of v that is a c -vertex associated with x . Similarly, if it exists, let w_y denote the child of v that is a c -vertex associated with y . Suppose that, when all of the graphs in $\mathcal{G} = \{G(T_w) :$*

w is a t -vertex and a child of v in T_G are fixed at x and y , there are g isomorphic classes and the i th isomorphic class has m_i copies of the connected graph G_i ; i.e., $\mathcal{G} = m_1 G_1 \cup m_2 G_2 \cup \dots \cup m_g G_g$. If $\text{Aut}(G(T_v); xy) = \text{Aut}(G(T_v); x, y)$, then $D(G(T_v), k; xy) = D(G(T_v), k; x, y)$. Otherwise, $\text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x) \neq \emptyset$, so $G(T_{w_x}) \cong G(T_{w_y})$, and

$$D(G(T_v), k; xy) = [D(G(T_v), k; x, y) - B(G(T_v), k; x, y)]/2,$$

where $B(G(T_v), k; x, y)$ equals

$$k \max\{D(G(T_{w_x}), k; x)/k, 1\} \prod_{i=1}^g \sum_{l=0}^{\lfloor m_i/2 \rfloor} \binom{D_1(G_i, k; xy)/k}{l} \binom{[D(G_i, k; x, y) - 2D(G_i, k; xy)]/k}{m_i - 2l}.$$

Proof. When $\text{Aut}(G(T_v); xy) = \text{Aut}(G(T_v); x, y)$, $\mathcal{L}(G(T_v), k; xy) = \mathcal{L}(G(T_v), k; x, y)$, and so it follows that $D(G(T_v), k; xy) = D(G(T_v), k; x, y)$. Otherwise, $\text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x) \neq \emptyset$. Hence, if they exist, $G(T_{w_x}) \cong G(T_{w_y})$ and $\text{Aut}(G_i; xy) \neq \text{Aut}(G_i; x, y)$ for $i = 1, \dots, g$. In computing $D(G(T_v), k; x, y)$, we noted that there are three sets of parameters that describe the equivalence classes of $\mathcal{L}(G(T_v), k; x, y)$: (i) the labels assigned to x and y , (ii) the equivalence classes of $\mathcal{L}(G(T_{w_x}), k; x)$ that contain the labelings of $G(T_{w_x})$ and $G(T_{w_y})$, and (iii) the set of m_i equivalence classes of $\mathcal{L}(G_i, k; x, y)$ that contain the labelings of the m_i copies of G_i for $i = 1, \dots, g$. We shall extend them to characterize the equivalence classes in $\mathcal{B}(G(T_v), k; x, y)$ —i.e., the equivalence classes of $\mathcal{L}(G(T_v), k; x, y)$ whose labelings are preserved by some automorphism in $\text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x)$.

CLAIM. An equivalence class of $\mathcal{L}(G(T_v), k; x, y)$ belongs to $\mathcal{B}(G(T_v), k; x, y)$ if and only if

- (i) the labels assigned to x and y are the same for every labeling in the class,
- (ii) the equivalence classes that contain the labelings of $G(T_{w_x})$ and $G(T_{w_y})$ are the same, and
- (iii) for $i = 1, \dots, g$, the set of m_i equivalence classes of $\mathcal{L}(G_i, k; x, y)$ that contain the labelings of the m_i copies of G_i can be partitioned into l_i groups of size 2 and $m_i - 2l_i$ groups of size 1 for some $0 \leq l_i \leq \lfloor m_i/2 \rfloor$ so that the pairs of equivalence classes that belong to a group of size 2 are partners in $\mathcal{L}(G_i, k; x, y)$ and the equivalence classes that belong to a group of size 1 are in $\mathcal{B}(G_i, k; x, y)$.

Proof of claim. Let $\phi \in \mathcal{L}(G(T_v), k; x, y)$ belong to an equivalence class that satisfies conditions (i), (ii), and (iii) above. For $i = 1, \dots, g$, denote the m_i copies of G_i as $G_{i,1}, \dots, G_{i,m_i}$. Without loss of generality, assume that the equivalence classes that contain the labelings of $G_{i,2j-1}$ and $G_{i,2j}$ are partners in $\mathcal{L}(G_i, k; x, y)$ for $j = 1, \dots, l_i$ and the equivalence classes that contain the labelings of each of the remaining copies of G_i belong to $\mathcal{B}(G_i, k; x, y)$. Thus, condition (iii) implies that there are automorphisms⁵ in $\text{Aut}(G_i; x \rightarrow y, y \rightarrow x)$ that map $(G_{i,2j-1}, \phi)$ to $(G_{i,2j}, \phi)$ and vice versa for $j = 1, \dots, l_i$; similarly, there is also some automorphism in $\text{Aut}(G_i; x \rightarrow y, y \rightarrow x)$ that preserves $(G_{i,j}, \phi)$ for $j = 2l_i + 1, \dots, m_i$. Furthermore, condition (ii) implies that there are some automorphisms in $\text{Aut}(G(T_{w_x}); x)$ that map

⁵Technically, we are referring to the automorphisms implicitly defined by the isomorphisms that map $(G_{i,2j-1}, \phi)$ to $(G_{i,2j}, \phi)$ and vice versa since $G_{i,2j-1}$ and $G_{i,2j}$ are copies of G_i . We shall keep this usage throughout the proof for ease of discussion.

$(G(T_{w_x}), \phi)$ to $(G(T_{w_y}), \phi)$ and vice versa. By combining these automorphisms, we conclude that some automorphism in $\text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x)$ preserves ϕ ; that is, the equivalence class that contains ϕ belongs to $\mathcal{B}(G(T_v), k; x, y)$.

On the other hand, suppose that $\phi \in \mathcal{L}(G(T_v), k; x, y)$ and some automorphism $\pi \in \text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x)$ preserves ϕ . Clearly, π maps x to y and vice versa, and so condition (i) is true. It also maps $G(T_{w_x})$ to $G(T_{w_y})$ and vice versa, and so condition (ii) is true. For $i = 1, \dots, g$, if π maps $G_{i,j}$ to itself, then ϕ must have assigned $G_{i,j}$ a labeling that destroys all automorphisms in $\text{Aut}(G_i; x, y)$ since $\phi \in \mathcal{L}(G(T_v), k; x, y)$ but is still preserved by some automorphism in $\text{Aut}(G_i; x \rightarrow y, y \rightarrow x)$ since $\pi \in \text{Aut}(G(T_v); x \rightarrow y, y \rightarrow x)$. That is, the equivalence class that contains the labeling of $G_{i,j}$ belongs to $\mathcal{B}(G_i, k; x, y)$. If π maps $G_{i,j}$ to $G_{i,j'}$, $j \neq j'$, then there is some automorphism in $\text{Aut}(G_i; x \rightarrow y, y \rightarrow x)$ that maps $(G_{i,j}, \phi)$ to $(G_{i,j'}, \phi)$ so that the equivalence classes that contain the labelings assigned by ϕ to $G_{i,j}$ and $G_{i,j'}$ are partners in $\mathcal{L}(G_i, k; x, y)$. Finally, if π maps $G_{i,j}$ to $G_{i,j'}$ and $G_{i,j'}$ to $G_{i,j''}$, where j, j' and j'' are distinct, then the equivalence classes that contain the labelings assigned by ϕ to $G_{i,j}$ and $G_{i,j'}$ are partners and those of $G_{i,j'}$ and $G_{i,j''}$ are partners as well. But this implies that the equivalence classes that contain the labelings assigned by ϕ to $G_{i,j}$ and $G_{i,j''}$ are exactly the same, contradicting the assumption that ϕ assigned inequivalent labelings to the m_i copies of G_i since $\phi \in \mathcal{L}(G(T_v), k; x, y)$. Thus, condition (iii) must be true.

By combining conditions (i) and (iii), we note that each group of size 2 in condition (iii) corresponds to an equivalence class of $\mathcal{L}_1(G_i, k; xy)$. Moreover, because no two of the equivalence classes that contain the labelings of the m_i copies of G_i are identical, distinct groups of size 2 correspond to distinct equivalence classes of $\mathcal{L}_1(G_i, k; xy)$. By using the claim, we can now compute $B(G(T_v), k; x, y)$. An equivalence class in $\mathcal{B}(G(T_v), k; x, y)$ is defined by (i) the label assigned to x and y , (ii) the equivalence class of $\mathcal{L}(G(T_{w_x}), k; x)$ that contains the labelings of $G(T_{w_x})$ and $G(T_{w_y})$, and (iii) the set of l_i equivalence classes of $\mathcal{L}_1(G_i, k; xy)$ and the set of $m_i - 2l_i$ equivalence classes in $\mathcal{B}(G_i, k; x, y)$ which together contain the labelings of the m_i copies of G_i for $i = 1, \dots, g$. There are k ways of assigning the same labels to x and y , say, l . Once l is fixed, there are $D(G(T_{w_x}), k; x)/k$ choices for the equivalence class of (ii), $\binom{D_1(G_i, k; xy)/k}{l_i}$ choices for the set of l_i equivalence classes, and $\binom{B(G_i, k; x, y)/k}{m_i - 2l_i}$ choices for the set of $m_i - 2l_i$ equivalence classes of (iii). Thus, $B(G(T_v), k; x, y)$ equals

$$k \binom{D(G(T_{w_x}), k; x)/k}{1} \prod_{i=1}^g \sum_{l=0}^{\lfloor m_i/2 \rfloor} \binom{D_1(G_i, k; xy)/k}{l} \binom{[D(G_i, k; x, y) - 2D(G_i, k; xy)]/k}{m_i - 2l}.$$

Once $B(G(T_v), k; x, y)$ is computed, we can determine $D(G(T_v), k; xy)$ by using Lemma 4.4. $\square$

An important implication of Theorems 4.3 and 4.6 and Lemma 4.5 is that both $D(G(T_v), k; x, y)$ and $D(G(T_v), k; xy)$ can be computed given the values of $D(G(T_{w_x}), k; x)$ and $D(G(T_{w_y}), k; y)$ and those of $D(G_i, k; x, y)$ and $D(G_i, k; xy)$ for $i = 1, \dots, g$.

Let us now consider the case when v is a t -vertex. Let H be the triconnected component associated with v . We need to solve for $D(G(T_v), k; H, A)$, where A is the structure associated with the parent of v in T_G (if the parent exists). Our goal is to create a formula for $D(G(T_v), k; H, A)$ that is dependent on H and the values of $D(G(T_w), k; *)$ only, where w is a child of v in T_G and $*$ is the structure associated with

FIG. 6. Graph G and its tree decomposition. Again, $r = r(T_G)$. Note that $D(G(T_r), k; H) = D(G, k)$.

w , so that the formula can be computed efficiently. Our approach follows section 3 closely; the difference is that in our current setting $G(T_v)$ is made up of H together with components hanging off of the cut vertices and separating pairs of G in H , whereas in section 3 we dealt only with the graph H . We demonstrate our approach by solving for $D(G(T_v), k; H)$; others can be solved similarly. To aid us in our discussion, we shall use the graph in Figure 6 for illustration. In particular, we will compute for $D(G(T_r), k; H)$, which equals $D(G, k)$.

Let $\mathcal{C}_H$ contain the cut vertices of G in H whose corresponding vertices in T_G are children of v . Let $\mathcal{S}_H$ contain the separating pairs of G in H used in creating T_G whose corresponding vertices in T_G are children of v . When $a \in \mathcal{C}_H$ and w is the child of v that is associated with a , we shall refer to $G(T_w)$ as G_a for ease of notation. We do the same for each pair $\{x, y\} \in \mathcal{S}_H$. We begin by considering $\mathcal{L}^*(G(T_v), k)$, the set that contains all of the k -labelings ϕ of $G(T_v)$, so that ϕ when restricted to G_a belongs to $\mathcal{L}(G_a, k; a)$ for every cut vertex $a \in \mathcal{C}_H$ and ϕ when restricted to $G_{x,y}$ belongs to $\mathcal{L}(G_{x,y}, k; x, y)$ for every separating pair $\{x, y\} \in \mathcal{S}_H$. For instance, a labeling that assigns all of the nodes of G in Figure 6 the same label belongs to $\mathcal{L}^*(G(T_r), k)$ because every $G_{a_i, a_{i+1}}$ fixed at a_i and a_{i+1} has no nontrivial automorphisms. Clearly, every labeling in $\mathcal{L}(G(T_v), k; H)$ also belongs to $\mathcal{L}^*(G(T_v), k)$; otherwise, some nontrivial automorphism in $\text{Aut}(G(T_v); H)$ is not destroyed. We shall use PIE to weed out the labelings in $\mathcal{L}^*(G(T_v), k)$ that are not part of $\mathcal{L}(G(T_v), k; H)$.

Let $\text{Aut}_v(H)$ consist of all of the automorphisms in $\text{Aut}(G(T_v); H)$ when restricted to H . Suppose that $P \subseteq \text{Aut}_v(H)$. Let $N_{\geq}(P)$ denote the number of labelings ϕ in $\mathcal{L}^*(G(T_v), k)$ so that, for every $\sigma \in P$, some extension of σ in $\text{Aut}(G(T_v); H)$ preserves ϕ . Define $N_{=}(P)$ similarly except that aside from the automorphisms in P no other automorphism in $\text{Aut}_v(H)$ has extensions that preserve ϕ . We now state the formulas for $L(G(T_v), k; H)$ and $D(G(T_v), k; H)$.

THEOREM 4.7. *Let v be a t -vertex in T_G and H be the triconnected component associated with v . Let $\text{Aut}_v(H)$ consist of the automorphisms in $\text{Aut}(G(T_v); H)$ when*

restricted to H and σ_0 be the identity automorphism in $\text{Aut}_v(H)$. Then

$$L(G(T_v), k; H) = N_{=}(\{\sigma_0\}) = \sum_{\{\sigma_0\} \subseteq P \subseteq \text{Aut}_v(H)} (-1)^{|P|-1} N_{\geq}(P)$$

and

$$D(G(T_v), k; H) = \frac{1}{|\text{Aut}_v(H)|} \sum_{\{\sigma_0\} \subseteq P \subseteq \text{Aut}_v(H)} \frac{(-1)^{|P|-1} N_{\geq}(P)}{\prod_{a \in \mathcal{C}_H} |\text{Aut}(G_a; a)| \prod_{\{x, y\} \in \mathcal{S}_H} |\text{Aut}(G_{x, y}; x, y)|}.$$

Proof. It is straightforward to verify that $N_{=}(\{\sigma_0\}) = \sum_{\{\sigma_0\} \subseteq P \subseteq \text{Aut}_v(H)} (-1)^{|P|-1} N_{\geq}(P)$ is the number of labelings in $\mathcal{L}^*(G(T_v), k)$ that is preserved by some extension of σ_0 and by no other automorphism in $\text{Aut}_v(H)$. But by the way we defined $\mathcal{L}^*(G(T_v), k)$, if some extension of σ_0 preserves a labeling of $\mathcal{L}^*(G(T_v), k)$, that extension must be the identity automorphism of $G(T_v)$. The first equation of the theorem follows. Now $|\text{Aut}(G(T_v); H)| = |\text{Aut}_v(H)| \times \prod_{a \in \mathcal{C}_H} |\text{Aut}(G_a; a)| \times \prod_{\{x, y\} \in \mathcal{S}_H} |\text{Aut}(G_{x, y}; x, y)|$ since every automorphism in $\text{Aut}(G(T_v); H)$ can be decomposed into an automorphism in $\text{Aut}_v(H)$ and automorphisms of the connected components that hang off of H fixed at the cut vertices or separating pairs that connect them to H . Hence, dividing $L(G(T_v), k; H)$ by $|\text{Aut}(G(T_v); H)|$ gives us the second equation of the theorem. $\square$

COROLLARY 4.8. *When $\text{Aut}_v(H)$ is cyclic, dihedral, or isomorphic to $Z_t \times Z_2$ or $D_t \times Z_2$ for some integer t , the formulas in Theorems 3.5, 3.6, and 3.7 for $N_{=}(\{\sigma_0\})$, where σ_0 is the identity automorphism, still apply.*

Suppose that, instead of $D(G(T_v), k; H)$, we wish to compute $D(G(T_v), k; H, a)$ (or $D(G(T_v), k; H, x, y)$ or $D(G(T_v), k; H, xy)$). Let Γ denote the subgroup of $\text{Aut}_v(H)$ that fixes a (or x and y or xy). By replacing $\text{Aut}_v(H)$ with Γ , the formula in Theorem 4.7 still holds.

Next, we describe a method for computing $N_{\geq}(P)$, $P \subseteq \text{Aut}_v(H)$. For each $\sigma \in P$, let H_σ be the graph whose vertex set is $V(H)$ and edge set is $\{(v, \sigma(v)) : v \in V(H)\}$. Let SP_σ be the graph whose vertex set consists of xy and yx whenever $\{x, y\} \in \mathcal{S}_H$ and whose edge set is $\{(xy, \sigma(x)\sigma(y)), (yx, \sigma(y)\sigma(x)) : \{x, y\} \in \mathcal{S}_H\}$. In $\cup_{\sigma \in P} SP_\sigma$, let $SP_P(xy)$ denote the component that contains the vertex xy . Notice that if a and a' are part of the same component in $\cup_{\sigma \in P} H_\sigma$, then both a and a' are cut vertices or both are not; and when both of them are, then $G_a \cong G_{a'}$. Similarly, when xy and $x'y'$ are part of the same component in $\cup_{\sigma \in P} SP_\sigma$, $G_{x, y} \cong G_{x', y'}$. Finally, when $yx \in SP_P(xy)$, then, for every $x'y' \in SP_P(xy)$, $y'x' \in SP_P(xy)$ as well. The following can easily be verified: $\phi \in \mathcal{L}^*(G(T_v), k)$ is counted in $N_{\geq}(P)$ if and only if (i) whenever two vertices are part of the same component in $\cup_{\sigma \in P} H_\sigma$, ϕ assigns them the same label; (ii) whenever two cut vertices a and a' are part of the same component in $\cup_{\sigma \in P} H_\sigma$, ϕ when restricted to G_a and $G_{a'}$ belong to the same equivalence class of $\mathcal{L}(G_a, k; a)$; and (iii) when xy and $x'y'$ are part of the same component in $\cup_{\sigma \in P} SP_\sigma$, ϕ when restricted to $G_{x, y}$ and $G_{x', y'}$ belong to the same equivalence class of $\mathcal{L}(G_{x, y}, k; x, y)$.

In SP_σ , we have chosen to represent the separating pair $\{x, y\}$ as two vertices xy and yx to capture situations in which an automorphism in $\text{Aut}_v(H)$ maps x to y and y to x . However, such a representation can introduce redundancies in the sense that two different components in SP_σ may be capturing the same relationships between the same sets of separating pairs. As such, we shall say that a collection

of components $\{SP_P(x_i y_i), i = 1, \dots, g\}$ forms a *partition* of $\cup_{\sigma \in P} SP_\sigma$ if for every separating pair $\{x, y\} \in \mathcal{S}_H$ exactly one component in the collection contains xy or yx or both. In Figure 6, let $\pi_\rho \in \text{Aut}_r(H)$ be the rotation that maps a_i to a_{i+1} , $i = 1, \dots, 5$, and $\pi_\tau \in \text{Aut}_r(H)$ be the reflection that fixes a_1 . A partition for SP_{π_ρ} contains only one component, while a partition for SP_{π_τ} contains three components—e.g., $SP(a_1 a_5)$, $SP(a_5 a_4)$, and $SP(a_4 a_3)$, where $a_3 a_4 \in SP(a_4 a_3)$.

THEOREM 4.9. *Let $\{\sigma_0\} \subseteq P \subseteq \text{Aut}_v(H)$. Suppose that $\cup_{\sigma \in P} H_\sigma$ has t components, where the i th component contains the vertex a_i , and the collection $\{SP_P(x_i y_i), i = 1, \dots, g\}$ forms a partition of $\cup_{\sigma \in P} SP_\sigma$. Let $\kappa(a_i) = D(G_{a_i}, k; a_i)$ if a_i is a cut vertex and is equal to k otherwise. Let $\kappa(x_i, y_i) = [D(G_{x_i, y_i}, k; x_i, y_i) - 2D(G_{x_i, y_i}, k; x_i y_i)]/k$ if $y_i x_i \in SP_P(x_i y_i)$ and is equal to $D(G_{x_i, y_i}, k; x_i, y_i)/k^2$ otherwise. Then*

$$N_{\geq}(P) = \prod_{i=1}^t \kappa(a_i) \times \prod_{i=1}^g \kappa(x_i, y_i) \times \prod_{a \in \mathcal{C}_H} |\text{Aut}(G_a; a)| \times \prod_{\{x, y\} \in \mathcal{S}_H} |\text{Aut}(G_{x, y}; x, y)|.$$

Proof. To create a labeling ϕ that is counted in $N_{\geq}(P)$, we do the following. (1) If a_i is not a cut vertex, pick a label that will be assigned to it and all of the vertices in the same component as a_i in $\cup_{\sigma \in P} H_\sigma$. (2) If a_i is a cut vertex, pick an equivalence class of $\mathcal{L}(G_{a_i}, k; a_i)$ that will contain the labelings of G_{a_i} and all of the G_u 's, where u and a_i are in the same component of $\cup_{\sigma \in P} H_\sigma$. Then for a_i and each of the vertices u , pick a labeling from the equivalence class just chosen. (3) For each $\{x_i, y_i\}$, pick an equivalence class of $\mathcal{L}(G_{x_i, y_i}, k; x_i, y_i)$ that will contain the labelings of G_{x_i, y_i} and all $G_{u, w}$'s, where uw and $x_i y_i$ are in the same component of $\cup_{\sigma \in P} SP_\sigma$. Additionally, this equivalence class must respect the labels that have already been assigned to x_i and y_i in step 2. Then for $\{x_i, y_i\}$ and each $\{u, w\}$, pick a labeling from the equivalence class just chosen.

There are k ways of doing step 1 and $D(G_{a_i}, k; a_i) \times |\text{Aut}(G_{a_i}; a_i)|^{j_i}$ ways of doing step 2, where j_i is the number of vertices in the same component as a_i . Thus, there are $\prod_{i=1}^t \kappa(a_i) \times \prod_{a \in \mathcal{C}_H} |\text{Aut}(G_a; a)|$ ways of doing steps 1 and 2 since, whenever the a_i and u are in the same component of $\cup_{\sigma \in P} H_\sigma$, both vertices are cut vertices or both are not and $\text{Aut}(G_{a_i}; a_i) \cong \text{Aut}(G_u; u)$.

To do step 3, we need to differentiate between the case when $y_i x_i$ also belongs to $SP_P(x_i y_i)$ and when it doesn't. In the former case, ϕ when restricted to G_{x_i, y_i} must destroy all of the automorphisms of G_{x_i, y_i} when x_i and y_i are fixed but is preserved by some automorphism of the graph that maps x_i to y_i and vice versa. In other words, the equivalence class containing the labeling belongs to $\mathcal{B}(G_{x_i, y_i}, k; x_i, y_i)$. Since the labels of x and y have already been chosen in step 1 or 2 (note that they had to be the same), from Lemma 4.4 there are exactly $[D(G_{x_i, y_i}, k; x_i, y_i) - 2D(G_{x_i, y_i}, k; x_i y_i)]/k$ equivalence classes to choose from in step 3. On the other hand, when $y_i x_i$ does not belong to $SP_P(x_i y_i)$, ϕ when restricted to G_{x_i, y_i} must simply belong to $\mathcal{L}(G_{x_i, y_i}, k; x_i, y_i)$, and so, once the labels of x_i and y_i have been chosen in steps 1 and 2, there are exactly $D(G_{x_i, y_i}, k; x_i, y_i)/k^2$ equivalence classes to choose from in step 3. Finally, when the equivalence classes have been selected, then there are $|\text{Aut}(G_{x_i, y_i}; x_i, y_i)|^{j_i}$ labelings that can be assigned to the $G_{u, w}$'s, $uw \in SP_P(x_i y_i)$, where j_i is the number of distinct separating pairs in $SP(x_i y_i)$. There are $\prod_{i=1}^g \kappa(x_i, y_i) \prod_{\{x, y\} \in \mathcal{S}_H} |\text{Aut}(G_{x, y}; x, y)|$ ways of doing step 3 because, again, whenever $x_i y_i$ and uw are in the same component in $\cup_{\sigma \in P} SP_\sigma$, $\text{Aut}(G_{x_i, y_i}; x_i, y_i) \cong \text{Aut}(G_{u, w}; u, w)$. The theorem follows. $\square$

By using the formula for $N_{\geq}(P)$ above, we can now simplify the second formula in Theorem 4.7 as

$$D(G(T_v), k; H) = \frac{1}{|Aut_v(H)|} \sum_{\{\sigma_0\} \subseteq P \subseteq Aut_v(H)} (-1)^{|P|-1} \prod_{i=1}^t \kappa(a_i) \prod_{i=1}^g \kappa(x_i, y_i).$$

Hence, $D(G(T_v), k; H)$ (and $D(G(T_v), k; H, a)$, $D(G(T_v), k; H, x, y)$, and $D(G(T_v), k; H, xy)$) can be computed once the automorphisms in $Aut_v(H)$ and the values of $D(G(T_w), k; *)$ are known, where w is a child of v in T_G and $*$ is the structure associated with w .

FindDist(G, k). Let us now describe our algorithm *FindDist*(G, k) for computing $D(G, k)$. First, construct T_G and root it at $r(T_G)$. Then, for $i = \text{height}(T_G)$ to 0, do the following for each vertex v at depth i . When v is a c -vertex, compute $D(G(T_v), k; a)$, where a is the cut vertex associated with v using Theorem 4.2. When v is an s -vertex, compute $D(G(T_v), k; x, y)$ and $D(G(T_v), k; xy)$, where $\{x, y\}$ is the separating pair associated with v using Theorems 4.3 and 4.6. When v is a t -vertex and H is the triconnected component associated with v , compute $D(G(T_v), k; H, *)$, where $*$ is the structure associated with $p(v)$, the parent of v , if it exists. (That is, if $p(v)$ is a c -vertex, compute $D(G(T_v), k; H, a)$, where a is the cut vertex associated with $p(v)$; if $p(v)$ is an s -vertex, compute $D(G(T_v), k; H, x, y)$ and $D(G(T_v), k; H, xy)$, where $\{x, y\}$ is the separating pair associated with $p(v)$; if v has no parent, compute $D(G(T_v), k; H)$.) Do all computations according to Theorem 4.7, Corollary 4.8, and Theorem 4.9. Finally, if the root node $r(T_G)$ is a c -vertex or a t -vertex, return the value computed at depth 0; otherwise, if $r(T_G)$ is an s -vertex, return $D(G(T_v), k; xy)$.

It is not obvious that at every iteration the algorithm can compute $D(G(T_v), k; *)$ based on the values obtained for v 's children in the previous iterations. We shall now show that this, in fact, is the case.

- *When v is a c -vertex.* Let a be the cut vertex associated with v . From Theorem 4.2, $D(G(T_w), k; a)$ is needed. If w is an s -vertex and associated with some separating pair $\{a, b\}$, $D(G(T_w), k; a, b)$ was computed in the previous iterations. But from Lemma 2.7, $Aut(G(T_w); a, b) = Aut(G(T_w); a)$; i.e., a labeling of $G(T_w)$ destroys all automorphisms in $Aut(G(T_w); a, b)$ if and only if it destroys all automorphisms in $Aut(G(T_w); a)$. Hence, $D(G(T_w), k; a, b) = D(G(T_w), k; a)$. If w is a t -vertex, w is associated with some triconnected component H , and so $D(G(T_w), k; H, a)$ was computed in the previous iteration. From Lemma 2.7, $Aut(G(T_w); H, a) = Aut(G(T_w); a)$ and, consequently, $D(G(T_w), k; H, a) = D(G(T_w), k; a)$.
- *When v is an s -vertex.* Let $\{x, y\}$ be the separating pair associated with v . This time, according to Theorems 4.3 and 4.6, if w is a c -vertex associated with x (or y), $D(G(T_w), k; x)$ (or $D(G(T_w), k; y)$) is needed and was clearly computed in the previous iterations by the algorithm. On the other hand, if w is a t -vertex whose associated triconnected component is H , $D(G(T_w), k; x, y)$ and $D(G(T_w), k; xy)$ are needed. Now $D(G(T_w), k; H, x, y)$ and $D(G(T_w), k; H, xy)$ were computed in the previous iterations. But from Lemma 2.8, $Aut(G(T_w); H, x, y) = Aut(G(T_w); x, y)$ and $Aut(G(T_w); H, xy) = Aut(G(T_w); xy)$. It follows that $D(G(T_w), k; H, x, y) = D(G(T_w), k; x, y)$ and $D(G(T_w), k; H, xy) = D(G(T_w), k; xy)$.
- *When v is a t -vertex.* Let H be the triconnected component associated with v . According to Theorem 4.9, if w is a c -vertex associated with a , $D(G(T_w), k; a)$ is needed, and if w is an s -vertex associated with the separating pair $\{x, y\}$,

$D(G(T_w), k; x, y)$ and $D(G(T_w), k; xy)$ are needed. All of these values were computed in the previous iterations.

From Theorems 4.2, 4.3, 4.6, 4.7, and 4.9, we know that all of the $D(G(T_v), k; *)$ values computed by the algorithm are correct. Now the algorithm returned the value $D(G(T_v), k; A)$, where $v = r(T_G)$ and A is the structure associated with $r(T_G)$. But $G(T_{r(T_G)}) = G$, and, according to Lemma 2.6, $\text{Aut}(G; A) = \text{Aut}(G)$. It follows that the algorithm returned $D(G, k)$.

THEOREM 4.10. *When G is a connected graph, $\text{FindDist}(G, k)$ returns the value $D(G, k)$.*

Example 1. Consider the graph and its tree decomposition in Figures 2 and 3. By using the formulas given in this section, it is easy to verify the following: $D(G(T_{v_3}), k; e) = k^5$, $D(G(T_{v_1}), k; e, j) = k^3(k-1)/2$, and $D(G(T_{v_1}), k; ej) = k^2(k-1)^2/4$. According to Theorem 4.3,

$$\begin{aligned} D(G(T_r), k; e, j) &= k^2 [D(G(T_{v_3}), k; e)/k]^2 \binom{D(G(T_{v_1}), k; e, j)/k^2}{2} \\ &= k^2 (k^4)^2 \binom{k(k-1)/2}{2} \\ &= (k+1)k^{11}(k-1)(k-2)/8. \end{aligned}$$

Next, let us compute $B(G(T_r), k; e, j)$. We have

$$B(G(T_{v_1}), k; e, j) = D(G(T_{v_1}), k; e, j) - 2D(G(T_{v_1}), k; ej) = k^2(k-1)/2.$$

Notice that $D_1(G(T_{v_1}), k; ej) = 0$ because any labeling that assigns e and j the same label cannot destroy the automorphism that maps e to j , j to e , f to itself, and g to itself. According to Theorem 4.6,

$$\begin{aligned} B(G(T_r), k; e, j) &= k D(G(T_{v_3}), k; e)/k \sum_{l=0}^1 \binom{D_1(G(T_{v_1}), k; e, j)/k}{l} \binom{B(G(T_{v_1}), k; e, j)/k}{2-2l} \\ &= k k^4 \sum_{l=0}^1 \binom{0}{l} \binom{k(k-1)/2}{2-2l} \\ &= k^5 \left[\binom{0}{0} \binom{k(k-1)/2}{2} + \binom{0}{1} \binom{k(k-1)/2}{0} \right] \\ &= (k+1)k^6(k-1)(k-2)/8. \end{aligned}$$

Consequently, $D(G, k) = D(G(T_r), k; ej) = [D(G(T_r), k; e, j) - B(G(T_r), k; e, j)]/2 = (k+1)k^6(k-1)(k-2)(k^5-1)/16$. Since $D(G, 1) = D(G, 2) = 0$ and $D(G, 3) > 0$, $D(G) = 3$.

Example 2. This time, consider the graph in Figure 6, and let us determine $D(G(T_r), k; H)$. Since $\text{Aut}_r(H) \cong D_5$, we can make use of the computations we made in the example after Theorem 3.6. It is easy to verify that $D(G_{a_i, a_{i+1}}, k; a_i, a_{i+1}) = k^4$ and $D(G_{a_i, a_{i+1}}, k; a_i a_{i+1}) = (k^4 - k^2)/2$ for $i = 1, \dots, 5$. Let $\alpha = \prod_{i=1}^5 |\text{Aut}(G_{a_i, a_{i+1}}; a_i, a_{i+1})|$. From Theorem 4.9, we have $N_{\geq}(\emptyset)/\alpha = k^5 \times (k^2)^5 = k^{15}$, $N_{\geq}(\{\pi_\rho\})/\alpha = k \times k^2 = k^3$, $N_{\geq}(\{\pi_{\tau\rho^i}\})/\alpha = k^3 \times (k^2)^2 (k^4 - 2(k^4 - k^2)/2)/k = k^8$, and $N_{\geq}(\{\pi_{\tau\rho^i}, \pi_\rho\})/$

$\alpha = k \times (k^4 - 2(k^4 - k^2)/2)/k = k^2$. Thus,

$$\begin{aligned} D(G(T_r), k; H) &= \frac{1}{10} \left[N_{\geq}(\emptyset)/\alpha - N_{\geq}(\{\pi_\rho\})/\alpha - \sum_{i=0}^4 (N_{\geq}(\{\pi_{\tau\rho^i}\})/\alpha - N_{\geq}(\{\pi_{\tau\rho^i}, \pi_\rho\})/\alpha) \right] \\ &= \frac{1}{10} \left[k^{15} - k^3 - \sum_{i=0}^4 (k^8 - k^2) \right] \\ &= \frac{1}{10} [k^{15} - 5k^8 - k^3 + 5k^2]. \end{aligned}$$

Since $D(G, 1) = 0$ and $D(G, 2) > 0$, we conclude that $D(G) = 2$.

In order for $\text{FindDist}((G, k))$ to run efficiently for a family of graphs, we note that a few ingredients are necessary. It must have an efficient graph isomorphism testing algorithm to determine the isomorphism classes of $\mathcal{G}$ in Theorems 4.2, 4.3, and 4.6. There must also be an efficient algorithm that can determine the automorphisms of its triconnected components which are needed in Theorem 4.7. Finally, there must be a way to apply the PIE formula in Theorem 4.7 to its triconnected components in an efficient manner. Since the family of planar graphs satisfies these criteria, we can now proceed to prove the main result of the paper. We first show that $D(G(T_v), k; *)$, when v is a t -vertex, can be computed efficiently when the appropriate values are known.

LEMMA 4.11. *Let G be a connected planar graph on n vertices and k be a positive integer. Let v be a t -vertex in T_G , H be the triconnected component on n_H vertices associated with v , and $\mathcal{S}_H$ contain the separating pairs of G in H used in the construction of T_G . Suppose that all of the automorphisms in $\text{Aut}_v(H)$ and the values of $D(G(T_w), k; *)$, w a child of v in T_G , are known. Then $D(G(T_v), k; *)$ can be computed in $O(n_H^2 n^2 \log^2 k (n_H + |\mathcal{S}_H|))$ time.*

Proof. As in Theorems 4.7 and 4.9, we will prove the theorem for $D(G(T_v), k; H)$; others can be argued similarly. Let $\alpha = \prod_{a \in \mathcal{C}_H} |\text{Aut}(G_a; a)| \times \prod_{\{x, y\} \in \mathcal{S}_H} |\text{Aut}(G_{x, y}; x, y)|$. First, let us consider the time it takes to compute $N_{\geq}(P)/\alpha$. Constructing $\cup_{\sigma \in P} H_\sigma$ and finding its t connected components can be done in $O(|P| \times n_H)$. Similarly, constructing $\cup_{\sigma \in P} SP_\sigma$ and finding a collection $\{SP_P(x_i y_i), i = 1, \dots, g\}$ that forms a partition of $\cup_{\sigma \in P} SP_\sigma$ takes $O(|P| \times |\mathcal{S}_H|)$ time. Finally, since $N_{\geq}(P) \leq k^n$, every multiplication in $\prod_{i=1}^t \kappa(a_i) \times \prod_{i=1}^g \kappa(x_i y_i)$ takes at most $O(n^2 \log^2 k)$ time; that is, finding the said product takes $O((t + g)n^2 \log^2 k) = O((n_H + |\mathcal{S}_H|)n^2 \log^2 k)$ time. Therefore, computing $N_{\geq}(P)/\alpha$ takes $O((n_H + |\mathcal{S}_H|)(|P| + n^2 \log^2 k))$ time.

Since G is a connected planar graph, each of its blocks B are as well. It is easy to verify that, when the split operation is applied to B , the resulting split graphs remain planar. Hence, the triconnected component associated with v is either a bond, a cycle, or a triconnected planar graph, and $\text{Aut}_v(H)$ belongs to one of the groups mentioned in Lemma 3.8. From Corollary 4.8, we noted that we can apply the formulas in Theorems 3.5, 3.6, and 3.7 for $N_{\geq}(\{\sigma_0\})$. Consequently, we can use $\text{TriconnectCount}(H, k)$ to compute $D(G(T_v), k; H)$ by doing two modifications—we replace every occurrence of $N_{\geq}(P)$ with $N_{\geq}(P)/\alpha$ (keeping in mind that the k -labelings counted in $N_{\geq}(P)$ belong to $\mathcal{L}^*(G(T_v), k)$ and are computed by using Theorem 4.9) and return the value $L(H, k)/|\text{Aut}_v(H)|$ instead of $L(H, k)$. It is easy to check that the value returned is $D(G(T_v), k; H)$. By applying the same analysis in Theorem 3.9, the bottleneck of the algorithm is in computing the $O(n_H^2) N_{\geq}(P)/\alpha$ terms. By using the result from the previous paragraph and the fact that $|P| \leq \log n_H$, the run time of the algorithm is $O(n_H^2 (n_H + |\mathcal{S}_H|)(\log n_H + n^2 \log^2 k))$ time. $\square$

Finding $D(G(T_v), k; *)$ can take significantly more time than finding $D(H, k)$, because $N_{\geq}(P)$ in the former case has to be explicitly computed from the $D(G(T_w), k; *)$ values whereas, in the latter case, $N_{\geq}(P)$ is always some power of k which we precomputed ahead of time.

THEOREM 4.12. *Let G be an n -vertex connected planar graph and k be a positive integer. $\text{FindDist}(G, k)$ can be implemented in $O(n^5 \log^2 k)$ time. Consequently, computing $D(G)$ takes $O(n^5 \log^3 n)$ time.*

Proof. To implement $\text{FindDist}(G, k)$, we need to do some preprocessing steps.

1. *Isomorphism testing.* For each c - and s -vertex, determine the isomorphism classes of the graphs in $\mathcal{G}$ fixed at the appropriate vertices as described in Theorems 4.2, 4.3, and 4.6. Additionally, for each s -vertex whose associated separating pair is $\{x, y\}$, determine if $G(T_{w_x})$ fixed at x is isomorphic to $G(T_{w_y})$ fixed at y . For each t -vertex, group together its children based on their type—i.e., if they are c -vertices or s -vertices—and then for each group determine the isomorphism classes of $\{G(T_w) : w \text{ is a child of } v \text{ and a } c\text{-vertex (or an } s\text{-vertex)}\}$ fixed at the appropriate vertices. By using the linear-time planar graph isomorphism testing algorithm, the isomorphism testing tasks at each v can be done in $O(\deg(v)^2 n)$ time, where $\deg(v)$ is the degree of vertex v in T_G . The total time to do all of the isomorphism testing then takes $O(n^3)$ time since the size of T_G is $O(n)$.

2. *Finding automorphisms.* For each t -vertex v whose associated triconnected component is H , find all of the automorphisms in $\text{Aut}(H)$ by using the algorithm described in section 3.1. Apply the information obtained from the first preprocessing step to determine which of the automorphisms also belong to $\text{Aut}_v(H)$ (or $\text{Aut}_v(H; *)$, where $*$ depends on $p(v)$). That is, for each $\pi \in \text{Aut}(H)$, verify that π maps cut vertices and separating pairs to cut vertices and separating pairs, respectively; moreover, π also maps the subgraphs hanging from these vertices and pairs to isomorphic structures. Finding $\text{Aut}(H)$ takes $O(n_H^2)$ time, where n_H is the number of vertices in H . Determining if $\pi \in \text{Aut}(H)$ also belongs to $\text{Aut}_v(H)$ takes $O(n_H + |\mathcal{S}_H|)$ time, so finding $\text{Aut}_v(H)$ takes $O(n_H^2 + |\text{Aut}(H)|(n_H + |\mathcal{S}_H|)) = O(n_H^2 + n_H |\mathcal{S}_H|)$ time. Finding $\text{Aut}_v(H)$ for all t -vertices v then takes $O(n^2)$ time, since from Lemma 2.10 $\sum_H n_H = O(n)$ and $\sum_H |\mathcal{S}_H| = O(n)$.

Let us now consider $\text{FindDist}(G, k)$. Constructing T_G takes $O(n^2)$ time. The number of arithmetic operations for computing $D(G(T_v), k; *)$ when v is a c -vertex and an s -vertex is $O(\deg(v))$ and $O(\deg^2(v))$, respectively. Since the values involved in each operation is at most k^n , the total amount of work at v takes $O(\deg^2(v)n^2 \log^2 k)$ time. By summing this up for all c - and s -vertices in T_G , the total work takes $O(n^4 \log^2 k)$ time because the size of T_G is $O(n)$. When v is a t -vertex, according to Lemma 4.11, computing $D(G(T_v), k; *)$ takes $O(n_H^2 n^2 \log^2 k (n_H + |\mathcal{S}_H|))$ time. Thus, for all t -vertices, the total work is $O(n^5 \log^2 k)$ time. From our analysis, the bottleneck of $\text{FindDist}(G, k)$ is in processing the t -vertices. The run time in the theorem follows. $\square$

COROLLARY 4.13. *Let G be an n -vertex planar graph. Then $D(G)$ can be computed in $O(n^5 \log^3 n)$ time.*

Proof. By using the linear-time planar graph isomorphism testing algorithm, group together isomorphic connected components of G . So suppose that $G = m_1 G_1 \cup m_2 G_2 \cup \dots \cup m_g G_g$, where each G_i has n_i vertices. For each G_i , find k_i so that $k_i = \min\{k : D(G_i, k) \geq m_i\}$. This can be done by implementing $\text{FindDist}(G_i, k)$ $O(\log n)$ times. Finally, $D(G) = \max_i \{k_i\}$, so $D(G)$ can be found in $O(\sum_{i=1}^g n_i^5 \log^2 n_i \log n) = O(n^5 \log^3 n)$ time. $\square$

5. Final comments. In this paper, we considered $D(G, k)$, the number of inequivalent distinguishing k -labelings of graph G . We have applied the principle of inclusion-exclusion and developed recursive formulas to compute its value for a fixed k . When a graph G is planar, we showed that these techniques led to an algorithm for computing $D(G)$ that runs in time polynomial in the size of G . There are other interesting aspects about $D(G, k)$ as well, as noted in the next theorem.

THEOREM 5.1. *Let G be a graph on n vertices. Then $D(G, k)$ is a polynomial in k whose degree is n and whose constant term is 0. If G has no nontrivial automorphisms, then $D(G, k) = k^n$; otherwise, the sum of the coefficients of $D(G, k)$ is 0.*

Proof. In Theorem 3.2, $N_{\geq}(P)$ equals k^n when $P = \{\pi_0\}$ and k^t , $t < n$, otherwise, so $D(G, k)$ must be a polynomial in k whose degree is n . Furthermore, $D(G, 0) = 0$, so the constant term in $D(G, k)$ must be 0. When G has no nontrivial automorphism, every k -labeling of G is distinguishing and no two are equivalent; hence, $D(G, k) = k^n$. When G has some nontrivial automorphisms, $D(G, 1) = 0$, so it must be the case that the sum of the coefficients of $D(G, k)$ is 0. $\square$

We now call $D(G, k)$ the *distinguishing polynomial* of G . An interesting research direction would be to study this polynomial along the lines of the more famous chromatic polynomial of G .

Next, consider Lemma 3.4 and its implications. According to the lemma, if S is the largest subset of $\text{Aut}(G)$ that preserves a k -labeling ϕ of G , then S must be a subgroup of $\text{Aut}(G)$. This suggests that, instead of considering all of the subsets of $\text{Aut}(G)$ as we do in PIE, we should just consider the subgroup lattice $(\mathcal{S}, \leq)$ of $\text{Aut}(G)$, where $\mathcal{S}$ is the set that contains all of the subgroups of $\text{Aut}(G)$. For each $S \in \mathcal{S}$, define $N_{\geq}(S)$ and $N_{=}(S)$ as we did in the PIE formulation. Since $N_{\geq}(S) = \sum_{S' \geq S} N_{=}(S')$ for every $S \in \mathcal{S}$, according to the principle of Möbius inversion, the following must be true.

THEOREM 5.2. *Let $(\mathcal{S}, \leq)$ be the subgroup lattice of $\text{Aut}(G)$ and $\mu(*, *)$ be the Möbius function of $(\mathcal{S}, \leq)$. Let S_0 be the subgroup of $\text{Aut}(G)$ consisting of the identity automorphism of G . Then*

$$L(G, k) = N_{=}(S_0) = \sum_{S \in \mathcal{S}: S \geq S_0} \mu(S_0, S) N_{\geq}(S).$$

By using the formula above, the number of $N_{\geq}(S)$ terms we have to compute to determine $L(G, k)$ is $|\mathcal{S}|$ as opposed to $\Omega(2^{|\text{Aut}(G)|})$ in the PIE formulation. This, of course, comes at a price—we must now find all of the subgroups of $\text{Aut}(G)$, determine the structure of $(\mathcal{S}, \leq)$, and then compute the $\mu(S_0, S)$ values. We leave it up to the reader to apply Theorem 5.2 when $\text{Aut}(G) \cong Z_t, D_t, Z_t \times Z_2$, or $D_t \times Z_2$.

Another direction in which we use Lemma 3.4 is a generalization of Theorem 3.5.

THEOREM 5.3. *Let S^* be a subset of $\text{Aut}(G)$ that does not contain the identity automorphism. Suppose that every nontrivial subgroup of G contains at least one element of S^* . Then*

$$L(G, k) = \sum_{S \subseteq S^*} (-1)^{|S|} N_{\geq}(S).$$

In the above theorem, the number of $N_{\geq}(S)$ terms to compute is $2^{|S^*|}$ so the smaller $|S^*|$ is, the better. Finding the smallest S^* , however, is nontrivial; it is the *hitting set problem* and is known to be NP-hard in general [13]. Again, we leave it up

to the reader to formulate a generalization of Theorem 3.6 similar to Theorem 5.3. Finally, we pose the following open problem.

Open problem: Let $\mathcal{G}$ be a family of graphs for which there is an efficient algorithm for testing graph isomorphism. Can the distinguishing number of graphs in $\mathcal{G}$ be computed efficiently? More specifically, is there a polynomial-time algorithm for computing $D(G)$ if G is a bounded degree graph or a bounded genus graph?

Acknowledgments. The second author thanks Jeb Willenbring for discussions she had with him on section 3 of the paper and Tom Tucker for providing her with copies of his papers [12, 20]. The authors are also grateful to the anonymous referees for their comments, which improved the presentation of the paper.

LARGE NEARLY REGULAR INDUCED SUBGRAPHS*

NOGA ALON[†], MICHAEL KRIVELEVICH[‡], AND BENNY SUDAKOV[§]

Abstract. For a real $c \geq 1$ and an integer n , let $f(n, c)$ denote the maximum integer f such that every graph on n vertices contains an induced subgraph on at least f vertices in which the maximum degree is at most c times the minimum degree. Thus, in particular, every graph on n vertices contains a regular induced subgraph on at least $f(n, 1)$ vertices. The problem of estimating $f(n, 1)$ was posed long ago by Erdős, Fajtlowicz, and Staton. In this paper we obtain the following upper and lower bounds for the asymptotic behavior of $f(n, c)$: (i) For fixed $c > 2.1$, $n^{1-O(1/c)} \leq f(n, c) \leq O(cn/\log n)$. (ii) For fixed $c = 1 + \varepsilon$ with $\varepsilon > 0$ sufficiently small, $f(n, c) \geq n^{\Omega(\varepsilon^2/\ln(1/\varepsilon))}$. (iii) $\Omega(\ln n) \leq f(n, 1) \leq O(n^{1/2} \ln^{3/4} n)$. An analogous problem for not necessarily induced subgraphs is briefly considered as well.

Key words. induced subgraphs, regular subgraphs, Ramsey-type problem

AMS subject classification. 05C35

1. Introduction. All graphs considered here are finite and simple. For a graph $G = (V, E)$, let $\Delta(G)$, $\delta(G)$, and $d(G) = \frac{2|E|}{|V|}$ denote its maximum degree, minimum degree, and average degree, respectively. The *density* of G is $p = |E|/\binom{|V|}{2}$; clearly, this is a number between 0 and 1. For $U \subseteq V$, let $G[U]$ denote the subgraph of G induced on U .

DEFINITION 1. A graph G is c -nearly regular if $\Delta(G) \leq c \cdot \delta(G)$.

For a graph $G = (V, E)$ and a constant $c \geq 1$, let

$$f(G, c) = \max\{|U| : G[U] \text{ is a } c\text{-nearly regular graph}\}.$$

Define

$$f(n, c) = \min\{f(G, c) : |V(G)| = n\}.$$

Thus, every graph G on n vertices contains a c -nearly regular induced subgraph on at least $f(n, c)$ vertices. In particular, for $c = 1$ every such G contains a strictly regular induced subgraph on at least $f(n, 1)$ vertices.

The problem of estimating $f(n, 1)$ was posed by Erdős, Fajtlowicz, and Staton (cf. [3] or [2, page 85]). By the known estimates for graph Ramsey numbers (cf.,

e.g., [6]), every graph on n vertices contains either a clique or an independent set of order $\Omega(\ln n)$. This implies that $f(n, 1) \geq \Omega(\ln n)$. Erdős, Fajtlowicz, and Staton conjectured that the ratio $f(n, 1)/\ln n$ tends to infinity as n tends to infinity. We are unable to prove or disprove this conjecture and can only obtain several bounds, which are listed in the following results. The first deals with the case of large c .

PROPOSITION 1.1. *There exists an absolute constant b so that for all $K \geq 2.1$, $f(n, K) \geq n^{1-b/K}$.*

The problem of obtaining a nontrivial lower bound for values of c close to 1 is more interesting. Here we first deal with the case of graphs with positive density and show that any such graph must contain a nearly regular subgraph on a linear number of vertices.

THEOREM 1.2. *Let $\varepsilon > 0$ be a small real, and let p satisfy $0 < p < 1$. Then, for every sufficiently large n , any graph $G = (V, E)$ on n vertices with density at least p contains an induced $(1 + \varepsilon)$ -nearly regular subgraph on at least*

$$0.5 \left(\frac{\varepsilon}{6} \right)^{\frac{144}{\varepsilon^2} \ln(\frac{1}{p})} \cdot n$$

vertices.

For general (possibly sparse) graphs we have the following.

THEOREM 1.3. *Let $\varepsilon > 0$ be a sufficiently small constant. Then*

$$f(n, 1 + \varepsilon) \geq n^{\frac{\varepsilon^2}{250 \ln(1/\varepsilon)}}$$

for all sufficiently large n .

Our upper bounds for $f(n, c)$ are rather far from the lower bounds. For the strictly regular case we prove the following.

THEOREM 1.4. $f(n, 1) \leq O(n^{1/2} \log^{3/4} n)$.

This is a slight improvement of an earlier estimate of Bollobás (cf. [2]), who showed that for every $\epsilon > 0$, $f(n, 1) \leq c(\epsilon)n^{1/2+\epsilon}$. For the nearly regular case we have the following.

PROPOSITION 1.5. *For every constant $K \geq 2$, $f(n, K) \leq 7K \frac{n}{\log n}$.*

The lower bounds are proved in the next section, and the upper bounds are presented in section 3. We conclude in section 4 with a few open problems and a brief discussion of an analogous problem for not necessarily induced subgraphs. Throughout this paper we assume, whenever needed, that the number of vertices n of the graphs discussed is sufficiently large. To simplify the presentation, we make no attempt to optimize the absolute constants, and we omit all floor and ceiling signs whenever these are not crucial. We also use the following standard asymptotic notation: For two functions $f(n)$, $g(n)$ of a natural valued parameter n , we write $f(n) = o(g(n))$ whenever $\lim_{n \rightarrow \infty} f(n)/g(n) = 0$; $f(n) = O(g(n))$ if there exists a constant $C > 0$ such that $f(n) \leq Cg(n)$ for all n ; and $f(n) = \Omega(g(n))$ if $g(n) = O(f(n))$.

2. Lower bounds. For a graph $G = (V, E)$ and a subset $U \subseteq V$, the number of edges of G spanned by U in G is denoted by $e_G(U)$; the number of edges between disjoint subsets U, W of vertices of G is denoted by $e_G(U, W)$.

2.1. Large c . In this subsection we prove Proposition 1.1, which provides a lower bound for $f(n, c)$ when c is a relatively large constant.

We need the following rather standard argument, allowing one to pass from a graph with a large average degree to one with a large minimum degree.

PROPOSITION 2.1. *Let $K > 1, \alpha < 1/2$ be constants. Then every graph $G = (V, E)$ on $|V| = n$ vertices with $\Delta(G) \leq Kd(G)$ contains an induced (K/α) -nearly regular subgraph G^* with at least $\frac{1-2\alpha}{K-2\alpha}n$ vertices and at least $\frac{K-2K\alpha}{2K-4\alpha}nd$ edges.*

Proof. Denote the average degree $d(G)$ of G by d . We can obviously assume that $d > 0$. Start with G and delete repeatedly vertices of degree less than αd until there are none left. Denote the resulting graph by G^* . Then G^* is an induced subgraph of G , satisfying $\Delta(G^*) \leq \Delta(G)$, $\delta(G^*) \geq \alpha d$, implying

$$\Delta(G^*) \leq \Delta(G) \leq Kd \leq \frac{K}{\alpha} \delta(G^*),$$

and thus G^* is a (K/α) -nearly regular graph. We now estimate the number of vertices of G^* . Denote the latter by t . While creating G^* from G , we deleted less than $(n-t)\alpha d$ edges, and thus

$$\Delta(G^*) \geq d(G^*) > \frac{2(|E(G)| - (n-t)\alpha d)}{t} = \frac{nd - 2(n-t)\alpha d}{t}.$$

But $\Delta(G^*) \leq \Delta(G) \leq Kd$, implying

$$\frac{nd - 2(n-t)\alpha d}{t} \leq Kd.$$

Solving the above inequality for t , we get $t \geq \frac{1-2\alpha}{K-2\alpha}n$, supplying the required lower bound for the number of vertices of G^* . To bound the number of its edges, note that the number of vertices deleted is $n-t$, and hence the number of edges deleted is at most $(n-t)\alpha d$, leaving at least

$$\frac{1}{2}nd - (n-t)\alpha d = \left(\frac{1}{2} - \alpha\right)nd + t\alpha d \geq \left(\frac{1}{2} - \alpha\right)nd + \frac{1-2\alpha}{K-2\alpha}n\alpha d = \frac{K-2K\alpha}{2K-4\alpha}nd,$$

as needed. $\square$

Remark 1. It is instructive to observe that the above argument breaks down completely for $\alpha \geq 1/2$. Therefore, when estimating $f(n, c)$ from below for small c , in particular for $c < 2$, we will adapt a different strategy.

We proceed with the following result, whose proof resembles that of one of the results in [4].

PROPOSITION 2.2. *Let $K > 1$ be a constant. Every graph $G = (V, E)$ on $|V| = |V(G)| = n$ vertices contains an induced subgraph G^* on at least $n^{1+\log_2(1-\frac{1}{K})}$ vertices, for which $\Delta(G^*) \leq Kd(G^*)$.*

For large K the above estimate behaves like $n^{1-\Theta(\frac{1}{K})}$. Therefore, the assertions of Propositions 2.1 and 2.2 imply that of Proposition 1.1.

Proof of Proposition 2.2. Set $G_0 = G$, $k^* = \log_2 n$. For $i = 0, \dots, k^*$ repeat the following loop. Set

$$n_i = |V(G_i)|, \quad \Delta_i = \Delta(G_i), \quad d_i = d(G_i).$$

If $\Delta_i \leq Kd_i$, abort the loop. Otherwise, delete repeatedly vertices of degree at least $Kd_i/2$ from G_i until there are none left. Let G_{i+1} be the resulting graph and increment i .

Denote by G^* the resulting graph of the above described process. Observe that at iteration i we delete at most $|E(G_i)|/(Kd_i/2) = (n_i d_i/2)/(Kd_i/2) = n_i/K$ vertices,

and thus $n_{i+1} \geq (1 - 1/K)n_i$. It follows that

$$|V(G^*)| \geq \left(1 - \frac{1}{K}\right)^{k^*} n = n^{1 + \log_2(1 - \frac{1}{K})}.$$

If G^* was created when the above loop was aborted due to $\Delta(G_i) \leq Kd(G_i)$, then obviously the obtained graph satisfies the assertion of the theorem. Otherwise, G^* was obtained after k^* iterations. At each such iteration i , we have $\Delta_{i+1} \leq Kd_i/2$ and $d_i \leq \Delta_i/K$, implying $\Delta_{i+1} \leq \Delta_i/2$. Therefore, in this case

$$\Delta(G^*) \leq \Delta_0 \cdot \left(\frac{1}{2}\right)^{k^*} < n \cdot \left(\frac{1}{2}\right)^{\log_2 n} = 1,$$

implying that G^* has no edges, and thus $\Delta(G^*) = d(G^*) = 0$, and G^* can again serve as the required graph. $\square$

2.2. Small c . Next we treat the more challenging case where the constant c in $f(n, c)$ is very close to 1. Throughout this subsection ε denotes a small positive real.

We start with several lemmas.

LEMMA 2.3. *Let $G = (V, E)$ be a graph on n vertices with density p , and let $\varepsilon > 0$. Then G contains an induced subgraph G' of density $p' \geq p$ on a set of*

$$n' \geq \varepsilon^{\frac{2}{\varepsilon} \ln(\frac{1}{p})} n$$

vertices so that every set of $t \geq \varepsilon n'$ vertices of G' spans at most $\binom{t}{2} p'(1 + \varepsilon)$ edges.

Proof. Set $G_0 = G$. For $i = 0, 1, \dots$ repeat the following loop. Set

$$n_i = |V(G_i)|, \quad m_i = |E(G_i)|, \quad p_i = \frac{m_i}{\binom{n_i}{2}}.$$

If G_i contains a subset $U \subseteq V(G_i)$ of at least εn_i vertices such that $e_{G_i}(U) \geq \binom{|U|}{2} p_i(1 + \varepsilon)$, then set $G_{i+1} := G_i[U]$, $i := i + 1$.

Observe that after k iterations of the above loop, the density p_k of the current graph G_k satisfies $p_k \geq (1 + \varepsilon)^k p_0$. Thus, if the loop is repeated at least $\frac{2}{\varepsilon} \ln(\frac{1}{p})$ times, we have

$$p_k \geq (1 + \varepsilon)^{\frac{2}{\varepsilon} \ln(\frac{1}{p})} \cdot p > 1,$$

which is a contradiction. It follows that the above process concludes after less than $\frac{2}{\varepsilon} \ln(\frac{1}{p})$ iterations. The resulting graph G_k has n_k vertices and m_k edges. Observe that at each iteration the number of vertices of the new graph is at least an ε -proportion of the number of vertices of the previous graph. Therefore,

$$n_k \geq \varepsilon^k |V(G)| \geq \varepsilon^{\frac{2}{\varepsilon} \ln(\frac{1}{p})} n.$$

We can thus take $G' = G_k$, $n' = n_k$ to complete the proof. $\square$

LEMMA 2.4. *Let $G = (V, E)$ be a graph on $|V| = n$ vertices with $m = |E|$ edges and density $p = m/\binom{n}{2} \geq n^{-a}$ for some constant $0 < a < 1$. Suppose that*

$$(1) \quad \text{every } t \geq \varepsilon n \text{ vertex in } G \text{ spans at most } \binom{t}{2} p(1 + \varepsilon) \text{ edges.}$$

Then for every subset $U \subseteq V$ of cardinality $|U| = \varepsilon n$ in G , there are at most

$$\varepsilon n^2 p(1 + 2\sqrt{\varepsilon})$$

edges between U and its complement in G .

Proof. Assume that $U \subset V$ contradicts the above statement. Denote

$$e_1 = e_G(U), \quad e_2 = e_G(U, V - U), \quad e_3 = e_G(V - U).$$

Then $e_1 + e_2 + e_3 = m = \binom{n}{2}p$.

Choose uniformly at random a subset $X \subset V - U$ of cardinality $|X| = x = \sqrt{\varepsilon}|V - U| = \sqrt{\varepsilon}(1 - \varepsilon)n$. Then the expected number of edges of G spanned by $U \cup X$ is

$$\begin{aligned} E[e_G(U \cup X)] &= e_1 + \frac{x}{|V - U|}e_2 + \frac{x(x-1)}{|V - U|(|V - U| - 1)}e_3 \\ &> e_1 + \frac{x}{n - \varepsilon n}e_2 + \frac{x^2}{(n - \varepsilon n)^2} \left(1 - \frac{1}{x}\right) e_3 \\ &= e_1 + \sqrt{\varepsilon}e_2 + \varepsilon e_3 - O(n) = e_1 + \sqrt{\varepsilon}e_2 + \varepsilon(m - e_1 - e_2) - O(n) \\ &\geq (\sqrt{\varepsilon} - \varepsilon)e_2 + \varepsilon m - O(n) \geq (\sqrt{\varepsilon} - \varepsilon)\varepsilon n^2 p(1 + 2\sqrt{\varepsilon}) + \varepsilon m - O(n) \\ &= (\sqrt{\varepsilon} - \varepsilon)\varepsilon(1 + 2\sqrt{\varepsilon})n^2 p + \frac{\varepsilon n^2 p}{2} - O(n) =: A. \end{aligned}$$

On the other hand, by the assumption on G , every such set $U \cup X$ satisfies

$$\begin{aligned} e_G(U \cup X) &\leq \left(\varepsilon n + \sqrt{\varepsilon}(1 - \varepsilon)n\right)p(1 + \varepsilon) \\ &\leq \frac{\varepsilon n^2 p}{2}(1 + \sqrt{\varepsilon} - \varepsilon)^2(1 + \varepsilon) = \frac{\varepsilon n^2 p}{2}(1 + 2\sqrt{\varepsilon} - \varepsilon - 2\varepsilon^{3/2} + \varepsilon^2)(1 + \varepsilon) \\ &= \frac{\varepsilon n^2 p}{2}(1 + 2\sqrt{\varepsilon} + O(\varepsilon^{5/2})) =: B. \end{aligned}$$

Let us compare the asymptotic (in small ε) behavior of the two quantities A and B defined above. We have

$$\begin{aligned} A &= \frac{\varepsilon n^2 p}{2}(1 + (2\sqrt{\varepsilon} - 2\varepsilon)(1 + 2\sqrt{\varepsilon})) - O(n) \\ &= \frac{\varepsilon n^2 p}{2}(1 + 2\sqrt{\varepsilon} + 2\varepsilon - 4\varepsilon^{3/2}) - O(n). \end{aligned}$$

Since $n = o(n^2 p)$, we have that $A > B$ for ε small enough, which is a contradiction. $\square$

LEMMA 2.5. *Let $G = (V, E)$ be a graph on $|V| = n$ vertices with $m = |E|$ edges and density $p = m/\binom{n}{2} \geq n^{-a}$ for some constant $0 < a < 1$. Suppose that (1) holds. Then, for all sufficiently large n , G contains an induced subgraph G^* on at least $(1 - \varepsilon - 2\sqrt{\varepsilon})n > n/2$ vertices with maximum degree $\Delta(G^*) \leq (1 + 3\sqrt{\varepsilon})pn$ and minimum degree $\delta(G^*) \geq (1 - 2\sqrt{\varepsilon})np$. In particular, G^* is c -nearly regular for $c = (1 + 6\sqrt{\varepsilon})$.*

Proof. Let U be a set of εn vertices of highest degrees in G (ties are broken arbitrarily). Set $H = G[V - U]$. We claim that all vertex degrees in H are at most

$np(1 + 3\sqrt{\varepsilon})$. If this is not so, then the degrees of all vertices of U in G are at least $np(1 + 3\sqrt{\varepsilon})$, implying (through condition (1))

$$\begin{aligned} e_G(U, V - U) &\geq \varepsilon n^2 p(1 + 3\sqrt{\varepsilon}) - 2e_G(U) \geq \varepsilon n^2 p(1 + 3\sqrt{\varepsilon}) - \varepsilon^2 n^2 p(1 + \varepsilon) \\ &> \varepsilon n^2 p(1 + 2\sqrt{\varepsilon}) \end{aligned}$$

for small enough ε , thus contradicting Lemma 2.4. Therefore, H is an induced subgraph of G on $|V(H)| = (1 - \varepsilon)n$ vertices, of maximum degree $\Delta(H) \leq np(1 + 3\sqrt{\varepsilon})$, still satisfying condition (1), and having

$$\begin{aligned} |E(H)| &\geq \binom{n}{2} p - \frac{\varepsilon^2 n^2}{2} p(1 + \varepsilon) - \varepsilon n^2 p(1 + 2\sqrt{\varepsilon}) \\ (2) \quad &\geq \binom{n}{2} p - 2\varepsilon n^2 p \end{aligned}$$

edges.

We now repeatedly delete from H vertices of degree less than $np(1 - 2\sqrt{\varepsilon})$ until there are no such vertices, or until we have deleted $2\sqrt{\varepsilon}n$ of them. Assume the latter case and denote the set of $2\sqrt{\varepsilon}n$ deleted vertices by W . Then the set $V(H) - W$ has $|V(H) - W| = (1 - \varepsilon - 2\sqrt{\varepsilon})n$ vertices and by (2) spans at least

$$\begin{aligned} e_H(V(H) - W) &\geq |E(H)| - 2\sqrt{\varepsilon}n \cdot np(1 - 2\sqrt{\varepsilon}) \\ &\geq \binom{n}{2} p - 2\varepsilon n^2 p - 2\sqrt{\varepsilon}n^2 p(1 - 2\sqrt{\varepsilon}) \\ &= \binom{n}{2} p - 2\sqrt{\varepsilon}n^2 p + 2\varepsilon n^2 p = \frac{n^2 p}{2} (1 - 4\sqrt{\varepsilon} + 4\varepsilon) - O(np) \end{aligned}$$

edges. On the other hand, by condition (1), the set $V(H) - W$ satisfies

$$\begin{aligned} e_H(V(H) - W) &\leq \binom{(1 - 2\sqrt{\varepsilon} - \varepsilon)n}{2} p(1 + \varepsilon) \leq (1 - 2\sqrt{\varepsilon} - \varepsilon)^2 (1 + \varepsilon) \frac{n^2 p}{2} \\ &= \frac{n^2 p}{2} (1 - 4\sqrt{\varepsilon} + 3\varepsilon + O(\varepsilon^{3/2})). \end{aligned}$$

Comparing the above two estimates for $e_H(V(H) - W)$, we get a contradiction for small enough ε .

It follows that the above deletion process stops before $2\sqrt{\varepsilon}n$ vertices have been deleted. Denote the resulting graph by G^* . Then G^* has $|V(G^*)| \geq n - \varepsilon n - 2\sqrt{\varepsilon}n > \frac{n}{2}$ vertices and has maximum degree $\Delta(G^*) \leq np(1 + 3\sqrt{\varepsilon})$ and minimum degree $\delta(G^*) \geq np(1 - 2\sqrt{\varepsilon})$. Hence

$$\Delta(G^*) \leq \frac{1 + 3\sqrt{\varepsilon}}{1 - 2\sqrt{\varepsilon}} \delta(G^*) < (1 + 6\sqrt{\varepsilon}) \delta(G^*),$$

completing the proof of the lemma. $\square$

We are now ready to prove Theorems 1.2 and 1.3.

Proof of Theorem 1.2. By Lemma 2.3 (with $\frac{\varepsilon^2}{36}$ playing the role of ε), G contains an induced subgraph G' of density $p' \geq p$ on

$$n' \geq \left(\frac{\varepsilon^2}{36}\right)^{\frac{72}{\varepsilon^2} \ln(\frac{1}{p})} \cdot n = \left(\frac{\varepsilon}{6}\right)^{\frac{144}{\varepsilon^2} \ln(\frac{1}{p})} \cdot n$$

vertices, such that every set of $t \geq \frac{\varepsilon^2}{36} n'$ vertices of G' spans at most $\binom{t}{2} p' (1 + \frac{\varepsilon^2}{36})$ edges. Since $p' \geq p > n^{-1/2}$ (as $p > 0$ is a constant and n is large), Lemma 2.5 implies that G' contains an induced subgraph G^* on at least $n'/2$ vertices which is c -nearly-regular for $c = 1 + 6\sqrt{\frac{\varepsilon^2}{36}} = 1 + \varepsilon$, as needed. $\square$

Proof of Theorem 1.3. Set

$$\varepsilon_0 = \frac{\varepsilon^2}{36}, \quad a = \frac{\varepsilon_0}{3 \ln(1/\varepsilon_0)}.$$

Let $G = (V, E)$ be a graph on n vertices. Denote by $p = |E|/\binom{n}{2}$ the density of G . The average degree of G is at most np and by Turán's theorem G contains an independent set U of size $n/(np + 1)$. Therefore we can assume that $p \geq n^{-a}$, as otherwise,

$$\begin{aligned} \frac{n}{np + 1} &\geq \frac{n}{n^{1-a} + 1} \geq (1 - o(1))n^a = (1 - o(1))n^{\frac{\varepsilon_0}{3 \ln(1/\varepsilon_0)}} \\ &= (1 - o(1))n^{\frac{\varepsilon^2}{108 \ln(36/\varepsilon^2)}} > n^{\frac{\varepsilon^2}{250 \ln(1/\varepsilon)}}, \end{aligned}$$

where here we used the assumptions that ε is sufficiently small and n is sufficiently large. This gives an induced 0-regular subgraph of G , and we can thus indeed assume that $p \geq n^{-a}$.

By Lemma 2.3, G contains an induced subgraph G' of density $p' \geq p$ on

$$n' \geq \varepsilon_0^{\frac{2}{\varepsilon_0} \ln(n^a)} \cdot n = \varepsilon_0^{\frac{2}{3 \ln(1/\varepsilon_0)} \ln n} \cdot n = n^{\frac{1}{3}}$$

vertices, in which the density of the induced subgraph on any set of at least $\varepsilon_0 n'$ vertices does not exceed $p'(1 + \varepsilon_0)$. By Lemma 2.5, G' (and hence G) contains an induced subgraph on at least $0.5n' \geq 0.5n^{1/3}$ vertices, which is $(1 + 6\sqrt{\varepsilon_0}) = (1 + \varepsilon)$ -nearly regular, completing the proof. $\square$

Remark 2. Note that we have actually proved the following result, which is stronger than the assertion of Theorem 1.3: Every graph on n vertices contains either an independent set of size at least $n^{\frac{\varepsilon^2}{250 \ln(1/\varepsilon)}}$, or a $(1 + \varepsilon)$ -nearly regular induced subgraph on at least $0.5n^{1/3}$ vertices.

3. Upper bounds.

3.1. The strictly regular case.

Proof of Theorem 1.4. Fix an integer k satisfying

$$k \geq Cn^{1/2} \ln^{3/4} n,$$

where $C > 0$ is a sufficiently large constant to be set later.

We will work with the following model of random graphs on n vertices which we denote by $G(n, \bar{p})$. Let $\bar{p} = (p_1, \dots, p_n)$, where

$$p_i = \frac{1}{4} + \frac{i}{2n}, \quad i = 1, \dots, n.$$

Then $G(n, \bar{p})$ is the probability space of graphs with vertex set $[n] = \{1, \dots, n\}$, where for each pair $1 \leq i \neq j \leq n$, (i, j) is an edge of $G(n, \bar{p})$ with probability $p_i p_j$, independently of all other pairs. Notice that the probability of each individual pair (i, j) to be an edge of $G(n, \bar{p})$ is strictly between $1/16$ and $9/16$.

PROPOSITION 3.1. *Let $X_1, \dots, X_t$ be independent Bernoulli random variables, where $\Pr[X_i = 1] = \rho_i$, $i = 1, \dots, t$. Let $X = X_1 + \dots + X_t$. Assume that $1/16 \leq \rho_i \leq 9/16$ for $i = 1, \dots, t$. Then for every integer $0 \leq s \leq t$, $\Pr[X = s] \leq c_0/\sqrt{t}$ for some absolute constant $c_0 > 0$.*

Proof. For every $1 \leq i \leq t$, we represent X_i as a product $X_i = Y_i \cdot Z_i$, where $\{Y_i, Z_i\}$ is a collection of mutually independent Bernoulli random variables defined by $\Pr[Y_i = 1] = \frac{9}{16}$, $\Pr[Z_i = 1] = \frac{16}{9}\rho_i$, $i = 1, \dots, t$.

Set $I_0 = \{1 \leq i \leq t : Z_i = 1\}$. Since $\rho_i \geq 1/16$ for all $1 \leq i \leq t$, we have that $\Pr[Z_i = 1] \geq \frac{1}{9}$ and $E[|I_0|] \geq \frac{t}{9}$. By standard large deviation arguments, $|I_0| \geq t/10$ with probability $1 - o(\frac{1}{\sqrt{t}})$. Thus

$$\begin{aligned} \Pr[X = s] &= \sum_{I \subseteq [t]} \Pr[I_0 = I] \cdot \Pr\left[\sum_{i \in I} Y_i = s\right] = \sum_{I \subseteq [t]} \Pr[I_0 = I] \Pr[B(|I|, 9/16) = s] \\ &\leq \Pr[|I_0| < t/10] + \sum_{|I| \geq t/10} \Pr[I_0 = I] \Pr[B(|I|, 9/16) = s]. \end{aligned}$$

Here $B(n, p)$ denotes the binomial random variable with parameters n and p . From known estimates on binomial random variables, we obtain that $\Pr[B(r, \frac{9}{16}) = s] \leq \frac{c}{\sqrt{r}} \leq \frac{4c}{\sqrt{t}}$ for every $r \geq \frac{t}{10}$, where $c > 0$ is an absolute constant. Plugging this estimate into the inequality above, we get the claimed result. $\square$

LEMMA 3.2. *Let $U \subseteq [n]$ be a fixed set of $|U| = k$ vertices. Then the probability that in $G(n, \bar{p})$, with $\bar{p}$ as defined above, the graph $G[U]$ is a regular graph is at most $n \left(\frac{c_1}{k}\right)^{k/2}$ for some absolute constant $c_1 > 0$.*

Proof. Fix the degree of regularity d of the regular subgraph $G[U]$ (this can be done in n ways). Let $U = \{u_1, u_2, \dots, u_k\}$. We bound the probability that the induced subgraph $G[U]$ is d -regular as follows.

Expose the edges of $G[U]$ by first exposing the edges from u_1 to $U - \{u_1\}$, then from u_2 to $U - \{u_1, u_2\}$, etc. If vertex u_i gets t_i neighbors in $\{u_1, \dots, u_{i-1}\}$, then u_i should have exactly $d - t_i$ neighbors in $\{u_{i+1}, \dots, u_k\}$. Recall that all edge probabilities in $G(n, \bar{p})$ are between $1/16$ and $9/16$. Thus Proposition 3.1 applies, and the probability of the latter event is at most $c_0/\sqrt{k-i}$. Multiplying these probabilities for $i = 1, \dots, k$, we derive that the probability that U is a d -regular graph is at most

$$\prod_{i=1}^{k-1} \frac{c_0}{\sqrt{k-i}} = \frac{(c_0)^{k-1}}{\sqrt{(k-1)!}} \leq \left(\frac{c_1}{k}\right)^{k/2},$$

where $c_1 > 0$ is an absolute constant and the last inequality follows by applying the Stirling formula. $\square$

We can now complete the proof of Theorem 1.4. We bound the probability that in $G(n, \bar{p})$ there exists a set U of size $|U| = k$ such that $U = (u_1 < \dots < u_{k/\ln k} = a < \dots < u_{k-k/\ln k} = b < \dots < u_k)$ and $G[U]$ is a regular graph by considering two possible cases depending on the difference $t = b - a$ between a and b .

Case 1. $t \leq c_2 k^{3/2}$, where $c_2 > 0$ is a small positive constant to be determined later.

The probability that there exists such a U is at most

$$(3) \quad \binom{n}{2k/\ln k} n^2 \binom{t}{k-2k/\ln k} \cdot n \left(\frac{c_1}{k}\right)^{k/2}.$$

Indeed, there are less than $\binom{n}{2k/\ln k}$ ways to choose the vertices

$$u_1, \dots, u_{k/\ln k-1}, u_{k-k/\ln k+1}, \dots, u_k,$$

less than n^2 ways to choose the vertices a and b so that the difference between them, t , is at most $c_2 k^{3/2}$, and less than $\binom{t}{k-2k/\ln k}$ ways to choose the vertices $u_{k/\ln k+1}, \dots, u_{k-k/\ln k-1}$. For each such choice, the probability that the induced subgraph on $\{u_1, u_2, \dots, u_k\}$ is regular is at most $n \left(\frac{c_1}{k}\right)^{k/2}$, by Lemma 3.2.

A simple computation shows that the expression in (3) is (much) smaller than, say, $1/n^2$ for an appropriate choice of c_2 . Indeed, since $n \leq k^2$ and $\binom{t}{k-2k/\ln k} \leq \binom{2t}{k} \leq (2et/k)^k$, this expression is at most

$$n^3 k^{4k/\ln k} \left(\frac{2et}{k}\right)^k \left(\frac{c_1}{k}\right)^{k/2} \leq n^3 2^k e^{5k} c_2^k c_1^{k/2} = n^3 [4e^{10} c_2^2 c_1]^{k/2},$$

implying the required estimate by choosing, for example, $c_2 = \frac{1}{3e^5 \sqrt{c_1}}$.

Case 2. $t \geq c_2 k^{3/2}$.

Let $U = (u_1 < \dots < u_{k/\ln k} = a < \dots < u_{k-k/\ln k} = b < \dots < u_k)$. Denote the first (smallest) $k/2$ vertices of U by U_1 , and the last $k/2$ vertices by U_2 . Observe that if $G[U]$ is a regular graph, then the two induced subgraphs $G[U_1]$ and $G[U_2]$ have the same average degree. This is highly improbable. Indeed, by the definition of $G(n, \bar{p})$ the probability of each pair inside U_1 to become an edge is strictly less than the probability of each pair inside U_2 to become an edge. In addition, since $b - a = t$, the probability that each pair $i, j \in U_1$ with $i < j, i \leq a$ is an edge is less than the probability that each pair $i', j' \in U_2$ with $i' < j', j' \geq b$ is an edge by $\Omega(t/n)$ —this is because in this case,

$$\begin{aligned} \left(\frac{1}{4} + \frac{i'}{2n}\right) \left(\frac{1}{4} + \frac{j'}{2n}\right) - \left(\frac{1}{4} + \frac{i}{2n}\right) \left(\frac{1}{4} + \frac{j}{2n}\right) &\geq \Omega\left(\frac{i' + j' - i - j}{2n}\right) \\ &\geq \Omega\left(\frac{j' - i}{2n}\right) \geq \Omega\left(\frac{t}{n}\right). \end{aligned}$$

It follows that the expected number of edges inside U_2 exceeds that inside U_1 by $\Omega(\frac{k^2 t}{n \ln k})$. By Chernoff's inequality (cf., e.g., [1, Appendix A]), we obtain that the probability that $G[U_1]$ and $G[U_2]$ have the same average degree in $G(n, \bar{p})$ is at most $\exp\{-c_3 k^2 t^2 / (n^2 \ln^2 k)\}$ for some absolute constant $c_3 > 0$.

Thus, recalling our assumption on t , we derive that the probability that there is U as above for which $G[U]$ is a regular graph is at most

$$\binom{n}{k} e^{-\frac{c_3 k^2 t^2}{n^2 \ln^2 k}} \leq \left(\frac{en}{k}\right)^k e^{-\frac{c_3 c_2^2 k^5}{n^2 \ln^2 k}} = \left(\frac{en}{k} e^{-\frac{c_3 c_2^2 k^4}{n^2 \ln^2 k}}\right)^k.$$

Finally, as $k \geq Cn^{1/2} \ln^{3/4} n$ and $\ln k = \Theta(\ln n)$, we can choose $C > 0$ to be large enough so that the above expression is (much) smaller than $1/n^2$.

Combining the two cases, we conclude that the probability that for any fixed k which is at least $Cn^{1/2} \ln^{3/4} n$ our graph contains an induced regular subgraph on k vertices is smaller than $2/n^2 < 1/n$, and as there are less than n choices for k , this shows that with positive probability the graph contains no such subgraph. This completes the proof of Theorem 1.4. $\square$

3.2. The nearly regular case.

Proof of Proposition 1.5. We will prove that for every (large) n there exists a graph G on n vertices in which every K -nearly regular induced subgraph has at most $7Kn/\log n$ vertices.

Assume first that n is of the form $n = (s+1)2^s$ for a positive integer s . Notice that $s = (1 - o(1)) \log_2 n$. Take a set V of n vertices and partition it into $s+1$ disjoint equally sized subsets $V_0, \dots, V_s$, $|V_i| = 2^s$. Now we define G as follows. For $i = 0, \dots, s$ the set V_i spans 2^{s-i} disjoint cliques of size 2^i each. There are no edges between the cliques inside V_i and no edges between distinct subsets $V_i \neq V_j$ in G .

Assume now that a subset $U \subseteq V$ spans a graph $G[U]$ satisfying $\delta(G[U]) = d$, $\Delta(G[U]) \leq Kd$. Observe that the degrees of all vertices from V_i in G are $2^i - 1$, and thus if $2^i - 1 < d$, then $U \cap V_i = \emptyset$. Let now $2^i \geq d+1$. Since $\Delta(G[U]) \leq Kd$, U has at most $Kd+1$ vertices in each clique spanned by V_i , implying $|U \cap V_i| \leq 2^{s-i}(Kd+1)$. Therefore,

$$\begin{aligned} |U| &= \sum_{i=0}^s |U \cap V_i| = \sum_{i: 2^i \geq d+1} |U \cap V_i| \\ &\leq \sum_{i=\lceil \log_2(d+1) \rceil}^s 2^{s-i}(Kd+1) < (Kd+1)2^{s-\lceil \log_2(d+1) \rceil+1} \\ &\leq \frac{2(Kd+1)}{d+1} 2^s = \frac{2(Kd+1)}{d+1} \frac{n}{s+1} \leq (2+o(1))K \frac{n}{\log n}, \end{aligned}$$

implying the desired result.

For n not of the form $n = (s+1)2^s$, choose a minimal s satisfying $(s+1)2^s \geq n$. Let $n' = (s+1)2^s$. It is easy to verify that $n' \leq 3n$. Now we can apply the above construction to create a graph G' on n' vertices in which every K -nearly induced subgraph has at most $(2+o(1))Kn'/\log n' \leq 7Kn/\log n$ vertices, and then take G to be an arbitrary induced subgraph of G' on exactly n vertices. $\square$

4. Open problems. The most intriguing open problem is that of obtaining a better estimate for $f(n, 1)$. In particular, the conjecture of Erdős, Fajtlowicz, and Staton that $f(n, 1)/\ln n$ tends to infinity as n tends to infinity remains open. The values of $f(n, 1)$ for $n \leq 17$ have been determined by the authors of [5] and by McKay, and these are indeed larger than the bounds that follow from the corresponding Ramsey numbers.

Our upper and lower bounds for $f(n, c)$ for $c > 1$ are also rather far from each other, and it will be nice to better understand the behavior of this function.

One can also study a variant of the problems considered here that deals with not necessarily induced subgraphs. Of course, every graph contains a regular subgraph on all vertices (the subgraph with no edges), and hence in this case it is natural to look for regular or nearly regular subgraphs with a large number of *edges*. For every two positive integers n, m with $m \leq \binom{n}{2}$ and a real $c \geq 1$, let $g(n, m, c)$ denote the largest g so that every graph with n vertices and m edges contains a (not necessarily

induced) c -nearly regular subgraph with at least g edges. The problems of determining or estimating the behavior of this function seems interesting. Here we can establish tighter estimates than the ones obtained for the induced case.

Consider first the case $c = 1$. Since the complete graph on n vertices can be covered by n matchings (and by $(n-1)$ for even n), it follows that every graph with m edges contains a matching of size at least m/n . This implies that $g(n, m, 1) \geq m/n$. The star $K_{1, n-1}$ shows that for some values of m and n this is essentially tight, and that $g(n, m, 1) = 1$ for all $1 \leq m < n$. By a simple application of Szemerédi's regularity lemma it can be shown (see [8]) that for every fixed $p > 0$ there is a $\delta = \delta(p) > 0$ so that $g(n, pn^2, 1) \geq \delta n^2$. This bound was significantly improved by Rödl and Wysocka [9], who proved that every graph with n vertices and pn^2 edges contains an r -regular subgraph with $r \geq \alpha p^3 n$ for some positive constant α .

For a larger constant c observe, first, that complete bipartite graphs show that for $m \geq n$, $g(n, m, c) \leq O(c(m/n)^2) = O(cd^2)$, where $d = 2m/n$ is the average degree of a graph with n vertices and m edges. Indeed, a complete bipartite graph $K_{k, n-k}$ with $k \leq n/2$ has average degree $d = \Theta(k)$. Every c -nearly regular subgraph in it has minimum degree at most k , and hence maximum degree at most ck . Thus it cannot have more than $k \cdot ck = ck^2$ edges. Therefore, for every fixed $c > 1$ there exists some $C = C(c)$ so that $g(m, n, c) \leq C(m/n)^2$ for all $m > n$. We can show that for $c > 2$ this is tight, up to a constant factor; namely, for any $c > 2$ there is a $b = b(c) > 0$ so that $g(n, m, c) \geq b(m/n)^2$ for all $m > n$. For simplicity we present the proof only for $c = 5$; the proof for any other $c > 2$ is similar.

THEOREM 4.1. *Let $G = (V, E)$ be a graph with $|V| = n$ vertices, $|E| = m > n$ edges, and average degree $d = d(G) = 2m/n$. Then G contains a 5-nearly regular subgraph with at least $\frac{d^2}{2^{12}}$ edges.*

Proof. We apply the method of Pyber [7] together with a few extra twists. Clearly we may assume that $d \geq 2^6$. First, omit from G repeatedly vertices of degree smaller than $d/2$, as long as there are such vertices. As this process can only increase the average degree, it ends with a nonempty graph G' with minimum degree at least $d/2$. Now take a spanning bipartite subgraph of G' with the maximum number of edges. It is easy to see and well known that the degree of every vertex in this bipartite subgraph is at least half its degree in G' , giving a bipartite graph H with minimum degree at least $d/4$. Put $H_1 = H$. Let A and B denote the two vertex classes of H , where $|A| \geq |B|$. Let $A_1 \subseteq A$ be a nonempty subset of A which satisfies $|N_{H_1}(A_1)| \leq |A_1|$ and A_1 is minimal with respect to containment (subject to the condition above and to being nonempty). Clearly there is such an A_1 , as $|N_{H_1}(A)| \leq |A|$ and $|N_{H_1}(v)| \geq d/4 > 1$ for all $v \in A$. Put $N_{H_1}(A_1) = B_1$ and note that by the minimality of A_1 , $|A_1| = |B_1|$. By the minimality, again, and by Hall's theorem, there is a matching M_1 saturating A_1 and B_1 . Let H_2 be the graph obtained from H_1 by deleting all edges of M_1 . Now let $A_2 \subseteq A_1$ be a nonempty, minimal subset of A_1 satisfying $|N_{H_2}(A_2)| \leq |A_2|$. As before, there is such a set, as $|N_{H_2}(A_1)| \leq |N_{H_1}(A_1)| = |A_1|$. The minimality shows, again, that in fact $|N_{H_2}(A_2)| = |A_2|$, and that there is a matching M_2 saturating A_2 and $N_{H_2}(A_2) = B_2$. Proceeding in this manner we define a sequence of sets

$$\emptyset \neq A_{d/4} \subseteq A_{d/4-1} \subseteq \cdots \subseteq A_2 \subseteq A_1 \subseteq A$$

and

$$\emptyset \neq B_{d/4} \subseteq B_{d/4-1} \subseteq \cdots \subseteq B_2 \subseteq B_1 \subseteq B$$

where $|A_i| = |B_i|$ for all i , and a sequence of pairwise edge-disjoint matchings $M_{d/4}, \dots, M_2, M_1$, where M_i is a perfect matching between A_i and B_i . Note that, indeed,

this process does not terminate before these $d/4$ phases, as initially all degrees in H are at least $d/4$, and with the omission of each matching the degrees drop by 1.

For convenience we assume, from now on, that d is a power of 2 (otherwise, simply consider only the first $d'/4$ sets A_i, B_i and matchings M_i , where $d' > d/2$ is the largest power of 2 that does not exceed d). Note that $|A_{d/8}| > d/8$, since every vertex of $B_{d/4}$ is incident with an edge of each of the matchings M_i for $d/8 \leq i \leq d/4$, and all these edges are incident with vertices of $A_{d/8}$. We consider two possible cases.

Case 1. For every i , $0 \leq i \leq \log_2 d - 4$,

$$|A_{d/2^{i+4}}| > 2|A_{d/2^{i+3}}|.$$

In this case,

$$|A_1| > 2^{\log_2 d - 3} |A_{d/8}| \geq \frac{d^2}{64},$$

and the matching M_1 is a regular subgraph with more than $d^2/64$ edges, supplying the desired result (with room to spare).

Case 2. There is an i , $0 \leq i \leq \log_2 d - 4$, such that

$$|A_{d/2^{i+4}}| \leq 2|A_{d/2^{i+3}}|.$$

In this case, take the minimum i for which this holds. Then

$$|A_{d/2^{i+3}}| > 2^i |A_{d/8}| \geq 2^{i-3} d.$$

Let H' be the graph consisting of the $\frac{d}{2^{i+4}}$ matchings M_j for $\frac{d}{2^{i+4}} \leq j < \frac{d}{2^{i+3}}$. The vertices of H' are all those saturated by the largest matching among those, namely, $M_{\frac{d}{2^{i+4}}}$. Then the maximum degree in H' is exactly $\frac{d}{2^{i+4}}$ (as every vertex of $A_{d/2^{i+3}}$ has that degree), and the average degree is at least half of that, since each of the $\frac{d}{2^{i+4}}$ matchings M_j above is of size at least half that of the largest one, which is spanning. As in H' the degree of every vertex of $A_{d/2^{i+3}}$ is exactly $\frac{d}{2^{i+4}}$, and the total number of edges of H' is at least

$$|A_{d/2^{i+3}}| \cdot \frac{d}{2^{i+4}} \geq 2^{i-3} d \cdot \frac{d}{2^{i+4}} = 2^{-7} d^2.$$

Thus, H' is a graph with maximum degree that exceeds the average degree by a factor of at most $K = 2$. We can now apply Proposition 2.1 with $K = 2$ and $\alpha = 0.4$ to conclude that H' contains a $K/\alpha = 5$ -nearly regular subgraph with at least

$$\frac{K - 2K\alpha}{2K - 4\alpha} |E(H')| \geq \frac{1}{6} 2^{-7} d^2$$

edges, completing the proof. $\square$

PERFECT CODES OF LENGTH n WITH KERNELS OF DIMENSION $n - \log(n + 1) - 3^*$

OLOF HEDEN[†]

Abstract. Perfect 1-error correcting binary codes are considered. Those of length n and with a kernel of dimension $n - \log(n + 1) - 3$ are shown to be obtainable by the Phelps construction.

Key words. perfect codes, tilings, Phelps codes

AMS subject classification. 94B25

DOI. 10.1137/060658643

1. Introduction. A perfect e -error correcting q -ary code of length n is a subset C of a direct product of n alphabets F_q with q elements,

$$C \subseteq F_q^n = F_q \times F_q \times \dots \times F_q,$$

with the property that every word of F_q^n is at distance at most e from a unique word of the code C . The distance we will be concerned with here is the *Hamming distance*:

$$d(\bar{c}, \bar{d}) = |\{i \mid c_i \neq d_i\}|, \quad \bar{c} = (c_1, c_2, \dots, c_n), \quad \bar{d} = (d_1, d_2, \dots, d_n).$$

In the case where q is a prime power and $e \geq 2$, there are only two possibilities for perfect codes: the two Golay codes [7] that have the parameters $(n, q, e) = (23, 2, 3)$, respectively, $(n, q, e) = (11, 3, 2)$; see [22] or [16].

The situation in the case $e = 1$ and $q = 2$ is quite different. There are rather many different constructions of perfect codes in this case, more than 20, and the number of different perfect codes is large [21]. Krotov [13] proved that the number of different perfect binary 1-error correcting codes of length n is at least¹

$$2^{2^{\frac{n+1}{2} - \log_2(n+1)}} \cdot 3^{2^{\frac{n-3}{4}}} \cdot 2^{2^{\frac{n+5}{4} - \log_2(n+1)}}.$$

Two binary codes C and C' are *equivalent* if there is a word $\bar{d}$ and a permutation π of the set of coordinate positions such that

$$C' = \pi(\bar{d} + C).$$

It is remarkable that, even if we count the number of equivalence classes of perfect codes, the number of perfect codes will be extremely large. For example, in the case of perfect codes of length 31, it follows from the formula above, by using the trivial estimate $31! \leq (2^5)^{31}$ for the number of permutations of the set of 31 coordinate positions, that the number of equivalence classes of perfect codes will be at least

$$\frac{2^{2^{\frac{31+1}{2} - \log_2(31+1)}} \cdot 3^{2^{\frac{31-3}{4}}} \cdot 2^{2^{\frac{31+5}{4} - \log_2(31+1)}}}{2^{155} \cdot 2^{31}} = 2^{2040} \cdot 3^{128}.$$

¹This lower bound has been improved; see [15]. Their new formula is, however, far too complicated to be described here.

The case where $e = 1$ and q is an odd prime power is less studied than the binary case, but it is known that, also in this case, the situation is similar to the binary case.

Here we are concerned only with perfect 1-error correcting binary codes. These will below be called *perfect codes*. We will just consider a special class of perfect codes and show that they all can be constructed by using the Phelps construction from 1984 [18]. The Phelps construction was one of the first constructions of nonlinear perfect codes. Phelps construction is very useful for producing interesting examples of perfect codes.

The special class of perfect codes that we will consider is defined by the dimension of its kernel. This concept will now be defined.

A word $\bar{p}$ is a *period* of a set of words C if

$$\bar{p} + \bar{c} \in C \quad \text{for every } \bar{c} \in C.$$

The *kernel* of a set of words C , $\ker(C)$, is the set of all periods of C . The kernel is always a subspace of $\mathbb{Z}_2^n$ and if the all zero word $\bar{0} = (0, 0, \dots, 0)$ belongs to C , then $\ker(C)$ is a subset of C .

Our main result is the following: *Every perfect 1-error correcting binary code of length n and with a kernel of dimension $n - \log(n + 1) - 3$ can be constructed by using the Phelps construction.*

Let us give a remark on the dimension k of the kernel of perfect codes in general. It is now well known [3], [19] which the possibilities are for the integer k . Let the *rank* r of a perfect code C be the dimension of the linear space $\langle C \rangle$, spanned by the words of C . Then, for any perfect code C of length n and containing the all zero word $\bar{0}$,

$$(1) \quad k \geq \begin{cases} (n-1)/2 & \text{if } r = n - \log(n+1) + 1, \\ 2^{n-r} & \text{if } n - \log(n+1) + 2 \leq r \leq n, \end{cases}$$

and

$$(2) \quad r \leq k - 1 + 2^{n - \log(n+1) - k}.$$

Further, for all triples (n, r, k) satisfying all of the inequalities (1) and (2), there are, with just a very few exceptions, perfect codes of length n , rank r , and with a kernel of dimension k ; see, e.g., [3] and [9]. So the remark must be that our theorem covers just a very particular case.

Let us also remark that it is not very difficult to prove; see, e.g., [1], that every perfect code of rank $n - \log(n + 1) + 1$ can be constructed by using the Vasil'ev construction [23]. If the rank of the perfect code equals $n - \log(n + 1) + 2$, then it is known [2] that the perfect code is a Phelps code. In [24], Zinoviev and Zinoviev enumerated all of the perfect codes of length 15 and of rank 13. There they raised the problem whether or not there are perfect codes of length 15 and of rank 14 that are not obtainable by the Solov'eva-Phelps construction; see [20] and [17]. In [10], it was shown that there actually exist non-Phelps codes of length 15 and rank 14. It must also be remarked that in [25], all of the extended perfect codes of length 16 and rank 14 were enumerated by Zinoviev and Zinoviev. Further, it was proved in [8] that every non-full rank perfect code is obtainable by the Krotov construction [14].

Finally, in the last section, section 5, we give a *description of all of the perfect codes of length $n = 2^m - 1$, rank $r = n - \log(n + 1) + 4$ and with a kernel of dimension $k = n - \log(n + 1) - 3$* . In fact, we show that every such code can be described by a family of $t + 1 = 2^{m-4}$ perfect codes $C_0, C_1, \dots, C_t$ of length 7 such that the words in

the union of these codes span $\mathbb{Z}_2^7$. Further, each such family describe a perfect code with the above given values of length, rank, and a dimension of kernel.

We must remark that these particular results of section 5 are almost immediate consequences of the results on the tilings of [5]. In our description of this class of perfect codes, equivalence is not considered. But we wish to give the following remark: Hessler [12] defined two perfect codes C and C' , both of length n , to be *linear equivalent* if there is a nonsingular linear map of the vector space $\mathbb{Z}_2^n$ that maps the words of C onto the set of the words of C' . Hessler also gave a simple characterization when two perfect codes are linear equivalent. From that result and our description in section 5, it follows that the set of the perfect codes of length n , rank $n - \log(n+1) + 4$ and with a kernel of dimension $n - \log(n+1) - 3$ just consist of one linear equivalence class.

2. Some preliminary results. The *dual code* $C^\perp$ of a linear code C of length n consists of those words $\bar{d} = (d_1, d_2, \dots, d_n) \in \mathbb{Z}_2^n$ such that

$$c_1 d_1 + c_2 d_2 + \dots + c_n d_n \equiv 0 \pmod{2}$$

for every word $\bar{c} = (c_1, c_2, \dots, c_n) \in C$.

A *simplex code* of length $n = 2^m - 1$ is a subspace S of $\mathbb{Z}_2^n$, with the property that every nonzero word of S has weight $(n+1)/2$. The following lemma is well known [11].

LEMMA 1. *The dual code of the linear span $\langle C \rangle$, of the words of any perfect code C of length n , constitutes a simplex code S of length n and dimension $n - r$, where $r = \text{rank}(C)$.*

Let S be any simplex code of length n and dimension $n - r$. If we define an equivalence relation on the set of coordinate positions $\{1, 2, \dots, n\}$ by

$$i \sim j \quad \text{if} \quad s_i = s_j \quad \text{for every} \quad \bar{s} = (s_1, s_2, \dots, s_n) \in S,$$

then this equivalence relation induces a partition $\mathcal{P}$ of the set $\{1, 2, \dots, n\}$ into mutually disjoint equivalence classes $I_0, I_1, \dots, I_t$. It can be proved; see, e.g., [4], that with a suitable enumeration of these sets,

$$(3) \quad |I_0| + 1 = |I_1| = |I_2| = \dots = |I_t| = s, \quad \text{where} \quad t = 2^{n-r} - 1 \quad \text{and} \quad s = \frac{n+1}{t+1}.$$

Any perfect code C of rank r is equivalent to a perfect code C' , of which the simplex code $\langle C' \rangle^\perp$ gives the following partition $\mathcal{P}$:

$$(4) \quad I_0 = \{1, 2, \dots, s-1\}, I_1 = \{s, s+1, \dots, 2s-1\}, \dots, I_t = \{ts, ts+1, \dots, n\}$$

of the set of coordinate positions $\{1, 2, \dots, n\}$. To simplify our notation we will always assume that the dual code of the linear span of the perfect code we consider will induce this partition of the set of coordinate positions.

If a perfect code C of length n and of rank r is under consideration, then we use the following notation of the words of $\mathbb{Z}_2^n$:

$$(x_1, x_2, \dots, x_n) = (\bar{x}_0 | \bar{x}_1 | \dots | \bar{x}_t),$$

where

$$\bar{x}_0 = (x_1, x_2, \dots, x_{s-1}), \quad \text{and} \quad \bar{x}_i = (x_{is}, x_{is+1}, \dots, x_{(i+1)s-1}), \quad i = 1, 2, \dots, t.$$

The *weight* $w(\bar{c})$ of a word $\bar{c} = (c_1, c_2, \dots, c_n)$ is the number of nonzero coordinates c_i , $i = 1, 2, \dots, n$, or equivalently, $w(\bar{c}) = d(\bar{c}, \bar{0})$.

For any word $\bar{c} \in C$ we define the *parity weight vector* of a word $\bar{c} = (\bar{c}_0 \mid \bar{c}_1 \mid \dots \mid \bar{c}_t)$ to be the binary word

$$w_{\mathcal{P}}(\bar{c}) = (h_1, h_2, \dots, h_t) \in \mathbb{Z}_2^t, \quad \text{where } h_i \equiv w(\bar{c}_i) \pmod{2}, \quad i = 1, 2, \dots, t,$$

where $\mathcal{P}$ is the partition of the coordinate set described above.

One of the ingredients of a Phelps code is a MDS-code. We now show that every perfect code of length n and rank $r < n$ defines a MDS-code.

Let F_s denote the finite field with s elements, where s is a power of the integer two. The set of the elements of F_s constitutes an alphabet that we denote by $\mathcal{A}$:

$$(5) \quad \mathcal{A} = \{\beta_0 = 0, \beta_1, \beta_2, \dots, \beta_{s-1}\}.$$

Let $\bar{e}_1, \bar{e}_2, \dots, \bar{e}_{s-1}$ denote the following words of length $s-1$:

$$\bar{e}_1 = (1, 0, 0, \dots, 0, 0), \quad \bar{e}_2 = (0, 1, 0, \dots, 0, 0), \quad \dots, \quad \bar{e}_{s-1} = (0, 0, 0, \dots, 0, 1).$$

We define a map φ_0 from $\mathcal{A}$ to $\mathbb{Z}_2^{s-1}$ by

$$\varphi_0(\alpha) = \begin{cases} (0, 0, \dots, 0) & \text{if } \alpha = 0, \\ \bar{e}_i & \text{if } \alpha = \beta_i, \quad i = 1, 2, \dots, s-1. \end{cases}$$

We also define maps φ_j from $\mathcal{A}$ to $\mathbb{Z}_2^s$, for $j = 1, 2, \dots, t$, by just adding an extra parity check:

$$\varphi_j(\alpha) = \begin{cases} (0, 0, \dots, 0 \mid 0) & \text{if } \alpha = 0, \\ (\bar{e}_i \mid 1) & \text{if } \alpha = \beta_i, \quad i = 1, 2, \dots, s-1. \end{cases}$$

We extend these maps to a map φ from $\mathcal{A}^{t+1}$ to $\mathbb{Z}_2^{s(t+1)-1}$ by

$$\varphi((\alpha_0, \alpha_1, \alpha_2, \dots, \alpha_t)) = (\varphi_0(\alpha_0) \mid \varphi_1(\alpha_1) \mid \varphi_2(\alpha_2) \mid \dots \mid \varphi_t(\alpha_t)).$$

Consider any perfect code C , with corresponding simplex code $S = \langle C \rangle^\perp$. Let $M(C)$ be defined to be the set of words

$$M(C) = \{\bar{\alpha} = (\alpha_0, \alpha_1, \alpha_2, \dots, \alpha_t) \in \mathcal{A}^{t+1} \mid \varphi(\bar{\alpha}) \in C\}.$$

Just to avoid any possibility of misunderstanding, we give an example.

Example 1. Let $s = 4$, $t = 3$, and $\mathcal{A} = \{0, \beta_1, \beta_2, \beta_3\}$. Then, e.g.,

$$\varphi((\beta_1, 0, \beta_3, \beta_2)) = (1, 0, 0 \mid 0, 0, 0, 0 \mid 0, 0, 1, 1 \mid 0, 1, 0, 1).$$

Further there is no 4-tuple $\bar{\alpha} = (\alpha_0, \alpha_1, \alpha_2, \alpha_3) \in \mathcal{A}^4$ such that

$$\varphi(\bar{\alpha}) = (1, 1, 1 \mid 1, 1, 1, 1 \mid 1, 1, 1, 1 \mid 1, 1, 1, 1).$$

LEMMA 2. *For any perfect code C of length n and rank r such that $n - \log(n+1) < r < n$ and containing the all zero word, the code $M(C)$ is a MDS-code in $\mathcal{A}^{t+1}$ of size $|\mathcal{A}|^t$ and with minimum distance 2, where $t = 2^{n-r}$.*

Proof. We prove that $|M(C)| = s^t$ and that the minimum distance of $M(C)$ will be equal to 2. This is equivalent to saying that $M(C)$ is a MDS-code of length $t+1$ over an alphabet, with s elements and with a minimum distance equal to 2.

Assume that there are words $\bar{\alpha} = (\alpha_0, \dots, \alpha_t)$ and $\bar{\alpha}' = (\alpha'_0, \dots, \alpha'_t)$ in $M(C)$ such that $d(\bar{\alpha}, \bar{\alpha}') = 1$. Let i be the coordinate position in which $\bar{\alpha}$ and $\bar{\alpha}'$ differ. Then

$$d(\varphi(\bar{\alpha}), \varphi(\bar{\alpha}')) = d(\varphi(\alpha_i), \varphi(\alpha'_i)) = w(\varphi_i(\alpha_i) - \varphi_i(\alpha'_i)) = 2,$$

which is impossible as the minimum distance of C is three.

Now consider any word

$$\bar{\beta} = (0, \alpha_1, \alpha_2, \dots, \alpha_t) \in \mathcal{A}^{t+1}.$$

There is a unique word $\bar{c} = (\bar{c}_0 | \bar{c}_1 | \dots | \bar{c}_t)$ of C such that

$$(6) \quad d(\varphi(\bar{\beta}), \bar{c}) \leq 1.$$

Let S be the dual space of $\langle C \rangle$. From Lemma 1 and the definition of the map φ , it follows that $\varphi(\bar{\beta})$ belongs to $S^\perp$. By the definition of the simplex code S , the word $\bar{c}$ will belong to $S^\perp$. Hence also $\bar{c} - \varphi(\bar{\beta}) \in S^\perp$. By the above equation (6), this word has weight at most one. Thus, we may conclude that the only possibility is that

$$\bar{c} - \varphi(\bar{\beta}) = (\varphi_0(\alpha_0), 0, 0, \dots, 0)$$

for some element $\alpha_0 \in \mathcal{A}$. This gives that

$$(\varphi_0(\alpha_0), \varphi_1(\alpha_1), \varphi_2(\alpha_2), \dots, \varphi_t(\alpha_t)) = \bar{c} \in C$$

or equivalently that

$$(\alpha_0, \alpha_1, \alpha_2, \dots, \alpha_t) \in M(C).$$

The lemma is proved. $\square$

3. Tilings and perfect codes. One of the most fruitful approaches to perfect codes goes via tilings; see [5], [6]. A *tiling* of $\mathbb{Z}_2^n$ is a couple (V, A) of two subsets V and A of $\mathbb{Z}_2^n$ such that every word $\bar{x}$ of $\mathbb{Z}_2^n$ uniquely can be written as a sum of a word $\bar{v} \in V$ and a word $\bar{a} \in A$.

We will consider the words in the sets V and A as column vectors. To each of these sets we will associate matrices $\mathbf{V}$ and $\mathbf{A}$, respectively. If the words of V and A are enumerated as follows:

$$V = \{\bar{v}_1, \bar{v}_2, \dots, \bar{v}_{|V|}\} \quad \text{and} \quad A = \{\bar{a}_1, \bar{a}_2, \dots, \bar{a}_{|A|}\},$$

then these columns are placed in that order in the matrices $\mathbf{V}$ and $\mathbf{A}$. Sometimes we will exclude a zero column in these matrices. This will be declared each time it will occur.

The next lemma says that, to every perfect code C , we may associate a tiling.

Let C be any perfect code of length n , and let G be any linear subspace of the kernel of C . Consider the matrix $\mathbf{V}$, in which the rows constitute a base for the dual space of G . Let A be the set of columns

$$(7) \quad A = \{\mathbf{V}\bar{c}^T \mid \bar{c} \in C\},$$

and let V denote the set of columns of the matrix $\mathbf{V}$ together with the all zero word.

LEMMA 3. *If C is a perfect code of length n with A and V defined as above, then the couple (V, A) is a tiling of $\mathbb{Z}_2^g$, where $g = \dim(G^\perp)$.*

This lemma is well known [5]; the proof is a trivial exercise of verifications.

We will say that the tiling (V, A) , described in the above Lemma 3, is the *tiling associated with the perfect code C* . Let us just give two examples, that actually will be used in the sections 4 and 5, respectively.

Example 2. The *Hamming code H* of length 7 is defined to be the set of words $\bar{c} \in \mathbb{Z}_2^7$ satisfying

$$\begin{bmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix} \bar{c}^T = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}.$$

The rows of the matrix above span the dual space of the Hamming code. If V denotes the set of columns of the 3×7 matrix above, complemented with the zero column, and A the zero column of length three, then, perhaps trivially, the couple (V, A) constitutes a tiling of $\mathbb{Z}_2^3$.

Example 3. Let C be any perfect code of length n . Let A consist of all of the words of weight less than or equal to one, and let V consist of the words of the code C . Then $|V| = 2^{n-\log(n+1)}$ and $|A| = n + 1$. From the definition of a perfect code, it follows immediately that the couple (V, A) constitutes a tiling of $\mathbb{Z}_2^n$.

We now consider any tiling (V, A) of $\mathbb{Z}_2^n$ such that $\bar{0} \in V$. Let $\mathbf{V}$ denote the matrix which as columns has the nonzero columns of V , and let $n = |V| - 1$. We will denote by $C(V, A)$ the set of words

$$C(V, A) = \{ \bar{c} \in \mathbb{Z}_2^n \mid \mathbf{V} \bar{c}^T \in A \}.$$

The following lemma is well known; see, e.g., [5], and is also a converse of Lemma 3.

LEMMA 4. *For any tiling (V, A) of $\mathbb{Z}_2^g$ such that $\bar{0} \in V$, the code $C(V, A)$ is a perfect code of length $n = 2^m - 1$, where $m = \log(|V|)$.*

We will say that $C(V, A)$ is the *perfect code associated to the tiling (V, A)* .

For any tiling (V, A) of $\mathbb{Z}_2^g$, with $|V| = n$, we will let $C^0(V, A)$ denote the set

$$C^0(V, A) = \{ \bar{c} \in \mathbb{Z}_2^n \mid w(\bar{c}) \equiv 0 \pmod{2} \text{ and } \mathbf{V} \bar{c}^T \in A \},$$

where $\mathbf{V}$ denotes a matrix, which as columns has the columns of the set V .

LEMMA 5. *For any tiling (V, A) of $\mathbb{Z}_2^g$, the code $C^0(V, A)$ is an extended perfect code of length n .*

The proof of this lemma is an easy exercise in coding theory, and further, the result can also partly be seen as an extension of Lemma 4.

We shall say that $C^0(V, A)$ is the *extended perfect code of even weight words associated to the tiling (V, A)* . Note that different orderings of the columns in the matrix $\mathbf{V}$ will give equivalent perfect codes.

Consider any tiling (V, A) . Let $Im(C(V, A))$ denote the following set of columns:

$$Im(C(V, A)) = \{ \mathbf{V} \bar{c}^T \in A \mid \bar{c} \in C(V, A) \}.$$

Similarly the set $Im(C^0(V, A))$ is defined.

LEMMA 6. *For any tiling (V, A) of $\mathbb{Z}_2^g$ such that $\bar{0} \in V$,*

$$|Im(C(V, A))| = |Im(C^0(V, A))| = 2^{\text{rank}(V) - \log(|V|)}.$$

If $\text{rank}(V) = g$, then

$$\text{Im}(C(V, A)) = \text{Im}(C^0(V, A)) = A.$$

Proof. We prove the statements of the lemma just for the set $\text{Im}(C(V, A))$. The proof for the set $\text{Im}(C^0(V, A))$ is quite similar.

The code $C(V, A)$ is a perfect code of length $|V| - 1$, and thus

$$(8) \quad |C(V, A)| = 2^{|V|-1-\log|V|}.$$

Let D be the null space of $\mathbf{V}$. Then

$$C(V, A) = (\bar{p}_1 + D) \cup (\bar{p}_2 + D) \cup \cdots \cup (\bar{p}_z + D)$$

for some words $\bar{p}_1, \bar{p}_2, \dots, \bar{p}_z$. The integer z will be equal to

$$(9) \quad z = |C(V, A)|/|D|,$$

and the words $\bar{p}_1, \bar{p}_2, \dots, \bar{p}_z$ will have the properties: $\mathbf{V}\bar{p}_i^T \in A$ for $i = 1, 2, \dots, z$, and $\mathbf{V}\bar{p}_i^T \neq \mathbf{V}\bar{p}_j^T$ for $i \neq j$. Hence, from the definition of $\text{Im}(C(V, A))$, it thus follows that $|\text{Im}(C(V, A))| = z$. As the subspace D of $\mathbb{Z}_2^{|V|-1}$ is the null space of the matrix $\mathbf{V}$, we get that $\dim(D) = |V| - 1 - \text{rank}(\mathbf{V})$. By combining the equations (8) and (9), we now get the first statement of the lemma.

If V has rank g , then any vector of $\mathbb{Z}_2^g$ belongs to the column space of $\mathbf{V}$; see any elementary text book in linear algebra. From the definition of the code $C(V, A)$ and the set $\text{Im}(C(V, A))$, the second statement of the lemma now follows. $\square$

The next two lemmas will be crucial in our investigations. In both lemmas we will let $\bar{v}_1, \bar{v}_2, \bar{v}_3, \dots$ denote the columns number 1, 2, 3, etc., of the matrix $\mathbf{V}$.

LEMMA 7. Consider any tiling (V, A) of $\mathbb{Z}_2^g$ and assume that the all zero word belongs to both A and V . Let

$$W = \{i \mid \bar{0} \neq \bar{v}_i \in \text{Im}(C(A, V))\}.$$

If the word $\bar{e}_i$ of weight one belongs to the linear span $\langle C(V, A) \rangle$, then $i \in W$. If further V has maximal rank, then for any $i \in W$, the word $\bar{e}_i$ belongs to $\langle C(V, A) \rangle$.

Proof. As the all zero column belongs to A , we conclude that the dual space of the row space of $\mathbf{V}$ belongs to $C(V, A)$. Remind, that in this case, we assume that the matrix $\mathbf{V}$ does not contain the all zero column.

Let $\bar{g}_1, \bar{g}_2, \dots, \bar{g}_r$ be a set of base vectors for $\langle C(V, A) \rangle$ such that $\mathbf{V}\bar{g}_i^T = \bar{a}_i$, for $i = 1, 2, \dots, t$, and such that $\bar{g}_{t+1}, \bar{g}_{t+2}, \dots, \bar{g}_r$ constitute a base for the dual space of the row space of $\mathbf{V}$. We note that

$$\mathbf{V}\bar{g}_i^T \neq \mathbf{V}\bar{g}_j^T \quad \text{for any } 1 \leq i < j \leq t.$$

This implies by Lemma 6 that if $\mathbf{V}$ has maximal rank, then

$$(10) \quad |A \setminus \{\bar{0}\}| = t.$$

Assume that $\bar{e}_i \in \langle C(V, A) \rangle$, that is,

$$\bar{e}_i = \sum_{j=1}^r \lambda_j \bar{g}_j.$$

Then

$$\bar{v}_i = \mathbf{V} \left(\sum_{j=1}^r \lambda_j \bar{g}_j \right)^T = \sum_{j=1}^t \lambda_j \bar{a}_j, \quad \text{where } \bar{a}_j \neq \bar{0}, \quad j = 1, 2, \dots, t.$$

This implies that

$$(\lambda_1, \lambda_2, \dots, \lambda_t, 0, 0, \dots, 0) \in C(A, V),$$

and consequently that $i \in W$.

Next assume that $\mathbf{V}$ has maximal rank. Then, as $\bar{0} \in A$, we get from Lemma 6 that to any $\bar{a} \in A$ there is a word $\bar{c} \in C(V, A)$ such that $\bar{a} = \mathbf{V}\bar{c}^T$.

Assume that i is any element of W . Then, for some word $(\lambda_1, \dots, \lambda_t) \in C(A, V)$, compare equation (10),

$$\mathbf{V}\bar{e}_i^T = \bar{v}_i = \sum_{j=1}^t \lambda_j \bar{a}_j = \mathbf{V} \left(\sum_{j=1}^t \lambda_j \bar{g}_j \right)^T.$$

This implies that

$$\mathbf{V} \left(\sum_{j=1}^t \lambda_j \bar{g}_j - \bar{e}_i \right)^T = \bar{0},$$

and thus

$$\sum_{j=1}^t \lambda_j \bar{g}_j - \bar{e}_i = \sum_{j=t+1}^r \lambda_j \bar{g}_j.$$

The lemma is proved. $\square$

Similarly one may prove the following.

LEMMA 8. Consider any tiling (V, A) of $\mathbb{Z}_2^g$ such that the all zero word belongs to V . Let

$$W = \{i \mid \bar{0} \neq \bar{v}_i \in \text{Im}(C^0(A, V))\}.$$

If the word $\bar{e}_i$ of weight one belongs to $\langle C(V, A) \rangle$, then $i \in W$. If further V has maximal rank, then for any $i \in W$, the word $\bar{e}_i$ belongs to $\langle C(V, A) \rangle$.

Proof. In the case where $\bar{0} \in A$, then

$$\text{Im}(C^0(A, V)) = \text{Im}(C(A, V)),$$

and the lemma follows immediately from the previous lemma.

If $\bar{0} \notin A$, then consider any word $\bar{c}$ of the perfect code $C(V, A) = \{\bar{c} \mid \mathbf{V}\bar{c}^T \in A\}$. Let $\bar{a} = \mathbf{V}\bar{c}^T$.

As $\langle \bar{c} + C(V, A) \rangle = \langle C(V, A) \rangle$ we note that

$$(11) \quad \bar{e}_i \in \langle C(V, A) \rangle \Leftrightarrow \bar{e}_i \in \langle \bar{c} + C(V, A) \rangle.$$

However, the code $\bar{c} + C(V, A)$ is the perfect code associated to the tiling $(V, \bar{a} + A)$. Further, as all of the words of $C^0(A, V)$ have even weight, we note that

$$\text{Im}(C^0(A, V)) = \text{Im}(C^0(\bar{a} + A, V)).$$

Hence

$$(12) \quad \bar{v}_i \in \text{Im}(C^0(A, V)) \Leftrightarrow \bar{v}_i \in \text{Im}(C^0(\bar{a} + A, V)).$$

As $\bar{0} \in \bar{a} + A$, the lemma now follows from (11), (12), and the first case considered above. $\square$

4. Proof of the theorem. In the first part of this section we consider any perfect code C of length n , containing the all zero word, and with a kernel of dimension k .

Let $\mathbf{V}$ be a matrix in which the rows $\bar{r}_i$, for $i = 1, 2, \dots, n - k$ constitute a set of base vectors for the dual space of the kernel of C . It is well known that, for any perfect code C , the dual space of the linear span $\langle C \rangle$ belongs to the kernel of C [11], and by definition, that

$$\langle C \rangle^\perp \subseteq \ker(C)^\perp.$$

Let r denote the rank of C . We will always assume that the first $n - r$ rows $\bar{r}_1, \bar{r}_2, \dots, \bar{r}_{n-r}$ of $\mathbf{V}$ constitute a base of $\langle C \rangle^\perp$.

Let (V, A) be the tiling of $\mathbb{Z}_2^{n-k}$ associated to the perfect code C . The element a_{ij} in the matrix $\mathbf{A} = (a_{ij})$ will then, by Lemma 6 as V has maximal rank, be the dot product of the row $\bar{r}_i$, with at least one word of C . It now follows, from the fact that the first $n - r$ rows of the matrix $\mathbf{V}$ all belong to the dual space of C , that the first $n - r$ rows of the matrix $\mathbf{A}$ must be rows of just zeros:

$$\mathbf{A} = \begin{pmatrix} \bar{0} & \bar{0} & \cdots & \bar{0} \\ \bar{v}_1 & \bar{v}_2 & \cdots & \bar{v}_{|A|} \end{pmatrix}.$$

In the matrix above, the vector $\bar{0}$ is a column vector. Also the vectors $\bar{v}_1, \bar{v}_2, \dots, \bar{v}_{|A|}$ are column vectors, and we will let V' denote the set of these vectors. (Similar notations are used below.) If we combine this fact with the fact that (V, A) is a tiling, we observe that *any possible column vector of length $n - r$ appears at least once in the submatrix of the matrix $\mathbf{V}$ consisting of the first $n - r$ rows of $\mathbf{V}$.*

As we are interested in the structure of a perfect code, we may apply any permutation π on the set of coordinate positions and thus, without any loss of generality, we may assume that the matrix $\mathbf{V}$ can be described as the matrix

$$\mathbf{V} = \left(\begin{array}{ccc|ccc|ccc|ccc|ccc|ccc} 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 1 & \cdots & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 0 & \cdots & 0 & 1 & \cdots & 1 \\ 0 & \cdots & 0 & 0 & \cdots & 0 & 1 & \cdots & 1 & 1 & \cdots & 1 & 1 & \cdots & 1 & 1 & \cdots & 1 \\ 0 & \cdots & 0 & 1 & \cdots & 1 & 0 & \cdots & 0 & 1 & \cdots & 1 & 1 & \cdots & 1 & 1 & \cdots & 1 \\ \hline \bar{a}_1^{(0)} & \cdots & \bar{a}_{s_0}^{(0)} & \bar{a}_1^{(1)} & \cdots & \bar{a}_{s_1}^{(1)} & \bar{a}_1^{(2)} & \cdots & \bar{a}_{s_2}^{(2)} & \bar{a}_1^{(3)} & \cdots & \bar{a}_{s_3}^{(3)} & \cdots & \bar{a}_1^{(t)} & \cdots & \bar{a}_{s_t}^{(t)} \end{array} \right).$$

We must also remark that here the set V consists of the columns of the matrix $\mathbf{V}$ and the all zero column. Further, $C = C(V, A)$.

Let, for $i = 1, 2, \dots, t$, $\mathbf{A}^{(i)}$ denote the matrix which as columns has the columns in the set $A^{(i)} = \{\bar{a}_1^{(i)}, \bar{a}_2^{(i)}, \dots, \bar{a}_{s_i}^{(i)}\}$ and $\mathbf{A}^{(0)}$ a matrix with columns in the set $A^{(0)} = \{\bar{a}_1^{(0)}, \bar{a}_2^{(0)}, \dots, \bar{a}_{s_0}^{(0)}\}$. We will later use the abbreviation

$$\mathbf{V} = \left(\begin{array}{c|c|c|c|c|c} 0 & 1 & 2 & 3 & \cdots & t \\ \hline \mathbf{A}^{(0)} & \mathbf{A}^{(1)} & \mathbf{A}^{(2)} & \mathbf{A}^{(3)} & \cdots & \mathbf{A}^{(t)} \end{array} \right)$$

for the above matrix.

We will also consider the $(n - r) \times (2^{n-r} - 1)$ matrix, denoted by $\mathcal{H}$, which as columns has all possible nonzero words of length $n - r$, and in the same order as they appear as columns in the matrix $\mathbf{V}$.

As noted above, the first $n - r$ rows of the matrix $\mathbf{A}$ consist just of zeros. Thus, as a consequence of the fact that (V, A) is a tiling, we may conclude that also each couple $(V', A^{(i)})$, for $i = 1, 2, \dots, t$, as well as the couple $(V', A^{(0)} \cup \{\bar{0}\})$, are tilings of $\mathbb{Z}_2^{r-k}$.

As for any tiling (V, A) of a set $\mathbb{Z}_2^g$, it is true that $|A| = 2^g / |V|$ we may conclude that, compare equation (3),

$$s_0 + 1 = s_1 = s_2 = s_3 = \dots = s_t.$$

The all zero word belongs to the perfect code C , and hence one of the columns $\bar{v}_i$ is the all zero column, which we assume to be the column $\bar{v}_{|A|}$.

From now on we assume that the kernel of C has dimension $n - \log(n + 1) - 3$. The set A will then consist of eight columns. Further, the nonzero rows of the matrix $\mathbf{A}$ must be linearly independent, and thus the matrix

$$\mathbf{V}' = \begin{pmatrix} \bar{v}_1 & \bar{v}_2 & \dots & \bar{v}_7 \end{pmatrix}$$

has maximal rank. Let V' denote the set of columns of this matrix $\mathbf{V}'$ together with the all zero column.

LEMMA 9. For $i = 1, 2, \dots, t$ and for any word $\bar{d}_i \in C^0(A^{(i)}, V')$,

$$(13) \quad \mathbf{A}^{(i)} \bar{d}_i^T = \bar{0}.$$

Further, for any word $\bar{d} \in C(A^{(0)}, V')$,

$$(14) \quad \mathbf{A}^{(0)} \bar{d}^T = \bar{0}.$$

Proof. We will apply Lemma 7 and Lemma 8.

The length of the perfect code $C(V', A^{(i)})$ will, for each $i = 1, 2, \dots, t$, be equal to 7. For this length of perfect codes, there are only linear perfect codes, all equivalent to the perfect code given in Example 2. Hence, the linear span of the words of $C(V', A^{(i)})$ does not contain any word of weight one. As already observed above, the matrix $\mathbf{V}'$ has maximal rank. This implies, by Lemma 8 and with notation from that lemma, that $W = \emptyset$. This proves equation (13).

The proof of equation (14) is quite similar and will thus be omitted. $\square$

LEMMA 10. For the kernel of $C = C(V, A)$, the following is true:

$$C(A^{(0)}, V') \times C^0(A^{(1)}, V') \times C^0(A^{(2)}, V') \times \dots \times C^0(A^{(t)}, V') \subseteq \ker(C(V, A)).$$

Proof. It is sufficient to prove that, for any $i = 0, 1, 2, \dots, t$,

$$\{\bar{0}\} \times \{\bar{0}\} \times \dots \times \{\bar{0}\} \times C^0(A^{(i)}, V') \times \{\bar{0}\} \times \dots \times \{\bar{0}\} \subseteq \ker(C(V, A)).$$

Now consider any word $\bar{c} \in C(V, A)$ and any word $\bar{d}_i \in C^0(A^{(i)}, V')$. Let $\bar{d} = (\bar{0}|\bar{0}|\dots|\bar{0}|\bar{d}_i|\bar{0}|\dots|\bar{0})$, where $1 \leq i \leq t$. As $\mathbf{V}\bar{c}^T \in A$, we get from Lemma 9 that

$$\mathbf{V}(\bar{c} + \bar{d})^T = \mathbf{V}\bar{c}^T + \bar{0}^T \in A,$$

and hence $\bar{c} + \bar{d} \in C$. Thus $\bar{d}$ is a period of $C = C(V, A)$. The case $\bar{d} = (\bar{d}_0|\bar{0}|\dots|\bar{0})$ is treated in the same way. The lemma is proved. $\square$

We are now ready to prove our main theorem.

THEOREM 1. *Every perfect code C of length n , containing the all zero word, of rank $n - \log(n+1) + r$, where $r \geq 2$, and with a kernel of dimension $n - \log(n+1) - 3$ is equivalent to some Phelps code.*

Proof. Let H be the Hamming code that as parity check matrix has the matrix $\mathcal{H}$. We first find a partition of the perfect code C into mutually disjoint subsets $C_{\bar{h}}$, $\bar{h} \in H$.

Let $\mathcal{P}$ denote the partition (4) given by the dual code of $\langle C \rangle$, compare section 2.

The code H' will be the set of parity weight vectors that we get from C :

$$H' = \{w_{\mathcal{P}}(\bar{c}) \mid \bar{c} \in C\}.$$

Define the subset $C_{\bar{h}}$ of C , for $\bar{h} \in H'$, to be the set of those words of C that has the parity weight vector $\bar{h}$:

$$C_{\bar{h}} = \{\bar{c} \in C \mid w_{\mathcal{P}}(\bar{c}) = \bar{h}\}, \quad \bar{h} \in H'.$$

As the first $n - r$ rows of the matrix $\mathbf{A}$ just consists of zeros, we get that, for the matrix $\mathcal{H}$, defined above, and for any word $\bar{h}$ of H' :

$$\bar{h} \in H' \quad \Rightarrow \quad \mathcal{H}\bar{h}^T = \bar{0}^T.$$

Hence H' must be a subset of the Hamming code H .

We now show that indeed H' is that Hamming code H . So assume that $\bar{h}$ is such that $\mathcal{H}\bar{h}^T = \bar{0}^T$. Let $\bar{x}$ be any word of length n such that $w_{\mathcal{P}}(\bar{x}) = \bar{h}$. Then

$$\mathbf{V}\bar{x}^T = (y_1, y_2, \dots, y_{n-k})^T, \quad \text{where } y_i = 0 \quad \text{for } i = 1, 2, \dots, n - r.$$

As the couple $(A^{(0)}, V')$ is a tiling, we get that there are columns $\bar{a}_i^{(0)}$ of $A^{(0)}$ and $\bar{v}_j$ of V' such that

$$(y_{n-r+1}, y_{n-r+2}, \dots, y_{n-k})^T = \bar{a}_i^{(0)} + \bar{v}_j.$$

This implies that the word $\bar{x}$ differs in position i from a word $\bar{c} \in C$. As the coordinate position i belongs to the set of positions $\{1, 2, \dots, s_0 - 1\}$, we note that

$$w_{\mathcal{P}}(\bar{c}) = \bar{h}, \quad \text{and hence } \bar{c} \in C_{\bar{h}}.$$

We may conclude that

$$(15) \quad \mathcal{H}\bar{h}^T = \bar{0}^T \quad \Rightarrow \quad C_{\bar{h}} \neq \emptyset.$$

This proves that H' actually is a Hamming code.

By (15), for any $\bar{h} \in H$, we know that $C_{\bar{h}} \neq \emptyset$. Hence we may choose a fixed word $\bar{c}_{\bar{h}}$ in each of the subsets $C_{\bar{h}}$, $\bar{h} \in H$, of C . Let us, for each $\bar{h} \in H$, define a code $M_{\bar{h}}$ by (notation as in section 2)

$$(16) \quad M_{\bar{h}} = M(C + \bar{c}_{\bar{h}}).$$

We note that

$$\langle C \rangle = \langle C + \bar{c}_{\bar{h}} \rangle,$$

and hence, by Lemma 2, the code $M_{\bar{h}}$ is a MDS-code.

To prove our theorem, we also need a family of t partitions of the sets $\mathbb{Z}_2^{s_i}$, $i = 1, 2, \dots, t$, into extended perfect codes, and one partition of the set $\mathbb{Z}_2^{s_0}$ into perfect codes. The partition of $\mathbb{Z}_2^{s_0}$ consists of the translates of the perfect code $C(A^{(0)}, V')$. For each $i = 1, 2, 3, \dots, t$, we get a partition of $\mathbb{Z}_2^{s_i}$ by using the translates of the perfect codes $C^0(A^{(i)}, V')$.

Let φ be defined as in section 2. We conclude, from equation (16) and Lemma 10, that the set $C_{\bar{h}}$, for each $\bar{h} \in H$, equals the set

$$C_{\bar{h}} = \cup_{\bar{\alpha} \in M_{\bar{h}}} (\bar{c}_{\bar{h}} + \varphi(\bar{\alpha}) + C(A^{(0)}, V') \times C^0(A^{(1)}, V') \times \dots \times C^0(A^{(t)}, V')).$$

That C is a union of these sets $C_{\bar{h}}$, for $\bar{h} \in H$, is equivalent to the fact that C is a Phelps code; see [18] for a definition of that most well-known construction of perfect codes. The theorem is proved. $\square$

5. The perfect codes of rank $n - \log(n + 1) + 4$ and with kernels of dimension $n - \log(n + 1) - 3$. The results in this section are not directly connected to Phelps codes but are consequences of the general considerations in this paper and concern perfect codes of length n , with kernels of dimension $n - \log(n + 1) - 3$ and of rank $n - \log(n + 1) + 4$. Although they follow almost directly from the results of [5], we think the results are beautiful enough to be presented somewhere. We state the result as a theorem and use the same notation as in the previous section. Below, $\mathbf{I}_7$ denotes the 7×7 -identity matrix and $\mathbf{0}_{n \times m}$ the $n \times m$ zero matrix, and t will denote the integer $(n + 1)/16 - 1$.

THEOREM 2. *A perfect code C , with $\bar{0} \in C$, of length n and of rank $r = n - \log(n + 1) + 4$ has a kernel of dimension $k = n - \log(n + 1) - 3$ if and only if C is equivalent to a perfect code $C(V, A)$ satisfying the following three conditions:*

(i)

$$\mathbf{V} = \left(\begin{array}{c|c|c|c|c} 0 & 1 & 2 & \dots & t \\ \hline \mathbf{A}^{(0)} & \mathbf{A}^{(1)} & \mathbf{A}^{(2)} & \dots & \mathbf{A}^{(t)} \end{array} \right) \quad \text{and} \quad \mathbf{A} = \left(\begin{array}{c|c} \mathbf{0}_{s \times 7} & \mathbf{0}_{s \times 1} \\ \hline \mathbf{I}_7 & \mathbf{0}_{7 \times 1} \end{array} \right).$$

(ii) *The set of the columns in each of the matrices $\mathbf{A}^{(i)}$, $i = 1, 2, \dots, t$, constitutes the set of the words of a perfect code C_i of length 7. The set of the columns of the matrix $\mathbf{A}^{(0)}$ constitutes the set of nonzero words of a perfect code C_0 of length 7 such that $\bar{0} \in C_0$.*

(iii) *The rank of the union of the words in the perfect codes $C_0, C_1, C_2, \dots, C_t$ will be equal to seven.*

Note that, from the theorem above, it immediately follows that there are no perfect codes with the parameters $(n, r, k) = (16, 16, 8)$.

Proof. Assume that C satisfies the conditions of the theorem. Then each code $C(V', A^{(i)})$ will be a perfect code of length 7. As the matrix $\mathbf{V}'$ in this case just consists of the columns of weight 1, we get that the set of columns in each matrix $\mathbf{A}^{(i)}$ constitutes the set of the words of the code $C(V', A^{(i)})$; compare Example 3 of section 3. The theorem now follows from Lemma 6. $\square$

INCIDENCE MATRICES OF PROJECTIVE PLANES AND OF SOME REGULAR BIPARTITE GRAPHS OF GIRTH 6 WITH FEW VERTICES*

C. BALBUENA†

Abstract. Let q be a prime power and $r = 0, 1, \dots, q - 3$. Using the Latin squares obtained by multiplying each entry of the addition table of the Galois field of order q by an element distinct from zero, we obtain the incidence matrices of projective planes and the incidence matrices of $(q - r)$ -regular bipartite graphs of girth 6 and $q^2 - rq - 1$ vertices in each partite set. Moreover, in this work two Latin squares of order $q - 1$ with entries belonging to $\{0, 1, \dots, q\}$, not necessarily the same, are defined to be quasi row-disjoint if and only if the Cartesian product of any two rows contains at most one pair (x, x) with $x \neq 0$. Using these quasi row-disjoint Latin squares we find $(q - 1)$ -regular bipartite graphs of girth 6 with $q^2 - q - 2$ vertices in each partite set. Some of these graphs have the smallest number of vertices known so far among the regular graphs with girth 6.

Key words. incidence matrices, Latin squares, projective plane, girth, cages

AMS subject classifications. 05C35, 51A45

DOI. 10.1137/070688225

1. Introduction. Throughout this paper, only undirected simple graphs without loops or multiple edges are considered. Unless otherwise stated, we follow the book by Godsil and Royle [12] and the book by Lint and Wilson [14] for terminology and definitions.

Let $G = (V(G), E(G))$ be a graph with vertex set $V = V(G)$ and edge set $E = E(G)$. The *girth* of a graph G is the number $g = g(G)$ of edges in a smallest cycle. The *degree* of a vertex $v \in V$ is the number of vertices adjacent to v . A graph is called *regular* if all the vertices have the same degree. A *cage* is a k -regular graph with girth g having the smallest possible number of vertices. Simply counting the number of vertices in the distance partition with respect to a vertex yields a lower bound $n_0(k, g)$ on the number of vertices in a cage $n(k, g)$, with the precise form of the bound depending on whether g is even or odd.

$$(1.1) \quad n_0(k, g) = \begin{cases} 1 + k + k(k - 1) + \dots + k(k - 1)^{(g-3)/2} & \text{if } g \text{ is odd;} \\ 2(1 + (k - 1) + \dots + (k - 1)^{g/2-1}) & \text{if } g \text{ is even.} \end{cases}$$

Biggs [6] calls an *excess* of a k -regular graph G the difference $|V(G)| - n_0(k, g)$. Cages have been studied intensely since they were introduced by Tutte [20] in 1947. Erdős and Sachs [9] proved the existence of a graph for any value of the regularity k and the girth g ; thus most of the work carried out has been focused on constructing a smallest one [1, 3, 5, 8, 10, 11, 17, 15, 16, 22]. Biggs is the author of an impressive report on distinct methods for constructing cubic cages [7]. Royle [19] keeps a website in which all the cages known so far appear. More details about constructions on cages can be found in the survey by Wong [22] or in the survey by Holton and Sheehan [13].

†Departament de Matemàtica Aplicada III, Universitat Politècnica de Catalunya, Barcelona, Spain (m.camino.balbuena@upc.edu).

It is conjectured that cages with even girth are bipartite [18, 22]. If the vertices of a bipartite graph are ordered in such a way that the vertices of one partite set come first, then the adjacency matrix can be written in the form

$$(1.2) \quad A = \begin{pmatrix} 0 & N \\ N^\top & 0 \end{pmatrix}.$$

An *incidence graph* is a bipartite graph in which the elements of one partite set are declared as *lines* and the elements of the other partite set are declared as *points*. The terminology for incidence graphs is geometric. A point and a line are said to be *incident* if they are adjacent, thus the submatrix N of (1.2) is called an *incidence matrix* of the bipartite graph. If the number of points and the number of lines coincide, then N is clearly a square matrix. An incidence matrix N defines a *partial plane* when

- any line has at least two points, and
- two points are incident with at most one line.

Consequently, two lines of a partial plane have at most one point in common. The corresponding bipartite graph is called the *incidence graph of the partial plane*. Clearly the incidence graph of a partial plane has even girth $g \geq 6$.

In this work we are interested in the construction of k -regular bipartite graphs of girth 6 with small excess. When the degree $k = p^n + 1$, where $q = k - 1 = p^n$ is a prime power, $(k, 6)$ -cages are obtained as the incidence graphs of *projective planes of order* $q = k - 1$. A projective plane is a partial plane satisfying the following conditions:

- (i) Any two lines meet at a single point.
- (ii) Any two points lie on a single line.
- (iii) There exists a set of four points of which no three are collinear.

As a consequence of these conditions, it follows that a projective plane has $q^2 + q + 1$ lines and $q^2 + q + 1$ points, thus it is said to have *order* q . The incidence graph of a projective plane is a $(q + 1)$ -regular bipartite graph with diameter 3 and girth six. It has $q^2 + q + 1$ vertices in each partite set, and then this graph is a $(q + 1, 6)$ cage because its order achieves the lower bound given in (1.1).

One way for obtaining a projective plane when q is a prime power is to consider the 3-dimensional vector space $\mathbb{F}_q^3$ over the field $\mathbb{F}_q$ with q elements. The points are the 1-dimensional subspaces and the lines are the 2-dimensional subspaces. A point is incident with a line if the 1-dimensional is contained in the 2-dimensional subspace. It is not hard to see that there are $(q^3 - 1)/(q - 1) = q^2 + q + 1$ points and the same number of lines, so this structure is a projective plane denoted by $PG(2, q)$. For more details on this construction of projective planes, see, for example, [4, 12, 14].

In this work we present an alternative way to construct projective planes of order a prime power, and other partial planes whose incidence graphs are k -regular bipartite graphs of girth 6 with small excess. Let us recall that a *Latin square* of order q is a $q \times q$ matrix with entries from a set of q symbols such that each symbol occurs exactly once in each row and exactly once in each column. Using the Latin squares obtained by multiplying each entry of the addition table of the Galois field of order q by an element distinct from zero, we obtain the incidence matrices of projective planes and the incidence matrices of $(q - r)$ -regular bipartite graphs of girth 6 and $q^2 - rq - 1$ vertices in each partite set. q -regular bipartite graphs with q a prime power and $2(q^2 - 1)$ vertices of girth 6 have recently been obtained in [1]. We also improve this result for $r = 1$, finding $(q - 1)$ -regular bipartite graphs of girth 6 with $2(q^2 - q - 2)$ vertices. To do this we use a family of Latin squares called *quasi row-disjoint*, a property that will be introduced in the last section. It follows from (1.1)

that the $(q-1)$ -regular bipartite graphs constructed in this work have an excess $|V(G)| - n_0(q-1, 6) = 2(2q-5)$. The $(q-r)$ -regular bipartite graphs for $r \geq 2$ have an excess of $|V(G)| - n_0(q-r, 6) = 2(rq + q - r^2 - r - 2) = 2(q-r)(r+1) - 4$. In fact, some of these graphs have the smallest number of vertices known so far among the regular graphs with girth 6.

2. C_4 -free set of matrices. Throughout this work let $[[n]]$ denote the set of nonnegative integers $\{0, 1, \dots, n\}$ and $(n) = [[n]] \setminus \{0\} = \{1, \dots, n\}$. Let A be a matrix of order $\alpha \times \beta$ whose elements are subsets of $[[n]]$. Let $P_x(A)$ be a matrix of zeros and ones of the same order as A that satisfies

$$(P_x(A))_{ij} = 1 \text{ if and only if } x \in A_{ij}.$$

Thus, $P_x(A)$ is called the *position matrix of the symbol x in A* . The position matrices of all the symbols in A different from zero give rise to the following $(0, 1)$ -matrix $\mathcal{P}(A)$ of order $\alpha \times n\beta$ called *position matrix of A* :

$$[\mathcal{P}(A)] = [P_1(A) \cdots P_n(A)].$$

Let $\{A^1, A^2, \dots, A^s\}$ be a family of s matrices of the same number of columns whose elements are subsets of $[[n]]$. Then the $(0, 1)$ -matrix spanned by the position matrices of all of them

$$(2.1) \quad \begin{pmatrix} \mathcal{P}(A^1) \\ \mathcal{P}(A^2) \\ \vdots \\ \mathcal{P}(A^s) \end{pmatrix} = \begin{pmatrix} P_1(A^1) & \cdots & P_n(A^1) \\ P_1(A^2) & \cdots & P_n(A^2) \\ & \vdots & \\ P_1(A^s) & \cdots & P_n(A^s) \end{pmatrix}$$

is said to be the *position matrix of the family $\mathcal{F} = \{A^1, A^2, \dots, A^s\}$* . The next example shows two matrices of order 2×2 whose elements are subsets of $[[2]]$ and the position matrix of them. From now on, if there is no confusion the 1-sets will be indicated as integers.

$$(2.2) \quad A^1 = \begin{pmatrix} 1 & 1 \\ 2 & 2 \end{pmatrix}, \quad A^2 = \begin{pmatrix} \{1, 2\} & 0 \\ 0 & \{1, 2\} \end{pmatrix},$$

$$\begin{pmatrix} \mathcal{P}(A^1) \\ \mathcal{P}(A^2) \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{pmatrix}.$$

As already mentioned in the introduction, our main aim is to obtain incidence matrices of bipartite k -regular graphs of girth 6 with small excess. Such incidence matrices shall be incidence matrices of partial planes. A basic known fact is that a $(0, 1)$ -matrix N is the incidence matrix of a partial plane if N is free of any submatrix J_2 of order 2×2 full of ones. Then, to achieve our purpose we propose the following definitions.

DEFINITION 2.1. A family of matrices $\mathcal{F} = \{A^1, A^2, \dots, A^s\}$ of the same number of columns whose elements are subsets of $[[n]]$ is said to be C_4 -free if the position matrix of $\mathcal{F}$ does not contain a submatrix J_2 of order 2×2 full of ones.

Notice that if the position matrix of $\{A^1, A^2\}$ in (2.2) is free of J_2 , then according to Definition 2.1, the set $\{A^1, A^2\}$ is C_4 -free.

Let I_n be the identity matrix and denote by SI_n the matrix obtained from I_n replacing each one with a subset S of $(n]$. It is also clear that the position matrix of SI_n is the incidence matrix of a partial plane consisting of n parallel lines. The above example (2.2) is a particular case of the following helpful remark.

Remark 1. Let A be any C_4 -free matrix of n columns whose entries are 1-sets of $[[n]]$ and S a subset of $(n]$. Then the set $\{A, SI_n\}$ is C_4 -free.

Proof. Note that $P_x(SI_n) = I_n$ for each symbol x in S . Therefore, the position matrix of the set $\{A, SI_n\}$ is J_2 -free because the entries of A are 1-sets. $\square$

Our immediate concern is to obtain some method for constructing families of C_4 -free matrices in such a way that the position matrix of all of them will be a J_2 -free $(0, 1)$ -matrix.

Let us recall that two Latin squares L^1 and L^2 of order n with n distinct symbols are *orthogonal* if all the n^2 pairs of $L^1 \times L^2$ are distinct. The $(1, 3)$ *conjugate* of a Latin square L of order n on n symbols denoted by $(1, 3)L$ is defined by $((1, 3)L)_{ij} = a$ if and only if $(L)_{aj} = i$; that is to say, the $(1, 3)$ conjugate of L is obtained by interchanging the roles of rows and symbols.

THEOREM 2.2. *Let L and Q be two Latin squares of order n both with entries from $(n]$. If L and Q are orthogonal, then their $(1, 3)$ conjugates form a family $\{(1, 3)L, (1, 3)Q\}$ C_4 -free.*

Proof. Suppose $(L)_{ab} = i$, $(L)_{cd} = i$, and $(Q)_{ab} = k$. Since L and Q are orthogonal, then the row x for which $(Q)_{xd} = k$ is never equal to c . The $(1, 3)$ conjugates are $((1, 3)L)_{ib} = a$, $((1, 3)L)_{id} = c$, $((1, 3)Q)_{kb} = a$, and $((1, 3)Q)_{kd} = x$, with $x \neq c$. Therefore, the position matrix of $\{(1, 3)L, (1, 3)Q\}$ is J_2 -free because

$$\begin{pmatrix} (P_a((1, 3)L))_{ib} & (P_c((1, 3)L))_{id} \\ (P_a((1, 3)Q))_{kb} & (P_c((1, 3)Q))_{kd} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}. \quad \square$$

Let q be a prime power and $\mathbb{F}_q$ the Galois field of order q . A set of $q - 1$ mutually orthogonal Latin squares (MOLS) of order q with entries $[[q - 1]]$ are obtained according to the following rule (see [14]):

$$(2.3) \quad (L^u)_{ij} = ui + j, \quad u, i, j \in \mathbb{F}_q, \quad u \neq 0.$$

Let L_q^u be the matrix as defined in (2.3), but the symbol zero is replaced with q . Clearly, the set $\{L_q^u : u \in \mathbb{F}_q \setminus \{0\}\}$ is a set of $q - 1$ MOLS of order q with entries in $[q]$. As a consequence of Theorem 2.2 we obtain the following result.

THEOREM 2.3. *Let q be a prime power and $\mathbb{F}_q$ the Galois field of order q . Then the following assertions hold:*

- (i) *For each $u \in \mathbb{F}_q$, $u \neq 0$ defines the matrix Σ_q^u by $(\Sigma_q^u)_{ij} = u(i + j)$ for $i, j \in \mathbb{F}_q$, $i \neq -j$, and q otherwise. Then $\{\Sigma_q^u : u \in \mathbb{F}_q, u \neq 0\}$ is C_4 -free.*
- (ii) *For each $u \in \mathbb{F}_q$, $u \neq 0$ defines the matrix Υ_q^u by $(\Upsilon_q^u)_{ij} = u(i + j)^{-1}$ for $i, j \in \mathbb{F}_q$, $i \neq -j$, and q otherwise. Then $\{\Upsilon_q^u : u \in \mathbb{F}_q, u \neq 0\}$ is C_4 -free.*
- (iii) *Let Σ^u, Υ^u be the Latin squares obtained from Σ_q^u and Υ_q^u , respectively, by replacing symbol q with zero. If M is the position matrix of $\{\Sigma^u : u \in \mathbb{F}_q, u \neq 0\}$, then the transpose of M is the position matrix of $\{\Upsilon^u : u \in \mathbb{F}_q, u \neq 0\}$.*

Proof. (i) Let $a = u(i + j)$ for $u, i, j \in \mathbb{F}_q$, $u \neq 0$, $i \neq -j$. Then the entry (a, j) of the $(1, 3)$ conjugate of the Latin square Σ^u is $((1, 3)\Sigma^u)_{aj} = i = u^{-1}a - j$; and for $i = -j$ we have $((1, 3)\Sigma^u)_{qj} = -j$ because $(\Sigma^u)_{-j, j} = q$. According to (2.3) the family $\{(1, 3)\Sigma^u : u \in \mathbb{F}_q, u \neq 0\}$ is a set of $q - 1$ MOLS of order q with entries from $[q]$. Hence by Theorem 2.2 we obtain that $\{\Sigma^u : u \in \mathbb{F}_q, u \neq 0\}$ is C_4 -free. Thus point (i) is valid.

(ii) Let $b = u(i + j)^{-1}$ for $u, i, j \in \mathbb{F}_q, u \neq 0, i \neq -j$. Then the entry (b, j) of the $(1, 3)$ conjugate of the Latin square Υ^u is $((1, 3)\Upsilon^u)_{bj} = i = ub^{-1} - j$; and for $i = -j$ we have $((1, 3)\Upsilon^u)_{qj} = -j$ because $(\Upsilon^u)_{-j,j} = q$. Then $\{\Upsilon_q^u : u \in \mathbb{F}_q, u \neq 0\}$ is a set of $q - 1$ MOLS of order q with entries from $(q]$ and again by Theorem 2.2 we conclude point (ii).

(iii) Let $P_x(\Sigma^u)$ be the position matrix of the element x in Σ^u , and observe that $P_x(\Sigma^u)$ is a symmetric matrix because $(P_x(\Sigma^u))_{ij} = 1$ if and only if $u(i + j) = x$, $i, j, x, u \in \mathbb{F}_q, u, x \neq 0$. Similarly let $P_x(\Upsilon^w)$ denote the position matrix of element x in Υ^w , which is also symmetric. According to (2.1), the position matrix of $\{\Sigma^u : u \in \mathbb{F}_q, u \neq 0\}$ is

$$M = \begin{pmatrix} P_1(\Sigma^1) & \cdots & P_{q-1}(\Sigma^1) \\ \vdots & \vdots & \vdots \\ P_1(\Sigma^{q-1}) & \cdots & P_{q-1}(\Sigma^{q-1}) \end{pmatrix},$$

and the position matrix of $\{\Upsilon^u : u \in \mathbb{F}_q, u \neq 0\}$ is

$$M^D = \begin{pmatrix} P_1(\Upsilon^1) & \cdots & P_{q-1}(\Upsilon^1) \\ \vdots & \vdots & \vdots \\ P_1(\Upsilon^{q-1}) & \cdots & P_{q-1}(\Upsilon^{q-1}) \end{pmatrix}.$$

To see that M^D is the transpose of M let us show that the column x of M is the row x of M^D ; i.e., let us show that $P_x(\Sigma^w) = P_w(\Upsilon^x)$. Since $(P_x(\Sigma^w))_{ij} = 1$ if and only if $w(i + j) = x$, then $i \neq -j$ because $x \neq 0$, hence $w = x(i + j)^{-1}$ yielding $(P_w(\Upsilon^x))_{ij} = 1$. Therefore the theorem is valid. $\square$

3. Method. Let us call *array of r symbols and n columns* the matrix of order $r \times n$

$$O_{r,n} = \begin{pmatrix} 1 & \cdots & 1 \\ 2 & \cdots & 2 \\ \vdots & \vdots & \vdots \\ r & \cdots & r \end{pmatrix}.$$

When $r = n$ the array is denoted by O_n . It is easy to see that $O_{r,n}$ is a C_4 -free matrix defined on $(r]$. Let $(k)]I_n$ denote the matrix obtained from the identity matrix I_n of order n by replacing each one with the set $(k]$.

The following theorem is a consequence of Theorem 2.3, and gives a general method for constructing the desired k -regular bipartite graphs of girth 6 when $k = q, q + 1$. The position matrix of $O_{q,n}$ will play an important role in what follows, and as in the above sections it will be denoted by $[\mathcal{P}(O_{q,n})]$.

THEOREM 3.1. *Let q be a prime power and $\mathbb{F}_q$ a finite Galois field of q elements. Let us consider the Latin squares $\Sigma^u = [u(i + j)]$ with $u, i, j \in \mathbb{F}_q, u \neq 0$, and the Latin squares Σ_q^u obtained from Σ^u by replacing 0 with q . Then the following assertions hold:*

- (i) *Assume $q \geq 3$. The position matrix of $\{\Sigma_q^1, \Sigma_q^2, \dots, \Sigma_q^{q-1}, (q)]I_q\}$ (given by (2.1)) is the incidence matrix of a q -regular bipartite graph of girth 6 and q^2 vertices in each partite set.*
- (ii) *The position matrix A of $\{\Sigma_q^1, \Sigma_q^2, \dots, \Sigma_q^{q-1}, (q)]I_q, O_q\}$ is the incidence matrix of an affine plane of order q .*

Let j_{q+1} be the row-matrix of order $1 \times (q+1)$ full of ones. The following $(0,1)$ -matrix

$$(3.1) \quad \begin{array}{|c|c|} \hline A & \mathcal{P}(O_{q+1,q})^\top \\ \hline 0 \cdots 0 & j_{q+1} \\ \hline \end{array}$$

is the incidence matrix of a projective plane of order q .

- (iii) Let M be the position matrix of $\{\Sigma^1, \Sigma^2, \dots, \Sigma^{q-2}, (q-1][I_q, O_{q-1,q}\}$. Then $[M | \mathcal{P}(O_{q-1,q})^\top]$ is the incidence matrix of a q -regular bipartite graph of girth 6 and $q^2 - 1$ vertices in each partite set.

Proof. (i) From Theorem 2.3 we know that $\{\Sigma_q^u : u \in \mathbb{F}_q \setminus \{0\}\}$ is C_4 -free, and moreover, by Remark 1, we know that $\{(q)[I_q, \Sigma_q^u]\}$ is C_4 -free. Thus it follows that $\mathcal{F} = \{\Sigma_q^1, \Sigma_q^2, \dots, \Sigma_q^{q-1}, (q)[I_q]\}$ is a C_4 -free family; that is, the position matrix N of $\mathcal{F}$ is free of J_2 . Since each matrix of $\mathcal{F}$ has q symbols in each one of its rows, then there are q ones in each row of N . On the other hand, the position matrix B of $\{\Sigma^1, \Sigma^2, \dots, \Sigma^{q-1}\}$ is a submatrix of N obtained by deleting the q last rows and the q last columns of N . From item (iii) of Theorem 2.3, it follows that the transpose $B^\top$ of B is the position matrix of $\{\Upsilon^1, \Upsilon^2, \dots, \Upsilon^{q-1}\}$. By the definition of the matrices Υ^u it is clear that there are $q-1$ ones in each row of $B^\top$. Therefore B also has $q-1$ ones in each column, and hence N has q ones in each column; thus N is the incidence matrix of a q -regular bipartite graph of q^2 vertices in each partite set of girth 6 (notice that the number of vertices of the constructed graphs is strictly less than the lower bound given in (1.1) for $g = 8$).

(ii) From Theorem 2.3 and by Remark 1, it follows that the position matrix A of $\{\Sigma_q^1, \Sigma_q^2, \dots, \Sigma_q^{q-1}, (q)[I_q, O_q]\}$ is free of J_2 , and clearly, there are q ones in each row of A . By item (i) we know that the position matrix of $\{\Sigma_q^1, \Sigma_q^2, \dots, \Sigma_q^{q-1}, (q)[I_q]\}$ has order $q^2 \times q^2$ and q ones in each row and column. Consequently, the matrix A has order $(q^2 + q) \times q^2$ and has q ones in each row and $q+1$ ones in each column. Hence, considering the rows of A as lines of a partial plane and the columns as points, the matrix A may be seen as the incidence matrix of an affine plane of order q . Thus a projective plane can be obtained by adding $q+1$ points (columns) and one new line (row) containing them. The $q+1$ points correspond to the last $q+1$ columns of (3.1) and the new line is the last row.

(iii) The position matrix M of $\{\Sigma^1, \Sigma^2, \dots, \Sigma^{q-2}, (q-1)[I_q, O_{q-1,q}]\}$ is a submatrix of the block A of (3.1). Indeed, Σ^u is obtained by replacing q with 0 in Σ_q^u . This is equivalent to deleting in A the last q columns. Moreover, now matrix Σ^{q-1} is not considered, which is equivalent to deleting in A the q rows corresponding to the position matrix of Σ^{q-1} . And take $O_{q-1,q}$ instead of O_q is the same as deleting in A the last row. Therefore $[M | \mathcal{P}(O_{q-1,q})^\top]$ is a submatrix of (3.1) and so is free of J_2 . This $(0,1)$ -matrix has $q^2 - 1$ rows and $(q^2 - q) + (q - 1) = q^2 - 1$ columns and, by construction, there are q ones in each row and in each column. Hence, it is the incidence matrix of a q -regular bipartite graph of $q^2 - 1$ vertices in each partite set and girth 6 (notice that the number of vertices of the constructed graphs is strictly less than the lower bound given in (1.1) for $g = 8$). $\square$

To illustrate the method contained in Theorem 3.1, let us consider the first cases $q = 2, 3, 4$. From now on, if there is no confusion a t -set $\{x_1, x_2, \dots, x_t\}$ will be denoted as a sequence of integers $x_1 x_2 \cdots x_t$.

Case $q = 2, 3$. The Latin squares provided by Theorem 2.3 and the incidence matrix of projective plane $PG(2, 2)$ (called Fano plane) and the incidence matrix of projective plane $PG(2, 3)$ given in (3.1) are the following:

Σ_2^1	2	1	0	1	0	1	0	0
	1	2	1	0	0	1	1	0
$(2)]I_2$	12	0	1	0	1	0	0	1

	3	3	3	3	3	0	0	0	0	0	0	0	0	1	1	1	1	0	0	0

$$\Sigma_2^1 = \begin{bmatrix} 0 & 1 & 2 & 0 & 0 \\ 1 & 2 & 0 & 0 & 0 \\ 2 & 3 & 0 & 0 & 1 \\ 3 & 0 & 0 & 1 & 2 \\ 0 & 0 & 1 & 2 & 0 \end{bmatrix} \quad \Sigma_2^2 = \begin{bmatrix} 0 & 2 & 0 & 1 & 0 \\ 2 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 2 \\ 1 & 3 & 0 & 2 & 0 \\ 3 & 0 & 2 & 0 & 1 \end{bmatrix} \quad \Sigma_2^{2*} = \begin{bmatrix} 1 & 3 & 0 & 2 & 0 \\ 3 & 0 & 2 & 0 & 1 \end{bmatrix} \quad O_{2,5}^* = \begin{bmatrix} 0 & 1 & 1 & 1 & 0 \\ 2 & 2 & 0 & 0 & 2 \end{bmatrix}$$

$$(3)_I I_5^* = \begin{bmatrix} 123 & 0 & 0 & 0 & 0 \\ 0 & 123 & 0 & 0 & 0 \\ 0 & 0 & 123 & 0 & 0 \\ 0 & 0 & 3 & 12 & 0 \\ 0 & 0 & 3 & 0 & 12 \end{bmatrix} \quad O_* = \boxed{1 \ 1 \ 0 \ 0 \ 1}$$

Proof. Note that $[M \mid \mathcal{P}(O^*)^\top]$ is a matrix free of J_2 because it is a submatrix of (3.1) by changing some ones for zeros. Besides, M has order $(q^2 - rq - 1) \times q(q - r)$,

and the last $q - r - 1$ columns of M are full of zeros, because in the last $q - r - 1$ columns of each Σ_r^u we have replaced the entry $q - r$ with zero. Thus, we consider the matrix M' once eliminating from M these columns full of zeros. Hence M' has order $(q^2 - rq - 1) \times (q(q - r) - (q - r - 1))$. Furthermore, notice that each of the $q^2 - rq - q + r + 1$ columns of M' has $q - r$ ones according to the definition of M' . On the other hand, the rows of the position matrix corresponding to $\{\Sigma_{r*}^{q-r-1}, (q - r)]I_q^*, O_{q-r-1,q}^*\}$ have $q - r$ ones each because of the definition of these matrices. Therefore, since the value $q - r$ remains in the first r columns of each Σ_r^u , $u = 1, \dots, q - r - 2$, then there are $(q - r - 2)(q - r)$ rows in M' having $q - r - 1$ ones, and the remaining rows have $q - r$ ones each. By joining $\mathcal{P}(O_*)^\top$ to M' we put $q - r - 2$ more columns, that due to the definition of O_* add an additional one just in the rows which had $q - r - 1$ ones in M' . Therefore $[M' | \mathcal{P}(O_*)^\top]$ is the incidence matrix of a $(q - r)$ -regular bipartite graph with $q^2 - rq - 1$ vertices in each partite set and girth at least 6. Since the number of vertices of the constructed graphs is strictly less than the lower bound given in (1.1) for $q = 8$, then the girth is 6. $\square$

To illustrate the method of Theorem 3.2 let us consider the first cases $q = 4, 5$.

Case $q = 4$ and $r = 1$. The matrices of Theorem 3.2 and the incidence matrix of a 3-regular bipartite graph of girth 6 with 11 vertices in each partite set are the following:

Σ_1^1	0	1	2	0	0	1	0	0	0	0	0	1	0	0	0	0	1
	1	0	0	2	1	0	0	0	0	0	0	1	0	0	0	0	1

The matrix M' of Theorem 3.2 is obtained by deleting columns 14 and 15 which are full of zeros.

4. Improvement for $(q-1)$ -regular bipartite graphs of girth 6. In this section we improve Theorem 3.2 for $r = 1$, finding incidence matrices of $(q-1)$ -regular bipartite graphs of girth 6 with $q^2 - q - 2$ vertices in each partite set. To this end we need to introduce the following definition.

DEFINITION 4.1. Two C_4 -free matrices A^1 and A^2 of the same number of columns whose elements are 1-sets of $[[n]]$ are said to be quasi row-disjoint if and only if the Cartesian product of any two rows $(A^1)_i, (A^2)_h$ contains at most one pair $(x, x) \in (A^1)_i \times (A^2)_h$ with $x \neq 0$.

An example of two quasi row-disjoint Latin squares of order 3×3 , one with entries in $\{3\}$ and the other with entries in $\{3\} \setminus \{1\}$, is the following.

$$(4.1) \quad L^1 = \begin{pmatrix} 1 & 2 & 3 \\ 2 & 3 & 1 \\ 3 & 1 & 2 \end{pmatrix} \quad L^2 = \begin{pmatrix} 0 & 3 & 2 \\ 3 & 2 & 0 \\ 2 & 0 & 3 \end{pmatrix}.$$

We can check by superimposing any two rows of L^1 and L^2 that there is at most one resulting pair (x, x) with $x \neq 0$. Then L^1 and L^2 are quasi row-disjoint.

THEOREM 4.2. Let Q^1 and Q^2 be two C_4 -free matrices of the same number of columns and whose elements are 1-sets of $[[n]]$. Then Q^1 and Q^2 are quasi row-disjoint if and only if the family $\{Q^1, Q^2\}$ is C_4 -free.

Proof. Let $(Q^\ell)_i$ denote the row i of Q^ℓ , $\ell = 1, 2$. Assume that $(x, x) \in (Q^1)_i \times (Q^2)_h$ with $x \in [[n]]$, $x \neq 0$. Then $x = (Q^1)_{ij} = (Q^2)_{hj}$ or, equivalently $(P_x(Q^1))_{ij} = (P_x(Q^2))_{hj} = 1$, for some column j , where $P_x(Q^\ell)$ is the position matrix of x in Q^ℓ .

If Q^1 and Q^2 are not quasi row-disjoint, then there exists $(y, y) \in (Q^1)_i \times (Q^2)_h$ with $y \in [[n]] \setminus \{x, 0\}$. This implies that $(P_y(Q^1))_{ik} = (P_y(Q^2))_{hk} = 1$ with $k \neq j$, and therefore the position matrix of $\{Q^1, Q^2\}$ contains a submatrix J_2 ; i.e., $\{Q^1, Q^2\}$ is not C_4 -free.

Conversely, if the position matrix of $\{Q^1, Q^2\}$ contains J_2 as a submatrix, then there exists $y \in [[n]] \setminus \{x, 0\}$ such that $(P_y(Q^1))_{ik} = (P_y(Q^2))_{hk} = 1$, or in other words, $y = (Q^1)_{ik} = (Q^2)_{hk}$, $k \neq j$. Hence Q^1, Q^2 are not quasi row-disjoint. $\square$

As a consequence of Theorems 2.3, Remark 1, and Theorem 4.2, the following corollary is now clear.

COROLLARY 4.3. Let q be a prime power and $\mathbb{F}_q$ the Galois field of order q . The family $\{\Sigma_q^u : u \in \mathbb{F}_q\} \cup \{(q)I_q, O_q\}$ is a set of $q+1$ quasi row-disjoint matrices of order q with entries in $[[q]]$.

Next, we construct a family of mutually quasi row-disjoint matrices of order $q-1$ by adding to each entry of the product table of the cyclic group $(\mathbb{F}_q \setminus \{0\}, \cdot)$ an element of the Galois field $\mathbb{F}_q$.

THEOREM 4.4. Let $q \geq 4$ be a prime power and $\mathbb{F}_q$ the Galois field of order q . Then the following assertions are true.

- (i) For every $u \in \mathbb{F}_q$ define the matrix Π^u by $(\Pi^u)_{ij} = u + ij$, $i, j \in \mathbb{F}_q, i, j \neq 0$. Then the family $\{\Pi^u : u \in \mathbb{F}_q\}$ is C_4 -free.
- (ii) For every $u \in \mathbb{F}_q$ define the matrix D^u by $(D^u)_{ij} = u - ij$, $i, j \in \mathbb{F}_q, i, j \neq 0$. Then the family $\{D^u : u \in \mathbb{F}_q\}$ is C_4 -free.
- (iii) If N is the position matrix of $\{\Pi^u : u \in \mathbb{F}_q, u \neq 0\}$, then the transpose of N is the position matrix of $\{D^u : u \in \mathbb{F}_q, u \neq 0\}$.
- (iv) Let N be the position matrix of $\{\Pi^3, \dots, \Pi^{q-1}, \Pi^0, (q-1)I_{q-1}, O_{q-1}^2\}$, where O_{q-1}^2 is the matrix obtained from O_{q-1} by deleting the first two rows. Then

the $(0, 1)$ -matrix $[N|\mathcal{P}(O_{q-3,q-1})^\top]$ is the incidence matrix of a $(q-1)$ -regular bipartite graph of girth 6 and $q^2 - q - 2$ vertices in each partite set.

Proof. (i) Clearly $\{\Pi^u = [ij + u] : u, i, j \in \mathbb{F}_q, i, j \neq 0\}$ is a set of q Latin squares of order $q - 1$, each one with entries from $[[q - 1]] \setminus \{u\}$, because $ij + u = u$ implies $i = 0$ or $j = 0$ which is impossible by definition of Π^u . Let us see that they are mutually quasi row-disjoint. Suppose $(\Pi^w)_{ij} = (\Pi^u)_{kj}$ for some $u, w \in \mathbb{F}_q$ with $u \neq w$ and $i, j, k \neq 0$. Therefore

$$ij + w = kj + u.$$

If the Latin squares are not quasi row-disjoint, then there exists $h \neq j$, $h \neq 0$, such that $(\Pi^w)_{ih} = (\Pi^u)_{kh}$, that is,

$$ih + w = kh + u.$$

Hence $i(j - h) = k(j - h)$. As $j \neq h$, then $j - h$ has an inverse respect to the product in the cyclic group $\mathbb{F}_q \setminus \{0\}$ yielding $i = k$, thus $u = w$ which is a contradiction. Therefore Π^u and Π^w are quasi row-disjoint, and hence by Theorem 4.2 we conclude that $\{\Pi^u : u \in \mathbb{F}_q\}$ is C_4 -free.

(ii) The proof of this item is the same as the proof of item (i).

(iii) Reasoning as in the proof of item (iii) of Theorem 2.3, it is enough to prove that $P_k(\Pi^w) = P_w(D^k)$ for all $k, w \in \mathbb{F}_q$, $k \neq 0$. Since $(P_k(\Pi^w))_{ij} = 1$ if and only if $w + ij = k$, hence $w = k - ij$ if and only if $(P_w(D^k))_{ij} = 1$. Then (iii) is valid.

(iv) By point (i) we know that $\{\Pi^u : u \in \mathbb{F}_q\}$ is C_4 -free. It is not difficult to see that O_{q-1} is quasi row-disjoint with each Π^u , and using Remark 1 we obtain that $\{\Pi^u : u \in \mathbb{F}_q\} \cup \{(q-1)I_{q-1}, O_{q-1}\}$ is a C_4 -free family of $q + 2$ mutually quasi-row-disjoint C_4 -free matrices of order $(q-1) \times (q-1)$ whose entries are subsets of $[[q-1]]$. Therefore the position matrix N of $\{\Pi^3, \dots, \Pi^{q-1}, \Pi^0, (q-1)I_{q-1}, O_{q-1}^2\}$ is free of J_2 .

Moreover, we have for all $u \in \mathbb{F}_q$ that the entries of Π^u belong to $[[q-1]] \setminus \{u\}$. Hence the rows of the position matrix of each Π^u have $q-2$ ones for $u \neq 0$, and $q-1$ ones for $u = 0$. Let A be the position matrix of $\{\Pi^1, \dots, \Pi^{q-1}\}$. From item (iii) it follows that $A^\top$ is the position matrix of $\{D^1, \dots, D^{q-1}\}$. This implies that the columns of matrix A have $q-2$ ones. Then deleting the matrices Π^1 and Π^2 results in a submatrix A' of A which has $q-3$ ones in $2(q-1)$ columns and $q-4$ ones in the $(q-3)(q-1)$ remaining columns. Let B be the position matrix of $\{\Pi^0, (q-1)I_{q-1}\}$, which is readily seen to have 2 ones in each column and $q-1$ ones in each row. Therefore joining to A' the rows of B we obtain a matrix C which has $q-1$ ones in $2(q-1)$ columns and $q-2$ ones in the $(q-3)(q-1)$ remaining columns. Finally, adding to C the rows of the position matrix of O_{q-1}^2 we obtain the matrix N having $q-1$ ones in each column. Thus, $[N|\mathcal{P}(O_{q-3,q-1})^\top]$ is the incidence matrix of a $(q-1)$ -regular bipartite graph of girth 6 and $q^2 - q - 2$ vertices in each partite set. $\square$

To illustrate the method contained in Theorem 4.4, let us consider the case $q = 4$.

Case $q = 4$. The C_4 -free quasi row-disjoint matrices provided by Theorem 4.4 and the incidence matrix of a 3-regular bipartite graph of girth 6 with 10 vertices in each partite set are the following:

5. Conclusions. We have presented a method providing the incidence matrices of both affine planes and projective planes of order q , and q -regular bipartite graphs with $q^2 - 1$ vertices in each partite set when q is a prime power. From these incidence matrices, we obtain the incidence matrices of $(q - r)$ -regular bipartite graphs of girth 6 having $q^2 - rq - 1$ vertices in each partite set. Furthermore, using quasi row-disjoint Latin squares we improve this result for $r = 1$ finding $(q - 1)$ -regular bipartite graphs of girth 6 with $q^2 - q - 2$ vertices in each partite set. Table 5.1 shows a comparison between the number of vertices of some known smallest graphs [1, 19] and the graphs provided by the method proved in this work. We consider only degrees k in the interval $[q - r, q + 1]$ in which the only prime power is q , and $q - r$ is different from a prime power plus one.

Acknowledgments. I would like to express my thanks to the referees for their helpful comments and suggestions. Overall I want to thank to Kevin Phelps for suggesting to me that the Latin squares obtained by multiplying each entry of the addition table of the Galois field by an element distinct from zero are the $(1, 3)$ conjugates of Latin squares of a complete set of MOLS.

NEARLY OPTIMAL VISIBILITY REPRESENTATIONS OF PLANE GRAPHS*

XIN HE[†] AND HUAMING ZHANG[‡]

Abstract. The *visibility representation* (VR for short) is a classical representation of plane graphs. The VR has various applications and has been extensively studied in the literature. One of the main focuses of the study is to minimize the size of the VR. It is known that there exists a plane graph G with n vertices, where any VR of G requires a size at least $(\lfloor \frac{2n}{3} \rfloor) \times (\lfloor \frac{4n}{3} \rfloor - 3)$. For upper bounds, it is known that every plane graph has a VR with height at most $\lfloor \frac{4n-1}{5} \rfloor$, and a VR with width at most $\lfloor \frac{13n-24}{9} \rfloor$. In this paper, we prove that every plane graph has a VR with height at most $\frac{2n}{3} + 2\lceil \sqrt{n/2} \rceil$, and a VR with width at most $\frac{4n}{3} + 2\lceil \sqrt{n} \rceil$. These representations are nearly optimal in the sense that they differ from the lower bounds only by a lower order additive term. Both representations can be constructed in linear time. Our presentations use Schnyder's realizer to construct the *st*-orientations of plane graphs with special properties. As the *st*-orientation is a very useful concept in other applications, this result may be of independent interest.

Key words. plane graph, plane triangulation, visibility representation, *st*-orientation

1. Introduction. Drawing plane graphs has emerged as a fast growing research area in recent years (see [7] for a survey). Several important concepts have been introduced for solving graph drawing problems, including the *canonical orderings* and *canonical ordering trees* of 3-connected plane graphs [10, 11, 12]; the *orderly spanning trees*, which generalize canonical ordering trees [5, 4, 6, 16]; the *well-orderly trees*, which are canonical ordering trees with some special properties [2], and *Schnyder's realizers* [23, 24]. These concepts and techniques have been successfully used in graph drawing, graph encoding, and graph generation [3, 1, 9, 18].

A *visibility representation* (VR for short) of a plane graph G is a drawing of G , where the vertices of G are represented by nonoverlapping horizontal line segments (called *vertex segments*), and each edge of G is represented by a vertical line segment touching the vertex segments of its end vertices. Figure 2.1 shows a VR of a plane graph G . The problem of computing a compact VR is important not only in algorithmic graph theory, but also in practical applications. A simple linear time VR algorithm was given in [22, 25] for 2-connected plane graphs. It uses an *st*-orientation of G and the corresponding *st*-orientation of its *st*-dual G^* to construct a VR. Using this approach, the height of the VR is bounded by $(n - 1)$ and the width of the VR is bounded by $(2n - 5)$ [22, 25].

As in many other graph drawing problems, one of the main concerns in the VR research is to minimize the size of the representation. For the lower bounds, it was shown in [27] that there exists a plane graph G with n vertices where any VR of G

requires a size at least $(\lfloor \frac{2n}{3} \rfloor) \times (\lfloor \frac{4n}{3} \rfloor - 3)$. Some work has been done to reduce the height and the width of the VR by carefully constructing special *st*-orientations. The following table summarizes related previous results.

Plane graph		4-connected plane graph	
Width	Height	Width	Height
$\leq (2n - 5)$ [22, 25]	$\leq (n - 1)$ [22, 25]		
$\leq \lfloor \frac{3n-6}{2} \rfloor$ [13]			
$\leq \lfloor \frac{22n-42}{15} \rfloor$ [17]		$\leq (n - 1)$ [14]	
	$\leq \lfloor \frac{5n}{6} \rfloor$ [27]		
$\leq \lfloor \frac{13n-24}{9} \rfloor$ [28]	$\leq \lfloor \frac{4n-1}{5} \rfloor$ [29]		$\leq \lceil \frac{3n}{4} \rceil$ [26]

All these results concentrated on one dimension of the VR (either the width or the height), with the other dimension bounded by the trivial upper bound (namely, $n - 1$ for the height and $2n - 5$ for the width). In [20, 21], heuristic algorithms were developed aiming at reducing the height and the width of VRs simultaneously.

In this paper, we prove that every plane graph of n vertices has a VR with height at most $\frac{2n}{3} + 2\lceil \sqrt{n/2} \rceil$ (and width at most $2n - 5$), and another VR with width at most $\frac{4n}{3} + 2\lceil \sqrt{n} \rceil$ (and height at most $n - 1$). These representations are nearly optimal in the sense that they differ from the lower bounds only by a lower order additive term. Both representations can be constructed in linear time. Our VRs use Schnyder's realizer to construct *st*-orientations of plane graphs with special properties. As the *st*-orientation is a very useful concept in other applications, this result may be of independent interest.

The present paper is organized as follows. Section 2 introduces preliminaries. Section 3 presents the construction of a VR with nearly optimal height. Section 4 presents the construction of a VR with nearly optimal width. Section 5 concludes the paper.

2. Preliminaries. In this section, we give definitions and preliminary results. Definitions not mentioned here are standard.

A *planar graph* is a graph G such that the vertices of G can be drawn in the plane and the edges of G can be drawn as nonintersecting curves. Such a drawing is called an *embedding*. The embedding divides the plane into a number of connected regions. Each region is called a *face*. The unbounded face is the *external face*. The other faces are *internal faces*. A *plane graph* is a planar graph with a fixed embedding. A *plane triangulation* is a plane graph where every face is a triangle (including the external face). We abbreviate the words “counterclockwise” and “clockwise” as ccw and cw, respectively.

When discussing VRs, we assume the input graph G is a plane triangulation. (If not, we get a plane triangulation G' by adding dummy edges into G . After constructing a VR for G' , we can get a VR of G by deleting the vertical line segments for the dummy edges.)

A *numbering* $\mathcal{O}$ of a set $S = \{a_1, \dots, a_k\}$ is a one-to-one mapping between S and the set $\{1, 2, \dots, k\}$. We write $\mathcal{O} = \langle a_{i_1}, a_{i_2}, \dots, a_{i_k} \rangle$ to indicate $\mathcal{O}(a_{i_1}) = 1$, $\mathcal{O}(a_{i_2}) = 2$, etc. A set S with a numbering written this way is called an *ordered list*. For two elements a_i and a_j , if a_i is assigned a smaller number than a_j in $\mathcal{O}$, we write $a_i \prec_{\mathcal{O}} a_j$. Let S_1 and S_2 be two disjoint sets. If $\mathcal{O}_1$ is a numbering of S_1 and $\mathcal{O}_2$ is a numbering of S_2 , their concatenation, written as $\mathcal{O} = \langle \mathcal{O}_1, \mathcal{O}_2 \rangle$, is the numbering of $S_1 \cup S_2$, where $\mathcal{O}(x) = \mathcal{O}_1(x)$ for all $x \in S_1$ and $\mathcal{O}(y) = \mathcal{O}_2(y) + |S_1|$ for all $y \in S_2$.

G is called a *directed graph* (digraph for short) if each edge of G is assigned a direction. An *orientation* of an (undirected) graph G is a digraph obtained from G by assigning a direction to each edge of G . We will use G to denote both the resulting digraph and the underlying undirected graph unless otherwise specified. (Its meaning will be clear from the context.)

Let $G = (V, E)$ be an undirected graph. A numbering $\mathcal{O}$ of V induces an orientation of G as follows: each edge of G is directed from its lower numbered end vertex to its higher numbered end vertex. The resulting digraph is called the *orientation derived from $\mathcal{O}$* which, obviously, is an acyclic digraph. We use $\text{length}_G(\mathcal{O})$ (or simply $\text{length}(\mathcal{O})$ if G is clear from the context) to denote the length of the longest path in the orientation of G derived from $\mathcal{O}$. (The length of a path is the number of edges in it.)

For a 2-connected plane graph G and an external edge (s, t) , an orientation of G is called an *st-orientation* if the resulting digraph is acyclic with s as the only source and t as the only sink. Such a digraph is also called an *st-graph*. Lempel, Even, and Cederbaum [15] showed that for every 2-connected plane graph G and an external edge (s, t) , there exists an *st-orientation*. For more properties of *st-orientation* and *st-graph*, we refer readers to [19].

Let G be a 2-connected plane graph and (s, t) an external edge. An *st-numbering* of G is a one-to-one mapping $\xi : V \rightarrow \{1, 2, \dots, n\}$, such that $\xi(s) = 1$, $\xi(t) = n$, and each vertex $v \neq s, t$ has two neighbors u, w with $\xi(u) < \xi(v) < \xi(w)$, where u (w , respectively) is called a *smaller neighbor* (*bigger neighbor*, respectively) of v . Given an *st-numbering* ξ of G , the orientation of G derived from ξ is obviously an *st-orientation* of G . On the other hand, if $G = (V, E)$ has an *st-orientation* $\mathcal{O}$, we can define a one-to-one mapping $\xi : V \rightarrow \{1, \dots, n\}$ by topological sort. It is easy to see that ξ is an *st-numbering* and the orientation derived from ξ is $\mathcal{O}$. From now on, we will interchangeably use the term “an *st-numbering*” of G and the term “an *st-orientation*” of G , where each edge of G is directed accordingly.

DEFINITION 2.1. Let G be a plane graph with an *st-orientation* $\mathcal{O}$, where (s, t) is an external edge drawn at the left on the external face of G . The *st-dual graph* G^* of G and the dual orientation $\mathcal{O}^*$ of $\mathcal{O}$ is defined as follows:

- Each face f of G corresponds to a node f^* of G^* . In particular, the unique internal face adjacent to the edge (s, t) corresponds to a node s^* in G^* ; the external face corresponds to a node t^* in G^* .
- For each edge $e \neq (s, t)$ of G separating a face f_1 on its left and a face f_2 on its right, there is a dual edge e^* in G^* from f_1^* to f_2^* .
- The dual edge of the external edge (s, t) is directed from s^* to t^* .

Figure 2.1(1) shows an *st-graph* G and its *st-dual graph* G^* (where circles and solid lines denote the vertices and the edges of G ; squares and dashed lines denote the nodes and the edges of G^*). It is well known that the *st-dual graph* G^* defined above is an *st-graph* with source s^* and sink t^* . The correspondence between an *st-orientation* $\mathcal{O}$ of G and the dual *st-orientation* $\mathcal{O}^*$ is a one-to-one correspondence. The following theorem was given in [22, 25].

THEOREM 2.2. Let G be a 2-connected plane graph with an *st-orientation* $\mathcal{O}$. Let $\mathcal{O}^*$ be the dual *st-orientation* of the *st-dual graph* G^* . A VR of G can be obtained from $\mathcal{O}$ in linear time. The height of the VR is $\text{length}(\mathcal{O}) \leq n - 1$. The width of the VR is $\text{length}(\mathcal{O}^*) \leq 2n - 5$.

Figure 2.1(2) shows a VR of the graph G shown in Figure 2.1(1). The width of the VR is $\text{length}(\mathcal{O}^*) = 4$. The height of the VR is $\text{length}(\mathcal{O}) = 3$.

FIG. 2.1. (1) An st -graph G and its st -dual graph G^* ; (2) a VR of G .FIG. 2.2. Edge pattern around an internal vertex v .

The following concept was introduced in [23] and is of central importance in our VR construction.

DEFINITION 2.3. Let G be a plane triangulation of n vertices with three external vertices v_1, v_2, v_n in ccw order. A realizer $\mathcal{R} = \{T_1, T_2, T_n\}$ of G is a partition of its internal edges into three sets T_1, T_2, T_n of directed edges such that the following hold:

- For each $i \in \{1, 2, n\}$, the internal edges incident to v_i are in T_i and directed towards v_i .
- For each internal vertex v of G , v has exactly one edge leaving v in each of T_1, T_2, T_n . The ccw order of the edges incident to v is leaving in T_1 , entering in T_n , leaving in T_2 , entering in T_1 , leaving in T_n , and entering in T_2 . Each entering block may be empty. (See Figure 2.2.)

Figure 2.3 shows a realizer of a plane triangulation G . The dashed lines (dotted lines and solid lines, respectively) are the edges in T_1 (T_2 and T_n , respectively).

In [23], Schnyder showed that every plane triangulation G has a realizer which can be constructed in linear time. It was also shown that each set T_i of a realizer is a tree rooted at v_i . For each T_i , we denote by $\bar{T}_i$ the tree composed of T_i augmented with the two edges of the external face incident to the root v_i of T_i . Obviously $\bar{T}_i$ is a spanning tree of G . For example, in Figure 2.3, $\bar{T}_n$ is T_n (the tree in solid lines)

FIG. 2.3. A plane triangulation G and a realizer $\mathcal{R}$ of G .

augmented with the edges (v_1, v_n) and (v_2, v_n) , which is a spanning tree of G .

For each internal vertex v of G and $i \in \{1, 2, n\}$, $p_i(v)$ denotes the path in $\bar{T}_i$ from v to the root v_i of $\bar{T}_i$. It was shown in [23] that $p_1(v)$, $p_2(v)$, and $p_n(v)$ have only the vertex v in common, and for two vertices $u \neq v$ and two indices $i \neq j$, $p_i(u)$ and $p_j(v)$ can have at most one common vertex. The following property was shown in [2, 5].

Property 1. Let v be an internal vertex of G .

1. All ancestors of v in $\bar{T}_1$ ($\bar{T}_2$, $\bar{T}_n$, respectively) constitute a nonempty set and they appear before v in the ccw postordering of the vertices of G with respect to $\bar{T}_n$ ($\bar{T}_1$, $\bar{T}_2$, respectively).
2. All ancestors of v in $\bar{T}_2$ ($\bar{T}_n$, $\bar{T}_1$, respectively) constitute a nonempty set and they appear before v in the cw postordering of the vertices of G with respect to $\bar{T}_n$ ($\bar{T}_1$, $\bar{T}_2$, respectively).

For example, in Figure 2.3, the numbering of the vertices of G is the ccw postordering with respect to $\bar{T}_n$. For the internal vertex 5, its ancestor set in $\bar{T}_1$ is $\{1, 3\}$. It is nonempty and all its elements appear before 5 in this numbering.

3. Visibility representation of nearly optimal height. By Theorem 2.2, we need to find an st -numbering $\mathcal{O}$ of G such that $\text{length}(\mathcal{O})$ is bounded. To do this, we use a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$ of G . We will describe how to construct an st -numbering $\mathcal{O}_i$ of G from $\bar{T}_i$ (for each $i \in \{1, 2, n\}$) and show that, for one i , $\text{length}(\mathcal{O}_i)$ has the needed upper bound.

DEFINITION 3.1. Let $T = (V, E)$ be a tree drawn in the plane. The balanced partition of T is the partition of V into three ordered subsets A, B, C as follows. Let a_i be the i th vertex of T in ccw postordering and b_i the i th vertex of T in cw postordering. We mark the vertices of T in the order $a_1, b_1, a_2, b_2, \dots, a_i, b_i, \dots$. Continue this process and stop when one of the following two conditions occurs: (i) when trying to mark a_{k+1} , it has been marked already (as a vertex b_i for some $i \leq k$), or (ii) when trying to mark b_{k+1} , it has been marked (as a vertex a_i for some $i \leq k+1$). When the marking process stops, we define $A = \langle a_1, a_2, \dots, a_k \rangle$, $B = \langle b_1, b_2, \dots, b_k \rangle$, and $C = V - A - B$.

The vertex $a_{k+1} \in C$ is called the merge vertex of T .

Let $P = \langle c_1 (= a_{k+1}), c_2, \dots, c_p \rangle$ be the path in T ordered from the merge vertex to the root of T . We claim $C = P$ and call this path the *leftover* path of T . We prove this claim for case (ii). (The proof for case (i) is similar.) Let $P' = P - \{a_{k+1}\}$ and $R = V - A - P$. We need to show $B = R$. Note that in the ccw postordering of T , the vertices in A are numbered first, then the vertex a_{k+1} , then the vertices in $P' \cup R$. When the marking process stops, none of the vertices in B has been marked as an a_i vertex. Thus, we must have $B \subseteq P' \cup R$. Towards a contradiction, suppose there is a vertex $x \in B \cap P'$. Then in the cw postordering, x has been numbered as a b_i , while the merge vertex a_{k+1} has not been numbered. Since x is an ancestor of a_{k+1} in T , this is impossible. Thus, we must have $P' \cap B = \emptyset$ implying $B \subseteq R$. Towards another contradiction, suppose that there is a vertex $y \in R - B$. When the marking process stops, the vertex b_{k+1} has been marked as an a_i vertex for some $i \leq k+1$. So $b_{k+1} \in A \cup \{a_{k+1}\}$. On the other hand, y has not been marked. However, in the cw postordering of T , all vertices in R are numbered before the vertices in $A \cup \{a_{k+1}\}$. So this is impossible. Hence $R - B = \emptyset$, implying that $B = R$ is to be shown.

For example, the balanced partition of the tree $\bar{T}_n$ in Figure 2.3 is as follows: $A = \langle 1, 2, 3, 4, 5, 6 \rangle$, $B = \langle 13, 11, 12, 9, 8, 10 \rangle$, and $C = \langle 7, 14 \rangle$.

DEFINITION 3.2. Let $T = (V, E)$ be a tree with the balanced partition (A, B, C) . A numbering $\mathcal{O}$ of V is consistent with respect to T if the following hold.

1. For any $i < j$, $a_i \prec_{\mathcal{O}} a_j$, $b_i \prec_{\mathcal{O}} b_j$, and $c_i \prec_{\mathcal{O}} c_j$.
2. For any vertices $a_i \in A, b_j \in B$, and $c_l \in C$, $a_i \prec_{\mathcal{O}} c_l$ and $b_j \prec_{\mathcal{O}} c_l$.

By the definition of the consistent numbering, it is easy to see that the following property holds.

Property 2. Let T be a tree with balanced partition (A, B, C) and $\mathcal{O}$ a numbering consistent with respect to T . If u is a child of v in T , then $u \prec_{\mathcal{O}} v$.

LEMMA 3.3. Let $\mathcal{R} = \{T_1, T_2, T_n\}$ be a realizer of a plane triangulation G . For $i \in \{1, 2, n\}$, let $\mathcal{O}_i$ be a consistent numbering with respect to $\bar{T}_i$. Then $\mathcal{O}_i$ is an *st*-numbering of G .

Proof. We prove only the case $i = n$. The other two cases are symmetric. Let (A, B, C) be the balanced partition of $\bar{T}_n$.

For any vertex other than the root of $\bar{T}_n$, its parent is assigned a bigger number in $\mathcal{O}_n$. The root of $\bar{T}_n$ is assigned n .

For any nonleaf vertex of $\bar{T}_n$, their children are assigned smaller numbers in $\mathcal{O}_n$ by Property 2. Consider a leaf $u \neq v_1, v_2$ of $\bar{T}_n$. Clearly, u is an internal vertex of G . If $u \in A$ or $u \in C$ is the merge vertex, then according to Property 1(1), its ancestor set in $\bar{T}_1$ is nonempty and all its members appear before u in ccw postordering with respect to $\bar{T}_n$. Thus the parent of u is a smaller neighbor of u . Similarly, by Property 1(2), if $u \in B$, the parent of u in $\bar{T}_2$ is a smaller neighbor of u . For v_1 and v_2 , one of them is assigned 1, and it becomes a smaller neighbor of the other. Thus $\mathcal{O}_n$ is an *st*-numbering of G . $\square$

Our algorithm will use one *st*-numbering $\mathcal{O}_i$ mentioned in Lemma 3.3. However, if $\mathcal{O}_i$ is constructed arbitrarily, $\text{length}(\mathcal{O}_i)$ may be too large for our need. In the following, we explore how to construct $\mathcal{O}_i$ in order to bound $\text{length}(\mathcal{O}_i)$, by using a substructure defined below.

DEFINITION 3.4. A ladder graph of order k is a plane graph $L = (V_L, E_L)$. The vertex set V_L is partitioned into two ordered lists $A = \langle a_1, a_2, \dots, a_k \rangle$ and $B = \langle b_1, b_2, \dots, b_k \rangle$. $E_L = E_A \cup E_B \cup E_{\text{cross}}$, where $E_A = \{(a_i, a_{i+1}) | 1 \leq i < k\}$; $E_B = \{(b_i, b_{i+1}) | 1 \leq i < k\}$; E_{cross} consists of edges between a vertex $a_i \in A$ and a vertex

$b_j \in B$; and no two edges in E_{cross} cross each other. The edges in E_{cross} are called cross edges of L .

For a cross edge (a_i, b_j) , we define $\text{slope}(a_i, b_j) = i - j$. A cross edge (a_i, b_j) is called a level (or up or down, respectively) edge if $\text{slope}(a_i, b_j) = 0$ (or $\text{slope}(a_i, b_j) < 0$ or $\text{slope}(a_i, b_j) > 0$, respectively).

A numbering $\mathcal{O}$ of the vertices of a ladder graph $L = (A \cup B, E_L)$ is consistent with respect to L if for any $i < j$, $a_i \prec_{\mathcal{O}} a_j$ and $b_i \prec_{\mathcal{O}} b_j$.

LEMMA 3.5. Let $L = (A \cup B, E_L)$ be a ladder graph of order k . Let l be the number of level edges in L . Then L has a consistent numbering $\mathcal{O}$ such that $\text{length}(\mathcal{O}) \leq (k - 1) + l$. This numbering can be constructed in linear time.

Proof. Let $E_{\text{cross}} = \langle e_1, e_2, \dots, e_p \rangle$ be the ordered list of cross edges of L ordered from bottom up. (This ordering exists because the edges in E_{cross} do not cross each other.) We partition E_{cross} into blocks $E_1, E_2, \dots, E_q$. Each E_j is a maximal sublist of E_{cross} that contains only up edges, or level edges, or down edges. E_j is called an up, or a level, or a down block accordingly.

For each block E_j , let x_j be the largest index such that either a_{x_j} or b_{x_j} is incident to an edge in E_j . The span interval of E_j (for $1 \leq j \leq q$) is defined to be $I_1 = [1, x_1]$; $I_j = (x_{j-1}, x_j]$ (for $1 < j < q$); $I_q = (x_{q-1}, k]$. Note that $I_1, \dots, I_q$ partition the interval $[1, k]$. For each j ($1 \leq j \leq q$), we define a numbering $\mathcal{O}_j$ of the vertex set $\{a_t, b_t \mid t \in I_j\}$ as follows.

If E_j is an up or a level block, let $\mathcal{O}_j = \langle a_{x_{j-1}+1}, a_{x_{j-1}+2}, \dots, a_{x_j}, b_{x_{j-1}+1}, b_{x_{j-1}+2}, \dots, b_{x_j} \rangle$.

If E_j is a down block, let $\mathcal{O}_j = \langle b_{x_{j-1}+1}, b_{x_{j-1}+2}, \dots, b_{x_j}, a_{x_{j-1}+1}, a_{x_{j-1}+2}, \dots, a_{x_j} \rangle$.

Define a numbering of the vertices in L by $\mathcal{O} = \langle \mathcal{O}_1, \mathcal{O}_2, \dots, \mathcal{O}_q \rangle$.

It is clear that $\mathcal{O}$ is a consistent numbering of L and the following hold: (i) the path consisting of the edges in E_A and the path consisting of the edges in E_B each has length $k - 1$; (ii) up edges and down edges do not increase the length of the longest path in the orientation of L derived from $\mathcal{O}$; and (iii) each level edge can increase the length of the longest path in the orientation of L derived from $\mathcal{O}$ by at most 1. Thus $\text{length}(\mathcal{O}) \leq k - 1 + l$. It is straightforward to construct $\mathcal{O}$ in linear time. $\square$

For an example, Figure 3.1(1) shows a ladder graph L of order 7. E_{cross} is partitioned into 6 blocks: $E_1 = \{e_1\}$, $E_2 = \{e_2, e_3\}$, $E_3 = \{e_4, e_5\}$, $E_4 = \{e_6\}$, $E_5 = \{e_7, e_8\}$, and $E_6 = \{e_9\}$. $I_1 = [1, 2]$, $I_2 = (2, 3]$, $I_3 = (3, 5]$, $I_4 = (5, 5] = \emptyset$, $I_5 = (5, 7]$, and $I_6 = (7, 7] = \emptyset$. The numbering constructed according to Lemma 3.5 is $\mathcal{O} = \langle b_1, b_2, a_1, a_2, a_3, b_3, a_4, a_5, b_4, b_5, a_6, a_7, b_6, b_7 \rangle$, where $\text{length}(\mathcal{O}) = 8$.

LEMMA 3.6. Let $L = (A \cup B, E_L)$ be a ladder graph of order k . Then L has a consistent numbering $\mathcal{O}$ such that $\text{length}(\mathcal{O}) \leq k + 2\lceil\sqrt{k}\rceil - 1$. $\mathcal{O}$ can be constructed in linear time.

Proof. Let E_A be the set of the edges in L between the vertices in A , E_B the set of the edges in L between the vertices in B , and E_{cross} the set of the cross edges in L . Clearly $|E_A| = |E_B| = k - 1$.

If $|E_{\text{cross}}| \leq 1$, then obviously $|E_{\text{cross}}| \leq 2k - 1$. Otherwise, the external face of L has at least $2k$ edges. Since L is a plane graph with $2k$ vertices, by Euler formula, $|E_L| \leq 3(2k) - (3 + 2k) = 4k - 3$. Thus $|E_{\text{cross}}| = |E_L| - (|E_A| + |E_B|) \leq (4k - 3) - (2k - 2) = 2k - 1$.

Let $p = \lceil\sqrt{k}\rceil$. For each i ($-p \leq i \leq p$), let C_i be the set of cross edges in L with slope i . Since $C_{-p}, \dots, C_{-1}, C_0, C_1, \dots, C_p$ are disjoint, there exists t such that $|C_t| \leq \frac{|E_{\text{cross}}|}{2p+1} \leq \frac{2k-1}{2p+1} \leq \lceil\sqrt{k}\rceil$.

We consider only the case $t \geq 0$. (If $t < 0$, the construction is symmetric.)

FIG. 3.1. (1) A ladder graph L ; (2) proof of Lemma 3.6.

Let $A' = \langle a_{t+1}, a_{t+2}, \dots, a_k \rangle$ and $B' = \langle b_1, b_2, \dots, b_{k-t} \rangle$. Let L' be the ladder graph consisting of the vertex set $A' \cup B'$ and all cross edges in L that are between the vertices in A' and B' . (See Figure 3.1(2).) L' is a ladder graph of order $k - t$ and all level edges of L' are in C_t . By Lemma 3.5, L' has a consistent numbering $\mathcal{O}'$ with $\text{length}(\mathcal{O}') \leq k - t - 1 + |C_t|$.

Let $\mathcal{O} = \langle a_1, \dots, a_t, \mathcal{O}', b_{k-t+1}, \dots, b_k \rangle$. Clearly $\mathcal{O}$ is a consistent numbering of L and $\text{length}(\mathcal{O}) = \text{length}(\mathcal{O}') + 2t \leq (k - t - 1 + |C_t|) + 2t = k - 1 + t + |C_t| \leq k + 2\lceil \sqrt{k} \rceil - 1$. It is straightforward to construct $\mathcal{O}$ in linear time. $\square$

LEMMA 3.7. Let $G = (V, E)$ be a plane triangulation with n vertices. Let $\bar{T}$ be a tree obtained from a realizer $\mathcal{R}$ of G . Let (A, B, C) be the balanced partition of $\bar{T}$. Then G has an st -numbering $\mathcal{O}$ such that $\text{length}(\mathcal{O}) \leq n/2 + |C|/2 + 2\lceil \sqrt{n/2} \rceil - 1$. $\mathcal{O}$ can be constructed in linear time.

Proof. Let $k = (n - |C|)/2$. Then $|A| = |B| = k$. Let $L = (A \cup B, E_L)$ be a graph constructed as follows. The vertex set of L is $A \cup B$. E_L contains the edges $\{(a_i, a_{i+1}), (b_i, b_{i+1}) \mid 1 \leq i < k\}$ and all edges of G between A and B (since G is planar, these edges do not cross). Thus L is a ladder graph of order k . By Lemma 3.6, L has a consistent numbering $\mathcal{O}_L$ with $\text{length}(\mathcal{O}_L) \leq k + 2\lceil \sqrt{k} \rceil - 1$.

Define $\mathcal{O} = \langle \mathcal{O}_L, C \rangle$. Clearly this is a numbering of G consistent with respect to $\bar{T}$. By Lemma 3.3, $\mathcal{O}$ is an st -numbering of G . We have $\text{length}(\mathcal{O}) \leq |C| + \text{length}(\mathcal{O}_L) \leq |C| + (n - |C|)/2 + 2\lceil \sqrt{k} \rceil - 1 \leq n/2 + |C|/2 + 2\lceil \sqrt{n/2} \rceil - 1$. It is straightforward to construct $\mathcal{O}$ in linear time. $\square$

LEMMA 3.8. Let G be a plane triangulation of n vertices with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$. For $i \in \{1, 2, n\}$, let (A_i, B_i, C_i) be the balanced partition of the tree $\bar{T}_i$. Then there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq n/3 + 1$.

Proof. Each C_i is a path in $\bar{T}_i$. By the property of realizers, if $i \neq j$, C_i and C_j can intersect at at most one vertex. Thus there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq (n + 3)/3 = n/3 + 1$. $\square$

We now can prove our main theorem in this section.

THEOREM 3.9. Let G be a plane triangulation with n vertices. Then G has a VR

with height $\leq 2n/3 + 2\lceil\sqrt{n/2}\rceil$ and width $\leq 2n - 5$, which can be constructed in linear time.

Proof. Let $\mathcal{R} = \{T_1, T_2, T_n\}$ be a realizer of G . For each $i \in \{1, 2, n\}$, let (A_i, B_i, C_i) be the balanced partition of $\overline{T}_i$. By Lemma 3.8, there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq n/3 + 1$. By Lemma 3.7, the st -numbering $\mathcal{O}_i$ associated with this $\overline{T}_i$ satisfies $\text{length}(\mathcal{O}_i) \leq n/2 + |C_i|/2 + 2\lceil\sqrt{n/2}\rceil - 1 \leq n/2 + n/6 + 2\lceil\sqrt{n/2}\rceil - 1 + 1 = 2n/3 + 2\lceil\sqrt{n/2}\rceil$. By Theorem 2.2, the st -numbering $\mathcal{O}_i$ leads to a VR with height at most $2n/3 + 2\lceil\sqrt{n/2}\rceil$.

By Lemma 3.7 and Theorem 2.2, we can construct this VR in linear time. $\square$

4. Visibility representation of nearly optimal width. In order to find a VR of bounded width for a plane triangulation G , we construct an st -numbering $\mathcal{O}^*$ of the st -dual graph G^* with proper bound on $\text{length}(\mathcal{O}^*)$. By the one-to-one correspondence between st -orientations of G and the dual st -orientations of G^* , we can construct the st -orientation $\mathcal{O}$ for G that corresponds to $\mathcal{O}^*$. By Theorem 2.2, this will lead to a VR of G with the desired width.

In order to find such a numbering $\mathcal{O}^*$, our approach is parallel to that in section 3: starting with a realizer $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$ of the dual graph G^* , we find an st -numbering $\mathcal{O}_i^*$ of G^* for each $i \in \{1, 2, n\}$ and show that one of them has the desired upper bound. However, the dual graph G^* is a 3-regular plane graph, not a plane triangulation. Therefore the concept of realizer defined in Definition 2.3 must be modified. In [8], the realizer concept is generalized from plane triangulation to 3-connected plane graph as follows.

DEFINITION 4.1. *Let G be a 3-connected plane graph with three external vertices v_1, v_2, v_n in ccw order. A realizer of G is a triplet of rooted spanning trees $\{T_1, T_2, T_n\}$ of G with the following properties.*

1. *For $i \in \{1, 2, n\}$, the root of T_i is v_i ; the edges of G are directed from children to parent in T_i .*
2. *Each edge e of G is contained in at least one and at most two spanning trees. If e is contained in two spanning trees, then it has different directions in the two trees.*
3. *For each vertex $v \notin \{v_1, v_2, v_n\}$ of G , v has exactly one edge leaving v in each of T_1, T_2, T_n . The ccw order of the edges incident to v is leaving in T_1 , entering in T_n , leaving in T_2 , entering in T_1 , leaving in T_n , and entering in T_2 . Each entering block may be empty. An edge with two opposite directions is considered twice. The first and the last incoming edges are possibly coincident with the outgoing edges. (Figure 4.1 shows two examples of edge pattern around an interval vertex v . In the second example, the edge leaving v in T_2 and an edge entering v in T_2 are the same edge.)*
4. *For $i \in \{1, 2, n\}$, all the edges incident to v_i belong to T_i .*

We color the edges in T_1 blue, T_2 green, and T_n red. According to the definition, each edge of G is assigned one or two colors, and is said to be 1-colored or 2-colored, respectively.

Consider a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$ (as defined in Definition 2.3) of a plane triangulation G . The triplet of the three trees $\{\overline{T}_1, \overline{T}_2, \overline{T}_n\}$ (each of the three external edges $(v_1, v_2), (v_2, v_n), (v_n, v_1)$ is in two trees) is a special case of the realizer for 3-connected plane graphs defined here, where the three external edges are the only 2-colored edges.

For each vertex v of G and $i \in \{1, 2, n\}$, $p_i(v)$ denotes the path in T_i from v to the root v_i of T_i . A subpath of $p_i(v)$ between the end vertex v and an ancestor u of v

FIG. 4.1. Two examples of edge pattern around an internal vertex v .

in T_i is denoted by $p_i(v, u)$. The subpath of the external face of G , with end vertices v_1 and v_2 , and not containing v_n , is denoted by $ext(v_1, v_2)$. The subpaths $ext(v_2, v_n)$ and $ext(v_n, v_1)$ are defined similarly.

It was shown in [8] that every 3-connected plane graph has a realizer, which can be computed in linear time. The properties of realizers have been studied extensively in [8] and are summarized in the following lemma.

LEMMA 4.2. *Let $G = (V, E)$ be a 3-connected plane graph with $|V| = n$ and $|E| = m$. Let $\mathcal{R} = (T_1, T_2, T_n)$ be a realizer of G , where T_i is rooted at the vertex v_i for $i \in \{1, 2, n\}$.*

1. *The number of 2-colored edges of G is $3n - m - 3$.*
2. *For each vertex v of G , $p_1(v)$, $p_2(v)$, and $p_n(v)$ have only the vertex v in common.*
3. *For $i, j \in \{1, 2, n\}$ ($i \neq j$) and two vertices u and v , the intersection of $p_i(u)$ and $p_j(v)$ is either empty or a common subpath.*
4. *For vertices v_1, v_2, v_n , the following hold: $p_1(v_2) = p_2(v_1) = ext(v_1, v_2)$; $p_2(v_n) = p_n(v_2) = ext(v_2, v_n)$; $p_n(v_1) = p_1(v_n) = ext(v_n, v_1)$.*

Similar to plane triangulations, we have the following version of Property 1 for 3-connected plane graph G with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$.

Property 3. Let v be an internal vertex of G .

1. All ancestors of v in T_1 (T_2, T_n , respectively) constitute a nonempty set and they appear before v in the ccw postordering of the vertices of G with respect to T_n (T_1, T_2 , respectively).
2. All ancestors of v in T_2 (T_n, T_1 , respectively) constitute a nonempty set and they appear before v in the cw postordering of the vertices of G with respect to T_n (T_1, T_2 , respectively).

DEFINITION 4.3 (see [8]). *Let $G = (V, E)$ be a 3-connected plane graph, with three external vertices v_1, v_2, v_n in ccw order. The extended dual graph G_e^* of G is defined as follows.*

1. *Each internal face f of G corresponds to a node f^* in G_e^* ; the external face of G corresponds to three nodes v_1^*, v_2^* , and v_n^* in G_e^* .*
2. *Each edge e of G corresponds to an edge e^* in G_e^* .*
3. *Two nodes f_1^* and f_2^* of G_e^* (different from v_1^*, v_2^* , and v_n^*) are connected by an edge $e^* = (f_1^*, f_2^*)$ in G_e^* if and only if the corresponding faces f_1 and f_2 in G have the edge e in common.*

FIG. 4.2. (1) A plane triangulation G with a realizer $\mathcal{R}$; (2) its extended dual G_e^* with dual realizer $\mathcal{R}^*$.

4. v_1^* is adjacent to all the nodes of G_e^* corresponding to faces of G incident to an edge of $\text{ext}(v_2, v_n)$; v_2^* is adjacent to all the nodes of G_e^* corresponding to faces of G incident to an edge of $\text{ext}(v_n, v_1)$; v_n^* is adjacent to all the nodes of G_e^* corresponding to faces of G incident to an edge of $\text{ext}(v_1, v_2)$.

5. (v_1^*, v_2^*) , (v_2^*, v_n^*) , and (v_n^*, v_1^*) are three edges in G_e^* .

Figure 4.2(1) shows a plane triangulation G . Figure 4.2(2) shows its extended dual G_e^* . Note that the extended dual G_e^* of a 3-connected plane triangulation G is also a 3-connected plane graph.

Let $G = (V, E)$ be a 3-connected plane graph with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$. Let G_e^* be the extended dual of G . In [8], it was shown that $\mathcal{R}$ induces a dual realizer $\mathcal{R}^* = (T_1^*, T_2^*, T_n^*)$ of G_e^* . In our application, we need only the case where G is a plane triangulation. The following definition of $\mathcal{R}^*$ is restricted to this special case.

DEFINITION 4.4. Let $G = (V, E)$ be a plane triangulation with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$. Then $\mathcal{R}$ induces a dual realizer $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$ of the extended dual G_e^* as follows.

1. Let $f^* \notin \{v_1^*, v_2^*, v_n^*\}$ be a node of G_e^* . Let f be the face of G corresponding to f^* and e an edge of G that is on the boundary of f . We color and direct the dual edge e^* in G_e^* according to the following rules.
 - (a) If e is blue (i.e., in T_1), then e^* is colored by green and red (i.e., e^* is in both T_2^* and T_n^*). If e is cw on f , then e^* is an outgoing red and incoming green edge for f^* . If e is ccw on f , then e^* is an outgoing green and incoming red edge for f^* .
 - (b) If e is green (i.e., in T_2), then e^* is colored by red and blue (i.e., e^* is in both T_n^* and T_1^*). If e is cw on f , then e^* is an outgoing blue and incoming red edge for f^* . If e is ccw on f , then e^* is an outgoing red and incoming blue edge for f^* .
 - (c) If e is red (i.e., in T_n), then e^* is colored by blue and green (i.e., e^* is in both T_1^* and T_2^*). If e is cw on f , then e^* is an outgoing green and incoming blue edge for f^* . If e is ccw on f , then e^* is an outgoing blue and incoming green edge for f^* .

2. The dual edge of (v_1, v_2) is red (i.e., in T_n^*) and directed to v_n^* . The dual edge of (v_2, v_n) is blue (i.e., in T_1^*) and directed to v_1^* . The dual edge of (v_n, v_1) is green (i.e., in T_2^*) and directed to v_2^* .
3. The edge (v_1^*, v_2^*) is blue and green (i.e., in both T_1^* and T_2^*). The edge (v_2^*, v_n^*) is green and red (i.e., in both T_2^* and T_n^*). The edge (v_n^*, v_1^*) is red and blue (i.e., in both T_n^* and T_1^*).

Figure 4.2(1) shows a plane triangulation G and a realizer $\mathcal{R}$. Figure 4.2(2) shows the dual realizer $\mathcal{R}^*$ of the extended dual graph G_e^* . The extended dual graph G^* and the dual realizer $\mathcal{R}^*$ of a plane triangulation G with a realizer $\mathcal{R}$ satisfy the following property.

Property 4. Let $\mathcal{R}$ be a realizer of a plane triangulation G with n vertices, and $\mathcal{R}^*$ the dual realizer of $\mathcal{R}$ of the extended dual graph G_e^* .

1. The number N of nodes in G_e^* is the number of faces of G plus 2 (since the external face of G corresponds to three nodes in G_e^*). Thus $N = 2n - 4 + 2 = 2n - 2$.
2. The three edges $(v_1, v_2)^*$, $(v_2, v_n)^*$, $(v_n, v_1)^*$ are the only 1-colored edges in $\mathcal{R}^*$.
3. Since $\mathcal{R}^*$ is just a special case of realizers defined for 3-connected plane graphs, Property 3 holds for $\mathcal{R}^*$.

For each tree T_i^* ($i \in \{1, 2, n\}$) of $\mathcal{R}^*$, we can define the balanced partition of T_i^* , and the consistent numbering $\mathcal{O}_i^*$ with respect to T_i^* , exactly the same way as in section 3.

Having covered the necessary concepts and properties, we now proceed to the construction of the VR with nearly optimal width. The approach is parallel to that in section 3. It turns out that almost all results in section 3 remain valid and with almost identical proof (with one major exception). In particular, the corresponding versions of Lemmas 3.3 and 3.7 are given below.

LEMMA 4.5. *Let G be a plane triangulation with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$. Let G_e^* be the extended dual of G and $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$ the dual realizer of $\mathcal{R}$. For $i \in \{1, 2, n\}$, let $\mathcal{O}_i^*$ be a consistent numbering with respect to T_i^* . Then $\mathcal{O}_i^*$ induces an st -numbering, denoted by $\mathcal{O}_i^{*r}$, of the st -dual graph G^* of G .*

Proof. We prove only the case $i = n$. The other cases are symmetric. Note that $\mathcal{O}_n^*$ always assigns N to the node v_n^* and assigns the numbers $\{1, k\}$ to the nodes $\{v_1^*, v_2^*\}$ (where $1 < k < N$). First, we merge v_1^* , v_2^* , and v_n^* into a single node t^* . After the merging operation, G_e^* becomes the st -dual graph G^* of G as defined in Definition 2.1. (The merged node t^* corresponds to the external face of G .) The node t^* is still numbered by 1. Adjust $\mathcal{O}_n^*$ (closing the gap for the number k) so that it becomes a numbering of G^* . After the merging, the node with the largest number must be the child of v_n^* in T_n^* other than v_1^* and v_2^* , which corresponds to the internal face of G adjacent to the external edge (v_1, v_2) of G . Denote this node by s^* .

Let $\mathcal{O}_n^{*r}$ be the numbering of the st -dual graph G^* by reversing the numbering $\mathcal{O}_n^*$. Thus $\mathcal{O}_n^{*r}$ assigns 1 to s^* and $N - 2$ to t^* . By repeating the proof of Lemma 3.3, except that we use Property 3 here instead of Property 1, we can show that $\mathcal{O}_n^{*r}$ is an st -numbering of the st -dual graph G^* , in which s^* is the source and t^* is the sink. $\square$

LEMMA 4.6. *Let $G = (V, E)$ be a plane triangulation of n vertices with a realizer $\mathcal{R}$. Let G_e^* be the extended dual of G with $N = 2n - 2$ nodes. Let $\mathcal{R}^*$ be the dual realizer of $\mathcal{R}$. Let (A, B, C) be the balanced partition of a tree T^* in $\mathcal{R}^*$. Then the st -dual graph G^* has an st -numbering $\mathcal{O}^{*r}$ such that $\text{length}(\mathcal{O}^{*r}) \leq N/2 + |C|/2 + 2\lceil\sqrt{N/2}\rceil - 1$.*

FIG. 4.3. (1) Case 1a; (2) Case 1b.

$\mathcal{O}^{*r}$ can be constructed in linear time.

Proof. By using the identical proof of Lemma 3.7, we can show that $\text{length}(\mathcal{O}^*)$ satisfies the given upper bound. When converting $\mathcal{O}^*$ to $\mathcal{O}^{*r}$, note that merging three nodes from G_e^* into one node in G^* and reversing the ordering of $\mathcal{O}^*$ does not increase the length of the longest path. $\square$

To complete our construction of the VR with nearly optimal width, we also need Lemma 3.8. However, although its conclusion holds, the proof of Lemma 3.8 is not valid here. Its proof relied on a simple fact: For a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$ of a plane triangulation G , the leftover paths C_i and C_j ($i \neq j$) can intersect at at most one vertex. For the dual realizer $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$, this is not true because the leftover paths C_i and C_j (for T_i^* and T_j^*) can have a common subpath of unbounded length. In the following we restate and prove the version of Lemma 3.8 needed here.

LEMMA 4.7. *Let G be a plane triangulation of n vertices with a realizer $\mathcal{R} = \{T_1, T_2, T_n\}$. Let G_e^* be the extended dual of G with $N = 2n - 2$ nodes, and $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$ the dual realizer of $\mathcal{R}$. For each $i \in \{1, 2, n\}$, let (A_i, B_i, C_i) be the balanced partition of T_i^* . Then there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq N/3 + 4$.*

Proof. The proof heavily depends on the properties of the dual realizer $\mathcal{R}^*$. We refer readers to [8] for the detailed discussions of these properties. There are several cases.

Case 1. There exist $i, j \in \{1, 2, n\}$ such that C_i and C_j do not have any common node. We assume C_1 and C_n have no common node. The other cases are similar. Let v^* be the starting node of C_n . Let Q be the path in T_1^* from v^* to the root v_1^* of T_1^* . Consider the path C_1 .

Case 1a. C_1 is on the right of Q (see Figure 4.3(1)). Then $C_1 \subseteq A_n$ and $|C_1| \leq |A_n| = (N - |C_n|)/2$. This implies $2|C_1| + |C_n| \leq N$. Hence, either $|C_1|$ or $|C_n|$ is $\leq N/3$.

Case 1b. C_1 is on the left of Q (see Figure 4.3(2)). Then $C_n \subseteq B_1$ and $|C_n| \leq |B_1| = (N - |C_1|)/2$. This implies $|C_1| + 2|C_n| \leq N$. Again, either $|C_1|$ or $|C_n|$ is $\leq N/3$.

Case 2. For every pair $i, j \in \{1, 2, n\}$, C_i and C_j intersect at at least one node, but no node is common to all three leftover paths C_1, C_2, C_n . By the property of the realizer, the intersection pattern of C_1, C_2 , and C_n must be one of the two cases shown in Figure 4.4. We consider only the first case. The other case is symmetric.

The three paths partition the internal region of G^* into several subregions: W is

FIG. 4.4. Two possible subcases of Case 2.

FIG. 4.5. Proof of Case 2.

bounded by C_1, C_2 , and C_n ; R_1 is bounded by C_2 and C_n ; R_2 is bounded by C_n and C_1 ; R_n is bounded by C_1 and C_2 (see Figure 4.4(1)).

By the definition of balanced partition, we have

$$(4.1) \quad |A_1| = |B_1|, \quad |A_2| = |B_2|, \quad |A_n| = |B_n|.$$

Partition the path C_1 into 5 subpaths $p_{11}, p_{12}, \dots, p_{15}$ from root v_1^* to the merge node: where p_{11} is incident to v_1^* , p_{12} overlaps with C_n , p_{13} bounds the region W , p_{14} overlaps with C_2 , and p_{15} is in the left of C_2 (see Figure 4.5). Some of these subpaths may be empty. Partition C_2 and C_3 similarly. Thus $p_{12} = p_{n4}$, $p_{22} = p_{14}$, $p_{n2} = p_{24}$. For the region R_1 , let $R_{11} = R_1 \cap A_1$ and $R_{12} = R_1 \cap B_1$. Thus R_{11} , p_{15} , and R_{12} partition R_1 . Partition the regions R_2 and R_n similarly (see Figure 4.5). In the following, $|p_{ij}|$ and $|R_{ij}|$ denote the number of vertices in p_{ij} and R_{ij} , respectively. We have

$$\begin{aligned} |A_1| &= |R_{n1}| + |p_{n5}| + |R_{n2}| + |p_{21}| + |R_{11}| - 2, \\ |A_2| &= |R_{11}| + |p_{15}| + |R_{12}| + |p_{n1}| + |R_{21}| - 2, \\ |A_n| &= |R_{21}| + |p_{25}| + |R_{22}| + |p_{11}| + |R_{n1}| - 2. \end{aligned}$$

FIG. 4.6. *Proof of Case 3.*

(In the equation for $|A_1|$, the last term -2 is because one end node of p_{n5} and one end node p_{21} belong to C_1 , so they should not be counted in $|A_1|$. Similarly for $|A_2|$ and $|A_3|$.) Similarly,

$$\begin{aligned} |B_1| &= |R_{22}| + |p_{25}| + |R_{21}| + |p_{n3}| + |p_{n2}| + |p_{n1}| + |W| + |p_{23}| + |R_{12}| - 6, \\ |B_2| &= |R_{n2}| + |p_{n5}| + |R_{n1}| + |p_{13}| + |p_{12}| + |p_{11}| + |W| + |p_{n3}| + |R_{22}| - 6, \\ |B_n| &= |R_{12}| + |p_{15}| + |R_{11}| + |p_{23}| + |p_{22}| + |p_{21}| + |W| + |p_{13}| + |R_{n2}| - 6. \end{aligned}$$

(In the equation for $|B_1|$, the last term -6 is because one end node of p_{n3} and one end node of p_{23} belong to C_1 ; the common node of p_{n3} , p_{23} , and p_{n2} is counted three times, and the common node of p_{n2} , p_{25} , and p_{n1} is counted three times. Similarly for $|B_2|$ and $|B_3|$.)

Plug these values into (4.1), add them together, and simplify:

$$\begin{aligned} |R_{11}| + |R_{21}| + |R_{n1}| &= (|R_{12}| + |R_{22}| + |R_{n2}|) + 3|W| + 2(|p_{13}| + |p_{23}| + |p_{n3}|) \\ &\quad + (|p_{12}| + |p_{22}| + |p_{n2}|) - 12 \\ (4.2) \quad &\geq (|p_{12}| + |p_{22}| + |p_{n2}|) - 12. \end{aligned}$$

Let $Q_1 = (C_1 - p_{12}) \cup R_{n1}$, $Q_2 = (C_2 - p_{22}) \cup R_{11}$, and $Q_n = (C_n - p_{n2}) \cup R_{21}$. Since Q_1 , Q_2 , Q_n are disjoint, we have

$$(4.3) \quad |Q_1| + |Q_2| + |Q_n| \leq N.$$

By the definition of Q_i and inequalities (4.2) and (4.3), we get

$$(4.4) \quad |C_1| + |C_2| + |C_n| = |Q_1| + |Q_2| + |Q_n| + (|p_{12}| + |p_{22}| + |p_{n2}|) - (|R_{11}| + |R_{21}| + |R_{n1}|)$$

$$(4.5) \quad \leq |Q_1| + |Q_2| + |Q_n| + 12 \leq N + 12.$$

Thus, there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq N/3 + 4$.

Case 3. C_1, C_2, C_n have a node v^* in common.

Case 3a. All three edges in G_e incident to v^* are 2-colored (see Figure 4.6(1)). This is a special case of Case 2 where $W = \emptyset$. The proof of Case 2 still holds.

Case 3b. Exactly two edges incident to v^* are 2-colored (see Figure 4.6(2)). Since $\mathcal{R}^*$ is the dual realizer of a realizer $\mathcal{R}$ of a plane triangulation, the only 1-colored edges of G_e^* are the three internal edges incident to v_1^*, v_2^* , and v_n^* . So there exists i such that C_i consists of a single edge and $|C_i| = 1$.

Case 3c. At most one edge incident to v^* is 2-colored. Similar to Case 3b, one C_i satisfies $|C_i| = 1$. $\square$

We now can prove our main theorem in this section.

THEOREM 4.8. *Let G be a plane triangulation of n vertices. Then G has a VR with width $\leq 4n/3 + 2\lceil\sqrt{n}\rceil$ and height $\leq n - 1$, which can be constructed in linear time.*

Proof. Let $\mathcal{R} = \{T_1, T_2, T_n\}$ be a realizer of G . Let G_e^* be the extended dual of G with $N = 2n - 2$ nodes, and $\mathcal{R}^* = \{T_1^*, T_2^*, T_n^*\}$ the dual realizer of $\mathcal{R}$. For $i \in \{1, 2, n\}$, let (A_i, B_i, C_i) be the balanced partition of T_i^* .

By Lemma 4.7, there exists $i \in \{1, 2, n\}$ such that $|C_i| \leq N/3 + 4$. Consider the numbering $\mathcal{O}_i^*$ of the extended dual graph G_e^* consistent with respect to this T_i^* . By Lemma 4.6, $\mathcal{O}_i^*$ induces an st -numbering $\mathcal{O}_i^{*r}$ of the st -dual G^* such that $\text{length}(\mathcal{O}_i^{*r}) \leq N/2 + |C_i|/2 + 2\lceil\sqrt{N/2}\rceil - 1 \leq N/2 + N/6 + 2\lceil\sqrt{N/2}\rceil - 1 + 2 = 2N/3 + 2\lceil\sqrt{N/2}\rceil + 1 < 4n/3 + 2\lceil\sqrt{n}\rceil$. By Theorem 2.2, this st -numbering leads to a VR of G with width at most $4n/3 + 2\lceil\sqrt{n}\rceil$, which can be constructed in linear time. $\square$

5. Conclusion. In this paper, we present two constructions for VR of plane graphs, one with nearly optimal height $2n/3 + 2\lceil\sqrt{n/2}\rceil$, and one with nearly optimal width $4n/3 + 2\lceil\sqrt{n}\rceil$. Recently, a new algorithm, based on the results in this paper, was polished that constructs a VR with optimal height $\leq 2n/3$ and width $\leq (2n - 5)$ [30]. We conclude the paper by mentioning two open problems:

1. Find a VR construction with optimal width $\leq 4n/3$.
2. Find a VR that simultaneously achieves optimal bounds on width and height.

HAMILTON CYCLES IN PLANAR LOCALLY FINITE GRAPHS*

HENNING BRUHN[†] AND XINGXING YU[‡]

Abstract. A classical theorem by Tutte ensures the existence of a Hamilton cycle in every finite 4-connected planar graph. Extensions of this result to infinite graphs require a suitable concept of an infinite cycle. Such a concept was provided by Diestel and Kühn, who defined circles to be homeomorphic images of the unit circle in the Freudenthal compactification of the (locally finite) graph. With this definition we prove a partial extension of Tutte’s result to locally finite graphs.

Key words. Hamilton cycles, infinite graphs, Tutte

AMS subject classification. 05C45

DOI. 10.1137/050631458

1. Introduction. While Hamilton cycles have been investigated intensively in finite graphs, comparatively little attention has been paid to Hamilton cycles in infinite graphs. One reason for this is that it is not entirely clear what the infinite analogon of a cycle should be.

Adomaitis [1] avoided this question by defining a graph to be Hamiltonian if for every finite subset of the vertex set there is a spanning cycle. In contrast, Nash-Williams [8] addressed the problem and proposed spanning double rays as infinite analogons of Hamilton cycles. He noticed that for a spanning double ray to exist the graph needs to be 3-indivisible. (A graph is k -indivisible if the deletion of finitely many vertices leaves at most $k - 1$ infinite components.) Generalizing the following classical result by Tutte, Nash-Williams conjectured that a 3-indivisible 4-connected planar graph contains a spanning double ray.

THEOREM 1 (see Tutte [11]). *Every finite 4-connected planar graph has a Hamilton cycle.*

Recently, Yu [13, 14, 15, 16, 12] announced a proof of Nash-Williams’s conjecture.

The restriction to 3-indivisible graphs is a quite serious one that at first appears unavoidable. Yet, while double rays are the obvious first choice for an infinite analogon of cycles, there is a more subtle alternative which was introduced by Diestel and Kühn [5, 6]. They call the homeomorphic image C of the unit circle in the Freudenthal compactification of a locally finite graph G a *circle*; the subgraph $C \cap G$ is then a *cycle*—for finite graphs this definition coincides with the usual one. In a series of papers it has been shown that this notion is very successful and more suitable than double rays; see Diestel [3] for an introduction and a survey.

These circles overcome the restriction to 3-indivisible graphs. Indeed, in Figure 1 we see an infinite *Hamilton cycle* in a graph that is not k -indivisible for any k . The example is due to Diestel and Kühn [5]. Bruhn (see [3]) conjectured that, in this sense, Theorem 1 extends to locally finite graphs.

FIG. 1. A Hamilton circle (in bold).

CONJECTURE 2. Let G be a locally finite 4-connected planar graph. Then G has a Hamilton cycle.

In this paper we will present a partial result in this direction.

THEOREM 3. Let G be a locally finite 6-connected planar graph that is k -indivisible for some finite $k \in \mathbb{N}$. Then G has a Hamilton cycle.

Since submission of this paper, there has been some further work on infinite Hamilton cycles. Cui, Wang, and Yu [2] proved that a locally finite 4-connected planar graph has a Hamilton cycle, provided it has a *VAP-free* drawing, that is, a drawing without any vertex accumulation point. This is a substantial special case of Conjecture 2. Furthermore, Georgakopoulos [7] extended Fleischner's theorem on Hamilton cycles in squares of graphs to locally finite graphs.

2. Definitions. In general, our notation will be that of Diestel [4]. If not otherwise noted, all graphs will be simple. A 1-way infinite path is called a *ray*, a 2-way infinite path is a *double ray*, and the subrays of a ray or double ray are its *tails*. Let $G = (V, E)$ be any locally finite graph. Two rays in G are *equivalent* if no finite set of vertices separates them; the corresponding equivalence classes of rays are the *ends* of G . In several places we will implicitly use that every connected locally finite but infinite graph contains a ray, and thus an end.

We say that a finite vertex set S *separates* an end ω from a vertex set U if every ray $R \in \omega$ that starts in a vertex of U meets S . In a similar manner, S separates two ends ω and ω' if every double ray with one tail in ω and the other in ω' goes through S .

We define a topology on G together with its ends; i.e., our topological space consists of all vertices, all inner points of edges, and all ends of G . On G the topology will be that of a 1-complex. Thus, the basic open neighborhoods of an inner point on an edge are the open intervals on the edge containing that point, while the basic open neighborhoods of a vertex x are the unions of half-open intervals containing x , one from every edge at x . For every end ω and any finite set $S \subseteq V$ there is exactly one component $C = C(S, \omega)$ of $G - S$ which contains a tail of every ray in ω . We say that ω *belongs* to C and write $\overline{C}(S, \omega)$ for the component C together with all the ends belonging to it. Then the basic open neighborhoods of an end ω are all sets of the form

$$\hat{C}(S, \omega) := \overline{C}(S, \omega) \cup \mathring{E}(S, \omega).$$

$\overset{\circ}{E}(S, \omega)$ is the set of all inner points of edges between S and $C(S, \omega)$. This topological space will be denoted by $|G|$ and is also known as the *Freudenthal compactification* of G .

We will freely view G either as an abstract graph or as a subspace of $|G|$, i.e., the union of all vertices and edges of G with the usual topology of a 1-complex. It is not difficult to see that if G is connected and locally finite, then $|G|$ is compact. Note that in $|G|$ every ray converges to the end, of which it is an element.

A set $C \subseteq |G|$ is a *circle* if it is homeomorphic to the unit circle. Then C includes every edge of which it contains an inner point, and the graph consisting of these edges and their endvertices is the *cycle* defined by C . Conversely, $C \cap G$ is dense in C , so every circle is the closure in $|G|$ of its cycle and hence defined uniquely by it. Note that every finite cycle in G is also a cycle in this sense, but there can also be infinite cycles; see Diestel [3, 4] for examples and for more information. A *Hamilton cycle* is a cycle that contains every vertex of G ; the corresponding circle will then cover all ends.

G is called *planar* if there is an embedding of G (as a 1-complex) in the sphere S^2 . Since we work in $|G|$ rather than in G , the following fact is quite convenient.

THEOREM 4 (see Richter and Thomassen [9]). *Let G be a locally finite 2-connected planar graph. Then $|G|$ embeds in the sphere.*

It should be noted that for an embedding $\varphi : |G| \rightarrow S^2$, the topological space $|G|$ coincides with the closure of $\varphi(G)$ in the sphere. We call every connected component of $S^2 \setminus \varphi(|G|)$ a *face*. Its boundary is a *face boundary*. It is not difficult to see that each face boundary is (or, more precisely, corresponds to) the closure of a subgraph of G . The following lemma follows immediately from Proposition 3 in [9].

LEMMA 5. *Let G be a locally finite 2-connected graph with an embedding $\varphi : |G| \rightarrow S^2$. Then the face boundaries of $\varphi(|G|)$ are circles of $|G|$.*

For a subgraph H of G , an *H-bridge* is either a chord $e \notin E(H)$ together with its endvertices both of which lie in $V(H)$ or a component K of $G - H$ together with all edges between K and H , denoted by $E(K, H)$, and their incident vertices. We say that an *H-bridge* B is *chordal* if $E(B)$ consists of a single edge. All the vertices of an *H-bridge* B in H are *attachments* of B . For a subgraph F of G , we call a path (resp., cycle) P an *F-Tutte path* (resp., *cycle*) in G if every P -bridge of G has at most three attachments, and if every P -bridge containing an edge of F has at most two attachments.

FIG. 2. The Herschel graph.

3. Discussion. The Herschel graph (see Figure 2) is a well-known example for a 3-connected planar graph without a Hamilton cycle which shows that in a sense

Theorem 1 is the best possible. In this section, let us briefly demonstrate that Conjecture 2 is also false for infinite graphs if we only assume 3-connectivity.

Consider Figure 3. There we have arranged copies of the Herschel graph (shaded) in a hexagonal grid. The copies are glued together in such a way that each copy of the vertex v in Figure 2 does not receive an extra edge and thus still has degree 3. Now assume that the resulting graph has a Hamilton cycle C , and consider a copy of the Herschel graph H in that graph. If the Hamilton cycle enters H in u and leaves H in either x or y , then C induces a Hamilton cycle of H , which is impossible. Thus, C enters H in x and leaves it in y , which implies that H has a Hamilton path between x and y . However, this is impossible since both x and y belong to the smaller partition class in the odd bipartite graph H .

FIG. 3. An infinite 3-connected planar graph without a Hamilton cycle.

4. Proof of main result. Before we start proving Theorem 3, let us reformulate the theorem slightly. The notion of ends are central to the definition of infinite cycles, and we will therefore express the theorem in terms of ends. It is straightforward to see that a locally finite graph is k -indivisible if and only if it has at most $k - 1$ ends. Thus, we obtain the following alternative version of Theorem 3.

THEOREM 6. *Let G be a locally finite 6-connected planar graph with at most finitely many ends. Then G has a Hamilton cycle.*

Our main tool in the proof will be the following result of Thomassen, which itself implies Tutte's theorem.

THEOREM 7 (see Thomassen [10]). *Let G be a finite 2-connected plane graph with a face boundary C . Assume that $u \in V(C)$, $e \in E(C)$, and $v \in V(G) \setminus \{u\}$. Then G contains a C -Tutte path from u to v and through e .*

In order to make use of Thomassen's theorem, we need to chop all infinite parts off of the graph so that a finite part remains, in which we may apply Theorem 7. We then extend this finite Hamilton cycle to a finite part of the chopped off infinite components. For this to work, we need that we can separate 3-connected infinite components from some arbitrary finite vertex set. This is the task of our next lemma and, in particular, of its consequence, Lemma 10.

LEMMA 8. *Let G be a 4-connected locally finite planar graph with minimum degree at least 6, let $Y \subseteq V(G)$ be a finite vertex set, and let ω be an end of G . Then, there is a finite vertex set S such that for $C_\omega := C(S, \omega)$ the following hold:*

- (i) C_ω is disjoint from Y ; and
- (ii) if $X \subseteq V(C_\omega)$ with $|X| \leq 2$, then every component of $C_\omega - X$ is infinite.

Proof. We view G as a plane graph. Choose a finite vertex set S such that $C_\omega := C(S, \omega)$ is disjoint from Y and such that $|E(C_\omega, G - C_\omega)|$ is minimal with that property.

Suppose there is a set $X \subseteq V(C_\omega)$ with $|X| \leq 2$ such that there is a finite component K of $C_\omega - X$. Denote by K' the subgraph obtained by adding to K the vertices in X and the edges between X and K . In particular, note that any possibly existing edges between vertices in X are not included in K' . Put $r := |E(K, G - C_\omega)|$ and $s := |E(X, K)|$. We will show that $s < r$. Then $S' := S \cup V(K)$ leads to a smaller cut between $C(S', \omega)$ and the rest of the graph, which is a contradiction.

First, assume that K' is not a triangulation. Thus, putting $n := |V(K)|$, Euler's formula implies $|E(K')| < 3(n + |X|) - 6 \leq 3(n + 2) - 6 = 3n$. On the other hand,

$$2|E(K')| = \sum_{v \in V(K')} d_{K'}(v) = |E(X, K)| + \sum_{v \in V(K)} d_K(v) \geq s + 6n - r.$$

For the last inequality recall that the minimum degree of G is at least 6. Hence, $3n + (s - r)/2 \leq |E(K')| < 3n$, and thus $s < r$, as desired.

Second, let K' be a triangulation. We may assume that some vertices in S lie in the outer face of K' . Since G is 4-connected and since the face boundary of the outer face of K' is a triangle, T , say, no vertices of G can be contained in the interior face of T . Thus, $T = K'$, and consequently the set X consists of exactly one vertex as there are no edges between vertices of X in K' . This implies that there are exactly two edges between X and K , i.e., $s = 2$. Since the minimum degree is at least 6 in G , and as exactly two vertices in K can have at most one edge between them, it follows that $r \geq 3$. Again, we get $s < r$, as desired. $\square$

LEMMA 9. *Let G be a k -connected graph, and let $V(G) = A \cup B$ be a partition such that $G[B]$ is l -connected. Consider $X \subseteq A$ with $|X| \leq k - l$. Then, for every component K of $G[A] - X$ the graph $G[K \cup B]$ is still l -connected.*

Proof. Suppose there is a vertex set $Y \subseteq V(K) \cup B$ with $|Y| < l$ so that $G[K \cup B] - Y$ has (at least) two distinct components C and D . If both C and D contain vertices of B , then $Y \cap B$ separates two vertices of $G[B]$, contradicting that $G[B]$ is l -connected. So we may assume that $C \subseteq K$. Then, $X \cup Y$ separates C from B in G , but $|X \cup Y| < (k - l) + l = k$, which is a contradiction. $\square$

Lemma 10 will be used in each of the induction steps of the proof of Theorem 6.

LEMMA 10. *Let G be a locally finite planar 6-connected graph, let Y be a finite vertex set, and let ω be an end of G . Let $S \subseteq V(G)$ be a finite vertex set such that $C := C(S, \omega)$ is 2-connected and such that no end other than ω belongs to $C(S \cup Y, \omega)$. Then there is a finite vertex set S' such that $C(S', \omega) \subseteq C$ is 3-connected and disjoint from Y , and such that $C - C(S', \omega)$ is 2-connected.*

Proof. By adding finitely many vertices from C to the set $(Y \cup N(S)) \cap V(C)$, we can ensure that for the resulting finite set $Y' \subseteq V(C)$, the subgraph $G[Y']$ of C is 2-connected. Applying Lemma 8 to Y' and ω yields a finite vertex set $\tilde{S}$. Clearly, as $D := C(\tilde{S}, \omega)$ is disjoint from Y' it is also disjoint from Y . Since $Y' \supseteq N(S) \cap V(C)$, it follows that $D \subseteq C$. Moreover, D is 3-connected because of (ii) in Lemma 8 and the fact that there is only one end, namely, ω , belonging to D . Next, observe that since $G[Y'] \subseteq C$ is 2-connected, there is a block B of $C - D$ containing Y' .

We claim that $N(C - B) =: S'$ is finite and that $C(S', \omega) = C - B$ is 3-connected. As $C - B$ is disjoint from Y , because of $Y' \subseteq V(B)$, the statement of the lemma follows from this claim.

FIG. 4. Illustration of the proof of Lemma 10.

So, let us prove the claim. The vertex set of $C - B$ consists of vertices in D and of vertices from components of $C - D - B$. Let us consider such a component K of $C - D - B$ as illustrated in Figure 4. Observe that K may have at most one neighbor in B since any path between two vertices of a block lies entirely in the block. Also, K cannot have neighbors outside C as K is disjoint from $Y' \supseteq N(S) \cap V(C)$. Thus, all neighbors of K in G , except possibly one, lie in D . Consequently, Lemma 9 (set $X = N(K) \cap V(B)$) implies that $G[D \cup K]$ is 3-connected. Moreover, as G is 2-connected, K has a neighbor in D and thus meets the finite set $\tilde{S} \supseteq N(D)$. Therefore, $C - D - B$ has only finitely many components. Now, enlarging D , one by one, by the components of $C - D - B$, we see that $C - B$ is 3-connected.

Finally, it remains to show that $|S'| < \infty$. But this is easy: a vertex in S' either is contained in $N(D) \subseteq \tilde{S}$ (which is finite) or is the single neighbor in B of a component of $C - D - B$, of which, as shown above, there are only finitely many. $\square$

We will construct our Hamilton cycle in a piecewise manner. Slightly more precisely, we will construct finite nested subgraphs G_i of our locally finite graph G in which the application of Theorem 7 will yield subgraphs H_i that are finite approximations of the desired infinite Hamilton cycle. The following definition and lemma make sure that these subgraphs H_i indeed tend to a cycle, i.e., that $\bigcup_{i=1}^{\infty} H_i$ is a cycle.

If G' is a subgraph of G , then denote by G'^+ the subgraph obtained by adding to G' the edges in $E(V(G'), V(G - G'))$ together with their incident endvertices. We call a sequence $(G_1, H_1), \dots, (G_k, H_k)$ of finite induced subgraphs $G_1 \subseteq \dots \subseteq G_k \subseteq G$ and subgraphs $H_1 \subseteq \dots \subseteq H_k \subseteq G$ good if for $i = 1, \dots, k$ the following hold:

- (i) $G_{i-1}^+ \subseteq G_i$ for $i \geq 2$;
- (ii) $E(H_i \cap G_{i-1}^+) = E(H_{i-1})$ for $i \geq 2$;
- (iii) $V(G_i) \subseteq V(H_i) \subseteq V(G_i^+)$;
- (iv) if K is an infinite component of $G - G_i$, then $|E(K, G - K) \cap E(H_i)| = 2$; and
- (v) there is a finite cycle Z such that $Z \cap G_i = H_i \cap G_i$.

LEMMA 11. Let G be a locally finite connected graph with at most finitely many ends, and let every finite initial segment of $(G_1, H_1), (G_2, H_2), \dots$ be good. Then $H := \bigcup_{i=1}^{\infty} H_i$ is a Hamilton cycle of G .

Proof. By (i) it holds that $V(G) = \bigcup_{i=1}^{\infty} V(G_i)$, and hence (iii) implies $V(H) = V(G)$. Therefore, H is a Hamilton cycle if we can prove that it is a cycle at all. For this, we first show that no finite cut $F \subseteq E(G)$ avoiding $E(H)$ separates two vertices of H . Suppose that on the contrary there is such a cut F and that it separates $u, v \in V(H)$, say. Because of (i) we can choose N large enough so that $F \subseteq E(G_N)$ and $u, v \in V(G_N)$. Then a cycle Z as in (v) contains a $u-v$ path in G that is disjoint from F as $E(Z) \cap F = E(Z) \cap F \cap E(G_N) = E(H_N) \cap E(G_N) \cap F = \emptyset$, which is a contradiction.

Assume that one of the components of H , C , say, is a finite cycle. Since the edges between $V(C)$ and $V(G - C)$ then constitute a finite cut that avoids $E(H)$ but separates C from the rest of the graph, we obtain that $H = C$, and we are done.

So, as (v) implies that H is 2-regular, we may assume that H is the disjoint union of double rays. Let the set of these be $\mathcal{D}$. We define a multigraph H' with $\Omega(G)$ as vertex set and $\mathcal{D}$ as edge set: each $D \in \mathcal{D}$ will be incident with the ends it contains tails of. In particular, if all tails of D lie in the same end ω , then D becomes a loop at ω . Conditions (ii) and (iv) ensure that H' is 2-regular.

Suppose that H' is not connected. Let X be a component of H' , and set $Y := H' - X$. Choose N large enough so that no component of $G - G_N$ has more than one end belonging to it. Because of (iv) this prevents any infinite component of $G - G_N$ from meeting both a double ray from $E(X)$ and of $E(Y)$. Contracting each infinite component of $G - G_N$ (keeping parallel edges but deleting loops) yields a finite minor G' of G , in which no edge belonging to a double ray in $E(X)$ is adjacent with an edge lying in a double ray in $E(Y)$. Therefore, there is a cut F of G' separating these two sets of edges. This cut then also separates two vertices of H in G , contradicting what we have shown earlier. Consequently, H' is a cycle, and hence H is an infinite cycle in G . $\square$

Let us introduce one useful definition before we finally start with the proof. We call a vertex set U in a graph G *externally k -connected* if $|U| \geq k$ and if for every set $X \subseteq V(G)$ with $|X| < k$ there is a path between any two vertices of $U \setminus X$ in $G - X$.

Proof of Theorem 6. By Theorem 4, $|G|$ can be embedded in the sphere. We will identify $|G|$ with that embedding and thus view G as a plane graph.

Inductively, we will construct connected finite induced subgraphs $G_1 \subseteq G_2 \subseteq \dots \subseteq G$ and subgraphs $H_1 \subseteq H_2 \subseteq \dots \subseteq G$ such that for every $i \geq 1$ it holds that

- (a) $(G_1, H_1), \dots, (G_i, H_i)$ is good;
- (b) if $\mathcal{C}_i$ is the set of components of $G - G_i$, then each $C \in \mathcal{C}_i$ is 3-connected and there is exactly one end belonging to C ; and
- (c) for each $C \in \mathcal{C}_i$ it follows that $|V(C) \cap V(H_i)| = 2$.

If this can be achieved, then, by Lemma 11, $\bigcup_{i=1}^{\infty} H_i$ is a Hamilton cycle.

Before we proceed, let us give a rough outline of the proof. Ideally, we would like to perform infinitely many steps as follows. In the first step, our foremost task is to separate all the ends. For this, we will find a finite subgraph G_1 so that all components of $G - G_1$ are 3-connected and have exactly one end belonging to them. By contracting these components we will obtain a minor of G , in which the application of Theorem 7 will deliver us the initial piece H_1 of the Hamilton cycle. Slightly more precisely, Theorem 7 yields a Tutte path in the minor—its edges, viewed as edges of G , together with the incident vertices in G form H_1 . In the second step, we need to extend H_1 into each of the components of $G - G_1$. We will treat one component after the other, starting with C , say. In C we will find a finite subgraph G'_C so that the unique component D of $C - G'_C$ is 3-connected. We will use Theorem 7 in the minor obtained from C by contracting D . As we will require the resulting Tutte path H'_C to start in one of the two vertices in $H_1 \cap C$ and end in the other (here, note (c)), H'_C and H_1 will fit together. Doing this for all components of $G - G_1$, we will construct H_2 ; G_2 will be defined to be the (induced subgraph of the) union of G_1 and all the G'_C . Then, we will repeat the second step infinitely often. See Figure 5 for an illustration.

We wrote “ideally” at the beginning of this outline, and that was for a reason: in one aspect the procedure has to be amended in order to work. It is crucial that the H_i cover all vertices of the G_i —otherwise $\bigcup H_i$ will never be a Hamilton cycle.

FIG. 5. Outline: Bridge K is not covered by H_2 .

However, H'_C will, in general, miss some vertices of G'_C and thus produce nonchordal H'_C -bridges in G'_C . Fortunately, and here the fact that the components of $G - G_i$ are 3-connected will come in handy, we will be able to force such a nonchordal bridge to have all its neighbors in $G'_C \cup D$. This will allow us to “put the bridge back”: it will be merged with D and, thus, covered in later steps.

Let us continue with the proof. As the construction of the base case, i.e., when $i = 1$, is quite similar to the general case, i.e., when $i \geq 2$, we will treat both at once. However, for some of the steps we will need to make case distinctions. Put $G_0 := \emptyset$, $H_0 := \emptyset$, and $\mathcal{C}_0 = \{G\}$, and assume (G_{i-1}, H_{i-1}) to be constructed for some $i \geq 1$. Consider a component $C \in \mathcal{C}_{i-1}$.

First, let $i = 1$, and note that as $C = G$ has only finitely many ends, we can choose a finite vertex set W such that no two ends belong to the same infinite component of $G - W$. Denote by F_C a face boundary of $|G|$, and pick an edge $x_C y_C \in E(F_C)$, a vertex $u_C \in V(F_C)$ with $u_C \notin \{x_C, y_C\}$, and a vertex $v_C \notin \{u_C, x_C, y_C\}$ that is adjacent to u_C . Put $U_C := W \cup \{u_C, v_C, x_C, y_C\}$.

For $i \geq 2$, observe that, by (c), H_{i-1} contains exactly two vertices of C , u_C and v_C , say. By (iii), u_C and v_C are neighbors of G_{i-1} . In the embedding of $\overline{C}$ induced by $|G|$, all the neighbors of the connected graph G_{i-1} that lie in C are contained in the same face boundary F_C of $\overline{C}$. Pick an edge $x_C y_C \in E(F_C)$ such that $x_C y_C \neq u_C v_C$, and let U_C be the union of $\{u_C, v_C, x_C, y_C\}$ together with all neighbors of G_{i-1} in C . Thus, $U_C \subseteq V(F_C)$ separates C from the rest of G .

For later use, we note that

$$(4.1) \quad \text{if } i = 1, \text{ then } U_C \text{ separates the ends of } G, \text{ and if } i \geq 2, \text{ then } U_C \subseteq V(F_C) \text{ separates } C \text{ from } G - C$$

and

$$(4.2) \quad u_C \neq v_C \text{ and } |\{u_C, v_C, x_C, y_C\}| \geq 3 \text{ (resp., } = 4 \text{ for } i = 1).$$

Since C is 3-connected (resp., 4-connected for $i = 1$) there are three (resp., four) internally disjoint paths in C between any two vertices in U_C . Denote by Y_C the vertex set of the union of three (resp., four) such paths for each pair of vertices in U_C . Clearly, U_C is externally 3-connected (resp., externally 4-connected for $i = 1$) in $C[Y_C]$.

Let $\omega_1, \dots, \omega_n$ be the ends belonging to C . (Note that if $n \geq 2$, then $i = 1$.) Setting $S_1 := N(C)$ we apply Lemma 10 to Y_C, ω_1, S_1 , which yields a finite vertex set S'_1 , so that $C(S'_1, \omega_1)$ is 3-connected and disjoint from Y_C and so that $C - C(S'_1, \omega_1)$

is 2-connected. Now, proceeding by induction, we set $S_j := S_{j-1} \cup (N(S'_{j-1}) \cap V(C(S'_{j-1}, \omega_{j-1})))$ and denote by S'_j the finite vertex set that the application of Lemma 10 to Y_C, ω_j, S_j yields. Note that $C(S'_j, \omega_j)$ is 3-connected and disjoint from Y_C and that $C(S_j, \omega_j) - C(S'_j, \omega_j) = C - \bigcup_{l=1}^j C(S'_l, \omega_l)$ is 2-connected. Having done this for $j = 1 \dots n$, we set $G'_C := C - \bigcup_{j=1}^n C(S'_j, \omega_j)$ and observe that G'_C is a finite graph: it is connected but cannot contain any ray, since each ray has a tail in one of the $C(S'_j, \omega_j)$. Since $C[Y_C] \subseteq G'_C$, it holds therefore that

$$(4.3) \quad G'_C \text{ is a finite 2-connected graph, and } U_C \text{ is externally 3-connected (resp., externally 4-connected for } i = 1) \text{ in } G'_C.$$

Moreover, as $U_C \subseteq V(G'_C)$ contains all neighbors of G_{i-1} in C , it follows that

$$(4.4) \quad G'_i := G[V(G_{i-1} \cup \bigcup_{B \in \mathcal{C}_{i-1}} G'_B)] \text{ is connected, and every component of } G - G'_i \text{ is 3-connected and has exactly one end of } G \text{ belonging to it.}$$

The graph G'_i will serve as a precursor to G_i . Note that each component of $G - G'_i$ is of the form $C(S'_j, \omega_j)$ for some j and $C \in \mathcal{C}_{i-1}$, and vice versa. To avoid several indices we will from now on denote the set of components of $G - G'_i$ that lie in a $C \in \mathcal{C}_{i-1}$ by $\mathcal{D}_C$. Observe that for $i > 1$ it holds that $|\mathcal{D}_C| = 1$.

As stated in the outline above, we now want to use Theorem 7 in the minor obtained from C by contracting all elements of $\mathcal{D}_C$. Working in this minor, instead of in G'_C , say, has the advantage that we can force the resulting Tutte path $\tilde{H}_C$ to go through each contraction vertex. If $E(\tilde{H}_C)$ is viewed as a subset of $E(G)$, then this means that $E(\tilde{H}_C)$ uses exactly two edges in the cut $E(G - D, D)$ for every $D \in \mathcal{D}_C$, which is (iv). However, we need slightly more: we need that these two edges are not incident with the same vertex in D —see condition (c). To achieve this, we will delete some edges from $E(G - D, D)$ before forming the minor. This is what we will do next; see Figure 6 for an illustration.

So, consider a $D \in \mathcal{D}_C$. Let M_D be obtained from $E(D, G - D)$ by deleting for each vertex in D all but one of the incident edges in $E(D, G - D)$. Thus,

$$(4.5) \quad \text{every neighbor of } G'_C \text{ in } D \text{ is incident with exactly one edge of } M_D.$$

Starting from G'_C define a 2-connected finite plane graph $\tilde{G}_C$ as follows: for every $D \in \mathcal{D}_C$ put a vertex z_D into the face of G'_i that contains D and link z_D to the vertices in G'_C that are incident with an edge in M_D . We will identify these linking edges with the edges in M_D . Note that the resulting graph, which is a minor of G , may have parallel edges. Then, since, for $i = 1$, F_C is a face boundary of $|G|$ such that $u_C, x_C, y_C \in V(F_C)$ and since, for $i \geq 2$, $U_C \subseteq V(F_C)$, this also holds for a face boundary $\tilde{F}_C$ of $\tilde{G}_C$, i.e.,

$$(4.6) \quad \text{for } i = 1 \text{ we have } u_C, x_C, y_C \in V(\tilde{F}_C), \text{ and for } i \geq 2 \text{ it holds that } U_C \subseteq V(\tilde{F}_C).$$

We apply Theorem 7 to $\tilde{G}_C$ and obtain an $\tilde{F}_C$ -Tutte path (resp., cycle for $i = 1$) $\tilde{H}_C$ from u_C to v_C (resp., through $u_C v_C$) and through $x_C y_C$. (More precisely, if $\tilde{G}_C$ has parallel edges, we first subdivide these before using Theorem 7; the obtained Tutte path then induces a Tutte path in $\tilde{G}_C$.) From (4.2) it follows that

$$(4.7) \quad |V(\tilde{H}_C) \cap U_C| \geq 3 \text{ (resp., } \geq 4 \text{ for } i = 1).$$

FIG. 6. Claims (4.1)–(4.5).

Next, we show that

- (4.8) *for every nonchordal $\tilde{H}_C$ -bridge K in $\tilde{G}_C$, $K - \tilde{H}_C$ is disjoint from U_C , and all its neighbors in G lie in $G'_C \cup D$ for some $D \in \mathcal{D}_C$.*

Suppose that $K - \tilde{H}_C$ meets U_C . If $i \geq 2$, then K contains an edge of $\tilde{F}_C$, as $U_C \subseteq V(\tilde{F}_C)$ by (4.6). Thus, K has at most two (resp., three for $i = 1$) attachments as $\tilde{H}_C$ is an $\tilde{F}_C$ -Tutte path (resp., cycle). Since U_C is externally 3-connected (resp., externally 4-connected) in G'_C by (4.3), this implies $U_C \subseteq V(K)$. Thus, by (4.7), $K - \tilde{H}_C$ contains a vertex in $V(\tilde{H}_C) \cap U_C$, which is a contradiction. Therefore, $K - \tilde{H}_C$ is disjoint from U_C .

To prove the second assertion, first assume that $i = 1$. Then $C = G$ consists of G'_C and $\bigcup_{D \in \mathcal{D}_C} D$ (plus edges between these graphs). Let there be a neighbor of $K - \tilde{H}_C$ in $D \in \mathcal{D}$ (i.e., $z_D \in V(K)$). As $U_C \subseteq V(G'_C)$, all the $D' \in \mathcal{D}_C$ are disjoint from U_C . On the other hand, U_C separates the ends of G , by (4.1), and thus D from all $D' \in \mathcal{D}_C$, $D' \neq D$. Consequently, $K - \tilde{H}_C$, which is disjoint from U_C , cannot have neighbors in any $D' \in \mathcal{D}_C$ other than D . If, on the other hand, $i \geq 2$, then $\mathcal{D}_C$ consists of only one element, D , say. As $G'_C = C - D$ and as $K - \tilde{H}_C$ is disjoint from U_C , the assertion follows from (4.1).

It holds that

- (4.9) $z_D \in V(\tilde{H}_C)$ for every $D \in \mathcal{D}_C$.

Indeed, suppose there is a $D \in \mathcal{D}_C$ with $z_D \notin V(\tilde{H}_C)$. Thus, $z_D \in V(K - \tilde{H}_C)$ for some $\tilde{H}_C$ -bridge K . Denote by f_D the face of $G - D$ that contains D . Then there exists a vertex a in the face boundary of f_D that does not lie in $V(K)$. Indeed, otherwise the at most three attachments of K separate D from $U_C \setminus V(K) \neq \emptyset$ in G , contradicting that G is 6-connected. (Note here that because of (4.8) and as $z_D \in V(K - \tilde{H}_C)$, all vertices of attachment of K are indeed vertices of G .)

Next, observe that a is not incident with any edge in M_D as $z_D \in V(K - \tilde{H}_C)$. Therefore, there is a unique face $f \subseteq f_D$ of (the closure of) $(G - D) \cup D \cup M_D$ whose face boundary F contains a . Furthermore, F contains exactly two edges of M_D ; let these be uc and bw , where $u, b \in V(D)$; see Figure 7. As G is 6-connected, there is then a path P between a vertex $v \in V(D)$ and a that avoids u, b , and the at most three vertices of attachment of K (which are vertices of G , as above). We may assume that v is the only vertex on P in D . We note that $v \notin V(F)$: as the first edge on P lies in $E(D, G - D)$, v is incident with an edge in M_D , by (4.5), but the only two vertices in $V(F)$ incident with edges in M_D are u, b .

FIG. 7. Subdivision of $K_{3,3}$ in (4.9).

We claim now that by adding some (noncrossing) edges in the plane graph $(G - D) \cup D \cup \{uc, bw, vv'\}$, we obtain a subdivision of $K_{3,3}$ with partition sets $\{a, b, c\}$ and $\{u, v, w\}$, which clearly contradicts planarity. We already have the edges uc and bw , and the v - a path P . Since all of a, u, w lie in F , we can add new edges, drawn in f , between a and each of u, w . We add another new edge, between v and c , which will be drawn in $f_D \setminus f$; this is possible since $v \notin V(F)$. As D is 3-connected, there are two disjoint paths in D , one from b to u and the second from b to v ; these yield two more subdivided edges in the $K_{3,3}$. All that remains now is to find a path from c to w . As endvertices of edges in M_D , both c and w lie in K (because $z_D \in V(K - \tilde{H}_C)$). Thus, if $K - z_D$ is connected (in G), there will be c - w path in $K - z_D$ avoiding all the other subdivided edges—note that P is disjoint from $K - z_D$ as it could only leave K through one of its vertices of attachment.

So, suppose that $K - z_D$ has two components. Because of (4.8), each component must contain a vertex in the boundary of f_D . As K has at most three vertices of attachment, one of the components, K' , say, has at most one vertex in the boundary of f_D . But then this single vertex separates K' from the rest of G , which is a contradiction. This establishes (4.9).

Consider $E(\tilde{H}_C)$ as a subset of $E(G)$, and let H_C be the subgraph of G consisting of the edges $E(\tilde{H}_C)$ and the incident vertices. Put $H_i := H_{i-1} \cup \bigcup_{C \in \mathcal{C}_{i-1}} H_C$, and observe that the pair (G'_i, H_i) already satisfies almost all of the desired properties. Clearly, (b) is (4.4), and (c) holds because of (4.9) and the definition of M_D . Moreover, for (a), $(G_1, H_1), \dots, (G_{i-1}, H_{i-1}), (G'_i, H_i)$ should be a good sequence, and indeed, it at least satisfies (i), (ii), (iv), (v): (i) holds because of $U_C \subseteq V(G'_C)$ for every $C \in \mathcal{C}_{i-1}$ (for $i \geq 2$), (ii) because no H_C uses edges of G_{i-1}^+ , and (iv) because of (4.9). To see (v), add a path through D between the two vertices of H_i in D for every $D \in \mathcal{D}_C$, and denote the resulting subgraph by Z . Clearly, Z is connected, and every $w \in V(Z)$ has degree two: if $w \in V(G_{i-1})$, then because of (v) for $i - 1$, if $w \in \{u_C, v_C\}$, then because $u_C \neq v_C$, if $w \in V(H_i - H_{i-1})$ because H_i is a disjoint union of paths for every C , and finally if $w \in V(Z - H_i)$ because $Z - H_i$ is a disjoint union of paths. Thus, Z is a cycle.

However, (iii) may fail. To fix this, consider a nonchordal H_i -bridge K in G'_i . By (iii) for $i - 1$, we deduce that $K - H_i$ is disjoint from G_{i-1} . Observe that for each $C \in \mathcal{C}_{i-1}$, $K \cap G'_C$ is empty, a chord, or a union of H_C -bridges. Thus, $K - H_i$ is disjoint from U_C , by (4.8), which implies with Lemma 9 that $G'_i - (K - H_i)$ still satisfies

(i) and (b) and then also (i), (ii), (iv), (v), and (c). Thus, putting $G_i := G'_i - (G'_i - H_i)$, we see that for the pair (G_i, H_i) conditions (a)–(c) hold. $\square$

PROLIFIC CODES WITH THE IDENTIFIABLE PARENT PROPERTY*

SIMON R. BLACKBURN[†], TUVI ETZION[‡], AND SIAW-LYNN NG[†]

Abstract. Let $\mathcal{C}$ be a code of length n over an alphabet of size q . A word $\mathbf{d}$ is a *descendant* of a pair of codewords $\mathbf{x}, \mathbf{y} \in \mathcal{C}$ if $d_i \in \{x_i, y_i\}$ for $1 \leq i \leq n$. A code $\mathcal{C}$ is an *identifiable parent property* (IPP) code if the following property holds. Whenever we are given $\mathcal{C}$ and a descendant $\mathbf{d}$ of a pair of codewords in $\mathcal{C}$, it is possible to determine at least one of these codewords. The paper introduces the notion of a prolific IPP code. An IPP code is *prolific* if all q^n words are descendants. It is shown that linear prolific IPP codes fall into three infinite (“trivial”) families, together with a single sporadic example which is ternary of length 4. There are no known examples of prolific IPP codes which are not equivalent to a linear example: the paper shows that for most parameters there are no prolific IPP codes, leaving a relatively small number of parameters unsolved. In the process the paper obtains upper bounds on the size of a (not necessarily prolific) IPP code which are better than previously known bounds.

Key words. error-correcting codes, identifiable parent property, linear codes, MDS codes, orthogonal arrays, copyright protection

AMS subject classifications. 94B60, 94A60, 94B65

DOI. 10.1137/070695551

1. Introduction. Codes with the identifiable parent property were first introduced by Hollmann et al. [9] in 1998, motivated by an application to prevent software piracy. IPP codes and various generalizations have since been intensively studied; see, for example, the papers of Alon et al. [1], Alon, Fischer, and Szegedy [2], Alon and Stav [3], Barg et al. [4], Barg and Kabatiansky [5], Blackburn [6], Lindkvist, Löfvenberg, and Svanström [10], Löfvenberg [11], Staddon, Stinson, and Wei [13], Tô and Safavi-Naini [14], van Trung and Martirosyan [15], and Yemane [16].

To define IPP codes we need the notion of a descendant, which is defined as follows. Let F be an alphabet of size q . Let $\mathbf{x} = x_1x_2 \dots x_n \in F^n$ and $\mathbf{y} = y_1y_2 \dots y_n \in F^n$ be q -ary words of length n . The set of *descendants* $\text{desc}(\mathbf{x}, \mathbf{y})$ of $\mathbf{x}$ and $\mathbf{y}$ is defined to be

$$\text{desc}(\mathbf{x}, \mathbf{y}) = \{d_1d_2 \dots d_n \in F^n : d_i \in \{x_i, y_i\} \text{ for } i = 1, 2, \dots, n\}.$$

If $\mathbf{d} \in \text{desc}(\mathbf{x}, \mathbf{y})$, we say that $\mathbf{d}$ is a *descendant* of $\mathbf{x}$ and $\mathbf{y}$, and we say that $\{\mathbf{x}, \mathbf{y}\}$ is a set of *parents* of $\mathbf{d}$. We say that the parent $\mathbf{x}$ *contributes to the i th component of $\mathbf{d}$* if $x_i = d_i$. Clearly $|\text{desc}(\mathbf{x}, \mathbf{y})| = 2^{d(\mathbf{x}, \mathbf{y})}$, where $d(\mathbf{x}, \mathbf{y})$ is the Hamming distance between $\mathbf{x}$ and $\mathbf{y}$.

Let $\mathcal{C}$ be an (n, q, M) -code (so $\mathcal{C}$ is a q -ary code of length n , containing M codewords). Informally, $\mathcal{C}$ has the identifiable parent property (we say $\mathcal{C}$ is an *IPP code* or an (n, q, M) -*IPP code*) if, whenever we are given a descendant $\mathbf{d}$ of two codewords,

we are able to identify one of the parents. More formally, $\mathcal{C}$ is an IPP code if the following holds. For $\mathbf{d} \in F^n$, define

$$P_{\mathbf{d}} = \{\{\mathbf{x}, \mathbf{y}\} \subseteq \mathcal{C} : \mathbf{d} \in \text{desc}(\mathbf{x}, \mathbf{y})\}.$$

Then $\mathcal{C}$ is an IPP code if for all $\mathbf{d} \in F^n$ which are descendants of one or more pairs of codewords

$$\bigcap_{\{\mathbf{x}, \mathbf{y}\} \in P_{\mathbf{d}}} \{\mathbf{x}, \mathbf{y}\} \neq \emptyset.$$

The following lemma, due to Hollmann et al. [9], gives simple criteria for a code to have the identifiable parent property.

LEMMA 1.1. *An (n, q, M) -code $\mathcal{C}$ is an IPP code if and only if the following hold:*

- IPP1. *For any three distinct codewords $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathcal{C}$ there exists $i \in \{1, 2, \dots, n\}$ such that x_i, y_i , and z_i are distinct.*
- IPP2. *For any four codewords $\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{v} \in \mathcal{C}$ such that $\{\mathbf{x}, \mathbf{y}\} \cap \{\mathbf{z}, \mathbf{v}\} = \emptyset$, there exists $i \in \{1, 2, \dots, n\}$ such that $\{x_i, y_i\} \cap \{z_i, v_i\} = \emptyset$.*

Hollmann et al. [9] observed that the ternary Hamming code of length 4 is an example of a $(4, 3, 9)$ -IPP code:

$$\mathcal{C} = \{0000, 0111, 0222, 1012, 1120, 1201, 2021, 2102, 2210\}.$$

To see why $\mathcal{C}$ is an IPP code, note that since all codewords are at distance 3, a descendant $\mathbf{d} \in \text{desc}(\mathbf{x}, \mathbf{y})$ is at distance at most 1 from exactly one of its parents $\mathbf{x}, \mathbf{y}$. But the minimum distance of the code shows that $\mathbf{d}$ cannot be of distance at most 1 from two distinct codewords. Thus $\mathcal{C}$ is an IPP code, with the identified parent of a descendant $\mathbf{d}$ being the unique codeword at distance at most 1 from $\mathbf{d}$.

This example has the beautiful property that every possible word is a descendant. We say that a code is *prolific* if every word is a descendant of some pair of codewords. The main question this paper asks is, What other examples of prolific IPP codes are there? This question is motivated by an attempt to draw parallels between error-correcting codes and IPP codes. There are clear connections between the two areas: at a most basic level, we observed above that the size of the set of descendants is related to Hamming distance; moreover, error-correcting codes of high minimum distance provide good explicit constructions of IPP codes (see Hollmann et al. [9, Theorem 4], for example). From this perspective, prolific IPP codes may be thought of as analogues of perfect error-correcting codes.

There are three *trivial* families of prolific IPP codes. First, the set F of all words of length 1 is a prolific $(1, q, q)$ -IPP code. Second, the repetition code of length 2 (with codewords of the form aa , where $a \in F$) is a prolific $(2, q, q)$ -IPP code. Third, any binary word and its complement form a prolific $(n, 2, 2)$ -IPP code. It is easy to see that a prolific IPP code which has length 1 or 2, or which is a binary code, must be equivalent to a member of one of these three families, and so from now on we assume that $n \geq 3$ and $q \geq 3$.

All the examples above are linear codes. One main goal of the paper is to show that the $(4, 3, 9)$ -code above is the only nontrivial example of a linear prolific IPP code (up to equivalence). In general, we conjecture that there are no more examples of prolific IPP codes (linear or not). We do not know how to show this, but we are able to prove that there are no more examples when $n \leq 5$ (due to space constraints, we just provide a sketch proof for the case $n = 5$). In addition, we rule out many

other parameters. As a side-benefit of our investigations, we are able to provide new upper bounds on the size of a (not necessarily prolific) IPP code.

For the rest of this paper, $\mathcal{C}$ will be a q -ary code of length n with M codewords. We write words and subwords in a bold font to distinguish them from components of codewords. We write $\ell(\mathbf{x})$ for the length of the (sub)word $\mathbf{x}$.

The paper is structured as follows. In section 2, we provide some simple upper and lower bounds for the size of a prolific IPP code. Section 3 shows that there are no nontrivial linear prolific IPP codes other than the $(4, 3, 9)$ -code above. We then turn our attention away from the linear case. We provide new upper bounds for (not necessarily prolific) IPP codes in section 4. Sections 5 and 6 show that there are no nontrivial examples of prolific IPP codes for lengths 3 and 4, respectively, other than the $(4, 3, 9)$ example. Section 7 contains a sketch proof that there are no nontrivial examples of length 5. Finally, section 8 summarizes the parameters where it is unknown whether a prolific IPP code exists and comments on possibilities for future work.

2. General bounds for prolific IPP codes. Since prolific IPP codes have many descendants, it seems intuitively plausible that they must be fairly large. This is indeed the case, and this section makes this precise by establishing lower bounds on the size of a prolific IPP code. For many parameters these lower bounds conflict with known upper bounds on the size of an IPP code, and so the bounds rule out the existence of a prolific IPP code for these parameters.

The simplest lower bound on the size of a prolific IPP code is stated in the following theorem.

THEOREM 2.1. *If $\mathcal{C}$ is an (n, q, M) prolific IPP code, then $\binom{M}{2}2^n \geq q^n$.*

Proof. There are at most $\binom{M}{2}$ pairs of codewords from $\mathcal{C}$. Each pair of codewords can produce at most 2^n descendants, since there are at most two possibilities for each component of a descendant once the pair of parents is fixed. So $\mathcal{C}$ has at most $\binom{M}{2}2^n$ descendants. The bound follows once we observe that all q^n words must be descendants since $\mathcal{C}$ is prolific. $\square$

The counting argument used above will tend to significantly overcount descendants which are close to a codeword (in terms of Hamming distance). We can overcome this problem by counting the descendants of the code in another way, giving us the following improvement on Theorem 2.1.

THEOREM 2.2. *Let $\mathcal{C}$ be an (n, q, M) prolific IPP code and let k be a positive integer. Then*

$$M \left(\sum_{i=0}^k \binom{n}{i} (q-1)^i + \frac{M-1}{2} \sum_{i=k+1}^{n-k-1} \binom{n}{i} \right) \geq q^n.$$

Proof. We count the descendants of $\mathcal{C}$ as follows. A sphere of radius k contains $\sum_{i=0}^k \binom{n}{i} (q-1)^i$ words, and so there are at most $M(\sum_{i=0}^k \binom{n}{i} (q-1)^i)$ descendants of $\mathcal{C}$ at distance at most k from the code. A descendant of a pair $\{\mathbf{c}_1, \mathbf{c}_2\} \subseteq \mathcal{C}$ of codewords is formed by choosing i components from $\mathbf{c}_1$ and the remaining $n-i$ components from $\mathbf{c}_2$ for some $i \in \{0, 1, \dots, n\}$. But when $0 \leq i \leq k$ or $n-k \leq i \leq n$ the resulting descendant is within distance k of the code. So each of the $\binom{M}{2}$ pairs of codewords gives rise to at most $\sum_{i=k+1}^{n-k-1} \binom{n}{i}$ descendants of distance greater than k from the code. Thus $\mathcal{C}$ has at most $M(\sum_{i=0}^k \binom{n}{i} (q-1)^i + \frac{M-1}{2} \sum_{i=k+1}^{n-k-1} \binom{n}{i})$ descendants, and the theorem follows by the same argument as in Theorem 2.1. $\square$

We finish this section by stating an upper bound on an IPP code due to Hollmann et al. [9]. For many parameters, this upper bound conflicts with the lower bounds above, showing that no prolific IPP codes exist for these parameters.

THEOREM 2.3. *Let $\mathcal{C}$ be an IPP code of length 3, where position i , $1 \leq i \leq 3$, of a codeword is taken from an alphabet Q_i . Then*

$$(2.1) \quad |\mathcal{C}| \leq |Q_1| + |Q_2| + |Q_3| - 1.$$

Hollmann et al. used (2.1) to obtain the following bounds on the size of IPP codes.

THEOREM 2.4. *Let $\mathcal{C}$ be an (n, q, M) -IPP code.*

(i) *If $n = 3\ell - 2$, then $M \leq q^\ell + 2q^{\ell-1} - 1$.*

(ii) *If $n = 3\ell - 1$, then $M \leq 2q^\ell + q^{\ell-1} - 1$.*

(iii) *If $n = 3\ell$, then $M \leq 3q^\ell - 1$.*

Proof. Write $n = k_1 + k_2 + k_3$, where $k_i \in \{\ell - 1, \ell\}$. Define $Q_i = F^{k_i}$. We may write any codeword in $\mathcal{C}$ in the form $\mathbf{x}_1\mathbf{x}_2\mathbf{x}_3$, where $\ell(\mathbf{x}_i) = k_i$. So $\mathcal{C}$ can be regarded as a length 3 code, with symbols in position i taken from the alphabet Q_i . It is easy to verify that $\mathcal{C}$ is still an IPP code when thought of in this way, and so the bound follows by Theorem 2.3. $\square$

3. Linear codes. The goal of this section is to prove Theorem 3.2, that there are no nontrivial linear prolific IPP codes other than the $(4, 3, 9)$ -code from the introduction. The most difficult step is to prove this result in the special case when the code is maximal distance separable (MDS); see Lemma 3.1. (Recall that an *MDS code* is a linear- (n, q, q^k) code of minimum distance $n - k + 1$.)

Note that an (n, q, q^k) -code of minimum distance $n - k + 1$ meets the Singleton bound. In particular, whenever we restrict all codewords to a set of k positions, we find that every word of length k appears exactly once as a restriction. We refer to this property as the *MDS property* of the code.

We use the well-known result that an (n, q, q^k) -code $\mathcal{C}$ with minimum distance $n - k + 1$ can exist only when $q \geq n - k + 1$. To see this, note that we can construct an $(n - k + 2, q, q^2)$ -code $\mathcal{C}'$ of minimum distance $n - k + 1$ by taking all codewords in $\mathcal{C}$ ending in $k - 2$ zeros, and then removing these zeros to produce words of length $n - k + 2$. But then $\mathcal{C}'$ implies the existence of a set of $n - k$ mutually orthogonal Latin squares of order q (see Hill [8, Theorem 10.20]), and such a set can have size at most $q - 1$ (see Hill [8, Theorem 10.18]).

LEMMA 3.1. *Let $\mathcal{C}$ be a linear (n, q, q^k) -code of minimum distance $n - k + 1$ (in other words, $\mathcal{C}$ is an MDS code). Let $n \geq 3$ and $q \geq 3$. If $\mathcal{C}$ is a prolific IPP code, then $n = 4$, $q = 3$, and $k = 2$. In particular, no MDS code of length strictly greater than 4 is a prolific IPP code.*

Proof. Assume that we are not in the case when $n = 4$, $q = 3$, and $k = 2$. We need to show that $\mathcal{C}$ is not a prolific IPP code. We deal with the length 3 and 4 cases first, and then go on to consider the remaining cases.

Suppose that $n = 3$. When $k = 0$ or $k = 1$, we see that $\mathcal{C}$ is too small to be a prolific code, by Theorem 2.1. When $k = 2$ or $k = 3$ we see that $\mathcal{C}$ is too large to be an IPP code, by Theorem 2.4. So we get a contradiction when $n = 3$, as required.

Suppose that $n = 4$. Theorem 2.1 implies that $k \geq 2$, and Theorem 2.4 implies that $k \leq 2$. So we may assume that $k = 2$, and thus $q > 3$ and $\mathcal{C}$ is a $(4, q, q^2)$ code of minimum distance 3. The union of spheres of radius 1 about codewords contains $q^2(1 + 4(q - 1))$ words, and since $q > 3$ we have that $q^2(1 + 4(q - 1)) < q^4$. So there exists a word $\mathbf{d} = d_1d_2d_3d_4$ of distance at least 2 from any codeword. By the

MDS property of $\mathcal{C}$, there exist codewords $\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3, \mathbf{c}_4 \in \mathcal{C}$ of the form $\mathbf{c}_1 = d_1 d_2 **$, $\mathbf{c}_2 = ** d_3 d_4$, $\mathbf{c}_3 = d_1 ** d_4$, and $\mathbf{c}_4 = * d_2 d_3 *$. These codewords are distinct, since $\mathbf{d}$ is at distance 2 from $\mathcal{C}$. But then the sets $\{\mathbf{c}_1, \mathbf{c}_2\}$ and $\{\mathbf{c}_3, \mathbf{c}_4\}$ violate IPP2. (Recall the definition of IPP2 from Lemma 1.1.) So we have a contradiction in this case.

It remains to consider the situation when $n > 4$. We distinguish between six cases. In the first two cases we show that $\mathcal{C}$ is not an IPP code; in the remaining cases we show that $\mathcal{C}$ cannot be prolific.

Case 1. $n \leq 3k - 3$. Define integers n_1, n_2 , and n_3 by $n_1 = \lceil \frac{n}{3} \rceil$, $n_2 = \lfloor \frac{n}{3} \rfloor$, and $n_3 = n - \lceil \frac{n}{3} \rceil - \lfloor \frac{n}{3} \rfloor$. We can write each codeword in the form $\mathbf{x}_1 \mathbf{x}_2 \mathbf{x}_3$, where $\ell(\mathbf{x}_i) = n_i$. Let $\mathbf{c}_0 = \mathbf{000}$ be the all-zero codeword. Since $n_1 \leq k$, there are exactly q^{k-n_1} codewords of the form $\mathbf{0}**$. Since $n_1 < k$, we have that $q^{k-n_1} > 1$, and so there exists a codeword $\mathbf{c}_1 \in \mathcal{C} \setminus \{\mathbf{c}_0\}$ of the form $\mathbf{c}_1 = \mathbf{0}*\mathbf{y}$ for some word $\mathbf{y}$ of length n_3 . Similarly, since $n_2 < k$ there exists a codeword $\mathbf{c}_2$ distinct from $\mathbf{c}_0$ of the form $\mathbf{c}_2 = *\mathbf{0}*$, and since $n_3 < k$ there is a codeword $\mathbf{c}_3$ distinct from $\mathbf{c}_1$ of the form $**\mathbf{y}$. If $\mathbf{y} = \mathbf{0}$, then the codewords $\mathbf{c}_0, \mathbf{c}_1$, and $\mathbf{c}_2$ violate IPP1; if $\mathbf{y} \neq \mathbf{0}$, then the sets $\{\mathbf{c}_0, \mathbf{c}_3\}$ and $\{\mathbf{c}_1, \mathbf{c}_2\}$ violate IPP2. So $\mathcal{C}$ is not an IPP code.

Case 2. $n = 3k - 2$. Note that since $n > 4$, we have that $k \geq 3$. Define $n_1 = n_2 = k - 1$ and $n_3 = k$. As before, we can write any codeword in the form $\mathbf{x}_1 \mathbf{x}_2 \mathbf{x}_3$, where $\ell(\mathbf{x}_i) = n_i$. Let $\mathbf{c}_0 \in \mathcal{C}$ be the all-zero codeword. Since $n_1 < k$, there exists a codeword $\mathbf{c}_1 \in \mathcal{C} \setminus \{\mathbf{c}_0\}$ of the form $\mathbf{0}*\mathbf{y}$ for some word $\mathbf{y}$ of length n_3 . Since $n_2 = k - 1$, there are $q - 1$ nonzero codewords of the form $*\mathbf{0}*$; moreover, no two distinct words of this form can agree anywhere in their last n_3 positions, as this would contradict the MDS property of the code. This implies (since $q \geq 3$ and $n_3 = k \geq 3$) that we may choose a codeword $\mathbf{c}_2$ distinct from $\mathbf{c}_0$ of the form $\mathbf{c}_2 = *\mathbf{0}\mathbf{z}$, where $d(\mathbf{y}, \mathbf{z}) \geq 2$. Let $\mathbf{w}$ be a word of length n_3 such that $\mathbf{w} \in \text{desc}(\mathbf{y}, \mathbf{z}) \setminus \{\mathbf{y}, \mathbf{z}\}$. Such a word exists since $d(\mathbf{y}, \mathbf{z}) \geq 2$. Let $\mathbf{c}_3$ be the (unique) codeword of the form $**\mathbf{w}$. The sets $\{\mathbf{c}_0, \mathbf{c}_3\}$, $\{\mathbf{c}_1, \mathbf{c}_2\}$ violate IPP2. Hence the code is not an IPP code.

Case 3. $n = 3k - 1$ and $k \geq 4$. We can write any word in the form $\mathbf{x}\mathbf{y}$, where $\ell(\mathbf{x}) = 2k - 2$ and $\ell(\mathbf{y}) = k + 1$. Consider the set $\mathcal{D}$ of all words of the form $\mathbf{0}\mathbf{y}$, where $\mathbf{y}$ has length $k + 1$, all entries in $\mathbf{y}$ are nonzero, and $\mathbf{y}$ does not occur as a suffix of a codeword. There are exactly $(q - 1)^k$ codewords that end in k nonzero symbols, and so $|\mathcal{D}| \geq (q - 1)^{k+1} - (q - 1)^k = (q - 1)^k(q - 2)$. We aim to show that $\mathcal{C}$ cannot be prolific since it cannot have all the words in $\mathcal{D}$ as descendants.

Note that the all-zero word cannot be a parent of any word $\mathbf{d} \in \mathcal{D}$. To see this, note that the all-zero word cannot contribute to any of the last $k + 1$ components of $\mathbf{d}$, and so these $k + 1$ components must come from the other parent. But this would mean that the last $k + 1$ entries of $\mathbf{d}$ would be a suffix of a codeword, contradicting the definition of $\mathcal{D}$.

The MDS property of the code shows that any nonzero codeword in $\mathcal{C}$ has at most $k - 1$ zero entries (for otherwise the codeword would be too close to the all-zero codeword). Since any word $\mathbf{d} \in \mathcal{D}$ begins with $2(k - 1)$ zeros, any pair of parents $\mathbf{c}_1$ and $\mathbf{c}_2$ for $\mathbf{d}$ must each have $k - 1$ zeros in their first $2(k - 1)$ positions, and the positions where the zeros of $\mathbf{c}_1$ occur must be disjoint from the positions where the zeros of $\mathbf{c}_2$ occur. Without loss of generality, we may assume that $\mathbf{c}_1$ has a zero in its first position. There are $\frac{1}{2} \binom{2k-2}{k-1}$ choices for the positions where $\mathbf{c}_1$ is zero; the positions where $\mathbf{c}_2$ is zero are determined by this choice. By the MDS property, there are exactly $q - 1$ choices for a nonzero codeword $\mathbf{c}_1$ with zeros in the specified positions; similarly, there are $q - 1$ choices for $\mathbf{c}_2$. Each pair of codewords $\{\mathbf{c}_1, \mathbf{c}_2\}$ gives rise to at most 2^{k+1} descendants which start with $2k - 2$ zeros. So the pair $\{\mathbf{c}_1, \mathbf{c}_2\}$ can have at most $2^{k+1} - 2$ descendants in $\mathcal{D}$, since no element of $\mathcal{D}$ ends with the suffix

of a codeword. Moreover, the MDS property shows that for every choice of $\mathbf{c}_1$, there is a unique choice for $\mathbf{c}_2$ that agrees with $\mathbf{c}_1$ in its last position. When $\mathbf{c}_2$ is of this form, the pair gives rise to at most $2^k - 2$ descendants in $\mathcal{D}$. Thus $\mathcal{C}$ can have at most

$$\frac{1}{2} \binom{2k-2}{k-1} (q-1) ((q-2)(2^{k+1}-2) + (2^k-2))$$

descendants in $\mathcal{D}$. For $\mathcal{C}$ to be prolific, all words in $\mathcal{D}$ must be descendants, and so

$$\binom{2k-2}{k-1} (q-1) ((q-2)(2^k-1) + (2^{k-1}-1)) \geq |\mathcal{D}| \geq (q-1)^k (q-2).$$

Using the fact that $q \geq n - k + 1 = 2k$, we find that there are no solutions k and q to this inequality, since we are assuming that $k \geq 4$. So there are no prolific codes in this case, as required.

Case 4. $n = 3k - 1$ with $k = 2$. Note that $(5, q, q^2)$ -codes of minimum distance $5 - 1 = 4$ do not exist when $q = 3$, and so we may assume that $q \geq 4$.

A descendant of $\mathcal{C}$ must agree with one of its parents in at least three positions, and so is at distance 2 from this parent. So the set of descendants is contained in the union of the spheres of radius 2 about codewords. We show that these spheres cannot cover all words, and so $\mathcal{C}$ cannot be prolific.

We begin by counting the number of words $\mathbf{d}$ that are in spheres of radius 2 about two codewords $\mathbf{c}_1$ and $\mathbf{c}_2$. Note that since all codewords are at distance at least 4, the word $\mathbf{d}$ has distance exactly 2 from both $\mathbf{c}_1$ and $\mathbf{c}_2$, and the distance from $\mathbf{c}_1$ to $\mathbf{c}_2$ is exactly 4. This implies that the positions where $\mathbf{c}_1$ and $\mathbf{d}$ differ must be disjoint from the positions where $\mathbf{c}_2$ and $\mathbf{d}$ differ, and so no codeword $\mathbf{d}$ lies in more than two spheres of radius 2 about codewords, since we cannot have three pairwise disjoint 2-subsets of a 5-set.

There are $5(q-1)$ codewords at distance 4 from a fixed codeword, and so the number of pairs of codewords at distance 4 is $5q^2(q-1)/2$. Each such pair gives rise to exactly $\binom{4}{2} = 6$ words that lie in spheres of radius 2 about both codewords. So the number of words that are in two spheres of radius 2 is exactly $15q^2(q-1)$ (and no words lie in three or more spheres). Hence the number of words in spheres of radius 2 about $\mathcal{C}$ is

$$q^2(1 + 5(q-1) + 10(q-1)^2) - 15q^2(q-1) = q^2(1 - 10(q-1) + 10(q-1)^2).$$

Since $q \geq 4$, this expression is less than q^5 , and so there are words that are not descendants of the code. Thus $\mathcal{C}$ is not a prolific IPP code, as required.

Case 5. $n = 3k - 1$ and $k = 3$. We may assume that $q \geq n - k + 1 = 6$. But q must be a prime power as $\mathcal{C}$ is linear, and so we may assume that $q \geq 7$. We show the code cannot be prolific by showing that the number of descendants of the code is less than q^8 .

There are $q^3(1 + 8(q-1) + \binom{8}{2}(q-1)^2)$ words within spheres of radius 2 about codewords. All these words are descendants, by the MDS property of the code. It remains to count descendants of distance at least 3 from every codeword.

Let p_i be the number of (unordered) pairs of codewords at distance i . So $p_i = 0$ when $1 \leq i \leq 5$. An upper bound for the number of descendants at distance at least 3 from the code is

$$(3.1) \quad p_6 \binom{6}{3} + p_7 \left(\binom{7}{3} + \binom{7}{4} \right) + p_8 \left(\binom{8}{3} + \binom{8}{4} + \binom{8}{5} \right).$$

Now $p_i = q^3 s_i / 2$, where s_i is the number of codewords of weight i . The weight distribution of any MDS code is known; indeed, we have that

$$\begin{aligned} s_6 &= 28q - 28, \\ s_7 &= 8q^2 - 56q + 48, \\ s_8 &= q^3 - 8q^2 + 28q - 21 \end{aligned}$$

by [12, Theorem 11.6], for example. Substituting these values into (3.1) above, and adding the term which counts descendants at distance at most 2 from the code, we can easily check that the number of descendants is less than q^8 whenever $q \geq 7$, and so $\mathcal{C}$ cannot be prolific in this case.

Case 6. $n \geq 3k$. Consider the set $\mathcal{D}$ of words $\mathbf{0y}$, where $\ell(\mathbf{y}) = k + 1$ and $\mathbf{y}$ is not a suffix of a codeword and contains no zero entries. Note that $|\mathcal{D}| \geq (q - 1)^{k+1} - (q - 1)^k = (q - 1)^k(q - 2) > 0$, and so $\mathcal{D}$ is nonempty. We show that no word in $\mathcal{D}$ can be a descendant of $\mathcal{C}$, and so $\mathcal{C}$ cannot be prolific.

Suppose, for a contradiction, that $\mathbf{d} \in \mathcal{D}$ is a descendant of $\mathcal{C}$. A descendant must agree with one of its parents in at least k of its first $2k - 1$ positions. Since $\mathbf{d}$ begins with $2k - 1$ zeros, one of its parents must have k zero entries and so must be the all-zero codeword. But the final $k + 1$ entries of $\mathbf{d}$ are nonzero, and so the other parent must have contributed them. But this implies that the last $k + 1$ entries of $\mathbf{d}$ are a suffix of this parent, contradicting the definition of $\mathcal{D}$ as required.

From these six cases we deduce that there are no prolific IPP (n, q, q^k) -codes of minimum distance $n - k + 1$ when $n \geq 3$, unless $n = 4$, $q = 3$, and $k = 2$. So the theorem is established. $\square$

We remark that Lemma 3.1 remains true when the assumption that $\mathcal{C}$ is linear is removed; see [7, Theorem 3.1] for details.

THEOREM 3.2. *The only linear nonbinary prolific IPP code of length 3 or more is the $(4, 3, 9)$ -IPP code.*

Proof. Let $\mathcal{C}$ be a prolific $[n, k]$ linear IPP code, where $n \geq 3$. By Lemma 3.1 there are no prolific MDS IPP codes other than the $(4, 3, 9)$ example, so we may assume that $\mathcal{C}$ is not an MDS code. The theorem follows if we can derive a contradiction from this assumption.

Since $\mathcal{C}$ is not MDS, we may permute the columns of the code so that the last k columns of the generator matrix $\mathcal{G}$ form a $k \times k$ matrix with rank $k - 1$.

We can write each codeword in the form $\mathbf{xy}$, where $\ell(\mathbf{x}) = n - k$ and $\ell(\mathbf{y}) = k$. Consider a word $\mathbf{0y}$ where $\mathbf{y}$ has no zeros and is not a suffix of any codeword. A choice for $\mathbf{y}$ certainly exists, since there are at most $(q - 1)^{k-1}$ suffixes of length k of codewords with no zeros, by our condition on the generator matrix $\mathcal{G}$, and so there are at least $(q - 1)^k - (q - 1)^{k-1}$ choices for $\mathbf{y}$.

Since $\mathcal{C}$ is prolific it follows that $\mathbf{0y}$ is a descendant, so there exist codewords $\mathbf{x}_1\mathbf{y}_1, \mathbf{x}_2\mathbf{y}_2 \in \mathcal{C}$ such that $\mathbf{0y} \in \text{desc}(\mathbf{x}_1\mathbf{y}_1, \mathbf{x}_2\mathbf{y}_2)$. Since $\mathbf{y}$ is not a suffix of a codeword, these parents are distinct; moreover, neither parent can be the all-zero codeword. Clearly, $\mathbf{0y}_1 \in \text{desc}(\mathbf{x}_1\mathbf{y}_1, \mathbf{x}_2\mathbf{y}_2)$. The suffix $\mathbf{y}_1$ appears in q codewords of $\mathcal{C}$ by our condition on $\mathcal{G}$, and hence there is a codeword $\mathbf{x}_3\mathbf{y}_1$, where $\mathbf{x}_3 \notin \{\mathbf{x}_1, \mathbf{x}_2\}$. But then we have that $\mathbf{0y}_1 \in \text{desc}(\mathbf{00}, \mathbf{x}_3\mathbf{y}_1)$, which implies that $\mathcal{C}$ is not an IPP code. This contradiction establishes the theorem, as required. $\square$

4. New upper bound on the size of IPP codes. This section establishes a new upper bound on the size of an IPP code, which improves the leading coefficient

in the bound of Theorem 2.4. When the code has length 5, our techniques yield especially good results (and we will need a good bound in section 7). We begin by considering this special case.

LEMMA 4.1. *Let $\mathcal{C}$ be a $(5, q, M)$ -IPP code, where $M > q^2$. Then the minimum distance $d(\mathcal{C})$ of $\mathcal{C}$ is at least 3.*

Proof. Assume, for a contradiction, that $d(\mathcal{C}) \leq 2$. Suppose $\mathbf{c}_1$ and $\mathbf{c}_2$ are codewords at distance 1 or 2. Without loss of generality, assume that $\mathbf{c}_1$ and $\mathbf{c}_2$ agree in their first three positions. Since $M > q^2$, there exist distinct codewords $\mathbf{c}_3$ and $\mathbf{c}_4$ that agree in their final two positions. If the sets $\{\mathbf{c}_1, \mathbf{c}_3\}$ and $\{\mathbf{c}_2, \mathbf{c}_4\}$ are disjoint, then IPP2 is violated. Otherwise, the set $\{\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3, \mathbf{c}_4\}$ has size 3 and IPP1 is violated. In either case, we have a contradiction, as required. $\square$

Theorem 2.4 implies that for a $(5, q, M)$ -IPP code we have $M \leq 2q^2 + q - 1$. The theorem below significantly improves this bound.

THEOREM 4.2. *If $\mathcal{C}$ is a $(5, q, M)$ -IPP code, then $M < \frac{5}{4}q^2 + 5q$.*

Proof. If there is a symbol $x \in F$ and a position $i \in \{1, 2, 3, 4, 5\}$ such that x occurs just once as the i th position of a codeword, we remove this codeword to produce a smaller code. Repeating this process as often as is necessary, we eventually obtain a code $\mathcal{C}'$ in which no symbol appears exactly once in any fixed position. Note that we have removed at most $5q$ codewords to obtain $\mathcal{C}'$, and so $\mathcal{C}'$ has M' codewords where $M - M' \leq 5q$. To prove the theorem, it suffices to show that $M' < \frac{5}{4}q^2$. The theorem follows trivially when $M' \leq q^2$, and so we may assume that $M' = q^2 + \mu$ for some positive integer μ .

For integers i and j such that $1 \leq i < j \leq 5$, define the subset $S_{ij} \subseteq \mathcal{C}'$ by

$$S_{ij} = \{\mathbf{x} \in \mathcal{C}' : \exists \mathbf{y} \in \mathcal{C}' \setminus \{\mathbf{x}\} \text{ such that } x_i = y_i \text{ and } x_j = y_j\}.$$

Note that $|S_{ij}| > \mu$.

We claim that $S_{ij} \cap S_{i'j'} = \emptyset$ whenever $\{i, j\}$ and $\{i', j'\}$ are disjoint pairs of positions. Without loss of generality, it is sufficient to show that $S_{12} \cap S_{34} = \emptyset$. Suppose, for a contradiction, that $\mathbf{c}_1 \in S_{12} \cap S_{34}$. Writing $\mathbf{c}_1 = x_1x_2x_3x_4x_5$, there exist codewords $\mathbf{c}_2, \mathbf{c}_3 \in \mathcal{C}' \setminus \{\mathbf{c}_1\}$ of the form $\mathbf{c}_2 = x_1x_2**y$ and $\mathbf{c}_3 = **x_3x_4z$. Note that $\mathbf{c}_2 \neq \mathbf{c}_3$, by Lemma 4.1. If $|\{x_5, y, z\}| < 3$, then $\{\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3\}$ violates IPP1. If x_5, y and z are distinct, let $\mathbf{c}_4 \in \mathcal{C}'$ be another codeword ending in y (which exists by our choice of $\mathcal{C}'$). Then the sets $\{\mathbf{c}_1, \mathbf{c}_4\}$, $\{\mathbf{c}_2, \mathbf{c}_3\}$ violate IPP2. This contradiction establishes our claim.

For any given disjoint pairs $\{i_1, j_1\}, \{i_2, j_2\} \subseteq \{1, 2, 3, 4, 5\}$ define $Q_{i_1j_1i_2j_2}$ to be the set of symbols that occur in the ℓ th positions of codewords in $S_{i_1j_1}$, where ℓ is the unique position not equal to any of i_1, j_1, i_2, j_2 .

We claim that $Q_{i_1j_1i_2j_2} \cap Q_{i_2j_2i_1j_1} = \emptyset$ for any disjoint pairs $\{i_1, j_1\}$ and $\{i_2, j_2\}$. (In particular, since there are q symbols in total, this claim implies that $|Q_{i_1j_1i_2j_2}| + |Q_{i_2j_2i_1j_1}| \leq q$.) To see why our claim holds, we show (without loss of generality) that $Q_{1234} \cap Q_{3412} = \emptyset$. Assume, for a contradiction, that $x \in Q_{1234} \cap Q_{3412}$. Then the following four codewords lie in $\mathcal{C}'$: $\mathbf{c}_1 = x_1x_2**x$, $\mathbf{c}_2 = x_1x_2***$, $\mathbf{c}_3 = **x_3x_4x$, and $\mathbf{c}_4 = **x_3x_4*$. (These codewords are distinct, since $S_{12} \cap S_{34} = \emptyset$.) But then the pairs $\{\mathbf{c}_1, \mathbf{c}_4\}$ and $\{\mathbf{c}_2, \mathbf{c}_3\}$ violate IPP2, and so our claim follows.

There are $\binom{5}{2}\binom{3}{2} = 30$ subsets $Q_{i_1j_1i_2j_2} \subseteq F$, and the previous paragraph shows that at least half of them are “small” in the sense of satisfying $|Q_{i_1j_1i_2j_2}| \leq \frac{1}{2}q$.

The map from S_{12} to $Q_{1235} \times Q_{1234}$, where $x_1x_2x_3x_4x_5 \mapsto x_4x_5$, is injective, since $S_{12} \cap S_{45} = \emptyset$. Thus $|S_{12}| \leq |Q_{1235}||Q_{1234}|$. Arguing similarly, we find that

$$|S_{12}| \leq \min\{|Q_{1234}||Q_{1235}|, |Q_{1234}||Q_{1245}|, |Q_{1235}||Q_{1245}|\}.$$

A similar inequality exists for any subset S_{ij} . There are in total $\binom{5}{2} = 10$ such inequalities, each involving three subsets $Q_{iji'j'}$. Averaging over all pairs $\{i, j\}$, the expected number of the subsets $Q_{iji'j'}$ in such an inequality which satisfy $|Q_{iji'j'}| \leq \frac{1}{2}q$ is at least $\frac{3}{2}$. So we may find a pair $\{i, j\}$ such that the inequality involves at least two sets $Q_{iji'j'}$ of size at most $\frac{1}{2}q$. But then the inequality implies that $|S_{ij}| \leq (\frac{1}{2}q)^2 = \frac{1}{4}q^2$. Since $\frac{1}{4}q^2 \geq |S_{ij}| > \mu$, we find that $M' = q^2 + \mu < \frac{5}{4}q^2$, as required. $\square$

We comment that, arguing more carefully, it is possible to reduce the term $5q$ in the bound above. Indeed, we have the outline of a proof (with many special cases) that the term can be eliminated. For the sake of simplicity, we content ourselves with proving a bound that eliminates this term in the case of prolific IPP codes.

THEOREM 4.3. *If $\mathcal{C}$ is a $(5, q, M)$ prolific IPP code, then $M < \frac{5}{4}q^2$.*

Proof. Suppose that there is no symbol x that appears just once as the i th position of a codeword. The argument of Theorem 4.2 (where $M = M'$ in our situation) now shows that $M < \frac{5}{4}q^2$. So we may assume that there is a symbol x and a position i such that x appears exactly once as the i th position of a codeword. Replacing $\mathcal{C}$ by an equivalent code if necessary, we may assume (without loss of generality) that $x = 0$, $i = 1$, and $\mathcal{C}$ contains the all-zero word $\mathbf{0}$. So no codeword starts with 0, other than the all-zero codeword.

The word 01111 is a descendant, since $\mathcal{C}$ is prolific. Now, $\mathbf{0}$ is a parent, since no other codeword can contribute to the first position of the descendant. But $\mathbf{0}$ cannot contribute to any of the remaining positions, and so there exists a codeword $\mathbf{c}_1$ of the form $\mathbf{c}_1 = *1111$. Similarly, considering the descendant 01112, there exists a codeword of the form $\mathbf{c}_2 = *1112$. But then $d(\mathbf{c}_1, \mathbf{c}_2) \leq 2$, and so Lemma 4.1 implies that $M \leq q^2 < \frac{5}{4}q^2$, as required. $\square$

We do not see how to generalize the bound of Theorem 4.2, as it is not clear what the analogue of the final paragraph of the proof should be. However, we are able to establish the following theorem.

THEOREM 4.4. *Let $\mathcal{C}$ be an (n, q, M) -IPP code, where $n = 3k - 1$. Then $M < \frac{3}{2}q^k + 3q^{k-1}$.*

Proof. We begin by proving the weaker bound

$$(4.1) \quad M < \frac{3}{2}q^k + \binom{n}{k-1}q^{k-1},$$

and we will then show how our argument can be modified to give the bound of the theorem.

If there are any codewords $\mathbf{c}$ that are uniquely defined by a set of $k - 1$ positions (so there exists a $(k - 1)$ -set X of positions such that $\{\mathbf{u} \in \mathcal{C} : c_i = u_i \text{ for all } i \in X\} = \{\mathbf{u}\}$), we remove them. Repeating this process as often as is necessary, we obtain a code $\mathcal{C}'$ with the property that for all $\mathbf{c} \in \mathcal{C}'$ and for all $(k - 1)$ -sets $X \subseteq \{1, 2, \dots, n\}$ we have that

$$|\{\mathbf{u} \in \mathcal{C}' : c_i = u_i \forall i \in X\}| \geq 2.$$

Note that $\mathcal{C}'$ is an (n, q, M') -code with $M - M' < \binom{n}{k-1}q^{k-1}$. If $M' \leq q^k$, then bound (4.1) holds trivially, and so we may assume that $M' > q^k$. Let μ be the positive integer such that $M' = q^k + \mu$. To show (4.1) holds, it suffices to show that $\mu \leq \frac{1}{2}q^2$.

For a subset $T \subseteq \{1, 2, \dots, n\}$ of k positions, define a subset $S_T \subseteq \mathcal{C}'$ by

$$S_T = \{\mathbf{x} \in \mathcal{C}' : \exists \mathbf{y} \in \mathcal{C}' \setminus \{\mathbf{x}\} \text{ such that } x_i = y_i \text{ for } i \in T\}.$$

Note that $|S_T| > \mu$. We claim that $S_{T_1} \cap S_{T_2} = \emptyset$ whenever T_1 and T_2 are disjoint. To see this, assume (without loss of generality) that $T_1 = \{1, 2, \dots, k\}$ and $T_2 = \{k+1, k+2, \dots, 2k\}$ and suppose (for a contradiction) that $\mathbf{c} \in S_{T_1} \cap S_{T_2}$. We may write $\mathbf{c} = \mathbf{x}\mathbf{y}\mathbf{z}$, where $\ell(\mathbf{x}) = \ell(\mathbf{y}) = k$ and $\ell(\mathbf{z}) = k-1$. Since $\mathbf{c} \in S_{T_1} \cap S_{T_2}$, there exist codewords $\mathbf{c}_2, \mathbf{c}_3 \in \mathcal{C}' \setminus \{\mathbf{c}_1\}$ of the form $\mathbf{c}_2 = \mathbf{x}\mathbf{w}$ and $\mathbf{c}_3 = \mathbf{y}\mathbf{u}$. Suppose that $|\{\mathbf{z}, \mathbf{w}, \mathbf{u}\}| < 3$. Then we find that IPP1 is violated. For if $\mathbf{c}_2 \neq \mathbf{c}_3$, then $\{\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3\}$ violates IPP1. Moreover, if $\mathbf{c}_2 = \mathbf{c}_3$ (which implies $\mathbf{z} \neq \mathbf{w}$), then $\{\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_4\}$ violates IPP1, where $\mathbf{c}_4 \in \mathcal{C}$ has $\mathbf{w}$ as a suffix and is distinct from $\mathbf{c}_2$. (Our construction of $\mathcal{C}'$ guarantees that $\mathbf{c}_4$ exists.) Now suppose that $|\{\mathbf{z}, \mathbf{w}, \mathbf{u}\}| = 3$. We find that IPP2 is violated by the sets $\{\mathbf{c}_1, \mathbf{c}_4\}$ and $\{\mathbf{c}_2, \mathbf{c}_3\}$, where $\mathbf{c}_4$ is defined as before. So we have a contradiction, and therefore our claim follows.

Define $S_1 = S_{\{1, 2, \dots, k\}}$ and $S_2 = S_{\{k+1, k+2, \dots, 2k\}}$. For $i = 1, 2$, let P_i be the set of length $k-1$ suffixes of codewords in S_i . We claim that $P_1 \cap P_2 = \emptyset$. To see this, suppose (for a contradiction) that there exists a suffix $\mathbf{z} \in P_1 \cap P_2$. Since $\mathbf{z} \in P_1$, there exist distinct codewords of the form $\mathbf{c}_1 = \mathbf{x}\mathbf{z}$ and $\mathbf{c}_2 = \mathbf{x}\mathbf{**}$. Since $\mathbf{z} \in P_2$, there exist distinct codewords of the form $\mathbf{c}_3 = \mathbf{y}\mathbf{z}$ and $\mathbf{c}_4 = \mathbf{y}\mathbf{*}$. Since $\{\mathbf{c}_1, \mathbf{c}_2\} \subseteq S_1$ and $\{\mathbf{c}_3, \mathbf{c}_4\} \subseteq S_2$, and since $S_1 \cap S_2 = \emptyset$, we find that the codewords $\mathbf{c}_i$ are pairwise distinct. But then the sets $\{\mathbf{c}_1, \mathbf{c}_4\}$ and $\{\mathbf{c}_2, \mathbf{c}_3\}$ violate IPP2. This contradiction shows that $P_1 \cap P_2 = \emptyset$, as required.

Since P_1 and P_2 are disjoint subsets of a set of the q^{k-1} possible suffixes of length $k-1$, we find that $|P_i| \leq \frac{1}{2}q^{k-1}$ for some i . Suppose that $|P_1| \leq \frac{1}{2}q^{k-1}$, so the number of length $k-1$ suffixes of codewords in S_1 is at most $\frac{1}{2}q^{k-1}$. The number of suffixes of length k of codewords in S_1 is therefore at most $\frac{1}{2}q^k$, and the length k suffixes of any two codewords in S_1 are distinct, since $S_1 \cap S_{\{2k, 2k+1, \dots, 3k-1\}} = \emptyset$. Thus $\frac{1}{2}q^k \geq |S_1| > \mu$, and so (4.1) holds in this case. In the case when $|P_2| \leq \frac{1}{2}q^{k-1}$, a similar argument establishes (4.1): instead of suffixes, we consider subwords consisting of the first component and the last $k-1$ components of a word, and we use the fact that $S_2 \cap S_{\{1, 2k+1, 2k+2, \dots, 3k-1\}} = \emptyset$.

It remains to show that the above argument can be tightened in order to establish the theorem.

The argument above uses the fact that $S_{T_1} \cap S_{T_2} = \emptyset$ for a limited range of sets T_1 and T_2 . (Indeed, it uses this equality when $T_1 = \{1, 2, \dots, k\}$ and $T_2 = \{k+1, k+2, \dots, 2k\}$, when $T_1 = \{1, 2, \dots, k\}$ and $T_2 = \{2k, 2k+1, \dots, 3k-1\}$, and when $T_1 = \{k+1, k+2, \dots, 2k\}$ and $T_2 = \{1, 2k+1, 2k+2, \dots, 3k-1\}$.) Because of this, we see that the argument still works when $\mathcal{C}'$ is defined to be a larger subcode, where less than $3q^{k-1}$ codewords have been removed: we remove codewords that are uniquely defined by their positions in X , where $X = \{2k+1, 2k+2, \dots, 3k-1\}$, $X = \{k+1, k+2, \dots, 2k-1\}$, or $X = \{2, 3, \dots, k\}$. This modification establishes the theorem, as required. $\square$

5. Prolific IPP codes of length 3. The goal of this section is to prove Theorem 5.7, which states that there are no nontrivial prolific IPP codes of length 3.

LEMMA 5.1. *Let $\mathcal{C}$ be a nonbinary prolific IPP code of length 3. Then $|\mathcal{C}| > q$, and the minimum distance $d(\mathcal{C})$ of $\mathcal{C}$ is at least 2.*

Proof. If $\mathcal{C}$ contains q or fewer codewords, then the bound of Theorem 2.1 is violated. So $|\mathcal{C}| > q$.

Suppose $\mathcal{C}$ contains codewords $\mathbf{x}$ and $\mathbf{y}$ at distance 1. There exist distinct codewords $\mathbf{u}, \mathbf{v} \in \mathcal{C}$ that agree at the position where $\mathbf{x}$ and $\mathbf{y}$ disagree, since $|\mathcal{C}| > q$. If the codewords $\mathbf{x}, \mathbf{y}, \mathbf{u}, \mathbf{v}$ are not distinct (and so form a set of size 3), then IPP1 is violated; if the codewords are distinct, then IPP2 is violated. This contradiction shows that $d(\mathcal{C}) \geq 2$. $\square$

LEMMA 5.2. *There are no nontrivial prolific IPP codes of length 3 when $q \geq 6$.*

Proof. Let $\mathcal{C}$ be a $(3, q, M)$ prolific IPP code. Every symbol must occur at least once at the start of a codeword, since if there are no codewords of the form $x**$, then there are no descendants of the form $x**$, contradicting the fact that $\mathcal{C}$ is prolific. Since $M \leq 3q - 1$ by Theorem 2.4, there is a symbol that occurs (A) exactly once, or (B) exactly twice as the first position of a codeword. Without loss of generality, suppose this value is 0.

Case (A). Without loss of generality, we may assume that $000 \in \mathcal{C}$ and that no other codeword starts with 0. There are $(q - 1)^2$ words $\mathbf{d}$ of the form $0ab$ where $a, b \neq 0$, and all of these must occur as descendants. Now 000 must be a parent of $\mathbf{d}$ (since no other codeword starts with 0) but cannot contribute to the remaining two positions of $\mathbf{d}$ (since $a, b \neq 0$). So the other parent must be a codeword of the form $*ab$. Thus there are at least $(q - 1)^2$ codewords not equal to 000 . But $|\mathcal{C}| \geq (q - 1)^2 + 1$ contradicts Theorem 2.4 since $q \notin \{3, 4\}$.

Case (B). We may assume that $000, 0xy \in \mathcal{C}$ for some $x, y \in \{0, 1, \dots, q - 1\}$ that are not both zero. A similar argument to (A), with the codewords d of the form $0ab$ where $a \notin \{0, x\}$ and $b \notin \{0, y\}$, shows that there are at least $(q - 2)^2$ other codewords, and so $|\mathcal{C}| \geq (q - 2)^2 + 2$ in this case. This contradicts Theorem 2.4 when $q \geq 6$.

Thus, no $(3, q, M)$ prolific IPP codes exist if $q \geq 6$. $\square$

The following lemma is a special case of a result of Tô and Safavi-Naini [14, Theorem 34]; see [7, Lemma 6.3] for an elementary proof.

LEMMA 5.3. *A 3-ary IPP code $\mathcal{C}$ of length 3 must have $|\mathcal{C}| \leq 4$.*

COROLLARY 5.4. *There is no 3-ary prolific IPP code of length 3.*

Proof. Suppose a 3-ary prolific IPP code $\mathcal{C}$ of length 3 exists. All symbols must occur as the start of a codeword, since $\mathcal{C}$ is prolific. Since $|\mathcal{C}| \leq 4$, there is a symbol that starts a unique codeword. So we are in Case (A) of the proof of Lemma 5.2. The argument there shows that $|\mathcal{C}| \geq 1 + (q - 1)^2 = 5$, and this contradicts Lemma 5.3, as required. $\square$

LEMMA 5.5. *There is no 4-ary prolific IPP code of length 3.*

Proof. Suppose, for a contradiction, that a symbol occurs exactly once as the start of a codeword. Without loss of generality, $000 \in \mathcal{C}$ and no other codeword starts with 0. Considering parents of the nine descendants of the form $0xy$, where $x, y \neq 0$, we see that there are codewords of the form $*xy$ for all x, y ; moreover, these codewords cannot start with 0, since 0 starts a unique codeword. But these nine codewords now form a 3-ary IPP code, and this contradicts Lemma 5.3.

Using the argument above on the second and third positions of $\mathcal{C}$, we may assume all symbols occur at least twice in every position in the code.

Choose a codeword $\mathbf{x}$. Choose a codeword $\mathbf{y} \neq \mathbf{x}$ such that $x_1 = y_1$. Choose a codeword $\mathbf{z} \neq \mathbf{y}$ such that $y_2 = z_2$. Choose a codeword $\mathbf{w} \neq \mathbf{z}$ such that $z_3 = w_3$. Since $\mathcal{C}$ has minimum distance 2, we find that $\mathbf{x} \neq \mathbf{z}$ and $\mathbf{y} \neq \mathbf{w}$. There are two cases as follows: If $\mathbf{x} \neq \mathbf{w}$, then the pairs $\{\mathbf{x}, \mathbf{z}\}$, and $\{\mathbf{y}, \mathbf{w}\}$ violate IPP2. If $\mathbf{x} = \mathbf{w}$, then $\{\mathbf{x}, \mathbf{y}, \mathbf{z}\}$ violates IPP1. We have produced a contradiction, and so the lemma follows. $\square$

LEMMA 5.6. *There is no 5-ary prolific IPP code of length 3.*

Proof. If such code $\mathcal{C}$ exists, then we cannot be in Case (A) in the proof of Lemma 5.2 (as $1 + (q - 1)^2 \geq 3q$, contradicting Theorem 2.4). So we may assume that for all positions i and symbols a there are at least two codewords equal to a in position i . But now the argument in the final paragraph of the proof of Lemma 5.5 shows that $\mathcal{C}$ cannot be an IPP code. This contradiction establishes the lemma. $\square$

The above results together show the following.

THEOREM 5.7. *There are no nonbinary prolific codes of length 3.*

6. Prolific IPP codes of length 4. This section aims to prove Theorem 6.5, which states that there are no nontrivial examples of prolific codes of length 4.

LEMMA 6.1. *Let $\mathcal{C}$ be a nonbinary prolific IPP code of length 4. Then the minimum distance $d(\mathcal{C})$ of $\mathcal{C}$ is at least 3.*

Proof. Suppose $\mathcal{C}$ has M codewords. Theorem 2.1 shows that $\binom{M}{2}2^4 \geq q^4$. If $M \leq q$, we have that $q^22^3 \geq q^4$, which implies that $q \leq 2^{3/2} < 3$, a contradiction. So we may assume that $M > q$.

Suppose, for a contradiction, that $d(\mathcal{C}) = 1$. Without loss of generality, we may assume that $0000, 0001 \in \mathcal{C}$. If there is another codeword whose final symbol is 0 or 1, then IPP1 is violated. If this is not the case, choose distinct codewords $\mathbf{c}_1$ and $\mathbf{c}_2$ that agree in their final position. (Such codewords exist since $|\mathcal{C}| > q$.) Then $\{0000, \mathbf{c}_1\}$ and $\{0001, \mathbf{c}_2\}$ violate IPP2. This contradiction shows that $d(\mathcal{C}) \geq 2$.

We claim that every symbol must occur at least twice in any position of the code. (The prolific property shows that every symbol must occur at least once.) For assume that a symbol, 0 say, occurs exactly once as the start of a codeword. Without loss of generality, we may assume that $0000 \in \mathcal{C}$. For $x, y, z \in F \setminus \{0\}$, the descendant $0xyz$ must have 0000 and $*xyz$ as parents. So there are at least $(q-1)^3$ codewords of the form $*xyz$, where x, y , and z are nonzero. None of these codewords can start with 0, and so we have a collection $\mathcal{C}'$ of $(q-1)^3$ codewords over an alphabet of size $q-1$. Since $(q-1)^3 > (q-1)^2$, we can find distinct codewords $\mathbf{c}_1, \mathbf{c}_2 \in \mathcal{C}'$ that agree in their first two positions. There are $q-2$ codewords in $\mathcal{C}' \setminus \{\mathbf{c}_2\}$ that agree with $\mathbf{c}_2$ in its last two positions: pick $\mathbf{c}_3$ of this form. Then $\mathbf{c}_1$ and $\mathbf{c}_3$ have $\mathbf{c}_2$ as their descendant. This contradiction establishes our claim.

Now suppose, for a contradiction, that we can find two distinct codewords $\mathbf{c}_1, \mathbf{c}_2$ that are at distance 2. Without loss of generality, we may take $\mathbf{c}_1 = 0000, \mathbf{c}_2 = 0011$. Let $\mathbf{c}_3 \in \mathcal{C} \setminus \{\mathbf{c}_1\}$ be of the form $**0*$. Similarly let $\mathbf{c}_4 \in \mathcal{C} \setminus \{\mathbf{c}_2\}$ be a codeword of the form $***1$. If $\mathbf{c}_3 = \mathbf{c}_4$, then the set $\{\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3\}$ violates IPP1. But if $\mathbf{c}_3 \neq \mathbf{c}_4$, then $\{\mathbf{c}_1, \mathbf{c}_4\}$ and $\{\mathbf{c}_2, \mathbf{c}_3\}$ violate IPP2. This contradiction shows that there are no pairs of codewords at distance less than 3, and so the lemma follows. $\square$

LEMMA 6.2. *Let $\mathcal{C}$ be a q -ary prolific IPP code of length 4, and let $i \in \{1, 2, 3, 4\}$. Then every symbol occurs in the i th position of either $q-1$ or q codewords.*

Proof. Without loss of generality, we may assume that $i = 1$.

Since $d(\mathcal{C}) \geq 3$, the first two positions of a codeword uniquely determine that codeword. So each symbol occurs at most q times as the start of a codeword (as there are q pairs starting with this symbol).

Suppose a symbol, 0 say, occurs less than q times as the start of a codeword. Then there exist symbols $x, y, z \in F$ such that there are no codewords of the form $0x**$, $0*y*$, or $0**z$. Without loss of generality, assume that $x = y = z = 0$.

Consider the descendant 0000 . One parent must start with 0, but this codeword cannot contribute to any of the remaining positions in the descendant. So there is a codeword of the form $w000$ for some w (and w is clearly nonzero). Since $d(\mathcal{C}) = 3$, we see that $w000$ is the unique codeword of the form $*00*$.

Now consider the descendant $000a$ where $a \neq 0$. One parent starts with 0 and this parent cannot contribute to the middle two positions. Hence $w000$ is the other parent. But $w000$ cannot contribute to the last position, and so there must be a codeword of the form $0**a$. Since we have $q-1$ choices for a , the symbol 0 occurs at least $q-1$ times as the start of a codeword. This proves the lemma. $\square$

LEMMA 6.3. *There is no q -ary prolific IPP code of length 4 when $q > 4$.*

Proof. Let C be a q -ary prolific IPP code of length 4. Consider the words starting with 0. By Lemma 6.2 there are at least $q - 1$ such words and no two of these words can agree in any position other than the first (since $d(C) = 3$). So, without loss of generality, we may assume the codewords starting with 0 are $0111, 0222, \dots, 0(q - 1)(q - 1)(q - 1)$, and possibly 0000 .

Fix a symbol $\ell \in F$. Choose $m \in F$ such that $\ell \neq m$ and there exists a codeword of the form $*\ell m*$. Such a choice for m exists; indeed, by Lemma 6.2 there are at least $(q - 1) - 1$ choices for m . Choose $n \in F$ such that for $\ell \neq n, m \neq n$, there exists a codeword of the form $**mn$ but there does not exist a codeword of the form $*\ell mn$. There are at least $q - 1$ choices for n such that there is a codeword of the form $**mn$, and at most three of these choices are ruled out by the other conditions we place on n . Since $q - 1 - 3 \geq 1$, there exists at least one choice for n .

Consider the descendant $0\ell mn$. This is a descendant of $0\ell\ell\ell$ and the codeword $**mn$, and of $0nnn$ and $*\ell m*$. Our choice of ℓ, m, n means that these sets of parents are disjoint. So we get a contradiction to IPP2, as required. $\square$

LEMMA 6.4. *There is no 4-ary prolific IPP code of length 4.*

Proof. The proof of Lemma 6.3 works (with $q - 1$ replaced by q at various points) when every symbol occurs four times in every position of a codeword. So we know that if a 4-ary prolific IPP code C of length 4 exists, then $12 = q(q - 1) \leq |C| < q^2 = 16$. We now argue that no such code can exist.

Let $M = |C|$. There are $M(1 + 4 \times 3) = 13M$ words at distance at most 1 from C . All the remaining words must be descendants, and indeed they must be descendants of a unique pair of codewords at distance 4. (Codewords at distance 3 can never produce descendants of distance more than 1 from the code.)

A pair of codewords at distance 4 produce exactly six descendants at distance 2 from the code. So $4^4 = 6M_4 + 13M$, where M_4 is the number of pairs of codewords at distance 4. Therefore

$$M_4 = \frac{256 - 13M}{6},$$

and so $256 - 13M \equiv 0 \pmod{6}$ and so $M \equiv 4 \pmod{6}$. But this cannot happen, as no number M such that $12 \leq M \leq 15$ is such that $M \equiv 4 \pmod{6}$. This proves the theorem. $\square$

THEOREM 6.5. *If C is a nonbinary prolific IPP code of length 4, then C is equivalent to the $(4, 3, 9)$ -code given in the introduction.*

Proof. Let C be a q -ary prolific IPP code of length 4, where $q > 2$. Lemmas 6.3 and 6.4 show that we must, in fact, have that $q = 3$.

Lemma 6.1 shows that $d(C) \geq 3$, and so the Singleton bound shows that $|C| \leq 9$. Moreover, we know from Lemma 6.2 that every symbol occurs at least twice in each position of the code.

We claim that $|C| = 9$. Suppose, for a contradiction, that $|C| \leq 8$ and so some symbol occurs twice at the start of a codeword. Without loss of generality, we may assume that 0 occurs just twice at the start of a codeword, and that $0000, 0111 \in C$. Since 0222 is a descendant of the code, we must have a codeword of the form $x222$ where $x \in \{1, 2\}$.

The descendant 0012 must either have parents 0000 and $**12$, or 0111 and $*0*2$. Since $d(C) \geq 3$, any word of the form $**12$ or $*0*2$ must in fact be of the form $*012$ (for otherwise there would be a codeword too close to 0000 , 0111 , or $x222$), and so we may deduce that C contains a codeword of the form $*012$. Indeed, if $a, b, c \in F$ are

distinct, we may argue in the same way (using the descendant $0abc$) that there exists a codeword of the form $*abc$. These six codewords, together with the codewords 0000, 0111, and $x222$ show that $|\mathcal{C}| \geq 9$, contradicting our assumption that $|\mathcal{C}| < 9$.

So we may assume that $|\mathcal{C}| = 9$. But this implies that $\mathcal{C}$ is an MDS code, and so is equivalent to the $(4, 3, 9)$ -code from the introduction. $\square$

7. Prolific IPP codes of length 5. This section provides a sketch proof of the following theorem. Full details can be found in [7, section 8].

THEOREM 7.1. *There are no nonbinary prolific IPP codes of length 5.*

Let $\mathcal{C}$ be a nonbinary prolific IPP code of length 5. We sketch a method for deriving a contradiction by breaking our argument up into a proof of various statements as follows:

1. *Each symbol in F appears at least twice in every coordinate of $\mathcal{C}$.* If a symbol occurs exactly once in some position, the argument in Case (A) of the proof of Lemma 5.2 shows that $|\mathcal{C}| \geq (q-1)^4 + 1$. This contradicts the upper bound of Theorem 4.3.

2. *The minimum distance of $\mathcal{C}$ is 3.* The difficult case is showing that $d(\mathcal{C}) \neq 4$. When $d(\mathcal{C}) = 4$, the Singleton bound shows that $|\mathcal{C}| \leq q^2$; the prolific property shows that all q^2 pairs of symbols must occur as prefixes of codewords. But then $\mathcal{C}$ is a $(5, q, q^2)$ -code, which cannot be a prolific IPP code by the nonlinear version of Lemma 3.1 (see the remark following the proof of the lemma).

3. *Let $\{i, j, k, \ell, m\} = \{1, 2, 3, 4, 5\}$. Let distinct codewords $\mathbf{c}_1, \mathbf{c}_2 \in \mathcal{C}$ agree in positions i and j . Then $\mathbf{c}_1$ does not agree with any other codeword $\mathbf{c}_3$ in positions k and ℓ .* Statement 1 implies that there exists another codeword $\mathbf{c}_4$ that agrees with $\mathbf{c}_1$ in position m . But then these four codewords provide a counterexample to the IPP property.

4. *Suppose that there exist codewords $\mathbf{c}_1, \mathbf{c}_2, \mathbf{c}_3, \mathbf{c}_4$ of the form $\mathbf{c}_1 = x_1x_2a**$, $\mathbf{c}_2 = x_1x_2***$, $\mathbf{c}_3 = **bx_4x_5$, and $\mathbf{c}_4 = ***x_4x_5$. Suppose that $\mathbf{c}_1 \neq \mathbf{c}_2$ and $\mathbf{c}_3 \neq \mathbf{c}_4$. Then $a \neq b$.* This follows easily from statement 3.

5. *No 3-ary prolific IPP code of length 5 exists.* Without loss of generality, we may assume that $00000, 00111 \in \mathcal{C}$. By statement 4, no pair of codewords can agree on two of the last three of their coordinates. In particular, $|\mathcal{C}| \leq 9$. But this also implies that any descendant $ab000$ with a and b nonzero must have a parent of the form $ab***$. This argument may be extended to show that all nine possible prefixes of length 2 must occur at the start of codewords. Thus $|\mathcal{C}| \geq 10$ and we have our contradiction. This argument is also useful in the case when $q > 3$ and can be used to establish the following two statements:

6. *Suppose (without loss of generality) that $00000, 00111 \in \mathcal{C}$. Then there exists a pair of codewords which agree in positions i and j , where $\{i, j\} \subseteq \{3, 4, 5\}$.*

7. *Suppose there are two codewords $\mathbf{c}, \mathbf{c}' \in \mathcal{C}$ that agree in positions i and j . Then for all $a, b \in F$ with $a \neq c_i$, $b \neq c_j$ there exists a codeword whose i th and j th positions are equal to a and b , respectively.*

8. *No set of $q-1$ codewords can pairwise agree in any fixed set of two positions.* Suppose a set X of $q-1$ codewords exists that agree in their (say) first two positions. By statement 2, all their remaining positions differ. But then we get a contradiction by statement 4 if there are two codewords that agree in two of their last three positions, and we get a contradiction by statement 6 if not.

9. *Every symbol occurs at least q times in each coordinate of $\mathcal{C}$.* Suppose, for example, there are less than q codewords starting with 0. Let $a, b, c, d \in F$ be such that there are no codewords of the form $0a***$, $0*b**$, $0**c*$, or $0***d$. For any $z \neq d$,

there must be a codeword of the form $0***z$ (consider the parents of $0abcz$). So there are exactly $q - 1$ codewords starting with 0, and all their last coordinates differ. By statement 8, there exist $u, v, w \in F$ such that there are no codewords of the form $*abu*$, $*abv*$, or $*abw*$. Consider parents of $0**uw$ and $0**vw$ to show that there exist distinct codewords starting with 0 and agreeing in their last position, giving us the contradiction we need.

10. *Assume that $00000, 00111 \in \mathcal{C}$ and that there are two codewords that agree in their last two positions. Then the nonzero codewords of the form $**0**$ must be of the form $**01a$ or $**0a1$ for some $a \in F \setminus \{0, 1\}$.* Using statement 3, it is not difficult to reduce this statement to proving that the word $\mathbf{c} = **022$ is not a codeword. If $\mathbf{c} \in \mathcal{C}$, then by statement 4, $\mathbf{c}$ is the only codeword of the form $***22$; by statement 3, 00111 is the only codeword of the form $***11$. So by statement 7, there exists $\mathbf{c}' \in \mathcal{C}$ of the form $***21$ or $***12$. But then the IPP property is violated, giving us the contradiction we need.

11. *Let $i, j \in \{1, 2, \dots, 5\}$ be a pair of positions. Then there cannot exist a set of three codewords that pairwise agree in position i and position j .* Without loss of generality, assume that $00000, 00111, 00222 \in \mathcal{C}$. By statement 6, we may assume that there is a pair of codewords that agree in their last two positions. Statement 10 implies that codewords of the form $**0**$ have the form $**01a$ or $**0a1$ where $a \geq 2$. Applying statement 10 with 1 replaced by 2, these codewords also have the form $**02b$ or $**0b2$ where $b \notin \{0, 2\}$. Since $d(\mathcal{C}) = 3$ and $q > 3$, this implies there are at most three codewords of the form $**0**$, contradicting statement 9.

12. *No q -ary length 5 prolific IPP code exists when $q \geq 5$.* Statements 10 and 11 imply that there are at most five codewords of the form $**0**$, and without loss of generality these have the forms $00000, **012, **013, **021$, and $**031$. Statement 11 and the fact that $\mathcal{C}$ is prolific imply that there are either one or two codewords of the form $***44$. So there are at least six choices for $a, b \in F$ such that there are no codewords of the form $a***44$ or $*b***44$. But then at least one of these choices has the property that there are no codewords of the form $ab0**$. This is a contradiction, as $ab044$ is not a descendant of $\mathcal{C}$.

13. *A 4-ary prolific IPP code $\mathcal{C}$ of length 5 has exactly 16 codewords.* Statement 9 implies that $|\mathcal{C}| \geq 16$. If no two codewords agree in a fixed pair of positions $|\mathcal{C}| \leq 16$ trivially, so we may assume that this does not happen. This implies that two pairs of symbols cannot appear more than once as the start of a codeword; for either we get a contradiction to the IPP property or we violate statement 4. So, by statement 11 we find $|\mathcal{C}| \leq 17$. When $|\mathcal{C}| = 17$, a short argument using statement 10 shows that two pairs of codewords must agree in their third and fourth positions, giving the contradiction we seek.

14. *No 4-ary prolific IPP code of length 5 exists.* By statement 13, $|\mathcal{C}| = 16$, and by statement 9 every symbol occurs exactly four times in any coordinate of the code. Assume $00000, 00111 \in \mathcal{C}$. Using statement 10 several times, we see that $\mathcal{C}$ must (without loss of generality) consist of codewords of the forms given in Table 7.1, where the last three positions of the final five codewords do not involve 0 or 1. There are $x, y \in F$ such that there are no codewords of the form $0x***$ or $y0***$. A codeword $\mathbf{c}$ exists of the form $**021, **210$, or $**102$ which is not of the form $xy***$. By statement 11, $\mathbf{c}$ is not of the form $00***$. But then $0xc_3c_4c_5$ and $y0c_3c_4c_5$ cannot both be descendants of the code, and we have a contradiction, as required.

8. Conclusion and open problems. As we stated in the introduction, we conjecture that there are no examples of prolific IPP codes other than those listed in

the introduction. We begin this section by discussing how close we are to proving this conjecture.

When $n \geq 3$ but $n \neq 4$, the lower bound of Theorem 2.2 and the upper bound due to Hollmann et al. (Theorem 2.4) together imply that for any fixed length n , there are no q -ary prolific IPP codes of length n provided that q is sufficiently large. When $n = 4$, the same is true if an improved, but less explicit, bound due to Alon, Fischer, and Szegedy [2] is used; or we may deduce this from Theorem 6.5. Sadly, we are not able to bring the number of open parameters n and q (where it is not known whether a prolific q -ary IPP code of length n exists) down to a finite number. In particular, when q is fixed and $3 \leq q \leq 8$, all the parameters n and q are open for $n \geq 6$. Table 8.1 lists the parameters for which the existence of a prolific (n, q, M) -IPP code is as yet undetermined. For the values of n listed in the table, a nonbinary prolific (n, q, M) -IPP code might exist for $3 \leq q \leq q_{max}$, and for $n > 68$, a nonbinary prolific (n, q, M) -IPP code might exist for $3 \leq q \leq 8$. We used the lower bound of Theorem 2.2 with $k = \lceil \frac{n}{3} \rceil$. We used the upper bound of Theorem 4.4 when $n \equiv 2 \pmod 3$, and the upper bound of Theorem 2.4 otherwise.

As a step towards proving the conjecture, is it possible to show that no q -ary prolific IPP code of length n exists for all sufficiently large n , where q is a fixed integer with $3 \leq q \leq 8$?

We remark that the notion of a prolific code makes sense for any class of code which has a natural notion of a descendant. In particular, are there non-trivial examples of prolific k -IPP codes where $k > 2$? (See Staddon, Stinson, and Wei [13] or Blackburn [6] for the definition of a k -IPP code.)

Is it possible to improve our upper bounds on IPP codes (Theorems 4.2 and 4.4) significantly? We believe that the constants in the leading terms of these upper bounds can be reduced. Indeed, it might be possible to prove more than this. Let n be fixed, and suppose that 3 does not divide n . Let ϵ be a positive constant. Is it the case that a q -ary IPP code $\mathcal{C}$ of length n must satisfy $|\mathcal{C}| \leq \epsilon q^{\lceil n/3 \rceil}$ when q is sufficiently large? This is true when $n = 4$, by a bound of Alon, Fischer, and Szegedy [2, Theorem 2.5].

Is it possible to generalize the techniques of Theorems 4.2 and 4.4 to provide better upper bounds for k -IPP codes when $k > 2$? We have established new bounds on 3-IPP codes using these techniques. We hope that these bounds will form the subject of a future paper, but we also hope that our techniques can be stretched further.

THE INDEPENDENT EVEN FACTOR PROBLEM*

SATORU IWATA[†] AND KENJIRO TAKAZAWA[‡]

Abstract. This paper deals with the independent even factor problem. For odd-cycle-symmetric digraphs, in which each arc in any odd dicycle has the reverse arc, a min-max formula is established as a common generalization of the Tutte–Berge formula for matchings and the min-max formula of Edmonds [*Submodular functions, matroids, and certain polyhedra*, in *Combinatorial Structures and Their Applications*, R. Guy et al., eds., Gordon and Breach, New York, 1970, pp. 69–87] for matroid intersection. We devise a combinatorial efficient algorithm to find a maximum independent even factor in an odd-cycle-symmetric digraph accompanied by general matroids, which commonly extends two of the alternating-path-type algorithms, the even factor algorithm of Pap [*Math. Program.*, 110 (2007), pp. 57–69], and the matroid intersection algorithms. This algorithm gives a proof of the min-max formula and contains a new operation on matroids, which corresponds to shrinking factor-critical components in the matching algorithm of Edmonds [*Canad. J. Math.*, 17 (1965), pp. 449–467]. The running time of the algorithm is $O(n^4Q)$, where n is the number of vertices and Q is the time for an independence test. The algorithm also gives a common generalization of the Edmonds–Gallai decomposition for matchings and the principal partition for matroid intersection.

1. Introduction. One of the most fundamental problems in combinatorial optimization is the matching problem. Tutte [24] characterized graphs that have a perfect matching. Then, Berge [1] showed that Tutte’s characterization implies a min-max formula, now called the Tutte–Berge formula. Edmonds [5] gave a combinatorial algorithm to find a maximum matching. This algorithm implies a structural result, which was also found independently by Gallai [9], and is now called the Edmonds–Gallai decomposition.

The matroid intersection problem is also of importance. Edmonds [6] presented a min-max formula for that problem. Polynomial-time algorithms for finding a maximum common independent set are known, such as those of Edmonds [7] and Lawler [15].

As a common generalization of the matching and matroid intersection problems, Cunningham and Geelen [3] introduced the notion of *independent path-matchings*. They showed a min-max formula, a totally dual integral polyhedral description, and polynomial-time solvability of the independent path-matching problem, which generalize those in the matching and matroid intersection problems. The independent path-matching problem with free matroids is called the *path-matching problem*. For the path-matching problem, Frank and Szegő [8] simplified the min-max formula of Cunningham and Geelen [3] and provided its combinatorial proof. Spille and Szegő [21] showed that the path-matching problem has a property which generalizes the Edmonds–Gallai structure for matchings.

The proof of polynomial-time solvability in Cunningham and Geelen [3] relies on the ellipsoid method. A combinatorial polynomial-time algorithm for finding an optimal path-matching had been of interest. Spille and Weismantel [22] proposed generalizing the combinatorial algorithms for the matching problem [5] and the matroid intersection problem [7, 15] to independent path-matchings.

For the sake of a combinatorial approach to path-matchings, Cunningham and Geelen [4] introduced the *even factor problem* in digraphs, which is yet a generalization of the path-matching problem. While finding a maximum even factor is NP-hard in general digraphs, they showed that the problem is solvable in polynomial time in *weakly symmetric* digraphs with an algebraic approach. A digraph is said to be weakly symmetric if every arc in any dicycle has the reverse arc. In addition, they presented a min-max formula and generalized the Edmonds–Gallai decomposition to the even factor problem in weakly symmetric digraphs, followed by simplifications of Pap and Szegő [18]. These properties are known to hold in a broader class of digraphs, called *odd-cycle-symmetric*. A digraph is odd-cycle-symmetric if each arc in any odd dicycle has the reverse arc. Pap [17] devised a combinatorial algorithm to find a maximum even factor in odd-cycle-symmetric digraphs, which provides an algorithmic proof of the min-max formula and the Edmonds–Gallai-type structure. This algorithm has some properties similar to Edmonds’ matching algorithm [5].

As for the weighted even factor problem, Király and Makai [14] considered odd-cycle-symmetric weighted digraphs, which are odd-cycle-symmetric digraphs accompanied by a weight vector such that the total weight of edges in an odd cycle is equal to that of the reverse cycle. For odd-cycle-symmetric weighted digraphs, a combinatorial algorithm to find a maximum weight even factor is given by Takazawa [23].

In fact, as mentioned above, the even factor problem leaves matroids out of consideration, or in other words, it deals only with free matroids. For a common generalization of matchings and matroid intersection, Cunningham and Geelen [4] proposed the notion of *basic even factors*. They showed a polynomial reduction of the basic even factor problem in weakly symmetric digraphs to the matroid intersection problem. In the resulting algorithm, one needs to compute the cardinality of a maximum even factor in a certain digraph for each independence test.

In this paper, we deal with the *independent even factor problem*, which is a variant of the basic even factor problem. Extending the approach of Cunningham and Geelen [4], we obtain a min-max formula for the independent even factor problem in odd-cycle-symmetric digraphs, which commonly extends the Tutte–Berge formula for matchings and the min-max formula for matroid intersection of Edmonds [6]. For the independent even factor problem in odd-cycle-symmetric digraphs accompanied by general matroids, we devise a combinatorial algorithm to find a maximum independent even factor. The algorithm commonly extends the even factor algorithm [17] and the matroid intersection algorithms [7, 15], in both of which the notion of *alternating-paths* plays an essential part. The algorithm runs in $O(n^4Q)$ time, where n is the cardinality of the vertex set of the digraph and Q is the time needed to test if a given set is independent. By this algorithm, we obtain a different proof of the min-max formula.

The algorithm also gives a common extension of the Edmonds–Gallai decomposition for matchings and the principal partition for matroid intersection (cf. [12, 13]). Unlike the existing theorems on the Edmonds–Gallai-type structure for path-matchings or even factors, we treat the two matroids equally to achieve a unified decomposition principle including the principal partition for matroid intersection.

The maximum independent even factor algorithm includes a new operation on matroids, called *shrinking*. For a matroid $\mathbf{M}$ and its independent set I , eliminate I and create a new element i to obtain a new matroid. We call this procedure *shrinking* I . Note that the resulting matroid differs from the one derived by contraction or deletion. This procedure corresponds to shrinking a factor-critical component in the matching algorithm of Edmonds [5] and the even factor algorithm of Pap [17].

Recently, Harvey [10, 11] gave a new algebraic characterization of basic path-matchings, which achieved a maximum basic path-matching algorithm. His approach needs the matroids to be linearly represented over the same field. The algorithm runs in $O(n^\omega)$ time, where n is the number of vertices and ω is the exponent for matrix multiplication, bounded by $\omega < 2.38$ (due to Coppersmith and Winograd [2]). One can easily extend this approach to obtain an $O(n^\omega)$ algorithm for the independent even factor problem in which the matroids are linearly represented over the same field. Our algorithm, however, does not need the assumption, that is, it can deal with general matroids.

Before closing this section, let us give some notations and definitions used in the following sections.

A digraph G with the vertex set V and the arc set A is denoted by $G = (V, A)$. For vertices u and v , let (u, v) denote an arc which starts in u and ends in v . For an arc $a = (u, v)$, let $\partial^+ a$ (resp., $\partial^- a$) denote the initial (resp., terminal) vertex of a , that is, $\partial^+ a = u$ and $\partial^- a = v$. For a vertex v , define $\delta^+ v = \{a \mid a \in A, \partial^+ a = v\}$ and $\delta^- v = \{a \mid a \in A, \partial^- a = v\}$. For an arc set B , define $\partial^+ B = \{v \mid v \in V, \exists a \in B, v = \partial^+ a\}$ and $\partial^- B = \{v \mid v \in V, \exists a \in B, v = \partial^- a\}$. For a vertex set U , denote $\delta^+ U = \{a \mid a \in A, \partial^+ a \in U, \partial^- a \notin U\}$ and $\delta^- U = \{a \mid a \in A, \partial^- a \in U, \partial^+ a \notin U\}$.

We denote the reverse arc of a by $\bar{a}$, i.e., $\bar{a} = (v, u)$ for $a = (u, v)$. An arc $a \in A$ is called *symmetric* if $\bar{a} \in A$. A digraph is said to be *symmetric* if every arc is symmetric.

For a subgraph H of G , the vertex set and the arc set of H are denoted by $V(H)$ and $A(H)$, respectively. We say H is *odd* (resp., *even*) if $|V(H)|$ is odd (resp., even). A strongly connected component C with $\delta^- V(C) = \emptyset$ (resp., $\delta^+ V(C) = \emptyset$) is called a *source-component* (resp., *sink-component*). For two vertex sets X^+ and X^- , let $G[X^+, X^-]$ denote the subgraph whose vertex set is $X^+ \cup X^-$ and arc set is $A[X^+, X^-] = \{a \mid a \in A, \partial^+ a \in X^+, \partial^- a \in X^-\}$. For a vertex set X , we abbreviate $G[X, X]$ and $A[X, X]$ as $G[X]$ and $A[X]$, respectively. We denote by $\text{odd}^+(X)$ (resp., $\text{odd}^-(X)$) the number of odd source-components (resp., odd sink-components) in $G[X]$.

For $v_0, v_1, \dots, v_k \in V$ and $a_1, \dots, a_k \in A$, a sequence $W = (v_0, a_1, v_1, a_2, v_2, \dots, v_{k-1}, a_k, v_k)$ is called a *walk* if $a_i = (v_{i-1}, v_i)$ for all $i = 1, \dots, k$. We denote the vertex set $\{v_0, \dots, v_k\} = V(W)$ and the arc set $\{a_1, \dots, a_k\} = A(W)$. For a walk $W = (v_0, a_1, v_1, \dots, v_{k-1}, a_k, v_k)$, the length k of W is denoted by $|W|$. A walk W is said to be *odd* (resp., *even*) if $|W|$ is odd (resp., even). A walk $W = (v_0, a_1, v_1, \dots, v_{k-1}, a_k, v_k)$ is called a *path* if $v_0, v_1, \dots, v_k$ are pairwise distinct and called a *cycle* if $v_0, v_1, \dots, v_{k-1}$ are pairwise distinct and $v_0 = v_k$. For a walk $W = (v_0, a_1, v_1, \dots, v_{k-1}, a_k, v_k)$, let $\bar{W}$ denote the reverse walk of W (if it exists), that is, $\bar{W} = (v_k, \bar{a}_k, v_{k-1}, \dots, v_1, \bar{a}_1, v_0)$. Recall that a digraph is *odd-cycle-symmetric* if any odd cycle has the reverse cycle.

For two vertex sets X^+ and X^- , we call (X^+, X^-) a *stable pair* if there is neither an arc $a \in A$ with $\partial^+ a \in X^+ \setminus X^-$ and $\partial^- a \in X^-$ nor $a \in A$ with $\partial^+ a \in X^+$ and $\partial^- a \in X^- \setminus X^+$. This definition generalizes that of Cunningham and Geelen [3], who first introduced the notion of stable pairs for the independent path-matching problem.

The outline of this paper is as follows. Section 2 introduces even factors and matroid intersection and describes some important results which are to be extended in independent even factors. Section 3 provides the operation of shrinking on matroids. Section 4 introduces independent even factors and proves a min-max formula structurally. Section 5 presents a new algorithm of ours. Finally, section 6 reveals the Edmonds–Gallai-type structure for independent even factors.

2. Even factors and matroid intersection.

2.1. Even factors. Let $G = (V, A)$ be a digraph. An *even factor* is the arc set of a vertex-disjoint collection of some paths and even cycles. For a digraph G , let $\nu(G)$ denote the cardinality of a maximum even factor in G .

One approach to computing $\nu(G)$ is extending the notion of the Tutte matrix in the matching problem [24]. Let $\{x_{uv} \mid (u, v) \in A\}$ be the indeterminates such that $x_{uv} = -x_{vu}$ for $(u, v), (v, u) \in A$. The *Tutte matrix* $T = (t_{uv})$ is defined by

$$t_{uv} = \begin{cases} x_{uv} & ((u, v) \in A), \\ 0 & (\text{otherwise}), \end{cases}$$

where rows and columns are both indexed by V . Cunningham and Geelen [4] asserted that

$$(2.1) \quad \nu(G) = \text{rank } T$$

if G is weakly symmetric. Based on this fact, the algorithm of Cunningham and Geelen [4] figures out $\nu(G)$ by computing $\text{rank } T$ for a weakly symmetric digraph G .

In fact, the proof of (2.1) in Cunningham and Geelen [4] applies to odd-cycle-symmetric digraphs. That is, (2.1) and their algorithm are valid for odd-cycle-symmetric digraphs.

THEOREM 2.1. *Let G be an odd-cycle-symmetric digraph and let T be the Tutte matrix of G . Then $\nu(G) = \text{rank } T$ holds.*

Another approach to $\nu(G)$, proposed by Pap [17], is extending the matching algorithm of Edmonds [5]. Pap's algorithm finds a maximum even factor in an odd-cycle-symmetric digraph and brings about the following min-max formula.

THEOREM 2.2. *For an odd-cycle-symmetric digraph $G = (V, A)$, it holds that*

$$\nu(G) = \min_{(X^+, X^-)} \{ |V \setminus X^+| + |V \setminus X^-| + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \},$$

where (X^+, X^-) runs over all stable pairs.

This formula modestly extends that of Cunningham and Geelen [4, Theorem 1.3], in which the minimum is taken over all (X^+, X^-) such that $G[X^+, X^-]$ is symmetric. One easily sees that such (X^+, X^-) forms a stable pair.

2.2. Matroid intersection. Let V be a finite set and its subset family $\mathcal{I} \subseteq 2^V$ satisfy the following:

(I0) $\emptyset \in \mathcal{I}$;

(I1) $I \subseteq J \in \mathcal{I} \Rightarrow I \in \mathcal{I}$;

(I2) $I, J \in \mathcal{I}$, $|I| < |J| \Rightarrow \exists j \in J \setminus I$, $I \cup \{j\} \in \mathcal{I}$.

A set function $\rho : 2^V \rightarrow \mathbb{Z}_+$ is defined by

$$\rho(X) = \max\{|J| \mid J \subseteq X, J \in \mathcal{I}\} \quad (X \subseteq V).$$

For V , $\mathcal{I}$, and ρ defined above, we say $\mathbf{M} = (V, \mathcal{I}, \rho)$ forms a *matroid*. We call V the *ground set*, $\mathcal{I}$ the *independent set family*, $I \in \mathcal{I}$ an *independent set*, and ρ the *rank function*. A subset of V is said to be *dependent* if it is not an independent set.

Given a matroid $(V, \mathcal{I}, \rho)$, a subset $B \subseteq V$ is called a *base* if B is an inclusion-wise maximal independent set, and a subset $C \subseteq V$ is called a *circuit* if C is an inclusion-wise minimal dependent set.

The *closure function* $\text{cl} : 2^V \rightarrow 2^V$ is defined by

$$\text{cl}(X) = \{j \mid \rho(X \cup \{j\}) = \rho(X)\} \quad (X \subseteq V).$$

For any $I \in \mathcal{I}$ and $j \in \text{cl}(I) \setminus I$, the union $I \cup \{j\}$ contains a unique circuit, called the *fundamental circuit* denoted by $C(I \mid j)$.

Let us be given two matroids on the same ground set, say, $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$ and $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$. The *matroid intersection problem* is a problem for finding a maximum common independent set $I \in \mathcal{I}^+ \cap \mathcal{I}^-$.

A min-max formula for the matroid intersection problem is given by Edmonds [6].

THEOREM 2.3 (Edmonds [6]). *For two matroids $\mathbf{M}_1 = (V, \mathcal{I}_1, \rho_1)$ and $\mathbf{M}_2 = (V, \mathcal{I}_2, \rho_2)$, it holds that*

$$\max\{|I| \mid I \subseteq V, I \in \mathcal{I}_1 \cap \mathcal{I}_2\} = \min_{X \subseteq V} \{\rho_1(V \setminus X) + \rho_2(X)\}.$$

There are some combinatorial polynomial-time algorithms for finding a maximum common independent set, such as Lawler's [15] and Edmonds' [7]. We remark that the notion of *alternating-paths* plays an essential part in those algorithms, as is the case with the matching algorithm of Edmonds [5] and the even factor algorithm of Pap [17].

3. Shrinking of matroids. This section is devoted to the notion of *shrinking* of matroids. Note that it is different from the well-known notion of contraction of matroids. We remark that a similar notion is independently introduced by Pap in [16], where it is named *projection*.

3.1. Definition. Let $\mathbf{M} = (V, \mathcal{I}, \rho)$ be a matroid and $W \subseteq V$ be an independent set in $\mathbf{M}$. Then, consider $\tilde{V} = (V \setminus W) \cup \{w\}$, where w is a new element. Define a subset family $\tilde{\mathcal{I}}$ of $\tilde{V}$ and a set function $\tilde{\rho} : 2^{\tilde{V}} \rightarrow \mathbb{Z}_+$ by

$$\tilde{\mathcal{I}} = \{I \mid I \subseteq V \setminus W, \exists J \subseteq W, |J| = |W| - 1, I \cup J \in \mathcal{I}\}$$

$$\cup \{I \cup \{w\} \mid I \subseteq V \setminus W, I \cup W \in \mathcal{I}\},$$

$$\tilde{\rho}(X) = \max\{|J| \mid J \subseteq X, J \in \tilde{\mathcal{I}}\} \quad (X \subseteq \tilde{V}).$$

LEMMA 3.1. *The tuple $(\tilde{V}, \tilde{\mathcal{I}}, \tilde{\rho})$ forms a matroid.*

Proof. It is easily seen that $\tilde{\mathcal{I}}$ satisfies (I0) and (I1). We prove (I2) by showing that for any $\tilde{I}, \tilde{J} \in \tilde{\mathcal{I}}$ with $|\tilde{I}| < |\tilde{J}|$, there exists an element v such that

$$(3.1) \quad v \in \tilde{J} \setminus \tilde{I}, \quad \tilde{I} \cup \{v\} \in \tilde{\mathcal{I}}.$$

Suppose $w \in \tilde{I}$, i.e., $\tilde{I} = \tilde{I}' \cup \{w\}$ with $\tilde{I}' \subseteq V \setminus W$. As $\tilde{I}, \tilde{J} \in \tilde{\mathcal{I}}$, it follows that $I = \tilde{I}' \cup W \in \mathcal{I}$, and there exists $J \in \mathcal{I}$ with $|J| = |\tilde{J}| + |W| - 1$ and $J \setminus \tilde{J} \subseteq W$.

Then, $|I| < |J|$ holds, which implies that there exists $v \in J \setminus I$ such that $I \cup \{v\} \in \mathcal{I}$. Hence, it holds that $\tilde{I} \cup \{v\} \in \mathcal{I}$ and $v \in \tilde{J} \setminus \tilde{I}$. Thus, v satisfies (3.1).

Suppose $w \notin \tilde{I}$. Then, there exists $W_I \subseteq W$ such that $|W_I| = |W| - 1$ and $I = \tilde{I} \cup W_I \in \mathcal{I}$. Define J and v as mentioned above. If $v \notin W$, we have that v satisfies (3.1). So, we may assume $v \in W$, which implies $W = W_I \cup \{v\}$ and $\tilde{I} \cup \{w\} \in \tilde{\mathcal{I}}$. If $w \in \tilde{J}$, then w satisfies (3.1). Otherwise, let $W_J = J \setminus \tilde{J}$. Note that $|W_J| = |W| - 1$ and $W_J \subseteq W$. Then, it holds that $I' = \tilde{I} \cup W_J \subseteq \tilde{I} \cup W$. Hence, by (I1) we have $I' \in \mathcal{I}$, and $|I'| = |\tilde{I}| < |J|$. Therefore, there exists an element $u \in J \setminus I' \subseteq \tilde{J} \setminus \tilde{I}$ such that $I' \cup \{u\} \in \mathcal{I}$, which implies (3.1) holds for u . $\square$

We denote the new matroid $(\tilde{V}, \tilde{\mathcal{I}}, \tilde{\rho})$ defined above by $\mathbf{M}_W$. The procedure to obtain $\mathbf{M}_W$ is called *shrinking* W , and we say that W is *shrunk into* w . Conversely, if I_W is an independent set in $\mathbf{M}_W$, there exists at least one independent set $I \in \mathcal{I}$ such that $I_W \setminus \{w\} \subseteq I$ and $|I| = |I_W| + |W| - 1$. The procedure of obtaining I is said to be *expanding* W .

Lemma 3.1 can also be confirmed through combining well-known operations in matroid theory, induction through a bipartite graph, and contraction.

Let $\mathbf{M} = (V, \mathcal{I}, \rho)$ be a matroid and $W \subseteq V$ be its independent set. Make a copy $\mathbf{M}' = (V', \mathcal{I}', \rho')$ of $\mathbf{M}$. We denote the copy of $v \in V$ (resp., $U \subseteq V$) by v' (resp., U'). Then, construct a bipartite graph $G = (V', V; A)$, where

$$A = \{(u', v) \mid u, v \in W\} \cup \{(v', v) \mid v \in V \setminus W\}.$$

Define a subset family $\mathcal{I}^\circ$ of V associated with $\mathcal{I}'$ and G as follows: a subset $I \subseteq V$ belongs to $\mathcal{I}^\circ$ if and only if there exists a matching $M \subseteq A$ in G such that $\partial^- M = I$ and $\partial^+ M \in \mathcal{I}'$. Perfect [19] observed that $\mathcal{I}^\circ$ satisfies (I0)–(I2). We denote the resulting matroid by $\mathbf{M}^\circ = (V, \mathcal{I}^\circ, \rho^\circ)$.

Next, choose an arbitrary subset S of W with $|S| = |W| - 1$ and contract S in $\mathbf{M}^\circ$ to obtain a new matroid $\tilde{\mathbf{M}}$. By denoting the unique element in $W \setminus S$ by w , one easily checks that $\tilde{\mathbf{M}}$ is the same as $\mathbf{M}_W$.

From this construction, we obtain an explicit description of $\tilde{\rho}$.

THEOREM 3.2. *Let $\mathbf{M} = (V, \mathcal{I}, \rho)$ be a matroid, $W \subseteq V$ be an independent set in $\mathbf{M}$, and $\mathbf{M}_W = (\tilde{V}, \tilde{\mathcal{I}}, \tilde{\rho})$ be the matroid obtained by shrinking W . Then, for $X \subseteq \tilde{V}$, it holds that*

$$\tilde{\rho}(X) = \begin{cases} \rho(X \cup W) - |W| + 1 & (w \in X), \\ \min\{\rho(X), \rho(X \cup W) - |W| + 1\} & (w \notin X). \end{cases}$$

Proof. Given $\mathbf{M} = (V, \mathcal{I}, \rho)$ and $W \in \mathcal{I}$, define $G = (V', V; A)$ and $\mathbf{M}^\circ = (V, \mathcal{I}^\circ, \rho^\circ)$ as above. Let S be a subset of W with $|S| = |W| - 1$ and w be the unique element in $W \setminus S$. Then, for $X \subseteq \tilde{V}$, it holds that

$$\tilde{\rho}(X) = \rho^\circ(X \cup S) - \rho^\circ(S) = \min_{Y \subseteq X \cup S} \{\rho(\Gamma(Y)) + |X \cup S \setminus Y|\} - |W| + 1,$$

where $\Gamma(Y) = \{u \mid u \in V, \exists(u', v) \in A, v \in Y\}$ for $Y \subseteq V$.

Suppose $w \in X$. In this case, we have

$$\begin{aligned}
& \min_{Y \subseteq X \cup S} \{\rho(\Gamma(Y)) + |X \cup S \setminus Y|\} \\
&= \min \left\{ \min_{Y \subseteq X \setminus \{w\}} \{\rho(Y) + |X \cup S \setminus Y|\}, \min_{\substack{Y \subseteq X \cup S, \\ Y \cap W \neq \emptyset}} \{\rho(Y \cup W) + |X \cup S \setminus Y|\} \right\} \\
&= \min \{\rho(X \setminus \{w\}) + |W|, \rho(X \cup W)\} \\
&= \rho(X \cup W),
\end{aligned}$$

where the second equality can be seen through putting $Y = X \setminus \{w\}, X \cup S$.

Suppose $w \notin X$. In this case,

$$\begin{aligned}
& \min_{Y \subseteq X \cup S} \{\rho(\Gamma(Y)) + |X \cup S \setminus Y|\} \\
&= \min \left\{ \min_{Y \subseteq X} \{\rho(Y) + |X \cup S \setminus Y|\}, \min_{\substack{Y \subseteq X \cup S, \\ Y \cap S \neq \emptyset}} \{\rho(Y \cup W) + |X \cup S \setminus Y|\} \right\} \\
&= \min \{\rho(X) + |W| - 1, \rho(X \cup W)\},
\end{aligned}$$

where the second equality can be seen through putting $Y = X, X \cup S$. $\square$

3.2. Independence test. Here we describe how to test independence in matroids obtained by repeated shrinking. Suppose we have an independence oracle for a matroid $\mathbf{M} = (V, \mathcal{I}, \rho)$, and we obtained a matroid $\tilde{\mathbf{M}} = (\tilde{V}, \tilde{\mathcal{I}}, \tilde{\rho})$ by applying to $\mathbf{M}$ the procedure shrinking repeatedly. Let $w_1, \dots, w_k$ be the newly created elements in $\tilde{V}$, that is, $\{w_1, \dots, w_k\} = \tilde{V} \setminus V$, and denote the set of vertices shrunk into the pseudovortex w_i by $W_i \subseteq V$ ($i = 1, \dots, k$). If the vertices shrunk into w_i are nested (that is, w_i is obtained by shrinking vertices that includes pseudovertrices created in preceding shrinking), it suffices to deal with w_i as if we executed a single procedure of shrinking W_i into w_i .

Assume that we have an independent set $\tilde{I} \in \tilde{\mathcal{I}}$, and we know how to expand W_i ($i = 1, \dots, k$) to obtain an independent set $I \in \mathcal{I}$. We focus on testing whether $\tilde{I} \cup \{v\}$ is independent for all $v \in \tilde{V} \setminus \tilde{I}$. Moreover, if $\tilde{I} \cup \{v\} \notin \tilde{\mathcal{I}}$, we enumerate all $u \in \tilde{I}$ such that $(\tilde{I} \setminus \{u\}) \cup \{v\} \in \tilde{\mathcal{I}}$. These independence tests can be performed efficiently through constructing an auxiliary graph.

Construct an auxiliary graph $G^\natural = (V^\natural, A^\natural; S^1, S^2)$ as follows. The vertex set is $V^\natural = V^1 \cup V^2$, where V^1 and V^2 are copies of V . The copy of $v \in V$ (resp., $W \subseteq V$) in V^i is denoted by v^i (resp., W^i) for $i = 1, 2$. The arc set $A^\natural$ consists of $A^\natural = A_V \cup A_M \cup J$, where

$$\begin{aligned}
A_V &= \left(\bigcup_{i=1}^k \{(u^1, v^2) \mid u, v \in W_i\} \right) \cup \{(v^1, v^2) \mid v \in V \setminus (W_1 \cup \dots \cup W_k)\}, \\
A_M &= \{(v^2, v^1) \mid v \in I\}, \\
J &= \{(u^2, v^2) \mid u \in \text{cl}(I) \setminus I, v \in I, v \in C(I \mid u)\}.
\end{aligned}$$

The two subsets $S^1 \subseteq V^1$ and $S^2 \subseteq V^2$ are defined by

$$S^1 = \{v^1 \mid v \in V \setminus I\}, \quad S^2 = \{v^2 \mid v \in V \setminus I, I \cup \{v\} \in \mathcal{I}\}.$$

We refer to S^1 and S^2 as the set of *source-vertices* and *sink-vertices*, respectively, and refer to a path which starts from S^1 and ends in S^2 as a *source-sink path*.

Fix $v \in V \setminus I$. Assume v is not a pseudovortex. If there exists a source-sink path in $G^\natural$ which starts from v^1 , then $\tilde{I} \cup \{v\} \in \tilde{\mathcal{I}}$. If not, one can find all elements $u \in \tilde{I}$ which satisfy $(\tilde{I} \setminus \{u\}) \cup \{v\} \in \tilde{\mathcal{I}}$ as follows: For a vertex $u \in \tilde{I} \setminus \{w_1, \dots, w_k\}$, it holds that $(\tilde{I} \setminus \{u\}) \cup \{v\} \in \tilde{\mathcal{I}}$ if and only if there exists a path in $G^\natural$ which starts from v^1 and ends in u^2 ; for a pseudovortex $w_i \in \tilde{I}$, it holds that $(\tilde{I} \setminus \{w_i\}) \cup \{v\} \in \tilde{\mathcal{I}}$ if and only if there exists a path in $G^\natural$ which starts from v^1 and ends in w^2 with $w \in W_i$.

Assume v is a pseudovortex, say, $v = w_1$, and let $w_* \in V$ be the unique vertex in $W_1 \setminus I$. In that case, if there exists a source-sink path in $G^\natural$ which starts from w_*^1 , then $\tilde{I} \cup \{v\} \in \tilde{\mathcal{I}}$. If not, one can find all elements $u \in \tilde{I}$ which satisfy $(\tilde{I} \setminus \{u\}) \cup \{v\} \in \tilde{\mathcal{I}}$ as follows: For a vertex $u \in \tilde{I} \setminus \{w_1, \dots, w_k\}$, it holds that $(\tilde{I} \setminus \{u\}) \cup \{v\} \in \tilde{\mathcal{I}}$ if and only if there exists a path in $G^\natural$ which starts from w_*^1 and ends in u^2 ; for a pseudovortex $w_i \in \tilde{I}$, it holds that $(\tilde{I} \setminus \{w_i\}) \cup \{v\} \in \tilde{\mathcal{I}}$ if and only if there exists a path in $G^\natural$ which starts from w_*^1 and ends in w^2 with $w \in W_i$.

4. The independent even factor problem. From now on, we deal with the *independent even factor problem*, which is a variant of the *basic even factor problem* [4].

DEFINITION 4.1. Let $G = (V, A)$ be a digraph and $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$, $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids. An even factor M in G is called an *independent even factor* in $(G, \mathbf{M}^+, \mathbf{M}^-)$ if $\partial^+ M \in \mathcal{I}^+$ and $\partial^- M \in \mathcal{I}^-$. If $\partial^+ M$ and $\partial^- M$ are bases of $\mathbf{M}^+$ and $\mathbf{M}^-$, respectively, M is called a *basic even factor*.

For a digraph $G = (V, A)$ and matroids $\mathbf{M}^+ = (V, \mathcal{I}^+)$, $\mathbf{M}^- = (V, \mathcal{I}^-)$, let $\nu(G, \mathbf{M}^+, \mathbf{M}^-)$ denote the cardinality of a maximum independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$. The independent even factor problem contains the even factor problem and the matroid intersection problem as special cases.

Even factor problem. If $\mathbf{M}^+$ and $\mathbf{M}^-$ are free, an arc set is an independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$ if and only if it is an even factor in G .

Matroid intersection problem. Let $\mathbf{M}_1 = (V, \mathcal{I}_1, \rho_1)$ and $\mathbf{M}_2 = (V, \mathcal{I}_2, \rho_2)$ be an instance of the matroid intersection problem. Then, construct an associated bipartite digraph $G = (V_1, V_2; A)$ as follows. Both of the vertex sets V_1 and V_2 are copies of V , respectively, and the arc set A is given by

$$A = \{(v_1, v_2) \mid v \in V\},$$

where $v_1 \in V_1$ (resp., $v_2 \in V_2$) denotes the copy of $v \in V$. On the vertex set $V_1 \cup V_2$, define matroids $\mathbf{M}^+ = (V_1 \cup V_2, \mathcal{I}^+, \rho^+)$ and $\mathbf{M}^- = (V_1 \cup V_2, \mathcal{I}^-, \rho^-)$ by the following rank functions $\rho^+, \rho^- : 2^{V_1 \cup V_2} \rightarrow \mathbb{Z}_+$:

$$\rho^+(X) = \rho_1(X \cap V_1), \quad \rho^-(X) = \rho_2(X \cap V_2).$$

Then, a subset $I \subseteq V$ belongs to $\mathcal{I}_1 \cap \mathcal{I}_2$ if and only if the arc set $\{(v_1, v_2) \mid v \in I\}$ is an independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$.

For any independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$ and any stable pair in G , the following inequality holds.

LEMMA 4.2. Let $G = (V, A)$ be a digraph and $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$, $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids. Then, for any independent even factor M in $(G, \mathbf{M}^+, \mathbf{M}^-)$ and any stable pair (X^+, X^-) in G , it holds that

$$(4.1) \quad |M| \leq \rho^+(V \setminus X^+) + \rho^-(V \setminus X^-) + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-).$$

Proof. As (X^+, X^-) is a stable pair, it holds that $M = M_1 \cup M_2 \cup M_3$, where

$$(4.2) \quad M_1 = \{a \mid a \in M, \partial^+ a \in V \setminus X^+\},$$

$$(4.3) \quad M_2 = \{a \mid a \in M, \partial^- a \in V \setminus X^-\},$$

$$(4.4) \quad M_3 = \{a \mid a \in M, a \in A[X^+ \cap X^-]\}.$$

Note that M_1 and M_2 are not necessarily disjoint. We accomplish the proof by showing

$$(4.5) \quad |M_1| \leq \rho^+(V \setminus X^+), \quad |M_2| \leq \rho^-(V \setminus X^-), \quad |M_3| \leq |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-).$$

First, as M is an independent even factor, it follows that $\partial^+ M \in \mathcal{I}^+$, especially $\partial^+ M_1 \in \mathcal{I}^+$. By the definition of M_1 , we have $\partial^+ M_1 \subseteq V \setminus X^+$, which implies $|M_1| = |\partial^+ M_1| \leq \rho^+(V \setminus X^+)$.

Next, a similar argument shows that $|M_2| \leq \rho^-(V \setminus X^-)$.

Finally, let us estimate $|M_3|$ by counting $|\partial^- M_3|$. For a source-component C in $G[X^+ \cap X^-]$, it holds that $|V(C) \cap \partial^- M_3| = |A(C) \cap M_3|$. Hence, if C is odd and $|V(C) \cap \partial^- M_3| = |C|$, then $A(C) \cap M_3$ would contain an odd cycle, which contradicts that M is an even factor in G . Thus, for every odd source-component C in $X^+ \cap X^-$, it holds that $|V(C) \cap \partial^- M_3| \leq |C| - 1$, which implies $|M_3| = |\partial^- M_3| \leq |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-)$. $\square$

A stable pair (X^+, X^-) is called *minimizing* if (X^+, X^-) minimizes the right-hand side of (4.1). In fact, for a maximum independent even factor M and a minimizing stable pair (X^+, X^-) , (4.1) holds with equality if G is odd-cycle-symmetric.

THEOREM 4.3. For an odd-cycle-symmetric digraph $G = (V, A)$ and matroids $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$, $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$, it holds that

$$(4.6) \quad \nu(G, \mathbf{M}^+, \mathbf{M}^-) = \min_{(X^+, X^-)} \{ \rho^+(V \setminus X^+) + \rho^-(V \setminus X^-) + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \},$$

where (X^+, X^-) runs over all stable pairs.

One easily sees that Theorem 4.3 generalizes Theorems 2.2 and 2.3.

Theorem 4.3 can be proved by extending Cunningham and Geelen's approach [4]. Let $G = (V, A)$ be an odd-cycle-symmetric digraph, $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$ and $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids, and T be the Tutte matrix of G . Let us denote by $T[I^+, I^-]$ the submatrix of T whose row set is $I^+ \subseteq V$ and column set $I^- \subseteq V$. Note that the submatrix $T[I^+, I^-]$ is the Tutte matrix of the subgraph $G[I^+, I^-]$. By Theorem 2.1, we have that if a submatrix $T[I^+, I^-]$ such that $I^+ \in \mathcal{I}^+$ and $I^- \in \mathcal{I}^-$ is nonsingular, there exists an independent even factor M with $\partial^+ M = I^+$ and $\partial^- M = I^-$. As for such submatrices, there exists a min-max formula, which is a special case of Schrijver's one for linking systems [20, Theorem 3.6].

THEOREM 4.4. *Let T be a matrix whose row set and column set are both indexed by V , and let $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$ and $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids. Then, it holds that*

$$\begin{aligned} & \max \{ |I^+| \mid I^+ \in \mathcal{I}^+, I^- \in \mathcal{I}^-, T[I^+, I^-] \text{ is nonsingular} \} \\ &= \min_{U^+, U^- \subseteq V} \{ \rho^+(V \setminus U^+) + \rho^-(V \setminus U^-) + \text{rank } T[U^+, U^-] \}. \end{aligned}$$

We remark here that Schrijver [20] proved the min-max formula using Theorem 2.3. Combining Theorems 2.2 and 4.4 procures us a proof of Theorem 4.3.

Proof of Theorem 4.3. Let T be the Tutte matrix of G . By Theorem 4.4, we have

$$\nu(G, \mathbf{M}^+, \mathbf{M}^-) = \min_{U^+, U^- \subseteq V} \{ \rho^+(V \setminus U^+) + \rho^-(V \setminus U^-) + \text{rank } T[U^+, U^-] \}.$$

Moreover, we know by Theorems 2.1 and 2.2 that

$$\begin{aligned} \text{rank } T[U^+, U^-] &= \nu(G[U^+, U^-]) \\ &= \min_{(X^+, X^-)} \{ |U^+ \setminus X^+| + |U^- \setminus X^-| + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \}, \end{aligned}$$

where (X^+, X^-) runs over all stable pairs in $G[U^+, U^-]$. Note that the second equality follows from a variant of Theorem 2.2, which can also be proved by Pap's even factor algorithm [17]. Therefore, we have that $\nu(G, \mathbf{M}^+, \mathbf{M}^-)$ is equal to

$$\begin{aligned} & \min_{U^+, U^- \subseteq V} \left\{ \rho^+(V \setminus U^+) + \rho^-(V \setminus U^-) \right. \\ & \quad \left. + \min_{(X^+, X^-)} \{ |U^+ \setminus X^+| + |U^- \setminus X^-| + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \} \right\} \\ &= \min_{(X^+, X^-)} \left\{ \min_{U^+, U^-} \{ \rho^+(V \setminus U^+) + \rho^-(V \setminus U^-) + |U^+ \setminus X^+| + |U^- \setminus X^-| \right. \\ & \quad \left. + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \} \right\}, \end{aligned}$$

where U^+ and U^- satisfy that (X^+, X^-) is a stable pair in $G[U^+, U^-]$. The inner minimum in the right-hand side is achieved when $U^+ = X^+$ and $U^- = X^-$. Hence, it follows that $\nu(G, \mathbf{M}^+, \mathbf{M}^-)$ is equal to

$$\min_{(X^+, X^-)} \{ \rho^+(V \setminus X^+) + \rho^-(V \setminus X^-) + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) \},$$

where (X^+, X^-) runs over all stable pairs. $\square$

5. An alternating-path algorithm. In this section, we describe a combinatorial algorithm to find a maximum independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$, where G is odd-cycle-symmetric. This algorithm is a natural generalization of the maximum even factor algorithm [17] and the matroid intersection algorithms [7, 15], in both of which the notion of *alternating-path* plays an essential part. The algorithm also finds a minimizing stable pair which verifies (4.6).

5.1. The algorithm. Let $G = (V, A)$ be an odd-cycle-symmetric digraph, and let $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$ and $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids, whose closure functions and fundamental circuits are denoted by $\text{cl}^+(\cdot), \text{cl}^-(\cdot)$ and $C^+(\cdot | \cdot), C^-(\cdot | \cdot)$, respectively. Assume we have an independent even factor M in $(G, \mathbf{M}^+, \mathbf{M}^-)$. We show a procedure for finding an independent even factor M' with $|M'| = |M| + 1$ if it exists, and if not, determining that M is a maximum independent even factor.

For M , construct an auxiliary graph $G_M = (V^*, A^*; S^+, S^-)$ as follows. The vertex set V^* is given by $V^* = V^+ \cup V^-$, where V^+ and V^- are two copies of V . For a vertex $v \in V$, we denote the copy of v in V^+ (resp., V^-) by v^+ (resp., v^-).

The arc set A^* is composed of

$$A^* = A^\circ \cup M^\circ \cup J^+ \cup J^-,$$

where

$$\begin{aligned} A^\circ &= \{(u^+, v^-) \mid (u, v) \in A\} && \text{(copy of } A), \\ M^\circ &= \{(v^-, u^+) \mid (u, v) \in M\} && \text{(reverse copy of } M), \\ J^+ &= \{(u^+, v^+) \mid u \in \partial^+ M, v \in \text{cl}^+(\partial^+ M) \setminus \partial^+ M, u \in C^+(\partial^+ M | v)\}, \\ J^- &= \{(u^-, v^-) \mid u \in \text{cl}^-(\partial^- M) \setminus \partial^- M, v \in \partial^- M, v \in C^-(\partial^- M | u)\}. \end{aligned}$$

We call the arcs in J^+ and J^- the *jumping arcs*.

The two subsets $S^+ \subseteq V^+$ and $S^- \subseteq V^-$ are defined by

$$S^+ = \{v^+ \mid v \in V \setminus \text{cl}^+(\partial^+ M)\}, \quad S^- = \{v^- \mid v \in V \setminus \text{cl}^-(\partial^- M)\}.$$

We refer to S^+ and S^- as the set of *source-vertices* and *sink-vertices*, respectively.

A vertex $v \in V^*$ is called *source-reachable* if there exists a path which starts in S^+ and ends in v , and is called *sink-reachable* if there exists a path which starts in v and ends in S^- . A path P is called a *source-sink path* if P starts in S^+ and ends in S^- . For a path P in G_M , we denote the master copy of $A(P) \cap (A^\circ \cup M^\circ)$ by $A^\circ(P)$ (that is, $A^\circ(P) \subseteq A$).

Suppose that G_M has source-sink paths. Let P be the shortest source-sink path and $A^\circ(P) = \{a_1, m_1, a_2, \dots, a_k, m_k, a_{k+1}\}$, which is in order of appearance in P . Note that $a_1, \dots, a_{k+1} \in A \setminus M$ and $m_1, \dots, m_k \in M$. Then, we obtain an independent even factor M' with $|M'| = |M| + 1$ by putting $M' = M \triangle A^\circ(P) = (M \setminus \{m_1, \dots, m_k\}) \cup \{a_1, \dots, a_{k+1}\}$, if M' does not contain odd cycles. We refer to this procedure as $\text{Augment}(M, P)$.

If there exist odd cycles in M' , we avoid the creation of the cycles as follows. Denote

$$A^\circ(P_i) = \begin{cases} \emptyset & (i = 0), \\ \{a_1, m_1, a_2, \dots, a_i, m_i\} & (i = 1, \dots, k), \\ A^\circ(P) & (i = k + 1). \end{cases}$$

Let j be the smallest number such that $M \triangle A^\circ(P_j)$ contains odd cycles. Note that $M \triangle A^\circ(P_j)$ contains a unique odd cycle, denoted by C , and observe that $V(C) \in \mathcal{I}^+ \cap \mathcal{I}^-$. Now, take the symmetric difference of M and $A^\circ(P_{j-1})$, say, $N = M \triangle A^\circ(P_{j-1})$. Let us remark that N is an independent even factor with $|N| = |M|$ and $|N \cap A(C)| =$

$|C| - 1$. Then, shrink $V(C)$ into a new vertex v_C to obtain a new digraph $\tilde{G} = (\tilde{V}, \tilde{A})$ and matroids $\tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-$. In need of an explicit representation of the shrunk odd cycle, we shall denote $\tilde{G}$, $\tilde{V}$, and $\tilde{A}$ by G_C , V_C , and A_C , respectively. Note that the arc set $\tilde{N} = N \cap \tilde{A}$ is an independent even factor in $(\tilde{G}, \tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-)$ with $|\tilde{N}| = |N| - |C| + 1$. We call this procedure $\text{Shrink}(M, P, C)$.

We show the validity of the procedure $\text{Shrink}(M, P, C)$ by the propositions below. First, the following proposition ensures the odd-cycle-symmetry of $\tilde{G}$.

PROPOSITION 5.1 (Pap [17]). *Let $G = (V, A)$ be an odd-cycle-symmetric digraph. For an odd cycle C , it holds that $G_C = (V_C, A_C)$ is also odd-cycle-symmetric.* $\square$

By Lemma 3.1 and Proposition 5.1, it is ensured that the algorithm also runs in $(\tilde{G}, \tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-)$.

Next, for an independent even factor $\tilde{M}$ in $(\tilde{G}, \tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-)$, we describe how to obtain an independent even factor M in $(G, \mathbf{M}^+, \mathbf{M}^-)$ with $|M| = |\tilde{M}| + |C| - 1$.

Suppose $v_C \in \partial^+ \tilde{M} \cap \partial^- \tilde{M}$. Then, we have that $(\partial^+ \tilde{M} \setminus \{v_C\}) \cup V(C) \in \mathcal{I}^+$ and $(\partial^- \tilde{M} \setminus \{v_C\}) \cup V(C) \in \mathcal{I}^-$. In this case, it suffices to add $|C| - 1$ arcs in $A[V(C)]$ to $\tilde{M}$ so that the resulting arc set forms an even factor in G . Let us denote by a^+ (resp., a^-) the unique arc in $\delta^+ V(C) \cap \tilde{M}$ (resp., $\delta^- V(C) \cap \tilde{M}$). As C is odd and G is odd-cycle-symmetric, there exists an even path P from $\partial^- a^-$ to $\partial^+ a^+$ in C or $\bar{C}$. In addition, there exist cycles of length two that cover every vertex $v \in V(C)$ exposed by P exactly once. The union of $\tilde{M}$, $A(P)$, and the arcs in these cycles is an even factor in G of size $|\tilde{M}| + |C| - 1$, $\partial^+ M = (\partial^+ \tilde{M} \setminus \{v_C\}) \cup V(C)$, and $\partial^- M = (\partial^- \tilde{M} \setminus \{v_C\}) \cup V(C)$.

In the case where $v_C \notin \partial^+ \tilde{M}$, we know which $|C| - 1$ vertices in $V(C)$ are in $\partial^+ M$ by $G^\natural$, the auxiliary graph for the independence test in $\tilde{\mathbf{M}}^+$. The same applies to $\partial^- M$, and so an argument similar to the one above shows which $|C| - 1$ arcs in $A(C) \cup A(\bar{C})$ are to be added. We call this procedure $\text{Expand}(\tilde{M}, C)$.

The procedure $\text{Expand}(\tilde{M}, C)$ ensures that for every independent even factor $\tilde{M}$ in $(\tilde{G}, \tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-)$, there exists an independent even factor M in $(G, \mathbf{M}^+, \mathbf{M}^-)$ with $|M| = |\tilde{M}| + |C| - 1$. Hence, the following proposition holds.

PROPOSITION 5.2. *Let $G = (V, A)$ be an odd-cycle-symmetric digraph, and let $\mathbf{M}^+, \mathbf{M}^-$ be two matroids on V . For an odd cycle C with $V(C) \in \mathcal{I}^+ \cup \mathcal{I}^-$, it follows that*

$$\nu(G, \mathbf{M}^+, \mathbf{M}^-) \geq \nu(G_C, \mathbf{M}_{V(C)}^+, \mathbf{M}_{V(C)}^-) + |C| - 1.$$

We are now ready to describe the steps for finding an independent even factor of cardinality larger than M by one.

Step 1. Construct the auxiliary graph G_M . If there exists a source-sink path in G_M , then go to Step 2. Otherwise, go to Step 4.

Step 2. Let P be the shortest source-sink path. If $M \triangle A^\circ(P)$ does not contain any odd cycle, apply $\text{Augment}(M, P)$, and then go to Step 4. Otherwise, go to Step 3.

Step 3. Apply $\text{Shrink}(M, P, C)$, update $(G, \mathbf{M}^+, \mathbf{M}^-) := (\tilde{G}, \tilde{\mathbf{M}}^+, \tilde{\mathbf{M}}^-)$, and $M := \tilde{N}$. Then, go to Step 1.

Step 4. Apply $\text{Expand}(M, C)$ while there exists a pseudovortex v_C .

In the case that no source-sink path is found in Step 1, the algorithm determines that M is a maximum independent even factor. We certify this by showing that there exists a stable pair (X^+, X^-) such that M and (X^+, X^-) certify (4.6).

Algorithmic proof of Theorem 4.3. Let $(G, \mathbf{M}^+, \mathbf{M}^-)$ be the tuple in which no source-sink path was found in Step 1. Let R be the set of the source-reachable vertices in G_M , $X^+ = \{v \mid v^+ \in R\}$, and $X^- = \{v \mid v^- \notin R\}$. Observe that (X^+, X^-) is a

stable pair, and define $M_1, M_2, M_3 \subseteq M$ by (4.2)–(4.4). By the definition of R , we have that $M_1 \cap M_2 = \emptyset$, and $M_3 = \emptyset$. Moreover, $A[X^+ \cap X^-] = \emptyset$, which implies that $|X^+ \cap X^-| = \text{odd}^+(X^+ \cap X^-)$.

Pick up $v \in (V \setminus X^+) \setminus \partial^+ M$. As v^+ is not source-reachable, v^+ is not a source-vertex, that is, $\partial^+ M \cup \{v\} \notin \mathcal{I}^+$. Then, consider the fundamental circuit $C^+(\partial^+ M \mid v)$. If $C^+(\partial^+ M \mid v)$ and X^+ were to intersect at some vertex u , there would be a jumping arc from u^+ to v^+ , which contradicts that v^+ is not source-reachable. Hence, we have that $C^+(\partial^+ M \mid v) \subseteq V \setminus X^+$ for all $v \in (V \setminus X^+) \setminus \partial^+ M$, which implies that $|M_1| = \rho^+(V \setminus X^+)$. A similar argument shows that $|M_2| = \rho^-(V \setminus X^-)$. Therefore, it holds that $|M| = \rho^+(V \setminus X^+) + \rho^-(V \setminus X^-) + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-)$.

The argument above just ensures that (4.6) holds in $(G, \mathbf{M}^+, \mathbf{M}^-)$, which may be achieved as a result of applying $\text{Shrink}(\cdot, \cdot, \cdot)$ repeatedly. We show below that (4.6) holds before the repeated $\text{Shrink}(\cdot, \cdot, \cdot)$.

Suppose that $(G, \mathbf{M}^+, \mathbf{M}^-)$ is the tuple obtained by applying $\text{Shrink}(\hat{M}, P, C)$ to $(\hat{G}, \hat{\mathbf{M}}^+, \hat{\mathbf{M}}^-)$, where $\hat{G} = (\hat{V}, \hat{A})$, $\hat{\mathbf{M}}^+ = (\hat{V}, \hat{\mathcal{I}}^+, \hat{\rho}^+)$, and $\hat{\mathbf{M}}^- = (\hat{V}, \hat{\mathcal{I}}^-, \hat{\rho}^-)$. Associated with X^+ and X^- mentioned above, define $\hat{X}^+, \hat{X}^- \subseteq \hat{V}$ as the inverse-image of X^+, X^- , respectively, that is,

$$\hat{X}^+ = \begin{cases} X^+ & (v_C \notin X^+), \\ X^+ \cup V(C) & (v_C \in X^+), \end{cases}$$

as is $\hat{X}^-$. Now we prove that $(\hat{X}^+, \hat{X}^-)$ is a stable pair which certifies (4.6).

First, one can easily see that $(\hat{X}^+, \hat{X}^-)$ forms a stable pair in $\hat{G}$, which follows from the fact that (X^+, X^-) is a stable pair in G .

Second, we estimate the value $\hat{\rho}^+(\hat{V} \setminus \hat{X}^+) + \hat{\rho}^-(\hat{V} \setminus \hat{X}^-) + |\hat{X}^+ \cap \hat{X}^-| - \text{odd}^+(\hat{X}^+ \cap \hat{X}^-)$.

One can easily see that v_C is a source-vertex in G_M , which implies that $v_C \in X^+$. Then, by Theorem 3.2, we have $\hat{\rho}^+(\hat{V} \setminus \hat{X}^+) = \rho(V \setminus X^+)$, since $\hat{\rho}^+(\hat{V} \setminus \hat{X}^+) \leq \hat{\rho}^+((\hat{V} \setminus \hat{X}^+) \cup V(C)) - |C| + 1$ follows that we can extend M with $|C| - 1$ arcs in $A(C) \cup A(\bar{C})$ to obtain an independent even factor in $(\hat{G}, \hat{\mathbf{M}}^+, \hat{\mathbf{M}}^-)$.

Assume $v_C \in X^+ \cap X^-$. Then, we have $\hat{\rho}^-(\hat{V} \setminus \hat{X}^-) = \rho^-(V \setminus X^-)$ from an argument similar to the one above. Moreover, $|\hat{X}^+ \cap \hat{X}^-| - \text{odd}^+(\hat{X}^+ \cap \hat{X}^-) = |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) + |C| - 1$ follows from the following equations: $|\hat{X}^+ \cap \hat{X}^-| = |X^+ \cap X^-| + |C| - 1$; $\text{odd}^+(\hat{X}^+ \cap \hat{X}^-) = \text{odd}^+(X^+ \cap X^-)$.

Assume $v_C \in X^+ \setminus X^-$. In this case, Theorem 3.2 implies that $\hat{\rho}^-(\hat{V} \setminus \hat{X}^-) = \rho^-(V \setminus X^-) + |C| - 1$, and it is obvious that $|\hat{X}^+ \cap \hat{X}^-| - \text{odd}^+(\hat{X}^+ \cap \hat{X}^-) = |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-)$.

Therefore, in any case we have

$$(5.1) \quad \hat{\rho}^+(\hat{V} \setminus \hat{X}^+) + \hat{\rho}^-(\hat{V} \setminus \hat{X}^-) + |\hat{X}^+ \cap \hat{X}^-| - \text{odd}^+(\hat{X}^+ \cap \hat{X}^-) \\ = \rho^+(V \setminus X^+) + \rho^-(V \setminus X^-) + |X^+ \cap X^-| - \text{odd}^+(X^+ \cap X^-) + |C| - 1.$$

Hence, combining Lemma 4.2, Proposition 5.2, and (5.1), we have that (4.6) holds for $(\hat{G}, \hat{\mathbf{M}}^+, \hat{\mathbf{M}}^-)$. $\square$

5.2. Complexity. We discuss the complexity of the algorithm described in section 5.1. Let $(G, \mathbf{M}^+, \mathbf{M}^-)$, where $G = (V, A)$, $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$, and $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$, be the original instance. Recall that $n = |V|$ and Q is the time needed to test if a given set $U \subseteq V$ is independent in $\mathbf{M}^+$ or $\mathbf{M}^-$.

The most time-consuming part of the algorithm is the construction of the auxiliary graphs $G_M = (V', A'; S^+, S^-)$. We can identify the source-vertices S^+ , sink-vertices S^- , and jumping arcs J^+, J^- by searching paths in the auxiliary graphs $G^\natural$ described in section 3.2. The construction of the auxiliary graph $G^\natural$ takes $O(n^2Q)$ time. In the procedure $\text{Shrink}(\cdot, \cdot, \cdot)$, the number of vertices decreases by at least two, which implies that we have to construct $O(n)$ auxiliary graphs G_M between augmentations. Since there are at most n augmentations, the total time complexity of the algorithm is $O(n^4Q)$.

6. An Edmonds–Gallai-type structure. In this section, we show that independent even factors have a structure which generalizes both the Edmonds–Gallai decomposition for matchings or even factors, and the principal partition for matroid intersection.

Let $G = (V, A)$ be an odd-cycle-symmetric digraph, and let $\mathbf{M}^+ = (V, \mathcal{I}^+, \rho^+)$, $\mathbf{M}^- = (V, \mathcal{I}^-, \rho^-)$ be matroids. In the independent even factor algorithm, we obtain a stable pair (X^+, X^-) in the shrunk digraph when no source-sink path is found. Then, expand pseudovertrices to obtain a stable pair $(\hat{X}^+, \hat{X}^-)$ in the original graph G , which we have seen is minimizing in $(G, \mathbf{M}^+, \mathbf{M}^-)$; i.e., $(\hat{X}^+, \hat{X}^-)$ minimizes the right-hand side of (4.1) among all stable pairs. In addition, exchange the roles of $\mathbf{M}^+$ and $\mathbf{M}^-$ in the algorithm to obtain another stable pair $(\hat{Y}^+, \hat{Y}^-)$, which minimizes

$$(6.1) \quad \rho^+(V \setminus Y^+) + \rho^-(V \setminus Y^-) + |Y^+ \cap Y^-| - \text{odd}^-(Y^+ \cap Y^-)$$

among all stable pairs (Y^+, Y^-) . For these stable pairs, the following theorem holds.

THEOREM 6.1. *For the stable pairs $(\hat{X}^+, \hat{X}^-)$ and $(\hat{Y}^+, \hat{Y}^-)$ defined above, set $V_D^+ = \hat{X}^+$, $V_A^+ = V \setminus \hat{X}^-$, $V_D^- = \hat{Y}^-$, and $V_A^- = V \setminus \hat{Y}^+$. Then, the following four items hold:*

1. $V_D^+ = \{v \mid v \in V, \exists \text{ maximum independent even factor } M, v \notin \text{cl}^+(\partial^+ M)\}$, $V_D^- = \{v \mid v \in V, \exists \text{ maximum independent even factor } M, v \notin \text{cl}^-(\partial^- M)\}$.
2. Every strongly connected component C in $G[V_D^+ \cap (V \setminus V_A^+)]$ or in $G[V_D^- \cap (V \setminus V_A^-)]$ is an odd component with $V(C) \in \mathcal{I}^+ \cap \mathcal{I}^-$.
3. If M is a maximum independent even factor in $(G, \mathbf{M}^+, \mathbf{M}^-)$, then the following three items hold:
 - (i) For every strongly connected component C in $G[V_D^+ \cap (V \setminus V_A^+)]$ or in $G[V_D^- \cap (V \setminus V_A^-)]$, $|M \cap A(C)| = |C| - 1$.
 - (ii) $|(V \setminus V_D^+) \cap \partial^+ M| = \rho^+(V \setminus V_D^+)$, $|V_A^+ \cap \partial^- M| = \rho^-(V_A^+)$, $|V_A^- \cap \partial^+ M| = \rho^+(V_A^-)$, and $|(V \setminus V_D^-) \cap \partial^- M| = \rho^-(V \setminus V_D^-)$.
 - (iii) For a vertex $v \in V_A^+ \cap \partial^- M$, there exists a vertex $u \in V_D^+$ with $(u, v) \in M$, and for a vertex $v \in V_A^- \cap \partial^+ M$, there exists a vertex $u \in V_D^-$ with $(v, u) \in M$.
4. Any minimizing stable pair (X^+, X^-) satisfies that $V_D^+ \subseteq X^+$ and $V_D^- \subseteq X^-$. Similarly, any stable pair (Y^+, Y^-) that minimizes (6.1) satisfies that $V_D^+ \subseteq Y^+$ and $V_D^- \subseteq Y^-$.

Proof. Here we show only the statements on the stable pair $(V_D^+, V \setminus V_A^+)$. Those on $(V \setminus V_A^-, V_D^-)$ can be proved similarly by exchanging the roles of $\mathbf{M}^+$ and $\mathbf{M}^-$ in the maximum independent even factor algorithm.

Assertion 2 follows from the fact that $(V_D^+, V \setminus V_A^+)$ is the minimizing stable pair which the algorithm finds. The fact also implies that

$$V_D^+ \subseteq \{v \mid v \in V, \exists \text{ maximum independent even factor } M, v \notin \text{cl}^+(\partial^+ M)\}.$$

For a maximum independent even factor M , define M_1 , M_2 , and M_3 by (4.2)–(4.4), where $X^+ = V_D^+$ and $X^- = V \setminus V_A^+$. As M is a maximum independent

even factor and (X^+, X^-) is a minimizing stable pair, (4.5) hold with equalities and $M_1 \cap M_2 = \emptyset$. One checks that these conditions induce

$$V_D^+ \supseteq \{v \mid v \in V, \exists \text{ maximum independent even factor } M, v \notin \text{cl}^+(\partial^+ M)\}$$

and assertion 3 (cf. the proof of Lemma 4.2).

Now what is left is assertion 4. Suppose there exists a minimizing stable pair (X^+, X^-) such that there is a vertex u with $u \in V_D^+ \setminus X^+$. As $u \in V_D^+$, there is a maximum independent even factor M with $u \notin \text{cl}^+(\partial^+ M)$. On the other hand, the stable pair (X^+, X^-) and M satisfy (4.5) with equality. The equation $|M_1| = \rho^+(V \setminus X^+)$, however, contradicts that $u \in V \setminus X^+$ and $u \notin \text{cl}^+(\partial^+ M)$. Therefore, for any minimizing stable pair (X^+, X^-) , it holds that $V_D^+ \subseteq X^+$. $\square$

Let us describe how Theorem 6.1 generalizes the Edmonds–Gallai decomposition for matchings and the principal partition for matroid intersection.

Edmonds–Gallai decomposition for matchings. Let $G = (V, E)$ be an undirected graph with the vertex set V and the edge set E , and let $\vec{G} = (V, A)$ be a symmetric digraph whose arc set is

$$A = \{(u, v), (v, u) \mid \exists \text{ edge between } u \text{ and } v \text{ in } E\}.$$

Consider an instance of the matching problem G and an instance of the independent even factor problem $(\vec{G}, \mathbf{M}^+, \mathbf{M}^-)$, where $\mathbf{M}^+$ and $\mathbf{M}^-$ are free matroids. Then, it follows that $V_D^+ = V_D^- = V_D$, $V_A^+ = V_A^- = V_A$, where

$$V_D = \{v \mid v \in V, \exists \text{ maximum matching which does not cover } v\},$$

$$V_A = \{v \mid v \in V \setminus V_D, v \text{ is adjacent to some vertex in } V_D\}.$$

By Theorem 6.1, the following statements on the undirected graph G hold:

1. The cardinality of a maximum matching in G is equal to

$$\begin{aligned} \frac{1}{2} \nu(\vec{G}, \mathbf{M}^+, \mathbf{M}^-) &= \frac{1}{2} (|V \setminus V_D^+| + |V_A^+| + |V_D^+ \cap (V \setminus V_A^+)| - \text{odd}^+(V_D^+ \cap (V \setminus V_A^+))) \\ &= \frac{1}{2} (|V| + |V_A| - \text{odd}(V_D)), \end{aligned}$$

where $\text{odd}(X)$ denotes the number of odd component in $G[X]$ ($X \subseteq V$).

2. Every connected component C in $G[V_D]$ is odd and factor-critical.

3. If M is a maximum matching, then the following hold:

- (i) For every connected component C in $G[V_D]$, C has $(|C| - 1)/2$ edges in M ;
- (ii) every vertex in $V \setminus V_D$ is covered by M ; and
- (iii) for a vertex $v \in V_A$, there exists a vertex $u \in V_D$ such that an edge in M connects u and v .

4. For $V_D' \subseteq V$, define

$$V_A(V_D') = \{v \mid v \in V \setminus V_D', v \text{ is adjacent to some vertex in } V_D'\}.$$

If V_D' minimizes $|V_A(V_D')| - \text{odd}(V_D')$, it follows that $V_D \subseteq V_D'$.

These statements are exactly those of the Edmonds–Gallai decomposition.

Principal partition for matroid intersection. Let $\mathbf{M}_1 = (V, \mathcal{I}_1, \rho_1)$ and $\mathbf{M}_2 = (V, \mathcal{I}_2, \rho_2)$ be an instance of the matroid intersection problem, and define

$$V_D^1 = \{v \mid v \in V, \exists \text{ maximum common independent set } I, v \notin \text{cl}_1(I)\},$$

$$V_D^2 = \{v \mid v \in V, \exists \text{ maximum common independent set } I, v \notin \text{cl}_2(I)\}.$$

Recalling the instance of the independent even factor problem $(G, \mathbf{M}^+, \mathbf{M}^-)$ to which we reduced the matroid intersection instance in section 4, we have that

$$V_D^+ = V_A^+ = \bigcup_{v \in V_D^1} \{v_1, v_2\}, \quad V_D^- = V_A^- = \bigcup_{v \in V_D^2} \{v_1, v_2\}.$$

Applying Theorem 6.1 to $(G, \mathbf{M}^+, \mathbf{M}^-)$, we obtain the following statements.

1. The cardinality of a maximum common independent set in $\mathcal{I}_1 \cap \mathcal{I}_2$ is equal to

$$\nu(G, \mathbf{M}^+, \mathbf{M}^-) = \rho_1(V \setminus V_D^1) + \rho_2(V_D^1) = \rho_1(V_D^2) + \rho_2(V \setminus V_D^2).$$

2. If I is a maximum common independent set, then it holds that $|(V \setminus V_D^1) \cap I| = \rho_1(V \setminus V_D^1)$, $|V_D^1 \cap I| = \rho_2(V_D^1)$, $|V_D^2 \cap I| = \rho_1(V_D^2)$, and $|(V \setminus V_D^2) \cap I| = \rho_2(V \setminus V_D^2)$.

3. Any subset $X \subseteq V$ that minimizes $\rho_1(V \setminus X) + \rho_2(X)$ satisfies that $V_D^1 \subseteq X$ and $V_D^2 \subseteq V \setminus X$. That is, V_D^1 (resp., V_D^2) is the minimal (resp., maximal) subset minimizing the submodular function $\rho_1(V \setminus X) + \rho_2(X)$.

Acknowledgments. The authors are thankful to Kazuo Murota for his helpful comments.

MULTIDIMENSIONAL MANHATTAN STREET NETWORKS*

F. COMELLAS[†], C. DALFÓ[†], AND M. A. FIOL[†]

Abstract. We formally define the n -dimensional Manhattan street network M_n —a special case of an n -regular digraph—and we study some of its structural properties. In particular, we show that M_n is a Cayley digraph, which can be seen as a subgroup of the n -dimensional version of the wallpaper group pgg . These results induce a useful new representation of M_n , which can be applied to design a local (shortest-path) routing algorithm and to study some other metric properties, such as the diameter. We also show that the n -dimensional Manhattan street networks are Hamiltonian and, in the standard case (that is, in dimension two), we give sufficient conditions for a 2-dimensional Manhattan street network to be decomposable into two arc-disjoint Hamiltonian cycles.

Key words. Manhattan street network, line digraph, Cayley digraph, diameter, Hamiltonian cycle

1. Introduction. The study of a class of toroidal directed networks, commonly known in the literature as Manhattan street networks, has received significant attention since they were introduced independently (in different contexts) by Morillo, Fiol, and Fàbrega [18] and Maxemchuk [16], as a unidirectional regular mesh structure resembling locally the topology of the avenues and streets of Manhattan (or *l'Exemple* in downtown Barcelona); see Figure 2.1. More precisely, given two even integers N_i , $i = 1, 2$, the (2-dimensional) Manhattan street network $M_2 = M(N_1, N_2)$ is a 2-regular digraph with vertices $\mathbf{u} = (u_1, u_2)$, $u_i \in \mathbb{Z}_{N_i}$, and vertex $\mathbf{u}$ has two outgoing arcs: one horizontal $(u_1 + (-1)^{u_2}, u_2)$, and the other vertical $(u_1, u_2 + (-1)^{u_1})$.

A Manhattan street network must not be confused with the so-called “Manhattan network,” which, for a given set of points in the plane, consists of a set of axis-parallel line segments whose union contains an x - and y -monotone path for each pair of points (see, for instance, the paper of Benkert et al. [5]).

Back to the Manhattan street networks, Morillo, Fiol, and Fàbrega [18] related these networks to plane tessellations, and this association facilitates the study of some metric properties. Most of the work on Manhattan street networks has been devoted to the 2-dimensional case. Khasnabish [15] and Chung and Agrawal [7] gave the average distance of $M(N_1, N_2)$, which has the following expression when N_1 and N_2 are both divisible by 4:

$$(1.1) \quad \overline{D} = \frac{N_1 + N_2}{4} + 1 - \frac{4}{N_1 N_2}.$$

Maxemchuk [16] studied the generation of routing schemes of the Manhattan street network.

[†]Departament de Matemàtica Aplicada IV, Universitat Politècnica de Catalunya, Jordi Girona 1–3, Mòdul C3, Campus Nord, 08034 Barcelona, Catalonia, Spain (comellas@ma4.upc.edu, cdalfo@ma4.upc.edu, fiol@ma4.upc.edu).

These results have usually been inspired by conjectures supported by computer simulations. Also, the study of spanning trees (by Chung and Agrawal [7]) in the Manhattan street network $M(N_1, N_2)$ has allowed the computation of its diameter:

$$(1.2) \quad D = \begin{cases} N_1/2 + N_2/2 + 1 & \text{if } N_1 \equiv N_2 \equiv 0 \pmod{4}, \\ N_1/2 + N_2/2 & \text{otherwise,} \end{cases}$$

and the design of a multiport broadcasting algorithm. More recently, Varvarigos [21] evaluated again the mean internodal distance of such a network, and also provided a shortest path routing algorithm and two edge-disjoint Hamiltonian cycles in the 2-dimensional case $N_1 = N_2 = N$.

The multidimensional natural extension of the Manhattan street networks was considered by Banerjee, Jain, and Shah [2] and Banerjee, Mukherjee, and Ramamurthy [3] with the determination of the average distance of a 3-dimensional Manhattan street network $M(N_1, N_2, N_3)$, which, in the case $N_i \equiv 0 \pmod{4}$, $i = 1, 2, 3$, turns out to be

$$(1.3) \quad \overline{D} = \frac{N_1 + N_2 + N_3}{4} + 1 - \frac{4}{N_1 N_2 N_3},$$

a result to be compared with (1.1). Moreover, in the same paper the authors gave a conjecture for higher dimensions although, neither in the 3-dimensional nor in the n -dimensional case, no formal algebraic definition was provided, but only an idea of how the adjacencies should be. Namely, quoting Banerjee, Mukherjee, and Ramamurthy [3], “...in a torus network with unidirectional links, the number of nodes in each dimension is even and all adjacent links point in opposite directions.”

Finally, Chung and Agrawal [8] studied the diameter and provided routing schemes for a 3-dimensional construction based on 2-dimensional Manhattan street networks, although the proposed resulting network is not strictly a 3-dimensional Manhattan street network.

In this paper, we give a formal definition of an n -dimensional Manhattan street network M_n and its main properties (section 2). We show that M_n is a Cayley digraph (section 3). This fact allows us to introduce a new representation of M_n (section 3.1), which can be applied to prove a number of results, such as the design of a local (shortest-path) routing algorithm (section 4.2). We also analyze some of its distance-related parameters, such as the diameter in the cases 2-dimensional (section 4.1) and n -dimensional (section 4.3). Finally, we provide some details on the cycle structure and a proof of the Hamiltonicity of these digraphs, and we give sufficient conditions for a 2-dimensional Manhattan street network to be decomposable into two arc-disjoint Hamiltonian cycles (section 5). Consequently, according to the survey of Banerjee, Jain, and Shah [2], such n -dimensional Manhattan street networks would be good candidates for modeling regular logical (multihoop) topologies for lightwave networks.

Some notation on digraphs. Recall that a digraph $G = (V, A)$ consists of a set of vertices V , together with a set of arcs A , which can be seen as ordered pairs of vertices $A \subset V \times V = \{(u, v) : u, v \in V\}$. An arc (u, v) is usually depicted by an arrow with *initial vertex* u and *terminal vertex* v ; that is, $u \rightarrow v$. In this case we say that v is *adjacent from* u or that u is *adjacent to* v . The *out-neighborhood* $\Gamma^+(u)$ (respectively, *in-neighborhood* $\Gamma^-(u)$) of a vertex u is the set of vertices adjacent from (respectively, to) u . The *outdegree* of vertex u is $\delta^+(u) = |\Gamma^+(u)|$, whereas its *indegree* is $\delta^-(u) = |\Gamma^-(u)|$. (Equivalently $\delta^+(u)$ and $\delta^-(u)$ are the numbers of arcs with initial and terminal vertex u , respectively.) Then G is δ -regular when $\delta^-(u) = \delta^+(u) = \delta$ for

FIG. 1.1. The Cayley digraph $\text{Cay}(\mathbb{Z}_6, \{1, 2\})$.

every vertex $u \in V$. Given a digraph $G = (V, A)$, its *converse* digraph $\overline{G} = (V, \overline{A})$ is obtained from G by reversing all of the orientations of the arcs in A ; that is, $(u, v) \in \overline{A}$ if and only if $(v, u) \in A$.

A (directed) *path* $\mathbf{p}$ is a subdigraph of the form $u_0 \rightarrow u_1 \rightarrow u_2 \rightarrow \cdots \rightarrow u_\ell$ with *initial* vertex u_0 , *terminal* vertex u_ℓ , and *interior* vertices $u_1, u_2, \dots, u_{\ell-1}$. The *length* of $\mathbf{p}$ is defined as the number of arcs: $\|\mathbf{p}\| = \ell$. If $\mathbf{p}$ has the minimum number of arcs, then its length is the *distance* $\text{dist}(u_1, u_\ell)$ from the initial vertex u_1 to the terminal vertex u_ℓ . The *eccentricity* $\text{ecc}(u)$ of vertex u is then defined as the maximum distance from u to all of the other vertices. Then, the *diameter* of a digraph G , denoted by $D = D(G)$, is the maximum of all of the eccentricities of its vertices. A digraph is *strongly connected* when, for any pair of vertices u, v , there is a directed path from u to v (in other words, $D(G)$ is finite). Note that G is strongly connected if and only if its converse digraph $\overline{G}$ is. More precisely, $D(G) = D(\overline{G})$.

Given a group Γ with (finite) generating set Δ , the *Cayley digraph* $\text{Cay}(\Gamma, \Delta)$ has vertices representing the elements of Γ and arcs of the form $(g, h\partial)$ where $g, h \in \Gamma$ and $\partial \in \Delta$. The Cayley digraph $\text{Cay}(\Gamma, \Delta)$ is a vertex-transitive strongly connected regular digraph. As an example, Figure 1.1 shows the Cayley digraph of the cyclic group $\Gamma = \mathbb{Z}_6$ with generating set $\Delta = \{1, 2\}$.

A *homomorphism* Ψ from a digraph G to a digraph H is a mapping from the vertex set of G to the vertex set of H preserving adjacencies; that is, if (u, v) is an arc of G , then $(\Psi(u), \Psi(v))$ is an arc of H . Moreover, if both digraphs are arc-colored (all arcs with the same initial or terminal vertex receive different colors) and Ψ preserves the colors, then we say that Ψ is a *colored homomorphism* or simply that it is *color-preserving*. A (colored) *automorphism* of a digraph G is simply a (colored) homomorphism from G to itself (note that, in this case, the above mapping corresponds to a permutation of the vertices of G). The set of (colored) automorphisms of G forms a group called the (colored) *automorphism group* of the digraph. The well-known characterization result of Sabidussi [19] states that a digraph is a Cayley digraph (for some pair Γ, Δ) if and only if its automorphism group contains a regular subgroup (that is, a subgroup which, for every pair of vertices u, v , contains exactly one permutation mapping u into v).

Other standard definitions and basic results about graphs and digraphs not recalled here can be found, for instance, in the textbooks of Bang-Jensen and Gutin [4] or Chartrand and Lesniak [6].

2. Definition and structure. Recall that the standard Manhattan street network $M(N_1, N_2)$ is defined as a 2-regular digraph in the following way. Every vertex is represented by a pair of integers $\mathbf{u} = (u_1, u_2)$, with $0 \leq u_i \leq N_i - 1$, for some even integers N_i , $i = 1, 2$, and vertex $\mathbf{u}$ has two outgoing arcs: one horizontal ($u_1 \pm 1, u_2$), and the other vertical ($u_1, u_2 \pm 1$) (where the sign depends on the parity of the other component, and arithmetic must be understood to be modulo N_i). More precisely, a horizontal arc points *east* (respectively, *west*) when it is on an *even* (respectively, *odd*) row. Similarly, a vertical arc points *north* (respectively, *south*) if it is on an *even* (respectively, *odd*) column.

Locally the structure is as shown in Figure 2.1, and corresponds to a standard pattern for the allowed traffic directions in some neighborhoods of our modern cities, like New York or Barcelona, with their system of straight orthogonal streets. In many papers, such as those of Maxemchuk [16], Chung and Agrawal [7], and Comellas and Dalfo [9], the above mentioned toroidal version of M_2 was considered, whereas Morillo, Fiol, and Fàbrega [18] aimed to construct locally Manhattan street networks with the maximum number of vertices for a given diameter.

FIG. 2.1. The local pattern of a Manhattan street network and two real-life examples: Orthogonal streets of Manhattan and l'Eixample in Barcelona.

A formal definition of the toroidal version for the general n -dimensional case is the following.

DEFINITION 2.1. Given n even positive integers $N_1, N_2, \dots, N_n$, the n -dimensional Manhattan street network $M_n = M(N_1, N_2, \dots, N_n)$ is a digraph with vertex set $V(M_n) = \mathbb{Z}_{N_1} \times \mathbb{Z}_{N_2} \times \dots \times \mathbb{Z}_{N_n}$. Thus, each of its vertices is represented by an n -vector $\mathbf{u} = (u_1, u_2, \dots, u_n)$, with $0 \leq u_i \leq N_i - 1$, $i = 1, 2, \dots, n$. The arc set $A(M_n)$ is defined by the following adjacencies (here called i -arcs):

$$(2.1) \quad (u_1, \dots, u_i, \dots, u_n) \rightarrow (u_1, \dots, u_i + (-1)^{\sum_{j \neq i} u_j}, \dots, u_n) \quad (1 \leq i \leq n).$$

Therefore, M_n is an n -regular digraph on $N = \prod_{i=1}^n N_i$ vertices.

In particular, notice that when $N_i = 2$, $1 \leq i \leq n$, we always have $(-1)^{\sum_{j \neq i} u_j} = 1$. Hence, in this case the n -dimensional Manhattan street network is isomorphic to the symmetric digraph Q_n^* , with Q_n being the hypercube of dimension n (the n -cube).

Some other simple consequences of the definition of M_n are presented in the following lemma.

LEMMA 2.2. *Every n -dimensional Manhattan street network $M_n = M(N_1, N_2, \dots, N_n)$ satisfies the following properties:*

- (a) *Given any permutation σ of the numbers $N_1, N_2, \dots, N_n$, say $P_1, P_2, \dots, P_n$, the Manhattan street networks M_n and $M_n^\sigma = M(P_1, P_2, \dots, P_n)$ are isomorphic digraphs.*
- (b) *M_n is isomorphic to its converse $\overline{M}_n$.*
- (c) *For any $n - k$ fixed integers $x_i \in \mathbb{Z}_{N_i}$, $i = k + 1, k + 2, \dots, n$, the subdigraph of M_n induced by the vertices of the form $(u_1, u_2, \dots, u_k, x_{k+1}, \dots, x_n)$ is either the k -dimensional Manhattan street network $M_k = M(N_1, N_2, \dots, N_k)$ or its converse $\overline{M}_k$, depending on whether $\alpha := \sum_{i=k+1}^n x_n$ is even or odd, respectively.*
- (d) *M_n is both a 2^n -partite and bipartite digraph.*
- (e) *There exists a homomorphism from M_n to the symmetric digraph of the hypercube Q_n^* .*

Proof. The result in (a) is clear with σ acting on the (components of the) vertices of M_n . To prove (b), note that in the converse digraph $\overline{M}_n$, the adjacencies are just

$$(2.2) \quad (u_1, \dots, u_i, \dots, u_n) \rightarrow (u_1, \dots, u_i - (-1)^{\sum_{j \neq i} u_j}, \dots, u_n) \quad (1 \leq i \leq n).$$

Hence, it is readily checked that the mapping $\varphi : V(M_n) \rightarrow V(\overline{M}_n)$ defined by $\varphi(\mathbf{u}) = -\mathbf{u}$ is the required isomorphism. The result in (c) follows from the “converse adjacencies” in (2.2) and the fact that $(-1)^{\sum_{j=1, j \neq i}^k u_i + \alpha} = \pm(-1)^{\sum_{j=1, j \neq i}^k u_i}$ depending on the parity of α . Moreover, (d) holds since M_n is a 2^n -partite digraph with independent sets $V_{\mathbf{b}}$, where $\mathbf{b} = (b_1, b_2, \dots, b_n)$ is an n -binary string. A vertex $\mathbf{u} = (u_1, u_2, \dots, u_n)$ belongs to $V_{\mathbf{b}}$ when the parities of u_i and b_i coincide for every $1 \leq i \leq n$. In particular, M_n is bipartite with stable vertex sets V_0 and V_1 constituted by the vertices whose corresponding binary string represents an even or odd number, respectively. Finally, the claimed homomorphism in (e) is simply

$$(u_1, u_2, \dots, u_n) \mapsto (\pi(u_1), \pi(u_2), \dots, \pi(u_n)),$$

where the parity function π takes the expected values in $\{0, 1\}$. $\square$

Concerning property (d), let us mention that Morillo, Fiol, and Fàbrega [18] introduced the local structure of a standard (2-dimensional) Manhattan street network as a type of 4-partite digraph in the following way: Let a digraph $G = (V, A)$ have order $N = |V|$, a multiple of 4, with $V = V_0 \cup V_1 \cup V_2 \cup V_3$, where

$$(2.3) \quad V_j = \{i : 0 \leq i \leq N - 1; i \equiv j \pmod{4}\} \quad (0 \leq j \leq 3),$$

with every vertex i being adjacent to the vertices $i + a_j$, $i + b_j \pmod{N}$, for some given integers $a_j \equiv 3$, and $b_j \equiv 1 \pmod{4}$ satisfying

$$a_0 + a_2 \equiv -a_1 - a_3 \equiv b_0 + b_2 \equiv -b_1 - b_3 \pmod{N}.$$

See Figure 2.2 to check whether the above conditions impose a local Manhattan street structure.

The line digraph structure. Here we show that the standard Manhattan street network, which is the 2-dimensional case M_2 , has the structure of a line digraph. To the knowledge of the authors, this relevant fact has not been published before,

FIG. 2.2. An alternative definition of the local structure of a 2-dimensional Manhattan street network seen as a 4-partite digraph. (All vertices in V_j are denoted by j .)

although it was used in the thesis by Villar [22]. As a consequence, M_2 can be seen as the line digraph of a digraph M'_2 whose order is one half of the order of M_2 and, what is more important, some properties of M_2 can be derived from those of M'_2 .

First, recall that given a digraph $G = (V, A)$ with n vertices and m arcs, its line digraph $L(G) = (V_L, A_L)$ has vertices representing the arcs of G ; so that we identify each vertex $ij \in V_L$ with the arc $(i, j) \in A$, and its adjacencies are naturally induced by the arc adjacencies in G . More precisely, vertex $ij \in V_L$ is adjacent to vertex jk since the arc $(i, j) \in A$ has the same terminal vertex as the initial vertex of (j, k) . Thus, the order of $L(G)$ equals the size m of G and, if G is δ -regular, so is $L(G)$ and it has δn vertices. Also, it is known that if G is different from a (directed) cycle and has diameter D , then its line digraph $L(G)$ has diameter $D + 1$; see Fiol, Yebra, and Alegre [13]. Some other interesting metric properties of line digraphs were given by Comellas et al. [10] and Fiol, Yebra, and Alegre [13]. With respect to the spectral properties, Balbuena et al. [1] showed that the spectrum of the line digraph $L(G)$ has the same nonzero eigenvalues as G , including (algebraic) multiplicities. In fact, the eigenvalue sets differ only in the number of zeros since their corresponding characteristic polynomials, $p_{L(G)}$ and p_G , satisfy $p_{L(G)}(x) = x^{m-n}p_G(x)$.

As stated before, the next result shows that the line digraph structure is inherent to the 2-dimensional case.

LEMMA 2.3. *For any N_1, N_2 , the 2-dimensional Manhattan street network M_2 is a line digraph.*

Proof. It suffices to check Heuchenne's condition [14], which says that a digraph is a line digraph if and only if it has no multiple arc and the out-neighbor (in-neighbor) sets of any two of its vertices are either identical or disjoint. With this aim, assume that two different vertices, $\mathbf{u} = (u_1, u_2)$ and $\mathbf{v} = (v_1, v_2)$, have a common out-neighbor $\mathbf{w}$. Then we claim that the arcs $\mathbf{u} \rightarrow \mathbf{w}$ and $\mathbf{v} \rightarrow \mathbf{w}$ must be of different type; that is, one 1-arc and the other a 2-arc. Otherwise, if both were 1-arcs, say, we would have

$$\mathbf{w} = (u_1 + (-1)^{u_2}, u_2) = (v_1 + (-1)^{v_2}, v_2),$$

which leads to $u_2 = v_2$ and $u_1 = v_1$, so that $\mathbf{u} = \mathbf{v}$ against the hypothesis. The same contradiction is reached if we suppose that both adjacencies are 2-arcs. Thus assume, without loss of generality, that $\mathbf{u} \rightarrow \mathbf{w}$ is a 1-arc and $\mathbf{v} \rightarrow \mathbf{w}$ is a 2-arc. Then,

$$\mathbf{w} = (u_1 + (-1)^{u_2}, u_2) = (v_1, v_2 + (-1)^{v_1}),$$

whence

$$\begin{aligned} u_1 &= v_1 - (-1)^{u_2} = v_1 - (-1)^{v_2+(-1)^{v_1}} = v_1 + (-1)^{v_2}, \\ v_2 &= u_2 - (-1)^{v_1} = u_2 - (-1)^{u_1+(-1)^{u_2}} = u_2 + (-1)^{u_1}, \end{aligned}$$

which imply the existence of another common out-neighbor w' of u and v , such that $u \rightarrow w'$ is a 2-arc and $v \rightarrow w'$ is a 1-arc, namely

$$w' = (u_1, u_2 + (-1)^{u_1}) = (v_1 + (-1)^{v_2}, v_2).$$

We then get the claimed result. $\square$

Summarizing, we have seen that two different vertices u, v have the same out-neighborhood if and only if they are of the form

$$u = (a, b), \quad v = (a + (-1)^b, b + (-1)^a),$$

for some integers $a \in \mathbb{Z}_{N_1}$, $b \in \mathbb{Z}_{N_2}$. Then, according to the parity (equal “●” or distinct “■” in Figure 2.3) of a, b , we have the two possible situations shown on the left of the figure. From this, notice that the digraph G which M_2 comes from (that is, $M_2 = L(G)$) is also bipartite, with independent sets $\{\bullet\}$ and $\{\blacksquare\}$. In fact, the infinite pattern corresponds to another planar crystallographic group; namely, the one denoted by $p4$.

FIG. 2.3. The local structure of a 2-dimensional Manhattan street network M_2 (thin lines and white vertices) and the digraph (thick lines and black vertices) whose line digraph is M_2 .

It is worth noting that the property of being line digraphs is not shared, in general, by the Manhattan street networks with dimension greater than two. For instance, $M(8, 6, 10)$ does not satisfy Heuchenne’s condition since the out-neighborhoods

$$\Gamma^+((1, 1, 5)) = \{(2, 1, 5), (1, 2, 5), (1, 1, 6)\} \text{ and}$$

$$\Gamma^+((6, 1, 4)) = \{(1, 1, 6), (2, 2, 6), (2, 1, 5)\}$$

are neither equal nor disjoint.

Two simple consequences of Lemma 2.3 are the following: First, M_2 is Hamiltonian, as it is the line digraph of a 2-regular, and thus is a Eulerian digraph (see, for instance, Chartrand and Lesniak [6]). In fact, in section 5 we show that the Hamiltonian property is shared by all n -dimensional Manhattan street networks. Second, from the commented results of Balbuena et al. [1] (see also Fiol and Mitjana [12]) it follows that the spectrum of $M_2 = M(N_1, N_2)$ has the eigenvalue 0 with (geometric) multiplicity at least $N_1 N_2 / 2$.

3. The colored automorphism group. Here we investigate the symmetries of the Manhattan street networks.

THEOREM 3.1. *The n -dimensional Manhattan street network M_n is the Cayley digraph of the group*

$$(3.1) \quad \Gamma = \langle a_1, a_2, \dots, a_n \mid a_i^{N_i} = (a_i a_j)^2 = (a_i a_j^{-1})^2 = 1, \ i, j = 1, \dots, n \rangle.$$

Proof. Let us show that the mappings ϕ_j , $1 \leq j \leq n$, defined by

$$(3.2) \quad \phi_j(u_1, \dots, u_j, \dots, u_n) = (-u_1, \dots, -u_{j-1}, u_j + 1, -u_{j+1}, \dots, -u_n),$$

are all isomorphisms of M_n mapping i -arcs into i -arcs. Indeed, let $\gamma_i^+ \mathbf{u}$ denote the vertex adjacent from vertex $\mathbf{u} = (u_1, \dots, u_n)$ through the i -arc. Then, assuming first that $j \neq i$, say $j < i$,

$$\begin{aligned} \phi_j(\gamma_i^+ \mathbf{u}) &= \phi_j(u_1, \dots, u_j, \dots, u_i + (-1)^{\sum_{k \neq i} u_k}, \dots, u_n) \\ &= (-u_1, \dots, u_j + 1, \dots, -u_i + (-1)^{1 + \sum_{k \neq i} u_k}, \dots, -u_n) \\ &= \gamma_i^+(-u_1, \dots, u_j + 1, \dots, -u_i, \dots, -u_n) \\ &= \gamma_i^+ \phi_j(\mathbf{u}). \end{aligned}$$

Otherwise, if $j = i$, then we have

$$\begin{aligned} \phi_i(\gamma_i^+ \mathbf{u}) &= \phi_i(u_1, \dots, u_i + (-1)^{\sum_{k \neq i} u_k}, \dots, u_n) \\ &= (-u_1, \dots, u_i + 1 + (-1)^{\sum_{k \neq i} u_k}, \dots, -u_n) \\ &= \gamma_i^+(-u_1, \dots, u_i + 1, \dots, -u_n) \\ &= \gamma_i^+ \phi_i(\mathbf{u}). \end{aligned}$$

Therefore, the mappings ϕ_j , $1 \leq j \leq n$, are all color-preserving automorphisms of M_n . Let us now show that the permutation group $\langle \phi_i \mid 1 \leq i \leq n \rangle$ acts transitively on the set $\mathbb{Z} \times \mathbb{Z} \times \dots \times \mathbb{Z}$ (and, hence, also on the vertex set of $M_n = M(N_1, N_2, \dots, N_n)$). With this aim, it is enough to show that any vertex $\mathbf{u} = (u_1, u_2, \dots, u_n)$ can be mapped into vertex $\mathbf{0} = (0, 0, \dots, 0)$. Let us first distinguish two cases depending on the sign of u_n (the superscripts of the isomorphisms indicate how many times they are applied):

- $u_n < 0$:

$$(u_1, u_2, \dots, u_n) \xrightarrow{\phi_n^{|u_n|}} (\pm u_1, \pm u_2, \dots, 0);$$

- $u_n > 0$:

$$\begin{aligned} (u_1, \dots, u_i, \dots, u_n) &\xrightarrow{\phi_i} (-u_1, \dots, u_i + 1, \dots, -u_n) \\ &\xrightarrow{\phi_n^{u_n}} (\pm u_1, \dots, \pm(u_i + 1), \dots, 0), \end{aligned}$$

where $i < n$, and, in both cases, the sign in $\pm$ depends on the parity of u_n .

Then, by applying the same procedure $n - 1$ times, we obtain a vertex of the form $(v_1, 0, \dots, 0)$. From this vertex, the desired path is obtained by taking into

consideration the following cases. Let k be a nonnegative integer:

- $v_1 = -k$:

$$(-k, 0, \dots) \xrightarrow{\phi_1^k} (0, 0, \dots).$$

- $v_1 = 2k + 1$:

$$(2k + 1, 0, \dots) \xrightarrow{\phi_2} (-2k - 1, 1, \dots) \xrightarrow{\phi_1^{2k+1}} (0, -1, \dots) \xrightarrow{\phi_2} (0, 0, \dots).$$

- $v_1 = 2k$:

$$(2k, 0, \dots) \xrightarrow{\phi_2} (-2k, 1, \dots) \xrightarrow{\phi_1^{2k}} (0, 1, \dots) \xrightarrow{\phi_1} (1, -1, \dots) \\ \xrightarrow{\phi_2} (-1, 0, \dots) \xrightarrow{\phi_1} (0, 0, \dots).$$

Thus, the group $\Gamma = \langle \phi_1, \dots, \phi_n \rangle$ is a regular subgroup of the automorphism group $\text{Aut } M_n$ and M_n is a Cayley digraph. Concerning the structure of Γ , let us check only the second defining relation in (3.1), as the others are proved similarly,

$$\begin{aligned} (\phi_i \phi_j)^2(\mathbf{u}) &= \phi_i \phi_j \phi_i \phi_j(u_1, \dots, u_i, \dots, u_j, \dots, u_n) \\ &= \phi_i \phi_j \phi_i(-u_1, \dots, -u_i, \dots, u_j + 1, \dots, -u_n) \\ &= \phi_i \phi_j(u_1, \dots, -u_i + 1, \dots, -u_j - 1, \dots, u_n) \\ &= \phi_i(-u_1, \dots, u_i - 1, \dots, -u_j, \dots, -u_n) \\ &= (u_1, \dots, u_i, \dots, u_j, \dots, u_n) = \mathbf{u}. \quad \square \end{aligned}$$

This structural result has some appealing consequences, the most evident being the following corollary.

COROLLARY 3.2. *The n -dimensional Manhattan street network M_n is a vertex-symmetric (but not necessarily arc-symmetric) digraph.*

The reader familiar with group theory will have already noted that, in the 2-dimensional case, the presentation in (3.1) without the first generating relations $a_1^{N_1} = a_2^{N_2} = 1$ corresponds to the (plane) crystallographic group $p\bar{g}g$; see, for instance, Coxeter and Moser [11]. Consequently, we have the following result.

COROLLARY 3.3. *The underlying Cayley digraph of the 2-dimensional Manhattan street network M_2 , with respect to the arc-coloring defined in (2.1), is a (normal) subgroup of the crystallographic group $p\bar{g}g$.*

In particular, for $N_1 = n$, $N_2 = 2$, we obtain the dihedral group D_n (the symmetry group in two dimensions of a regular n -gon). See Figure 3.1 for the standard drawing of $M(8, 2)$ and the Cayley digraph of D_8 .

3.1. An alternative definition. The previous results imply an alternative definition of the Manhattan street networks.

DEFINITION 3.4. *The vertex set of $M_n = M(N_1, N_2, \dots, N_n)$ is, as stated previously, $\mathbb{Z}_{N_1} \times \dots \times \mathbb{Z}_{N_n}$ and the (i -)arcs ($1 \leq i \leq n$) are now*

$$(3.3) \quad (u_1, \dots, u_i, \dots, u_n) \rightarrow (-u_1, \dots, -u_{i-1}, u_i + 1, -u_{i+1}, \dots, -u_n).$$

LEMMA 3.5. *The graphs defined by (2.1) and (3.3) are isomorphic.*

FIG. 3.1. Standard representations of the Manhattan street network $M(8,2)$ and the Cayley digraph of D_8 (each undirected edge stands for two opposite arcs).

Proof. We introduce the isomorphism from the standard definition to the new representation as follows:

$$(3.4) \quad \Psi(u_1, \dots, u_i, \dots, u_n) \\ = ((-1)^{\sum_{j \neq 1} u_j} u_1, \dots, (-1)^{\sum_{j \neq i} u_j} u_i, \dots, (-1)^{\sum_{j \neq n} u_j} u_n).$$

This application preserves the adjacencies and their “colors.” Indeed,

$$\begin{aligned} \Psi(u_1, \dots, u_i, \dots, u_n) &= ((-1)^{\sum_{j \neq 1} u_j} u_1, \dots, (-1)^{\sum_{j \neq i} u_j} u_i, \dots, (-1)^{\sum_{j \neq n} u_j} u_n) \\ &\rightarrow (-(-1)^{\sum_{j \neq 1} u_j} u_1, \dots, (-1)^{\sum_{j \neq i} u_j} u_i + 1, \dots, -(-1)^{\sum_{j \neq n} u_j} u_n) \\ &= ((-1)^{\sum_{j \neq 1} u_j} + (-1)^{\sum_{j \neq i} u_j} u_1, \dots, (-1)^{\sum_{j \neq i} u_j} (u_i + (-1)^{\sum_{j \neq i} u_j}), \dots, \\ &(-1)^{\sum_{j \neq n} u_j} + (-1)^{\sum_{j \neq i} u_j} u_n) = \Psi(u_1, \dots, u_i + (-1)^{\sum_{j \neq i} u_j}, \dots, u_n). \quad \square \end{aligned}$$

As an example, Figure 3.2 shows both the standard definition and the new representation of $M(6,4)$. (The torus surface is drawn as usual, where the directed dashed lines represent the identification of parallel sides of the rectangle.)

FIG. 3.2. The vertices with their standard labels and with labels induced by applying Ψ to the Manhattan street network $M(6,4)$.

As suggested by this example, it can be readily checked that Ψ is involutive, and hence the mapping from the alternative definition to the standard one is simply $\Psi^{-1} = \Psi$.

4. The diameter of Manhattan street networks. In the 2-dimensional case, the diameter of the Manhattan street network M_2 was first explicitly given by Chung and Agrawal [7] by using spanning trees, although it follows easily from the results of Varvarigos [21], where the mean distance was computed. The same result was proved by Comellas and Dalfó [9] from the comparison of the distance distribution in M_2 and the corresponding undirected toroidal mesh. In [21, 9], the distribution of vertices at each distance was also given, which allows closed formulas for the mean distance. In particular, for large values of N_1 and N_2 , the number of vertices at distance $k \geq 4$ from a given vertex, say $\mathbf{0}$, of $M_2(N_1, N_2)$, is $4(k-1)$ (see Figure 4.1 for the cases $k = 7, 8$). This was also noted by Morillo, Fiol, and Fàbrega [18] for the (not necessarily toroidal) 2-dimensional Manhattan street network with vertex set as in (2.3). Besides, in the same paper it was shown that, considering the digraph as bipartite, if it has diameter $D(> 4)$, then its order has the following Moore-like upper bound (see Miller and Širáň [17]):

$$N(2, D) = \begin{cases} 2(D-1)^2, & D \text{ odd,} \\ 2[(D-1)^2 + 1], & D \text{ even.} \end{cases}$$

In fact, if we do not impose the “toroidal closure” of the network, the above values can be attained since the corresponding tiles (that is, the sets of unit squares associated to the vertices which are at distance at most D from $\mathbf{0}$) tessellate the plane periodically (see Figure 4.1). More precisely, when D is odd, the “steps” (see Figure 2.2) for attaining the maximum order are, for instance,

$$\begin{aligned} a_0 &= 3, & a_1 &= 2D-3, & a_2 &= -2D+1, & a_3 &= -1; \\ b_0 &= 1, & b_1 &= -3, & b_2 &= -2D+3, & b_3 &= 2D-1; \end{aligned}$$

whereas, for D even, we have

$$\begin{aligned} a_0 &= -3, & a_1 &= 2D+1, & a_2 &= -2D+1, & a_3 &= 1; \\ b_0 &= -1, & b_1 &= 3, & b_2 &= -2D-1, & b_3 &= 2D-1. \end{aligned}$$

4.1. Dimension 2. As the reader will have already noted, in the toroidal case studied here, and for a given number of vertices $N = N_1 N_2$, the diameter is much greater than the expression obtained above. In this case we have the following result, which we use afterwards to study the n -dimensional case. As mentioned above, to the best of our knowledge this result was first proved by Chung and Agrawal [7] by using spanning trees. Here we give a constructive proof by explicitly deriving a shortest path from any vertex to vertex $(0, 0)$. Thus our proof leads to a local (shortest-path) routing scheme.

THEOREM 4.1. *The diameter of the Manhattan street network $M(N_1, N_2)$ is*

- (a) $D = \frac{N_1}{2} + \frac{N_2}{2} + 1$ if $N_1 \equiv N_2 \equiv 0 \pmod{4}$,
- (b) $D = \frac{N_1}{2} + \frac{N_2}{2}$ otherwise.

Proof. The proof is based on our Definition 3.4. Let α, β be some even and odd integers, respectively, in $[0, N_i/2 - 1]$, $i = 1, 2$. Similarly, let γ be any integer in the interval $[0, N_i/2 - 1]$. Because of the symmetry of the digraph, it suffices to consider a path from a generic vertex $\mathbf{u} = (u_1, u_2)$ to vertex $\mathbf{0} = (0, 0)$, whose length never exceeds the above values for D . With this aim, we first consider the cases where

FIG. 4.1. The vertices at distance 7 (“□”) and at distance 8 (“■”) from vertex $(0,0)$ (“○”), and the corresponding tessellations.

some u_i equals $\pm N_i/2$ (the sign is irrelevant since we are in $\mathbb{Z}_{N_i}$ with N_i even). Here the arrows and the numbers above them represent the paths and their lengths, respectively,

(i) $u_1 = N_1/2, u_2 = N_2/2$:

$$(N_1/2, N_2/2) \xrightarrow{+N_1/2} (0, N_2/2) \xrightarrow{+N_2/2} (0, 0).$$

(ii) $u_1 = N_1/2$ (even), $u_2 = -\gamma$:

$$(N_1/2, -\gamma) \xrightarrow{+N_1/2} (0, -\gamma) \xrightarrow{+\gamma} (0, 0).$$

(iii) $u_1 = N_1/2$ (even), $u_2 = \alpha$:

$$(N_1/2, \alpha) \xrightarrow{+1} (N_1/2 + 1, -\alpha) \xrightarrow{+\alpha} (N_1/2 + 1, 0) \xrightarrow{+N_1/2-1} (0, 0).$$

(iv) $u_1 = N_1/2$ (even), $u_2 = \beta$:

$$(N_1/2, \beta) \xrightarrow{+N_1/2} (0, \beta) \xrightarrow{+1} (1, -\beta) \xrightarrow{+\beta} (-1, 0) \xrightarrow{+1} (0, 0).$$

(v) $u_1 = N_1/2$ (odd), $u_2 = \gamma$:

$$(N_1/2, \gamma) \xrightarrow{+N_1/2} (0, -\gamma) \xrightarrow{+\gamma} (0, 0).$$

(vi) $u_1 = N_1/2$ (odd), $u_2 = -\gamma$:

$$(N_1/2, -\gamma) \xrightarrow{+\gamma} (N_1/2, 0) \xrightarrow{+N_1/2} (0, 0).$$

Note that all of the above paths have length $\text{dist}(\mathbf{u}, \mathbf{0}) \leq N_1/2 + N_2/2$, except in case (iv) where we have

$$(4.1) \quad \text{dist}(\mathbf{u}, \mathbf{0}) = \frac{N_1}{2} + \beta + 2 \leq \frac{N_1}{2} + \frac{N_2}{2} + 1,$$

and equality is attained when $\beta = N_2/2 - 1$ or, in the symmetric case, $u_1 = \beta = N_1/2 - 1$ and $u_2 = N_2/2$. Note that, in both cases, $N_1/2$ and $N_2/2$ must be even, so that we are in case (a) of the theorem. Besides, when $\beta = N_2/2 - 2$, (4.1) gives $\text{dist}(\mathbf{u}, \mathbf{0}) = N_1/2 + N_2/2$ (for $N_1/2$ even and $N_2/2$ odd); and the same holds in the symmetric case $u_1 = \beta = N_1/2 - 2$, $u_2 = N_2/2$ (for $N_1/2$ odd and $N_2/2$ even). Such cases correspond to case (b) in Theorem 4.1.

Moreover, when neither of the entries u_i equals $N_i/2$, we need to consider the following cases (as before, α_i and β_i represent even and odd integers, respectively, in the interval $[0, N_i - 1]$, $i = 1, 2$):

$$(1) \quad u_1 = -\alpha_1, u_2 = -\alpha_2:$$

$$(-\alpha_1, -\alpha_2) \xrightarrow{+\alpha_1} (0, -\alpha_2) \xrightarrow{+\alpha_2} (0, 0).$$

$$(2) \quad u_1 = -\alpha, u_2 = -\beta:$$

$$(-\alpha, -\beta) \xrightarrow{+\alpha} (0, -\beta) \xrightarrow{+\beta} (0, 0).$$

$$(3) \quad u_1 = -\beta_1, u_2 = -\beta_2:$$

$$(-\beta_1, -\beta_2) \xrightarrow{+\beta_1} (0, \beta_2) \xrightarrow{+1} (1, -\beta_2) \xrightarrow{+\beta_2} (-1, 0) \xrightarrow{+1} (0, 0).$$

$$(4) \quad u_1 = -\alpha, u_2 = \beta:$$

$$(-\alpha, \beta) \xrightarrow{+\alpha} (0, \beta) \xrightarrow{+1} (1, -\beta) \xrightarrow{+\beta} (-1, 0) \xrightarrow{+1} (0, 0).$$

$$(5) \quad u_1 = -\beta, u_2 = \alpha:$$

$$(-\beta, \alpha) \xrightarrow{+\beta} (0, -\alpha) \xrightarrow{+\alpha} (0, 0).$$

$$(6) \quad u_1 = -\alpha_1, u_2 = \alpha_2:$$

$$(-\alpha_1, \alpha_2) \xrightarrow{+1} (-\alpha_1 + 1, -\alpha_2) \xrightarrow{+\alpha_2} (-\alpha_1 + 1, 0) \xrightarrow{+\alpha_1 - 1} (0, 0).$$

$$(7) \quad u_1 = -\beta_1, u_2 = \beta_2:$$

$$(-\beta_1, \beta_2) \xrightarrow{+\beta_1} (0, -\beta_2) \xrightarrow{+\beta_2} (0, 0).$$

$$(8a) \quad u_1 = \alpha_1 < N_1/2 - 1, u_2 = \alpha_2:$$

$$\begin{aligned} &(\alpha_1, \alpha_2) \xrightarrow{+1} (\alpha_1 + 1, -\alpha_2) \xrightarrow{+\alpha_2} (\alpha_1 + 1, 0) \\ &\xrightarrow{+1} (-\alpha_1 - 1, 1) \xrightarrow{+\alpha_1 + 1} (0, -1) \xrightarrow{+1} (0, 0). \end{aligned}$$

$$(8b) \quad u_1 = \alpha_1 = N_1/2 - 1, u_2 = \alpha_2:$$

$$(\alpha_1, \alpha_2) \xrightarrow{+1} (\alpha_1 + 1, -\alpha_2) = (N_1/2, -\alpha_2) \xrightarrow{+\alpha_2} (N_1/2, 0) \xrightarrow{+N_1/2} (0, 0).$$

$$(9) \quad u_1 = \alpha, u_2 = \beta:$$

$$(\alpha, \beta) \xrightarrow{+1} (\alpha + 1, -\beta) \xrightarrow{+\beta} (-\alpha - 1, 0) \xrightarrow{+\alpha+1} (0, 0).$$

$$(10) \quad u_1 = \beta_1, u_2 = \beta_2:$$

$$(\beta_1, \beta_2) \xrightarrow{+1} (\beta_1 + 1, -\beta_2) \xrightarrow{+\beta_2} (-\beta_1 - 1, 0) \xrightarrow{+\beta_1+1} (0, 0).$$

Observe again that all of the above paths have length $\text{dist}(\mathbf{u}, \mathbf{0}) < N_1/2 + N_2/2$, except in the cases (4), (8b), (9) where we have

$$\text{dist}(\mathbf{u}, \mathbf{0}) = \frac{N_1}{2} + \frac{N_2}{2},$$

for different parities of $N_1/2$ and $N_2/2$. For instance, in case (8b) the maximum is attained when $\alpha_2 = N_1/2 - 1$; that is, for a vertex of the form $(N_1/2 - 1, N_2/2 - 1)$, where $N_1 \equiv N_2 \equiv 2 \pmod{4}$. (This and all of the other vertices at maximum distance are listed below.) This completes the proof. $\square$

Notice that, from the above proof, the vertices at maximum distance from $\mathbf{0}$ are, depending on the case (recall that we are using the alternative definition):

- (a) $N_1 \equiv N_2 \equiv 0 \pmod{4}$:
 - (iv): $(N_1/2, N_2/2 - 1), (N_1/2 - 1, N_2/2)$;
- (b1) $N_1 \equiv 0, N_2 \equiv 2 \pmod{4}$:
 - (i): $(N_1/2, N_2/2)$,
 - (iv): $(N_1/2, N_2/2 - 2)$,
 - (4): $(N_1/2 - 1, N_2/2 + 1)$,
 - (9): $(N_1/2 - 1, N_2/2 - 1)$;
- (b2) $N_1 \equiv 2, N_2 \equiv 0 \pmod{4}$:
 - (i): $(N_1/2, N_2/2)$,
 - (iv): $(N_1/2 - 2, N_2/2)$,
 - (4): $(N_1/2 + 1, N_2/2 - 1)$,
 - (9): $(N_1/2 - 1, N_2/2 - 1)$;
- (b3) $N_1 \equiv N_2 \equiv 2 \pmod{4}$:
 - (i): $(N_1/2, N_2/2)$,
 - (8b): $(N_1/2 - 1, N_2/2 - 1)$.

4.2. A routing scheme. As we have already mentioned, the interest of the above proof is that it leads to a shortest-path routing scheme. Indeed, by the symmetry of the network, it suffices to exhibit a path from each vertex to the vertex $(0, 0)$. More precisely, for every node $\mathbf{u} = (u_1, u_2)$ and from the cases (i)–(vi) and (1)–(10) considered in the proof, we can determine which is the shortest path from $\mathbf{u}$ to $(0, 0)$. This is illustrated in Figure 4.2 for the Manhattan street network $M(10, 8)$ where the small number above each vertex indicates the corresponding case. Note that sometimes, when one of the entries u_i is zero, there are two equivalent cases. A label with an apostrophe refers to the corresponding symmetric case obtained by interchanging the roles of u_1 and u_2 . The whole path from $\mathbf{u}$ to $(0, 0)$ is obtained from the case where $\mathbf{u}$ belongs to. For instance, vertex $(6, 1)$ belongs to case (4), which gives the following path (with thick lines in the figure):

$$(6, 1) \rightarrow (7, 7) \rightarrow (8, 1) \rightarrow (9, 7) \rightarrow (0, 1) \rightarrow (1, 7) \rightarrow (9, 0) \rightarrow (0, 0).$$

FIG. 4.2. The shortest paths to $(0,0)$ in $M(10,8)$, according to the proof of Theorem 4.1.

If in some step there is more than one option, then we always take the horizontal link. For instance, in the previous example, as node $(6,1)$ belongs to case (4), which gives the previous path, the next step must be horizontal. This leads us to node $(7,7)$, which belongs to case (3) yielding the subpath $(7,7) \rightarrow (8,1) \rightarrow \dots \rightarrow (0,0)$. Thus, the next step must be again horizontal to reach vertex $(8,1)$ belonging to case (4), and so on. We proceed in this way until we reach $(0,0)$.

Just for illustration, the four vertices $(5,4)$, $(3,4)$, $(6,3)$, and $(4,3)$ at maximum distance 9 to $(0,0)$ —case (b2) in the proof—are indicated by grey in Figure 4.2.

4.3. Dimension n . To derive the diameter of the n -dimensional Manhattan street network, we introduce the following notation: Given N (even) and $0 \leq u \leq N$, let $\|u\|_N$ be the distance between 0 and u in the undirected cycle C_N ; that is, $\|u\|_N = \min\{u \bmod N, -u \bmod N\}$ (so that $0 \leq \|u\|_N \leq N/2$).

LEMMA 4.2. Consider the vertices $\mathbf{0} = (0, 0, \dots, 0)$, $\mathbf{u} = (u_1, \dots, u_{n-1}, u_n)$ in $M_n = (N_1, \dots, N_{n-1}, N_n)$, $n > 2$; and $\mathbf{e}_1 = (1, 0, \dots, 0)$, $\mathbf{u}' = (u_1, \dots, u_{n-1})$ in $M_{n-1} = (N_1, \dots, N_{n-1})$. Let $\alpha = (-1)^{u_n}$. Then,

- (a) $\text{dist}_{M_n}(\mathbf{u}, \mathbf{0}) \geq \sum_{i=1}^n \|u_i\|_{N_i}$;
- (b) $\text{dist}_{M_n}(\mathbf{u}, \mathbf{0}) \leq \text{dist}_{M_{n-1}}(\alpha \mathbf{u}', \mathbf{0}) + \|u_n\|_{N_n}$, if $u_n \in [N_n/2, N_n]$;
- (c) $\text{dist}_{M_n}(\mathbf{u}, \mathbf{0}) \leq \text{dist}_{M_{n-1}}(\alpha(\mathbf{u}' + \mathbf{e}_1), \mathbf{0}) + \|u_n\|_{N_n} + 1$, if $u_n \in [0, N_n/2 - 1]$.

Proof. The inequality in (a) is a direct consequence of the fact that the underlying undirected graph of M_n is just the direct product of the cycles C_{N_i} , $1 \leq i \leq n_i$.

If $N_n/2 \leq u_n \leq N_n$, then there is a path of length $N_n - u_n = \|u_n\|_{N_n}$ from $\mathbf{u}$ to $(\alpha u_1, \dots, \alpha u_{n-1}, 0)$ in M_n . From this vertex, we will need at most $\text{dist}_{M_{n-1}}(\alpha \mathbf{u}', \mathbf{0})$ steps to reach $\mathbf{0}$. This proves (b).

Otherwise, when $0 \leq u_n \leq N_n/2 - 1$, we go first, in one step, from $\mathbf{u}$ to $(u_1 + 1, -u_2, \dots, -u_{n-1}, -u_n)$. Then, from this vertex we have a path of length $u_n = \|u_n\|_{N_n}$ to $(\alpha(u_1 + 1), -\alpha u_2, \dots, -\alpha u_{n-1}, 0)$, and reasoning as before we get (c). $\square$

As a consequence, from the vertex symmetry of the involved digraphs, we have

$$\sum_{i=1}^n \frac{N_i}{2} \leq \text{ecc}_{M_n}(\mathbf{0}) \leq \text{ecc}_{M_{n-1}}(\mathbf{0}) + \frac{N_n}{2}$$

since, in case (c), $\|u_n\|_{N_n} \leq N_n/2 - 1$, and the same formula applies for the respective diameters:

$$(4.2) \quad \sum_{i=1}^n \frac{N_i}{2} \leq D(M_n) \leq D(M_{n-1}) + \frac{N_n}{2}.$$

THEOREM 4.3. *The diameter of the n -dimensional Manhattan street network $M_n = M(N_1, \dots, N_n)$ is*

$$(a) \quad D(M_n) = \sum_{i=1}^n \frac{N_i}{2} + 1 \quad \text{if } N_i \equiv 0 \pmod{4} \text{ for every } 1 \leq i \leq n;$$

$$(b) \quad D(M_n) = \sum_{i=1}^n \frac{N_i}{2} \quad \text{otherwise.}$$

Proof. Since Lemma 4.2 clearly applies to any two components of the vertex $(u_1, u_2, \dots, u_n)$, we can apply recursively the above results to get

$$(4.3) \quad D(M_n) \leq D(M(N_j, N_k)) + \frac{1}{2} \sum_{i \neq j, k} N_i \quad (1 \leq j < k \leq n).$$

Then, under the hypothesis in (b), there is some $1 \leq j \leq n$ such that $N_j \not\equiv 0 \pmod{4}$ and $D(M(N_j, N_k)) = N_j/2 + N_k/2$ by Theorem 4.1. This, together with the lower bound in (4.2), proves the equality in (b).

Otherwise, if $N_i \equiv 0 \pmod{4}$ for any $1 \leq i \leq n$, then Theorem 4.1 and (4.3) yield

$$(4.4) \quad D(M_n) \leq \frac{1}{2} \sum_{i=1}^n N_i + 1.$$

Thus, to prove (a) we need only to show that equality is attained for some vertex. In fact, the vertices at maximum distance to $\mathbf{0}$ are, in this case,

$$\mathbf{u}_i = (N_1/2, N_2/2, \dots, N_i/2 - 1, \dots, N_n/2) \quad (1 \leq i \leq n)$$

(compare with the 2-dimensional case (a), after the proof of Theorem 4.1). For instance, let us check that $\text{dist}(\mathbf{u}_1, \mathbf{0})$ attains the upper bound in (4.4). With this aim, note that the first entry of $\mathbf{u}_1$, $N_1/2 - 1$, is odd, whereas the others, $N_i/2$, $2 \leq i \leq n$, are even. Moreover, for all $1 \leq i \leq n$, we need at least $N_i/2$ steps to bring the i th entry to 0, which gives $\text{dist}(\mathbf{u}_1, \mathbf{0}) \geq \sum_{i=1}^n N_i/2$. In particular, this requires changing, in some step, the first component from $N_1/2 - 1$ to $-N_1/2 + 1 = N_1/2 + 1$, which is accomplished when the number, say r , of previous steps going through j -arcs,

$$(u_1, \dots, u_j, \dots, u_n) \rightarrow (-u_1, \dots, u_j + 1, \dots, -u_n) \quad (2 \leq j \leq n),$$

is odd. Then, although we have taken r steps in the “right direction” to $\mathbf{0}$, there is some j such that the first and j th entries of the reached vertex $\mathbf{u}'$, $u'_1 = N_1/2 + 1$, and $u'_j \in [N_j/2 + 1, N_j - 1]$, are odd. But now, as in case (3) in the proof of Theorem 4.1,

it is impossible to bring these components to 0 without spending at least $\|u'_1\| + \|u'_j\| + 2$ steps (no matter what the other entries are). Hence, we have $\text{dist}(\mathbf{u}_1, \mathbf{0}) = \sum_{i=1}^n N_i/2 + 1$, which completes the proof. $\square$

From the previous results (Theorems 4.1 and 4.3, and Lemma 4.2) and their proofs, it is now apparent how a message can be routed along a path whose length is bounded by the diameter of M_n . Indeed, to go from vertex $(u_1, u_2, \dots, u_n)$ to $\mathbf{0}$ we first go to vertex $(0, \dots, u_i, \dots, u_j, \dots, 0)$ for some appropriately chosen i, j (proof of Lemma 4.2) and, to deal with this two remaining components, we follow the routing induced by the proof of Theorem 4.1—as we were in $M(N_i, N_j)$ —to get to the destination vertex $\mathbf{0}$.

5. Hamiltonian cycles. In this section we first show that Manhattan street networks are Hamiltonian digraphs. Moreover, in the 2-dimensional case, some sufficient conditions for M_2 to be decomposable into two (arc-disjoint) Hamiltonian cycles are derived.

THEOREM 5.1. *The Manhattan street network M_n is Hamiltonian.*

Proof. We proceed by induction over n . For $n = 1$, M_1 can be seen as a directed cycle and hence is trivially Hamiltonian. (We can also start from $N = 2$ since we already know that M_2 is Hamiltonian by Lemma 2.3.) Now suppose that there exists a Hamiltonian cycle for M_{n-1} . Then, we build a Hamiltonian cycle for M_n by appropriately joining N_n Hamiltonian cycles (without some arcs) of its N_n subdigraphs isomorphic to M_{n-1} (see Lemma 2.2(c)). More precisely, the cycle begins, say, in $(u_1, u_2, \dots, u_{n-2}, 0, 0)$ and goes from this vertex to the vertices $(u_1, u_2, \dots, u_{n-2}, 0, 1), \dots, (u_1, u_2, \dots, u_{n-2}, 0, N_n - 1)$. From this last vertex, we follow a clockwise Hamiltonian cycle in a subdigraph M_{n-1} (without the last step) until vertex $(u_1, u_2, \dots, u_{n-2}, N_{n-1} - 1, N_n - 1)$. Then, we go to vertex $(u_1, u_2, \dots, u_{n-2}, N_{n-1} - 1, N_n - 2)$ and, from it, we follow in a counterclockwise cycle until $(u_1, u_2, \dots, u_{n-2}, 1, N_n - 2)$. From here, we go to $(u_1, u_2, \dots, u_{n-2}, 1, N_n - 3)$. Now we repeat this pattern several times until we reach the counterclockwise Hamiltonian cycle of a M_{n-1} (without the last step), which finishes in $(u_1, u_2, \dots, u_{n-2}, 0, 0)$ and thus closes the Hamiltonian cycle of M_n (see Figure 5.1). $\square$

FIG. 5.1. A Hamiltonian cycle in M_n .

As an example of a Hamiltonian cycle in $M(N_1, N_2)$, see Figure 5.2.

Besides the Hamiltonian property, in some applications it is interesting to have a decomposition of the network into (two or more) edge-disjoint Hamiltonian cycles. In this context, Varvarigos [21] showed the presence of two edge-disjoint Hamiltonian cycles in the 2-dimensional Manhattan street network $M(N, N)$. Generalizing

 FIG. 5.2. A Hamiltonian cycle in $M(8,6)$.

his result, we give here some sufficient conditions for $M(N_1, N_2)$ to be Hamiltonian decomposable in such a way.

PROPOSITION 5.2. *Let $M_2 = M(N_1, N_2)$ be a 2-dimensional Manhattan street network. If the two following conditions hold:*

- (a) $\gcd\{N_1/2, N_2/2\} = d \geq 2$;
- (b) *there exist $d_1, d_2 > 0$, $d_1 + d_2 = d$, such that*

$$\gcd\{d_1, N_1/2\} = \gcd\{d_2, N_2/2\} = 1;$$

then M_2 contains two edge-disjoint Hamiltonian cycles.

Proof. The proof is based on a result of Trotter and Erdős [20], who showed that (a) and (b) are sufficient conditions for the Cartesian product of the directed cycles $C_{N_1/2} \times C_{N_2/2}$ to be Hamiltonian. For instance, such conditions are fulfilled with $N_1/2 = 6$ and $N_2/2 = 4$, since $d = 2$ and we can simply take $d_1 = d_2 = 1$, yielding the Hamiltonian cycle shown in Figure 5.3. Note that to obtain such a cycle we simply repeat periodically a subpath of d_1 horizontal steps and d_2 vertical steps. Then, Figure 5.4 illustrates how this Hamiltonian cycle (with arcs going east and north and constructed by taking into account only the even vertices, that is with both entries u_1, u_2 even) induces a Hamiltonian cycle in M_2 . The key idea is that, before closing, this east-north quasi-cycle—in black in the figure—changes its last step from vertical to horizontal and turns into the symmetric west-south quasi-cycle—in grey (now by considering only the odd vertices). Then, at the end, it changes again (last step from vertical to horizontal) to connect with the first quasi-cycle and completing the Hamiltonian cycle in M_2 . With respect to the other (edge-disjoint) cycle of $M(N_1, N_2)$, it is simply the complement of the first one. Alternatively, it can be seen as a Hamiltonian cycle constructed in the same way as the first one, but on the

FIG. 5.4. A decomposition of $M(12, 8)$ into two edge-disjoint Hamiltonian cycles.

converse digraph of the Manhattan street network $M(N_2, N_1)$; see again Figure 5.4 for the details. $\square$

PARTITIONS OF FAULTY HYPERCUBES INTO PATHS WITH PRESCRIBED ENDVERTICES*

TOMÁŠ DVOŘÁK† AND PETR GREGOR†

Abstract. Given a set $\mathcal{P} = \{a_i, b_i\}_{i=1}^m$ of pairs of vertices in a graph G , is there a collection of paths $\{P_i\}_{i=1}^m$ such that P_i connects a_i with b_i and $\{V(P_i)\}_{i=1}^m$ partitions $V(G)$? We study this problem for the graph $Q_n - \mathcal{F}$ obtained from the n -dimensional hypercube Q_n by removing a set $\mathcal{F}$ of faulty vertices. We show that an obvious necessary condition for the existence of such a partition is also sufficient provided $2|\mathcal{P}| + 3|\mathcal{F}| \leq n - 3$. As a corollary, we obtain a similar characterization for the existence of a hamiltonian cycle and a hamiltonian path of $Q_n - \mathcal{F}$ provided $|\mathcal{F}| \leq (n - 5)/3$. On the other hand, if the size of $\mathcal{F}$ is not limited, the problems are NP-complete.

Key words. path partition, hamiltonian cycle, hamiltonian path, hypercube, faulty vertex, fault tolerance, NP-complete

1. Introduction. The n -dimensional hypercube Q_n is a graph whose structural properties have been a subject of interest to graph theorists [12], but it has been also studied by computer scientists as a prospective architecture for interconnection networks [14]. This application also inspired questions related to the reliability of hypercubic networks: if some vertices or edges, corresponding to busy or faulty processors or links, are removed from Q_n , under what conditions does the resulting subgraph preserve the functionality of the original network?

Hamiltonian cycles in Q_n exist for all $n \geq 2$ and their properties and applications have been thoroughly explored [19]. The problem of existence of a hamiltonian cycle of Q_n avoiding an arbitrary number of faulty edges is known to be NP-complete, while in case that this number does not exceed $2n - 5$, a hamiltonian cycle exists provided the natural condition that every vertex is incident with at least two nonfaulty edges is satisfied [4]. The upper bound is optimal in the sense that for $n \geq 3$ there exists Q_n with $2n - 4$ faulty edges satisfying the natural condition but without a hamiltonian cycle avoiding the faulty edges. There is a similar result for hamiltonian paths with given endvertices [20] as well as a generalization to k -ary hypercubes Q_n^k for $k \geq 3$ [1].

The status of the problem for faulty vertices is, however, less satisfactory. It is known that for any distinct vertices u, v, w of Q_n there is a hamiltonian path between u and v in $Q_n - \{w\}$ iff u, v belong to the same partite set, which is different from that containing w [15]. Moreover, this path can avoid a given set of at most $n - 3$ faulty edges [21]. The other results say that Q_n with f faulty vertices contains a cycle of length at least $2^n - 2f$ if $f \leq 2n - 4$ [9] and a path of length at least $2^n - 2f - 1$ ($2^n - 2f - 2$) between two arbitrary vertices at odd (even) distance from each other if $f \leq n - 2$ [10].

The motivation of this article is to obtain results on hamiltonicity of hypercubes with faulty vertices forming a natural counterpart of the results for faulty edges.

†Faculty of Mathematics and Physics, Charles University, Malostranské nám. 25, 118 00 Prague, Czech Republic (tomas.dvorak@mff.cuni.cz, petr.gregor@mff.cuni.cz).

In order to accomplish this task, we study a more general problem: Given a set $\mathcal{P} = \{a_i, b_i\}_{i=1}^m$ of pairs of vertices in a graph G , is there a collection of paths $\{P_i\}_{i=1}^m$ such that P_i connects a_i with b_i and $\{V(P_i)\}_{i=1}^m$ partitions $V(G)$? This question was investigated previously for general graphs [8], hypercubes [3, 7], and hypercube-like interconnection networks with faulty edges and vertices [16]. We study this problem for the graph $Q_n - \mathcal{F}$ obtained from the n -dimensional hypercube Q_n by removing a set $\mathcal{F}$ of faulty vertices. We show that an obvious necessary condition for the existence of such a partition is also sufficient provided $2|\mathcal{P}| + 3|\mathcal{F}| \leq n - 3$. As a corollary, we obtain a similar characterization for the existence of a hamiltonian cycle of $Q_n - \mathcal{F}$ provided $|\mathcal{F}| \leq (n - 5)/3$. On the other hand, if $|\mathcal{F}|$ is not limited, both problems are NP-complete.

2. Preliminaries. The graph-theoretic terminology and notation used in this paper but not defined explicitly can be found, e.g., in [2]. A graph G with vertices $V(G)$ and edges $E(G)$ is a *spanning subgraph* of a graph H if $V(G) = V(H)$ and $E(G) \subseteq E(H)$. For a set $V \subseteq V(G)$, $\langle V \rangle$ denotes the subgraph of G induced by V , while $G - V$ denotes the subgraph $\langle V(G) \setminus V \rangle$. The distance of vertices u and v in G is denoted by $d_G(u, v)$, the subscript being omitted if no ambiguity may arise.

A path with endvertices a and b is denoted by P_{ab} . In particular, P_{aa} denotes the path consisting of a single vertex a . If paths P_{ab} and P_{cd} are vertex disjoint and vertices b and c are adjacent, $P_{ab} + P_{cd}$ denotes the path with endvertices a and d , obtained as a concatenation of P_{ab} with P_{cd} . Path P_1 is called a *subpath* of a path P_2 if P_1 forms a subgraph of P_2 . A collection $\{P_i\}_{i=1}^m$ of paths in a graph G forms a *path partition* of G if $\{V(P_i)\}_{i=1}^m$ partitions $V(G)$.

In this text n always denotes a positive integer, while $[n]$ stands for the set $\{1, 2, \dots, n\}$. Since it is sometimes convenient to deal with subsets of $[n]$ instead of binary vectors of $\{0, 1\}^n$, define a mapping $\pi : \{0, 1\}^n \rightarrow [n]$ which assigns to each $v = (v_1, v_2, \dots, v_n)$ the set $\pi(v) = \{i \in [n] \mid v_i = 1\}$. For binary vectors $u, v \in \{0, 1\}^n$ let $u \oplus v$ denote coordinatewise addition modulo 2. For any $x \in [n]$ let e_x^n denote the binary vector $\pi^{-1}(\{x\})$. In order to simplify the notation, write a^x instead of $a \oplus e_x^n$.

The n -dimensional hypercube Q_n is the graph with vertex set $V(Q_n) = \{0, 1\}^n$ and edge set $E(Q_n) = \{\{u, v\} \mid |\pi(u \oplus v)| = 1\}$. We define the *balance* $\beta(V)$ of a set $V \subseteq V(Q_n)$ by $\beta(V) = \sum_{v \in V} \beta(v)$, where $\beta(v) = (-1)^{|\pi(v)|}$ for any $v \in V(Q_n)$. A set V with $\beta(V) = 0$ is called *balanced*.

A set $\mathcal{P}$ of pairs $\{a_i, b_i\}_{i=1}^m$ of vertices of Q_n (of $V \subseteq V(Q_n)$) is called a *pair set* in Q_n (in V) if $\{a_i, b_i\} \cap \{a_j, b_j\} = \emptyset$ for all distinct $i, j \in [m]$. The union $\bigcup_{i=1}^m \{a_i, b_i\}$ is denoted by $\bigcup \mathcal{P}$. We extend the definition of balance to pair sets by setting $\beta(\mathcal{P}) = \sum_{\{a,b\} \in \mathcal{P}} \beta(a, b)$, where $\beta(a, b) = (\beta(a) + \beta(b))/2$ for any $a, b \in V(Q_n)$. A pair $\{a, b\} \in \mathcal{P}$ is called a *singleton* (*nonsingleton*) if $a = b$ ($a \neq b$). The set of all singletons of $\mathcal{P}$ is denoted by $s(\mathcal{P})$.

We say that a pair set $\mathcal{P}$ is

regular if $\mathcal{P}$ contains at least one nonsingleton,

strongly regular if $\mathcal{P}$ is nonempty and contains only nonsingletons,

balanced if $\beta(\mathcal{P}) = 0$,

connectable in G for some subgraph G of Q_n if there exists a path partition $\{P_{ab}\}_{\{a,b\} \in \mathcal{P}}$ of G , called a *connector* of $\mathcal{P}$ in G . The reference to G may be omitted if $G = Q_n$ and no ambiguity may arise.

Employing the terms introduced above, the main problems studied in this paper can be formulated in the following way.

Hamiltonian cycle in hypercube with faulty vertices ($HCQ_n - V$).

INSTANCE: A subset S of vertices of Q_n for some n .

QUESTION: Is the induced subgraph $\langle S \rangle$ of Q_n hamiltonian?

Hamiltonian path in hypercube with faulty vertices ($\text{HP}Q_n - V$).

INSTANCE: A subset S of vertices of Q_n for some n .

QUESTION: Does the induced subgraph $\langle S \rangle$ of Q_n contain a hamiltonian path?

Hamiltonian path with prescribed endvertices in hypercube with faulty vertices ($\text{HPP}Q_n - V$).

INSTANCE: A subset S of vertices of Q_n for some n and two distinct vertices $a, b \in S$.

QUESTION: Does the induced subgraph $\langle S \rangle$ of Q_n contain a hamiltonian path between a and b ?

Partition of hypercube with faulty vertices into paths with prescribed endvertices ($\text{PP}Q_n - V$).

INSTANCE: A subset S of vertices of Q_n for some n and a strongly regular pair set $\mathcal{P}$ in S .

QUESTION: Is $\mathcal{P}$ connectable in $\langle S \rangle$?

Recall that as $S \subseteq V(Q_n)$ is a set of binary vectors of length n , the instance size of any of the first three problems is $\Theta(n|S|)$, while the instance size of $\text{PP}Q_n - V$ is $\Theta(n(|S| + |\mathcal{P}|))$. It should also be noted that if $\{a, a\}$ is a singleton, then the only path connecting a with a is the path P_{aa} . Singletons can thus play the role of faulty vertices, and therefore it suffices to deal only with the connectability of regular pair sets in Q_n .

The main strategy used in this paper to attack the above problems is based on transformations of pair sets. In order to accomplish this task, we need a few more definitions. Let $x \in [n]$ and $\mathcal{P}$ be a pair set in Q_n . A vertex $v \in V(Q_n)$ is called x -free with respect to $\mathcal{P}$ if $\{v, v^x\} \cap \bigcup \mathcal{P} = \emptyset$. The reference to $\mathcal{P}$ may be omitted if no ambiguity may arise. For any $i \in \{0, 1\}$ let $V_{x,i}$ denote the set $\{(v_1, v_2, \dots, v_n) \in V(Q_n) \mid v_x = i\}$, and let $\mathcal{P}_{x,i}$ denote the set $\{\{a, b\} \in \mathcal{P} \mid \{a, b\} \subseteq V_{x,i}\}$, while $\mathcal{P}_{x,2} = \mathcal{P} \setminus (\mathcal{P}_{x,0} \cup \mathcal{P}_{x,1})$. The pair set $\mathcal{P}$ is called x -separate if $\mathcal{P}_{x,2} = \emptyset$; that is, we can deal with $\mathcal{P}_{x,0}$ in $V_{x,0}$ and $\mathcal{P}_{x,1}$ in $V_{x,1}$ separately.

DEFINITION 2.1. Let $\mathcal{P}, \bar{\mathcal{P}}$ be pair sets in Q_n and $x \in [n]$. We say that $\bar{\mathcal{P}}$ is obtained from $\mathcal{P}$ by

- (i) x -separation if $\bar{\mathcal{P}} = (\mathcal{P} \setminus \{\{a, b\}\}) \cup \{\{a, c\}, \{c^x, b\}\}$ for some $\{a, b\} \in \mathcal{P}_{x,2}$ and an x -free vertex c such that $a, c \in V_{x,i}$ for some $i \in \{0, 1\}$,
- (ii) x -detour if $\bar{\mathcal{P}} = (\mathcal{P} \setminus \{\{a, b\}\}) \cup \{\{a, c\}, \{c^x, d^x\}, \{d, b\}\}$ for some nonsingleton $\{a, b\} \in \mathcal{P}_{x,i}$ and distinct x -free vertices $c, d \in V_{x,i}$ for some $i \in \{0, 1\}$.

$\bar{\mathcal{P}}$ is called an x -extension of $\mathcal{P}$ if there is a sequence $\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_m$ of pair sets such that $\mathcal{P}_1 = \mathcal{P}$, $\mathcal{P}_m = \bar{\mathcal{P}}$, and $\mathcal{P}_{i+1}$ is obtained from $\mathcal{P}_i$ by an x -separation or x -detour for each $i \in [m-1]$.

To simplify the notation, throughout the rest of the paper we omit parentheses in $(A \setminus B) \cup C$ and write simply $A \setminus B \cup C$. We conclude this section with a list of properties preserved by x -extensions that shall be needed later.

PROPOSITION 2.2. Let $x \in [n]$ and $\bar{\mathcal{P}}$ be an x -extension of a pair set $\mathcal{P}$. Then

- (i) $s(\bar{\mathcal{P}}) = s(\mathcal{P})$,
- (ii) $\beta(\bar{\mathcal{P}}) = \beta(\mathcal{P})$,
- (iii) $v \in \bigcup \bar{\mathcal{P}} \setminus \bigcup \mathcal{P}$ iff $v^x \in \bigcup \bar{\mathcal{P}} \setminus \bigcup \mathcal{P}$,
- (iv) if $\bar{\mathcal{P}}_{x,i} = s(\bar{\mathcal{P}}_{x,i})$ for some $i \in \{0, 1\}$, then $\bar{\mathcal{P}} = \mathcal{P}$, and
- (v) if $\bar{\mathcal{P}}$ is connectable, so is $\mathcal{P}$.

Proof. Parts (i)–(iii) follow from the observation that both x -separation and x -detour preserve singletons, balance, and the condition in (iii).

To see why part (iv) is true, note that if $\bar{\mathcal{P}}$ was formed by x -separation or x -detour, then both $\bar{\mathcal{P}}_{x,0}$ and $\bar{\mathcal{P}}_{x,1}$ contain at least one nonsingleton.

Finally, to verify part (v), observe that if $\mathcal{C}$ is a connector of $\bar{\mathcal{P}}$ and $\bar{\mathcal{P}}$ is obtained from $\mathcal{P}$ by x -separation (x -detour), then $\mathcal{C} \setminus \{P_{ac}, P_{c^x b}\} \cup \{P_{ac} + P_{c^x b}\}$ ($\mathcal{C} \setminus \{P_{ac}, P_{c^x d^x}, P_{db}\} \cup \{P_{ac} + P_{c^x d^x} + P_{db}\}$) is a connector of $\mathcal{P}$. $\square$

3. History. This section provides a survey of known results on connectability in Q_n . We start with a simple observation saying that each connectable pair set satisfies an obvious necessary condition, which can be expressed in terms of balance.

PROPOSITION 3.1. *If pair set $\mathcal{P}$ is connectable in $\langle V \rangle$ for some $V \subseteq V(Q_n)$, then $\beta(\mathcal{P}) = \beta(V)$.*

Proof. If $\mathcal{P}$ is connectable in $\langle V \rangle$, then $\sum_{\{a,b\} \in \mathcal{P}} \beta(V(P_{ab})) = \sum_{v \in V} \beta(v) = \beta(V)$. Since $\beta(u) \neq \beta(v)$ for any $\{u, v\} \in E(Q_n)$, it follows that

$$\beta(V(P_{ab})) = \begin{cases} 0 = \beta(a, b) & \text{if } \beta(a) \neq \beta(b), \\ \beta(a) = \beta(b) = \beta(a, b) & \text{otherwise.} \end{cases}$$

Consequently, $\beta(\mathcal{P}) = \sum_{\{a,b\} \in \mathcal{P}} \beta(a, b) = \sum_{\{a,b\} \in \mathcal{P}} \beta(V(P_{ab})) = \beta(V)$. $\square$

In particular, this means that any connectable pair set in Q_n must be balanced. On the other hand, there are previous results showing that balanced pair sets are connectable if their size is limited. A classical theorem on hamiltonian paths in hypercubes may be in our terms formulated in the following way.

THEOREM 3.2 (see [13]). *A balanced pair set of size one is connectable in Q_n .*

There is a generalization to pair sets of size two.

THEOREM 3.3 (see [6]). *A pair set $\mathcal{P} = \{\{a_1, b_1\}, \{a_2, b_2\}\}$ is connectable in Q_n provided $\beta(a_1, b_1) = \beta(a_2, b_2) = 0$.*

A further generalization to a nonconstant number of pairs has been obtained by Caha and Koubek.

THEOREM 3.4 (see [3]). *A strongly regular balanced pair set $\mathcal{P}$ is connectable in Q_n provided $|\mathcal{P}| \leq n/6$.*

The bound on the size of $|\mathcal{P}|$ has been recently improved.

THEOREM 3.5 (see [11]). *A strongly regular balanced pair set $\mathcal{P}$ is connectable in Q_n provided $|\mathcal{P}| \leq (n-1)/2$.*

4. Construction. The aim of this section is to transform the problem of connectability of regular pair sets to the strongly regular case so that we can apply Theorem 3.5. We start with a rather technical lemma that provides a sufficient condition which guarantees that there are always enough x -free vertices needed for our constructions. Put $l_x(\mathcal{P}) = |\{\{v, v^x\} \mid \{v, v^x\} \subseteq \bigcup \mathcal{P}\}|$.

LEMMA 4.1. *Let $\mathcal{P}$ be a pair set in Q_n , $x \in [n]$. If $n \geq 6$ and $|\mathcal{P}| \leq n + l_x(\mathcal{P})/2 - 1$, then for any $i \in \{0, 1\}$, $j \in \{1, -1\}$,*

$$|\{v \in V_{x,i} \mid v \text{ is } x\text{-free and } \beta(v) = j\}| \geq n.$$

Proof. Denote the left-hand side of the last inequality by $l_{i,j}$ and put $l := l_x(\mathcal{P})$. Since there are exactly $|\bigcup \mathcal{P}| - l$ vertices in $V_{x,i}$ that are not x -free and

$$\left| \bigcup \mathcal{P} \right| \leq 2|\mathcal{P}| \leq 2(n + l/2 - 1) = 2n + l - 2,$$

it follows that

$$l_{i,j} \geq |\{v \in V_{x,i} \mid \beta(v) = j\}| - \left(\left| \bigcup \mathcal{P} \right| - l \right) \geq 2^{n-2} - (2n - 2) \geq n$$

for $n \geq 6$. $\square$

Now we are ready to transform regular pair sets to strongly regular ones so that the balance is preserved. In the first step we describe a transformation of a pair set to an x -separate one.

LEMMA 4.2. *Let $n \geq 6$, $x \in [n]$, and $\mathcal{P}$ be a balanced pair set in Q_n such that $|\mathcal{P}| + |\mathcal{P}_{x,2}| \leq n$. Then there is an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}$ such that for both $i \in \{0, 1\}$*

- (i) $|\bar{\mathcal{P}}_{x,i}| = |\mathcal{P}_{x,i}| + |\mathcal{P}_{x,2}|$,
- (ii) $|\beta(\bar{\mathcal{P}}_{x,i})| \leq \min\{|\beta(\mathcal{P}_{x,0})|, |\beta(\mathcal{P}_{x,1})|\}$.

Proof. First note that since $\mathcal{P}$ is balanced, we have

$$(1) \quad \beta(\mathcal{P}_{x,0}) + \beta(\mathcal{P}_{x,1}) + \beta(\mathcal{P}_{x,2}) = 0.$$

If $|\mathcal{P}_{x,2}| = 0$, put $\bar{\mathcal{P}} = \mathcal{P}$, and note that condition (i) is trivial, while (ii) follows from (1). If $|\mathcal{P}_{x,2}| > 0$, let $i \in \{0, 1\}$ be such that $|\beta(\mathcal{P}_{x,i})| \leq |\beta(\mathcal{P}_{x,1-i})|$. We can assume that $\mathcal{P}_{x,2} = \{a_k, b_k\}_{k=1}^m$ such that $a_k \in V_{x,i}$ and $b_k \in V_{x,1-i}$ for each $k \in [m]$. Since $|\mathcal{P}| \leq n - |\mathcal{P}_{x,2}| \leq n - 1 \leq n + l_x(\mathcal{P})/2 - 1$, Lemma 4.1 guarantees that for each $k \in [m]$ there is a distinct x -free vertex $c_k \in V_{x,i}$ such that

$$(2) \quad \beta(a_k, c_k) = 0,$$

which means that

$$(3) \quad \beta(c_k^x, b_k) = \beta(a_k, b_k).$$

Observe that

$$\bar{\mathcal{P}} := \mathcal{P} \setminus \{\{a_k, b_k\} \mid k \in [m]\} \cup \{\{a_k, c_k\}, \{c_k^x, b_k\} \mid k \in [m]\}$$

is an x -separate x -extension of $\mathcal{P}$ satisfying (i). From (2) we have $\beta(\bar{\mathcal{P}}_{x,i}) = \beta(\mathcal{P}_{x,i})$, while from (3) we obtain $\beta(\bar{\mathcal{P}}_{x,1-i}) = \beta(\mathcal{P}_{x,1-i}) + \beta(\mathcal{P}_{x,2})$, which equals $-\beta(\mathcal{P}_{x,i})$ by (1). Hence (ii) holds as well. $\square$

The next lemma shows how to perform a transformation so that the final x -separate pair set $\bar{\mathcal{P}}$ has both parts $\bar{\mathcal{P}}_{x,0}$ and $\bar{\mathcal{P}}_{x,1}$ balanced.

LEMMA 4.3. *Let $n \geq 6$, $x \in [n]$, and $\mathcal{P}$ be an x -separate regular balanced pair set in Q_n such that $|\mathcal{P}| + |\beta(\mathcal{P}_{x,0})| \leq n + l_x(\mathcal{P})/2$. Then there is an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}$ such that for both $i \in \{0, 1\}$,*

- (i) $\bar{\mathcal{P}}_{x,i}$ is balanced,
- (ii) $|\bar{\mathcal{P}}_{x,i}| = |\mathcal{P}_{x,i}| + |\beta(\mathcal{P}_{x,i})|$.

Proof. First note that since $\mathcal{P}$ is balanced and x -separate, $\beta(\mathcal{P}_{x,0}) = -\beta(\mathcal{P}_{x,1})$. We argue by induction on $|\beta(\mathcal{P}_{x,0})|$. If $|\beta(\mathcal{P}_{x,0})| = 0$, put $\bar{\mathcal{P}} = \mathcal{P}$. If $|\beta(\mathcal{P}_{x,0})| > 0$, note that since $\mathcal{P}$ is regular, there is a nonsingleton $\{a, b\} \in \mathcal{P}_{x,j}$ for some $j \in \{0, 1\}$. As $|\mathcal{P}| \leq |\mathcal{P}| + |\beta(\mathcal{P}_{x,0})| - 1 \leq n + l_x(\mathcal{P})/2 - 1$, by Lemma 4.1 we can select x -free vertices $c, d \in V_{x,j}$ satisfying $\beta(c) = \beta(d) = -\text{sgn}(\beta(\mathcal{P}_{x,j}))$. Then $\mathcal{P}^* := \mathcal{P} \setminus \{\{a, b\}\} \cup \{\{a, c\}, \{b, d\}, \{c^x, d^x\}\}$ is an x -extension of $\mathcal{P}$. Since $\beta(a, c) + \beta(b, d) - \beta(a, b) = \beta(c, d) = -\text{sgn}(\beta(\mathcal{P}_{x,j}))$ while $\beta(c^x, d^x) = -\text{sgn}(\beta(\mathcal{P}_{x,1-j}))$, it follows that $|\beta(\mathcal{P}_{x,j}^*)| = |\beta(\mathcal{P}_{x,1-j}^*)| = |\beta(\mathcal{P}_{x,0})| - 1$ and that $\mathcal{P}^*$ is balanced. Moreover, since $l_x(\mathcal{P}^*) = l_x(\mathcal{P}) + 2$, we have $|\mathcal{P}^*| + |\beta(\mathcal{P}_{x,0}^*)| = (|\mathcal{P}| + 2) + (|\beta(\mathcal{P}_{x,0})| - 1) \leq n + l_x(\mathcal{P})/2 + 1 = n + l_x(\mathcal{P}^*)/2$. Therefore, by the induction hypothesis, there exists an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}^*$ such that for both $i \in \{0, 1\}$

- (i) $\bar{\mathcal{P}}_{x,i}$ is balanced, and
 - (ii) $|\bar{\mathcal{P}}_{x,i}| = |\mathcal{P}_{x,i}^*| + |\beta(\mathcal{P}_{x,i}^*)| = (|\mathcal{P}_{x,i}| + 1) + (|\beta(\mathcal{P}_{x,i})| - 1) = |\mathcal{P}_{x,i}| + |\beta(\mathcal{P}_{x,i})|$,
- as desired. $\square$

Now we can put the previous two lemmas together.

LEMMA 4.4. *Let $x \in [n]$ and $\mathcal{P}$ be a regular balanced pair set in Q_n such that $2 \leq |\mathcal{P}| \leq (n - |s(\mathcal{P})| - 3)/2$. Then there is an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}$ such that for both $i \in \{0, 1\}$,*

- (i) $\bar{\mathcal{P}}_{x,i}$ is balanced,
- (ii) $|\bar{\mathcal{P}}_{x,i}| \leq |\mathcal{P}|$, and
- (iii) $\bar{\mathcal{P}}_{x,i}$ is either regular or empty.

Proof. First note that we can assume that $n \geq 7$, for otherwise $|\mathcal{P}| \leq (n - 3)/2 < 2$, contrary to our assumption. Since $|\mathcal{P}| + |\mathcal{P}_{x,2}| \leq 2|\mathcal{P}| \leq n - 3 < n$, we can use Lemma 4.2 to obtain an x -separate x -extension $\mathcal{P}^*$ of $\mathcal{P}$ such that for both $i \in \{0, 1\}$

$$(4) \quad |\mathcal{P}_{x,i}^*| + |\beta(\mathcal{P}_{x,i}^*)| \leq |\mathcal{P}_{x,i}| + |\mathcal{P}_{x,2}| + \min_{j \in \{0,1\}} |\mathcal{P}_{x,j}| \leq |\mathcal{P}|.$$

Consequently, as $|\mathcal{P}_{x,1}^*| = |\mathcal{P}_{x,1}| + |\mathcal{P}_{x,2}|$ by part (i) of Lemma 4.2, we obtain that

$$\begin{aligned} |\mathcal{P}^*| + |\beta(\mathcal{P}_{x,0}^*)| &= |\mathcal{P}_{x,1}^*| + |\mathcal{P}_{x,0}^*| + |\beta(\mathcal{P}_{x,0}^*)| \\ &= |\mathcal{P}_{x,1}| + |\mathcal{P}_{x,2}| + |\mathcal{P}_{x,0}^*| + |\beta(\mathcal{P}_{x,0}^*)| \leq 2|\mathcal{P}| \leq n - 3 < n. \end{aligned}$$

Since $\mathcal{P}^*$ is also a regular balanced pair set by Proposition 2.2, we can use Lemma 4.3 to obtain an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}^*$ such that for both $i \in \{0, 1\}$, $\bar{\mathcal{P}}_{x,i}$ is balanced and

$$|\bar{\mathcal{P}}_{x,i}| = |\mathcal{P}_{x,i}^*| + |\beta(\mathcal{P}_{x,i}^*)| \leq |\mathcal{P}|,$$

using (4) for the last inequality. This verifies the validity of parts (i) and (ii) for $\bar{\mathcal{P}}$.

If part (iii) fails for $\bar{\mathcal{P}}$, then $\bar{\mathcal{P}}_{x,j} = s(\bar{\mathcal{P}}_{x,j}) \neq \emptyset$ for some $j \in \{0, 1\}$. Consequently, part (iv) of Proposition 2.2 implies that $\bar{\mathcal{P}} = \mathcal{P}$. In this case, we construct the desired x -separate x -extension of $\mathcal{P}$ in a different way.

Since $\mathcal{P}$ is regular and x -separate, there exists a nonsingleton $\{a, b\} \in \mathcal{P}_{x,1-j}$. As $|\mathcal{P}| < n$, by Lemma 4.1 there are x -free vertices $c, d \in V_{x,1-j}$ with $\beta(c) \neq \beta(d)$. Then $\tilde{\mathcal{P}} := \mathcal{P} \setminus \{\{a, b\}\} \cup \{\{a, c\}, \{b, d\}, \{c^x, d^x\}\}$ is an x -separate x -extension of $\mathcal{P}$ satisfying

- (i) $\beta(\tilde{\mathcal{P}}_{x,i}) = \beta(\mathcal{P}_{x,i}) = 0$ as $\beta(a, c) + \beta(b, d) = \beta(a, b)$ and $\beta(c^x, d^x) = 0$,
- (ii) $|\tilde{\mathcal{P}}_{x,i}| = |\mathcal{P}_{x,i}| + 1 \leq |\mathcal{P}_{x,i}| + |\mathcal{P}_{x,1-i}| = |\mathcal{P}|$ as $\mathcal{P}_{x,0} \neq \emptyset \neq \mathcal{P}_{x,1}$, and
- (iii) $\tilde{\mathcal{P}}_{x,i}$ is regular as $\{c^x, d^x\} \in \tilde{\mathcal{P}}_{x,j}$ while $\{a, c\} \in \tilde{\mathcal{P}}_{x,1-j}$

for both $i \in \{0, 1\}$. $\square$

The last lemma of this section settles the connectability of pair sets with exactly one singleton.

LEMMA 4.5. *A regular balanced pair set $\mathcal{P}$ with exactly one singleton is connectable in Q_n provided $|\mathcal{P}| \leq (n - 4)/2$.*

Proof. Let $s(\mathcal{P}) = \{\{a, a\}\}$. We claim that there exists $x \in [n]$ such that

$$(5) \quad \text{the only neighbor of } a^x \text{ in } \bigcup \mathcal{P} \text{ is } a.$$

To prove the claim, we say that a vertex $v \in \bigcup \mathcal{P}$ kills the neighbor a^x of a if $v = a \oplus e_x^n \oplus e_y^n$ for some $y \neq x$. Note that if v kills a neighbor of a , then $d(v, a) = 2$, and therefore

- (i) $\beta(a) = \beta(v)$, and
- (ii) v kills exactly two neighbors of a .

Suppose that the claim does not hold. That is, every neighbor of a is killed. Then, there are at least $n/2$ killing vertices in $\bigcup \mathcal{P} \setminus \{a\}$ by (ii). Moreover, they have the

same balance $\beta(a)$ by (i). Since $\mathcal{P}$ is balanced, the set $\bigcup \mathcal{P}$ contains another at least $n/2$ vertices of the balance $-\beta(a)$. But then, $\mathcal{P}$ contains at least $n/2$ pairs apart from the singleton $\{a, a\}$, which yields a contradiction with $|\mathcal{P}| \leq (n-4)/2$. Hence there exists $x \in [n]$ satisfying (5).

Next, observe that as $|s(\mathcal{P})| = 1$ and the regularity of $\mathcal{P}$ implies $|\mathcal{P}| > |s(\mathcal{P})|$, we have

$$2 \leq |\mathcal{P}| \leq (n - |s(\mathcal{P})| - 3)/2.$$

Now Lemma 4.4 yields that there exists an x -separate x -extension $\bar{\mathcal{P}}$ of $\mathcal{P}$ satisfying the conclusions of Lemma 4.4. Fix $i \in \{0, 1\}$ so that $a \in V_{x,i}$ and use Lemma 4.1 to choose $b \in V_{x,i}$ which is x -free with respect to $\bar{\mathcal{P}}$ and for which $\beta(a) = \beta(b)$. Since $\bar{\mathcal{P}}_{x,i}$ is balanced, the same holds for $\mathcal{P}_1 := \bar{\mathcal{P}}_{x,i} \setminus \{\{a, a\}\} \cup \{\{a, b\}\}$. Moreover, as $\{a, a\}$ is, by part (i) of Proposition 2.2, the sole singleton of $\bar{\mathcal{P}}$, $\mathcal{P}_1$ is strongly regular and $|\mathcal{P}_1| = |\bar{\mathcal{P}}_{x,i}| \leq |\mathcal{P}| \leq (n-4)/2 < ((n-1)-1)/2$. Hence by Theorem 3.5 there exists a connector $\mathcal{C}_1$ of $\mathcal{P}_1$ in $\langle V_{x,i} \rangle$. Denote by c the neighbor of a on the path $P_{ab} \in \mathcal{C}_1$ and note that $c \notin \bigcup \bar{\mathcal{P}}$ (as $\bar{\mathcal{P}}$ is x -separate). Since $c^x \notin \bigcup \mathcal{P}$ by (5), part (iii) of Proposition 2.2 implies that $c^x \notin \bigcup \bar{\mathcal{P}}$. Furthermore, as $\beta(c) = -\beta(a) = -\beta(b)$, we have $\beta(c^x, b^x) = \beta(c, b) = 0$. It remains to show that $\bar{\mathcal{P}}$ is connectable, which by part (v) of Proposition 2.2 implies the desired connectability of $\mathcal{P}$. We consider two cases (cf. Figure 1).

FIG. 1. Two cases in the proof of Lemma 4.5.

1. $\bar{\mathcal{P}}_{x,1-i} \neq \emptyset$. Then $\bar{\mathcal{P}}_{x,1-i}$ is regular by part (iii) of Lemma 4.4 and therefore there is a nonsingleton $\{d, e\} \in \bar{\mathcal{P}}_{x,1-i}$. Since $\bar{\mathcal{P}}_{x,1-i}$ is balanced, the same holds for $\mathcal{P}_2 := \bar{\mathcal{P}}_{x,1-i} \setminus \{\{d, e\}\} \cup \{\{d, c^x\}, \{b^x, e\}\}$ as $\beta(d, c^x) + \beta(b^x, e) = \beta(d, e) + \beta(c^x, b^x) = \beta(d, e)$ (recall that $\beta(c^x, b^x) = 0$). Moreover, as $s(\mathcal{P}_2) = s(\bar{\mathcal{P}}_{x,1-i}) = s(\mathcal{P}_{x,1-i}) = \emptyset$, $\mathcal{P}_2$ is strongly regular and $|\mathcal{P}_2| = |\bar{\mathcal{P}}_{x,1-i}| + 1 \leq |\mathcal{P}| + 1 \leq ((n-1)-1)/2$. Hence by Theorem 3.5 there exists a connector $\mathcal{C}_2$ of $\mathcal{P}_2$ in $\langle V_{x,1-i} \rangle$. The connector of $\bar{\mathcal{P}}$ in Q_n can be formed by $(\mathcal{C}_1 \setminus \{P_{ab}\}) \cup (\mathcal{C}_2 \setminus \{P_{dc^x}, P_{b^x e}\}) \cup \{P_{dc^x} + P_{cb} + P_{b^x e}\}$, where P_{cb} is the subpath of P_{ab} .

2. $\bar{\mathcal{P}}_{x,1-i} = \emptyset$. Since $\bar{\mathcal{P}}_{x,i}$ is balanced and $s(\bar{\mathcal{P}}_{x,i}) = s(\mathcal{P}_{x,i}) = \{\{a, a\}\}$, there exists $\{d, e\} \in \bar{\mathcal{P}}_{x,i}$ with $\beta(d) = -\beta(a)$. It follows that $\beta(d) = \beta(c)$. Let f be the neighbor of d on the path $P_{de} \in \mathcal{C}_1$. Observe that $\beta(d^x, b^x) = \beta(c^x, f^x) = 0$, and hence by Theorem 3.3 there exists a connector $\{P_{d^x b^x}, P_{c^x f^x}\}$ of $\{\{d^x, b^x\}, \{c^x, f^x\}\}$ in $\langle V_{x,1-i} \rangle$. The connector of $\bar{\mathcal{P}}$ can be formed by $\mathcal{C}_1 \setminus \{P_{ab}, P_{de}\} \cup \{P_{dd} + P_{d^x b^x} + P_{bc} + P_{c^x f^x} + P_{fe}\}$, where P_{bc} and P_{fe} are subpaths of P_{ba} and P_{de} , respectively. $\square$

5. Results. Now we can employ the constructions of the previous section to prove the main positive results.

THEOREM 5.1. *Let $\mathcal{P}$ be a regular pair set in Q_n such that $2|\mathcal{P}| + |s(\mathcal{P})| \leq n - 3$. Then $\mathcal{P}$ is connectable iff it is balanced.*

Proof. The necessity of the condition was already demonstrated by Proposition 3.1. To verify the sufficiency, assume that $\mathcal{P}$ is balanced. We argue by induction on $|s(\mathcal{P})|$.

1. If $|s(\mathcal{P})| = 0$, then $\mathcal{P}$ is strongly regular and therefore connectable by Theorem 3.5.

2. If $|s(\mathcal{P})| = 1$, then $\mathcal{P}$ is connectable by Lemma 4.5.

3. If $s(\mathcal{P})$ contains distinct singletons $\{a, a\}, \{b, b\}$, choose $x \in \pi(a \oplus b)$ and let $\bar{\mathcal{P}}$ be the x -separate x -extension of $\mathcal{P}$ obtained by Lemma 4.4. Since $s(\bar{\mathcal{P}}) = s(\mathcal{P})$ by Proposition 2.2, it follows that $|s(\bar{\mathcal{P}}_{x,i})| \leq |s(\mathcal{P})| - 1$ for both $i \in \{0, 1\}$. Recall that $\bar{\mathcal{P}}_{x,i}$ is balanced and its size does not exceed $|\mathcal{P}|$, which means that

$$2|\bar{\mathcal{P}}_{x,i}| + |s(\bar{\mathcal{P}}_{x,i})| \leq 2|\mathcal{P}| + |s(\mathcal{P})| - 1 \leq (n-1) - 3$$

for both $i \in \{0, 1\}$. Moreover, since $\bar{\mathcal{P}}_{x,i}$ contains either $\{a, a\}$ or $\{b, b\}$, it is nonempty and therefore regular by part (iii) of the same lemma. Hence by the induction hypothesis there exist connectors $\mathcal{C}_i$ of $\bar{\mathcal{P}}_{x,i}$ in $\langle V_{x,i} \rangle$ for both $i \in \{0, 1\}$. Since $\bar{\mathcal{P}}$ is x -separate, $\mathcal{C}_0 \cup \mathcal{C}_1$ forms a connector of $\bar{\mathcal{P}}$ in Q_n . It remains to apply part (v) of Proposition 2.2 to obtain a connector of $\mathcal{P}$. $\square$

The following corollaries show how the above result provides a partial solution to the problems formulated in section 2.

COROLLARY 5.2. *Let $\mathcal{F} \subseteq V(Q_n)$ and $\mathcal{P}$ be a strongly regular pair set in $Q_n - \mathcal{F}$ such that $2|\mathcal{P}| + 3|\mathcal{F}| \leq n - 3$. Then $\mathcal{P}$ is connectable in $Q_n - \mathcal{F}$ iff $\beta(\mathcal{P}) + \beta(\mathcal{F}) = 0$.*

Proof. Put $\bar{\mathcal{P}} = \mathcal{P} \cup \{\{a, a\} \mid a \in \mathcal{F}\}$. Note that $\bar{\mathcal{P}}$ is connectable in Q_n iff $\mathcal{P}$ is connectable in $Q_n - \mathcal{F}$, and $\beta(\bar{\mathcal{P}}) = \beta(\mathcal{P}) + \beta(\mathcal{F})$. Since

$$2|\mathcal{P}| + 3|\mathcal{F}| = 2|\bar{\mathcal{P}}| + |s(\bar{\mathcal{P}})|,$$

the statement of the corollary follows from Theorem 5.1. $\square$

COROLLARY 5.3. *Let $\mathcal{F} \subseteq V(Q_n)$ and u, v be distinct vertices of $Q_n - \mathcal{F}$. If $|\mathcal{F}| \leq (n-5)/3$, then $Q_n - \mathcal{F}$ contains a hamiltonian path between u and v iff $\beta(u, v) + \beta(\mathcal{F}) = 0$.*

Proof. Put $\mathcal{P} = \{\{u, v\}\}$ and apply Corollary 5.2. $\square$

COROLLARY 5.4. *Let $\mathcal{F} \subseteq V(Q_n)$. If $|\mathcal{F}| \leq (n-5)/3$, then $Q_n - \mathcal{F}$ contains a hamiltonian path iff $|\beta(\mathcal{F})| \leq 1$.*

Proof. Observe that there are distinct vertices u and v in $Q_n - \mathcal{F}$ such that $\beta(u, v) + \beta(\mathcal{F}) = 0$ iff $\beta(\mathcal{F}) \in \{-1, 0, 1\}$, and apply Corollary 5.3. $\square$

COROLLARY 5.5. *Let $\mathcal{F} \subseteq V(Q_n)$. If $|\mathcal{F}| \leq (n-5)/3$, then $Q_n - \mathcal{F}$ is hamiltonian iff $\mathcal{F}$ is balanced.*

Proof. Choose an arbitrary $\{u, v\} \in E(Q_n - \mathcal{F})$ and apply Corollary 5.3. $\square$

6. NP-completeness. The results of the previous section imply that there are bounds on the number $|\mathcal{F}|$ of faulty vertices and the size $|\mathcal{P}|$ of a pair set such that $\mathbf{HC}Q_n - V$, $\mathbf{HP}Q_n - V$, $\mathbf{HPP}Q_n - V$, and $\mathbf{PP}Q_n - V$ are decidable in polynomial time. This section is, on the other hand, devoted to negative results. We show that if $|\mathcal{F}|$ is not limited, all problems are NP-complete. We start with a similar problem for faulty edges whose NP-completeness is already known [4].

Hamiltonian cycle in hypercube with faulty edges ($\mathbf{HC}Q_n - E$).

INSTANCE: A spanning subgraph G of Q_n for some n .

QUESTION: Is G hamiltonian?

For an instance of the problem $\mathbf{HC}Q_n - E$, we can assume that G has minimal degree at least two; otherwise it cannot contain a hamiltonian cycle. We will transform it to an instance of the problem $\mathbf{HC}Q_n - V$ in Q_{5n+2} . Each vertex $u \in V(G)$

FIG. 2. A scheme of routers.

will be replaced with a set $R(u)$ of vertices of Q_{5n+2} , called a router of u ; see Figure 2. It consists of a center $c(u)$, an in-gate $R^I(u)$, and an out-gate $R^O(u)$. The in-gate contains a set $I(u) \subset R^I(u)$ of special vertices called in-ports of u ; similarly, we define a set $O(u) \subset R^O(u)$ of out-ports of u . Our aim is to guarantee that for every edge $\{u, v\} \in E(G)$, routers $R(u)$ and $R(v)$ are joined with exactly two edges $\{u^I, v^O\}, \{u^O, v^I\}$ of Q_{5n+2} , where $u^I \in I(u)$, $u^O \in O(u)$, $v^I \in I(v)$, and $v^O \in O(v)$, while no other edge joins different routers.

There are two similar kinds of routers $R(u)$, depending on $\beta(u)$. A design of the out-gate $R^O(u)$ depends on the edges of G incident with u , while the design of the in-gate $R^I(u)$ is the same for all vertices u . The position of $R(u)$ in Q_{5n+2} is uniquely determined by its center $c(u)$, which will be specified later.

FIG. 3. Router details. The vertices in circles are ports.

Let $z_1 = e_{4n+1}^m$, $z_2 = e_{4n+2}^m$ and $x_i = e_i^m$, $y_i = e_{2n+i}^m$, where $i \in [2n]$ and $m = 5n+1$. For our convenience, put $x_0 = x_{2n}$, $y_0 = y_{2n}$ and $x_{2n+1} = x_1$, $y_{2n+1} = y_1$. First we describe $R(u)$ for $u \in V(G)$ with $\beta(u) = 1$. Recall that as G is a subgraph of Q_n , any edge $\{u, v\} \in E(G)$ satisfies $u \oplus v = e_i$ for some $i \in [n]$. Let $i_1 < \dots < i_k$ be all $i_j \in [n]$ with $\{u, u \oplus e_{i_j}\} \in E(G)$ for $j \in [k]$. Note that we have $k \geq 2$ since u

is incident with at least two edges. For our convenience, put $i_0 = i_k$ and $i_{k+1} = i_1$. Suppose we already have a center $c(u) \in V(Q_{5n+2})$, and define

$$\begin{aligned}
 (6) \quad & p = c(u) \oplus z_1, \\
 & I(u) = \{p \oplus x_{2l-1} \oplus x_{2l} \mid l \in [n]\}, \\
 & R^I(u) = \{p, p \oplus x_{2l-1}, p \oplus x_{2l}, p \oplus x_{2l} \oplus x_{2l+1} \mid l \in [n]\} \cup I(u), \\
 & o = c(u) \oplus z_2, \\
 & O(u) = \{o \oplus y_{2i_j-1} \oplus y_{2i_j} \mid j \in [k]\}, \\
 & R^O(u) = \{o, o \oplus y_{2i_j-1}, o \oplus y_{2i_j}, o \oplus y_{2i_j} \oplus y_{2i_{j+1}-1} \mid j \in [k]\} \cup O(u), \\
 & R(u) = R^O(u) \cup R^I(u) \cup \{c(u)\}.
 \end{aligned}$$

The router $R(u)$ for u with $\beta(u) = -1$ is constructed analogously; merely switch z_1 and z_2 . See Figure 3 for an illustration.

LEMMA 6.1. *For any spanning subgraph G of Q_n and $u \in V(G)$ the following properties hold:*

- (i) *For every $a \in I(u)$, $b \in O(u)$ there is a hamiltonian path of $\langle R(u) \rangle$ between a and b .*
- (ii) *Let $\mathcal{P} = \{P_{a_i b_i}\}_{i=1}^m$ be a path partition of $\langle R(u) \rangle$ such that $a_i, b_i \in I(u) \cup O(u)$ for all $i \in [m]$. Then $\mathcal{P} = \{P_{ab}\}$ for some $a \in I(u)$ and $b \in O(u)$.*

Proof. Let $l \in [n]$ and $j \in [k]$ be such that $a = p \oplus x_{2l-1} \oplus x_{2l}$ and $b = o \oplus y_{2i_j-1} \oplus y_{2i_j}$. Observe that

$$p \oplus x_1, p \oplus x_1 \oplus x_2, p \oplus x_2, p \oplus x_2 \oplus x_3, \dots, p \oplus x_{2n}, p \oplus x_{2n} \oplus x_1$$

is a hamiltonian cycle of $\langle R^I(u) \setminus \{p\} \rangle$. Similarly,

$$o \oplus y_{2i_1-1}, o \oplus y_{2i_1-1} \oplus y_{2i_1}, o \oplus y_{2i_1}, o \oplus y_{2i_1} \oplus y_{2i_2-1}, \dots, o \oplus y_{2i_k}, o \oplus y_{2i_k} \oplus y_{2i_1-1}$$

is a hamiltonian cycle of $\langle R^O(u) \setminus \{o\} \rangle$. Thus

$$\begin{aligned}
 & a, p \oplus x_{2l}, p \oplus x_{2l} \oplus x_{2l+1}, p \oplus x_{2l+1}, \dots, p \oplus x_{2l-2} \oplus x_{2l-1}, p \oplus x_{2l-1}, p, c(u), \\
 & o, o \oplus y_{2i_j-1}, o \oplus y_{2i_j-1} \oplus y_{2i_j}, \dots, o \oplus y_{2i_{j+1}-1}, o \oplus y_{2i_j} \oplus y_{2i_{j+1}-1}, o \oplus y_{2i_j}, b
 \end{aligned}$$

is a hamiltonian path of $\langle R(u) \rangle$ between a and b and part (i) holds.

If the assumption of part (ii) is satisfied, by Proposition 3.1 we have $\beta(R(u)) = \beta(\{a_i, b_i\}_{i=1}^m)$. Observe that $\beta(v)$ is the same for all $v \in I(u) \cup O(u)$, and therefore $\beta(\{a_i, b_i\}_{i=1}^m) \in \{m, -m\}$. Moreover, Proposition 3.1 applied to part (i) of this lemma reveals that $\beta(R(u)) \in \{1, -1\}$. It follows that $m = 1$. Moreover, (6) implies that $c(u)$ is a cutvertex of $\langle R(u) \rangle$ such that $I(u)$ and $O(u)$ belong to different components of $\langle R(u) - \{c(u)\} \rangle$. As $P_{a_1 b_1}$ must pass through $c(u)$, it cannot have both endvertices in $I(u)$ or both in $O(u)$. $\square$

At this point we are ready to describe the center of a router by defining the mapping $c : V(Q_n) \rightarrow V(Q_{5n+2})$ such that

$$(7) \quad c(u_1 u_2 \dots u_n) = u_1 u_1 u_2 u_2 \dots u_n u_n u_1 u_1 u_2 u_2 \dots u_n u_n 0 u_1 u_2 \dots u_n.$$

Note that this together with (6) uniquely determines the router $R(u)$ for any vertex $u \in V(G)$.

LEMMA 6.2. *For a spanning subgraph G of Q_n and two distinct vertices $u, v \in V(G)$, the set of all edges of Q_{5n+2} joining a vertex of $R(u)$ with a vertex of $R(v)$*

- (i) contains exactly two edges $\{u^I, v^O\}, \{u^O, v^I\}$ such that $u^I \in I(u)$, $u^O \in O(u)$, $v^I \in I(v)$, and $v^O \in O(v)$ if $\{u, v\} \in E(G)$, and
- (ii) is empty if $\{u, v\} \notin E(G)$.

Proof. Put $m = 5n + 2$ and let $a \in R(u)$, $b \in R(v)$ be arbitrary vertices. First note that as $d_{Q_m}(c(u), c(v)) = 5d_{Q_n}(u, v)$ by (7), the triangle inequality implies

$$(8) \quad d_{Q_m}(a, b) \geq 5d(u, v) - d_{Q_m}(c(u), a) - d_{Q_m}(c(v), b).$$

Moreover, $d_{Q_m}(a, c(u)), d_{Q_m}(b, c(v)) \leq 3$ by (6). Hence if $\{u, v\} \notin E(Q_n)$, then (8) implies $d_{Q_m}(a, b) \geq 4$, and therefore $R(u)$ and $R(v)$ are not joined by any edge in this case.

If $\{u, v\} \in E(Q_n)$, then $u \oplus v = e_i$ for some $i \in [n]$. We can assume without loss of generality that $\beta(u) = 1 = -\beta(v)$. Assume that $\{a, b\} \in E(Q_m)$. Since $\pi(a \oplus c(u)) \subseteq [4n + 2]$, $\pi(b \oplus c(v)) \subseteq [4n + 2]$, and $4n + 2 + i \in \pi(c(u), c(v))$ by (6) and (7), it follows that $a \oplus b = e_{4n+2+i}^m$. Moreover,

$$c(u) \oplus c(v) = x_{2i-1} \oplus x_{2i} \oplus y_{2i-1} \oplus y_{2i} \oplus e_{4n+2+i}^m$$

by (7), so

$$a \oplus b = c(u) \oplus c(v) \oplus x_{2i-1} \oplus x_{2i} \oplus y_{2i-1} \oplus y_{2i}.$$

From (6) observe that for every $r, s \in \{2l, 2l - 1 \mid l \in [n]\}$, the set $\pi(a \oplus c(u))$ cannot contain both x_r and y_s . Moreover, if $x_r \in \pi(a \oplus c(u))$ or $y_s \in \pi(a \oplus c(u))$, then $z_j \in \pi(a \oplus c(u))$ for some $j \in \{1, 2\}$. The same also holds for the set $\pi(b \oplus c(v))$. Hence we obtain that

$$a = c(u) \oplus z_j \oplus a', \quad b = c(v) \oplus z_j \oplus b',$$

where $j \in \{1, 2\}$ and

$$\{a', b'\} = \{x_{2i-1} \oplus x_{2i}, y_{2i-1} \oplus y_{2i}\}.$$

Therefore, we have either

$$a = c(u) \oplus z_1 \oplus x_{2i-1} \oplus x_{2i}, \quad b = c(v) \oplus z_1 \oplus y_{2i-1} \oplus y_{2i},$$

which means that $a \in I(u)$, $b \in O(v)$, or

$$a = c(u) \oplus z_2 \oplus y_{2i-1} \oplus y_{2i}, \quad b = c(v) \oplus z_2 \oplus x_{2i-1} \oplus x_{2i},$$

which means that $a \in O(u)$, $b \in I(v)$. It remains only to observe that if $\{u, v\} \in E(Q_n) \setminus E(G)$, then by (6) we have $b \notin R(v)$ in the former case or $a \notin R(u)$ in the latter case, which contradicts the assumption that $\{a, b\} \in E(Q_m)$. $\square$

THEOREM 6.3. **HCQ_n - V** and **HPPQ_n - V** are NP-complete problems.

Proof. Both problems are clearly in NP. To prove that they are also NP-hard, we describe polynomial-time transformations from **HCQ_n - E** to both **HCQ_n - V** and **HPPQ_n - V**.

Let G be a spanning subgraph of Q_n of minimum degree at least two, representing an instance of **HCQ_n - E**. We construct a set $S \subseteq V(Q_{5n+2})$ of size at most $(8n+3)2^n$ and a pair a, b of distinct vertices of S such that S is an instance of **HCQ_n - V**, while S, a, b is an instance of **HPPQ_n - V** satisfying

$$(9) \quad G \text{ is hamiltonian} \begin{cases} \text{(a) iff } \langle S \rangle \text{ is hamiltonian,} \\ \text{(b) iff } \langle S \rangle \text{ contains a hamiltonian path between } a \text{ and } b. \end{cases}$$

To that end, put $S = \bigcup_{u \in V(G)} R(u)$, where $R(u)$ is the router of u described by (6) and (7). Then choose an arbitrary $u \in V(Q_n)$ and put $a = c(u)$, $b = c(u) \oplus z_1$, where $c(u)$ and z_1 are defined by (7) and (6), respectively. This completes the construction. We leave it to the reader to verify that it really describes an algorithm whose time complexity is polynomial in the input size of G , which is $\Theta(n2^n)$.

To verify part (a) of (9), first suppose that there exists a hamiltonian cycle $u_1, u_2, \dots, u_{2^n}$ of G . Put $u_{2^n+1} = u_1$ and observe that Lemma 6.2 guarantees the existence of a pair of adjacent vertices $u_i^O \in O(u_i)$, $u_{i+1}^I \in I(u_{i+1})$ for all $i \in [2^n]$. Using part (i) of Lemma 6.1 we can connect u_i^I and u_i^O with a hamiltonian path P_i of $\langle R(u_i) \rangle$. Then the path $P_1 + P_2 + \dots + P_{2^n}$ with the edge $\{u_{2^n}^O, u_1^I\}$ appended forms a hamiltonian cycle of $\langle S \rangle$.

On the other hand, suppose there is a hamiltonian cycle H of $\langle S \rangle$. Then for any $u \in V(G)$, the subgraph of H induced by $R(u)$ forms a path partition $\mathcal{P}_u = \{P_{a_i b_i}\}_{i=1}^m$ of $\langle R(u) \rangle$. Moreover, Lemma 6.2 implies that $a_i, b_i \in I(u) \cup O(u)$ for all $i \in [m]$, while part (ii) of Lemma 6.1 says that then $\mathcal{P}_u = \{P_{a_u b_u}\}$ for some $a_u \in I(u)$ and $b_u \in O(u)$. It remains to apply Lemma 6.2 again to see that $\{b_u, a_v\} \in E(H)$ implies $\{u, v\} \in E(G)$, and therefore the cycle C with vertices $V(C) = V(G)$ and edges $E(C) = \{\{u, v\} \mid \{b_u, a_v\} \in E(H)\}$ forms a hamiltonian cycle of G .

Finally, to verify part (b) of (9), note that by (6), $c(u) \oplus z_1$ is one of the two neighbors of $c(u)$ in $\langle R(u) \rangle$. Moreover, Lemma 6.2 guarantees that there are no other edges incident with $c(u)$ in $\langle S \rangle$. Hence any hamiltonian cycle of $\langle S \rangle$ must pass through the edge $\{c(u), c(u) \oplus z_1\}$. It follows that $\langle S \rangle$ is hamiltonian iff $\langle S \rangle$ contains a hamiltonian path between a and b , and therefore the validity of part (a) implies that part (b) holds as well. $\square$

Since each instance of $\mathbf{HPPQ}_n - \mathbf{V}$ is also an instance of $\mathbf{PPQ}_n - \mathbf{V}$, we immediately obtain the following.

COROLLARY 6.4. $\mathbf{PPQ}_n - \mathbf{V}$ is an NP-complete problem.

The variant without prescribed vertices is also NP-complete.

COROLLARY 6.5. $\mathbf{HPQ}_n - \mathbf{V}$ is an NP-complete problem.

Proof. Transform $\mathbf{HPPQ}_n - \mathbf{V}$ to $\mathbf{HPQ}_n - \mathbf{V}$ using the observation that if G is an induced subgraph of Q_n and a, b distinct vertices of G , then graph G' obtained from G by adding new vertices a' and b' and edges $\{a, a'\}$, $\{b, b'\}$ is an induced subgraph of Q_{n+2} such that G contains a hamiltonian path between a and b iff G' contains a hamiltonian path. $\square$

The following problem is studied in [17, 18] for the purpose of data compression.

Traveling salesman in faulty hypercube ($\mathbf{TSQ}_n - \mathbf{V}$).

INSTANCE: A sequence $v_1, v_2, \dots, v_m$ of distinct vertices of Q_n for some n and a positive integer k .

QUESTION: Is there a permutation $p : [m] \rightarrow [m]$ such that

$$\sum_{i=1}^{m-1} d(v_{p(i)}, v_{p(i+1)}) \leq k?$$

Since each instance of $\mathbf{HPQ}_n - \mathbf{V}$ also forms an instance of $\mathbf{TSQ}_n - \mathbf{V}$ with $k = m - 1$, we obtain the following corollary.

COROLLARY 6.6. $\mathbf{TSQ}_n - \mathbf{V}$ is an NP-complete problem.

7. Concluding remarks. The results of section 5 provide bounds on the number of faulty vertices or on the size of a pair set, which guarantees that the four problems considered in this paper are polynomial. However, the values we obtained

are probably not optimal. In particular, let $f(n)$ denote the maximum integer such that the statement of Corollary 5.5 holds for every $\mathcal{F} \subseteq V(Q_n)$ with $|\mathcal{F}| \leq f(n)$. We showed that $f(n) \geq (n-5)/3$. On the other hand, consider a set $\mathcal{F}$ containing $n-1$ neighbors of some vertex u of Q_n and another $n-1$ vertices different from u but of the same balance as u . Then $\mathcal{F}$ is a balanced set of $2n-2$ vertices of Q_n , but $Q_n - \mathcal{F}$ is not hamiltonian since the vertex u has only one nonfaulty neighbor. It follows that $f(n) < 2n-2$. It is natural to ask, What is the exact value of $f(n)$?

In section 6 we showed that the existence of a hamiltonian cycle in an induced subgraph of Q_n is an NP-complete problem. We can proceed one step further and address the complexity of the same problem for distance-preserving subgraphs of a hypercube, also known as partial cubes. Note that the induced subgraph of Q_{5n+2} , constructed in the proof of Theorem 6.3 to form an instance of $\mathbf{HC}Q_n - \mathbf{V}$, is not a partial cube, so our method does not resolve this problem. It should be also noted that recognizing partial cubes is known to be polynomial [5].

Acknowledgments. We are very grateful to the anonymous referees for their insightful comments that essentially improved the exposition of the paper. We are also obliged to Václav Koubek for fruitful discussions on this topic.

TOTAL-COLORING OF PLANE GRAPHS WITH MAXIMUM DEGREE NINE*

ŁUKASZ KOWALIK[†], JEAN-SÉBASTIEN SERENI[‡], AND RISTE ŠKREKOVSKI[§]

Abstract. The central problem of the total-colorings is the total-coloring conjecture, which asserts that every graph of maximum degree Δ admits a $(\Delta + 2)$ -total-coloring. Similar to edge-colorings—with Vizing’s edge-coloring conjecture—this bound can be decreased by 1 for plane graphs of higher maximum degree. More precisely, it is known that if $\Delta \geq 10$, then every plane graph of maximum degree Δ is $(\Delta + 1)$ -totally-colorable. On the other hand, such a statement does not hold if $\Delta \leq 3$. We prove that every plane graph of maximum degree 9 can be 10-totally-colored.

Key words. total-coloring, planar graph, discharging method

AMS subject classification. 05C15

DOI. 10.1137/070688389

1. Introduction. Given a graph $G = (V, E)$ and a positive integer k , a k -total-coloring of G is a mapping $\lambda : V \cup E \rightarrow \{1, 2, \dots, k\}$ such that

- (i) $\lambda(u) \neq \lambda(v)$ for every pair u, v of adjacent vertices,
- (ii) $\lambda(v) \neq \lambda(e)$ for every vertex v and every edge e incident to v ,
- (iii) $\lambda(e) \neq \lambda(e')$ for every pair e, e' of incident edges.

This notion was independently introduced by Behzad [3] in his doctoral thesis and Vizing [15]. It is now a prominent notion in graph coloring, to which a whole book is devoted [17]. Both Behzad and Vizing made the celebrated *total-coloring conjecture*, stating that every graph of maximum degree Δ admits a $(\Delta + 2)$ -total-coloring. Notice that every such graph cannot be totally-colored with less than $\Delta + 1$ colors, and that a cycle of length 5 cannot be 3-totally-colored. The best general bound so far has been obtained by Molloy and Reed [10], who established that every graph of maximum degree Δ can be $(\Delta + 10^{26})$ -totally-colored. Moreover, the conjecture has been shown to be true for several special cases, namely for $\Delta = 3$ by Rosenfeld [11] and Vijayaditya [14], and then for $\Delta \in \{4, 5\}$ by Kostochka [9].

Another natural subclass to consider is the one of planar graphs, which has attracted a considerable amount of attention and for which several results were obtained. First, Borodin [5] proved that if $\Delta \geq 9$, then every plane graph of maximum degree Δ fulfills the conjecture. This result can be extended to the case where $\Delta = 8$ by the use of the four color theorem [1, 2], combined with Vizing’s theorem about edge coloring—the reader can consult the book by Jensen and Toft [8] for more details.

Elsewhere, Sanders and Zhao [12] solved the case $\Delta = 7$ of the total-coloring conjecture for plane graphs. So the only open case regarding plane graphs is $\Delta = 6$. Interestingly, $\Delta = 6$ is also the only remaining open case for Vizing's edge-coloring conjecture, after Sanders and Zhao [13] resolved the case $\Delta = 7$.

However, plane graphs with high maximum degree allow a stronger assertion. More precisely, Borodin [5] showed that if $\Delta \geq 14$, then every plane graph with maximum degree Δ is $(\Delta + 1)$ -totally-colorable, and asked whether 14 could be decreased. Borodin, Kostochka, and Woodall extended this result to the case where $\Delta \geq 12$ [6], and later to $\Delta = 11$ [7]. Recently, Wang [16] established the result for $\Delta = 10$. On the other hand, this bound is not true if $\Delta \leq 3$. The complete graphs K_2 , K_4 and the cycles of length $3k + 2$ with $k \geq 1$ are examples of plane graphs that cannot be $(\Delta + 1)$ -totally-colored. We continue along those lines and establish the following theorem.

THEOREM 1. *Every plane graph of maximum degree 9 is 10-totally-colorable.*

So, the values of Δ , for which it is not known whether all plane graphs of maximum degree Δ are $(\Delta + 1)$ -totally-colorable, are now 4, 5, 6, 7, and 8. Recall that the case where $\Delta = 6$ is even open for the total-coloring conjecture. We also note that if $\Delta \geq 3$, then every outerplane graph with maximum degree Δ can be $(\Delta + 1)$ -totally-colored [19]. Another result of the same type is that every Halin graph of maximum degree 4 admits a 5-total-coloring [18]. Note also that the complete r -partite balanced graph K_{r*n} , whose maximum degree Δ is $n(r - 1)$, admits a $(\Delta + 2)$ -total-coloring, and the cases where this bound can be decreased by 1 have been characterized [4].

We prove Theorem 1 by contradiction. From now on, we let $G = (V, E)$ be a minimum counterexample to the statement of Theorem 1, in the sense that the quantity $|V| + |E|$ is minimum. In particular, every proper subgraph of G is 10-totally-colorable. First, we establish various structural properties of G in section 2. Then, relying on these properties, we use the discharging method in section 3 to obtain a contradiction.

In what follows, a vertex of degree d is called a d -vertex. A vertex is a $(\leq d)$ -vertex if its degree is at most d ; it is a $(\geq d)$ -vertex if its degree is at least d . If f is a face of G , then the *degree of f* is its length, i.e., the number of its incident vertices. The notions of d -face, $(\leq d)$ -face, and $(\geq d)$ -face are defined analogously as for the vertices. Moreover, if a vertex v is adjacent to a d -vertex u , then we say that u is a d -neighbor of v . A cycle of length 3 is called a *triangle*. For integers a, b, c , an $(\leq a, \leq b, \leq c)$ -triangle is a triangle xyz of G with $\deg(x) \leq a$, $\deg(y) \leq b$, and $\deg(z) \leq c$. The notions of $(a, \leq b, \leq c)$ -triangles, $(a, b, \geq c)$ -triangles, and so on are defined analogously.

2. Reducible configurations. In this section, we establish some structural properties of the graph G . We prove that some planar graphs are *reducible configurations*; i.e., they cannot be subgraphs of G .

For convenience, we sometimes define configurations by depicting them in figures. In all of the figures of this paper, 2-vertices are represented by small black bullets, 3-vertices by black triangles, 4-vertices by black squares, and white bullets represent vertices whose degree is at least the one shown on the figure.

Let λ be a (partial) 10-total-coloring of G . For each element $x \in V \cup E$, we define $\mathcal{C}(x)$ to be the set of colors (with respect to λ) of vertices and edges incident or adjacent to x . Also, we set $\mathcal{F}(x) := \{1, 2, \dots, 10\} \setminus \mathcal{C}(x)$. If $x \in V$, then we define $\mathcal{E}(x)$ to be the set of colors of the edges incident to x . Moreover, λ is *nice* if only some (≤ 4) -vertices are not colored. Observe that every nice coloring can be greedily extended to a 10-total-coloring of G , since $|\mathcal{C}(v)| \leq 8$ for each (≤ 4) -vertex v ; i.e., v

has at most 8 forbidden colors. Therefore, in the rest of this paper, we shall always suppose that such vertices are colored at the very end. More precisely, every time we consider a partial coloring of G , we uncolor all (≤ 4)-vertices, and implicitly color them at the very end of the coloring procedure of G . We make the following observation about nice colorings and use it implicitly throughout this paper.

Observation. Let uv be an edge with $\deg(v) \leq 4$. There exists a nice coloring λ of $G - e$, in which u is colored and v is uncolored. Moreover, it then suffices to properly color the edge e with a color from $\{1, 2, \dots, 10\}$ to extend λ to a nice coloring of G .

We now study the structural properties of G in a series of lemmas.

LEMMA 2. *The graph G has the following properties:*

- (i) *the minimum degree is at least 2;*
- (ii) *if vu is an edge with $\deg(v) \leq 4$, then $\deg(u) \geq 11 - \deg(v)$;*
- (iii) *a 9-vertex is adjacent to at most one 2-vertex;*
- (iv) *a triangle incident to a 3-vertex must also contain a 9-vertex;*
- (v) *there is no $(4, \leq 7, \leq 8)$ -triangle;*
- (vi) *a triangle contains at most one (≤ 5) -vertex.*

Proof. (i) Suppose that v is a 1-vertex, and let u be its neighbor. By the minimality of G , the graph $G - v$ admits a nice coloring in which u is colored. Since the degree of u in $G - v$ is at most 8, we obtain $|\mathcal{C}(vu)| \leq 9$. Thus, the edge vu can be properly colored, which yields a nice coloring of G .

(ii) Suppose that $vu \in E$ with $\deg(v) \leq 4$ and $\deg(u) \leq 10 - \deg(v)$. There exists a nice coloring of $G' := G - vu$, in which u is colored and v is uncolored. Therefore, $|\mathcal{C}(vu)| \leq \deg(v) - 1 + \deg(u) - 1 + 1 \leq 9$. Hence we can color properly the edge vu , thereby obtaining a nice coloring of G .

(iii) Suppose that v is a 9-vertex adjacent to two 2-vertices x and y . Let x' be the neighbor of x different from v , and let y' be the neighbor of y different from v . Notice that we may have $x' = y'$. By the previous assertion, x' and y' are 9-vertices. It is enough to consider the following two possibilities.

v is adjacent to neither x' nor y' . Then, we construct the graph G' by first removing x and y , and then adding the edge vx' . If $y' \neq x'$, then we additionally add the edge vy' . Note that G' is a simple plane graph of maximum degree 9 with fewer vertices and edges than G . Therefore, it admits a nice coloring λ by the minimality of G . We easily modify λ to obtain a nice coloring of G . First, put $\lambda(xx') := \lambda(vy) := \lambda'(vx')$. Now, if $x' \neq y'$, then we put $\lambda(vx) := \lambda(yy') := \lambda'(vy')$. See Figure 1(a) for an illustration. And, if $x' = y'$, then we note that each of the edges yy' and vx has at most 9 forbidden colors. Thus, both of them can be colored and the obtained 10-total-coloring of G is nice.

v is adjacent to x' . Thus $vx x'$ is a triangle. Consider a nice coloring of $G - vy$. To extend it to G , it suffices to properly color the edge vy . If this cannot be done greedily, then $|\mathcal{C}(vy)| = 10$, and up to a permutation of the colors, we can assume that the coloring is the one shown in Figure 1(b). If $a \neq 10$, then recolor vx with 10 and color vy with 5 to obtain a nice coloring of G . And if $a = 10$, then we interchange the colors of vx' and xx' , and afterwards color vy with 4.

(iv) By (ii), a 3-vertex has only (≥ 8)-neighbors. Thus we may suppose that $v w u$ is a $(3, 8, 8)$ -triangle, with u being the 3-vertex. Consider a nice coloring of $G - vu$. To extend it to G , again it suffices to properly color the edge vu . If we cannot do this

FIG. 1. Configurations for the proof of Lemma 2.

greedily, then it means that $|\mathcal{C}(vu)| = 10$. Thus, up to a permutation of the colors, the coloring is the one shown in Figure 1(c). If the edge wu can be properly recolored, then we do so, and afterwards color the edge vu with 10, which gives a nice coloring of G . So we deduce that $|\mathcal{C}(wu)| = 9$. Consequently, $\{a, b, c, d, e, f, g\} = \{1, 2, 3, 4, 5, 6, 8\}$. Thus we obtain $9 \notin \mathcal{C}(vw)$. So, we can recolor vw with 9 and color vu with 7 to conclude the proof.

(v) By (ii), it is enough to prove that there is no $(4, 7, \delta)$ -triangle in G for $\delta \in \{7, 8\}$. Suppose that vwu is such a triangle with w having degree δ and u degree 4. Consider a nice coloring of $G - vu$. It is sufficient to properly color the edge vu to obtain a nice coloring of G . Again, $|\mathcal{C}(vu)| = 10$, so up to a permutation of the colors, we assume that the coloring is the one of Figure 1(d). If the edge wu can be properly recolored, then do so, and color vu with 8 to obtain a nice coloring of G . Thus, we deduce that $|\mathcal{C}(wu)| = 9$. Therefore, $\{1, 2, 3, 4, 5, 7\} \subset \{a, b, c, d, e, f, g\}$. From this we infer that $|\mathcal{C}(vw)| \leq 6 + \delta - 6 = \delta \leq 8$. Thus, the edge vw can be properly recolored, and so the edge vu can be colored with 6, yielding a nice coloring of G .

(vi) Let vu be a triangle with $\deg(u) = \deg(w) = 5$. Consider a total-coloring of $G - uw$, and uncolor the vertex w . Observe that $|\mathcal{F}(uw)| \geq 1$ and $|\mathcal{F}(w)| \geq 1$. Furthermore, these two sets must actually be equal and of size 1; otherwise we can extend the coloring to G . Up to a permutation of the colors, the coloring is the one shown in Figure 1(e), with $\{A, B, C, D\} = \{1, 2, 3, 4\}$. Notice that the colors of the

FIG. 2. Reducible configurations of Lemma 3(vi) and (vii).

edges vu and wu can be safely interchanged. Now, the vertex w can be properly colored with 6, and the edge uw with 10. $\square$

LEMMA 3. For the graph G , the following assertions hold.

- (i) There is no $(5, 6, 6)$ -triangle.
- (ii) A 6-vertex has at most two 5-neighbors.
- (iii) Suppose that v is a 7-vertex, and let x_1 be one of its neighbors. If v and x_1 have at least two common neighbors, then at most one of them has degree 4.
- (iv) Suppose that vwu and vwu' are two triangles with $\deg(u) = 2$. Then, $\deg(u') \geq 4$.
- (v) Suppose that v is a 9-vertex incident to a $(2, 9, 9)$ -triangle. Then it is not incident to a $(\leq 3, \geq 8, 9)$ -triangle.
- (vi) The configuration of Figure 2(a) is reducible.
- (vii) The configuration of Figure 2(b) is reducible.

Proof. (i) Suppose on the contrary that G contains a $(5, 6, 6)$ -triangle uvw with u being of degree 5. The proof is in two steps. In the first step, we prove the existence of a 10-total-coloring of G in which only u is uncolored. And in the second step, we establish that such a coloring can be extended to G . Consider a nice coloring of $G - vu$, and uncolor the vertex u . Our only goal in the first step is to properly color the edge vu . If we cannot do this greedily, then $|\mathcal{C}(vu)| = 10$, and thus we can assume that the coloring is the one of Figure 3(a). We infer that $\{6, 7, 8, 9, 10\} = \{a, b, c, d, e\}$; otherwise we can choose a color $\alpha \in \{6, 7, 8, 9, 10\} \setminus \{a, b, c, d, e\}$, recolor uw with α , and color vu with 4. Consequently, we have $\mathcal{C}(vw) = \{4, 6, 7, 8, 9, 10\}$. Thus, we can recolor vw with 1, and color vu with 5.

For the second step, consider a partial 10-total-coloring of G such that only u is not colored. If we cannot greedily extend it to G , then without loss of generality the coloring is the one of Figure 3(b). Note that if $|\mathcal{C}(vu)| \leq 8$, then we can recolor vu , and color u with 5. Thus, we infer that $\{a, b, c, d, e\} \supset \{7, 8, 9, 10\}$. Similarly, $\{e, f, g, h, i\} \supset \{6, 8, 9, 10\}$. Observe that $|\mathcal{C}(v)| = 9$; otherwise we just properly recolor v , and color u with 6.

We assert that we can assume that $e \in \{1, 2, 3\}$. If it is not the case, then $e \in \{8, 9, 10\}$, say $e = 10$. By what precedes, $|\mathcal{C}(vw)| \leq 12 - 4 = 8$ and $\{4, 5, 6, 7, 8, 9\} \subset \mathcal{C}(vw)$. Thus at least one color among 1, 2, 3 can be used to recolor vw , which proves the assertion. Therefore, $\{a, b, c, d\} = \{7, 8, 9, 10\}$ and $\{f, g, h, i\} = \{6, 8, 9, 10\}$. Thus vw can be recolored by every color of $\{1, 2, 3\}$. So, if there exists a color $\alpha \in \{1, 2, 3\} \setminus$

FIG. 3. Configurations for the proofs of Lemmas 3 and 4.

$\{A, B, C, D\}$, we can recolor vw with a color of $\{1, 2, 3\}$ different from α , recolor v with α , and color u with 6. Hence $\{1, 2, 3\} \subseteq \{A, B, C, D\}$. Now, recall that $|\mathcal{C}(v)| = 9$, thus $4 \in \{A, B, C, D\}$. Consequently, we can interchange safely the colors of vu and wu , recolor v with 5, and finally color u with 6.

(ii) Suppose that v is a 6-vertex with three 5-neighbors x_1, x_2, x_3 . By Lemma 2(vi), these three vertices are pairwise nonadjacent. Let λ be a nice coloring of $G - vx_1$, and uncolor the edges vx_2 and vx_3 as well as the vertices v, x_1, x_2 , and x_3 . Notice that $|\mathcal{C}(x_i)| \leq 8$ and $|\mathcal{C}(vx_i)| \leq 7$ for each $i \in \{1, 2, 3\}$. Moreover, $|\mathcal{C}(v)| \leq 6$. Recall that $\mathcal{F}(x) := \{1, 2, \dots, 10\} \setminus \mathcal{C}(x)$ for every $x \in V \cup E$. Observe that for each $i \in \{1, 2, 3\}$, we have $\mathcal{F}(v) \cap \mathcal{F}(x_i) \subseteq \mathcal{F}(vx_i)$. Hence, we infer that $\mathcal{F}(v) \cap (\mathcal{F}(vx_i) \cup \mathcal{F}(x_i)) = \mathcal{F}(v) \cap \mathcal{F}(vx_i)$. Consequently, there exists a color $\alpha \in \mathcal{F}(v)$ such that, after setting $\lambda(v) := \alpha$, it holds that $|\mathcal{F}(x_3)| \geq 2$ and $|\mathcal{F}(vx_3)| \geq 3$. If we color properly x_1, vx_1, x_2 , and vx_2 , then we will be able to color greedily x_3 and vx_3 , and hence the proof would be complete. Observe that if α does not belong to $\mathcal{F}(x_1)$ or to $\mathcal{F}(vx_2)$, then the coloring can be extended greedily to x_1, x_2, vx_1, vx_2 —just color x_1 or vx_2 last, respectively. Therefore we assume that α belongs to these two lists. Uncolor v and color x_1 and vx_2 with α . With respect to this coloring, note that $|\mathcal{F}(vx_1)| \geq 2$, $|\mathcal{F}(v)| \geq 3$, $|\mathcal{F}(x_2)| \geq 1$, $|\mathcal{F}(vx_3)| \geq 3$, and $|\mathcal{F}(x_3)| \geq 2$. Hence, we can color x_2 . Now, if there exists $\beta \in \mathcal{F}(vx_1) \cap \mathcal{F}(x_3)$, then we let $\lambda(vx_1) := \lambda(x_3) := \beta$, and afterwards greedily color v and vx_3 .

So, $\mathcal{F}(vx_1) \cap \mathcal{F}(x_3) = \emptyset$. If there exists $\kappa \in \mathcal{F}(v) \cap \mathcal{F}(x_3)$, then we set $\lambda(v) := \kappa$, and afterwards we greedily color x_3, vx_3 , and vx_1 in this order. This is possible since $\kappa \notin \mathcal{F}(vx_1)$. Otherwise, greedily coloring vx_1, v, vx_3 , and x_3 in this order yields a nice coloring of G .

(iii) Suppose that the statement is false, so the graph G contains the configuration of Figure 3(c). Consider a nice coloring λ of $G - vx_7$. If it cannot be extended to G , then $|\mathcal{C}(vx_7)| = 10$. Furthermore, $|\mathcal{C}(vx_2)| = 9$; otherwise we can color the edge vx_7 with $\lambda(vx_2)$ and greedily recolor the edge vx_2 , thereby obtaining a nice coloring of G . Therefore, we can assume that the coloring is the one shown in Figure 3(c). Then a nice coloring of G is obtained by interchanging the colors of the edges x_7x_1 and vx_1 , recoloring vx_2 with 1, and coloring vx_7 with 2, as shown in Figure 3(d).

(iv) Suppose on the contrary that G contains the configuration of Figure 3(e). Consider a nice coloring of $G - vx_9$. If the edge vx_9 cannot be greedily colored, then $|\mathcal{C}(vx_9)| = 10$. Thus we may assume that the coloring is the one shown in Figure 3(e). Notice that $a = 10$; otherwise we recolor vx_2 with 10 and color vx_9 with 2. So, the recoloring in Figure 3(f) is nice.

(v) Suppose that G contains the configuration of Figure 3(g), and consider a nice coloring λ of $G - vx_9$. Without loss of generality, we may assume that it is the one of Figure 3(g). Observe that $10 \in \{a, b\}$; otherwise we obtain a nice coloring of G by setting $\lambda(vx_6) := 10$ and $\lambda(vx_9) := 6$. Now, we consider two cases regarding b .

$b = 10$. If $a \neq 7$, then we can interchange the colors of the edges x_6x_7 and vx_7 , and color vx_9 with 7 to obtain a nice coloring of G . And if $a = 7$, then we interchange the colors of the edges x_9x_8 and vx_8 , and then we let $\lambda(vx_6) := 8$ and $\lambda(vx_9) := 6$.

$b \neq 10$. In this case, $a = 10$. We interchange the colors of x_9x_8 and vx_8 . Similar to before, we deduce that $b = 8$. Now, the previous case applies with 8 playing the role of color 10.

(vi) Suppose on the contrary that G contains the configuration of Figure 2(a). Up to a permutation of the colors, every nice coloring of $G - vx_9$ is as the one of Figure

2(a). Note that $d = 10$; otherwise recolor vx_8 with 10 and color vx_9 with 8. Similarly, $a = 10$. Now, interchange the colors of the edges x_1x_2 and vx_2 . If $b \neq 2$, then the obtained coloring extends to G by coloring vx_9 with 2. If $b = 2$, then interchange the colors of the edges x_9w and x_1w , thereby obtaining a nice coloring of $G - vx_9$. Since $d = 10 \neq 2$, observe that we can extend it to G as before; i.e., we recolor vx_8 with 2 and color vx_9 with 8.

(vii) Suppose that G contains the configuration of Figure 2(b). Consider a nice coloring of $G - vx_9$. Without loss of generality, we may assume that it is the one of Figure 2(b). Note that $10 \in \{a, b\}$; otherwise recolor vx_5 with 10 and color vx_9 with 5. By symmetry, we can assume that $a = 10$. Interchange the colors of the edges x_5x_4 and vx_4 . If $b \neq 4$, then we have a nice coloring of $G - vx_9$, and we extend it to G by coloring vx_9 with 4. Otherwise, $b = 4$, we interchange the colors of the edges x_5x_6 and vx_6 , and color vx_9 with 6, which yields a nice coloring of G . $\square$

LEMMA 4. *The configuration of Figure 3(h) is reducible.*

Proof. Consider a nice coloring of $G - vx_9$. If it cannot be greedily extended to G , then $|\mathcal{C}(vx_9)| = 10$, and so we can assume that the coloring is the one of Figure 3(h). First, we note that if $a \neq 7$, then $10 \in \{b, c\}$; otherwise, we recolor vx_7 by 10, and color vx_9 with 7. Similarly, if $a \neq 2$, then $10 \in \{d, e\}$. We now split the proof into three cases.

$a \notin \{6, 8\}$. Since a is different from either 2 or 7, we may assume that $a \neq 7$. As mentioned above, we must have $10 \in \{b, c\}$. Moreover, if we interchange the colors of the edges x_9x_8 and vx_8 , then we deduce as before that $8 \in \{b, c\}$, the color 8 playing the role of color 10. Hence $\{b, c\} = \{8, 10\}$. Now, interchange the colors of the edges x_7x_6 and vx_6 , and color vx_9 with 6. If $b = 10$, then the obtained coloring is proper, and if $b = 8$, then we additionally interchange the colors of the edges x_9x_8 and vx_8 to obtain the desired coloring.

$a = 8$. In this case $10 \in \{b, c\}$. By interchanging the colors of the edges x_9x_8 and vx_8 , and also of x_9x_1 and vx_1 , we infer that $1 \in \{b, c\}$. Hence $\{b, c\} = \{1, 10\}$. Similar to the previous case, interchange the colors of x_7x_6 and vx_6 , and afterwards color vx_9 with 6. If $b = 10$, then the obtained coloring of G is proper, and if $b = 1$, then it suffices to additionally interchange the colors of the edges x_9x_1 and vx_1 , and also of x_9x_8 and vx_8 , to obtain a nice coloring of G .

$a = 6$. Then, $10 \in \{d, e\}$. Note that the colors of the edges x_9x_8 and vx_8 can be interchanged safely, because $a \neq 8$. Therefore, as $a \neq 2$, we infer that $8 \in \{d, e\}$, and hence $\{d, e\} = \{8, 10\}$. We interchange now the colors of the edges x_2x_3 and vx_3 , and color vx_9 with 3. If $e = 10$, then the obtained coloring of G is proper. And, if $e = 8$, then it suffices to interchange the colors of the edges x_9x_8 and vx_8 to obtain the desired coloring. $\square$

LEMMA 5. *If uvw is a triangle with an 8-vertex v and a 3-vertex u , then v has no 3-neighbor distinct from u .*

Proof. Suppose that v is an 8-vertex that contradicts the lemma. Let u and w be two 3-neighbors of v , and assume that vuz is a triangle. We consider a nice coloring of $G - vu$. If we cannot extend it to G , then, without loss of generality, we may assume that the coloring is the one shown on Figure 4(a). Observe that $\{a, b\} = \{9, 10\}$; otherwise we obtain the desired coloring by recoloring vw with either 9 or 10, and coloring vu with 2. Now, as depicted in Figure 4(b), we interchange the colors of the edges uz and vz , recolor vw with 1, and color vu with 2 to obtain the sought coloring. $\square$

FIG. 4. Coloring and recoloring for the proof of Lemma 5.

FIG. 5. Configurations for Lemma 6.

LEMMA 6. *The configuration of Figure 5(a) is reducible.*

Proof. Consider a nice coloring of $G - vx_2$. Up to a permutation of the colors, it is the one of Figure 5(a). Note that $10 \in \{a, b\}$; otherwise we obtain a nice coloring of G by coloring vx_2 with 10. We split the proof into two cases, regarding the value of b .

Case 1. $b = 10$. If $a = 4$, then apply the recolorings of Figures 5(b) and (c),

FIG. 6. Configurations for Lemmas 7 and 8.

regarding whether d is 3.

Suppose now that $a \neq 4$. In this case, we deduce that $d = 10$; otherwise, we can recolor vx_4 with 10, and color vx_2 with 4. If $c \neq 5$, then the desired coloring can be obtained as follows. If $a \neq 5$, then interchange the colors of the edges x_4x_5 and vx_5 , and color vx_2 with 5, and if $a = 5$, then the recoloring of Figure 5(d) is nice.

We may assume now that $c = 5$. Interchange the colors of the edges x_4x_5 and vx_5 , and also of the edges x_4x_3 and vx_3 . If $a \neq 3$, then it suffices to color vx_2 with 3. And, if $a = 3$, then additionally interchange the colors of the edges x_2x_1 and vx_1 , recolor vx_4 with 1, and color vx_2 with 4 to obtain the sought coloring.

Case 2. $b \neq 10$. Therefore, $a = 10$. First, note that $10 \in \{c, d\}$; otherwise, we recolor vx_4 with 10, and color vx_2 with 4. Either the obtained coloring of G is nice, or $b = 4$. In the latter case, we additionally interchange the colors of x_2x_3 and x_4x_3 to obtain the desired coloring.

Suppose now that $c = 10$. Then, $b = 4$; otherwise, we uncolor vx_4 , color vx_2 with 4, and apply Case 1 to the obtained coloring with x_4 playing the role of the vertex x_2 . Now, interchange the colors of x_4x_3 and vx_3 . The obtained coloring is nice if $d \neq 3$, and we extend it to G by coloring vx_2 with 3. And, if $d = 3$, then we additionally interchange the colors of x_4x_5 and vx_5 , and color vx_2 with 5.

Finally, assume that $c \neq 10$, and hence $d = 10$. Up to interchanging the colors of x_2x_3 and x_4x_3 , we may assume that $b \neq 5$. Interchange the colors of x_4x_5 and vx_5 . If $c \neq 5$, the obtained coloring is nice, and we extend it to G by coloring vx_2 with 5. And, if $c = 5$, then we additionally interchange the colors of x_4x_3 and vx_3 , and color vx_2 with 3. $\square$

LEMMA 7. *The configuration of Figure 6(a) is reducible.*

Our proof of Lemma 7 uses the following result. Given a coloring λ and a vertex v , recall that $\mathcal{E}(v)$ is the set of colors assigned to the edges incident to v . Let $\mathcal{E}'(v) := \{1, 2, \dots, 10\} \setminus (\mathcal{E}(v) \cup \{\lambda(v)\})$.

LEMMA 8. *Suppose that G contains the configuration of Figure 6(b). Then, for every nice coloring λ of $G - vx_2$, it holds that $\mathcal{E}'(v) \cup \{\lambda(vx_6)\} \subseteq \mathcal{E}(x_2)$.*

Proof. Up to a permutation of the colors, the coloring λ is the one of Figure 6(b). Notice that $\mathcal{E}'(v) = \{10\}$, $\lambda(vx_6) = 6$, and $\mathcal{E}(x_2) = \{a, b\}$. First, $10 \in \{a, b\}$; otherwise, we just color vx_2 with 10. By symmetry, we may assume that $a = 10$. Thus, to finish the proof, it remains only to prove that $b = 6$. Suppose on the

contrary that $b \neq 6$. Note that $10 \in \{c, d\}$; otherwise, we recolor vx_6 with 10 and color vx_2 with 6. By symmetry, we may assume that $d = 10$. We consider two possibilities regarding the value of b .

$b = 1$. Interchange the colors of the edges x_6x_7 and vx_7 . The obtained coloring of G is nice if $c \neq 7$, and if $c = 7$ we additionally interchange the colors of x_6x_5 and vx_5 . Now, coloring vx_2 with 7 or 5 yields a nice coloring of G , a contradiction.

$b \neq 1$. In this case, $c = 1$. Indeed, if $c \neq 1$, then we recolor vx_6 with 1, interchange the colors of x_2x_1 and vx_1 , and color vx_2 with 6 to obtain a nice coloring of G . Now, if $b \neq 7$, then interchange the colors of x_6x_7 and vx_7 and color vx_2 with 7. And, if $b = 7$, then interchange the colors of x_6x_5 and vx_5 , and also of x_2x_1 and vx_1 , and color vx_2 with 5. $\square$

Proof of Lemma 7. Consider a nice coloring λ of $G - vx_2$. Up to a permutation of the colors, we assume that the coloring is the one of Figure 6(a). By Lemma 8, we have $\{a, b\} = \{6, 10\}$. We consider two cases.

$a = 10$ and $b = 6$. If there exists a color $\alpha \in \{1, 10\} \setminus \{e, f, g\}$, then recolor vx_4 with α , and color vx_2 with 4. The obtained coloring is nice if $\alpha = 10$. And, if $\alpha = 1$, then it suffices to additionally interchange the colors of x_2x_1 and vx_1 . Thus, $\{1, 10\} \subset \{e, f, g\}$.

Suppose that $6 \notin \{e, f, g\}$. We start by interchanging the colors of the edges x_2x_3 and x_4x_3 . If $e = 10$, then we additionally interchange the colors of x_2x_1 and vx_1 . Observe that the obtained coloring does not fulfill the conclusion of Lemma 8, a contradiction. Hence, $\{e, f, g\} = \{1, 6, 10\}$ and so $e \in \{1, 10\}$. We interchange the colors of x_4x_3 and vx_3 , and color vx_2 with 3. Either this coloring of G is nice, or $e = 1$ and hence additionally interchanging the colors of x_2x_1 and vx_1 yields a nice coloring of G .

$a = 6$ and $b = 10$. If there exists $\alpha \in \{3, 10\} \setminus \{f, g\}$, then recolor vx_4 with α , and color vx_2 with 4. If the obtained coloring is not nice, then $\alpha = 3$ and hence interchanging the colors of x_2x_3 and vx_3 yields a nice coloring of G , a contradiction. Observe that we may assume that $f = 3$ and $g = 10$. Indeed, if it is not the case, then we interchange the colors of x_2x_3 and vx_3 and obtain the desired condition, with 3 playing the role of color 10.

Furthermore, $e = 5$; otherwise, we interchange the colors of x_4x_5 and vx_5 , and color vx_2 with 5. Now, observe that $d = 10$; otherwise, we recolor vx_6 with 10, vx_4 with 6, and color vx_2 with 4 to obtain a nice coloring of G . Finally, we interchange the colors of x_6x_7 and vx_7 . If $c = 7$, then we additionally interchange the colors of x_6x_5 and vx_5 . Now, coloring vx_2 with 7 or 5 yields a nice coloring of G , a contradiction. $\square$

LEMMA 9. *The configurations of Figure 7 are reducible.*

Proof. Consider a nice coloring of $G - vu$. We may assume that the coloring is the one of Figure 7. Let $\alpha \in \{1, 7, 9, 10\} \setminus \{a, b, c\}$. We recolor vx_3 with α and color vu with 3. The obtained coloring of G is nice unless $\alpha \in \{1, 7\}$. If $\alpha = 1$, then we additionally interchange the colors of uw and vw . And if $\alpha = 7$, then we interchange the colors of ut and vt . $\square$

LEMMA 10. *A 6-vertex incident to 6 triangles is not adjacent to two 5-vertices.*

Proof. Suppose that v is a 6-vertex. We let $x_1, x_2, \dots, x_6$ be its neighbors, such that x_i is adjacent to x_{i+1} if $i \in \{1, 2, \dots, 5\}$ and x_6 is adjacent to x_1 . We also assume that x_6 is a 5-vertex, and we let w be the other 5-vertex. By symmetry and Lemma 2(vi), we may assume that $w \in \{x_2, x_3\}$. The proof is in two steps. In the

FIG. 7. Reducible configurations of Lemma 9. We assume that the degree of v in G is 8.

first step, we show that there exists a partial 10-total-coloring of G in which only x_6 is uncolored. In the second step, we show how to extend it to a 10-total-coloring of G .

Given a total-coloring and an element $x \in V \cup E$, recall that $\mathcal{C}(x)$ is the set of colors of all the elements of $V \cup E$ incident or adjacent to x . Recall also that if $x \in V$, then $\mathcal{E}(x)$ is the set of colors of all the edges incident to x .

Let λ be a total-coloring of $G - vx_6$, in which, furthermore, we uncolor the vertex x_6 . Our goal is to properly color the edge vx_6 . Note that $|\mathcal{C}(vx_6)| = 10$; otherwise, the edge vx_6 can be greedily colored. Without loss of generality, we may assume that the coloring is the one shown in Figure 8(a).

We want to color vx_6 with $\lambda(vw)$. Recall that w is either x_2 or x_3 . We set $\mathcal{E} := \mathcal{E}(w) \cup \{\lambda(w)\}$. If there exists a color $\alpha \in \{7, 8, 9, 10\} \setminus \mathcal{E}$, then we set $\lambda(vx_6) := \lambda(vw)$ and $\lambda(vw) := \alpha$. Furthermore, if $1 \notin \mathcal{E}$, then we interchange the colors of x_6x_1 and vx_1 , color vx_6 with $\lambda(vw)$, and recolor vw with 1. Thus, $1 \in \mathcal{E}$. Similarly, we deduce that $5 \in \mathcal{E}$. Finally, note that either 2 or 3 belongs to $\mathcal{E}$, according to whether w is x_2 or x_3 . Consequently, this shows that $|\mathcal{E}| \geq 7$. But w has degree 5, thus $|\mathcal{E}| = 6$, a contradiction. This concludes the first step.

Suppose now that we are given a partial 10-total-coloring of G in which only x_6 is not colored. If we cannot extend it to G , then, without loss of generality, we may assume that the coloring is the one shown in Figure 8(b). If there exists a color $\alpha \in \{2, 4, 6, 10\} \setminus \{a, b, c, d, e\}$, then recolor vx_6 with α and color x_6 with 7 to obtain a 10-total-coloring of G . Hence, $\{2, 4, 6, 10\} \subset \{a, b, c, d, e\}$. Suppose that $a \notin \{2, 4, 6\}$. In this case, $\{b, c, d, e\} = \{2, 4, 6, 10\}$, and thus $e \in \{2, 4, 10\}$. Interchange the colors of the edges x_6x_5 and vx_5 . Now, if $a \neq 5$, then the obtained coloring is proper, and we extend it to G by coloring x_6 with 5. And, if $a = 5$, then we additionally interchange the colors of x_6x_1 and vx_1 , and color v with 9. Consequently, we obtain $a \in \{2, 4, 6\}$.

If $9 \notin \{b, c, d, e\}$, then we can apply a similar recoloring. More precisely, we can interchange the colors of the edges x_6x_1 and vx_1 . The obtained coloring is proper and can be extended to G by coloring x_6 with 9. So $9 \in \{b, c, d, e\}$, and hence $5 \notin \mathcal{E}(v)$. We interchange the colors of x_6x_5 and vx_5 , and color x_6 with 5. Either the obtained 10-total-coloring of G is proper, or $e = 9$. In the latter case, we additionally interchange the colors of x_6x_1 and vx_1 to obtain the sought contradiction. $\square$

LEMMA 11. *The configuration of Figure 9(a) is reducible.*

Proof. Consider a nice coloring of $G - vx_9$. Without loss of generality, it is the one

FIG. 8. Proof of Lemma 10: (a) coloring of $G - vx_6$, (b) partial coloring of G in which x_6 is not colored.

FIG. 9. Precoloring and recoloring for the proof of Lemma 11.

of Figure 9(a). First, note that $a = 10$; otherwise, we can recolor the edge vx_8 with 10, and color vx_9 with 8. Next, we infer that $b = 7$; otherwise, we can interchange the colors of x_8x_7 and vx_7 , and color vx_9 with 7. Now, observe that $10 \in \{c, d\}$; otherwise, we recolor vx_2 with 10, and color vx_9 with 2. Furthermore, $7 \in \{c, d\}$; otherwise, we interchange the colors of x_8w and x_9w , and also of x_8x_7 and vx_7 , recolor vx_2 with 7, and color vx_9 with 10. Thus, $\{c, d\} = \{7, 10\}$. If $d = 7$ and $c = 10$, then we just interchange the colors of the edges x_2x_1 and vx_1 , and color vx_9 with 1. And, if $d = 10$ and $c = 7$, then the recoloring shown in Figure 9(b) is a nice coloring of G . $\square$

3. Discharging part. Recall that $G = (V, E)$ is a minimum counterexample to the statement of Theorem 1, in the sense that $|V| + |E|$ is minimum. We obtain a contradiction by using the discharging method. Here is an overview of the proof. We fix a planar embedding of G . Each vertex and face of G is assigned an initial charge. The total sum of the charges is negative by Euler's formula. Then, some redistribution rules are applied, and vertices and faces send or receive some charge

according to these rules. The total sum of the charges is not changed during this step, but at the end we infer that the charge of each vertex and face is nonnegative, a contradiction.

Initial charge. We assign a charge to each vertex and face. For every $x \in V \cup F$, we define the initial charge $\text{ch}(x)$ to be $\deg(x) - 4$, where $\deg(x)$ is the degree of x in G . By Euler's formula the total sum is

$$\sum_{v \in V} \text{ch}(v) + \sum_{f \in F} \text{ch}(f) = -8.$$

Rules. We need the following definitions to state the discharging rules. A 2-vertex is *bad* if it is not incident to a (≥ 5) -face. A triangle is *bad* if it contains a vertex of degree at most 4. Recall that a triangle with vertices x, y , and z is a $(\deg(x), \deg(y), \deg(z))$ -triangle.

Rule R0. A (≥ 5) -face sends 1 to each incident 2-vertex.

Rule R1. A 5-vertex v sends $1/5$ to each incident triangle.

Rule R2. A 6-vertex sends $13/35$ to each incident $(5, 6, \geq 7)$ -triangle, $1/3$ to each incident $(6, 6, 6)$ -triangle, and $2/7$ to each incident $(6, \geq 6, \geq 7)$ -triangle.

Rule R3. A 7-vertex sends $1/2$ to each incident bad triangle, $3/7$ to each incident nonbad $(\leq 7, \leq 7, 7)$ -triangle, and $1/3$ to each incident nonbad triangle containing a (≥ 8) -vertex.

Rule R4. A 8-vertex sends

- (i) $1/3$ to each adjacent 3-vertex,
- (ii) $1/2$ to each incident bad triangle,
- (iii) $7/15$ to each incident $(5, \leq 7, 8)$ -triangle and each incident $(6, 6, 8)$ -triangle,
- (iv) $2/5$ to each incident $(5, \geq 8, 8)$ -triangle, each incident $(6, 7, 8)$ -triangle, and each incident $(6, 8, 8)$ -triangle,
- (v) $1/3$ to each incident $(6, 8, 9)$ -triangle and each incident $(\geq 7, \geq 7, 8)$ -triangle.

Rule R5. A 9-vertex sends

- (i) 1 to each adjacent bad 2-vertex and $1/2$ to each adjacent nonbad 2-vertex,
- (ii) $1/3$ to each adjacent 3-vertex,
- (iii) $1/2$ to each incident bad triangle and each incident $(5, \leq 7, 9)$ -triangle,
- (iv) $3/7$ to each incident $(6, 6, 9)$ -triangle,
- (v) $2/5$ to each incident $(5, \geq 8, 9)$ -triangle and each incident $(6, \geq 7, 9)$ -triangle,
- (vi) $1/3$ to each incident $(\geq 7, \geq 7, 9)$ -triangle.

In what follows, we prove that the final charge $\text{ch}^*(x)$ of every $x \in V \cup F$ is nonnegative. Hence, we obtain

$$-8 = \sum_{v \in V} \text{ch}(v) + \sum_{f \in F} \text{ch}(f) = \sum_{v \in V} \text{ch}^*(v) + \sum_{f \in F} \text{ch}^*(f) \geq 0,$$

a contradiction. This contradiction establishes the theorem.

Final charge of faces. Let f be a d -face. Our goal is to show that $\text{ch}^*(f) \geq 0$. By Lemma 2(ii) and (iii), f is incident to at most $\lfloor \frac{d}{3} \rfloor$ vertices of degree 2. Therefore, if $d \geq 5$, then by Rule R0 we obtain $\text{ch}^*(f) \geq d - 4 - \lfloor \frac{d}{3} \rfloor = \lceil \frac{2d}{3} \rceil - 4 \geq 0$. A 4-face neither sends nor receives any charge, so its charge stays 0.

Finally, let $f = xyz$ be a triangle with $\deg(x) \leq \deg(y) \leq \deg(z)$. The initial charge of f is -1 , and we assert that its final charge $\text{ch}^*(f)$ is at least 0. We consider several cases and subcases according to the degrees of x, y , and z .

$\deg(x) = 2$. Then both y and z have degree 9 by Lemma 2(ii), and hence f receives $1/2$ from each of y and z by Rule R5(iii).

- $\deg(x) = 3$. In this case, by Lemma 2(ii) and (iv), we infer that $\deg(y) \geq 8$ and $\deg(z) = 9$. Thus, f receives $\frac{1}{2} + \frac{1}{2} = 1$ by Rules R4(ii) and R5(iii).
- $\deg(x) = 4$. Then, by Lemma 2(ii) and (v), $\deg(y) \geq 7$ and $\deg(z) \geq 8$. Hence, by Rules R3, R4(ii), and R5(iii), f receives $\frac{1}{2} + \frac{1}{2} = 1$ from y and z .
- $\deg(x) = 5$. According to Lemma 2(vi), $\deg(y) \geq 6$, and by Lemma 3(i), $\deg(z) \geq 7$. By Rule R1, f receives $1/5$ from x , so we need only to show that it receives at least $4/5$ from y and z together. Consider the following subcases.
- $\deg(z) = 7$. By Rule R3, z sends $3/7$ to f , and by Rules R2 and R3, y sends at least $13/35$. Thus, f receives at least $\frac{13}{35} + \frac{3}{7} = \frac{4}{5}$ from y and z , as needed.
- $\deg(z) = 8$. If $\deg(y) \leq 7$, then z sends $7/15$ to f by Rule R4(iii), and y sends at least $1/3$ by Rules R2 and R3. And, if $\deg(y) = 8$, then both y and z send $2/5$ to f by Rule R4(iv). So, in both cases f receives $4/5$ from y and z together.
- $\deg(z) = 9$. Suppose first that $\deg(y) \leq 7$. Then, by Rule R5(iii), z sends $1/2$ to f . Moreover, by Rules R2 and R3, y sends at least $1/3$ to f , which proves the assertion. Now, if $\deg(y) \geq 8$, then according to Rules R4(iv) and R5(v) f receives $2/5$ from each of y and z , as needed.
- $\deg(x) = 6$. First, if $\deg(z) = 6$, then f receives $1/3$ from each of its vertices by Rule R2. So we assume that $\deg(z) \geq 7$. In this case, f receives $2/7$ from x by Rule R2. Hence, we need only to show that y and z send at least $5/7$ to f in total. We consider several cases, regarding the degree of z .
- $\deg(z) = 7$. Then f receives $3/7$ from z by Rule R3, and at least $2/7$ from y by Rules R2 and R3, as desired.
- $\deg(z) = 8$. If $\deg(y) = 6$, then z sends $7/15$ by Rule R4(iii) and y sends $2/7$ by Rule R2. And, if $\deg(y) \geq 7$, then y sends at least $1/3$ by Rules R3 and R4(iv), and z sends at least $2/5$ by Rule R4(iv).
- $\deg(z) = 9$. If $\deg(y) = 6$, then f receives $2/7$ from y by Rule R2 and $3/7$ from z by Rule R5(iv). And, if $\deg(y) \geq 7$, then f receives at least $1/3$ from y by Rules R3, R4(v), and R5(v), and at least $2/5$ from z by Rule R5(v), which yields the result.
- $\deg(x) \geq 7$. The assertion follows from Rules R3, R4(v), and R5(vi).

Final charge of vertices. Let v be an arbitrary vertex of G . We have $\deg(v) \geq 2$ by Lemma 2(i). For every positive integer d , we define v_d to be the number of d -neighbors of v , and f_d to be the number of d -faces incident to v . Let $x_1, x_2, \dots, x_{\deg(v)}$ be the neighbors of v in clockwise order. We prove that the final charge of v is nonnegative. To do so, we consider several cases, regarding the degree of v .

If $\deg(v) = 2$, then its two neighbors are 9-vertices by Lemma 2(ii). If v is bad, then it receives 1 from each of its two 9-neighbors by Rule R5(i), while otherwise it receives at least 1 from its incident faces by Rule R0, and $1/2$ from each of its two 9-neighbors by Rule R5(i). Thus, in both cases its final charge is at least 0.

If $\deg(v) = 3$, then all of its neighbors have degree at least 8, so by Rules R4(i) and R5(ii) it receives $1/3$ from each of its neighbors, setting its final charge to 0. If $\deg(v) = 4$, then it neither sends nor receives anything, so its charge stays 0. If v is a 5-vertex, then by Rule R1 it sends $1/5$ to each of its at most five incident triangles; therefore, its final charge is nonnegative.

Suppose now that v is a 6-vertex. All of its neighbors have degree at least 5 by Lemma 2(ii). Note that if $f_3 \leq 5$, then, according to Rule R2, $\text{ch}^*(v) \geq 2 - 5 \cdot \frac{13}{35} > 0$. So, we assume now that $f_3 = 6$; i.e., v is incident to 6 triangles. Thus, we infer

from Lemma 10 that $v_5 \leq 1$. If $v_5 = 0$, then following Rule R2, the vertex v sends at most $6 \cdot \frac{1}{3} = 2$; therefore, its final charge is at least 0. And, if $v_5 = 1$, then let x_1 be the unique 5-neighbor of v . By Lemma 3(i), it holds that $\deg(x_2) \geq 7$ and $\deg(x_6) \geq 7$. Consequently, vx_3x_2 and vx_5x_6 are two $(6, \geq 6, \geq 7)$ -triangles. Thus, $\text{ch}^*(v) \geq 2 - 2 \cdot \frac{13}{35} - 2 \cdot \frac{1}{3} - 2 \cdot \frac{2}{7} = \frac{2}{105} > 0$ by Rule R2.

Suppose that v is a 7-vertex. If $f_3 \leq 6$, then $\text{ch}^*(v) \geq 3 - 6 \cdot \frac{1}{2} = 0$ by Rule R3. So, we assume now that $f_3 = 7$. We consider several cases, according to the number of 4-neighbors of v . Note that, by Lemmas 2(ii) and 3(iii), the vertex v has at most two such neighbors; i.e., $v_4 \leq 2$.

$v_4 = 0$. According to Rule R3, we have $\text{ch}^*(v) \geq 3 - 7 \cdot \frac{3}{7} = 0$.

$v_4 = 1$. Let x_1 be this 4-neighbor. So, x_2 and x_7 both are 9-vertices by Lemma 2(v).

According to Rule R3, the vertex v sends $1/3$ to each of vx_2x_3 and vx_5x_6 .

Furthermore, v is incident to exactly two bad triangles and sends at most $3/7$ to each nonbad triangle. Therefore, we obtain $\text{ch}^*(v) \geq 3 - 2 \cdot \frac{1}{2} - 3 \cdot \frac{3}{7} - 2 \cdot \frac{1}{3} = \frac{1}{21} > 0$.

$v_4 = 2$. Without loss of generality, we assume that x_1 has degree 4. According to Lemmas 2(ii) and 3(iii), the other 4-neighbor of v must be x_4 or x_5 , say x_4 by symmetry. By Lemma 2(v), the vertices x_2, x_7, x_3 , and x_5 all have degree 9.

Note that x_6 has degree at least 5. Consequently, $\text{ch}^*(v) = 3 - 4 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} = 0$.

Suppose now that v is an 8-vertex. If $v_3 = 0$, then $\text{ch}^*(v) \geq 4 - 8 \cdot \frac{1}{2} = 0$ by Rule R4. Thus, we assume now that x_1 is a 3-vertex. Notice that, by Lemma 5, if a 3-neighbor of v is on a triangle, then $v_3 = 1$. Therefore, $v_3 + f_3 \leq 9$. If $f_3 \leq 6$, then we obtain $\text{ch}^*(v) \geq 4 - 6 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} = 0$. If $f_3 = 7$, then we infer from Lemma 5 that $v_3 \leq 1$, and so $\text{ch}^*(v) \geq 4 - 7 \cdot \frac{1}{2} - \frac{1}{3} = \frac{1}{6} > 0$. Now we suppose that $f_3 = 8$, and thus $v_3 = 1$. According to Lemma 2(iv), it holds that $\deg(x_2) = 9$ and $\deg(x_9) = 9$. Moreover, by Lemma 9, all the vertices but x_1 have degree at least 5. Thus, by Rule R4, we infer that $\text{ch}^*(v) \geq 4 - \frac{1}{3} - 2 \cdot \frac{1}{2} - 4 \cdot \frac{7}{15} - 2 \cdot \frac{2}{5} = 0$.

Finally, suppose that v is a 9-vertex. By Lemma 2(iii), v is adjacent to at most one 2-vertex. We consider two cases.

Case 1. $v_2 = 0$. Suppose first that v is incident to a (≥ 4) -face; i.e., $f_3 \leq 8$. If $f_3 = 8$, then $v_3 \leq 3$ by Lemmas 4 and 6, and hence $\text{ch}^*(v) \geq 5 - 8 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} = 0$. If $f_3 \leq 7$, then we assert that $f_3 + v_3 \leq 12$. Indeed, if $v_3 \geq 6$, then, as two 3-vertices are not adjacent, we infer that $f_3 \leq 2(9 - v_3)$, which yields the assertion. So if $f_3 \leq 6$, then we obtain $\text{ch}^*(v) \geq 5 - 6 \cdot \frac{1}{2} - 6 \cdot \frac{1}{3} = 0$. If $f_3 = 7$, then we can see that $v_3 \leq 4$ by Lemmas 4 and 6. Consequently, $\text{ch}^*(v) \geq 5 - 7 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} = \frac{1}{6} > 0$. Now assume that $f_3 = 9$. Then, $v_3 \leq 2$ according to Lemma 4. If $v_3 \leq 1$, then $\text{ch}^*(v) \geq 5 - 9 \cdot \frac{1}{2} - \frac{1}{3} = \frac{1}{6} > 0$. Assume now that $v_3 = 2$. Without loss of generality, say that x_1 is a 3-vertex; thus both x_2 and x_9 are (≥ 8) -vertices. Note that by Lemma 6, both x_3 and x_8 are (≥ 4) -vertices. Therefore, up to symmetry, it suffices to consider the following two cases.

x_4 is the second 3-neighbor. Then $\deg(x_3) \geq 8$, so by Rule R5(vi) the vertex v sends $\frac{1}{3}$ to vx_2x_3 . Hence, we infer that $\text{ch}^*(v) \geq 5 - 2 \cdot \frac{1}{3} - 8 \cdot \frac{1}{2} - \frac{1}{3} = 0$.

x_5 is the second 3-neighbor. In this case, $\deg(x_4) \geq 8$ and $\deg(x_6) \geq 8$. Furthermore, $\deg(x_3) \geq 5$ by Lemma 7. Consequently, x_3x_2v and x_3x_4v are both $(\geq 5, \geq 8, 9)$ -triangles. Hence, v sends at most $\frac{2}{5}$ to each of them by Rule R5(v). So, $\text{ch}^*(v) \geq 5 - 2 \cdot \frac{1}{3} - 7 \cdot \frac{1}{2} - 2 \cdot \frac{2}{5} = \frac{1}{30} > 0$.

Case 2. $v_2 = 1$. Let x_1 be the 2-neighbor. Observe that by Lemma 3(vii), v cannot have a 3-neighbor on two triangles. Moreover, x_1 cannot be incident to two triangles, so $f_3 \leq 8$. We consider the following possibilities.

x_1 is on a triangle. Let this triangle be vx_1x_2 . From Lemma 3(iv) and (v), we infer that $f_3 + v_3 \leq 8$. So, $\text{ch}^*(v) \geq 5 - 1 - 8 \cdot \frac{1}{2} = 0$.

x_1 is bad but not on a triangle. In this case, x_1 is on two 4-faces; therefore, in particular, $f_3 \leq 7$. Note that by Lemma 3(vi), either one vertex among x_2, x_9 has degree at least 4, or $f_3 \leq 5$. Besides, according to Lemma 3(vii) there is no 3-neighbor on two triangles. Observe also that if both vx_2x_3 and vx_8x_9 are triangles, then Lemma 11 implies that $v_3 \leq 6$. Let us consider several cases regarding the value of f_3 .

$f_3 \leq 4$. Then $f_3 + v_3 \leq 10$; otherwise, we obtain a contradiction by Lemma 3(vi) and (vii). Thus, $\text{ch}^*(v) \geq 5 - 1 - 4 \cdot \frac{1}{2} - 6 \cdot \frac{1}{3} = 0$.

$f_3 = 5$. Using Lemma 3(vi) and (vii), a small case-analysis shows that $v_3 \leq 5$. Moreover, if $v_3 = 5$, then the obtained configuration is the one of Lemma 11, which is reducible. And, if $v_3 \leq 4$, then we obtain $\text{ch}^*(v) \geq 5 - 1 - 5 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} = \frac{1}{6} > 0$.

$f_3 = 6$. In this case, $v_3 \leq 3$ by Lemma 3(vi) and (vii). Thus, $\text{ch}^*(v) \geq 5 - 1 - 6 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} = 0$.

$f_3 = 7$. By Lemma 3(vi) and (vii), v has at most one 3-neighbor, namely x_2 or x_9 . Thus, $\text{ch}^*(v) \geq 5 - 1 - 7 \cdot \frac{1}{2} - \frac{1}{3} = \frac{1}{6} > 0$.

x_1 is neither bad nor on a triangle. Notice that $f_3 \leq 7$. Let us again consider several cases regarding the value of f_3 .

$f_3 \leq 5$. In this case, $f_3 + v_3 \leq 11$ by Lemma 3(vii). So, $\text{ch}^*(v) \geq 5 - \frac{1}{2} - 5 \cdot \frac{1}{2} - 6 \cdot \frac{1}{3} = 0$.

$f_3 = 6$. Similarly as before, we infer that $v_3 \leq 4$, and hence $\text{ch}^*(v) \geq 5 - \frac{1}{2} - 6 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} = \frac{1}{6} > 0$.

$f_3 = 7$. By Lemma 3(vii) the vertex v has at most two 3-neighbors, namely x_2 and x_9 . Thus, $\text{ch}^*(v) \geq 5 - \frac{1}{2} - 7 \cdot \frac{1}{2} - 2 \cdot \frac{1}{3} = \frac{1}{3} > 0$.

This establishes that the final charge of every vertex is nonnegative; therefore, the proof of Theorem 1 is now complete. $\square$

ODD MINIMUM CUT SETS AND b -MATCHINGS REVISITED*

ADAM N. LETCHFORD[†], GERHARD REINELT[‡], AND DIRK OLIVER THEIS[§]

Abstract. The famous Padberg–Rao separation algorithm for b -matching polyhedra can be implemented to run in $\mathcal{O}(|V|^2|E|\log(|V|^2/|E|))$ time in the uncapacitated case, and in $\mathcal{O}(|V||E|^2\log(|V|^2/|E|))$ time in the capacitated case. We give a new and simple algorithm for the capacitated case which can be implemented to run in $\mathcal{O}(|V|^2|E|\log(|V|^2/|E|))$ time.

1. Introduction. Let $G = (V, E)$ be an undirected graph, let $b \in \mathbb{Z}_+^V$ be a vector of vertex capacities, and let $u \in \mathbb{Z}_+^{|E|}$ be a vector of edge capacities. A u -capacitated b -matching is a family of edges, possibly containing multiple copies, such that

- for each $i \in V$, there are at most b_i edges in the family incident on i ;
- at most, u_e copies of edge e are used.

If we define for each edge e the integer variable x_e , representing the number of times e appears in the matching, then the incidence vectors of u -capacitated b -matchings are the solutions to

$$(1) \quad \sum_{e \in \delta(i)} x_e \leq b_i \quad \text{for all } i \in V,$$

$$(2) \quad 0 \leq x_e \leq u_e \quad \text{for all } e \in E,$$

$$(3) \quad x_e \in \mathbb{Z} \quad \text{for all } e \in E.$$

Here, as usual, $\delta(i)$ represents the set of edges incident on i .

The convex hull in $\mathbb{R}^{|E|}$ of solutions to (1)–(3) is called the u -capacitated b -matching polytope. Edmonds and Pulleyblank (see [Edm65] and [Pul73]) gave a complete linear description of this polytope. It is described by the *degree inequalities* (1), the *bounds* (2), and the following *blossom inequalities*:

$$(4) \quad \sum_{e \in E(W)} x_e + \sum_{f \in F} x_f \leq \left\lfloor \frac{b(W) + \sum_{f \in F} u_f}{2} \right\rfloor$$

for all $W \subset V, F \subset \delta(W)$ with $b(W) + \sum_{f \in F} u_f$ odd.

Here, $E(W)$ (respectively, $\delta(W)$) represents the set of edges with both endvertices (respectively, exactly one endvertex) in W , and $b(W)$ denotes $\sum_{i \in W} b_i$.

An important special case is where the upper bounds u_e are not present (or, equivalently, $u_{ij} \geq \max\{b_i, b_j\}$ for all $\{i, j\} \in E$). The associated *uncapacitated* b -matching polytope is described by the degree inequalities, the nonnegativity inequalities $x_e \geq 0$ for all $e \in E$, and the *simplified blossom inequalities*

$$(5) \quad \sum_{e \in E(W)} x_e \leq \left\lfloor \frac{b(W)}{2} \right\rfloor \quad \text{for all } W \subset V \text{ with } b(W) \text{ odd.}$$

In their seminal paper, Padberg and Rao [PR82] devised an efficient combinatorial *separation algorithm* for b -matching polytopes. A separation algorithm is (see [GLS88]) a procedure which, given a point $x^* \in \mathbb{Q}^{|E|}$ lying outside of the polytope, finds a linear inequality which is valid for the polytope yet violated by x^* . Clearly, testing if a degree inequality or bound is violated can be performed in linear time; therefore, the main contribution of [PR82] is to identify violated blossom inequalities.

For *uncapacitated* b -matching, the Padberg–Rao algorithm involves the solution of up to $|V| - 1$ max-flow problems on graphs with $\mathcal{O}(|V|)$ vertices and $\mathcal{O}(|E|)$ edges. Using the well-known *preflow push* algorithm [GT88] to solve the max-flow problems, this leads to an overall running time of $\mathcal{O}(|V|^2 |E| \log(|V|^2/|E|))$.

The Padberg–Rao separation algorithm for *capacitated* b -matching, however, is substantially more time consuming. It involves the solution of up to $|V| + |E| - 1$ max-flow problems on graphs with $\mathcal{O}(|E|)$ vertices and $\mathcal{O}(|E|)$ edges. Using the preflow push algorithm, this leads to a worst-case running time of $\mathcal{O}(|E|^3 \log|V|)$.

In 1987, Grötschel and Holland [GH87] observed that the max-flow computations needed in the capacitated case can in fact be carried out on graphs with only $\mathcal{O}(|V|)$ vertices and $\mathcal{O}(|E|)$ edges. Although the idea behind this is simple, it reduces the overall running time for the capacitated case to $\mathcal{O}(|V||E|^2 \log(|V|^2/|E|))$.

In this paper, we propose a new separation algorithm for the capacitated case, whose running time is the same as that for the uncapacitated case. As well as being faster than the previous approaches, the new algorithm is simpler and easier to implement. It also has a surprisingly simple proof of correctness. Like the previous algorithms, it can also be easily adapted to the case of *perfect* capacitated b -matchings, in which the inequalities (1) are changed to equations, and to certain other problems in the matching family.

The importance of blossom separation extends, of course, far beyond matching problems. This is because blossom-like inequalities can be defined for many important $\mathcal{NP}$ -hard combinatorial optimization problems involving constraints on vertex degrees and bounds on the variables. The most famous problem of this type is the *traveling salesman problem*, for which certain blossom inequalities are facet-inducing and make very useful cutting planes (see [GP79a], [GP79b], [PR90]). Other problems for which blossom-like inequalities can be defined and separated more quickly using the new algorithm include, for example, the *Capacitated Vehicle Routing Problem* [LLE04], the *Rural Postman Problem* [GL00], the *Capacitated Arc Routing Problem* [BB98], the *k-edge Connected Spanning Subgraph Problem* [Mah94], and the *Network Connectivity Problem* [GMS92].

Another very interesting application of blossom separation is described in [CF96]. In that paper, a family of cutting planes for general integer linear programs is defined, called $\{0, \frac{1}{2}\}$ -*Chvátal–Gomory cuts*, and it is shown that the associated separation problem can be solved in polynomial time if the constraint matrix satisfies certain

conditions. Under one of these conditions, the separation problem essentially reduces to blossom separation, and our algorithm can be used. (We omit details for the sake of brevity.)

Note: An extended abstract of this paper appeared in the proceedings of IPCO X [LRT04]. However, the proof of correctness of the algorithm has been simplified substantially.

2. Review of key concepts. To make the paper self-contained, and also for the sake of clarity, we review in this section some key concepts from the literature.

2.1. Cut-trees. The notion of a *cut-tree* was introduced by Gomory and Hu [GH61]. Let $G = (V, E)$ be an undirected graph, $w \in \mathbb{Q}_+^{|E|}$ a vector of edge weights, and $X \subset V$ a set of *terminal vertices*. A cut-tree is an edge-weighted tree, spanning X , that compactly represents the minimum cut in G between every pair of vertices in X . More formally, the cut-tree consists of a mapping $\pi: V \rightarrow X$ with $\pi(x) = x$ for all $x \in X$, and an adjacency relation $\sim$ on the set X . The adjacency relation shall make the set of terminal vertices into a tree, i.e., $x \sim y$ means that x and y are connected by an edge of the cut-tree. Deleting an edge $x \sim y$ of the cut-tree partitions the set X into two sets X_x and X_y , and thus defines a cut $(U, \bar{U})$ in G by letting $U := \pi^{-1}(X_x)$ and $\bar{U} := \pi^{-1}(X_y)$. We call this the cut *induced* by the edge $x \sim y$. Now, the following condition must hold:

- (6) for all pairs $x, y \in X$ with $x \sim y$, the cut induced by the edge $x \sim y$ is a minimum (x, y) -cut in G with respect to the weights w .

The Gomory–Hu algorithm for producing a cut-tree involves solving $|X| - 1$ max-flow/min-cut problems on a series of graphs obtained from G by suitable contractions. Using the preflow push algorithm as a subroutine, the Gomory–Hu algorithm runs in $\mathcal{O}(|X||V||E| \log(|V|^2/|E|))$ time.

2.2. Minimum odd cuts. We now move on to consider *minimum odd cuts*. As before, let $G = (V, E)$ be an undirected graph with edge weights $w \in \mathbb{Q}_+^{|E|}$. Let $T \subset V$, with $|T|$ even, be a set of vertices that are labelled *odd*. A cut $\delta(U)$ is called *T-odd*, or just *odd* for short, if $|T \cap U|$ is an odd number. The *minimum odd cut problem* asks for an odd cut $\delta(U)$ with minimum weight $w(\delta(U))$.

In [PR82], Padberg and Rao gave a surprisingly simple algorithm to compute minimum odd cuts. It involves simply invoking the Gomory–Hu algorithm with terminal set T and then checking each of the $|T| - 1$ cuts produced; see Algorithm 1. It is easy to show that the bottleneck of the algorithm is the Gomory–Hu call, and therefore the algorithm can be implemented to run in $\mathcal{O}(|T||V||E| \log(|V|^2/|E|))$ time.

2.3. The Padberg–Rao separation algorithms. Padberg and Rao then showed how to reduce the blossom separation problem to the minimum odd cut problem.

First, consider the uncapacitated case. We introduce, for each $i \in V$, the term $s_i := b_i - \sum_{e \in \delta(i)} x_e$, which can be viewed as the *slack* of the corresponding degree inequality (1). The simplified blossom inequality (5) can then easily be rewritten to take the following form:

$$(7) \quad \sum_{i \in W} s_i + \sum_{e \in \delta(W)} x_e \geq 1.$$

Now, let $x^* \in \mathbb{R}_+^{|E|}$ be a given vector satisfying the degree inequalities. Take the graph G and assign the weight x_e^* to each $e \in E$. Add a new *dummy* vertex v and, for each

Algorithm 1. Minimum odd cut [PR82]

Input:

Graph G , set $T \subset V$ of odd vertices, weight vector $w \in \mathbb{Q}_+^{|E|}$.

Output:

A minimum odd cut.

1: Let $r = \infty$.

2: Compute a cut-tree for the graph G with weights w and terminal vertex set T .

3: **For** each of the $|T| - 1$ edges of the cut-tree

4: Let $\delta(U)$ denote the cut induced by the cut-tree edge.

5: *Check the cut:*

 If $|T \cap U|$ is odd and $w(\delta(U)) < r$, then store U and set $r := w(\delta(U))$.

6: **End for**

7: Output the cut $\delta(U)$.

$i \in V$, an edge $\{i, v\}$ with weight $s_i^* := b_i - \sum_{e \in \delta(i)} x_e^*$. Denote the resulting graph by $G^+ = (V^+, E^+)$. Now, label the vertices $i \in V$ that have an odd value of $b(i)$ *odd*. Also label the dummy vertex v *odd* if $b(V)$ is odd.

Clearly, there is a violated blossom inequality in the form (7) if and only if there exists an odd cut in G^+ of weight less than 1. Thus, one can use the minimum odd cut algorithm described in the previous subsection. As a result, blossom separation can be performed in $\mathcal{O}(|V|^2|E| \log(|V|^2/|E|))$ time in the uncapacitated case. This is $\mathcal{O}(|V|^4)$ in the worst case.

The capacitated case is a little more complicated. First, the blossom inequality (4) needs to be rewritten in the following form:

$$(8) \quad \sum_{i \in W} s_i + \sum_{e \in \delta(W) \setminus F} x_e + \sum_{e \in F} (u_e - x_e) \geq 1.$$

Now, let x^* be a given vector satisfying the degree inequalities and bounds. Padberg and Rao begin by constructing the so-called split graph, which is obtained from the graph G^+ mentioned above by subdividing each edge $\{i, j\} \in E$ into two halves. (That is, each edge $\{i, j\} \in E$ is replaced with two edges, say $\{i, k\}$ and $\{j, k\}$.) One of the two halves (which we shall call the *normal* half) is given a weight of x_e^* , whereas the other half (which we shall call the *complemented* half) is given a weight of $u_e - x_e^*$.

Parities are then assigned to the edges and vertices of the split graph. The normal halves are labelled *even*, the complemented halves are labelled *even* or *odd* according to whether the corresponding upper bound u_e is even or odd, and the edge $\{i, v\}$ is labelled *even* or *odd* according to whether the upper bound b_i is even or odd. Finally, a vertex is labelled *even* or *odd* according to whether it is incident on an even or odd number of odd edges.

It can then be shown that there is a violated blossom inequality in the form (8) if and only if there exists an odd cut in the split graph of weight less than 1. Unfortunately, the split graph is substantially larger than G , with $|V| + |E| + 1$ vertices and $2|E| + |V|$ edges. Thus, the minimum odd cut computation now involves $\mathcal{O}(|E|)$ max-flow computations in graphs with $\mathcal{O}(|E|)$ vertices and edges. Using the preflow push algorithm, this leads to an overall running time $\mathcal{O}(|E|^3 \log |V|)$, or $\mathcal{O}(|V|^6 \log |V|)$ in the worst case.

2.4. The Grötschel–Holland modification. As mentioned in the introduction, a simple but significant improvement to the algorithm for the capacitated case

was made by Grötschel and Holland [GH87]. (In fact, they were only interested in 2-matchings, but the same argument applies in the general case.) Consider an arbitrary edge $e = \{i, j\} \in E$. It is obvious that the maximum amount of flow which can be directly sent from i to j in the split graph is equal to the minimum of x_e^* and $u_e - x_e^*$. Consequently, at each iteration of the Gomory–Hu algorithm, for each $e \in E$, one of the two halves can be contracted before computing a max-flow. As a result, the max-flow problems can be conducted on graphs which are of a similar size to G . This reduces the overall running time to $\mathcal{O}(|V||E|^2 \log(|V|^2/|E|))$, or $\mathcal{O}(|V|^5)$ in the worst case.

3. The new algorithm. We now present a new, faster algorithm for blossom separation in the capacitated case. In fact, our algorithm solves a slightly more general problem. Given a graph $G = (V, E)$ and a set $T \subset V$ of odd vertices, let us say that a *blossom* is a pair (U, F) consisting of a set of vertices $U \subset V$ and a set of edges $F \subset \delta(U)$ with the property that $|T \cap U| + |F|$ is an odd number. Now suppose that we are given, in addition, two nonnegative weight vectors $c, c' \in \mathbb{Q}_+^{|E|}$. We define the *blossom minimization problem* as the problem of finding a blossom whose *value*

$$\beta(U, F) := \sum_{e \in \delta(U) \setminus F} c_e + \sum_{f \in F} c'_f$$

is as small as possible. To cast the blossom separation problem in this form, it suffices to construct the graph G^+ used by Padberg and Rao for the uncapacitated case (see subsection 2.3), and set

$$(c_e, c'_e) := \begin{cases} (x_e^*, u_e - x_e^*) & \text{if } u_e \text{ is odd,} \\ (\min(x_e^*, u_e - x_e^*), \infty) & \text{if } u_e \text{ is even} \end{cases}$$

for all $e \in E$. For the edges $\{i, v\}$ of G^+ , we set $c_{iv} := s_i^*$ and $c'_{iv} := \infty$ (v is the dummy vertex in G^+). With this construction, it is an easy exercise to verify the following proposition.

PROPOSITION 3.1. *Let (U, F^+) be a blossom in G^+ with the weight vectors (c, c') just described. W.l.o.g. we may assume that the dummy vertex v is not in U . Let*

$$W := U \quad \text{and} \quad F := F^+ \cup \{e \in \delta(W) \mid u_e \text{ even and } u_e - x_e^* x_e^* < x_e^*\}.$$

Then W and F satisfy the conditions required in the definition of a blossom inequality, and therefore we have

$$(9) \quad \sum_{i \in W} s_i + \sum_{e \in \delta(W) \setminus F} x_e + \sum_{e \in F} (u_e - x_e) = \beta(U, F^+).$$

(The left-hand side of the equation is the left-hand side of inequality (8).) Conversely, every blossom inequality for which $F \subset \delta(W)$ is chosen such that the left-hand side in (8) is minimized defines a blossom (U, F^+) by letting $U := W$ and $F^+ := \{e \in F \mid u_e \text{ odd}\}$, for which (9) holds.

Our algorithm for the blossom minimization problem is displayed as Algorithm 2.

Remark 3.2. For fixed $U \subset V$, it has been observed by Padberg and Rinaldi [PR90] that

$$(10) \quad \beta(U) := \min \left\{ \beta(U, F) \mid F \subset \delta(U), |T \cap U| + |F| \text{ odd} \right\}$$

Algorithm 2. Blossom minimization**Input:**

Graph G , set $T \subset V$ of odd vertices, weight vectors $c, c' \in \mathbb{Q}_+^{|E|}$.

Output:

A minimum blossom.

- 1: Let $r = \infty$.
- 2: Compute a cut-tree for G with weights $\min(c, c')$ and terminal vertex set V .
- 3: **For** each of the $|V| - 1$ edges of the cut-tree
- 4: Let $\delta(U)$ denote the cut induced by the cut-tree edge.
- 5: *Check the cut:*
 Compute $\beta(U)$ as in (10).
- 6: If $\beta(U) < r$, then store U along with the arg-min F and set $r := \beta(U)$.
- 7: **End for**
- 8: Output the best blossom (U, F) .

can be computed in time $\mathcal{O}(|\delta(U)|)$ by first tentatively taking $F := \{e \in \delta(U) \mid c'_e < c_e\}$. Now if $|T \cap U| + |F|$ is odd, then we have found a minimizing F . Otherwise, find $f \in \delta(U)$ minimizing $|c_f - c'_f|$ over $f \in \delta(U)$, because then the symmetric difference of F and $\{f\}$ minimizes $\beta(U, \cdot)$.

This implies that the loop in steps 2–6 in Algorithm 2 runs in time $\mathcal{O}(|V|^2)$, and that the running time of Algorithm 2 is dominated by the computation of the cut-tree in step 1, which amounts to $\mathcal{O}(|V|^2|E| \log(|V|^2/|E|))$.

The similarity between the Padberg–Rao minimum odd cut Algorithm 1 and our blossom minimization Algorithm 2 is striking. Moreover, in the next section, we give a short and elegant proof of correctness of Algorithm 2, which is similar to a proof of correctness of Algorithm 1 given by Rizzi [Riz02].

We remark that, just like the original Padberg–Rao blossom separation algorithm, our algorithm can be modified so that it outputs every violated blossom inequality found, rather than only the most violated one. We also remark that the function $\beta(U)$ defined in (10), unlike the cut function $w(\delta(U))$, is not, in general, submodular.

4. A simple proof of the correctness of Algorithm 2. The proof makes use of a well-known fact concerned with T -odd cuts and so-called T -joins, which we briefly review. Let $G = (V, E)$ be a graph, and let $T \subset V$ (with $|T|$ even) be a set of odd vertices, as before. A set $F \subset E$ is called a T -join if it has the following property: a vertex of G is odd if and only if there is an odd number of edges in F incident on it. The fact that we need is the following: if F is a T -join and U is an arbitrary subset of V , then $|U \cap T|$ is odd if and only if $|\delta(U) \cap F|$ is odd. That is, a cut is T -odd if and only if it meets every T -join an odd number of times.

Consider once again a graph $G = (V, E)$, a weight vector $w \in \mathbb{Q}^{|E|}$, and a set $T \subset V$ of odd vertices. Suppose that we have computed a cut-tree with terminal vertex set V . We say that an edge $x \sim y$ of the cut-tree is T -odd if the vertex sets on each shore of the cut defined by $x \sim y$ are T -odd. This defines a T -join in the cut-tree. The next theorem, due to Rizzi [Riz02], is an extension of a key theorem in [PR82]. For the sake of clarity, we repeat the proof of Rizzi.

THEOREM 4.1 (see [Riz02]). *One of the T -odd edges of the cut-tree induces a minimum odd cut in G .*

Proof. Let $U \subset V$ be an odd set such that $\delta(U)$ is a minimum odd cut in G . Since U is an odd set, there exists an odd number of T -odd cut-tree edges leaving U . Let

$x \sim y$ be one of them, and let $\delta(U')$ be the minimum (x, y) -cut that it induces in G (by property (6)). Since $\delta(U)$ is also an (x, y) -cut in G , we have $w(\delta(U')) \leq w(\delta(U))$. Since $x \sim y$ is a T -odd cut-tree edge, $\delta(U')$ is a minimum odd cut in G . $\square$

Now we come to the proof of correctness of Algorithm 2.

THEOREM 4.2. *One of the edges of the cut-tree computed in Algorithm 2 induces a set $U \subset V$ that minimizes $\beta(\cdot)$.*

Proof. Let $E' := \{e \in E \mid c'_e < c_e\}$ and T' denote the set of vertices that are incident on an odd number of edges in E' . This way, E' is a T' -join. Define the set T^Δ as the symmetric difference of T with T' . Furthermore, let $w := \min(c, c')$ denote the weight function used in Algorithm 2. We note the following facts:

- (a) A set U is T^Δ -odd if and only if $|T \cap U| + |E' \cap \delta(U)|$ is odd.
- (b) For all sets U , we have $\beta(U) \geq w(\delta(U))$. If U is T^Δ -odd, then the equality holds. If U is not T^Δ -odd, then, by Remark 3.2,

$$\beta(U) = w(\delta(U)) + \min_{e \in \delta(U)} |c'_e - c_e|.$$

Item (4) follows from the elementary fact about T -cuts and T -joins mentioned previously by taking a T -join J and noting that the symmetric difference of J and E' is a T^Δ -join.

Now let $U \subset V$ be a set that minimizes $\beta(\cdot)$. We distinguish two cases.

Case 1: U is T^Δ -odd. The proof of Theorem 4.1, applied to T^Δ and w , shows that there exists a T^Δ -odd edge of the cut-tree which, by (4), determines a set $U' \subset V$ minimizing $\beta(\cdot)$.

Case 2: U is not T^Δ -odd. Let $f = \{i, j\} \in \delta(U)$ have the minimal value of $|c_f - c'_f|$ among all edges in $\delta(U)$. On the path from i to j in the cut-tree, at least one edge $x \sim y$ has one end in U and the other not in U . Let $\delta(U')$ be the minimum (x, y) -cut in G corresponding to this edge. Notice that $f \in \delta(U')$. We then have

$$\beta(U) = w(\delta(U)) + |c_f - c'_f| \geq w(\delta(U')) + |c_f - c'_f| \geq \beta(U').$$

The first inequality holds because $\delta(U)$ is an (x, y) -cut in G . The second follows from the definition of the function $\beta(\cdot)$ and the fact that $f \in \delta(U')$. $\square$

ANALYSIS OF SERIAL TURBO CODES OVER ABELIAN GROUPS FOR SYMMETRIC CHANNELS*

FEDERICA GARIN[†] AND FABIO FAGNANI[†]

Abstract. In this paper we study serial turbo interconnections of Abelian group codes to be used on symmetric channels. Particular attention is devoted to AWGN channel with input restricted to m -PSK constellation with corresponding group structure $\mathbb{Z}_m$. We establish the exact asymptotic decay of the average symbol and word error probabilities when the interleaver length goes to infinity (interleaver gain). Moreover, we give a detailed characterization of the distance parameter characterizing the behavior for the signal-to-noise ratio going to infinity (effective free distance). Some of our results are new also in the binary context; in particular, the lower bound to the error probability decay.

Key words. serial interconnected codes, turbo codes, trellis-coded modulation, average error probability, codes over groups, effective distance

1. Introduction. Turbo codes made their appearance in 1993 with the pioneering work [6] (see also [5]). Since then, there has been a huge effort to understand their great performance by a significant number of researchers in the field, e.g., [3, 4, 9, 10, 12, 14, 28, 35, 37, 38, 39, 40, 41]. In the meanwhile, many variations and extensions have been proposed with respect to the original parallel concatenated scheme in [5]. A particularly relevant scheme is the serially concatenated version, first proposed in [2] and studied further in [28]. Other significant variations concern the possibility to work with a more restricted class of coupling interleavers [7, 11] in order to achieve a higher convergence abscissa in the iterative decoding algorithm.

In the theoretical analysis of these coding schemes we can find two main lines: on the one hand, they have been studied in combination with the suboptimal iterative decoding algorithm (see, e.g., [35, 10, 14]), and on the other hand, they have been studied in a more classical setting, considering optimal maximum likelihood (ML) decoding. This second approach separates the analysis of the coding schemes from the use of the suboptimal iterative decoding (see, e.g., [3, 4, 2, 9, 12, 28, 37, 39, 40]). The results in [4, 2, 28] provide upper bounds for the decay of the averaged bit error rate $\overline{P_b(e)}$, of type $CN^{-\alpha}$ where α is a parameter, called interleaver gain, depending only on the constituent codes of the turbo scheme. Further, a more refined analysis has been done for the situation when the Bhattacharyya parameter γ of the channel goes to zero, showing that the above constant C could be estimated as $C = K\gamma^{d^*}$ where d^* is a sort of generalized minimum distance of the scheme and K is a universal constant. The main contribution of this line of research has been to discover these two parameters, α and d^* , and their relation to the constituent encoders, which makes them interesting from a design point of view.

Another significant extension of the theory of turbo codes has been the study of schemes for nonbinary alphabets, in order to use them over channels with a nonbinary input alphabet.

Mostly, the construction of such nonbinary turbo codes has followed the so-called *pragmatic design* approach: turbo codes are designed for the binary case and optimized independently from the external high-order input constellation. Joint optimization is very little, usually regarding the mapping of the coded bits into the constellation signals. Performance evaluation is typically obtained by simulation. As a matter of fact, almost all schemes presented in the literature belong to this class (see, e.g., [31, 36, 21]).

On the contrary, in the so-called *analytical design* turbo codes are designed and optimized by taking into account the chosen nonbinary channel. This is the same philosophy of classical trellis coded modulation (TCM) schemes. Pioneering works in this direction are [23, 34, 16]. This approach exploits the symmetries of some important families of codes, such as additive Gaussian channels with geometrically uniform input constellation, by using a suitable algebraic structure matched to the channel. There are two fundamental difficulties in the theoretical developments of such turbo schemes, new with respect to the binary case:

- in general, the relevant distance affecting error probability and its estimations is not Hamming distance, e.g., for Gaussian channels Euclidean distance matters;
- in order to obtain bit or word error rate to be independent from the transmitted information word, one needs to carefully choose the algebraic structure of the constituent encoders. For example, the so-called bit-geometrically-uniform encoders [23, 16] ensure a sort of isometry in the scheme between the input Hamming distance and the output Euclidean distance; these encoders give a bit error rate independent from the information word, but this independence is only reached in the average sense and not for a single realization of the interleaver and, moreover, it forces the use of encoders on non-Abelian groups, creating many algebraic technical problems in the treatment of the convolutional codes.

This paper also follows the *analytical design* approach, but taking a different road with respect to previous works. Here, we study serial turbo interconnections on an Abelian group (typically $\mathbb{Z}_m$). The constituent encoders are chosen to be homomorphic, which does not guarantee the bit error rate $P_b(e)$ (or its average version $\overline{P_b(e)}$) to be independent from the transmitted information word. However, if we consider the symbol error rate $P_s(e)$, where the symbol is to be intended as a suitable aggregation of the input bits in order to form the input group of the encoder (typically $\mathbb{Z}_m$ again), then this independence is ensured. Of course $P_s(e)$ and $P_b(e)$ are strictly linked to each other, so that estimations on the former lead to estimations on the latter. Moreover, the choice to work with Abelian groups allows us to use a much richer and flexible theory at the level of convolutional codes, widely studied in the past [29, 17, 18, 19].

In this paper, we study the average symbol and word error rate $\overline{P_s(e)}$, $\overline{P_w(e)}$ for such schemes on symmetric channels and under ML decoding. We determine the asymptotic decay $N^{-\alpha}$ when the interleaver length N goes to infinity. Our results extend and complete the bounds given in [2, 28]. The extension is two-fold: we pass from binary codes to schemes over generic Abelian groups, and we move from the uniform interleaver assumption by also considering structured families of interleavers. Moreover, we provide a lower bound which was missing even for the binary case.

Technical proofs are inspired by [15], which analyzes parallel interconnection schemes for binary codes.

Finally, we carry on a detailed investigation of the asymptotic analysis when the signal-to-noise ratio (SNR) goes to infinity. Similar to results in [2] for the binary case, we find that the leading term of both word and symbol error probabilities (for $N \rightarrow +\infty$) depends on the channel's SNR through a sort of distance parameter q^* , which is a function of the constituent encoders. However, different from the binary case, the exact characterization of q^* is given as the solution of a combinatorial optimization problem involving both constituent encoders.

Here, we give a brief outline of this paper. Sections 2 and 3 contain some basic notation and results on block and convolutional encoders over Abelian groups: special attention is devoted to homomorphic state-space realizations, which play a fundamental role in all of our estimations. In section 4 we introduce the serially concatenated schemes and the specific examples we want to focus on. Section 5 contains the fundamental original theoretical results of this paper: Theorem 5.4 describes the asymptotic estimations for word and symbol error probabilities when $N \rightarrow +\infty$ and, further, when the SNR goes to infinity. In particular, the expression for the interleaver gain α is derived and the combinatorial optimization problem describing the effective distance q^* is formulated. All proofs are given in section 6. Section 7 gives a detailed account of the computation of α and d^* for all of our examples. An appendix containing some results on the algebraic properties of encoders over $\mathbb{Z}_m$ completes the paper.

2. Homomorphic block encoders for symmetric channels.

2.1. Notation. Given a set Ω and $A \subseteq \Omega$, the symbol $\chi_A : \Omega \rightarrow \{0, 1\}$ will denote the indicator function of A , i.e., $\chi_A(x) = 1$ if and only if $x \in A$. $|A|$ will denote the cardinality of A . We will denote by $\mathbb{N}$ the set of nonnegative integers and by $\mathbb{N}^*$ the set of positive integers. Throughout this paper, vectors will always be column vectors and be denoted by boldface letters. Given a vector $\mathbf{w} \in \mathbb{N}^k$, we let $|\mathbf{w}| = \sum_j w_j$. We will denote by $\mathbf{e}_j$ a vector of the appropriate length (clear by the context or explicitly stated) made by all zeros except a one in position j . Given two sets, A and B , B^A will denote vectors with entries in B , having length $|A|$, and components indexed by elements of A instead of integers $1, \dots, |A|$. By $\log$ and $\exp$ we will denote logarithm and exponential with respect to the same base $b > 1$. Given groups G and H , $\text{Hom}(G, H)$ will denote the group of all homomorphisms from G to H , while $\text{Aut}(G)$ will be the group of automorphisms of G .

2.2. Symmetric channels. A memoryless channel is described by:

- an input alphabet $\mathcal{X}$ (which we will always assume is finite),
- an output alphabet $\mathcal{Y}$, endowed with a σ -algebra $\mathcal{B} \subseteq 2^{\mathcal{Y}}$ and a probability measure μ ,
- and a family of transition probability densities $W(\cdot|x)$ on $\mathcal{Y}$, indexed by the inputs $x \in \mathcal{X}$.

Such a channel will be denoted by $(\mathcal{X}, \mathcal{Y}, W)$. In most applications, either $\mathcal{Y}$ is finite and μ is the counting measure so $W(\cdot|x)$ are simply probability vectors, or $\mathcal{Y} = \mathbb{R}^n$ and μ is the Lebesgue measure.

To give a formal definition of symmetric memoryless channels, we need to recall some definitions of group actions. Given a group $(G, +)$ with neutral element 0 and given a set A , G acts on A if for every $g \in G$ there exists a map $a \mapsto ga$ from A to A , such that $(h + g)a = h(ga)$ for all $h, g \in G$, $a \in A$, and $0a = a$ for all $a \in A$. For finite A , the group action of G on A is said to be (simply) transitive if for every

$a, b \in A$, there exists a (unique) element $g \in G$ such that $ga = b$. If G acts simply transitively on A , then G and A are in bijection through the map $\theta : G \rightarrow A$ defined by $\theta(g) = ga_0$ for an arbitrary but fixed $a_0 \in A$.

Given a probability space $\mathcal{Y}$ with σ -algebra $\mathcal{B}$ and probability measure μ , we say that a group G acts isometrically on $\mathcal{Y}$ if there exists an action of G on $\mathcal{Y}$ consisting of measurable bijections such that $\mu(gA) = \mu(A)$ for all $A \in \mathcal{B}$, for all $g \in G$. If $\mathcal{Y}$ is finite, then all group actions on $\mathcal{Y}$ are isometric. If $\mathcal{Y} = \mathbb{R}^n$, then an action is isometric when all maps $y \mapsto gy$ are isometries of $\mathbb{R}^n$.

Given a group G , a memoryless channel $(\mathcal{X}, \mathcal{Y}, W)$ is called G -symmetric if

1. G acts simply transitively on $\mathcal{X}$,
2. G acts isometrically on $\mathcal{Y}$,
3. $W(y|x) = W(gy|gx)$ for every $g \in G$, $x \in \mathcal{X}$, $y \in \mathcal{Y}$.

In this case, the bijection $\theta : G \rightarrow \mathcal{X}$ defined by $\theta(g) = gx_0$ for some fixed $x_0 \in \mathcal{X}$ is called an isometric labelling.

The most common examples of G -symmetric channels are the following.

- **Binary-input output-symmetric channels.** $\mathbb{Z}_2$ -symmetric channels are known in the coding literature as binary-input output-symmetric (BIOS) channels. Well-known examples are binary symmetric channel (BSC), binary erasure channel (BEC), and binary-input AWGN (BIAWGN) channel.
- **Geometrically uniform AWGN channels.** An n -dimensional constellation is a finite subset $S \subset \mathbb{R}^n$ that spans $\mathbb{R}^n$; we denote with $\Gamma(S)$ its symmetry group, i.e., the group of Euclidean isometries of $\mathbb{R}^n$ mapping S into S itself. A constellation S is said to be geometrically uniform (GU) with generating group G if G is a subgroup of $\Gamma(S)$ whose action on S is simply transitive. The simplest example of GU constellation is the 1-dimensional antipodal constellation $\{-1, 1\}$ (a.k.a. 2-points pulse amplitude modulation (2-PAM)). A 2-dimensional example is the m -PSK constellation

$$S = \{e^{\frac{2\pi il}{m}} : l = 0, \dots, m-1\} \subseteq \mathbb{C} \simeq \mathbb{R}^2$$

which always has the generating group $\mathbb{Z}_m$ (seen as rotations of angles multiple of $2\pi/m$) and, if m is even, then also has the non-Abelian generating group $D_{m/2}$. For a complete theory of GU constellations and generating groups, see [20] and [32].

Given a GU constellation $S \subset \mathbb{R}^q$ with generating group G , define the S -AWGN channel as the memoryless channel $(S, \mathbb{R}^n, W)$ where the family W of n -dimensional transition densities is given by $W(y|x) = N(y-x)$ for any $x \in S$; $N(\cdot)$ is the density of an n -dimensional diagonal Gaussian random variable (r.v.) $N(y) = (2\pi\sigma^2)^{-n/2} e^{-\|y\|^2/(2\sigma^2)}$.

Other examples of G -symmetric channels can be obtained from the S -AWGN by suitable symmetric quantizations of the channel output, e.g., quantizing with respect to the Voronoi regions of the same constellation S .

- **m -ary symmetric channels.** This is a simple generalization of the BSC: $\mathcal{X} = \mathcal{Y} = \{0, 1, \dots, m-1\}$ and $W(y|x) = \epsilon/(m-1)$ if $y \neq x$, $W(y|x) = 1 - \epsilon$ if $y = x$. This channel is G -symmetric for any group G with $|G| = m$; in particular, for $G = \mathbb{Z}_m$.

Now fix a G -symmetric channel $(\mathcal{X}, \mathcal{Y}, W)$, and denote by W_n , μ_n , and θ the natural extensions of W , μ , and θ to multiple uses of the channel. Define the pairwise equivocation probability of a word $\mathbf{c} \in G^n$, $P(\mathbf{0} \rightarrow \mathbf{c})$, to be the probability that, for some fixed decoding rule, the decoder will prefer $\mathbf{c}$ to $\mathbf{0}$, given that $\theta(\mathbf{0})$ was transmitted. In this paper, we consider maximum likelihood decoding, with the choice

to break ties uniformly at random, so that

$$\begin{aligned} P(\mathbf{0} \rightarrow \mathbf{c}) &= \int_{\mathcal{Y}^n} W_n(\cdot | \boldsymbol{\theta}(\mathbf{0})) \chi_{\{W_n(\cdot | \boldsymbol{\theta}(\mathbf{c})) > W_n(\cdot | \boldsymbol{\theta}(\mathbf{0}))\}} d\mu_n \\ &\quad + \frac{1}{2} \int_{\mathcal{Y}^n} W_n(\cdot | \boldsymbol{\theta}(\mathbf{0})) \chi_{\{W_n(\cdot | \boldsymbol{\theta}(\mathbf{c})) = W_n(\cdot | \boldsymbol{\theta}(\mathbf{0}))\}} d\mu_n. \end{aligned}$$

Note that $P(\mathbf{0} \rightarrow \mathbf{c})$ depends only on the number of occurrences in $\mathbf{c}$ of each nonzero element of G . We will call the type of $\mathbf{c}$, denoted $\mathbf{w}_T(\mathbf{c}) \in \mathbb{N}^{G \setminus \{0\}}$, a counter of such occurrences: $(\mathbf{w}_T(\mathbf{c}))_g = \sum_{i=1}^n \chi_{\{g\}}(\mathbf{c}_i)$. Given $\mathbf{w} \in \mathbb{N}^{G \setminus \{0\}}$, we will use the notation $Q(\mathbf{w})$ to denote $P(\mathbf{0} \rightarrow \mathbf{c})$ for any $\mathbf{c}$ with $\mathbf{w}_T(\mathbf{c}) = \mathbf{w}$.

In what follows, we will use the following two estimations of $P(\mathbf{0} \rightarrow \mathbf{c})$, both involving $w_H(\mathbf{c})$, the Hamming weight of $\mathbf{c}$ (number of nonzero elements). The well-known Bhattacharyya upper bound is

$$\begin{aligned} P(\mathbf{0} \rightarrow \mathbf{c}) &\leq \int_{\mathcal{Y}^n} W_n(\cdot | \boldsymbol{\theta}(\mathbf{0})) \chi_{\{W_n(\cdot | \boldsymbol{\theta}(\mathbf{c})) \geq W_n(\cdot | \boldsymbol{\theta}(\mathbf{0}))\}} d\mu_n \\ &\leq \prod_{i=1}^n \int_{\mathcal{Y}} \sqrt{W(\cdot | \boldsymbol{\theta}(0)) W(\cdot | \boldsymbol{\theta}(c_i))} d\mu \\ &\leq \gamma^{w_H(\mathbf{c})}, \end{aligned}$$

where γ is the (worse) Bhattacharyya noise parameter of the channel defined as

$$\gamma = \max_{g \neq 0} \int_{\mathcal{Y}} \sqrt{W(\cdot | \boldsymbol{\theta}(0)) W(\cdot | \boldsymbol{\theta}(g))} d\mu.$$

A lower bound for pairwise equivocation probability is easily obtained,

$$\begin{aligned} P(\mathbf{0} \rightarrow \mathbf{c}) &\geq \int_{\mathcal{Y}^n} W_n(\cdot | \boldsymbol{\theta}(\mathbf{0})) \chi_{\{W_n(\cdot | \boldsymbol{\theta}(\mathbf{c})) > W_n(\cdot | \boldsymbol{\theta}(\mathbf{0}))\}} d\mu_n \\ &\geq \prod_{i=1}^n \int_{\mathcal{Y}} W(\cdot | \boldsymbol{\theta}(0)) \chi_{\{W(\cdot | \boldsymbol{\theta}(c_i)) > W(\cdot | \boldsymbol{\theta}(0))\}} d\mu \\ &\geq p^{w_H(\mathbf{c})}, \end{aligned}$$

where p is the (worse) equivocation probability of the channel defined as

$$p = \min_{g \neq 0} \int_{\mathcal{Y}} W(\cdot | \boldsymbol{\theta}(0)) \chi_{\{W(\cdot | \boldsymbol{\theta}(c_i)) > W(\cdot | \boldsymbol{\theta}(0))\}} d\mu.$$

Let's see what these definitions give in the examples of G -symmetric channels we have presented.

- **BIOS channels.** The names Bhattacharyya parameter and equivocation probability for γ and p are mostly used only in this context, where there is only one nonzero $g \in G$ and so there is no maximization (resp., minimization) in the definition of γ (resp., p).

For BSC with crossover probability ϵ , if $w_H(\mathbf{c}) = w$, then $P(\mathbf{0} \rightarrow \mathbf{c}) = Q(w)$ with

$$Q(w) = \begin{cases} \sum_{r=\lceil w/2 \rceil}^w \binom{w}{r} \epsilon^r (1-\epsilon)^{w-r} & \text{if } w \text{ is odd} \\ \sum_{r=1+w/2}^w \binom{w}{r} \epsilon^r (1-\epsilon)^{w-r} + \frac{1}{2} \binom{w}{w/2} \epsilon^{w/2} (1-\epsilon)^{w/2} & \text{if } w \text{ is even.} \end{cases}$$

The Bhattacharyya parameter is $\gamma = 2\sqrt{\epsilon(1-\epsilon)}$, while the equivocation probability is $p = \epsilon$.

For BEC with erasure probability ϵ , the only terms in $P(\mathbf{0} \rightarrow \mathbf{c})$ come from breaking ties: if $w_H(\mathbf{c}) = w$, then $P(\mathbf{0} \rightarrow \mathbf{c}) = Q(w) = \frac{1}{2}\epsilon^w$. Here $\gamma = \epsilon$, while $p = 0$.

For BIAWGN channel, see below.

- **S-AWGN channels.** Here, with $S \subset \mathbb{R}^d$ and codewords of length n ,

$$P(\mathbf{0} \rightarrow \mathbf{c}) = \int_{\mathbb{R}^{dn}} W_n(\cdot | \boldsymbol{\theta}(\mathbf{0})) \chi_{\{W_n(\cdot | \boldsymbol{\theta}(\mathbf{c})) > W_n(\cdot | \boldsymbol{\theta}(\mathbf{0}))\}} d\mu_n = \frac{1}{2} \operatorname{erfc} \left(\frac{\|\boldsymbol{\theta}(\mathbf{c}) - \boldsymbol{\theta}(\mathbf{0})\|}{2\sqrt{2\sigma^2}} \right),$$

where $\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^{+\infty} e^{-t^2} dt$ and $\|\cdot\|$ denotes Euclidean norm.

It is well known that all points of a GU constellation lie on a sphere, and it is usually assumed that constellations have barycenter in the origin, so the radius of the sphere, squared, is the signal energy per transmitted symbol E_s . This remark allows us to find explicit dependence of $P(\mathbf{0} \rightarrow \mathbf{c})$ on the SNR:

$$P(\mathbf{0} \rightarrow \mathbf{c}) = \frac{1}{2} \operatorname{erfc} \left(\frac{\|\boldsymbol{\theta}(\mathbf{c}) - \boldsymbol{\theta}(\mathbf{0})\|}{2\sqrt{E_s}} \sqrt{\frac{E_s}{N_0}} \right),$$

where E_s/N_0 is the SNR per transmitted symbol.

Clearly, having fixed S and θ , $P(\mathbf{0} \rightarrow \mathbf{c})$ depends only on $\mathbf{w}_T(\mathbf{c})$: with the notation $\mathbf{h} = \mathbf{w}_T(\mathbf{c})$, one can write $\|\boldsymbol{\theta}(\mathbf{c}) - \boldsymbol{\theta}(\mathbf{0})\| = \sqrt{\sum_g \mathbf{h}_g \|\theta(g) - \theta(0)\|^2}$.

However, the expression for $P(\mathbf{0} \rightarrow \mathbf{c})$ suggests defining a different weight, which better captures the geometry of S ; it is a rescaled squared Euclidean distance from zero, which we will call Euclidean weight: $w_E(\mathbf{c}) = \|\boldsymbol{\theta}(\mathbf{c}) - \boldsymbol{\theta}(\mathbf{0})\|^2 / (4E_s)$.

One can also compute $\gamma = \max_{g \neq 0} e^{-\|\theta(g) - \theta(0)\|^2 / (8\sigma^2)} = (e^{-E_s/N_0})^{\min_{g \neq 0} w_E(g)}$.

Finally, $p = \min_{g \neq 0} \frac{1}{2} \operatorname{erfc} \left(\frac{\|\theta(g) - \theta(0)\|}{2\sqrt{2\sigma^2}} \right) = \frac{1}{2} \operatorname{erfc} \sqrt{\max_{g \neq 0} w_E(g) \frac{E_s}{N_0}}$.

- **m-ary symmetric channels.** A symmetric channel with alphabet size m and error probability ϵ has

$$P(\mathbf{0} \rightarrow \mathbf{c}) = \sum_{s=1}^w \binom{w}{s} \left[\left(1 - \frac{1}{m-1}\right) \epsilon \right]^{w-s} \sum_{r=\lfloor s/2 \rfloor + 1}^s \binom{s}{r} \left(\frac{\epsilon}{m-1} \right)^r (1-\epsilon)^{s-r} \\ + \frac{1}{2} \sum_{s=0}^{\lfloor w/2 \rfloor} \binom{w}{2s} \left[\left(1 - \frac{1}{m-1}\right) \epsilon \right]^{w-2s} \binom{2s}{s} \left(\frac{\epsilon(1-\epsilon)}{m-1} \right)^s.$$

In this case, $\gamma = \sqrt{\frac{\epsilon}{m-1}} (2\sqrt{1-\epsilon} + (m-2)\sqrt{\frac{\epsilon}{m-1}})$ and $p = \frac{\epsilon}{m-1}$.

2.3. Weights. In this paper, we will deal with different kinds of weight: we have already seen Hamming, type, and Euclidean weight, in relation to the channel's noise, but we will need other weights related to the coding schemes. In this section, we present a general definition and establish some useful properties.

DEFINITION 2.1. A weight on an Abelian group Z consists of a positive integer p and a map $\mathbf{w} : Z \rightarrow \mathbb{N}^p$ satisfying the following properties:

1. $\mathbf{w}(0) = \mathbf{0}$,
2. $|\mathbf{w}(z^1 + z^2)| \leq |\mathbf{w}(z^1)| + |\mathbf{w}(z^2)|$ for every $z^1, z^2 \in Z$,
3. $\{\mathbf{e}_1, \dots, \mathbf{e}_\rho\} \subseteq \mathbf{w}(Z)$ (here $\mathbf{e}_j \in \mathbb{N}^\rho$).

A few considerations on the above definition:

- Item 2 says that the summation in Z cannot create any extra weight.
- Item 3 is a simple minimality assumption which ensures that the full semi-group structure of $\mathbb{N}^\rho$ is used.

Whenever we have a weight $\mathbf{w}$ we will consider its natural extension to vectors by componentwise sum $\mathbf{w} : Z^N \rightarrow \mathbb{N}^\rho$, defined by $\mathbf{w}(\mathbf{z}) = \sum_j \mathbf{w}(z_j)$.

Given $\mathbf{h} \in \mathbb{N}^\rho$, we will use the following notation: $Z_{\mathbf{h}}^N = \{\mathbf{z} \in Z^N : \mathbf{w}(\mathbf{z}) = \mathbf{h}\}$. Moreover, if $\mathbf{h} \in \mathbb{N}^\rho$ we will use the notation

$$\binom{N}{\mathbf{h}} = \begin{cases} \frac{N!}{\mathbf{h}_1! \cdots \mathbf{h}_\rho! (N - |\mathbf{h}|)!} & \text{if } |\mathbf{h}| \leq N \\ 0 & \text{otherwise.} \end{cases}$$

The following result will be useful later.

LEMMA 2.2. *Suppose $\mathbf{w}$ is a weight on Z . For every $\mathbf{h} \in \mathbb{N}^\rho$ we have that*

$$\binom{N}{\mathbf{h}} \leq |Z_{\mathbf{h}}^N| \leq (|Z| N)^{|\mathbf{h}|}.$$

Proof. For $i = 1, \dots, \rho$, let $\eta_i \in Z$ be such that $\mathbf{w}(\eta_i) = \mathbf{e}_i \in \mathbb{N}^\rho$ (which surely exist by point 3 of the definition of weight). The lower bound is trivially true if $|\mathbf{h}| > N$. Otherwise, consider the words in Z^N with support cardinality $|\mathbf{h}|$ made by exactly $\mathbf{h}_j$ times η_j , for $j = 1, \dots, \rho$: there are $\binom{N}{\mathbf{h}}$ such words, and all of them have invariants weight vector $\mathbf{h}$.

The upper bound is clearly true if $\mathbf{h} = \mathbf{0}$. Therefore assume that $\mathbf{h} \neq \mathbf{0}$. For any $\mathbf{z} \in Z_{\mathbf{h}}^N$ consider the subset $\mathcal{J}$ of indices $j \in \{1, \dots, N\}$ for which $z_j \neq 0$. Clearly, $1 \leq |\mathcal{J}| \leq |\mathbf{h}|$. It thus follows that the number of elements in $Z_{\mathbf{h}}^N$ can be upper bound considering all possible subsets $\mathcal{J}$ of cardinality $1 \leq |\mathcal{J}| \leq |\mathbf{h}|$ and all possible elements of Z in the positions in $\mathcal{J}$. In other words

$$|Z_{\mathbf{h}}^N| \leq \sum_{j=1}^{|\mathbf{h}|} \binom{N}{j} |Z|^j \leq |Z|^{|\mathbf{h}|} \sum_{j=1}^{|\mathbf{h}|} \binom{N}{j}.$$

It is now sufficient to use the inequality $\sum_{j=1}^{|\mathbf{h}|} \binom{N}{j} \leq N^{|\mathbf{h}|}$ to obtain the result. $\square$

Hamming weight and type weight are examples of weights always available on any set Z :

- **Hamming weight:** $\rho = 1$, $w_H(z) = 1 - \chi_{\{0\}}(z)$.
- **Type weight:** $\rho = |Z| - 1$, or better $\mathbf{w}_T(z) \in \mathbb{N}^{Z \setminus \{0\}}$, because we prefer indexing the components of $\mathbf{w}_T(z)$ directly by the elements in $Z \setminus \{0\}$ instead of by integers $1, \dots, |Z| - 1$; define $\mathbf{w}_T(z)_a = \chi_{\{a\}}(z)$ for every $a \in Z \setminus \{0\}$.

Clearly, $|\mathbf{w}_T(z)| = w_H(z)$ and, moreover, for any weight $\mathbf{w}$ on Z , it necessarily holds that

$$w_H(\mathbf{z}) \leq |\mathbf{w}(\mathbf{z})| \leq w_{\max} w_H(\mathbf{z}),$$

where $w_{\max} = \max_{z \in Z} |\mathbf{w}(z)|$.

On Abelian groups, it will be particularly important to consider the weights compatible with the algebraic structure, as defined below.

DEFINITION 2.3. *Given an Abelian group U , a distance d on U is called compatible with the group structure of U if $d(u, v) = d(u + w, v + w)$ for all $u, v, w \in U$.*

A weight $\mathbf{w} : U \rightarrow \mathbb{N}$ is called compatible with the group U if there exists a distance d compatible with U such that, for all $u \in U$, $\mathbf{w}(u) = d(u, 0)$.

Notice that if d is a compatible distance on U , the natural extension (by componentwise summation) on U^k remains compatible and it will be denoted with the same symbol d , as well as the associated weight w . Also notice that Hamming and type weights are always compatible with any fixed group U .

2.4. Homomorphic block encoders. Word and symbol error rate. We fix a finite Abelian group Γ and consider transmission on a memoryless Γ -symmetric channel. Given another finite Abelian group U , we define a block encoder of rate k/n over Γ with inputs in U to be any injective group homomorphism $\phi : U^k \rightarrow \Gamma^n$; we define the corresponding code to be the image of the encoder.

We let ξ be a r.v. uniformly distributed on U^k (ξ is the word to be sent) and independent from the channel noise. We let $\hat{\xi}$ be the ML estimate of ξ from the received word y . In this setting, we can clearly define the word error probability of our code in the usual way:

$$P_w(e|\mathbf{u}) = \mathbb{P}(\hat{\xi} \neq \mathbf{u} | \xi = \mathbf{u}), \quad P_w(e) = \mathbb{P}(\hat{\xi} \neq \xi) = \frac{1}{|U|^k} \sum_{\mathbf{u} \in U^k} P_w(e|\mathbf{u}).$$

Our assumptions ensure that the uniform error property holds, i.e., the word error probability does not depend on which word has been sent and, in particular, we can assume that the all-zero word has been sent: $P_w(e) = P_w(e|\mathbf{0})$.

Another interesting property of a code (or, more precisely, of an encoder) is its bit error rate. In our abstract setting, it is more convenient to consider a symbol error rate, where symbols can be, for example, the elements of U or, as we will see, also something smaller. We propose the following definition.

Given a distance d compatible with U and such that $d(u, 0) \neq 0$ for all $u \neq 0$, we define a *symbol error rate* with respect to d as

$$P_s(e|\mathbf{u}) = \sum_{\hat{\mathbf{u}} \in U^k} \frac{d(\hat{\mathbf{u}}, \mathbf{u})}{k\rho_U} \mathbb{P}(\hat{\xi} = \hat{\mathbf{u}} | \xi = \mathbf{u}),$$

where ρ_U is the diameter of U with respect to d . Moreover, we put

$$P_s(e) = \frac{1}{|U|^k} \sum_{\mathbf{u} \in U^k} P_s(e|\mathbf{u}).$$

The compatibility of the distance with U , together with the previous assumptions, ensures that also for $P_s(e)$ the uniform error property holds true:

$$P_s(e) = P_s(e|\mathbf{0}) = \sum_{\hat{\mathbf{u}} \in U^k} \frac{\mathbf{w}(\hat{\mathbf{u}})}{k\rho_U} \mathbb{P}(\hat{\xi} = \hat{\mathbf{u}} | \xi = \mathbf{0}),$$

where $\mathbf{w}$ is the weight associated with the distance d . In this case, $\rho_U = \max_{u \in U} \mathbf{w}(u)$, and we have the inequality

$$P_s(e) \geq \frac{1}{N} \frac{\min_{u \in U, u \neq 0} \mathbf{w}(u)}{\max_{u \in U} \mathbf{w}(u)} P_w(e).$$

When d and w are Hamming distance and weight, respectively, the above definition simply gives the usual symbol error rate, where symbols are elements in U , and if $U = \mathbb{Z}_2$, then this is the classical bit error rate. When $U = \mathbb{Z}_2^a$, in addition to the symbol error rate, we can find also the bit error rate taking as distance the number of different bits (Hamming weight in $(\mathbb{Z}_2^a)^k$ identified with $\mathbb{Z}_2^{ak}$) instead of the number of different symbols.

3. Convolutional encoders over Abelian groups. In this section we will recall some basic facts of the theory of convolutional codes over Abelian groups which will be needed for what follows. Further details can be found in [29, 17, 18, 19] and the reference therein.

3.1. State maps and error events. Let U and Y be two finite Abelian groups. Consider the spaces of sequences $U^{\mathbb{N}}$ and $Y^{\mathbb{N}}$, respectively, both equipped with the componentwise group structure. Convolutional codes for us will be homomorphic maps $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$ satisfying some properties which are introduced below. In coding theory the only maps between sequence spaces which are really relevant are those which admit a realization through finite state maps.

A (homomorphic) state map η from $U^{\mathbb{N}}$ to $Y^{\mathbb{N}}$ consists of another Abelian group X and of four homomorphisms

$$\begin{aligned} F : X &\rightarrow X, & L : U &\rightarrow X, \\ R : X &\rightarrow Y, & S : U &\rightarrow Y. \end{aligned}$$

X is called the *state space* of the state map, and if X is finite, then the state map is said to be a finite state map. A state map is formally denoted by the quadruple $\eta = (F, L, R, S)$. A finite state map can be pictorially described by a trellis in the usual way: at each time step, we draw vertices corresponding to the elements of X ; then we draw an edge from vertex x at time t to vertex x' at time $t+1$, with input tag u and output label y if and only if $x' = Fx + Lu$ and $y = Rx + Su$.

Given a homomorphic state map η and a state $x \in X$, we can define a map $\eta_x : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$ mapping $\mathbf{u} \in U^{\mathbb{N}}$ into $\mathbf{y} = \eta_x(\mathbf{u})$ computed recursively starting from the initial condition $x_0 = x$, as follows:

$$(3.1) \quad \begin{cases} x_{t+1} &= Fx_t + Lu_t, \\ y_t &= Rx_t + Su_t \end{cases} \quad \forall t \in \mathbb{N}.$$

Explicitly, we can write

$$(3.2) \quad y_t = RF^t x + R \sum_{j=1}^t F^j Lu_{t-j} + Su_t.$$

Notice that η_0 is a homomorphism.

A homomorphic map $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$ is said to be a *convolutional encoder* if there exists a homomorphic finite state map $\eta = (F, L, R, S)$ such that $\phi = \eta_0$. In this case η is said to be a *state space realization* of ϕ . Given a convolutional encoder $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$, there may exist many homomorphic finite state maps realizing ϕ . A state map η is said to be a *minimal realization* of ϕ if it has the state space with the minimal number of states among the possible realizations of ϕ . An important consequence of minimality ([13, p. 48] or [30, p. 192]) is the following properties:

- **Observability:** Let $\mathbf{u}', \mathbf{u}'' \in U^{\mathbb{N}}$ and $\mathbf{x}', \mathbf{x}'' \in X^{\mathbb{N}}$ be such that both pairs $(\mathbf{u}', \mathbf{x}')$ and $(\mathbf{u}'', \mathbf{x}'')$ satisfy the first relation of (3.1). Let $\mathbf{y}', \mathbf{y}''$ be the corresponding output sequences. If $\mathbf{u}'_t = \mathbf{u}''_t$ and $\mathbf{y}'_t = \mathbf{y}''_t$ for all $t = 0, \dots, |X| - 1$, then $\mathbf{x}'_0 = \mathbf{x}''_0$ must hold.
- **Reachability:** For any $x, x' \in X$ there exist $t \leq |X| - 1$, $\mathbf{u} \in U^{\mathbb{N}}$, and $\mathbf{x} \in X^{\mathbb{N}}$ satisfying the first relation in (3.1) such that $\mathbf{x}_0 = x$ and $\mathbf{x}_t = x'$. The smallest t for which this condition holds for any $x, x' \in X$ is called the *reachability index* of η which is denoted by ν .

From now on, whenever we are considering a convolutional encoder $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$, we will assume that an underlying minimal state space representation η has been fixed once and for all: in particular, to any given $\mathbf{u} \in U^{\mathbb{N}}$ and initial state x we can unambiguously associate a state sequence $\mathbf{x} \in X^{\mathbb{N}}$. Whenever the initial state x is not explicitly mentioned, we assume that $x = 0$. Notice, moreover, that x_t depends only on $\mathbf{u}$ up to time $t - 1$.

We now define the key concept of error event.

DEFINITION 3.1. Let $\mathbf{u} \in U^{\mathbb{N}}$ be an input sequence with associated state sequence $\mathbf{x}$. $\mathbf{u}$ is said to be an input error event for ϕ if there exist $t_1 \leq t_2$ such that

- (i) $u_t = 0 \ \forall t < t_1 \text{ and } t > t_2$,
- (ii) $x_t = 0 \ \forall t \leq t_1 \text{ and } t > t_2$,
- (iii) $x_t \neq 0 \ \forall t \in]t_1, t_2]$.

The corresponding codeword $\mathbf{y} = \phi(\mathbf{u})$ is said to be an error event. We call $[t_1, t_2]$ the active window and $t_2 - t_1$ the length of the (input) error event, which we denote by $l(\mathbf{u})$ or by $l(\mathbf{y})$.

The following property shows that the length of an error event cannot grow unbounded. We omit the proof since it is a straightforward generalization of Lemma 20 in [15] (binary case) using the observability property of the minimal realization.

PROPOSITION 3.2. Given a convolutional encoder $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$, there exists a constant $L > 0$ such that any error event $\mathbf{u}$ has length $l(\mathbf{u}) \leq L (\mathbf{w}_H(\mathbf{u}) + \mathbf{w}_H(\phi(\mathbf{u})))$.

The support of a sequence $\mathbf{u} \in U^{\mathbb{N}}$ is defined by

$$\text{supp}(\mathbf{u}) = \{t \in \mathbb{N} : u_t \neq 0\}.$$

$\mathbf{u}$ is said to have *finite support* if its support has finite cardinality. Notice that the cardinality of the support of a sequence coincides with Hamming weight.

3.2. Laurent series formalism. In many situations the description of a convolutional encoder through a state representation or the corresponding trellis is sufficient and quite appropriate. As in the classical binary case there are also more algebraic but equivalent ways to describe convolutional codes which, on the other hand, turn out to be quite useful in investigating concepts like recursiveness, noncatastrophicity, etc. This is what we are going to do next.

Given a group U , we consider the group of *Laurent series*

$$U((D)) = \left\{ \sum u_k D^k : u_k \in U, \exists k_0 \in \mathbb{Z} u_k = 0 \ \forall k < k_0 \right\}.$$

Inside $U((D))$ there are two relevant subgroups: the polynomials $U[D]$ and the usual formal power series $U[[D]]$.

Relation (3.2), for $x = 0$, can be interpreted as a multiplicative operator (product being defined in the Cauchy style) from $U((D))$ to $G((D))$ with the multiplicative

symbol given by

$$(3.3) \quad \phi(D) = \sum_{j=1}^{\infty} (RF^j L) D^j + S \in \text{Hom}(U, Y)[[D]].$$

$\phi(D)$ is called the *transfer function* associated with ϕ . Conversely, given a generic $\phi(D) \in \text{Hom}(U, Y)[[D]]$, we can ask whether it is the transfer function of a convolutional encoder. The answer is that this is true if and only if $\phi(D)$ is rational. Rationality is defined similarly to the field case. Consider the ring $\mathbb{Z}((D))$ of Laurent series with coefficients in $\mathbb{Z}$. The invertible elements in $\mathbb{Z}((D))$ are those Laurent series whose trailing coefficient is equal to 1 or -1 ; we denote this subset with the symbol $\mathbb{Z}((D))^*$. Given any Abelian group U , $U((D))$ is naturally a $\mathbb{Z}((D))$ -module. We define the submodule of *rational elements* of $U((D))$ as

$$U(D) = \{u(D) \in U((D)) : \exists p(D) \in \mathbb{Z}[D] \cap \mathbb{Z}((D))^*, p(D)u(D) \in U[D]\}.$$

Notice that rational Laurent series can always be represented as a fraction $u(D) = p(D)^{-1}v(D)$ for some suitable polynomials $p(D) \in \mathbb{Z}[D] \cap \mathbb{Z}((D))^*$ and $v(D) \in U[D]$. The assumption on $p(D)$ is exactly to make sure that $1/p(D)$ is a meaningful element of $\mathbb{Z}((D))$. It can be proven that $\phi(D) = \sum_{k=0}^{\infty} \phi_k D^k \in \text{Hom}(U, Y)[[D]]$ is the transfer function of a convolutional encoder if and only if it is rational (see Proposition 5.2 in [17]). Rationality has a useful characterization at the level of the underlying sequence ϕ_k : $\phi(D)$ is rational if and only if ϕ_k is periodic for sufficiently large k . Special types of convolutional encoders are the polynomial ones, namely those for which $\phi(D) \in \text{Hom}(U, Y)[D]$.

In what follows we will often confuse the group sequence $U^{\mathbb{N}}$ with the formal power series $U[[D]]$ through the one-to-one correspondence

$$(u_t)_{t \in \mathbb{N}} \leftrightarrow \sum_t u_t D^t.$$

In particular, $u_0 D^{t_0}$ will often be used to denote the sequence $\mathbf{u}$ which is equal to u_0 at time t_0 and equal to 0, otherwise. Notice that finite support sequences are represented in this way by polynomials in D and polynomial encoders transform polynomials into polynomials.

3.3. Properties of convolutional encoders. In this section we describe how some classical properties can be generalized to our setting; we will need them to analyze our concatenated schemes. Some further properties, specific for the case when the input and output groups are free $\mathbb{Z}_m$ -modules, will be given in the appendix.

3.3.1. Noncatastrophicity. The classical definition of noncatastrophic encoders is the following.

DEFINITION 3.3. *A convolutional encoder $\phi : U^{\mathbb{N}} \rightarrow V^{\mathbb{N}}$ is noncatastrophic if, for all $\mathbf{u} \in U^{\mathbb{N}}$, $w_H(\phi(\mathbf{u})) < \infty$ implies that $w_H(\mathbf{u}) < \infty$.*

An useful remark is that systematic encoders are surely noncatastrophic. Also, noncatastrophic encoders have the following nice characterization (direct consequence of [19, Corollary 1, p. 41]).

PROPOSITION 3.4. *Let $\phi : U^{\mathbb{N}} \rightarrow V^{\mathbb{N}}$ be a convolutional encoder. The following conditions are equivalent:*

1. ϕ is noncatastrophic,
2. ϕ admits a polynomial left inverse,
3. there exists $\mu > 0$ such that, for all $\mathbf{u} \in U^{\mathbb{N}}$, $w_H(\mathbf{u}) \leq \mu w_H(\phi(\mathbf{u}))$ holds.

Notice that condition 2 gives a practical tool for testing if an encoder is noncatastrophic, and it also shows that noncatastrophicity is a property stronger than injectivity. Instead condition 3 is a sort of continuity reformulation.

3.3.2. Recursiveness. Binary convolutional encoders are defined to be recursive when no input word with Hamming weight 1 can give a finite-weight output; this property can be easily generalized to our setting.

DEFINITION 3.5. *Given a weight $\mathbf{w} : U \rightarrow \mathbb{N}^\rho$, a convolutional encoder $\phi : U^\mathbb{N} \rightarrow Y^\mathbb{N}$ is $\mathbf{w}$ -recursive if, for all $\mathbf{u} \in U^\mathbb{N}$ such that $|\mathbf{w}(\mathbf{u})| = 1$, $w_H(\phi(\mathbf{u})) = +\infty$ holds.*

When $\mathbf{w}$ is the Hamming weight, this is the usual definition of recursiveness.

See the appendix for a characterization of recursive encoders on free $\mathbb{Z}_m$ -modules which allows one to easily test for recursiveness.

3.3.3. Small input-weight codewords. All convolutional encoders, including the recursive ones, admit nonzero finite support input sequences whose image also has finite support. This fact is obvious from the rationality property. Indeed, if the transfer function $\phi(D)$ is of type $\phi(D) = p(D)^{-1}\phi'(D)$, where $p(D) \in \mathbb{Z}((D))^* \cap \mathbb{Z}[D]$ and $\phi'(D) \in \text{Hom}(U, Y)[D]$, we can observe that any polynomial input of type $u(D) = p(D)v(D)$ for some $v(D) \in U[D]$ is transformed into another polynomial $\phi(D)u(D) = \phi'(D)v(D)$.

We now present a sharper result which shows how to construct input sequences with support of cardinality 2, whose image has finite support: this will be useful later on.

PROPOSITION 3.6. *Let $\phi : U^\mathbb{N} \rightarrow Y^\mathbb{N}$ be a convolutional encoder, and let $u_1, \dots, u_r \in U$ be such that $\sum u_i = 0$. We can find time instants $t_1, \dots, t_r$ such that given $\mathbf{u} = \sum u_j D^{t_j}$ we have that $\phi(\mathbf{u})$ has finite support.*

Proof. Consider the transfer function $\phi(D) = \sum_k \phi_k D^k$. By rationality we know there exist $k_0 \in \mathbb{N}$ and $T \in \mathbb{N}$ such that $\phi_k = \phi_{k+T}$ for every $k \geq k_0$. Consider now the input sequence $\mathbf{u} = \sum_j u_j D^{(j-1)T}$. We have that

$$\phi(\mathbf{u})_t = \sum_{j=1}^r \phi_{t-(j-1)T} u_j.$$

Notice that if we choose $t \geq k_0 + (r-1)T$, then we can easily obtain that $\phi_{t-(j-1)T} = \phi_t$ for every j , and therefore $\phi(\mathbf{u})_t = 0$. This proves the result. $\square$

From the above result, we obtain as an immediate corollary the following property—well known at least for the binary case.

PROPOSITION 3.7. *Given a recursive convolutional encoder $\phi : U^\mathbb{N} \rightarrow Y^\mathbb{N}$, there exists $\delta \in \mathbb{N}$ such that for any $u \in U$ the input sequence $\mathbf{u} = u - uD^\delta$ is an error event.*

3.3.4. Free distance. In the classical analysis by Benedetto et al. [2], an essential design parameter is the free distance of the outer encoder. When the concatenating group is not the group of all permutations (the classical uniform interleaver), we have to consider a slightly different parameter; instead of taking the minimum Hamming weight among non-zero outer codewords, we minimize some other suitable weight.

DEFINITION 3.8. *Given a convolutional encoder $\phi : U^\mathbb{N} \rightarrow Y^\mathbb{N}$ and a weight $\mathbf{w} : Y^\mathbb{N} \rightarrow \mathbb{N}^\rho$, we define the $\mathbf{w}$ -free distance of ϕ to be*

$$d_f(\phi, \mathbf{w}) = \min\{|\mathbf{w}(\mathbf{c})| : \mathbf{c} = \phi(\mathbf{u}), \mathbf{u} \in U^\mathbb{N}, \mathbf{u} \neq \mathbf{0}\}.$$

The classical free distance is the w_H -free distance.

3.4. Terminated convolutional encoders. Suppose $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$ is a convolutional encoder with minimal state space X . We now define the terminated block codes associated with ϕ as follows.

Fix $N \in \mathbb{N}^*$. Given a vector $\mathbf{u} = (u_0, \dots, u_{N-1}) \in U^N$, let x_N be the corresponding state at time N . Because of the reachability condition it is possible to find input elements $\tilde{u}_N, \dots, \tilde{u}_{N+\nu-1}$ such that the state at time $N + \nu - 1$ is equal to 0. This input string may not be unique and we assume we have fixed a specific one as a function of the terminal state x_N we had reached in such a way that the mapping

$$x_N \mapsto (\tilde{u}_N, \dots, \tilde{u}_{N+\nu-1})$$

is a homomorphism. It is a straightforward algebraic verification that this is always indeed possible. Given $\mathbf{u} = (u_0, \dots, u_{N-1}) \in U^N$, we now consider the associated input sequence $\tilde{\mathbf{u}} = (u_0, \dots, u_{N-1}, \tilde{u}_N, \dots, \tilde{u}_{N+\nu-1}, 0, 0, \dots)$. We then define the *N-terminated block encoder* as

$$\phi^N : U^N \rightarrow Y^{N+\nu}, \quad \phi^N(\mathbf{u}) = \phi(\tilde{\mathbf{u}})|_{[0, N+\nu-1]}.$$

For the assumptions made, ϕ^N is also a homomorphism. $\mathcal{C}^N = \text{Im } \phi^N$ is called the *N-block code* associated to ϕ^N .

An input vector $\mathbf{u} \in U^N$ is an input error event for ϕ^N if $\tilde{\mathbf{u}} \in U^{\mathbb{N}}$ is an input error event for ϕ . In this case $\mathbf{c} = \phi^N(\mathbf{u})$ is called an error event for ϕ^N . Suppose the active window of $\tilde{\mathbf{u}}$ is equal to $[t_1, t_2]$. Then, the (input) error event is said to be *regular* if $t_2 \leq N$, otherwise it is called *terminated*. For a terminated error event, we define its length to be $N - t_1$.

Notice that any codeword $\mathbf{c} \in \mathcal{C}^N$ can be written as $\mathbf{c} = \sum_{j=1}^{n+1} \mathbf{c}_j$, where $\mathbf{c}_j$ are regular error events for $j = 1, \dots, n$ and $\mathbf{c}_{n+1}$ is either zero or a terminating error event and the active windows of all of these events are disjoint. We will use the notation $n(\mathbf{c})$ to denote the number of regular error events in the above decomposition of $\mathbf{c}$. Also notice that the above decomposition is unique, up to a permutation of the regular error events.

Some codewords have a decomposition in error events which is the same up to shifts of their error events, and for this reason they share many important properties. More formally, we propose the following definition:

- Two error events $\mathbf{c} = \phi^N(\mathbf{u})$ and $\mathbf{c}' = \phi^{N'}(\mathbf{u}')$ (notice that possibly $N \neq N'$) are said to be *shift equivalent* if the corresponding extended inputs $\tilde{\mathbf{u}}, \tilde{\mathbf{u}}' \in U^{\mathbb{N}}$ differ only by a shift.
- Two codewords $\mathbf{c} = \phi^N(\mathbf{u})$ and $\mathbf{c}' = \phi^{N'}(\mathbf{u}')$ are said to be *shift equivalent* if there exist error event decompositions $\mathbf{c} = \sum_{j=1}^{n+1} \mathbf{c}_j$ and $\mathbf{c}' = \sum_{i=1}^{n'+1} \mathbf{c}'_i$ such that $\mathbf{c}_i$ and $\mathbf{c}'_i$ are shift equivalent for all i .

Notice that, given two shift equivalent codewords $\mathbf{c}$ and $\mathbf{c}'$, it is clear that $n(\mathbf{c}) = n(\mathbf{c}')$ and, moreover, given a weight $\mathbf{w}$ on the alphabet Y , $\mathbf{w}(\mathbf{c}) = \mathbf{w}(\mathbf{c}')$.

Remark 3.9. Now we want to underline a property which is somehow similar to an inclusion of $\mathcal{C}^N$ in $\mathcal{C}^{N'}$ for $N \leq N'$ (while strictly speaking an inclusion cannot occur, as the two codes are subsets of different spaces). If $N \leq N'$, then for all $\mathbf{c} \in \mathcal{C}^N$ we can construct $\mathbf{c}' \in \mathcal{C}^{N'}$ such that $\mathbf{c}$ and $\mathbf{c}'$ are shift equivalent, by properly adding zeros.

3.5. Enumerating functions and growth estimates. A fundamental concept for all encoders is the so-called weight enumerating function, since it is well known to play a basic role in all performance evaluations. While in the binary case,

there is only one possible weight to be considered, namely the Hamming one, in our setting many choices are possible, and we will need to consider different possibilities in later sections. We start by defining the basic possibility based on the Hamming weights in the input and output groups.

DEFINITION 3.10. *Given a convolutional encoder $\phi : U^{\mathbb{N}} \rightarrow Y^{\mathbb{N}}$, consider its associated N -terminated block encoder $\phi^N : U^N \rightarrow Y^{N+\nu}$. Define its input/output support enumerating coefficients as*

$$\Lambda_{w,d,n}^N = |\{\mathbf{u} \in U^N : w_H(\mathbf{u}) = w, w_H(\phi^N(\mathbf{u})) = d, n(\phi^N(\mathbf{u})) = n\}|.$$

In some cases, we will need to replace the Hamming weight with other possible weights in the input and the output. We will use the notation $\Lambda_{\mathbf{w},\mathbf{d},n}^N$ to denote enumerating coefficients relative to some specified input weight $\mathbf{w}$ and output weight $\mathbf{d}$.

The following proposition gives a growth estimation for input/output support enumerating coefficients, which will allow us to have general bounds (even if quite loose) on all of the different weight enumerators. We omit the proof, which is a straightforward generalization of Proposition 10 in [15].

PROPOSITION 3.11. *There exist two positive constants a and b such that*

$$\Lambda_{w,d,n}^N \leq \binom{N+n}{n} a^w b^d.$$

4. Serial ensembles.

4.1. Serial interconnections. We now precisely define the serial interconnected schemes we are going to consider. We start with a Γ -symmetric channel. We also fix the *input* Abelian group U . All encoders we will consider will be driven by words on U and will output symbols in Γ . The interconnection will take place through a third Abelian group, say Y , called the *interconnection* group. We now fix two convolutional encoders denoted, respectively, the *outer* and *inner* encoder:

$$\phi_o : U^{\mathbb{N}} \rightarrow (Y^r)^{\mathbb{N}}, \quad \phi_i : (Y^s)^{\mathbb{N}} \rightarrow (\Gamma^l)^{\mathbb{N}}.$$

Denote by ν_o and ν_i the reachability indices of ϕ_o and ϕ_i , respectively, and define the set $\mathcal{N} = \{N \in \mathbb{N}^* : s|r(N + \nu_o)\}$. Consider now the terminations for $N \in \mathcal{N}$:

$$\phi_o^N : U^N \rightarrow Y^{r(N+\nu_o)}, \quad \phi_i^N : Y^{sM_N} \rightarrow \Gamma^{l(M_N+\nu_i)},$$

where $sM_N = r(N + \nu_o)$. We now fix, for every $N \in \mathbb{N}^*$, a subgroup $G_N \subseteq \text{Aut}(Y^{r(N+\nu_o)})$. The triple $(\phi_o, \phi_i, (G_N)_{N \in \mathcal{N}})$ is said to be a *serial interconnected ensemble*. The asymptotic rate of the serial interconnected ensemble above is defined by the product

$$R = \frac{\log |U|}{r} \frac{s}{l} \text{ bits per channel use.}$$

To the serial interconnected ensemble above we can associate a random sequence of encoders and codes as follows. Define Π_N to be a r.v. uniformly distributed over G_N , and consider the corresponding homomorphic encoder $\Phi^N = \phi_i^N \circ \Pi_N \circ \phi_o^N$ and group code $\mathcal{C}^N = \text{Im}(\Phi^N)$, which are called, respectively, the *random encoder* and the *random code* associated with the given ensemble.

The following picture describes the above construction:

$$U^N \xrightarrow{\quad} \boxed{\phi_o^N} \xrightarrow{Y^{r(N+\nu_o)}} \boxed{\Pi_N} \xrightarrow{Y^{sM_N}} \boxed{\phi_i^N} \xrightarrow{\Gamma^{l(M_N+\nu_i)}}.$$

In what follows we will denote by $\mathbb{P}$ and $\mathbb{E}$ probability and expected value, respectively, made with respect to the probabilistic space underlying the sequence Π_N . We will also use the notation $\overline{P_w(e)}$ and $\overline{P_s(e)}$, respectively, for the average word and symbol error probabilities.

4.2. Regular ensembles. Our aim is to give asymptotic results for $\overline{P_w(e)}$ and $\overline{P_s(e)}$ when $N \rightarrow \infty$, keeping fixed the constituent encoders. To do so, we need to make further assumptions on the groups G_N : roughly, we need to enforce some compatibility among the groups as N varies, and to avoid that the number of invariants of the group action grows with N . Following [15] we propose the following definition.

DEFINITION 4.1. *The sequence of groups G_N (and the corresponding ensemble) is said to be regular if there exists a weight $\mathbf{w}_G : Y \rightarrow \mathbb{N}^\rho$ such that, for every N and for all $\mathbf{y}, \mathbf{z} \in Y^{r(N+\nu_0)}$, it holds that*

$$\mathbf{w}_G(\mathbf{y}) = \mathbf{w}_G(\mathbf{z}) \Leftrightarrow \exists \sigma \in G_N : \sigma \mathbf{y} = \mathbf{z}.$$

$\mathbf{w}_G(\mathbf{y})$ will be called the invariants weight vector of $\mathbf{y} \in Y^{r(N+\nu_0)}$.

Property of regularity simply says that all actions of the groups G_N on the sets $Y^{r(N+\nu_0)}$ can be described through a finite (constant) family of invariants: the ρ components of the weight $\mathbf{w}_G$. We will use the notation $Y_{\mathbf{h}}^L = \{\mathbf{x} \in Y^L : \mathbf{w}_G(\mathbf{x}) = \mathbf{h}\}$. Moreover, we denote by $G_N(\mathbf{y}, \mathbf{z})$ the subset of elements in G_N mapping $\mathbf{y}$ to $\mathbf{z}$. Using standard results on group actions (the class formula) [26], we can show the following remark.

Remark 4.2.

$$\frac{|G_N(\mathbf{u}, \mathbf{v})|}{|G_N|} = \begin{cases} 0 & \text{if } \mathbf{w}_G(\mathbf{u}) \neq \mathbf{w}_G(\mathbf{v}) \\ 1/|Y_{\mathbf{h}}^{r(N+\nu_0)}| & \text{if } \mathbf{w}_G(\mathbf{u}) = \mathbf{w}_G(\mathbf{v}) = \mathbf{h}. \end{cases}$$

This technical result will be needed later.

LEMMA 4.3. *Assume that $\mathbf{y}, \mathbf{z} \in Y^{r(N+\nu_0)}$ are such that for every index $i \in \{0, \dots, N + \nu_0 - 1\}$, $\mathbf{y}_i \neq \mathbf{0}$ yields $\mathbf{z}_i = \mathbf{0}$. Then, given any $\sigma \in G_N$ and given any i we have that $(\sigma \mathbf{y})_i \neq \mathbf{0} \Rightarrow (\sigma \mathbf{z})_i \neq (\sigma \mathbf{y})_i$.*

Proof. Notice that $|\mathbf{w}_G(\sigma \mathbf{y} + \sigma(-\mathbf{z}))| = |\mathbf{w}_G(\mathbf{y} - \mathbf{z})| = |\mathbf{w}_G(\mathbf{y})| + |\mathbf{w}_G(-\mathbf{z})|$. On the other hand, if $\sigma \mathbf{y}$ and $\sigma \mathbf{z}$ were equal in an index where they are not equal to $\mathbf{0}$, then by point 2 of Definition 2.1 we would have

$$|\mathbf{w}_G(\sigma \mathbf{y} + \sigma(-\mathbf{z}))| < |\mathbf{w}_G(\sigma \mathbf{y})| + |\mathbf{w}_G(\sigma(-\mathbf{z}))| = |\mathbf{w}_G(\mathbf{y})| + |\mathbf{w}_G(-\mathbf{z})|.$$

This ends the proof. $\square$

We now present two fundamental examples of regular actions.

1. *Symbol permutation.* In this case we simply take $G_N = S_{r(N+\nu_0)}$, i.e., the full symmetric group acting on $Y^{r(N+\nu_0)}$ by standard permutation. In this case the invariant weight is the type weight: $\rho = |Y| - 1$ and $\mathbf{w}_G(y) \in \mathbb{N}^\rho$ by $(\mathbf{w}_G(y))_a = \chi_a(y)$ as a varies in $Y \setminus \{0\}$. Notice that

$$|Y_{\mathbf{h}}^{r(N+\nu_0)}| = \binom{r(N+\nu_0)}{\mathbf{h}}.$$

2. *Separate channels symbol permutation.* Assume $Y = Y_1 \times Y_2$, and assume $G_{N,1}$ and $G_{N,2}$ are sequences of groups acting regularly on $Y_1^{r(N+\nu_0)}$ and $Y_2^{r(N+\nu_0)}$, respectively, with invariant weights $\mathbf{w}_G^1 : Y_1 \rightarrow \mathbb{N}^{\rho_1}$ and $\mathbf{w}_G^2 : Y_2 \rightarrow \mathbb{N}^{\rho_2}$, respectively. Then, we can consider a regular action given by $G_N = G_{N,1} \times G_{N,2}$ acting

componentwise on $Y_1 \times Y_2$. Its invariant weight is given by $\mathbf{w}_G : Y_1 \times Y_2 \rightarrow \mathbb{N}^{\rho_1 + \rho_2}$, $\mathbf{w}_G(y_1, y_2) = (\mathbf{w}_G^1(y_1), \mathbf{w}_G^2(y_2))$. Notice that in this case

$$\left| Y_{\mathbf{h}_1, \mathbf{h}_2}^{r(N+\nu_o)} \right| = \binom{r(N+\nu_o)}{\mathbf{h}_1} \binom{r(N+\nu_o)}{\mathbf{h}_2}.$$

4.3. Examples of serial ensembles. Below we assume that $\Gamma = \mathbb{Z}_m$.

- *Repeat-convolute codes.* We choose $U = Y = \mathbb{Z}_m$ and $\phi_o = \text{Rep}_r : \mathbb{Z}_m^{\mathbb{N}} \rightarrow (\mathbb{Z}_m^r)^{\mathbb{N}}$ to be the r -repetition encoder $\text{Rep}_r(\mathbf{u})_t = (u_t, \dots, u_t)$. We let $\phi_i : (\mathbb{Z}_m^s)^{\mathbb{N}} \rightarrow (\mathbb{Z}_m^s)^{\mathbb{N}}$ be a rate-1 noncatastrophic convolutional encoder. Finally, we choose for the coupling interleavers the symbol permutation groups $G_N = S_{rN}$. The corresponding invariant weight is thus the type weight $\mathbf{w}_T : \mathbb{Z}_m^r \rightarrow \mathbb{N}^{m-1}$, where $(\mathbf{w}_T(\mathbf{y}))_j$ is the number of elements equal to j in the vector $\mathbf{y} \in \mathbb{Z}_m^r$. The rate of the scheme is

$$R = \frac{\log m}{r} \text{ bits per channel use.}$$

For this ensemble, we will need the assumption that ϕ_i is $\mathbf{w}$ -recursive, which is the same as requiring that it is $\mathbf{w}_H$ -recursive.

- *Structured LDPC codes.* We choose $U = \mathbb{Z}_m$, $Y = \mathbb{Z}_m^c \times \mathbb{Z}_m$, and the systematic encoder $\phi_o : \mathbb{Z}_m^{\mathbb{N}} \rightarrow (\mathbb{Z}_m^c \times \mathbb{Z}_m)^{\mathbb{N}}$, $\phi_o(\mathbf{u}) = (\text{Rep}_c(\mathbf{u}), \mathbf{u})$. Instead ϕ_i is itself the serial interconnection of two encoders. We consider $\text{Sum}_d : (\mathbb{Z}_m^d)^{\mathbb{N}} \rightarrow \mathbb{Z}_m^{\mathbb{N}}$ defined by $\text{Sum}_d(\mathbf{y}) = (y_1 + \dots + y_d, y_{d+1} + \dots + y_{2d}, \dots)$, and we take a $\mathbf{w}_H$ -recursive noncatastrophic rate-1 convolutional encoder $\psi : \mathbb{Z}_m^{\mathbb{N}} \rightarrow \mathbb{Z}_m^{\mathbb{N}}$. Finally, we take $\phi_i : (\mathbb{Z}_m^d \times \mathbb{Z}_m)^{\mathbb{N}} \rightarrow (\mathbb{Z}_m \times \mathbb{Z}_m)^{\mathbb{N}}$, defined by

$$\phi_i(\mathbf{y}^1, \mathbf{y}^2) = ((\psi \circ \text{Sum}_d)(\mathbf{y}^1), \mathbf{y}^2).$$

When taking the truncated versions of these encoders, we must make sure to have suitable lengths, so we take $\phi_o^N : \mathbb{Z}_m^{dN} \rightarrow \mathbb{Z}_m^{cdN} \times \mathbb{Z}_m^{dN}$ and $\phi_i^N : \mathbb{Z}_m^{cdN} \times \mathbb{Z}_m^{dN} \rightarrow \mathbb{Z}_m^{cN+\nu_\psi} \times \mathbb{Z}_m^{dN} = \Gamma^{(c+d)N+\nu_\psi}$. Therefore, the design rate of the serial encoder $\phi^N = \phi_i^N \circ \Pi_N \circ \phi_o^N$ is $R = \log m \frac{d}{c+d}$.

As an interconnection group, we choose the separated channels symbol permutation $G_N = S_{cdN} \times S_{dN}$.

This family of codes is a generalization of the repeat-convolute codes: the additional summator Sum_d is the same as the grouping factor introduced in irregular repeat accumulate codes [27].

We can easily construct a parity-check matrix for the code $\mathcal{C}^N = \text{Im}(\Phi^N) \subseteq \mathbb{Z}_m^{(c+d)N+\nu_\psi}$, which is sparse and has a structured and a random part, so that we have a structured LDPC ensemble, generalizing staircase LDPC codes. In fact, notice that

$$\begin{aligned} (\mathbf{c}^1, \mathbf{c}^2) \in \mathcal{C}^N &\Leftrightarrow \mathbf{c}^1 = \psi^N \circ \text{Sum}_d \circ \pi_N^1 \circ \text{Rep}_c \circ (\pi_N^2)^{-1}(\mathbf{c}^2) \\ &\Leftrightarrow (\psi^N)^{-1}(\mathbf{c}^1) = \text{Sum}_d \circ \pi_N^1 \circ \text{Rep}_c \circ (\pi_N^2)^{-1}(\mathbf{c}^2). \end{aligned}$$

It is clear that the permutation π_N^2 does not play any essential role: we needed it only to fit this scheme in our assumptions, but we can take it out without changing the performance of the scheme.

Note that the noncatastrophicity of ϕ_i is needed to make the syndrome matrix low density, i.e., with a number of nonzero elements per row and per column

which is small and does not grow with N . More precisely, the matrix $H_2 = \text{Sum}_d \pi_N^1 \text{Rep}_d$ is a random low density matrix with entries in $\{0, 1\}$, depending only on c , d , and π_N , with at most c elements equal to 1 in each column and at most d on any row. Instead $H_1 = (\psi^N)^{-1}$ depends on the choice of ψ and is also low density, having a number of nonzero elements per row and per column at most equal to the degree of the polynomial $\psi^{-1}(D)$.

5. Main result: Interleaver gain. The well-known analysis by Benedetto et al. [2] showed an interleaver gain, in the sense that average error probability is asymptotically vanishing when the interleaver length grows. Their result holds true under the assumption that both constituent encoders are systematic recursive convolutional encoders and that the free distance of the outer encoder was $d_f^o \geq 2$ to ensure $\overline{P_b(e)} \rightarrow 0$ and $d_f^o \geq 3$ to have also $\overline{P_w(e)} \rightarrow 0$.

In this section, we will comment on how the classical assumptions on the constituent encoders can be adapted to our setting, and we will state our results on the interleaver gain; all of the proofs will be given in section 6. Proofs' techniques are inspired by [15], but they cannot be seen as consequences of the results in [15]: the fact of working with serial interconnections and in a nonbinary situation makes the derivation quite different and the combinatorics more involved.

From now on, we will be always considering a regular serial ensemble (see Definition 4.1) with outer encoder $\phi_o : U^{\mathbb{N}} \rightarrow (Y^r)^{\mathbb{N}}$ and inner encoder $\phi_i : (Y^s)^{\mathbb{N}} \rightarrow (\Gamma^l)^{\mathbb{N}}$, and with a family of interconnection groups (G_N) with invariants weight vector $\mathbf{w}_G$. The symbol error probability will be with respect to a fixed weight on the input group U , denoted $\mathbf{w}_{\text{in}}$, with the requirement that $\mathbf{w}_{\text{in}}(u) \neq 0$ for all $u \neq 0$.

First of all, we have to generalize the assumptions about the constituent encoders introduced in [2].

When considering one single convolutional encoder, noncatastrophicity is usually needed to ensure good asymptotic properties. However, when dealing with a concatenated scheme the assumption that all constituent encoders are noncatastrophic can be slightly weakened, as it was already recognized, for example in [15] and [25] (in the latter, the authors consider serial schemes where the inner encoder is heavily punctured and becomes not injective). The essential assumption is that the overall scheme is noncatastrophic, and this can be obtained by asking classical noncatastrophicity of the outer encoder and a weaker property of the inner encoder: ϕ_i must be noncatastrophic when restricted to the inputs he will actually receive, i.e., the permuted outer codewords.

When we are dealing with ensembles of concatenated codes, each code of the ensemble must be noncatastrophic in the sense specified above. This leads to the following definition.

DEFINITION 5.1. *A regular serial ensemble with constituent encoders $\phi_o : U^{\mathbb{N}} \rightarrow (Y^r)^{\mathbb{N}}$ and $\phi_i : (Y^s)^{\mathbb{N}} \rightarrow (\Gamma^l)^{\mathbb{N}}$ and regular group family (G_N) is concatenatedly noncatastrophic if there exist two positive constants μ_o and μ_i such that for all $N \in \mathbb{N}^*$ and for all $\mathbf{u} \in U^{\mathbb{N}}$:*

1. $w_H(\mathbf{u}) \leq \mu_o |\mathbf{w}_G(\phi_o^N(\mathbf{u}))|$,
2. for all $\pi \in G_N$, $|\mathbf{w}_G(\phi_o^N(\mathbf{u}))| \leq \mu_i w_H(\phi_i^N \circ \pi \circ \phi_o^N(\mathbf{u}))$.

Notice that 1. is equivalent to the noncatastrophicity of ϕ_o (see Proposition 3.4). In the examples introduced in section 4.3, we have an example where both encoders are noncatastrophic (repeat-convolute), and an example where only concatenated noncatastrophicity is true (structured LDPC). In fact, in this second example, noncatastrophicity of ψ ensures sparsity of the parity-check matrix, but due to noninjectivity

of Sum_d the inner encoder is indeed catastrophic; overall noncatastrophicity of the concatenated scheme is ensured by the systematic branch.

Concerning the other classical assumptions on the constituent encoders ($d_f^o \geq 3$ and recursiveness of ϕ_i), clearly they must be restated considering the suitable connecting weight $\mathbf{w}_G$ instead of Hamming weight, using the definitions introduced in section 3. However, we will comment later in this section why these assumptions are sufficient and not necessary to obtain some interleaver gain, and how they can be weakened.

Now we will introduce some useful definitions, and then state the interleaver gain result, which will answer the questions: Is the average error probability asymptotically vanishing when the interleaver length grows to infinity? If so, how fast is the decay? From now on, we will always assume that we are considering a concatenatedly noncatastrophic ensemble.

Let $\mathcal{C}_o^N = \phi_o^N(U^N) \subseteq Y^{r(N+\nu_o)}$ be the outer block code, and let

$$H = \{\mathbf{w}_G(\mathbf{c}) : \mathbf{c} \in \mathcal{C}_o^N \text{ for some } N, \mathbf{c} \neq \mathbf{0}\}.$$

Notice that, with this notation, (2) in Definition 5.1 is equivalent to

$$\forall N \in \mathbb{N}^*, \forall \mathbf{h} \in H, \forall \mathbf{c} \in Y^{r(N+\nu_o)} \text{ such that } \mathbf{w}_G(\mathbf{c}) = \mathbf{h}, |\mathbf{h}| \leq \mu_i |\mathbf{w}_T(\phi_i^N(\mathbf{c}))|.$$

Given $\mathbf{h} \in H$, we look at the decomposition of codewords in error events, as defined in sections 3.1 and 3.4, and we define

- $n_o(\mathbf{h}) = \max\{n(\mathbf{c}) \text{ such that } \exists N, \exists \mathbf{c} \in \mathcal{C}_o^N : \mathbf{w}_G(\mathbf{c}) = \mathbf{h}\},$
- $n_i(\mathbf{h}) = \max\{n(\mathbf{x}) \text{ s.t. } \exists N, \exists \mathbf{u} \in Y^{r(N+\nu_o)} : \mathbf{x} = \phi_i^N(\mathbf{u}), \mathbf{w}_G(\mathbf{u}) = \mathbf{h}\},$
- $f(\mathbf{h}) = 1 + |\mathbf{h}| - n_o(\mathbf{h}) - n_i(\mathbf{h}).$

Remark 5.2. Both maxima in the above definition are well defined, since we clearly have $n(\mathbf{c}) \leq |\mathbf{h}|$, $n(\mathbf{x}) \leq |\mathbf{h}|$. Moreover, notice that, because of Remark 3.9 in section 3.4, the sequence of sets $\{n(\mathbf{c}) \text{ such that } \exists \mathbf{c} \in \mathcal{C}_o^N : \mathbf{w}_G(\mathbf{c}) = \mathbf{h}\}$ is increasing in N . Therefore there exists $\bar{N}(\mathbf{h})$ such that

$$n_o(\mathbf{h}) = \max\{n(\mathbf{c}) \text{ such that } \exists \mathbf{c} \in \mathcal{C}_o^{\bar{N}(\mathbf{h})} : \mathbf{w}_G(\mathbf{c}) = \mathbf{h}\}.$$

An analogous statement holds true for $n_i(\mathbf{h})$.

It is also clear that the maximum defining $n_o(\mathbf{h})$ can always be obtained with a codeword which admits only regular error events, while this is not necessarily true for $n_i(\mathbf{h})$.

Finally, we define

$$(5.1) \quad \alpha = \inf\{f(\mathbf{h}), \mathbf{h} \in H\}.$$

Notice that the function f takes values in $\mathbb{Z}$ and H is nonempty, so either $\alpha = -\infty$ or $\alpha = \min\{f(\mathbf{h}), \mathbf{h} \in H\}$.

Our main result (formally stated in Theorem 5.4) is that, for sufficiently good channels, if $\alpha \geq 1$, then

$$\overline{P_s(e)} \asymp N^{-\alpha} \quad \text{and} \quad \overline{P_w(e)} \asymp N^{-\alpha+1} \quad \text{for } N \rightarrow \infty.$$

We will give sufficient conditions ensuring that $\alpha \geq 1$, enforcing some properties on the constituent encoders (Propositions 5.5 and 5.7).

In addition to the decay of $\overline{P_s(e)}$ and $\overline{P_w(e)}$ asymptotically in N , we want to underline the dependence of the error probability on the channel's SNR, following

the steps of Benedetto et al. [2] and looking for a design parameter analogous of the classical effective free distance.

We define the set of the vectors $\mathbf{h}$ minimizing $f(\mathbf{h})$:

$$\mathcal{H} = \{\mathbf{h} \in H : f(\mathbf{h}) = \alpha\},$$

and we define the effective distance

$$q^* = \max_{\mathbf{h} \in \mathcal{H}} \{q^*(\mathbf{h})\},$$

where

$$q^*(\mathbf{h}) = \max\{P(\mathbf{0} \rightarrow \mathbf{x}) : \exists N, \exists \mathbf{u} \in Y^{r(N+\nu_o)} : \mathbf{x} = \phi_i^N(\mathbf{u}), \mathbf{w}_G(\mathbf{u}) = \mathbf{h}, n(\mathbf{x}) = n_i(\mathbf{h})\}.$$

Remark 5.3. We can prove that maxima in the definitions of $q^*(\mathbf{h})$ and q^* are well defined. In principle the number of $\mathbf{x}$ involved in the maximum defining $q^*(\mathbf{h})$ is infinite. However, we can always restrict the search to a finite set in the following way. As a first step, we can find an upper bound on the values of $P(\mathbf{0} \rightarrow \mathbf{x})$ to consider trivially by computing $\bar{q} = P(\mathbf{0} \rightarrow \bar{\mathbf{x}})$ for one admissible $\bar{\mathbf{x}}$. Then we restrict our search to the set

$$\bar{X} = \{\mathbf{x} : P(\mathbf{0} \rightarrow \mathbf{x}) \geq \bar{q} \text{ and } \exists N, \exists \mathbf{u} \in Y^{r(N+\nu_o)} : \mathbf{x} = \phi_i^N(\mathbf{u}), \mathbf{w}_G(\mathbf{u}) = \mathbf{h}, n(\mathbf{x}) = n_i(\mathbf{h})\}.$$

Now note that $P(\mathbf{0} \rightarrow \mathbf{x}) \geq \bar{q}$ implies $\gamma^{\mathbf{w}_H(\mathbf{x})} \geq \bar{q}$; i.e., $\mathbf{w}_H(\mathbf{x}) \leq \log \bar{q} / \log \gamma$. Now, by Proposition 3.2, we can bound the length of all error events in the decomposition of $\mathbf{x} \in \bar{X}$. This implies that, up to shift equivalence, the family of all possible error events appearing in $\mathbf{x} \in \bar{X}$ is finite. Therefore, $\bar{X}$, up to shift equivalence, is finite. The same argument also applies to q^* .

Later, we will also see that under suitable assumptions $\mathcal{H}$ is a finite set (Proposition 5.6).

Using the definition of q^* , we can state the interleaver gain result in a stronger way that underlines, additionally to the decay with N , also the dependence on the channel.

THEOREM 5.4. *Consider a regular and concatenatedly noncatastrophic serial ensemble $(\phi_o, \phi_i, (G_N)_{N \in \mathcal{N}})$ corresponding to the encoding scheme*

$$\xrightarrow{U^N} \boxed{\phi_o^N} \xrightarrow{Y^{r(N+\nu_o)}} \boxed{\pi_N} \xrightarrow{Y^{sM_N}} \boxed{\phi_i^N} \xrightarrow{\Gamma^{l(M_N+\nu_i)}}.$$

If $\alpha \geq 1$, then there exist positive constants c, c_1, c_2 , and γ_0 , depending only on ϕ_o, ϕ_i , and (G_N) , such that for all Γ -symmetric channels with Bhattacharyya parameter $\gamma < \gamma_0$

$$c q^* N^{-\alpha} \leq \overline{P_w(e)} \leq c_1 q^* c_2^{(\log q^* / \log \gamma)} N^{-\alpha} + O(N^{-\alpha-1}).$$

Moreover, for a given input weight $\mathbf{w}_{\text{in}}$ (compatible with U and satisfying $\mathbf{w}_{\text{in}}(u) \neq 0$ for all $u \neq 0$),

$$c \frac{\mathbf{w}_{\text{in}}^{\max}}{\mathbf{w}_{\text{in}}^{\min}} q^* N^{-\alpha+1} \leq \overline{P_s(e)} \leq c_1 \frac{\mathbf{w}_{\text{in}}^{\max}}{\mathbf{w}_{\text{in}}^{\min}} q^* c_2^{(\log q^* / \log \gamma)} N^{-\alpha+1} + O(N^{-\alpha}),$$

where $\mathbf{w}_{\text{in}}^{\max} = \max_{u \in U} \mathbf{w}_{\text{in}}(u)$ and $\mathbf{w}_{\text{in}}^{\min} = \min_{u \in U \setminus \{0\}} \mathbf{w}_{\text{in}}(u)$.

The terms q^* in the lower bound and $q^* c_2^{(\log q^* / \log \gamma)}$ in the upper bound describe the behavior of $\overline{P_s(e)}$ and $\overline{P_w(e)}$ with respect to the channel's noise. Note that $q^* =$

$P(\mathbf{0} \rightarrow \mathbf{c})$ for some word $\mathbf{c}$, so that, with the notation $w^* = w_H(\mathbf{c})$, we have $q^* \leq \gamma^{w^*}$, and $\frac{\log q^*}{\log \gamma} \leq w^*$. Theorem 5.4 holds true for any Γ -symmetric channel with $\gamma \leq \gamma_0$. However, it is particularly relevant for families of channels where $\gamma \rightarrow 0$ by preserving the geometry of the channel, thus having constant w^* for all the family: in this case, q^* fully describes the decay of error probability when $\gamma \rightarrow 0$ (i.e., SNR grows to infinity). For example, one can consider BSC with crossover probability ϵ and let $\epsilon \rightarrow 0$, or an S -AWGN channel, fix the shape of the constellation and let $E_s/N_0 \rightarrow \infty$.

Now we will show how the free distance of ϕ_o and the recursiveness of ϕ_i come into the picture. First of all, we generalize the classical assumptions in the most natural way, simply replacing Hamming weight with the interconnection weight $\mathbf{w}_G$, which will ensure that there is an interleaving gain (namely that $\alpha \geq 1$). From now on, let's denote by d_f^o the $\mathbf{w}_G$ -free distance of ϕ_o .

PROPOSITION 5.5. *Assume that $d_f^o \geq 2$ and ϕ_i is $\mathbf{w}_G$ -recursive. Then*

$$\lfloor (d_f^o + 1)/2 \rfloor \leq \alpha \leq d_f^o.$$

In particular, $\alpha \geq 1$, and if $d_f^o \geq 3$, then $\alpha \geq 2$.

In some particular cases we will give tighter upper bounds on α (see section 7).

The strong assumptions used in Proposition 5.5 have another interesting consequence.

PROPOSITION 5.6. *If $d_f^o \geq 3$ and ϕ_i is $\mathbf{w}_G$ -recursive, then $\mathcal{H}$ is a finite set.*

However, these assumptions are not necessary to obtain an interleaver gain. For example, in the case of parallel concatenations with multiple branches, these assumptions would mean that all constituent encoders are recursive, while it is known that there is an interleaver gain, even if smaller, when only some of them are recursive [15]. Also, a relaxation of the classical assumptions will allow us to give results about very interesting examples, such as the heavily punctured serial schemes considered in [25], or the class of structured LDPC interpreted as serial schemes that we introduced in section 4.3. Thus, we are interested in a generalization of Proposition 5.5.

PROPOSITION 5.7. *Assume that the interconnection weight has the structure $\mathbf{w}_G = (\mathbf{w}_1, \mathbf{w}_2) : Y^{sM} \rightarrow \mathbb{N}^{\rho_1} \times \mathbb{N}^{\rho_2}$ (possibly $\rho_2 = 0$, but $\rho_1 \geq 1$); denote by $d_{f,1}^o$ the $\mathbf{w}_1$ -free distance of ϕ_o . Assume that $d_{f,1}^o \geq 2$ and ϕ_i is $\mathbf{w}_1$ -recursive. Then,*

$$\lfloor (d_{f,1}^o + 1)/2 \rfloor \leq \alpha \leq d_{f,1}^o.$$

In particular, $\alpha \geq 1$, and if $d_{f,1}^o \geq 3$, then $\alpha \geq 2$.

Notice that Proposition 5.5 is a particular case of Proposition 5.7, where $\rho_2 = 0$ and therefore $d_f^o = d_{f,1}^o$.

6. Proofs of the main results. In this section, we prove our main results; i.e., Theorem 5.4 and Proposition 5.7. We prove the upper bound for $\overline{P_s(e)}$ and the lower bound for $\overline{P_w(e)}$; the whole result stated in Theorem 5.4 is then obtained by the simple remark

$$\overline{P_s(e)} \geq \frac{1}{N} \frac{\mathbf{w}_{\text{in}}^{\min}}{\mathbf{w}_{\text{in}}^{\max}} \overline{P_w(e)}.$$

6.1. Upper bound. This proof is based on the union-Bhattacharyya bound (see, e.g., [28]) and on estimations of the weight enumerating coefficients of the constituent encoders.

We will consider only the case when the symbol error rate $P_s(e)$ is defined with respect to Hamming input weight ($\mathbf{w}_{\text{in}} = \mathbf{w}_H$); however, this will give results true for every other compatible weight, up to a positive constant factor.

The well-known union bound gives

$$(6.1) \quad \overline{P_s(e)} \leq \sum_w \sum_{\mathbf{d}} \frac{w}{N} \overline{A_{w,\mathbf{d}}}^N Q(\mathbf{d}),$$

where $\overline{A_{w,\mathbf{d}}}^N$ is the average number of codewords of a serial ensemble with input Hamming weight w and output type weight $\mathbf{d}$.

The standard technique (see [28, 2]) is to express $\overline{A_{w,\mathbf{d}}}^N$ as a function of suitable enumerating coefficients of the constituent encoders. Here, we need the following:

- $A_{w,\mathbf{h}}^{o,N}$, the number of codewords of ϕ_o^N with input Hamming weight w , and output invariants weight vector $\mathbf{h}$,
- $A_{\mathbf{h},\mathbf{d}}^{i,N}$, the number of codewords of ϕ_i^N with input invariants weight vector $\mathbf{h}$, and output type weight $\mathbf{d}$.

PROPOSITION 6.1. $\overline{A_{w,\mathbf{d}}}^N = \sum_{\mathbf{h} \in H} \frac{A_{w,\mathbf{h}}^{o,N} A_{\mathbf{h},\mathbf{d}}^{i,N}}{|Y_{\mathbf{h}}^{r(N+\nu_o)}|}$.

Proof.

$$\overline{A_{w,\mathbf{d}}}^N = \sum_{\mathbf{u}: \mathbf{w}_H(\mathbf{u})=w} \sum_{\mathbf{v}: \mathbf{w}_T(\phi_i^N(\mathbf{v}))=\mathbf{d}} \mathbb{P}(\Pi_N(\phi_o^N(\mathbf{u})) = \mathbf{v}).$$

By Remark 4.2,

$$\mathbb{P}(\Pi_N(\phi_o^N(\mathbf{u})) = \mathbf{v}) = \frac{|G_N(\phi_o^N(\mathbf{u}), \mathbf{v})|}{|G_N|} = \begin{cases} 0 & \text{if } \mathbf{w}_G(\phi_o^N(\mathbf{u})) \neq \mathbf{w}_G(\mathbf{v}) \\ \frac{1}{|Y_{\mathbf{h}}^{r(N+\nu_o)}|} & \text{if } \mathbf{w}_G(\phi_o^N(\mathbf{u})) = \mathbf{w}_G(\mathbf{v}) = \mathbf{h}. \end{cases}$$

Substituting in the expression above, we obtain the thesis. $\square$

By Lemma 2.2, we know that $|Y_{\mathbf{h}}^{r(N+\nu_o)}| \geq \binom{r(N+\nu_o)}{\mathbf{h}}$. Thus, by the inequality (6.1) and Proposition 6.1 we have

$$(6.2) \quad \overline{P_s(e)} \leq \sum_{w,\mathbf{h},\mathbf{d}} \frac{w}{N} \frac{1}{\binom{r(N+\nu_o)}{\mathbf{h}}} A_{w,\mathbf{h}}^{o,N} A_{\mathbf{h},\mathbf{d}}^{i,N} Q(\mathbf{d}).$$

We have some inequalities involving the indexes $w, \mathbf{h}, \mathbf{d}$ which are necessary conditions to have nonzero $A_{w,\mathbf{h}}^{o,N} A_{\mathbf{h},\mathbf{d}}^{i,N}$. They are listed in Definition 6.2 and Proposition 6.3.

DEFINITION 6.2. Let $I \subseteq \mathbb{N}^* \times H \times \mathbb{N}^{\Gamma \setminus \{0\}}$ be the set of triples $(w, \mathbf{h}, \mathbf{d})$ satisfying the following conditions:

- $1 \leq w \leq N$,
- $|\mathbf{d}| \leq l(M_N + \nu_i)$,
- $w \leq \mu_o |\mathbf{h}|$ and $|\mathbf{h}| \leq \mu_i |\mathbf{d}|$ (μ_o and μ_i as in Definition 5.1).

PROPOSITION 6.3. If $(w, \mathbf{h}, \mathbf{d}) \notin I$, then $A_{w,\mathbf{h}}^{o,N} A_{\mathbf{h},\mathbf{d}}^{i,N} = 0$.

Proof. The first two inequalities are trivial remarks about the length of the input and codewords and the definition of free distance; the last one is the concatenated noncatastrophicity of the ensemble (see Definition 5.1). $\square$

Now, we need to estimate the product $A_{w,\mathbf{h}}^{o,N} A_{\mathbf{h},\mathbf{d}}^{i,N}$ when it is nonzero. We start with the following inequalities derived from Proposition 3.11.

PROPOSITION 6.4. There exist some positive constants a_o, a_i, b_o, b_i such that, for every $(w, \mathbf{h}, \mathbf{d}) \in I$,

$$\begin{aligned}
 1. \quad A_{w, \mathbf{h}}^{o, N} &\leq \sum_{n_o=1}^{n_o(\mathbf{h})} \binom{N+n_o}{n_o} a_o^w b_o^{|\mathbf{h}|}. \\
 2. \quad A_{\mathbf{h}, \mathbf{d}}^{i, N} &\leq \sum_{n_i=0}^{n_i^{\max}} \binom{N+n_i}{n_i} a_i^{|\mathbf{h}|} b_i^{|\mathbf{d}|}, \quad \text{where } n_i^{\max} = \begin{cases} n_i(\mathbf{h}) & \text{if } Q(\mathbf{d}) \leq q^*(\mathbf{h}) \\ n_i(\mathbf{h}) - 1 & \text{if } Q(\mathbf{d}) > q^*(\mathbf{h}). \end{cases}
 \end{aligned}$$

Proof. Let $w_{\max} = \max\{|\mathbf{w}_G(v)| : v \in Y^r\}$, so that $|\mathbf{w}_G(\mathbf{v})|/w_{\max} \leq w_H(\mathbf{v}) \leq |\mathbf{w}_G(\mathbf{v})|$ for all $\mathbf{v} \in Y^{r(N+\nu_o)}$. Then

$$A_{w, \mathbf{h}}^{o, N} \leq \sum_{n_o=1}^{n_o(\mathbf{h})} \sum_{h'=\lfloor |\mathbf{h}|/w_{\max} \rfloor}^{|\mathbf{h}|} \Lambda_{w, h', n_o}^{o, N},$$

where $\Lambda_{w, h', n_o}^{o, N}$ is the input/output support enumerating coefficient of ϕ_o^N , as defined in section 3.5. The conclusion now follows in a straightforward way from Proposition 3.11.

The proof for the inner encoder is similar, but we want to exploit the fact that, by definition of $q^*(\mathbf{h})$, there are no codewords of input weight $\mathbf{h}$ and output weight $\mathbf{d}$ such that $Q(\mathbf{d}) > q^*(\mathbf{h})$ having $n_i(\mathbf{h})$ error events in their decomposition. To do so, we need to define $A_{\mathbf{h}, \mathbf{d}, n}^{i, N}$ to be the number of codewords of ϕ_i^N with input invariants weight vector $\mathbf{h}$, output type weight $\mathbf{d}$, and n error events in the decomposition, so that

$$A_{\mathbf{h}, \mathbf{d}}^{i, N} = \sum_{n_i=0}^{n_i(\mathbf{h})} A_{\mathbf{h}, \mathbf{d}, n_i}^{i, N} = \sum_{n_i=0}^{n_i^{\max}} A_{\mathbf{h}, \mathbf{d}, n_i}^{i, N}$$

because $A_{\mathbf{h}, \mathbf{d}, n_i(\mathbf{h})}^{i, N} = 0$ if $Q(\mathbf{d}) > q^*(\mathbf{h})$. Then we conclude the proof as for the outer encoder, with $\hat{w}_{\max} = \max\{|\mathbf{w}_T(g)| : g \in \Gamma^l\}$:

$$A_{\mathbf{h}, \mathbf{d}}^{i, N} \leq \sum_{n_i=1}^{n_i^{\max}} \sum_{h'=\lfloor \frac{|\mathbf{h}|}{w_{\max}} \rfloor}^{|\mathbf{h}|} \sum_{d'=\lfloor \frac{|\mathbf{d}|}{\hat{w}_{\max}} \rfloor}^{|\mathbf{d}|} \Lambda_{h', d', n_i}^{i, N}. \quad \square$$

We now prove the following combinatorial inequality.

PROPOSITION 6.5. *There exists a constant $C > 0$ such that for all $\mathbf{h} \in H$ with $|\mathbf{h}| \leq w_{\max} r(N + \nu_o)$ (where $w_{\max} = \max\{|\mathbf{w}_G(v)| : v \in Y^r\}$),*

$$\frac{1}{\binom{r(N+\nu_o)}{\mathbf{h}}} \sum_{n_o=1}^{n_o(\mathbf{h})} \sum_{n_i=0}^{n_i^{\max}} \binom{N+n_o}{n_o} \binom{N+n_i}{n_i} \leq \begin{cases} C^{|\mathbf{h}|} \frac{|\mathbf{h}|^{f(\mathbf{h})-1}}{N^{f(\mathbf{h})-1}} & \text{if } n_i^{\max} = n_i(\mathbf{h}) \\ C^{|\mathbf{h}|} \frac{|\mathbf{h}|^{f(\mathbf{h})}}{N^{f(\mathbf{h})}} & \text{if } n_i^{\max} = n_i(\mathbf{h}) - 1. \end{cases}$$

Proof. First, we have $\binom{r(N+\nu_o)}{\mathbf{h}} \geq \left\lceil \frac{r(N+\nu_o)}{e|\mathbf{h}|} \right\rceil^{|\mathbf{h}|}$. This gives $\frac{1}{\binom{r(N+\nu_o)}{\mathbf{h}}} \leq C^{|\mathbf{h}|} \left[\frac{|\mathbf{h}|}{N} \right]^{|\mathbf{h}|}$ for some constant $C > 0$.

For the other terms, we use the following simple combinatorial inequalities:

- $\binom{N+n}{n} \leq \left\lceil \frac{s}{N} \right\rceil^{s-n} \binom{N+s}{s} \quad \forall n \geq 0, s, N \geq 1$ satisfying $s \geq n$,
- there exists a constant $c > 0$ such that $\binom{N+n}{n} \leq c \left[\frac{N+n}{N} \right]^N \left[\frac{N+n}{n} \right]^n \quad \forall n, N \geq 1$,
- $\left[\frac{N+n}{N} \right]^N \leq e^n \quad \forall n \geq 0, N \geq 1$.

As $n_o(\mathbf{h}) \leq |\mathbf{h}|$, these inequalities give

$$\begin{aligned} \sum_{n_o=1}^{n_o(\mathbf{h})} \binom{N+n_o}{n_o} &\leq \sum_{n_o=1}^{n_o(\mathbf{h})} \left[\frac{|\mathbf{h}|}{N} \right]^{|\mathbf{h}|-n_o} c e^{|\mathbf{h}|} \left[\frac{N+|\mathbf{h}|}{|\mathbf{h}|} \right]^{|\mathbf{h}|} \\ &\leq c_o^{|\mathbf{h}|} \sum_{n_o=1}^{n_o(\mathbf{h})} |\mathbf{h}|^{-n_o} N^{n_o} \\ &\leq C_o^{|\mathbf{h}|} |\mathbf{h}|^{-n_o(\mathbf{h})} N^{n_o(\mathbf{h})} \end{aligned}$$

(for some positive constants c_o and C_o). The second inequality is true thanks to the assumption that $|\mathbf{h}| \leq w_{\max} r(N + \nu_o)$. Similar estimation can be obtained for the summation concerning the inner encoder which yields the result. $\square$

If we substitute the estimations given by Propositions 6.4 and 6.5 into the expression (6.2) and use Proposition 6.3, we get, for some positive constants C_1, C_2, C_3 ,

$$(6.3) \quad \overline{P_s(e)} \leq \sum_{\substack{(w, \mathbf{h}, \mathbf{d}) \in I: \\ Q(\mathbf{d}) \leq q^*(\mathbf{h})}} \frac{|\mathbf{h}|^{f(\mathbf{h})-1}}{N^{f(\mathbf{h})}} C_1^w C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) + \sum_{\substack{(w, \mathbf{h}, \mathbf{d}) \in I: \\ Q(\mathbf{d}) > q^*(\mathbf{h})}} \frac{|\mathbf{h}|^{f(\mathbf{h})}}{N^{f(\mathbf{h})+1}} C_1^w C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}).$$

Now, we split the first summation into two terms, separating $\mathbf{h} \in \mathcal{H}$ from $\mathbf{h} \notin \mathcal{H}$. Define

- $I_\alpha = \{(w, \mathbf{h}, \mathbf{d}) \in I : f(\mathbf{h}) = \alpha, Q(\mathbf{d}) \leq q^*(\mathbf{h})\}$,
- $I_> = \{(w, \mathbf{h}, \mathbf{d}) \in I : f(\mathbf{h}) > \alpha, Q(\mathbf{d}) \leq q^*(\mathbf{h})\}$,
- $I_* = \{(w, \mathbf{h}, \mathbf{d}) \in I : Q(\mathbf{d}) > q^*(\mathbf{h})\}$.

Equation (6.3) can be rewritten as follows:

$$\begin{aligned} \overline{P_s(e)} &\leq \frac{1}{N^\alpha} \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_\alpha} |\mathbf{h}|^{\alpha-1} C_1^w C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ &\quad + \frac{1}{N^{\alpha+1}} \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_>} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h})-\alpha-1} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ &\quad + \frac{1}{N^{\alpha+1}} \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_*} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h})-\alpha} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}). \end{aligned}$$

In the following, we will show that the first summation is bounded by the expression $c q^* \exp(\log q^* / \log \gamma)$ (Proposition 6.6), and that the second and third summations are bounded by a constant $c'(\gamma)$ (Proposition 6.7), thus ending the proof of the upper bound.

PROPOSITION 6.6. *There exist some positive constants γ_0 and c such that, for any BIOS channel with $\gamma < \gamma_0$,*

$$\sum_{(w, \mathbf{h}, \mathbf{d}) \in I_\alpha} |\mathbf{h}|^{\alpha-1} C_1^w C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \leq c q^* \exp(\log q^* / \log \gamma).$$

Proof. Recall that $(w, \mathbf{h}, \mathbf{d}) \in I_\alpha$ implies that $w \leq \mu_o |\mathbf{h}|$, $|\mathbf{h}| \leq \mu_i |\mathbf{d}|$, and $Q(\mathbf{d}) \leq q^*(\mathbf{h}) \leq q^*$. So therefore,

$$\begin{aligned} & \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_\alpha} |\mathbf{h}|^{\alpha-1} C_1^w C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ & \leq \sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*}} \sum_{\substack{\mathbf{h} \in \mathbb{N}^\rho \\ |\mathbf{h}| \leq \mu_i |\mathbf{d}|}} |\mathbf{h}|^{\alpha-1} C_2^{|\mathbf{h}|} \left(\sum_{w \leq \mu_o |\mathbf{h}|} C_1^w \right) C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ & \leq \sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*}} \sum_{\substack{\mathbf{h} \in \mathbb{N}^\rho \\ |\mathbf{h}| \leq \mu_i |\mathbf{d}|}} |\mathbf{h}|^{\alpha-1} C_2^{|\mathbf{h}|} \mu_o |\mathbf{h}| C_1^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ & \leq \sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*}} K^{|\mathbf{d}|} Q(\mathbf{d}) \quad (\text{for some suitable } K > 0). \end{aligned}$$

Now, we split the summation, recalling the Bhattacharyya bound $Q(\mathbf{d}) \leq \gamma^{|\mathbf{d}|}$:

$$\sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*}} K^{|\mathbf{d}|} Q(\mathbf{d}) = \sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*, \gamma^{|\mathbf{d}|} > q^*}} K^{|\mathbf{d}|} q^* + \sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ \gamma^{|\mathbf{d}|} \leq q^*}} K^{|\mathbf{d}|} \gamma^{|\mathbf{d}|}.$$

Now let's find a bound for the number of $\mathbf{d}$'s involved in the first summation: $\gamma^{|\mathbf{d}|} > q^*$ means $|\mathbf{d}| < \log q^* / \log \gamma$ and so there are less than $(|\Gamma| - 1)^{\log q^* / \log \gamma}$ type weights satisfying this inequality:

$$\sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ Q(\mathbf{d}) \leq q^*, \gamma^{|\mathbf{d}|} \geq q^*}} K^{|\mathbf{d}|} q^* \leq ((|\Gamma| - 1)K)^{\log q^* / \log \gamma} q^*.$$

For the second term, note that for $\gamma < 1/K$, the series is convergent and bounded by a constant times its first term, which has $|\mathbf{d}| = \log q^* / \log \gamma$; i.e.,

$$\sum_{\substack{\mathbf{d} \in \mathbb{N}^{\Gamma \setminus \{0\}} \\ \gamma^{|\mathbf{d}|} \leq q^*}} K^{|\mathbf{d}|} \gamma^{|\mathbf{d}|} \leq CK^{(\log q^* / \log \gamma)} q^*. \quad \square$$

PROPOSITION 6.7. *There exists a constant $\gamma_0 > 0$ depending on ϕ_o, ϕ_i and (G_N) , and there exists $c'(\gamma) > 0$ depending only on γ such that for all $\gamma < \gamma_0$*

$$\begin{aligned} & \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_>} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h}) - \alpha - 1} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \\ & + \sum_{(w, \mathbf{h}, \mathbf{d}) \in I_*} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h}) - \alpha} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|\mathbf{d}|} Q(\mathbf{d}) \leq c'(\gamma). \end{aligned}$$

Proof. Notice that for $(w, \mathbf{h}, \mathbf{d}) \in I_>$, $0 \leq f(\mathbf{h}) - \alpha - 1 \leq |\mathbf{h}| \leq cN$, where the first inequality holds true because $\mathbf{h} \in H \setminus \mathcal{H}$, the second immediately follows from the definitions of $f(\mathbf{h})$ and α , and the third is true, for a suitable $c > 1$, because $|\mathbf{h}| \leq r(N + \nu_o)$

for all $\mathbf{h} \in H$. These inequalities imply that $(|\mathbf{h}|/N)^{f(\mathbf{h})-\alpha-1} \leq c^{|\mathbf{h}|}$. Analogously, for all $(w, \mathbf{h}, d) \in I_*$, $0 \leq f(\mathbf{h}) - \alpha \leq |\mathbf{h}| \leq cN$ and so $(|\mathbf{h}|/N)^{f(\mathbf{h})-\alpha} \leq c^{|\mathbf{h}|}$.

This gives

$$\begin{aligned} & \sum_{(w, \mathbf{h}, d) \in I_>} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h})-\alpha-1} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|d|} Q(d) \\ & + \sum_{(w, \mathbf{h}, d) \in I_*} C_1^w \left(\frac{|\mathbf{h}|}{N} \right)^{f(\mathbf{h})-\alpha} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|d|} Q(d) \\ & \leq \sum_{(w, \mathbf{h}, d) \in I} C_1^w c^{|\mathbf{h}|} C_2^{|\mathbf{h}|} C_3^{|d|} Q(d). \end{aligned}$$

Noticing also that $\sum_{w \leq \mu_o |\mathbf{h}|} C_1^w \leq \mu_o |\mathbf{h}| C_1^{|\mathbf{h}|}$, we have

$$\sum_{(w, \mathbf{h}, d) \in I} C_1^w c^{|\mathbf{h}|} C_2^{|\mathbf{h}|} C_3^{|d|} Q(d) \leq \sum_{d \in \mathbb{N}^{\Gamma \setminus \{0\}}} \sum_{\mathbf{h}: |\mathbf{h}| \leq \mu_i |d|} \mu_o |\mathbf{h}| C_1^{|\mathbf{h}|} c^{|\mathbf{h}|} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} C_3^{|d|} Q(d).$$

Now notice that, for some $K > 1$,

$$\sum_{\mathbf{h}: |\mathbf{h}| \leq \mu_i |d|} \mu_o |\mathbf{h}| C_1^{|\mathbf{h}|} c^{|\mathbf{h}|} |\mathbf{h}|^\alpha C_2^{|\mathbf{h}|} \leq K^{|d|}.$$

Finally, we use the Bhattacharyya bound.

$$\sum_{d \in \mathbb{N}^{\Gamma \setminus \{0\}}} (KC)_3^{|d|} Q(d) \leq \sum_{d \in \mathbb{N}} \sum_{d \in \mathbb{N}^{\Gamma \setminus \{0\}}: |d|=d} (KC_3 \gamma)^d = c'(\gamma) < \infty$$

if γ is sufficiently small to ensure convergence. $\square$

6.2. Lower bound. The lower bound is based on the following simple remark involving the equivocation probability.

Remark 6.8. If $\mathbf{c} \in \mathcal{C}^N$, then $P_w(e) \geq \mathbb{P}(\mathbf{0} \rightarrow \mathbf{c})$. Therefore, if one defines $Q_{\max}(\pi_N) = \max\{\mathbb{P}(\mathbf{0} \rightarrow \mathbf{c}), \mathbf{c} \in \phi_i^N \circ \pi_N \circ \phi_o^N(U^N)\}$, then, for any q ,

$$\overline{P_w(e)} \geq q \mathbb{P}(Q_{\max}(\Pi_N) \geq q).$$

We focus our attention on the value $q = q^*$, and we find the following lower bound to $\mathbb{P}(Q_{\max}(\Pi_N) \geq q)$, thus ending the proof of the lower bound in Theorem 5.4.

PROPOSITION 6.9. *If $\alpha \geq 1$, there exists a constant $C > 0$ such that*

$$\mathbb{P}(Q_{\max}(\Pi_N) \geq q) \geq CN^{-\alpha+1}.$$

In the remainder of this section, we will prove Proposition 6.9. To do so, we need to define some particular codewords which are essential for the bound. We start fixing once and for all the following objects:

1. A weight vector $\mathbf{h} \in H$ such that $q^*(\mathbf{h}) = q^*$.
2. An outer codeword $\mathbf{c}^* \in \phi_o^N(U^N)$ such that $\mathbf{w}_G(\mathbf{c}^*) = \mathbf{h}$ and $n(\mathbf{c}) = n_o(\mathbf{h})$. Let $n_o = n_o(\mathbf{h})$, and let $\mathbf{c}^* = \mathbf{c}_1^* + \dots + \mathbf{c}_{n_o+1}^*$ be an error event decomposition of $\mathbf{c}^*$ (see section 3.4). Denote by l_k the length of $\mathbf{c}_k^*$, and define $l_{\max} = \max\{l_1, \dots, l_{n_o}\}$. If $\alpha = 1$, we need a slightly different definition: $l_{\max} = \max\{l_1, \dots, l_{n_o}, L\}$ for a suitable constant L , which will be chosen in Lemma 6.12.

3. An input word $\mathbf{u}^*$ for the inner encoder, such that $\mathbf{w}_G(\mathbf{u}^*) = \mathbf{h}$ and such that $\mathbf{x}^* = \phi_i^N(\mathbf{u}^*)$, has equivocation $P(\mathbf{0} \rightarrow \mathbf{x}^*) = q^*(\mathbf{h})$ and $n(\mathbf{x}^*) = n_i(\mathbf{h})$. Let $n_i = n_i(\mathbf{h})$, and let $\mathbf{x}^* = \mathbf{x}_1^* + \dots + \mathbf{x}_{n_i+1}^*$ be an error event decomposition of $\mathbf{x}^*$. Denote by $\mathbf{u}_k^*$ the input error event corresponding to $\mathbf{x}_k^*$ and by λ_k its length (with $\lambda_{n_i+1} = 0$ if there is no terminating event). Define $\lambda_{\max} = \max\{\lambda_1, \dots, \lambda_{n_i}\}$. Again, for $\alpha = 1$ we need a different definition $\lambda_{\max} = \max\{\lambda_1, \dots, \lambda_{n_i}, \Lambda\}$ for a suitable constant Λ described in Lemma 6.12.

Notice that $\mathbf{c}^*$ can be chosen in such a way that it doesn't have any terminating event and does not depend on N , while this may not be possible for $\mathbf{u}^*$. However, we can assume that the error events $\mathbf{x}_k^*$ and their inputs $\mathbf{u}_k^*$ remain the same apart from some possible translations (see Remark 3.9). Also remember that $n_o \geq 1$, $n_i \geq 0$.

Now, we select a sufficiently big set of shift equivalent words for both $\mathbf{c}^*$ and $\mathbf{x}^*$, choosing many positions for the error events of $\mathbf{c}^*$ and for the input error events of $\mathbf{u}^*$, across all the time axis $[0, N + \nu_o - 1]$ for $\mathbf{c}^*$ and $[0, M_N - 1]$ for $\mathbf{u}^*$.

Let's start with $\mathbf{c}^*$. Define $\mathcal{A} = [0, \lfloor \frac{N}{n_o \lambda_{\max}} \rfloor - 1]$. Given $\mathbf{a} \in \mathcal{A}^{n_o}$, we define $\mathbf{c}_\mathbf{a}^*$ to be the outer codeword which, for every $k = 1, \dots, n_o$, contains exactly one shifted copy of the error event $\mathbf{c}_k^*$ starting at time $a_k \lambda_{\max} + (k-1)|\mathcal{A}| \lambda_{\max}$. Clearly by construction all error events in $\mathbf{c}_\mathbf{a}^*$ have disjoint support.

In the same way, we consider the inner input word $\mathbf{u}^*$. For $n_i \geq 1$, define $\mathcal{B} = [0, \lfloor \frac{M_N - \lambda_{n_i+1}}{n_i \lambda_{\max}} \rfloor - 1]$. Given $\mathbf{b} \in \mathcal{B}^{n_i}$ we define $\mathbf{u}_\mathbf{b}^*$ to be the inner input word which, for every $k = 1, \dots, n_i$, contains exactly one translated copy of the input error event $\mathbf{u}_k^*$ starting at time $b_k \lambda_{\max} + (k-1)|\mathcal{B}| \lambda_{\max}$, while the terminating event $\mathbf{u}_{n_i+1}^*$ (if there is one) remains fixed in its position in the interval $[M_N - \lambda_{n_i+1} - 1, M_N - 1]$. Let $\mathbf{x}_\mathbf{b}^*$ be the output $\mathbf{x}_\mathbf{b}^* = \phi_i^N(\mathbf{u}_\mathbf{b}^*)$.

Given $\mathbf{a} \in \mathcal{A}^{n_o}$ and $\mathbf{b} \in \mathcal{B}^{n_i}$, if $n_i \geq 1$ we define the event

$$E_{\mathbf{a}, \mathbf{b}} = \{\Pi_N(\mathbf{c}_\mathbf{a}^*) = \mathbf{u}_\mathbf{b}^*\} = G_N(\mathbf{c}_\mathbf{a}^*, \mathbf{u}_\mathbf{b}^*),$$

and we also define $E_\mathbf{a} = \bigcup_{\mathbf{b} \in \mathcal{B}} E_{\mathbf{a}, \mathbf{b}}$ (notice that this is a union of disjoint events). If $n_i = 0$, then we simply let $E_\mathbf{a} = \{\Pi_N(\mathbf{c}_\mathbf{a}^*) = \mathbf{u}^*\} = G_N(\mathbf{c}_\mathbf{a}^*, \mathbf{u}^*)$.

Remark 6.10. Clearly $\pi_N \in E_{\mathbf{a}, \mathbf{b}}$ implies $Q_{\max}(\pi_N) \geq P(\mathbf{0} \rightarrow \mathbf{x}_\mathbf{b}^*) = q^*$. Hence,

$$\mathbb{P}(Q_{\max}(\Pi_N) \geq q^*) \geq \mathbb{P}\left(\bigcup_{\mathbf{a} \in \mathcal{A}^{n_o}} E_\mathbf{a}\right).$$

Our aim is now to estimate this last probability, using

$$\mathbb{P}\left(\bigcup_{\mathbf{a} \in \mathcal{A}^{n_o}} E_\mathbf{a}\right) \geq \sum_{\mathbf{a} \in \mathcal{A}^{n_o}} \mathbb{P}(E_\mathbf{a}) - \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_\mathbf{a} \cap E_{\mathbf{a}'}).$$

We will prove a lower bound for the first term (Lemma 6.11) and an upper bound for the second term (Lemma 6.12).

LEMMA 6.11.

$$\sum_{\mathbf{a} \in \mathcal{A}^{n_o}} \mathbb{P}(E_\mathbf{a}) \geq |\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i} \frac{1}{\lceil |Y| r(N + \nu_o) \rceil |\mathbf{h}|},$$

where in the case $n_i = 0$ (for which $\mathcal{B}$ is not defined), we define $|\mathcal{B}| = 1$.

Proof. Clearly

$$\mathbb{P}(E_{\mathbf{a}}) = \frac{|E_{\mathbf{a}}|}{|G_N|} = \frac{|\mathcal{B}|^{n_i} |G_N(\mathbf{c}^*, \mathbf{u}^*)|}{|G_N|}.$$

By Remark 4.2 and Lemma 2.2,

$$\frac{|G_N(\mathbf{c}^*, \mathbf{u}^*)|}{|G_N|} = \frac{1}{|Y_{\mathbf{h}}^{r(N+\nu_o)}|} \geq \frac{1}{[|Y|r(N+\nu_o)]^{|\mathbf{h}|}}. \quad \square$$

LEMMA 6.12. *If $\alpha \geq 2$, then*

$$\sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) \leq |\mathcal{A}|^{2n_o} |\mathcal{B}|^{2n_i} \left(\frac{2e|\mathbf{h}|}{r(N+\nu_o)} \right)^{2|\mathbf{h}|},$$

while if $\alpha = 1$, then

$$\sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) \leq \frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} C$$

for some constant $0 < C < \frac{1}{|Y|^{|\mathbf{h}|}}$.

Proof. We have

$$E_{\mathbf{a}} \cap E_{\mathbf{a}'} = \bigcup_{\mathbf{b}, \mathbf{b}' \in \mathcal{B}^{n_i}} (E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'}).$$

Consequently, by the union bound,

$$\sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) \leq \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \sum_{\mathbf{b}, \mathbf{b}' \in \mathcal{B}^{n_i}} \mathbb{P}(E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'}).$$

Now we need to deal with $\mathbb{P}(E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'})$. First of all, note that if there is an incomplete error event in $\mathbf{u}^*$, surely $\mathbb{P}(E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'}) = 0$ for all $\mathbf{a} \neq \mathbf{a}'$ and for all $\mathbf{b}, \mathbf{b}'$. Now consider the case of only regular events. Fix any $\mathbf{a} \neq \mathbf{a}'$ and $\mathbf{b}, \mathbf{b}'$ such that there exists $\pi \in E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'}$. By the definition of $\mathbf{c}_{\mathbf{a}}^*$ and $\mathbf{c}_{\mathbf{a}'}^*$, we can find outer codewords $\tilde{\mathbf{c}}^*$, $\tilde{\mathbf{c}}_{\mathbf{a}}^*$, $\tilde{\mathbf{c}}_{\mathbf{a}'}^*$ (possibly $\tilde{\mathbf{c}}^* = \mathbf{0}$) having disjoint supports, each consisting of some of the error events $\mathbf{c}_k^*$, such that $\mathbf{c}_{\mathbf{a}}^* = \tilde{\mathbf{c}}^* + \tilde{\mathbf{c}}_{\mathbf{a}}^*$ and $\mathbf{c}_{\mathbf{a}'}^* = \tilde{\mathbf{c}}^* + \tilde{\mathbf{c}}_{\mathbf{a}'}^*$. More precisely, letting $\tilde{n}_o = d_H(\mathbf{a}, \mathbf{a}')$, i.e., the number of i 's such that $\mathbf{a}_i \neq \mathbf{a}'_i$, $\tilde{\mathbf{c}}^*$ consists of $n_o - \tilde{n}_o$ error events, and $\tilde{\mathbf{c}}_{\mathbf{a}}^*$ consists of $\tilde{n}_o$ error events and is shift equivalent to $\tilde{\mathbf{c}}_{\mathbf{a}'}^*$. Clearly, $\mathbf{w}_G(\tilde{\mathbf{c}}_{\mathbf{a}}^*) = \mathbf{w}_G(\tilde{\mathbf{c}}_{\mathbf{a}'}^*) = \mathbf{h} - \mathbf{w}_G(\tilde{\mathbf{c}}^*)$.

Similarly, we can find inner input words $\tilde{\mathbf{u}}^*$, $\tilde{\mathbf{u}}_{\mathbf{b}}^*$, $\tilde{\mathbf{u}}_{\mathbf{b}'}^*$ (possibly $\tilde{\mathbf{u}}^* = \mathbf{0}$ or $\tilde{\mathbf{u}}_{\mathbf{b}}^* = \tilde{\mathbf{u}}_{\mathbf{b}'}^* = \mathbf{0}$) having disjoint supports, each consisting of some of the input error events $\mathbf{u}_k^*$, such that $\mathbf{u}_{\mathbf{b}}^* = \tilde{\mathbf{u}}^* + \tilde{\mathbf{u}}_{\mathbf{b}}^*$ and $\mathbf{u}_{\mathbf{b}'}^* = \tilde{\mathbf{u}}^* + \tilde{\mathbf{u}}_{\mathbf{b}'}^*$. Letting $\tilde{n}_i = d_H(\mathbf{b}, \mathbf{b}')$, $\tilde{\mathbf{u}}^*$ has $n_i - \tilde{n}_i$ error events and $\tilde{\mathbf{u}}_{\mathbf{b}}^*$ has $\tilde{n}_i$ error events and is shift equivalent to $\tilde{\mathbf{u}}_{\mathbf{b}'}^*$. Clearly, $\mathbf{w}_G(\tilde{\mathbf{u}}_{\mathbf{b}}^*) = \mathbf{w}_G(\tilde{\mathbf{u}}_{\mathbf{b}'}^*) = \mathbf{h} - \mathbf{w}_G(\tilde{\mathbf{u}}^*)$.

As a consequence of Lemma 4.3, if $\pi \in E_{\mathbf{a}, \mathbf{b}} \cap E_{\mathbf{a}', \mathbf{b}'}$, then $\pi(\tilde{\mathbf{c}}^*) = \tilde{\mathbf{u}}^*$, $\pi(\tilde{\mathbf{c}}_{\mathbf{a}}^*) = \tilde{\mathbf{u}}_{\mathbf{b}}^*$ and $\pi(\tilde{\mathbf{c}}_{\mathbf{a}'}^*) = \tilde{\mathbf{u}}_{\mathbf{b}'}^*$. This implies that $\mathbf{w}_G(\tilde{\mathbf{u}}^*) = \mathbf{w}_G(\tilde{\mathbf{c}}^*)$ and that $\mathbf{w}_G(\tilde{\mathbf{u}}_{\mathbf{b}}^*) = \mathbf{w}_G(\tilde{\mathbf{u}}_{\mathbf{b}'}^*) = \mathbf{w}_G(\tilde{\mathbf{c}}_{\mathbf{a}}^*) = \mathbf{w}_G(\tilde{\mathbf{c}}_{\mathbf{a}'}^*) = \mathbf{h} - \mathbf{w}_G(\tilde{\mathbf{c}}^*)$. We will use the notation $\tilde{\mathbf{h}} = \mathbf{w}_G(\tilde{\mathbf{u}}_{\mathbf{b}}^*)$. Note that

if $\mathbb{P}(E_{\mathbf{a},\mathbf{b}} \cap E_{\mathbf{a}',\mathbf{b}'}) \neq 0$ and $(\mathbf{a}, \mathbf{b}) \neq (\mathbf{a}', \mathbf{b}')$, then surely both $\mathbf{a} \neq \mathbf{a}'$ and $\mathbf{b} \neq \mathbf{b}'$. Also note that

$$\mathbb{P}(E_{\mathbf{a},\mathbf{b}} \cap E_{\mathbf{a}',\mathbf{b}'}) \leq \mathbb{P}(\Pi_N(\tilde{\mathbf{c}}^* + \tilde{\mathbf{c}}_{\mathbf{a}}^* + \tilde{\mathbf{c}}_{\mathbf{a}'}^*) = \tilde{\mathbf{u}}^* + \tilde{\mathbf{u}}_{\mathbf{b}}^* + \tilde{\mathbf{u}}_{\mathbf{b}'}^*) = \frac{1}{Y_{\mathbf{h}+\tilde{\mathbf{h}}}^{r(N+\nu_o)}}.$$

In the simple case when $\tilde{\mathbf{h}} = \mathbf{h}$, this gives

$$\mathbb{P}(E_{\mathbf{a},\mathbf{b}} \cap E_{\mathbf{a}',\mathbf{b}'}) \leq \frac{1}{|Y_{2\mathbf{h}}^{r(N+\nu_o)}|} \leq \left(\frac{2e|\mathbf{h}|}{r(N+\nu_o)} \right)^{2|\mathbf{h}|},$$

where the last line comes from Lemma 2.2.

Now notice that $\tilde{\mathbf{h}} \in H$ and $\mathbf{h} - \tilde{\mathbf{h}} \in H \cup \{\mathbf{0}\}$, so that

$$(6.4) \quad 1 + |\tilde{\mathbf{h}}| - \tilde{n}_o - \tilde{n}_i \geq f(\tilde{\mathbf{h}}) \geq \alpha = 1 + |\mathbf{h}| - n_o - n_i$$

and, if $\tilde{\mathbf{h}} \neq \mathbf{h}$, then

$$(6.5) \quad 1 + |\mathbf{h} - \tilde{\mathbf{h}}| - (n_o - \tilde{n}_o) - (n_i - \tilde{n}_i) \geq f(\mathbf{h} - \tilde{\mathbf{h}}) \geq \alpha = 1 + |\mathbf{h}| - n_o - n_i.$$

Equations (6.4) and (6.5) together are possible only in the case when $\alpha = 1$. So, for $\alpha \geq 2$, surely $\mathbf{h} = \tilde{\mathbf{h}}$, which ends the proof, as follows:

$$\sum_{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o}, \mathbf{a} \neq \mathbf{a}'} \sum_{\mathbf{b}, \mathbf{b}' \in \mathcal{B}^{n_i}, \mathbf{b} \neq \mathbf{b}'} \mathbb{P}(E_{\mathbf{a},\mathbf{b}} \cap E_{\mathbf{a}',\mathbf{b}'}) \leq |\mathcal{A}|^{2n_o} |\mathcal{B}|^{2n_i} \left(\frac{2e|\mathbf{h}|}{r(N+\nu_o)} \right)^{2|\mathbf{h}|}.$$

For $\alpha = 1$, instead, note that in this case $\tilde{n}_0 + \tilde{n}_i = |\tilde{\mathbf{h}}|$ and $n_0 + n_i = |\mathbf{h}|$. We can estimate the following:

$$\begin{aligned} \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) &= \sum_{1 \leq \tilde{n}_o \leq n_o} \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ 1 \leq \text{d}_H(\mathbf{a}, \mathbf{a}') \leq \tilde{n}_o}} \sum_{1 \leq \tilde{n}_i \leq n_i} \sum_{\substack{\mathbf{b}, \mathbf{b}' \in \mathcal{B}^{n_i} \\ 1 \leq \text{d}_H(\mathbf{b}, \mathbf{b}') \leq \tilde{n}_i}} \mathbb{P}(E_{\mathbf{a},\mathbf{b}} \cap E_{\mathbf{a}',\mathbf{b}'}) \\ &\leq \sum_{1 \leq \tilde{n}_o \leq n_o} \binom{n_o}{\tilde{n}_o} |\mathcal{A}|^{n_o + \tilde{n}_o} \sum_{1 \leq \tilde{n}_i \leq n_i} \binom{n_i}{\tilde{n}_i} |\mathcal{B}|^{n_i + \tilde{n}_i} \left(\frac{e(|\mathbf{h}| + \tilde{n}_o + \tilde{n}_i)}{r(N+\nu_o)} \right)^{|\mathbf{h}| + \tilde{n}_o + \tilde{n}_i} \\ &\leq \frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} 2e|\mathbf{h}| \left[\left(1 + \frac{|\mathcal{A}|2e|\mathbf{h}|}{r(N+\nu_o)} \right)^{n_o} - 1 \right] \left[\left(1 + \frac{|\mathcal{B}|2e|\mathbf{h}|}{r(N+\nu_o)} \right)^{n_i} - 1 \right] \\ &\leq \frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} C \end{aligned}$$

for some constant $C > 0$. Choosing suitably large constants L and Λ in the definition of $l_{\max}$ and $\lambda_{\max}$ ensures that $|\mathcal{A}|$ and $|\mathcal{B}|$ are small enough to have $C < \frac{1}{|Y|^{|\mathbf{h}|}}$, which will be useful later. $\square$

Now we can conclude the proof of Proposition 6.9. Using Lemmas 6.11 and 6.12, for $\alpha \geq 2$ we get

$$\sum_{\mathbf{a} \in \mathcal{A}^{n_o}} \mathbb{P}(E_{\mathbf{a}}) - \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) \geq \frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} \left(\frac{1}{|Y|^{|\mathbf{h}|}} - |\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i} \frac{(2e|\mathbf{h}|)^{2|\mathbf{h}|}}{[r(N+\nu_o)]^{|\mathbf{h}|}} \right).$$

For $N \rightarrow \infty$, as $|\mathcal{A}| \asymp N$ and $|\mathcal{B}| \asymp N$, we have $\frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} \asymp N^{-\alpha+1}$. We conclude by noticing that $|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i} \frac{(2e|\mathbf{h}|)^{2|\mathbf{h}|}}{[r(N+\nu_o)]^{|\mathbf{h}|}} \asymp N^{-\alpha+1} \rightarrow 0$.

For $\alpha = 1$, Lemmas 6.11 and 6.12 give

$$\sum_{\mathbf{a} \in \mathcal{A}^{n_o}} \mathbb{P}(E_{\mathbf{a}}) - \sum_{\substack{\mathbf{a}, \mathbf{a}' \in \mathcal{A}^{n_o} \\ \mathbf{a} \neq \mathbf{a}'}} \mathbb{P}(E_{\mathbf{a}} \cap E_{\mathbf{a}'}) \geq \frac{|\mathcal{A}|^{n_o} |\mathcal{B}|^{n_i}}{[r(N+\nu_o)]^{|\mathbf{h}|}} \left(\frac{1}{|Y|^{|\mathbf{h}|}} - C \right)$$

for some $0 < C < \frac{1}{|Y|^{|\mathbf{h}|}}$. Then the equality $n_o + n_i = |\mathbf{h}|$ ensures that the right-hand side is bounded from below by a strictly positive constant.

6.3. Proof of Propositions 5.5, 5.6, and 5.7. We prove here Proposition 5.6 and Proposition 5.7; clearly the latter one also implies the weaker Proposition 5.5, which can be obtained as a special case just taking $\rho_2 = 0$ so that $\mathbf{w}_G = \mathbf{w}_1$ and $d_f^o = d_{f,1}^o$.

LEMMA 6.13. *Under the same assumptions as in Proposition 5.7 for all $\mathbf{h} = (\mathbf{h}_1, \mathbf{h}_2) \in H \subseteq \mathbb{N}^{\rho_1} \times \mathbb{N}^{\rho_2}$ we have the following:*

- $1 \leq n_o(\mathbf{h}) \leq \lfloor |\mathbf{h}_1|/d_{f,1}^o \rfloor$,
- $0 \leq n_i(\mathbf{h}) \leq \lfloor |\mathbf{h}_1|/2 \rfloor + |\mathbf{h}_2|$,
- $1 + |\mathbf{h}_1| - \lfloor |\mathbf{h}_1|/d_{f,1}^o \rfloor - \lfloor |\mathbf{h}_1|/2 \rfloor \leq f(\mathbf{h}) \leq |\mathbf{h}|$.

Proof. The upper bounds for $n_o(\mathbf{h})$ and $n_i(\mathbf{h})$ are an immediate consequence of the definition of $d_{f,1}^o$ and of the $\mathbf{w}_1$ -recursiveness of ϕ_i . For the lower bounds, see Remark 5.2. Then the estimations for $f(\mathbf{h})$ directly follow.

The definitions of d_f^o and H now clearly imply that $\alpha \leq d_f^o$, while the lower bound for α comes from the following property. We omit its easy proof, already sketched in [2].

PROPOSITION 6.14. *Given any constant $c \geq 2$, the function $g : \mathbb{N} \rightarrow \mathbb{N}$ defined by $g_c(h) = 1 + h - \lfloor h/c \rfloor - \lfloor h/2 \rfloor$ has $\min_{h \geq c} g_c(h) = \lfloor (c+1)/2 \rfloor$ and*

$$\arg \min_{h \geq c} g_c(h) = \begin{cases} 2\mathbb{N}^* & \text{if } c = 2 \\ \{c, c+1, 2c\} & \text{if } c = 3 \\ \{c, c+1\} & \text{if } c \text{ is odd, } c \geq 5 \\ \{c\} & \text{if } c \text{ is even, } c \geq 4. \end{cases}$$

The lower bound for $f(\mathbf{h})$ in Lemma 6.13 can be rewritten as $f(\mathbf{h}) \geq g_{d_{f,1}^o}(|\mathbf{h}_1|)$. For all $\mathbf{h} \in H$, clearly $|\mathbf{h}_1| \geq d_{f,1}^o$ and so, by Proposition 6.14,

$$\alpha = \min_{\mathbf{h} \in H} f(\mathbf{h}) \geq \lfloor (d_{f,1}^o + 1)/2 \rfloor.$$

Clearly, this lower bound for α immediately means that $d_{f,1}^o \geq 2$ gives $\alpha \geq 1$, and $d_{f,1}^o \geq 3$ gives $\alpha \geq 2$.

Finally, we prove that $\mathcal{H}$ is a finite set under the assumption that $\rho_2 = 0$ and $d_f^o \geq 3$. For any $\mathbf{h} \in \mathcal{H}$, i.e., such that $f(\mathbf{h}) = \alpha$, by Lemma 6.13 we get

$$\alpha = f(\mathbf{h}) \geq 1 + |\mathbf{h}| - \lfloor |\mathbf{h}|/d_f^o \rfloor - \lfloor |\mathbf{h}|/2 \rfloor \geq 1 + |\mathbf{h}| \left(\frac{1}{2} - \frac{1}{d_f^o} \right)$$

which gives $|\mathbf{h}| \leq (\alpha - 1) \frac{2d_f^o}{d_f^o - 2}$, thus proving that $\mathcal{H}$ is finite.

7. Examples. In this section we consider particular cases where we can characterize α and q^* exactly, or can give tighter bounds than the general ones. We will particularly focus on the relevant examples introduced in section 4.3. Throughout this section, we will consider $\Gamma = \mathbb{Z}_m$; in some cases we will restrict our attention to m -PSK-AWGN channels.

7.1. Classical free $\mathbb{Z}_m$ serial scheme. We call this scheme classical, because it is the simplest and most natural generalization of the classical binary serial concatenations introduced in [2].

In the general scheme, take $U = \mathbb{Z}_m^k$, $Y = \mathbb{Z}_m$, $\Gamma = \mathbb{Z}_m$, $G_N = S_{r(N+\nu_o)}$, and consider constituent encoders which are rational matrices $\phi_o \in \mathbb{Z}_m(D)^{k \times r}$ and $\phi_i \in \mathbb{Z}_m(D)^{s \times l}$. See the appendix for properties of convolutional encoders in this particular setting.

Consider symbol error probability with respect to Hamming weight on $\mathbb{Z}_m$ (extended componentwise). Take as interconnection group $G_N = S_{r(N+\nu_o)}$; i.e., all of the permutations moving around the elements of $\mathbb{Z}_m$. Clearly, the invariant weight w_G will be the type weight w_T on $\mathbb{Z}_m$ (extended componentwise). Notice that, in this scheme we can think of symbols in the most intuitive way; i.e., to be the elements of $\mathbb{Z}_m$, both in input and in the interconnection and at the output. Clearly, if one takes $m = 2$, then symbols are just bits, and type weight and Euclidean weight are equal to Hamming weight; therefore we get the classical binary schemes introduced in [2].

For this ensemble, we have an explicit expression for α if m is a power of 2, and tight bounds for α for general m ; we also have simple examples showing that, without more information about the constituent encoders, nothing tighter than these bounds can be found.

Let $m = p_1^{\alpha_1} \cdots p_l^{\alpha_l}$ be the prime factors decomposition of m , and let $\phi_{j,o} : \mathbb{Z}_{p_j}^{kN} \rightarrow \mathbb{Z}_{p_j}^{rN}$ be obtained by taking the restriction of ϕ_o to inputs in $\frac{m}{p_j} \mathbb{Z}_m^k$ and then identifying $\frac{m}{p_j} \mathbb{Z}_m$ with $\mathbb{Z}_{p_j}$ through the natural fields isomorphism. With this notation, the following bounds for α hold true.

PROPOSITION 7.1. *For the classical free $\mathbb{Z}_m$ ensemble,*

$$\lfloor (d_f^o + 1)/2 \rfloor \leq \alpha \leq d_f^o - \lfloor d_f^o/p_{\min} \rfloor,$$

where $p_{\min} = \min\{p_j : d_f^o = d_f(\phi_{j,o})\}$.

Proof. We already have the bound $\lfloor (d_f^o + 1)/2 \rfloor \leq \alpha \leq d_f^o$ (Proposition 5.5), so we just need to prove the tighter upper bound.

Notice that, by Proposition A.2, $\mathcal{P} := \{p_j : d_f^o = d_f(\phi_{j,o})\} \neq \emptyset$. We want to prove that $\alpha \leq d_f^o - \lfloor d_f^o/p \rfloor$ for all $p \in \mathcal{P}$. Therefore, we must fix any $p \in \mathcal{P}$; consider a word $\mathbf{c} \in \frac{m}{p} \phi_o^N(\mathbb{Z}_m^{kN})$ such that $w_H(\mathbf{c}) = d_f^o$; let $\mathbf{h} = \mathbf{w}_T(\mathbf{c})$.

Let $a_1, \dots, a_{d_f^o} \in \frac{m}{p} \mathbb{Z}_m \setminus \{0\}$ be the nonzero symbols of the word $\mathbf{c}$ (possibly with the same symbol repeated many times). Consider $a_1, \dots, a_p$. By Lemma A.3 (applied to $\mathbb{Z}_p$), there exist indexes $\{j_1, \dots, j_n\} \subseteq \{1, \dots, p\}$ such that $a_{j_1} + \dots + a_{j_n} = 0 \pmod{m}$. Then, by Proposition 3.6, there exist distinct times $t_1, \dots, t_n$ such that $\phi_i(a_{j_1} D^{t_1} + \dots + a_{j_n} D^{t_n})$ has finite support; i.e., is formed by some (at least one) error events. By applying the same argument to $a_{p+1}, \dots, a_{2p}$ and so on up to $a_{(\lfloor d_f^o/p \rfloor - 1)p+1}, \dots, a_{\lfloor d_f^o/p \rfloor p}$, we obtain that $n_i(\mathbf{h}) \geq \lfloor d_f^o/p \rfloor$. Clearly, $n_o(\mathbf{h}) = 1$ and so we can conclude that $\alpha \leq f(\mathbf{h}) \leq 1 + d_f^o - 1 - \lfloor d_f^o/p \rfloor$. $\square$

From Proposition 7.1, together with Proposition A.2 (see the appendix), we get the exact value of α for the case when m is a power of 2.

COROLLARY 7.2. *For the classical free $\mathbb{Z}_m$ ensemble, if m is a power of 2, then*

$$\alpha = \lfloor (d_f^o + 1)/2 \rfloor.$$

It is more difficult to get an explicit formula for q^* . We can just notice that whenever $\alpha = \lfloor (d_f^o + 1)/2 \rfloor$ (in particular for the classical free $\mathbb{Z}_m$ ensemble when m is a power of 2), the inequalities $n_o(\mathbf{h}) \leq \lfloor |\mathbf{h}|/d_f^o \rfloor$, $n_i(\mathbf{h}) \leq \lfloor |\mathbf{h}|/2 \rfloor$ (Lemma 6.13), and Proposition 6.14 make simpler the description of $\mathcal{H}$. When $m = 2$, the description of $\mathcal{H}$ gets even simpler, because the type weight is a scalar, equal to the Hamming weight, and for all $h \in H$, $n_i(h) = \lfloor h/2 \rfloor$. This allows us to find the following explicit formula $q^* = Q(d^*)$ in the binary classical ensemble (d^* was already described by Benedetto et al. [2], but here our result is more precise for odd values of d_f^o). Define $d_{f,2}^i$ and $d_{f,3}^i$ to be the minimum output Hamming weight of a regular error event of the inner encoder constrained to input Hamming weight 2 and 3, respectively ($d_{f,3} = +\infty$ if such an event does not exist). Also define $d_{1,\text{term}}^i$ to be the minimum output Hamming weight of a terminated error event with input Hamming weight 1.

PROPOSITION 7.3. *For the binary classical ensemble, $q^* = Q(d^*)$, where*

- if d_f^o is even, then $d^* = \frac{1}{2}d_f^o d_{f,2}^i$;
- if d_f^o is odd ($d_f^o \geq 5$), then

$$d^* = \begin{cases} \frac{d_f^o - 3}{2} d_{f,2}^i + \min \left\{ d_{f,2}^i + d_{1,\text{term}}^i, d_{f,3}^i, 2d_{f,2}^i \right\} & \text{if } d_f^o + 1 \in H, \\ \frac{d_f^o - 3}{2} d_{f,2}^i + \min \left\{ d_{f,2}^i + d_{1,\text{term}}^i, d_{f,3}^i \right\} & \text{if } d_f^o + 1 \notin H, \end{cases}$$

- if $d_f^o = 3$, then

$$d^* = \begin{cases} \min \left\{ d_{f,2}^i + d_{1,\text{term}}^i, d_{f,3}^i, 2d_{f,2}^i \right\} & \text{if } 4 \in H \\ \min \left\{ d_{f,2}^i + d_{1,\text{term}}^i, d_{f,3}^i, 3d_{f,2}^i \right\} & \text{if } 4 \notin H. \end{cases}$$

Now we give three examples with $\Gamma = \mathbb{Z}_m$ and with $G_N = S_{r(N+\nu_o)}$. For the computation of q^* , we consider the specific case of the m -PSK-AWGN channel, for which we can find an explicit expression. Remember that, for the S -AWGN channel, given a type $\mathbf{d}$, $Q(\mathbf{d}) = \frac{1}{2} \operatorname{erfc} \sqrt{(\sum_g d_g w_E(g)) E_s / N_0}$. Note that when S is m -PSK, $w_E(g) = \sin^2(g\pi/m)$.

Example 7.4 (repeat-accumulate codes). The encoders are $\phi_o = \operatorname{Rep}_r$ (with $r \geq 2$) and $\phi_i = \frac{1}{1-D}$. We assume that the termination rule for the accumulator is the one that always brings to the zero state in one trellis step (using the input $-a$ if we are in state a).

We obtain $\alpha = \min\{r-1, r - \lfloor r/p \rfloor\}$, where p is the smallest prime divisor of m , and $q^* = \frac{1}{2} \operatorname{erfc} \sqrt{d^* E_s / N_0}$, where we have the following:

- For $m = 2$, $d^* = \lfloor (r+1)/2 \rfloor$.
- For even $m \geq 4$,

$$d^* = \begin{cases} r w_E(1) & \text{if } r = 2 \text{ or } r = 3 \\ \lfloor (r+1)/2 \rfloor & \text{if } r \geq 4. \end{cases}$$

- For odd $m \geq 3$, let p be the smallest prime divisor of m , and let $n = m/p$. Define

$$d_*(r, m) = \left\lfloor \frac{r}{p} \right\rfloor \sum_{i=1}^{p-1} w_E(in) + \min_{1 \leq j \leq p-1} \sum_{i=1}^{r \bmod p} w_E(ijn \bmod p).$$

Then

$$d^* = \begin{cases} r\mathbf{w}_E(1) & \text{if } r < p \\ d_*(r, m) & \text{if } r \geq 2p \\ \min\{r\mathbf{w}_E(1), d_*(r, m)\} & \text{if } p \leq r < 2p. \end{cases}$$

A sketch of how to get this result follows:

- $m = 2$:

We can use the explicit expressions we have for α and d^* in the binary case. For Rep_r , $d_f^o = r$ and $d_f^o + 1 \notin \mathcal{H}$. For the accumulator, $d_{f,2}^i = d_{1,\text{term}}^i = 1$ and $d_{f,3}^i = +\infty$.

- even $m \geq 4$:

Notice that $d_f(\frac{m}{p_i}\text{Rep}_r) = r$ for all prime $p_i|m$, so that, if $2|m$ by Proposition 7.1, then $\alpha = \lfloor (r+1)/2 \rfloor$. Then compute the following:

- $H = (r\mathbb{N})^{m-1} \setminus \{\mathbf{0}\}$.
- If $r \geq 4$, then $\mathcal{H} = \{\mathbf{h} \in H : |\mathbf{h}| = r, n_o(\mathbf{h}) = 1, n_i(\mathbf{h}) = \lfloor |\mathbf{h}|/2 \rfloor\} = \{\mathbf{k}\}$, where $\mathbf{k}_{m/2} = r$, and $\mathbf{k}_i = 0$ for all $i \neq m/2$. This gives $d^* = \lfloor (r+1)/2 \rfloor \mathbf{w}_E(m/2)$. Notice that $\mathbf{w}_E(m/2) = 1$.
- If $r = 3$, then we have $\mathcal{H} = \{\mathbf{k}, 2\mathbf{k}, \mathbf{k}^{(1)}, \dots, \mathbf{k}^{(m/2-1)}\}$ with $\mathbf{k}$ as above and $\mathbf{k}^{(j)}$ defined by $\mathbf{k}_j^{(j)} = \mathbf{k}_{m-j}^{(j)} = r$ and $\mathbf{k}_i^{(j)} = 0$ for all $i \notin \{j, m-j\}$. Then

$$d^* = \min\{\lfloor \frac{r+1}{2} \rfloor \mathbf{w}_E(\frac{m}{2}), r\mathbf{w}_E(1), \dots, r\mathbf{w}_E(m)\} = \min\{2\mathbf{w}_E(\frac{m}{2}), 3\mathbf{w}_E(1)\}.$$

Then $m \geq 4$ implies $\mathbf{w}_E(1) \leq 1/2 = \mathbf{w}_E(m/2)/2$, so $d^* = 3\mathbf{w}_E(1)$.

- If $r = 2$, then $\mathcal{H} = \{\mathbf{h} \in H : \mathbf{h}_i = \mathbf{h}_{m-i} \forall i = 1, \dots, m/2 - 1\}$, and, with the same reasonings as above, we find again that $d^* = \lfloor (r+1)/2 \rfloor$ for $m = 2$ and $d^* = d^*((2, 0, \dots, 0, 2)) = 2\mathbf{w}_E(\phi_i(1-D)) = 2\mathbf{w}_E(1)$ for $m \geq 4$.

- odd $m \geq 3$:

- $H = (r\mathbb{N})^{m-1} \setminus \{\mathbf{0}\}$.
- Compute

$$\min_{\mathbf{h} \in H : |\mathbf{h}| = kr} f(\mathbf{h}) = \begin{cases} 1 + kr - k - \frac{k}{2}r & \text{if } k \text{ even,} \\ 1 + kr - k - \frac{k-1}{2}r - \lfloor r/p \rfloor & \text{if } k \text{ odd.} \end{cases}$$

Notice that both expressions are nondecreasing in k and increasing in k if $r \geq 3$, so that $\alpha = \min\{r-1, r - \lfloor r/p \rfloor\}$.

- If $r = 2$, then $\alpha = 1$ and $\mathcal{H} = \{\mathbf{h} \in H : \mathbf{h}_i = \mathbf{h}_{m-i} \forall i = 1, \dots, m/2 - 1\}$, so that $d^* = r\mathbf{w}_E(1)$, obtained for $\mathbf{h} = r\mathbf{e}_1 + r\mathbf{e}_{-1}$.
- If $2 < r < p$, then $\alpha = r-1$ and $\mathcal{H} = \{\mathbf{k}^{(1)}, \dots, \mathbf{k}^{((m-1)/2)}\}$, the $\mathbf{k}^j$'s defined as for even m . So again $d^* = r\mathbf{w}_E(1)$.
- If $r \geq 2p$, then $\alpha = r - \lfloor r/p \rfloor$ and $\mathcal{H} = \{r\mathbf{e}_{m/p}, r\mathbf{e}_{2m/p}, \dots, r\mathbf{e}_{(p-1)m/p}\}$, from which the expression for d^* easily follows.
- If $p \leq r < 2p$, then $\alpha = r-1 = r - \lfloor r/p \rfloor$, and $\mathcal{H}$ is the union of the set $\mathcal{H}$ computed for $r < p$ and the one computed for $r \geq 2p$; thus, d^* is the minimum of the two values obtained before.

The repeat-accumulate code on $\mathbb{Z}_3$ ($r \geq 3$) is an example where the upper bound $\alpha \leq d_f^o - \lfloor d_f^o/3 \rfloor$ is reached with equality. Now, we show another simple repeat-convolute code on $\mathbb{Z}_3$ such that the lower bound $\alpha \geq \lfloor (d_f^o + 1)/2 \rfloor$ is reached with

equality, showing that the bounds in Proposition 7.1 are the best possible for general m .

Example 7.5. Consider $m = 3$, $\phi_o = \text{Rep}_r$ ($r \geq 2$), and $\phi_i = 1/(1+D) = \sum_{t \geq 0} D^{2t} + 2D^{2t+1}$, with the termination rule that always brings the zero state back to zero in one trellis step (i.e., if at time t the codeword has $c_t = a$, we terminate using the input $u_{t+1} = -a$ if t is even, or a if t is odd).

Then, as for the repeat-accumulate, $H = r\mathbb{N}^2 \setminus \{(0,0)\}$, and given $\mathbf{h} = (rh_1, rh_2)$ we have $n_o(\mathbf{h}) = h_1 + h_2$. But now, when we look at the inner encoder to compute $n_i(\mathbf{h})$, we find $n_i(\mathbf{h}) = \lfloor |\mathbf{h}|/2 \rfloor$, because all of the following inputs produce a complete error event of ϕ_i : $\mathbf{u} = D^t + D^{t+1}$, $\mathbf{u} = 2D^t + 2D^{t+1}$, $\mathbf{u} = D^t + 2D^{t+2}$, and $\mathbf{u} = 2D^t + D^{t+2}$.

As a consequence,

$$\alpha = \lfloor (r+1)/2 \rfloor.$$

Let's compute $q^* = \frac{1}{2} \text{erfc} \sqrt{d^* E_s / N_0}$ for this example. First of all we need $\mathcal{H}$:

$$\mathcal{H} = \begin{cases} H & \text{if } r = 2 \\ \{(r,0), (0,r), (r,r), (2r,0), (0,2r)\} & \text{if } r = 3 \\ \{(r,0), (0,r)\} & \text{if } r > 3. \end{cases}$$

Now consider that $w_E(\phi_i(D^t + D^{t+1})) = w_E(D^t) = w_E(1) = 3/4$; analogously $w_E(\phi_i(2D^t + 2D^{t+1})) = w_E(2) = 3/4$; while $w_E(\phi_i(D^t + 2D^{t+2})) = w_E(D^t + 2D^{t+1}) = w_E(1) + w_E(2) = 3/2$ and $w_E(\phi_i(2D^t + D^{t+2})) = 3/2$. Assuming that termination is always done in one single step, we also have that $w_E(\phi_i^N(D^{N-1})) = w_E(\phi_i^N(2D^{N-1})) = 3/4$. Finally, we get $d^* = \frac{3}{4} \lfloor \frac{r+1}{2} \rfloor$.

Notice that for repeat-accumulate codes (Example 7.4), $\alpha = \lfloor (r+1)/2 \rfloor$ for all even m . This is true for all repeat-convolute codes by Proposition 7.1 together with the remark that $d_f(\frac{m}{p_i} \text{Rep}_r) = r$ for all prime $p_i | m$. However, for a general outer encoder ϕ_o this is not true: the assumption that m is a power of two is essential in Corollary 7.2, as shown by the following example.

Example 7.6. Let $m = 6$. Consider ϕ_o , which is the following slight variation of a repeat code: $\phi_o = [1, 1, 1, 1, 3]^T$. Let the inner encoder be the accumulator $\phi_i = \frac{1}{1-D}$. For $p_1 = 2$ we have $\phi_{1,o} = [1, 1, 1, 1, 1]^T$, which has $d_f(\phi_{1,o}) = 5$, while for $p_2 = 3$ we have $\phi_{2,o} = [1, 1, 1, 1, 0]^T$, which has $d_f(\phi_{2,o}) = 4$, and so $d_f^o = d_f(\phi_{2,o}) = 4$. The bounds given in Proposition 7.1 give us $2 \leq \alpha \leq 3$, and now we will show that $\alpha = 3$. Notice that $f(\mathbf{h}) = \alpha$ implies that $1 + |\mathbf{h}| - \frac{|\mathbf{h}|}{d_f^o} - \frac{|\mathbf{h}|}{2} \leq \alpha \leq 3$ and then $|\mathbf{h}| \leq 8$, so $\mathcal{H} \subseteq \{\mathbf{h} \in H : |\mathbf{h}| \leq 8\}$. There are seven elements in H with $|\mathbf{h}| \leq 8$. By computing $f(\mathbf{h})$ for all of them, we get $\alpha = 3$, $\mathcal{H} = \{(0,4,0,0,0), (0,0,5,0,0), (0,0,0,4,0)\}$, and, finally, for 6-PSK-AWGN channel, $q^* = \frac{1}{2} \text{erfc} \sqrt{d^* E_s / N_0}$ with $d^* = 2w_E(2) + w_E(4) = 9/4$, reached when $\mathbf{h} = (0,4,0,0,0)$ and $\mathbf{h} = (0,0,0,4,0)$.

7.2. Subgroups of permutations for the $\mathbb{Z}_m$ scheme. In the previous section, we have considered $\mathbb{Z}_m$ -schemes

$$\xrightarrow{\mathbb{Z}_m^{kN}} \boxed{\phi_o^N} \xrightarrow{\mathbb{Z}_m^{r(N+\nu_o)}} \boxed{\pi_N} \xrightarrow{\mathbb{Z}_m^{sM_N}} \boxed{\phi_i^N} \xrightarrow{\mathbb{Z}_m^{l(M_N+\nu_i)}}$$

by taking $U = \mathbb{Z}_m^k$, $Y = \mathbb{Z}_m$, $\Gamma = \mathbb{Z}_m$ in the general serial scheme. However, we can also obtain some $\mathbb{Z}_m$ schemes by taking $Y = \mathbb{Z}_m^a$. Then, if we consider on $\mathbb{Z}_m^a$ a weight

given by the componentwise extension of the type weight on $\mathbb{Z}_m$, then we again get the same scheme as above. However, in this case we can also consider permutations moving around not single elements of $\mathbb{Z}_m$, but only the vectors in $\mathbb{Z}_m^a$, so that the invariant weight is the type weight on $\mathbb{Z}_m^a$. Or, on the contrary, we can consider a *separate channels permutation*: the invariant weight is $\mathbf{w} \in (\mathbb{N}^{m-1})^a$ given by the type weight on each separate component of $\mathbb{Z}_m^a$.

Even though these schemes are quite similar to the classical one, differing only for a restriction of the permutations to a subgroup of $S_{r(N+\nu_o)}$, Proposition A.2 and Corollary 7.2 do not hold true. We give here a simple example, for the binary case $m = 2$, and for the *separate channels permutation*, where $\alpha > \lfloor (d_f^o + 1)/2 \rfloor$.

Example 7.7. Consider the following outer and inner binary encoders:

$$\phi_o = \left[1, \frac{1}{1+D+D^3} \right]^T, \quad \phi_i = \begin{bmatrix} \frac{1}{1+D} & 0 \\ 0 & \frac{1}{1+D} \end{bmatrix},$$

and consider the *separate channels permutation* ensemble (here $m = 2$ and $a = 2$, and therefore $\mathbf{w} \in \mathbb{N}^2$ is the Hamming weight of the two streams). The outer encoder has free distance $d_f^o = 4$ and all of the words $\mathbf{c}$ of the outer code such that $d_H(\mathbf{c}) = d_f^o$ are obtained when input is $1 + D + D^3$ or its shifts and have $\mathbf{w}(\mathbf{c}) = (3, 1)$. The inner encoder is simply the rate-1 accumulator, but acting separately on the two input streams.

We claim that for this scheme $\alpha = 3 > \lfloor (d_f^o + 1)/2 \rfloor = 2$. In fact, we know that $\alpha \geq \lfloor (d_f^o + 1)/2 \rfloor = 2$, where equality could be reached only if there was $\mathbf{h} \in H$ such that $|\mathbf{h}| = 4$, $n_o(|\mathbf{h}|) = 1$, $n_i(\mathbf{h}) = 2$, but this is not possible as the only $\mathbf{h} \in H$ such that $|\mathbf{h}| = 4$ is $\mathbf{h} = (3, 1)$, which has $n_o(\mathbf{h}) = 1$ and $n_i(\mathbf{h}) = 1$, giving $f(\mathbf{h}) = 3$ so $\alpha = 3$.

By an exhaustive listing of all small-weight codewords, we can also find $\mathcal{H}$, noting that $\mathbf{h} \in \mathcal{H}$ implies $|\mathbf{h}| \leq 8$. Then we can find $q^* = Q(3)$.

Remark 7.8. The separate channels ensemble is particularly interesting because it allows us to also include in our generalized serial concatenations traditional parallel turbo codes (as it was already noticed, e.g., in [1]): a turbo code with b parallel branches, each with an encoder ψ_j of rate k_j/n_j , can always be seen as a repeat-convolute scheme, where $\phi_o = \text{Rep}_r$ and $r = \sum k_j$ as the interleaver acts separately on the b streams of $k_j \times N$ bits and ϕ_i is a block diagonal matrix where the blocks are the ψ_j 's.

7.3. Structured LDPC ensemble. For a description of these schemes, see section 4.3. Here we give some statements about the parameters α and d^* .

First of all, we have the following tight bounds for α .

PROPOSITION 7.9. *For the structured LDPC ensemble,*

$$\lfloor (c + 1)/2 \rfloor \leq \alpha \leq c - \lfloor c/p_{\min} \rfloor,$$

where $p_{\min} = \min\{p_j \geq 2 : p_j | m\}$.

Proof. By Proposition 5.7, we have $\alpha \geq \lfloor (d_{f,1}^o + 1)/2 \rfloor = \lfloor (c + 1)/2 \rfloor$. The proof of the upper bound is similar to the proof of Proposition 7.1. Notice that here $p_{\min}$ is computed considering all prime factors of m because the outer encoder is a simple repetition code. $\square$

In particular, this proposition implies that for all even m the interleaver gain is

$$\alpha = \lfloor (c + 1)/2 \rfloor.$$

In the binary case ($m = 2$), we can also characterize q^* . In fact, we can easily describe $\mathcal{H}$ as

$$\mathcal{H} = \begin{cases} \{(2w, w) : w \in \mathbb{N}^*\} & \text{if } c = 2 \\ \{(3, 1), (6, 2)\} & \text{if } c = 3 \\ \{(c, 1)\} & \text{if } c \geq 4. \end{cases}$$

Then compute $q^* = Q(d^*)$,

$$d^* = \begin{cases} 1 & \text{if } c \text{ is even} \\ 2 & \text{if } c = 3 \\ 1 + \min \{d_{1,\text{term}}(\psi), d_{f,3}(\psi)\} & \text{if } c \text{ is odd, } c \geq 5, \end{cases}$$

where $d_{1,\text{term}}(\psi), d_{f,3}(\psi)$ are defined as $d_{1,\text{term}}^i, d_{f,3}^i$ in Proposition 7.3 but referring here to ψ instead of ϕ_i . If the inner encoder is truncated instead of terminated, then $d^* = 2$ for all odd c .

Notice that the choice of ψ has almost no influence on d^* . This happens because pairs of bits which are repetition of a same information bit can be permuted by some interleaver in such a way that they are summed up by Sum_d , producing a zero output. The value of d^* is given by this worst case scenario. This remark suggests considering interleavers with a better spread, enforcing the fact that 1's coming from the same error event of Rep_c cannot end up in positions where they would be summed up by Sum_d . However, the analysis of such a smaller ensemble, with a set of interleavers which is not a group, is beyond the scope of this paper. See [24] for the results that can be obtained and a sketch of the techniques used; more details on structured LDPC codes will be given in a paper now in preparation.

For general m there is no explicit simple characterization of q^* , nor is there one for all even m . We can just notice that, on m -PSK-AWGN channels, by the same argument used for $m = 2$, if both m and c are even, then $q^* = \frac{1}{2} \text{erfc} \sqrt{d^* E_s / N_0}$ with $d^* \leq w_E(m/2) = 1$. This upper bound is achieved, for example, by simply taking $\psi = 1/(1-D)$. To see that this upper bound is not always achieved, take, for example, $m = 6$ and $\psi = 1/(1+D)$: we have that $\psi(1+D) = 1$, which is an error event of Euclidean weight $w_E(1) = 1/4$, so that for $c = 2$ or $c = 4$ we have $d^* = \frac{1}{4} + \frac{c}{2} \frac{1}{4} < 1$.

8. Conclusion. In this paper we have studied the average ML performance of a wide class of generalized serial turbo schemes, coupling two convolutional encoders over groups through an interleaver respecting the group structure; these codes are designed to be used on symmetric channels. A particularly relevant example is the case when the convolutional codes are modules on $\mathbb{Z}_m$, the interleaver is a permutation, and the channel is AWGN with m -PSK input constellation.

We have obtained the exact asymptotic decay of the symbol and word error probability when the interleaver length goes to infinity and also the behavior when the SNR goes to infinity. The performance is characterized by the interleaver gain α and the effective distance q^* , which are defined as the solution of an optimization problem and, in general, jointly depend on both constituent encoders, differently from the binary case. To make clear the meaning of these parameters, we have explicitly computed them in some examples encompassing most of the relevant scenarios.

This work is a first attempt to give a rigorous analysis of generalized serial turbo schemes for nonbinary modulations. It leaves many open questions among which the most natural ones are, in our opinion, the following:

- Our analysis provides design parameters. The next research step would be to extensively search for pairs of constituent encoders being good with respect to these parameters, and to confirm the validity of the approach by a significant simulation analysis, as it has already been done for the binary turbo codes. However, here the optimization of the constituent encoders under some fixed complexity bound (e.g., the size of the state spaces) seems a quite challenging problem, due to the complexity of the combinatorial optimization problem.
- The ensemble analysis in this paper is limited to the average behavior. The study of the average properties is usually only the first step in the understanding of a family of codes. The next step is to find the typical performance. For the binary classical serial turbo ensemble, the typical error probability turns out to be much better than the average, with subexponential vs. polynomial decay, but depending on the same design parameters [8]. This is analogous of the well-known behavior of ML-decoded LDPC codes (see [22, 33]): for the (c, d) -regular LDPC ensemble, with $c \geq 3$, the average error probability is known to decrease to zero as $N^{1-c/2}$ for even c and N^{2-c} for odd c , while the error probability of a typical code goes to zero exponentially fast. In both cases, the average is strongly affected by a small fraction of very bad codes, which can be expurgated. The proofs proposed in [8] heavily rely on properties of binary codes, and so the generalization to our setting is not straightforward.

Appendix. Properties of free $\mathbb{Z}_m$ convolutional encoders. In this section, we consider convolutional encoders $\phi : \mathbb{Z}_m^{k\mathbb{N}} \rightarrow \mathbb{Z}_m^{n\mathbb{N}}$ which can be represented as matrices $\phi \in \mathbb{Z}_m^{k \times n}(D) \simeq \mathbb{Z}_m(D)^{k \times n}$. We will call them free $\mathbb{Z}_m$ convolutional encoders. They are the most straightforward generalization of classical binary convolutional encoders, and they have some interesting properties. Let us start with a simple algebraic remark: we know that ϕ can be represented as $\phi = p(D)^{-1}q(D)$ for some $p(D) \in \mathbb{Z}[D] \cap \mathbb{Z}((D))^*$ and $q(D) \in \mathbb{Z}_m[D]^{k \times n}$. Since all of the algebraic structures involved are also $\mathbb{Z}_m$ -modules, it turns out that we can as well assume that $p(D) \in \mathbb{Z}_m[D] \cap \mathbb{Z}_m((D))^*$ which, in practice, means that $p(D)$ has all coefficients in $\mathbb{Z}_m$ and the trailing coefficient is in $\mathbb{Z}_m^*$.

In section 3.3.2, we gave a general definition of recursiveness. In the binary case (for simplicity consider scalar input, i.e., $\phi : \mathbb{Z}_2^{\mathbb{N}} \rightarrow \mathbb{Z}_2^{n\mathbb{N}}$), there are well-known characterizations of w_H -recursive encoders: ϕ is recursive when its shift-register state representation has a feedback, or, equivalently, when $\phi = \frac{1}{q(D)}[p_1(D), \dots, p_n(D)]$ (with $\gcd\{q, p_1, \dots, p_n\} = 1$) has nontrivial denominator, i.e., $q(D) \neq D^h$. This latter characterization allows us to check very easily if an encoder is recursive, which we will now generalize to recursiveness of free $\mathbb{Z}_m$ encoders with respect to Hamming or, equivalently, to type weight in $\mathbb{Z}_m$ (not the Hamming weight in $\mathbb{Z}_m^k$).

First of all, without loss of generality we can restrict ourselves to considering scalar encoders $\phi : \mathbb{Z}_m^{\mathbb{N}} \rightarrow \mathbb{Z}_m^{\mathbb{N}}$: if not so, notice that $\phi : \mathbb{Z}_m^{k\mathbb{N}} \rightarrow \mathbb{Z}_m^{n\mathbb{N}}$ is w -recursive (w being the Hamming or the type weight in $\mathbb{Z}_m$) if and only if each column of its matrix has at least one entry which is a scalar w -recursive encoder.

Then, if m is a prime (so that $\mathbb{Z}_m$ is a field), then $\phi = p(D)/q(D)$ with $p(D), q(D) \in \mathbb{Z}_m[D]$ and $\gcd(p, q) = 1$ is w -recursive if and only if $q(D) \neq D^t$: as in the binary case, we can identify recursive encoders at a glance, just looking at their denominator.

If m is not a prime, then let $m = p_1^{\alpha_1} \dots p_l^{\alpha_l}$ be its prime factors decomposition, and let $\phi_i : \mathbb{Z}_{p_i}^{\mathbb{N}} \rightarrow \mathbb{Z}_{p_i}^{\mathbb{N}}$ be obtained by taking the restriction of ϕ to inputs in $\frac{m}{p_i}\mathbb{Z}_m$ and then identifying $\frac{m}{p_i}\mathbb{Z}_m$ with $\mathbb{Z}_{p_i}$ through the natural fields isomorphism mapping.

PROPOSITION A.1. ϕ is $\mathbf{w}$ -recursive if and only if $\phi_1, \dots, \phi_l$ are $\mathbf{w}$ -recursive.

Proof. The first implication is trivial. Conversely, knowing that $\phi_1, \dots, \phi_l$ is recursive, but we want to show that $w_H(\phi(D)u) = +\infty$ for any $u \in \mathbb{Z}_m \setminus \{0\}$. Since $u < m$, there exist $i \in \{1, \dots, l\}$ and $r \in \mathbb{N}$ such that $p_i^r | u$, $p_i^{r+1} \nmid u$, and $p_i^{r+1} | m$. Consider $\tilde{u} = (p_i^{-1}m)(p_i^{-r}u) = (p_i^{-r-1}m)u$. Clearly, $\tilde{u} \neq 0$ and, by the assumptions made, $w_H(\phi(D)\tilde{u}) = \infty$. This clearly implies that $w_H(\phi(D)u) = \infty$ also. $\square$

The characterization given by Proposition A.1 is helpful because the encoders $\phi_1, \dots, \phi_l$ can be obtained very easily from ϕ : writing $\phi(D) = p(D)/q(D)$ with $p(D)$ and $q(D) \in \mathbb{Z}_m[D]$, we have $\phi_j(D) = \tilde{p}(D)/\tilde{q}(D)$, where $\tilde{p}(D), \tilde{q}(D)$ are polynomials in $\mathbb{Z}_{p_j}$ obtained multiplying each coefficient of $p(D)$ (resp., $q(D)$) by m/p_j (modulo m) and then identifying the corresponding element in $\mathbb{Z}_{p_j}$.

For example, the encoder $\phi : \mathbb{Z}_8^\mathbb{N} \rightarrow \mathbb{Z}_8^\mathbb{N}$ defined by $\phi(D) = \frac{1+3D^2}{1+7D}$ is not recursive, but we cannot tell by simply looking at the denominator, which is nontrivial. However, we can tell by using the definition given in section 3.3.2: notice that $\phi(D) = (1 + 3D^2) \sum_{t \geq 0} D^t$, and then input $u(D) = 2$ produces output $2\phi(D) = 2 + 2D \in \mathbb{Z}_8[D]$. We can also check the recursiveness of ϕ using Proposition A.1: as $m = 8$ has only one prime divisor $p_1 = 2$, we need to check only one encoder $\phi_1 = \frac{1+D^2}{1+D} = 1 + D$ which clearly isn't recursive.

By the same technique of looking at the encoders $\phi_1, \dots, \phi_l$ defined previously, we can obtain a characterization of the free distance of ϕ with respect to Hamming or type weight in $\mathbb{Z}_m$. This characterization is not interesting under a computational point of view, as the computation of the free distance of encoders over fields or rings does not have a different complexity, but it is essential to find tight bounds for the interleaver gain of free $\mathbb{Z}_m$ serial schemes (Proposition 7.1 and Corollary 7.2).

PROPOSITION A.2. Let d_f be the $\mathbf{w}$ -free distance of ϕ , and $d_f(\phi_j)$ be the $\mathbf{w}$ -free distance of ϕ_j , where $\mathbf{w}$ is Hamming or type weight in $\mathbb{Z}_m$ and $\mathbb{Z}_{p_j}$, respectively. Then

$$d_f = \min_{j=1, \dots, l} \{d_f(\phi_j)\}.$$

Proof. Clearly, for all $j = 1, \dots, l$, $d_f(\phi_j) = d_f(\frac{m}{p_j}\phi) \geq d_f$. Now we will prove that there exists at least one j such that $d_f(\phi_j) = d_f$.

Let $\mathcal{C} = \phi(\mathbb{Z}_m^k((D)))$, and let $\mathbf{x} \in \mathcal{C}$ be a codeword such that $w_H(\mathbf{x}) = d_f$. The key remark is that $w_H(\mathbf{x}) = d_f$ implies that all nonzero symbols (i.e., elements of $\mathbb{Z}_m$) of $\mathbf{x}$ have the same annihilator. In fact, $w_H(\mathbf{x}) = d_f$ means that for all $\mathbf{y} \in \mathcal{C} \setminus \{\mathbf{0}\}$, $w_H(\mathbf{y}) \geq w_H(\mathbf{x})$, which implies that

$$\nexists a \in \mathbb{Z}_m \text{ such that } 0 < w_H(a\mathbf{x}) < w_H(\mathbf{x}).$$

Therefore for all $a \in \mathbb{Z}_m$, either $a\mathbf{x} = \mathbf{0}$ or $w_H(a\mathbf{x}) = d_f$; i.e., $a\mathbf{x}_i \neq 0$ for all $\mathbf{x}_i \neq 0$.

This remark implies that there exists $d|m$ (possibly $d = 1$) and there exists p_j , a prime factor of m such that $w_H(d\mathbf{x}) = w_H(\mathbf{x})$ and $p_j d\mathbf{x} = \mathbf{0}$. Now, choosing $\mathbf{c} = d\mathbf{x}$ we have a codeword $\mathbf{c} \in \frac{m}{p_j}\mathcal{C}$ such that $w_H(\mathbf{c}) = d_f$, so that we can conclude that $d_f(\phi_j) = d_f(\frac{m}{p_j}\phi) = d_f$. $\square$

Finally, when proving Proposition 7.1 we also need the following simple lemma, even though it is just a property of $\mathbb{Z}_m$ and not of convolutional codes.

LEMMA A.3. Given $a_1, \dots, a_m \in \mathbb{Z}_m \setminus \{0\}$, there exist indexes $\{i_1, \dots, i_n\} \subseteq \{1, \dots, m\}$ such that $a_{i_1} + \dots + a_{i_n} = 0 \pmod m$.

Proof. By contradiction, assume that $\sum_{i \in \mathcal{I}} a_i \neq 0 \pmod m$ for all nonempty $\mathcal{I} \subseteq \{1, \dots, m\}$. Then, in particular, $\sum_{i=1}^n a_i \neq 0 \pmod m$ for all $n = 2, \dots, m$ and so

$a_1 \notin \{-a_2, -a_2 - a_3, \dots, -\sum_{j=2}^m a_j\}$, which, being a set of $m - 1$ distinct nonzero elements of $\mathbb{Z}_m$ is $\mathbb{Z}_m \setminus \{0\}$ itself, contradicts $a_1 \in \mathbb{Z}_m \setminus \{0\}$. $\square$

TROPICAL LINEAR SPACES*

DAVID E. SPEYER†

Abstract. We define the tropical analogues of the notions of linear spaces and Plücker coordinates and study their combinatorics. We introduce tropical analogues of intersection and dualization and define a tropical linear space built by repeated dualization and transverse intersection to be constructible. Our main result is that all constructible tropical linear spaces have the same f -vector and are “series-parallel”. We conjecture that this f -vector is maximal for all tropical linear spaces, with equality precisely for the series-parallel tropical linear spaces. We present many partial results towards this conjecture.

Key words. tropical linear space, tropical geometry, matroid, valuated matroid, f -vector conjecture

1. Introduction and summary. The last five years have shown an explosion of interest in the field of tropical geometry. In tropical geometry, multiplication is replaced by addition and addition by minimum. See [19] or [16] for an introduction. A polynomial is said to vanish tropically if, among the values of its terms, the minimum is not unique. For example, $xy + x + y$ vanishes tropically if $x = y \leq x + y$ or $x = x + y \leq y$ or $y = x + y \leq x$. One motivation for this definition is that this is the union of the three sets $x + y = \min(x, y)$, $x = \min(x + y, y)$, and $y = \min(x, x + y)$ which can be obtained by replacing multiplication by addition and addition by minimum in the various equations $-xy = x + y$, $-x = xy + y$, and $-y = xy + x$.

We will study the tropical analogues of the notions of linear spaces and Plücker coordinates. One of the pleasures of this theory is that it can be set up in a purely combinatorial manner without reference to general tropical theory. However, doing so requires defining slightly more inclusive notions of tropical linear space than if the theory were exactly set up to match the classical geometry. This is very similar to the situation of matroid theory, where the definition of a matroid is simple and almost every operation that can be performed with a vector arrangement has a corresponding operation for a general matroid. On the other hand, characterizing those matroids that come from vector arrangements—the realizable matroids—is very hard. Our approach in this paper will be to focus on pure combinatorics. In section 4.5 of my dissertation (see [18]) I give many examples and counter-examples regarding the subtle behaviors which can occur when one tries to study the tropical analogue of realizability.

Tropical linear spaces will be polyhedral complexes. Thus, we can ask about all of the invariants associated to polyhedral complexes. Ardila and Klivans [2] have studied the link of a vertex in a tropical linear space and have shown it to be homeomorphic to the chain complex of the lattice of flats of a certain matroid and thus homotopic to a wedge of spheres. The polytopes occurring in tropical linear spaces are Minkowski summands of permutahedra (Proposition 2.6). The topology of tropical linear spaces

†Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA 02139 (speyer@math.mit.edu).

is quite simple: they are contractible (Theorem 2.9). So we understand the local combinatorics and the local and global topology of tropical linear spaces.

The global combinatorics of tropical linear spaces, on the other hand, is quite intriguing. There is a great deal of theoretical and some experimental evidence for the following.

The f -vector conjecture. *The number of i -dimensional faces of a tropical d -plane in n -space which become bounded after being mapped to $\mathbb{R}^n/(1, \dots, 1)$ is at most*

$$\frac{(n-i-1)!}{(d-i)!(n-d-i)!(i-1)!}.$$

This conjecture is proven, in [17], in the case where the tropical linear space arises from a $\mathbb{C}((t))$ -valued point of the Grassmannian $G(d, n)$. That argument should probably be considered to be the best evidence for the f -vector conjecture at this point.

Remark 1.1. It would follow from the f -vector conjecture that the total number of i -dimensional faces of a tropical d -plane in n -space, without any boundedness condition, is at most $\binom{n-i-1}{d-i} \binom{2n-d-1}{i-1}$. See Proposition 2.11.

In section 2, we will define the basic concepts mentioned in this introduction and prove their essential properties. We will also introduce an operation called dualization, which is analogous to the classical operation of taking the orthogonal complement of a linear space.

In section 3, we will prove the f -vector conjecture in two special cases: where $i = 1$ and where $d = \lfloor n/2 \rfloor$. This section is largely independent of the rest of the paper and shows what we can accomplish with fairly direct arguments. We do warn the reader, however, that the notation $\Gamma(M, M')$ introduced in section 3 will recur throughout this paper. After this section, we move to the main tasks of this paper: defining constructible linear spaces and proving their main properties.

In section 4, we will introduce an operation of transverse intersection that produces new tropical linear spaces from old. We define a tropical linear space to be *constructible* if it can be built from tropical hyperplanes (equivalently, from points) by successive dualization and transverse intersection. Much of the rest of the paper will be devoted toward proving the following.

THEOREM 1.2. *Every constructible space achieves the f -vector of the f -vector conjecture.*

As we will explain in section 2, every tropical linear space is built out of a collection of matroids. A particularly nice class of matroids is the series-parallel matroids; the linear spaces that are built out of series-parallel matroids are called series-parallel linear spaces. In section 5 we will review standard results on series-parallel matroids and prove some new ones. In section 6, we will prove Theorem 1.3.

THEOREM 1.3. *Every constructible space is series-parallel.*

One unfortunate consequence of Theorem 1.3 is that it is quite hard to find a general method for writing down tropical linear spaces that are not series-parallel! More precisely, it is not so hard to produce degenerate limits of series-parallel linear spaces which are not themselves series-parallel. Writing down a large number of tropical linear spaces which are not limits of series-parallel tropical linear spaces, however, is a challenge—which is one of the reasons why experimentally testing the f -vector conjecture is tricky.

We pause in section 7 to prove a polyhedral lemma. In section 8 we undertake a very detailed study of how the combinatorics of the intersection of a pair of linear spaces changes when we perturb those linear spaces. We are then ready, in section 9, to prove Theorem 1.2. Our proof involves results from sections 5, 7, and 8, as well as several binomial coefficient identities.

Most of our vocabulary regarding matroids and polytopes is quite standard. We address a few issues here. The word *circuit* refers to a minimal dependent set in a matroid. This terminology is motivated by applications to graph theory which we will not discuss. There will be several graphs appearing in this paper, which we will not consider as matroids. When we want to refer to a cyclic induced subgraph of a given graph, we will use the term *cycle*. A *loop* of a matroid is an element which is not in any basis; a *coloop* is an element which is in every basis. The matroid consisting of an individual loop, or of an individual coloop, is connected. The *uniform matroid of rank d on a set S* , which we will denote by $\text{Uniform}(d, S)$, is the matroid on S whose bases are all d -element subsets of S . The next two definitions are not standard: a *filtration* of a matroid is an ascending chain of subsets $F_0 \subsetneq F_1 \subsetneq F_2 \subsetneq \cdots \subsetneq F_r$ of the ground set of M , with $F_0 = \emptyset$ and F_r the entire ground set of M . The *associated graded matroid of M with respect to $F_\bullet$* , denoted $\text{gr}(M, F_\bullet)$ is the matroid $\bigoplus (M|_{F_{i+1}})/F_i$. Note that each summand of $\text{gr}(M, F_\bullet)$ is a minor of M .

If P is a polytope, then $\mathbb{R}P$ is the vector space spanned by vectors of the form $p_1 - p_2$, with p_1 and p_2 in P . The dimension of P is the dimension of $\mathbb{R}P$. For Q a face of P , the *tangent cone* to P at Q denoted $T(P, Q)$ is the positive linear span of all vectors of the form $p - q$, with $p \in P$ and $q \in Q$. The *reduced tangent cone* to P at Q denoted $T_0(P, Q)$ is $T(P, Q)/\mathbb{R}Q$. The relative interior of P denoted $\text{Int}(P)$ is the set of points p in P which are not contained in any proper face of P .

2. Basic definitions and results. In this section, we introduce the definitions of a *tropical Plücker vector* and a *tropical linear space* by taking classical relations between Plücker coordinates and the linear spaces they describe and “tropicalizing” those relations. These are closely related to the valuated matroids and tight spans studied by Dress (see [9], [7], [10]). Tropical Plücker vectors give rise to subdivisions of a polytope known as the hypersimplex into smaller polytopes. Each of these smaller polytopes is associated to a combinatorial object known as a matroid, and for this reason we will frequently use tools from matroid theory. Just as ordinary linear spaces are determined by their Plücker coordinates, tropical linear spaces are determined by tropical Plücker coordinates. Specifically, if $\mathcal{D}$ is the subdivision of the hypersimplex associated to a tropical Plücker vector p , then the corresponding tropical linear space is a subcomplex of a dual subdivision $\mathcal{D}^\vee$ of $\mathbb{R}^n$.

For $f = \sum_{a \in A} f_a X^a$ a nonzero polynomial, where the coefficients f_a are nonzero and A is a finite subset of $\mathbb{Z}_{\geq 0}^n$, we denote by $\text{Trop}(f)$ the set of all points $(x_1, \dots, x_n)$ in $\mathbb{R}^n$ such that, if we form the collection of numbers $\sum_{i=1}^n a_i x_i$ for a ranging over A , then the minimum of this collection is not unique. Throughout the paper, we will use $\mathbf{X}$, $\mathbf{P}$, and $\mathbf{Q}$ to refer to variables in classical algebro-geometric coordinates and x , p , and q for the corresponding tropical variables. We will use classical algebraic geometry solely as an intuitive analogy to motivate our combinatorial constructions, but, of course, this analogy can be made far more precise.

Consider a collection of $\binom{n}{d}$ real numbers $p_{i_1 \dots i_d}$ indexed by the d element subsets of $[n] := \{1, \dots, n\}$. For any set S , we will write $\binom{S}{k}$ for the set of k -element subsets of S . We will say that p is a *tropical Plücker vector* if, for every $S \in \binom{[n]}{d-2}$ and every i, j, k , and l distinct members of $[n] \setminus S$, we have

$$(1) \quad (p_I) \in \text{Trop}(\mathbf{P}_{Sij}\mathbf{P}_{Sk l} - \mathbf{P}_{Sik}\mathbf{P}_{Sjl} + \mathbf{P}_{Sil}\mathbf{P}_{Sjk}).$$

(Here and elsewhere in this paper, we write Si as shorthand for $S \cup \{i\}$ and $\binom{S}{k}$ for the set of k -elements subsets of S .)

Remark 2.1. This definition is equivalent to saying that p_I is a valuated matroid with values in the semiring $(\mathbb{R}, +, \min)$. See [9] as well as the more general [7] and [10].

Let e_n be the standard basis of $\mathbb{R}^n$. Let $\Delta(d, n)$ denote the (d, n) -hypersimplex, defined as the convex hull of the points $e_{i_1} + \cdots + e_{i_d} \in \mathbb{R}^n$, where $\{i_1, \dots, i_d\}$ runs over $\binom{[n]}{d}$. (Here $e_1, \dots, e_n$ is the standard basis of $\mathbb{R}^n$.) We abbreviate $e_{i_1} + \cdots + e_{i_d}$ by $e_{i_1 \dots i_d}$. Consider a real-valued function $\{i_1, \dots, i_d\} \mapsto p_{i_1 \dots i_d}$ on the vertices of $\Delta(d, n)$. We define a polyhedral subdivision $\mathcal{D}_p$ of $\Delta(d, n)$ as follows: consider the points $(e_{i_1} + \cdots + e_{i_d}, p_{i_1 \dots i_d}) \in \Delta(d, n) \times \mathbb{R}$ and take their convex hull. Take the lower facets (those whose outward normal vector have last component negative) and project them back down to $\Delta(d, n)$; this gives us the subdivision $\mathcal{D}_p$. We will often omit the subscript p when it is clear from context. A subdivision which is obtained in this manner is called *regular*; see, for example, [24, Definition 5.3]. Another way of defining $\mathcal{D}$ is to say that a subset S of $\binom{[n]}{d}$ corresponds to a face of $\mathcal{D}$ if and only if there is an affine linear function $\lambda : \Delta(d, n) \rightarrow \mathbb{R}$, with $p_I - \lambda(e_I)$ minimized precisely at those I which lie in S .

Let P be a subpolytope of $\Delta(d, n)$. We say that P is *matroidal* if the vertices of P , considered as elements of $\binom{[n]}{d}$, are the bases of a matroid M . In this case, we write $P = \text{Poly}_M$. All faces of a matroidal polytope are also matroidal. Our references for matroid terminology and theory are White's anthologies [22] and [23].

PROPOSITION 2.2. *Let $p \mapsto p_I$ be a real-valued function on $\binom{[n]}{d}$. The following are equivalent:*

1. *The vector (p_I) is a tropical Plücker vector.*
2. *The one skeleta of $\mathcal{D}_p$ and $\Delta(d, n)$ are the same.*
3. *Every face of $\mathcal{D}_p$ is matroidal.*

Proof. $1 \implies 2$: Every edge of $\mathcal{D}$ joins two vertices of $\Delta(d, n)$. If e is an edge of $\mathcal{D}$ connecting e_I and e_J , we define the *length* of e , $\ell(e)$, to be $|I \setminus J| = |J \setminus I|$. Our claim is that every edge of e has length 1. We prove by induction on $\ell \geq 2$ that $\mathcal{D}$ has no edge of length ℓ .

We first consider the base case $\ell = 2$. If e is an edge with $\ell(e) = 2$, then $e = (e_{Sij}, e_{Skil})$ for some $S \in \binom{[n]}{d-2}$. The six vertices $e_{Sij}, e_{Sik}, e_{Sil}, e_{Sjk}, e_{Sjl}, e_{Skil}$ form the vertices of an octahedron O , with e_{Sij} and e_{Skil} opposite vertices. One can check that equation (1) implies that O is either a face of $\mathcal{D}$ or subdivided in $\mathcal{D}$ into two square pyramids (in one of three possible ways). In any of these cases, e is not an edge of $\mathcal{D}$.

Now consider the case where $\ell > 2$. Suppose (for contradiction) that e is an edge of $\mathcal{D}$. Let $e = (e_{ST}, e_{ST'})$, with $T \cap T' = \emptyset$, $|T| = |T'| = \ell$. Let F be the face of $\Delta(d, n)$ consisting of all vertices e_I , with $S \subset I \subset S \cup T \cup T'$. Then e must belong to some two-dimensional face of $\mathcal{D}$ contained in F ; call this two-dimensional face G .

Let γ be the path from e_{ST} to $e_{ST'}$ that goes around G the other way from e . No two vertices of F are more than distance ℓ apart, so the edges of γ have lengths less than or equal to ℓ . If γ contained an edge $(e_{SU}, e_{SU'})$ of length ℓ , then its midpoint $(e_{SU} + e_{SU'})/2$ would also be the midpoint of e , contradicting the convexity of G . Thus, every edge of γ has length less than ℓ and by induction must have length 1. So all of the edges of γ are in the direction $e_i - e_j$ for some i and $j \in [n]$. These vectors must span a two-dimensional space. This means either that there are $\{i_1, i_2, j_1, j_2\} \subset [n]$ such that all edges of γ are parallel to some $e_{i_r} - e_{j_s}$ or there are $\{i_1, i_2, i_3\} \subset [n]$ such that every edge of γ is parallel to some $e_{i_r} - e_{i_s}$. In either case, e has length at most 2, but that returns us to our base case.

2 $\implies$ 3: Let P be any polytope in $\mathcal{D}$. By assumption, all of the edges of P are edges of $\Delta(d, n)$. It is a theorem of Gelfand et al. ([13], Theorem 4.1) that this implies that P is matroidal.

3 $\implies$ 1: If 1 is false, $\mathcal{D}$ has a one-dimensional face of the form $\text{Hull}(e_{Sij}, e_{Skl})$, with i, j, k , and l distinct. This is not matroidal. $\square$

Now, suppose that $(p_I) \in \mathbb{R}^{\binom{[n]}{d}}$ is a tropical Plücker vector. Define $L(p) \subset \mathbb{R}^n$ by

$$(2) \quad L(p) := \bigcap_{1 \leq j_1 < \dots < j_{d+1} \leq n} \text{Trop} \left(\sum_{r=1}^{d+1} (-1)^r \mathbf{p}_{j_1 \dots \hat{j}_r \dots j_{d+1}} \mathbf{x}_{j_r} \right).$$

(The factor of $(-1)^r$ does not effect the right-hand side; we include it to emphasize the analogy with classical linear algebra.) We call any subset L of $\mathbb{R}^n$ which arises in this manner a *d-dimensional tropical linear space in n-space*. Rescaling all of the Plücker coordinates of a classical linear space by the same scalar does not alter the linear space. Similarly, it is clear from the definition that adding a constant to all of the tropical Plücker coordinates of a tropical linear space. See Proposition 2.8 for a converse result: A tropical linear space determines its Plücker coordinates up to this translation.

We can now define the term *series-parallel tropical Plücker vector*, used repeatedly in the introduction. A tropical Plücker vector p is called series-parallel if every facet of $\mathcal{D}_p$ corresponds to a series-parallel matroid; a tropical linear space $L(p)$ is called series-parallel if p is series-parallel. The definition and basic properties of series-parallel matroids are reviewed in section 5 and will be used continually in sections 6 and 8.

Let us compute two simple examples. First, let $d = 1$ and $n = 3$, and consider the tropical Plücker vector $(p_1, p_2, p_3) = (2, 5, 7)$. This is a tropical Plücker vector as equation (1) imposes no condition when $d = 1$ or $n - d = 1$. Then $L(p)$ is the set of points $(x_1, x_2, x_3) \in \mathbb{R}^3$ such that in each of the pairs $(x_1 + 5, x_2 + 2)$, $(x_1 + 7, x_3 + 2)$, and $(x_2 + 7, x_3 + 5)$ the minimum occurs more than once. The reader may check that this is precisely the set of triples $(x_1, x_2, x_3) = (2 + c, 5 + c, 7 + c)$, where c can be any real number. Alternatively, let $d = 2$, $n = 3$, and let $(p_{12}, p_{13}, p_{23}) = (3, 9, 13)$. Then $L(p)$ is the set of points $(x_1, x_2, x_3) \in \mathbb{R}^3$ such, among the triple $(x_1 + 13, x_2 + 9, x_3 + 3)$, the minimum occurs more than once. The reader may check that this is given by the union of three half-planes: $x_1 + 13 = x_2 + 9 \leq x_3 + 3$, $x_1 + 13 = x_3 + 3 \leq x_2 + 9$, and $x_2 + 9 = x_3 + 3 \leq x_1 + 13$.

The set $L(p)$ is essentially the same set as the tight span of p defined by Dress in [8]. There are two differences: The first is that Dress's sign conventions are opposite to ours. The second is that $L(p)$ is invariant under translation by $(1, \dots, 1)$, while Dress chooses a particular representative within each orbit for this translation. The choice makes many of the constructions in this paper more difficult to see.

While the defining equation (2) makes the connection to ordinary linear spaces most clear, for practically every purpose it is better to work with the alternate characterization which we now give. For any $w \in \mathbb{R}^n$, consider the subset of the vertices of $\Delta(d, n)$ at which $p_{i_1 \dots i_d} - \sum_{j=1}^d w_{i_j}$ is minimal. This is a face of $\mathcal{D}$ and thus is Poly_{M_w} for some matroid M_w .

PROPOSITION 2.3. *The point w is in $L(p)$ if and only if M_w is loop-free.*

Recall that a matroid is loop-free if every element of the matroid appears in at least one basis. There is a geometric way of recognizing when M is loop-free from the polytope Poly_M : M is loop-free if and only if Poly_M is not contained in any of the n facets of $\Delta(d, n)$ of the form $x_i = 0$. In particular, note that if Poly_M meets the interior of $\Delta(d, n)$, M is necessarily loop-free.

Proof. By replacing $p_{i_1 \dots i_d}$ by $p_{i_1 \dots i_d} - \sum_{j=1}^d w_{i_j} - (\text{constant})$, we may assume without loss of generality that $w = 0$ and $\min p_I = 0$. Then $M_w = M_0$ is simply the matroid whose bases correspond to those I for which $p_I = 0$. First, we assume that M_0 has a loop j and prove that $0 \notin L(p)$. Let $(i_1, \dots, i_d)$ be a basis of M_0 , clearly $j \notin (i_1, \dots, i_d)$. Then $p_{i_1 \dots i_d} = 0$, but $p_{j i_1 \dots \hat{i}_r \dots i_d} > 0$ for $1 \leq r \leq d$. Taking $(j_1, \dots, j_{d+1}) = (j, i_1, \dots, i_d)$ we see that $0 \notin \text{Trop}(\sum_{r=1}^{d+1} (-1)^r \mathbf{P}_{j_1 \dots \hat{j}_r \dots j_{d+1}} \mathbf{X}_{j_r})$.

The converse is more interesting. Fix $J = \{j_1, \dots, j_{d+1}\}$; our aim will be to prove $0 \in \text{Trop}(\sum_{r=1}^{d+1} (-1)^r \mathbf{P}_{j_1 \dots \hat{j}_r \dots j_{d+1}} \mathbf{X}_{j_r})$. Let $e_J = \sum_{r=1}^{d+1} e_{j_r}$ and, for any $s \in \mathbb{R}$, set $M_s = M_{-se_J}$. For s large enough, the bases of M_s will all be subsets of J ; more specifically, among the d -element subsets of J , they will be the subsets I at which p_I is minimized. In order to show that 0 is in $\text{Trop}(\sum_{r=1}^{d+1} (-1)^r \mathbf{P}_{j_1 \dots \hat{j}_r \dots j_{d+1}} \mathbf{X}_{j_r})$, it is equivalent to show that M_s has at least two bases for s sufficiently large. In other words, for s sufficiently large, we wish to show that j is not a loop of M_s , for j any element of J . By hypothesis, j is not a loop of M_0 , so it is enough to show that, if $j \in J$ is not a loop of M_0 , then it is not a loop of M_s for $s > 0$. We show the contrapositive—if j is a loop of M_s , then it is a loop of $M_{s'}$ for all $0 \leq s' < s$.

As s varies, M_s changes at a finite number of values of s ; call them $s_1 < s_2 < \dots < s_k$. Suppose that $s_i < s < s_{i+1}$, then Poly_{M_s} is a face of both $\text{Poly}_{M_{s_i}}$ and of $\text{Poly}_{M_{s_{i+1}}}$. The bases of M_s are precisely the bases of M_{s_i} which have the largest possible number of elements in common with J . Similarly, the bases of M_s are precisely the bases of $M_{s_{i+1}}$ which have the smallest possible number of elements in common with J . In other words,

$$(3) \quad M_s = M_{s_i}|_J \oplus M_{s_i}/J = M_{s_{i+1}}|_{[n] \setminus J} \oplus M_{s_{i+1}}/([n] \setminus J).$$

From equation (3), it follows that if $j \in J$ is a loop in $M_{s_{i+1}}$, then it is a loop in M_s . Similarly, if j is a loop in M_s , then it is a loop in M_{s_i} . Concatenating deductions of this sort, we see that, as promised, if j is a loop of M_s , then it is a loop of $M_{s'}$ for all $s' < s$ as desired. $\square$

It is clear from the defining equation (2) that $L(p)$ is invariant under translation by $(1, 1, \dots, 1)$. We will abuse notation by saying a face of $L(p)$ is bounded if its image in $\mathbb{R}^n/(1, \dots, 1)$ is bounded. However, when we refer to the dimensions of the faces of L we will always be speaking of L itself, without taking the quotient by $(1, \dots, 1)$.

Let $\mathcal{D}_p^\vee$ be the polyhedral subdivision of $\mathbb{R}^n$, where w and w' lie in the same face if $M_w = M_{w'}$. Then we see that L is a subcomplex of $\mathcal{D}_p^\vee$. We will often write $\mathcal{D}_p^\vee$ when p is clear from context. We warn the reader that, while the combinatorics of $\mathcal{D}_p^\vee$ is determined by the subdivision $\mathcal{D}_p$, the actual positions of the faces of $\mathcal{D}_p^\vee$ depend on p as well as on $\mathcal{D}_p$. In Figure 1, we show $\Delta(2, 4)$, which is an octahedron, subdivided into two square pyramids and draw the dual $L/(1, 1, 1, 1)$ in bold. We write $M^\vee$ for the face of $\mathcal{D}^\vee$ dual to Poly_M . If $v = M^\vee/(1, \dots, 1)$ is a vertex of $L/(1, \dots, 1)$, then we see that the link of $L/(1, \dots, 1)$ at v is the subcomplex of the normal fan of Poly_M . Specifically, the link of $L/(1, \dots, 1)$ at v consists of the cones dual to those faces of Poly_M which correspond to loop-free matroids. This fan was termed the Bergmann complex of M in [21, Chapter 9] and is studied in [2]. In Proposition 2.4, we summarize the main results of [2].

PROPOSITION 2.4. *Every face of Poly_M is of the form $\text{Poly}_{\text{gr}(M, F_\bullet)}$ for some filtration of M . The cones of the link $\text{link}_{M^\vee}(L)$ are dual to those faces of the form $\text{Poly}_{\text{gr}(M, F_\bullet)}$, where $F_\bullet$ is an ascending chain of flats. In this manner, the link $\text{link}_{M^\vee}(L)$ is homeomorphic to the chain complex of the lattice of flats of M and has a subdivision which is isomorphic (as a simplicial complex) to this chain complex.*

FIG. 1. A subdivision of $\Delta(2, 4)$ and the corresponding $L/(1, 1, 1, 1)$.

When $M^\vee/(1, \dots, 1)$ is positive-dimensional, Poly_M turns out to be a product of Poly_N 's.

PROPOSITION 2.5. *Let M be a matroid which decomposes as the direct sum of the connected matroids M_i . Then $\text{Poly}_M = \prod \text{Poly}_{M_i}$.*

Proof. By the definition of direct sum, the bases of M are all disjoint unions $\bigsqcup B_i$, where B_i is a basis of M_i . This is also precisely the definition of a product of polytopes. $\square$

We can now give a very restrictive condition on the faces of L . Recall that the braid arrangement $\mathcal{B}_r$ is the fan in $\mathbb{R}^r$ whose facets are the cones of the type $x_{\sigma(1)} \leq \dots \leq x_{\sigma(r)}$, where σ ranges over the symmetric group S_r .

PROPOSITION 2.6. *If $M^\vee$ is an r -dimensional face of L , then the normal fan of $M^\vee$ is a subfan of a coarsening of $\mathcal{B}_r$. When $M^\vee/(1, 1, \dots, 1)$ is bounded, $M^\vee/(1, 1, \dots, 1)$ is a Minkowski summand of some multiple of the r th permutahedron.*

For example, the two-dimensional faces of $L/(1, 1, \dots, 1)$ all have no more than 6 sides, and their sides point in at most 3 directions. The three-dimensional faces of L are the products with $\mathbb{R}$ of the two-dimensional faces of $L/(1, 1, \dots, 1)$.

Proof. The normal fan to $M^\vee$ is the same as the link of Poly_M in $\mathcal{D}$. Let Poly_N be a face of $\mathcal{D}$, with Poly_M a face of Poly_N . We must show that $T_0(\text{Poly}_N, \text{Poly}_M)$ is a union of cones of $\mathcal{B}_r$. But $T_0(\text{Poly}_N, \text{Poly}_M)$ is precisely the negative of the cone dual to Poly_M in the normal fan to Poly_N . From the description in [2], we see that the normal fan to Poly_N is a coarsening of $\mathcal{B}_n$, and that the cones dual to codimension r faces are the unions of cones of $\mathcal{B}_r$.

If $M^\vee$ is bounded, then its normal fan is complete and thus, by the last paragraph, a coarsening of $\mathcal{B}_r$. The fan $\mathcal{B}_r$ is the normal fan to the r th permutahedron. If P and Q are two polytopes such that the normal fan to Q refines that of P , then P is a Minkowski summand of tQ for t sufficiently large. $\square$

PROBLEM 2.7. *Let P be a polytope which is a Minkowski summand of some multiple of the r th permutahedron. Can P always occur as a face of a tropical linear space?*

For ordinary linear spaces, a linear space determines its Plücker coordinates up to scaling. For tropical linear spaces, a similar result holds.

PROPOSITION 2.8. *Let L be a tropical linear space with tropical Plücker coordinates p . Then L determines the p_I up to the addition of a common scalar. In other*

words, if p and p' are tropical Plücker vectors with $L(p) = L(p')$, then there is a constant c such that $p_I = p'_I + c$ for all $I \in \binom{[n]}{d}$.

Proof. Let S be a $d-1$ element subset of $[n]$, and let F denote the face of $\Delta(d, n)$ whose vertices are those e_I , where I contains S . Since F is an $(n-d)$ -simplex, it can not be subdivided in $\mathcal{D}$. Thus, F is a face of $\mathcal{D}$. The matroid Φ corresponding to F is loop-free, so it is dual to a face $\Phi^\vee$ of L . One can easily see that $\Phi^\vee$ is of the form $(\mathbb{R}_{\geq 0}^S + \mathbb{R}(1, \dots, 1)) + q$ for q a vector satisfying $q_i = p_{Si}$ for $i \notin S$. No other face of L is of the form $(\mathbb{R}_{\geq 0}^S \oplus \mathbb{R}(1, \dots, 1)) + q$, and q is unique up to translation by $(1, \dots, 1)$. Thus, L determines $p_{Si} - p_{Sj}$. As this is true for all S, i , and j , L determines the p_I up to adding the same constant to all of them. $\square$

THEOREM 2.9. *The polyhedral complex L is pure d -dimensional and contractible.*

Proof. To show that L is pure d -dimensional, it is enough to show that the link of any vertex v of $L/(1, \dots, 1)$ is a pure $(d-2)$ -dimensional complex. Let $v + (1, \dots, 1)$ be dual to Poly_M for some matroid M . By the results of [2] (Proposition 2.4), the link of v has a subdivision isomorphic to the order complex of the lattice of flats of M . This lattice is graded of length d , so its order complex is pure of dimension $d-2$.

We now show contractibility. It is easy to see that each tropical hyperplane is tropically convex in the sense of [6]. Thus, their intersection is tropically convex and hence contractible. (Theorem 2 of [6] contains all results on tropically convex spaces used in this argument.) $\square$

A slight extension of the argument in this theorem will show that a (nonempty) face $M^\vee$ is i -dimensional, where i is the number of connected components of M . We now discuss the bounded faces of L . Recall our abuse of language, that we call a face $M^\vee$ bounded when $M^\vee/(1, \dots, 1)$ is a bounded polytope.

PROPOSITION 2.10. *The following are equivalent:*

1. *The point w lies in a bounded face of L .*
2. *The polytope Poly_{M_w} is an interior face of $\mathcal{D}$.*
3. *The matroid M_w is loop-free and co-loop-free.*

Proof. $2 \iff 3$: To say that Poly_{M_w} is interior is to say that it is not contained in any facet of $\Delta(d, n)$. The facets of $\Delta(d, n)$ are of two types: $\{x \in \mathbb{R}^n : x_i = 1\}$ and $\{x \in \mathbb{R}^n : x_i = 0\}$ (where i is between 1 and n). Essentially by definition, Poly_{M_w} lies in the former type if and only if i is a coloop of M_w ; Poly_{M_w} lies in the latter type if and only if i is a loop of M_w .

$1 \iff 2$: If P is not an interior face of $\mathcal{D}$, the corresponding dual face is not bounded. Conversely, if P is internal, the corresponding dual face of $\mathcal{D}^\vee$ is bounded, so we just must check that this dual face is in $L(p)$. For this, we must check that M_w is loop-free. But we saw in the previous paragraph that this follows from Poly_{M_w} being internal. $\square$

At this point, we can prove our earlier remark.

PROPOSITION 2.11. *If the f -vector conjecture is true, then a tropical d -plane in n -space has no more than $\binom{n-i-1}{d-i} \binom{2n-d-1}{i-1}$ faces of dimension i .*

Proof. Let $\mathcal{D}$ be a matroidal decomposition of $\Delta(d, n)$; we must bound the number of faces Poly_M of $\mathcal{D}$ such that M has no loops and Poly_M has codimension $i-1$. For such a face Poly_M , let $C \subset [n]$ be the coloops of M , and let Δ be the face of $\Delta(d, n)$ whose vertices are the vertices e_I , where $I \in \binom{[n]}{d}$ contains C . The claim that M has no loops is equivalent to saying that Poly_M is an interior face of the decomposition of Δ . So we may count the total number of such faces by summing over Δ .

Let us look at those faces of $\Delta(d, n)$ which can play the role of Δ with $|C| = j$; there are $\binom{n}{j}$ such faces and each is isomorphic to $\Delta(d-j, n-j)$. A subpolytope

of such a face Δ has codimension $i - 1$ in $\Delta(d, n)$ if and only if it has codimension $i - j - 1$ in Δ . So, assuming the f -vector conjecture and writing the bound in the f -vector conjecture as $\binom{n-i-1}{d-i} \binom{n-d-1}{i-1}$, we have the following bound for the number of codimension $i - 1$ loop-free faces of $\mathcal{D}$:

$$\sum_j \binom{n}{j} \binom{(n-j)-(i-j)-1}{(d-j)-(i-j)} \binom{(n-j)-(d-j)-1}{(i-j)-1} = \binom{n-i-1}{d-i} \sum_j \binom{n}{j} \binom{n-d-1}{i-j-1} = \binom{n-i-1}{d-i} \binom{2n-d-1}{i-1}.$$

The last sum is evaluated by Vandermonde's convolution: $\sum_j \binom{p}{j} \binom{q}{r-j} = \binom{p+q}{r}$; see [14, (5.22)].

(Note that here and throughout this paper, we use the convention that $\binom{n}{k} = 0$ whenever $k < 0$ or $0 \leq n < k$. This permits us to often use, as we have above, the convention that $\sum_j f(j)$ denotes $\sum_{j=-\infty}^{\infty} f(j)$. See Chapter 5 of [14] for numerous examples of how these notations can simplify manipulations with binomial coefficients.) $\square$

Suppose that $p : \binom{[n]}{d} \rightarrow \mathbb{R}$ is a tropical Plücker vector. Define $p^\perp : \binom{[n]}{n-d} \rightarrow \mathbb{R}$ by $p_I^\perp = p_{[n] \setminus I}$. Then the subdivision $\mathcal{D}^\perp$ of $\Delta(n-d, n)$ induced by $p^\perp$ is simply the image of $\mathcal{D}$ under $(x_1, \dots, x_n) \mapsto (1 - x_1, \dots, 1 - x_n)$. This map replaces each matroidal polytope with the polytope of the dual matroid; in particular, $p^\perp$ also obeys the tropical Plücker relations.

We denote $L(p^\perp)$ by $L^\perp$. One can easily check that $L \mapsto L^\perp$ is an inclusion reversing bijection from the set of tropical linear spaces in $\mathbb{R}^n$ to itself. This fact is implicit in Example 6.2 and Proposition 6.3 of [20].

PROPOSITION 2.12. *The bounded part of $L^\perp$ is (-1) times the bounded part of L . If L is a tropical linear space of dimension d in n -space, then the bounded part of L is at most $\min(d, n-d)$ -dimensional.*

Proof. We saw above that $\mathcal{D}^\perp$ is the image of $\mathcal{D}$ under the map $(x_1, \dots, x_n) \mapsto (1 - x_1, \dots, 1 - x_n)$ from $\Delta(d, n)$ to $\Delta(n-d, n)$. So the dual subdivision $(\mathcal{D})^\vee$ is the negative of $(\mathcal{D}^\perp)^\vee$. The bounded faces of $(\mathcal{D}^\perp)^\vee$ are the negatives of the bounded faces of $(\mathcal{D})^\vee$ because being loop- and coloop-free is self dual. We know that L is d -dimensional and $L^\perp$ is $(n-d)$ -dimensional; as the bounded part of L is isomorphic to a subcomplex of both it is at most $\min(d, n-d)$ -dimensional. $\square$

3. Special cases of the f -vector conjecture. In this section we will prove the following results, which are special cases of the f -vector conjecture.

THEOREM 3.1. *Let L be a d -dimensional tropical linear space in n -space. Then L has at most $\binom{n-2}{d-1}$ vertices, with equality if and only if L is series-parallel.*

THEOREM 3.2. *Let L be a d -dimensional tropical linear space in n -space, with $n = 2d$ or $n = 2d + 1$. Then L has at most 1 bounded facet if $n = 2d$ and at most d if $n = 2d + 1$.*

We first recall the definition of the Tutte polynomial of a matroid. For M a rank d matroid on the ground set $[n]$ and Y a subset of $[n]$, let $\rho_M(Y)$ denote the rank of the flat spanned by Y . The polynomial

$$r_M(x, y) = \sum_{Y \subseteq [n]} x^{|Y| - \rho_M(Y)} y^{d - \rho_M(Y)}$$

is known as the rank-generating function of M . The polynomial

$$t_M(z, w) = r_M(z - 1, w - 1)$$

is known as the Tutte polynomial of M . Almost all matroid invariants can be computed in terms of the Tutte polynomial; see Chapter 6 of [23] for a survey of its importance. Write $t_M(z, w) = \sum t_{ij} z^i w^j$. Although not obvious from this definition, all of the t_{ij} are nonnegative. For $n \geq 2$, we have $t_{10} = t_{01}$; this number is known as the beta (or Crapo) invariant of M and denoted $\beta(M)$.

We will need the following result.

PROPOSITION 3.3. *Let M be a matroid on at least 2 elements. Then $\beta(M) = 0$ if and only if M is disconnected and $\beta(M) = 1$ if and only if M is series-parallel.*

Proof. See [4, Theorem II] for the first statement and [3, Theorem 7.6] for the second. $\square$

The key to proving Theorem 3.1 will be proving the following formula.

LEMMA 3.4. *Let M be a matroid, and let $\mathcal{D}$ be a matroidal subdivision of Poly_M . Let $\mathring{\mathcal{D}}$ denote the set of internal faces of $\mathcal{D}$. Then*

$$t_M(z, w) = \sum_{\text{Poly}_\gamma \in \mathring{\mathcal{D}}} (-1)^{\dim(\text{Poly}_M) - \dim(\text{Poly}_\gamma)} t_\gamma(z, w).$$

Before proving Lemma 3.4, let us see why it implies Theorem 3.1. Considering the case where $M = \text{Uniform}(d, n)$ and comparing the coefficients of z on each side, we see that

$$\beta(\text{Uniform}(d, n)) = \binom{n-2}{d-1} = \sum_{\text{Poly}_\gamma \in \mathring{\mathcal{D}}} \beta(\gamma) = \sum_{\text{Poly}_\gamma \text{ a facet of } \mathcal{D}} \beta(\gamma).$$

To go from the first sum to the second, note that all nonfacets of $\mathring{\mathcal{D}}$ correspond to disconnected matroids and hence have beta invariant 0, and that every facet of $\mathcal{D}$ is in $\mathring{\mathcal{D}}$.

Every term in the right-hand sum is a positive integer. Thus, $\mathcal{D}$ has at most $\binom{n-2}{d-1}$ facets, with equality if and only if all of the facets have beta invariant 1, i.e., if and only if $\mathcal{D}$ is a decomposition into series-parallel matroids. $\square$

We now prove Lemma 3.4. Ardila, Fink, and Rincón have, since the initial circulation of this paper, found an alternate proof; see [1].

Proof. Since $t_M(z, w) = r_M(z - 1, w - 1)$, it is enough to prove

$$r_M(x, y) = \sum_{\text{Poly}_\gamma \in \mathring{\mathcal{D}}} (-1)^{\dim(\text{Poly}_M) - \dim(\text{Poly}_\gamma)} r_\gamma(x, y).$$

Plugging in the definition of r_M and interchanging summation, it is enough to show that, for every $Y \subseteq [n]$,

$$x^{|Y| - \rho_M(Y)} y^{d - \rho_M(Y)} = \sum_{\text{Poly}_\gamma \in \mathring{\mathcal{D}}} (-1)^{\dim(\text{Poly}_M) - \dim(\text{Poly}_\gamma)} x^{|Y| - \rho_\gamma(Y)} y^{d - \rho_\gamma(Y)}.$$

Comparing coefficients of $x^{|Y| - r} y^{d - r}$, we are thus being asked to show that

$$\sum_{\substack{\text{Poly}_\gamma \in \mathring{\mathcal{D}} \\ \rho_\gamma(Y) = r}} (-1)^{\dim(\text{Poly}_M) - \dim(\text{Poly}_\gamma)} = \begin{cases} 1 & \text{if } r = \rho_M(Y) \\ 0 & \text{if } r \neq \rho_M(Y) \end{cases}.$$

The sum is empty if $r > \rho_M(Y)$, so it is enough to prove the claim when $\rho_M(Y) \leq r$. Equivalently, we will show

$$\sum_{\substack{\text{Poly}_\gamma \in \hat{\mathcal{D}} \\ \rho_\gamma(Y) \geq r}} (-1)^{\dim(\text{Poly}_M) - \dim(\text{Poly}_\gamma)} = 1$$

for all $r \leq \rho_M(Y)$.

Let ℓ_Y be the linear function $\Delta(d, n) \rightarrow \mathbb{R}$ mapping $(x_i) \mapsto \sum_{i \in Y} x_i$. Then $\rho_\gamma(Y) = \max_{x \in \text{Poly}_\gamma} \ell_Y(x)$. Thus, we see that $\rho_\gamma(Y) \geq r$ if and only if γ has a nonempty intersection with the half-space $\ell_Y > r - 1/2$. The promised equality now follows by the following lemma applied to the polytope $\text{Poly}_M \cap \{x \in \mathbb{R}^n : \ell_Y(x) > r - 1/2\}$. $\square$

LEMMA 3.5. *Let P be any bounded polytope, and let Γ be the set of internal faces of a decomposition of P . Then $\sum_{\gamma \in \Gamma} (-1)^{\dim(P) - \dim(\gamma)} = 1$.*

Proof. This sum is $(-1)^{\dim P}(\chi(P) - \chi(\partial P))$, where χ is the Euler characteristic. As P is contractible and ∂P is a sphere of dimension $\dim(P) - 1$, the result follows. $\square$

We now begin to prove Theorem 3.2.

Suppose that L is a d -dimensional tropical linear space in n -space. Let $M^\vee$ be a bounded facet of L , dual to a polytope Poly_M . Then the matroid M has rank d and has d connected components none of which are loops. So $M = \bigoplus_{i=1}^d M_i$, where each M_i has rank 1. Let S_i be the ground set of M_i ; because $M^\vee$ is bounded, we know that $|S_i|$ is at least 2. The vertices of Poly_M are those subsets of $[n]$ that meet each S_i precisely once.

Now, consider two such facets $M^\vee$ and $(M')^\vee$ occurring in the same tropical linear space, and define S_i and S'_i as above. The polytope $\text{Poly}_M \cap \text{Poly}_{M'}$ must be either matroidal or empty. We now introduce a graph which will be useful in reformulating the condition that $\text{Poly}_M \cap \text{Poly}_{M'}$ be either matroidal or empty, and also at many other points throughout this paper.

Let M and M' be two matroids on $[n]$, with connected decomposition $M = \bigoplus_{c \in C} M_c$, $M' = \bigoplus_{c \in C'} M'_c$. Let S_c and S'_c be the ground sets of M_c and M'_c . Let $\Gamma(M, M')$ be the bipartite graph (possibly with multiple edges) whose vertex set is $C \sqcup C'$ and which has an edge between c and c' for each element of $S_c \cap S'_{c'}$. A *perfect matching* of a graph Γ is a collection of edges such that, for every vertex v of Γ , exactly one edge in the collection contains v .

LEMMA 3.6. *Let M and M' be two rank d matroids on $[n]$, and let $\Gamma = \Gamma(M, M')$. The graph Γ may have multiple edges; let $\bar{\Gamma}$ be the simple graph obtained by replacing each multiple edge of Γ by a single edge. Then $\text{Poly}_M \cap \text{Poly}_{M'}$ is empty if and only if $\bar{\Gamma}$ has no perfect matchings and $\text{Poly}_M \cap \text{Poly}_{M'}$ is matroidal if and only if $\bar{\Gamma}$ has precisely one perfect matching.*

Proof. The vertices of $\text{Poly}_M \cap \text{Poly}_{M'}$ are in bijection with the perfect matchings of $\Gamma(M, M')$. There is an obvious surjection from perfect matchings of $\Gamma(M, M')$ to perfect matchings of $\bar{\Gamma}(M, M')$. This proves the first claim.

Suppose that $\text{Poly}_M \cap \text{Poly}_{M'}$ is nonempty and matroidal. Let (B_1, B_2) be an edge of $\text{Poly}_M \cap \text{Poly}_{M'}$, so B_1 and B_2 correspond to perfect matchings of $\Gamma(M, M')$ that differ only by a single edge—say, $B_1 \setminus \{e_1\} = B_2 \setminus \{e_2\}$. Then e_1 and e_2 must have the same image in $\bar{\Gamma}(M, M')$ in order for both B_1 and B_2 to be perfect matchings. Since every pair of vertices of $\text{Poly}_M \cap \text{Poly}_{M'}$ is connected by a chain of edges, we see that every perfect matching of $\Gamma(M, M')$ gives rise to the same perfect matching of

$\bar{\Gamma}(M, M')$, or, in other words, $\bar{\Gamma}(M, M')$ has exactly one perfect matching. Conversely, if $\bar{\Gamma}(M, M')$ has exactly one perfect matching, it is clear that $\text{Poly}_M \cap \text{Poly}_{M'}$ is a product of simplices and hence matroidal. $\square$

We now turn to the cases we are interested in, when $n = 2d$ or $2d + 1$. Let $M^\vee$ and $(M')^\vee$ be bounded facets of L , and let Γ and $\bar{\Gamma}$ be as defined in the lemma. First, suppose that $n = 2d$. Then every S_i must have order 2 so the graph Γ must consist of disjoint cycles. The only way that $\bar{\Gamma}$ can have at most one perfect matching is if all of those cycles have length 2 so that $\bar{\Gamma}$ is a disjoint union of edges. But then $\{S_i\} = \{T_i\}$ and $M = M'$. So we see that a linear space of dimension d in $2n$ -space can have at most one bounded facet.

Now suppose that $n = 2d + 1$. Let $M^\vee$ be a bounded facet of L . Then all of the connected components have order 2 except for one, which has order 3. We denote the connected components of M by $(R, S_2, \dots, S_d)$, with R the component of order 3. Let $(M')^\vee$ be another bounded facet of L , with connected components $(R', S'_2, \dots, S'_d)$ as above. The graph $\Gamma(M, M')$ consists of several disjoint cycles, each of even length, and one other component C . This other component consists of a pair of vertices v and w of degree 3 and three disjoint paths $\gamma_1, \gamma_2, \gamma_3$. Either these paths all connect v to w or there is one path each from v to v , from v to w , and from w to w . Moreover, after switching v and w if necessary, we may assume that v corresponds to R and w to R' , so any path from v to w is of odd length.

In each of these cases, Γ has at least one perfect matching. One can check that the only case where $\bar{\Gamma}$ has only one perfect matching is when all of the cycles of $\Gamma \setminus C$ have length 2 and C consists of a path from v to w and two cycles of length 2, one containing v and the other containing w . The condition on C is equivalent to requiring that there are some indices i and i' such that $S'_{i'} \subset R$ and $S_i \subset R'$.

Let f be the number of bounded facets of L , and let $(R^r, S^r_2, \dots, S^r_d)$ be the partition of $[n]$ corresponding to the r th facet of L . Note that, if there is any pair of matroids M and M' with $R = R'$, then $S_i = S'_i$ for every i (after reordering), as otherwise Γ would have a cycle of length more than 2. So all of the triplets $R^1, R^2, \dots, R^f$ are different. We may thus show that $f \leq d$ by showing that the number of distinct R^r 's is at most d .

We now build a graph G whose vertices are the various R^r 's and the labels $\{1, \dots, n\}$. Let there be an edge between R^r and k if $k \in R^r$. This graph has $f + n = f + 2d + 1$ vertices and $3f$ edges. Thus, if $f > d$, then G has at least as many edges as vertices and must contain a cycle; we will use this cycle to obtain a contradiction. We renumber the facets so that our cycle is $(R^1, i_2, R^2, i_3, \dots, R^{g-1}, i_g, R^g, i_1)$. Let $R^r = \{i_r, i_{r+1}, j_r\}$. (Our indices are cyclic modulo g .)

Now, for any r and r' , the compatibility condition on $\bar{\Gamma}(M^r, M^{r'})$ states that there must be some s , with $2 \leq s \leq d$, such that $S^r_s \subset R^{r'}$. Consider first the case where $(r, r') = (1, 2)$. So there is some $s_2 \geq 2$ so that $S^1_{s_2} \subset R^2$. Since we know that i_2 is in R^1 , the set $S^1_{s_2}$ must be $\{j_2, i_3\}$. Now, consider when $(r, r') = (1, 3)$. Again, there must be some $s_3 \geq 2$ so that $S^1_{s_3} \subset R^3$. Since j_2 is in $S^1_{s_2}$ but not in R^3 , the indices s_2 and s_3 must be different, and thus $S^1_{s_2}$ and $S^1_{s_3}$ must be disjoint. Since i_3 is already contained in $S^1_{s_2}$, we must have $S^1_{s_3} = \{j_3, i_4\}$. Continuing in this manner, we get a sequence of indices s_k , for $2 \leq k \leq g$, such that $S^1_{s_k} = \{j_k, i_{k+1}\}$. But, when $k = g$, then $S^1_{s_g} = \{j_g, i_1\}$ and $R^1 = \{i_1, i_2, j_1\}$ intersect, a contradiction. This concludes the proof of Theorem 3.2. $\square$

The f -vector conjecture predicts that, if $n = 2d + e$, L should have at most $\binom{d+e-1}{e}$ bounded facets. In the cases $e = 0$ and $e = 1$, the graph Γ always has at least one perfect matching, and the requirement that $\bar{\Gamma}$ have exactly one is very restrictive.

Once $e = 2$, it is possible for $\bar{\Gamma}$ to have no perfect matchings, and the problem grows much harder.

Nonetheless, it seems that this kind of reasoning, looking only at the facets of L and not at the smaller spaces that contain them, is adequate to resolve the f -vector conjecture for facets.

CONJECTURE 3.7. *Let $n = 2d + e$. It is not possible to find more than $\binom{d+e-1}{e}$ distinct partitions of $[n]$ into d disjoint subsets, $[n] = S_1^r \sqcup \cdots \sqcup S_d^r$, where each S_s^r has order at least 2, and, for every r and r' , the graph $\bar{\Gamma}$ formed from $\{S_1^r, \dots, S_d^r\}$ and $\{S_1^{r'}, \dots, S_d^{r'}\}$ has at most one perfect matching.*

Remark. When $d = 2$, the condition that (S_1, S_2) and (S_1', S_2') be compatible precisely says that one of the four intersections $S_i \cap S_j'$, $1 \leq i, j \leq 2$ is empty. It is well known that, given a collection of partitions $[n] = S_1 \sqcup S_2$ which are compatible in this manner, there is a tree T with no vertices of degree 2 and the leaves labeled by $[n]$ such that each partition consists of the leaves on one side or the other of an edge of T . Thus, the conjecture in this case is simply the (straightforward) statement that a tree with n leaves and no vertices of degree 2 has at most $n - 3$ edges which do not end at a leaf. When L is a two-dimensional tropical linear space, the tree in question is simply $L/(1, 1, \dots, 1)$; this picture is discussed in great detail in [20].

Remark. Consider the case where $d = 3$. In this case, there is an elegant way to describe the compatibility condition between (S_1, S_2, S_3) and (S_1', S_2', S_3') . Two partitions of $[n]$ into triples (S_1, S_2, S_3) and (S_1', S_2', S_3') are compatible if and only if, after reordering the S_i and S_i' , we have $S_1 \subseteq S_1'$ and $S_1 \cup S_2 \subseteq S_1' \cup S_2'$.

4. Stable intersections. In ordinary geometry, if a d plane and a d' plane meet transversely in n -space, then their intersection is a $d + d' - n$ plane. For tropical linear spaces, the same holds true, as we will show in Proposition 4.8. However, the situation for tropical linear spaces is better than that for ordinary linear spaces. In this section, for any tropical d -plane L and tropical d' -plane L' , we define a $d + d' - n$ plane called the stable intersection of L and L' . The stable intersection is always contained in $L \cap L'$ and is equal to $L \cap L'$ when L and L' meet transversely. The combined operations of orthogonal complement (changing L to $L^\perp$) and stable intersection allow us to generate a wide variety of tropical linear spaces and to mimic most standard constructions from linear algebra. Throughout this section, we take d and d' to be positive integers, with $0 < d, d' < n$ and $d + d' > n$.

If L and L' are two ordinary linear spaces of dimensions d and d' in n -space which meet transversely, then $L \cap L'$ is a $(d + d' - n)$ -dimensional space whose Plücker coordinates are given by

$$\mathbf{P}_J(L \cap L') = \sum_{\substack{I \cap I' = J \\ |I|=d \\ |I'|=d'}} \pm \mathbf{P}_I(L) \mathbf{P}_{I'}(L').$$

We omit the rule for determining the sign of each summand, as we will only use this formula for motivation. Note that the summation conditions on I and I' guarantee that $I \cup I' = [n]$.

We will discuss a tropical version of this formula. If L and L' are tropical linear spaces of dimension d and d' , define a real-valued function $p(L \cap_{\text{st}} L')$ on $\binom{[n]}{d+d'-n}$ by

$$p_J(L \cap_{\text{st}} L') = \min_{\substack{I \cap I' = J \\ |I|=d \\ |I'|=d'}} (p_I(L) + p_{I'}(L')).$$

At the moment, $p_J(L \cap_{\text{st}} L')$ is just defined as a formal symbol, there is not yet any tropical linear space called $L \cap_{\text{st}} L'$. We will need several combinatorial lemmas.

LEMMA 4.1. *Let M and M' be two matroids of rank r on $[n]$. If the polytopes Poly_M and $\text{Poly}_{M'}$ intersect, then their intersection contains a vertex of $\Delta(r, n)$.*

Proof. Let $R \subset \mathbb{R}^n$ be the convex hull of the characteristic vectors of those subsets of $[n]$ which are independent in M . (The characteristic vector of a subset S of $[n]$ is $\sum_{s \in S} e_s$.) Similarly, define R' using the independent subsets of M' . Let λ be the sum of the coordinate functions. Then Poly_M and $\text{Poly}_{M'}$ are the faces of R and R' (respectively) on which λ achieves its maximum value, namely, r . Since the intersection of Poly_M and $\text{Poly}_{M'}$ is nonempty, the maximum value of λ on the polytope $R \cap R'$ is also r . Thus, there must be a vertex v of $R \cap R'$ such that $\lambda(v) = r$. By [11, Theorem 45], all of the vertices of $R \cap R'$ are 0–1 vectors. The only 0–1 vectors in $\Delta(r, n)$ are the vertices of $\Delta(r, n)$. $\square$

We introduce several polyhedral objects which we will use throughout this section. We define a convex piecewise linear function $\mathbf{p}$ on $\Delta(d, n)$ by defining $\mathbf{p}(x)$ to be the minimum of $\sum_{I \in \binom{[n]}{d}} \alpha_I p_I$, where the minimum ranges over all $\binom{[n]}{d}$ -tuples α_I of nonnegative real numbers such that $\sum_{I \in \binom{[n]}{d}} \alpha_I = 1$ and $\sum_{I \in \binom{[n]}{d}} \alpha_I e_I = x$. In other words, as x ranges over $\Delta(d, n)$, the points $(x, \mathbf{p}(x))$ sweep out the bottom faces of the convex hull of $\{(e_I, p_I)\}_{I \in \binom{[n]}{d}}$. So $\mathbf{p}(e_I) = p_I$, and the faces of $\mathcal{D}$ are the regions on which $\mathbf{p}$ is linear. Similarly, we use $\mathbf{p}'$ to define a piecewise linear convex function $\mathbf{p}'$ on $\Delta(d', n)$. We then define a piecewise linear convex function $\mathbf{q}$ on the Minkowski sum $\Delta(d, n) + \Delta(d', n)$ by

$$\mathbf{q}(y) = \min_{\substack{x+x'=y \\ x \in \Delta(d, n) \\ x' \in \Delta(d', n)}} (\mathbf{p}(x) + \mathbf{p}'(x')).$$

We include $\Delta(d + d' - n, n)$ into the Minkowski sum $\Delta(d, n) + \Delta(d', n)$ by $\iota : e \mapsto e + (1, \dots, 1)$.

LEMMA 4.2. *For $J \in \binom{[n]}{d+d'-n}$, we have $p(L \cap_{\text{st}} L')_J = \mathbf{q}(\iota(e_J))$.*

Proof. By definition, $\mathbf{q}(\iota(e_J))$ is the minimum, over all $x \in \Delta(d, n)$ such that $\iota(e_J) - x$ lies in $\Delta(d', n)$, of $\mathbf{p}(x) + \mathbf{p}'(\iota(e_J) - x)$. Let F be the subset of points x of $\Delta(d, n)$ such that $\iota(e_J) - x$ is in $\Delta(d', n)$. It is easy to check that F is a face of $\Delta(d, n)$, isomorphic to $\Delta(2n - d - d', n)$. So $\mathbf{q}(\iota(e_J))$ is the maximum of the function $r(x) := \mathbf{p}(x) + \mathbf{p}'(\iota(e_J) - x)$ on F . Similarly, $p(L \cap_{\text{st}} L')_J$ is the minimum value of $r(x)$, when x ranges over the vertices of F . As a sum of convex piecewise linear functions, r is a convex piecewise linear function. Let $\mathcal{A}$, $\mathcal{A}'$, and $\mathcal{B}$ be the regular subdivisions of F induced by the functions $\mathbf{p}(x)$, $\mathbf{p}'(\iota(e_J) - x)$ and $r(x)$. Then (by the convexity of r) the function r achieves its minimum on a face of $\mathcal{B}$. Call this face Y . The subdivision $\mathcal{B}$ is the simultaneous refinement of $\mathcal{A}$ and $\mathcal{A}'$, so Y is the intersection of a face X of $\mathcal{A}$ and a face X' of $\mathcal{A}'$.

Now, X is also a face of $\mathcal{D}_p$ and X' is the image of a face of $\mathcal{D}_{p'}$ under the linear map $x \mapsto \iota(e_J) - x$. So X and X' are both matroidal polytopes in $\Delta(2n - d - d', n)$. Since $Y = X \cap X'$ is nonempty, we know by Lemma 4.1 that Y contains a vertex of F . So the minimum value of r on F is achieved at this vertex, as desired. $\square$

There is an operation $M \wedge M'$, called matroid intersection ([22, section 7.6]), which takes two matroids of ranks d and d' and produces a third matroid. By definition, the spanning sets of $M \wedge M'$ are precisely the sets of the form $U \cap U'$, where U and U' span M and M' respectively. The matroid $M \wedge M'$ always has rank at least $d + d' - n$. It has rank precisely $d + d' - n$ if and only if there exists a pair (I, I') of bases of M

and M' (respectively) such that $I \cup I' = [n]$. Let us restate this in the language of polyhedral geometry.

LEMMA 4.3. *Let M and M' be matroids of ranks d and d' on $[n]$. If $(\text{Poly}_M + \text{Poly}_{M'}) \cap \iota(\Delta(d + d' - n, n))$ is nonempty, then $M \wedge M'$ has rank $d + d' - n$ and $(\text{Poly}_M + \text{Poly}_{M'}) \cap \iota(\Delta(d + d' - n, n)) = \iota(\text{Poly}_{M \wedge M'})$.*

We can now prove the following result.

PROPOSITION 4.4. *The vector $p(L \cap_{\text{st}} L')$ is a tropical Plücker vector. Every face of $\mathcal{D}_{p(L \cap_{\text{st}} L')}$ is of the form $\text{Poly}_{M \wedge M'}$ where Poly_M and $\text{Poly}_{M'}$ are faces of $\mathcal{D}_p$ and $\mathcal{D}_{p'}$.*

Proof. First, consider the regular subdivision of $\Delta(d, n) + \Delta(d', n)$ induced by the convex piecewise linear function $\mathbf{q}$. Every face of this subdivision is of the form $\text{Poly}_M + \text{Poly}_{M'}$, where Poly_M and $\text{Poly}_{M'}$ are faces of $\mathcal{D}_p$ and $\mathcal{D}_{p'}$. Now, consider the regular subdivision of $\Delta(d + d', n)$ induced by the convex piecewise linear function $\iota \circ \mathbf{q}$. We will call this subdivision $\mathcal{E}$. By Lemma 4.3, every face of $\mathcal{E}$ is matroidal and of the form $\text{Poly}_{M \wedge M'}$ where Poly_M and $\text{Poly}_{M'}$ are faces of $\mathcal{D}_p$ and $\mathcal{D}_{p'}$. So, there is a convex piecewise linear function on $\Delta(d + d' - n, n)$, inducing a regular matroidal subdivision of the required form, and, by Lemma 4.2, this function evaluates to $p(L \cap_{\text{st}} L')_J$ at the vertices of $\Delta(d + d' - n, n)$. Let $\mathbf{r}$ be the convex piecewise linear function on $\Delta(d + d' - n, n)$ induced by $p(L \cap_{\text{st}} L')$, so $\mathcal{D}_{p(L \cap_{\text{st}} L')}$ is the regular subdivision induced by $\mathbf{r}$. Then $\mathbf{r}$ is the unique convex piecewise linear function such that $\mathbf{r}(e_J) = p(L \cap_{\text{st}} L')_J$, and every domain of linearity of $\mathbf{r}$ is a convex hull of a subset of the vertices of $\Delta(d + d' - n, n)$. Since $\iota \circ \mathbf{q}$ also has these properties, we know that $\mathbf{r} = \iota \circ \mathbf{q}$. So $\mathcal{D}_{p(L \cap_{\text{st}} L')} = \mathcal{E}$ and is a matroidal subdivision of the required form. $\square$

We thus see that there is a well-defined tropical linear space $L \cap_{\text{st}} L'$. Our aim now is to justify the notation $L \cap_{\text{st}} L'$ by showing that $L \cap_{\text{st}} L'$ deserves to be called the stable intersection of L and L' . We first need to introduce some additional matroid constructions.

Let N and N' be matroids on the underlying ground sets S and S' , with $S \cap S' = \{e\}$. Assume that e is not a loop of either M or M' . Then the *parallel connection* of N and N' is the matroid on $S \cup S'$ whose bases are those sets J such that either $J \cap S$ is a basis of M and $(J \cap S') \cup \{e\}$ is a basis of M' , or else $(J \cap S) \cup \{e\}$ is a basis of M and $J \cap S'$ is a basis of M' . (It is possible that both cases hold; this can only happen if e is in J .) For the fact that this is a matroid and various basic facts about this matroid; see [22, section 7.6]. When N and N' are graphical matroids (see [22, section 6.1]) associated to graphs G and G' , the parallel connection of N to N' is the graph formed by gluing G to G' at edge e . For later use, we also define the *series connection* of M and M' : its bases are those sets J such that either $J \cap S$ is a basis of M and $(J \cap S') \setminus \{e\}$ is a basis of M' , or else $(J \cap S) \setminus \{e\}$ is a basis of M and $J \cap S'$ is a basis of M' .

It is possible to compose several parallel connections along a tree structure; this is alluded to in Figure 7.10 of [22] and the corresponding discussion. We will need a precise definition. Let M^α be a collection of matroids indexed by α running through a finite set A , with S^α the ground set of M^α . Assume that, for α, β , and γ distinct elements of A , the intersection $S^\alpha \cap S^\beta$ contains at most one element and the intersection $S^\alpha \cap S^\beta \cap S^\gamma$ is empty. Form a graph G whose vertices are A and where there is an edge between α and β if and only if $S^\alpha \cap S^\beta$ is nonempty; we impose the condition that G is a forest. Finally, we impose that, if $S^\alpha \cap S^\beta = \{e\}$, then e is not a loop of M^α or M^β . Then we can define a matroid, the *parallel connection* of the set of matroids $\{M^\alpha\}_{\alpha \in A}$, as follows: a subset J of $\bigcup_{\alpha \in A} S^\alpha$ is a basis of the parallel connection of $\{M^\alpha\}_{\alpha \in A}$ if and only if there is an orientation of the graph G such that,

for each $\alpha \in A$, the set $(J \cap S^\alpha) \cup \bigcup_{\alpha \rightarrow \beta} (S^\alpha \cap S^\beta)$ is a basis of M^α . Here the union runs over edges of G oriented from α to β . So, when A has two elements and G is a single edge, this is the notion of parallel connection in the previous paragraph.

PROPOSITION 4.5. *The collection of subsets of $\bigcup_{\alpha \in A} S^\alpha$ described above forms the set of bases of a matroid.*

Proof. Our proof is by induction on the number of edges of G . If G is a collection of disjoint vertices, so the sets S^α are all disjoint, then the parallel collection of $\{M_\alpha\}_{\alpha \in A}$ is simply the direct sum $\bigoplus_{\alpha \in A} M^\alpha$. If G has some edge, say connecting β to γ , then modify the collection $\{M_\alpha\}_{\alpha \in A}$ by deleting M^β and M^γ and adding, in their place, the parallel connection of M^β and M^γ . This modifies the graph G by contracting the edge between α and β , so the new graph is still a forest, and, by induction, the parallel connection of this modified set of matroids is a matroid. It is straightforward to check that this parallel connection of this modified set is the same as the parallel connection of the original set $\{M_\alpha\}_{\alpha \in A}$. $\square$

We see from the proof that the parallel connection of a set of matroids is built by repeatedly replacing pairs of matroids by their parallel connection.

We now introduce one more piece of terminology. Recall the definition of the graph $\Gamma(M, M')$ from section 3. We say that M and M' are *transverse* if $\Gamma(M, M')$ is a forest without multiple edges. When M and M' are transverse and loop-free, we may take the parallel connection of $\{M_c\}_{c \in C} \cup \{M'_{c'}\}_{c' \in C'}$, as the graph $\Gamma(M, M')$ will be the graph G which is required to be a tree in the definition of parallel connection. (We leave it to the reader to check the conditions on intersections.)

LEMMA 4.6. *Suppose that M and M' are transverse. Then $M \wedge M'$ is the parallel connection of the union of the set of connected components of M and the set of connected components of M' . In particular, $M \wedge M'$ is a loop-free matroid whose connected components are in bijection with the components of $\Gamma(M, M')$; each connected component of $M \wedge M'$ can be formed from connected components of M and M' by the repeated use of the operation of parallel connection and the rank of $M \wedge M'$ is $d + d' - n$.*

Proof. Let N be the parallel connection of the union of the set of connected components of M and the set of connected components of M' . Let J be a $(d + d' - n)$ -element subset of $[n]$. We will show that J is a basis of N if and only if there are bases I and I' of M , and I' such that $I \cap I' = J$. Once we have shown this, in particular, it will follow that there exists a pair (I, I') of bases of M and M' , with $|I \cap I'| = d + d' - n$. So the rank of $M \wedge M'$ is $d + d' - n$ and the bases of $M \wedge M'$ are precisely the sets J of this form. So this will show that $N = M \wedge M'$.

Assume that J is a basis of N . Fix a corresponding orientation of $G = \Gamma(M, M')$. Define a subset I of $[n]$ as follows: i is in I if either $i \in J$ or if the edge of $\Gamma(M, M')$ corresponding to i is oriented from its endpoint which is in C to its endpoint which is in C' . (It is possible that both are true, i in I in this case.) Similarly, i is in I' if either $i \in J'$ or if the edge of $\Gamma(M, M')$ corresponding to i is oriented from its endpoint which is in C' to its endpoint which is in C . Then $I \cup I' = [n]$ and $I \cap I' = J$. By construction, for each $c \in C$, the intersection of S_c with I is a basis of M_c . Thus, I is a basis of M . Similarly, I' is a basis of M' . This argument is easily reversed. $\square$

Remark. Without the hypothesis of transversality, it is possible that M and M' are loop-free but $M \wedge M'$ is not, even if $M \wedge M'$ has rank $d + d' - n$. For example, let M be the rank 2 matroid on $\{1, 2, 3\}$, where 1 and 2 are parallel and 3 is a coloop. Then $M \wedge M$ is the rank 1 matroid, where 1 and 2 are loops and 3 is still a coloop.

We will also occasionally need the following variant on Lemma 4.6.

LEMMA 4.7. *Let M and M' be two loop-free matroids on $[n]$, and let $\Gamma = \Gamma(M, M')$. Suppose that $M \wedge M'$ has rank $d + d' - n$ and is loop-free. Then the connected components of $M \wedge M'$ are the labels of the edges of the connected components of Γ .*

Proof. We first reduce to the case that $\Gamma(M, M')$ is connected. Let $G_1, G_2, \dots, G_r$ be the components of $\Gamma(M, M')$. For i between 1 and r , let M_i and M'_i be the summands of M and M' supported on the edge labels of G_i . So $M = \bigoplus M_i$ and $M' = \bigoplus M'_i$, and M_i has the same underlying ground set as M'_i , but M_i and M'_i are not necessarily connected. Then it is easy to check that $M \wedge M' = \bigoplus (M_i \wedge M'_i)$. So it is enough to check that each matroid $M_i \wedge M'_i$ is connected. Replacing M and M' by M_i and M'_i , we reduce to the case that $\Gamma(M, M')$ is connected.

Consider the polytope $\text{Poly}_M + \text{Poly}_{M'}$. We claim that this polytope has dimension $n - 1$. To see this, let λ be a linear function which is constant on $\text{Poly}_M + \text{Poly}_{M'}$, then λ must be constant on both Poly_M and $\text{Poly}_{M'}$. This means that we have $\lambda(e_i) = \lambda(e_j)$ whenever i and j label edges of $\Gamma(M, M')$ adjacent to the same vertex. Since the graph $\Gamma(M, M')$ is connected, this means that $\lambda(e_1) = \lambda(e_2) = \dots = \lambda(e_n)$. So the space of linear functions constant on $\text{Poly}_M + \text{Poly}_{M'}$ is one-dimensional, and we conclude that $\text{Poly}_M + \text{Poly}_{M'}$ has dimension $n - 1$. We want to conclude that $\text{Poly}_{M \wedge M'}$ also has dimension $n - 1$. Since $M \wedge M'$ has rank $d + d' - n$, the polytope $\text{Poly}_{M \wedge M'}$ is isomorphic (under the isometry ι) to $(\text{Poly}_M + \text{Poly}_{M'}) \cap \iota(\Delta(d + d' - n, n))$, so we want to show that $(\text{Poly}_M + \text{Poly}_{M'}) \cap \iota(\Delta(d + d' - n, n))$ has dimension $n - 1$.

If this intersection does not have dimension $n - 1$, then $\iota(\text{Poly}_{M \wedge M'}) = (\text{Poly}_M + \text{Poly}_{M'}) \cap \iota(\Delta(d + d' - n, n))$ must be contained in a facet of $\iota(\Delta(d + d' - n, n))$. Every facet of $\iota(\Delta(d + d' - n, n))$ is either of the form $\{x \in \mathbb{R}^n : x_i = 1\}$ or $\{x \in \mathbb{R}^n : x_i = 2\}$. If $\iota(\text{Poly}_{M \wedge M'})$ is contained in $\{x \in \mathbb{R}^n : x_i = 1\}$, then i is a loop of $M \wedge M'$, contrary to our hypothesis. If $\iota(\text{Poly}_{M \wedge M'})$ is contained in $\{x \in \mathbb{R}^n : x_i = 2\}$, then i is a coloop of $M \wedge M'$. We claim that this implies that i is a coloop of both M and M' . If i is not a coloop of M , then there is some basis B of M which does not contain i . Let B' be any basis of M' , then $B \cap B'$ is a spanning set of $M \wedge M'$ which does not contain i , contradicting our assumption that i is a coloop of $M \wedge M'$. So i is a coloop of both M and M' , and thus $\{i\}$ is a connected component of both M and M' . Then the edge of $\Gamma(M, M')$ labeled i is, in itself, a connected component of $\Gamma(M, M')$. Since we assumed that $\Gamma(M, M')$ is connected, this means that n is 1 and that M and M' both consist of a single coloop. In this case, $M \wedge M'$ is also a single coloop, and the claim is true in this case as well. $\square$

We now relate $L \cap_{\text{st}} L'$ to the intersection $L \cap L'$.

PROPOSITION 4.8. *Let $0 < d, d' < n$, with $d + d' > n$. Suppose that L and L' are tropical linear spaces in n -space of dimension d and d' . Then $L \cap_{\text{st}} L' \subseteq L \cap L'$. If L and L' meet transversely, then $L \cap_{\text{st}} L' = L \cap L'$.*

By “meet transversely” we mean that, if $w \in L \cap L'$ and $M^\vee$ and $(M')^\vee$ are the faces of L and L' whose relative interiors contain w , then the vector spaces $\mathbb{R}M^\vee$ and $\mathbb{R}(M')^\vee$ are transverse. We first must relate this notion of transversality to the notion of transversality of matroids defined above.

LEMMA 4.9. *Let L and L' be transverse tropical linear spaces in $\mathbb{R}^n$. Let w be a point of L and L' and $M := M_w$ and $M' := M'_w$ the corresponding loop-free matroids. Then the matroids M and M' are transverse.*

Proof. Let $M = \bigoplus_{c \in C} M_c$ and $M' = \bigoplus_{c' \in C'} M'_{c'}$ be the decompositions of M and M' into connected components. Let $|C| = r$ and $|C'| = r'$, so r and r' are the dimensions of $M^\vee$ and $(M')^\vee$. The linear space $\mathbb{R}M^\vee$ is cut out by the equations $x_i - x_j = 0$ when the edges of $\Gamma(M, M')$ labeled by i and j have the same endpoint in C ,

and similarly for $(M')^\vee$. Thus, $\mathbb{R}M^\vee \cap \mathbb{R}(M')^\vee$ is cut out by the equations $x_i - x_j = 0$ whenever the edges labeled by i and j are in the same component of $\Gamma(M, M')$. We assumed that L and L' meet transversely, so the dimension of $M^\vee \cap (M')^\vee$ must be $r + r' - n$, and Γ must have $r + r' - n$ connected components. A graph with $r + r'$ vertices, n edges, and $r + r' - n$ connected components must be a forest without multiple edges. $\square$

A very similar argument establishes the following more general result.

LEMMA 4.10. *Let L and L' be tropical linear spaces in $\mathbb{R}^n$, with w in $L \cap L'$. Suppose that $\mathbb{R}M^\vee + \mathbb{R}(M')^\vee$ has dimension $n - b$. Then the graph $\Gamma(M, M')$ has first betti number b .*

Proof of Proposition 4.8. Let $\mathcal{D}$, $\mathcal{D}'$, and $\mathcal{E}$ be the subdivisions of $\Delta(d, n)$, $\Delta(d', n)$, and $\Delta(d + d' - n, n)$ corresponding to L , L' , and $L \cap_{\text{st}} L'$. Let $\mathcal{D}^\vee$, $(\mathcal{D}')^\vee$, and $\mathcal{E}^\vee$ denote the dual subdivisions of $\mathbb{R}^n$. Recall the notations ι , $\mathbf{p}$, $\mathbf{p}'$, and $\mathbf{q}$ from the beginning of the section; so $\mathcal{D}$, $\mathcal{D}'$, and $\mathcal{E}$ are the regular matroidal subdivisions induced by the convex, piecewise linear functions $\mathbf{p}$, $\mathbf{p}'$, and $\iota \circ \mathbf{q}$.

Consider a particular $w \in \mathbb{R}^n$; we need to show that $w \in L \cap_{\text{st}} L'$ implies that $w \in L$ and $w \in L'$, and that the converse holds if L and L' meet transversely. Let $M^\vee$, $(M')^\vee$, and $N^\vee$ be the faces of $\mathcal{D}^\vee$, $(\mathcal{D}')^\vee$, and $\mathcal{E}^\vee$, respectively whose relative interiors contain w , and let Poly_M , $\text{Poly}_{M'}$, and Poly_N be the respective dual faces of $\mathcal{D}$, $\mathcal{D}'$, and $\mathcal{E}$. We must show that, if M or M' has a loop, then N has a loop, and that if L and L' meet transversely and N has a loop, then M or M' does as well.

First suppose that M has a loop; we will show that N has a loop as well. Without loss of generality, we may assume that $w = 0$. So the functions $\mathbf{p}$ and $\mathbf{p}'$ are minimized on Poly_M and $\text{Poly}_{M'}$, and hence $\mathbf{q}$ is minimized on $\text{Poly}_M + \text{Poly}_{M'}$; we will abbreviate $\text{Poly}_M + \text{Poly}_{M'}$ by A . Also, $\iota \circ \mathbf{q}$ is minimized on Poly_N . If A meets $\iota(\Delta(d + d' - n, n))$, then $M \wedge M'$ has rank $d + d' - n$. In that case, the minimum of $\iota \circ \mathbf{q}$ is achieved on $\text{Poly}_{M \wedge M'}$ and $N = M \wedge M'$. Since M has a loop, $N = M \wedge M'$ has a loop as well in that case. Now, let us consider the case where A does not meet $\iota(\Delta(d + d' - n, n))$. We adopt the abbreviation B for $\iota(\text{Poly}_N)$, so $\mathbf{q}$ is constant on both A and B , with $\mathbf{q}|_A < \mathbf{q}|_B$. Suppose (for the purpose of contradiction) that N does not have a loop, and hence B is not contained in $\{z \in \mathbb{R}^n : z_e = 1\}$ for any $e \in [n]$. Then there is some point, call it b , in B where none of the coordinate functions are 1. Let a be a point of A , and let $\overline{ab}$ be the line segment joining a to b . By assumption, $q(a) < q(b)$, and, as q is convex, we have $q(v) < q(b)$ for all $v \in \overline{ab} \setminus \{b\}$. This means that $\overline{ab}$ meets $\iota(\Delta(d + d' - n, n))$ only at b . So there is either some coordinate e for which $b_e = 1$ and $a_e < 1$, or there is some coordinate $e \in [n]$ for which $b_e = 2$ and $a_e > 2$. But the first possibility violates our assumption that none of the coordinates of b_e are 1, and the second violates the fact that a lies in $\Delta(d, n) + \Delta(d', n)$. So we have a contradiction, B is contained in $\{z \in \mathbb{R}^n : z_e = 1\}$ for some $e \in [n]$ and this e is a loop of N .

Now assume that M and M' have no loops. For every e in $[n]$, this implies that both Poly_M and $\text{Poly}_{M'}$ have points where $z_e = 1$, and hence there is a point of $\text{Poly}_M + \text{Poly}_{M'}$ where $z_e \geq 2$. Since the hyperplanes cutting out $\iota(\Delta(d + d' - n, n))$ inside of $\Delta(d, n) + \Delta(d', n)$ are all of the form $\{z \in \mathbb{R}^n : z_e \leq 1\}$, we know that $\text{Poly}_M + \text{Poly}_{M'}$ meets $\iota(\Delta(d + d' - n, n))$. Thus, $M \wedge M'$ has rank $d + d' - n$ and $N = M \wedge M'$. Now, assume further that L and L' are transverse. Then, by Lemma 4.9, the matroids M and M' are transverse. From Lemma 4.6, this implies that $M \wedge M'$ is loop-free. $\square$

The next theorem explains the motivation for the notation $L \cap_{\text{st}} L'$ and the geometric meaning of $L \cap_{\text{st}} L'$ when L and L' are not transverse.

THEOREM 4.11. *Let L and L' be tropical linear spaces. Then, for a generic $v \in \mathbb{R}^n$, L and $L' + v$ meet transversely. We have $L \cap_{\text{st}} L' = \lim_{v \rightarrow 0} (L \cap (L' + v))$ as long as v approaches 0 along a generic direction.*

By *generic* we mean “for an open dense subset of the appropriate parameter space.” That is to say, L meets $L' + v$ transversely for v in an open dense subset of $\mathbb{R}^n$, and $L \cap_{\text{st}} L' = \lim_{v \rightarrow 0} (L \cap (L' + v))$ as long as v approaches 0 along a ray whose direction lies in an open dense subset of S^{n-1} . This result will hold for virtually any reasonable topology on the set of polyhedral complexes in $\mathbb{R}^n$ —we use the Hausdorff metric D induced from the metric $d(x, y) := \max_{j \in [n]} |x_j - y_j|$. Explicitly, for X and Y closed subsets of $\mathbb{R}^n$, the distance $D(X, Y)$ is given by $\max(\sup_{x \in X} \inf_{y \in Y} d(x, y), \sup_{y \in Y} \inf_{x \in X} d(x, y))$. (This is equivalent to the Hausdorff metric induced by the standard Euclidean metric on $\mathbb{R}^n$.)

Proof. Let F and F' be faces of L and L' . Suppose that $\mathbb{R}F + \mathbb{R}F'$ is not $\mathbb{R}^n$. Then, for v outside a proper subspace of $\mathbb{R}^n$, $F \cap (F' + v) = \emptyset$. Thus, for a generically chosen v , every such F and $F' + v$ fail to meet. The only faces of L and $L' + v$ that do meet, then, meet transversely.

We now need to check that the function $p \mapsto L(p)$ is continuous. More specifically, we show that $D(L(p), L(p')) \leq \delta(p, p') := \max_{I \in \binom{[n]}{d}} |p_I - p'_I|$. First, note that this is obvious when $\dim L(p) = 1$, as then $L(p) = (p_1, \dots, p_n) + \text{Span}_{\mathbb{R}}(1, \dots, 1)$. Now we handle the general case where $\dim L(p) = \dim L(p') = d$. Let $\delta = \delta(p, p')$, and let $x \in L(p)$. We must show that there is a point x' of $L(p')$, with $d(x, x') \leq \delta$. Let $L(p'')$ be any tropical linear space of dimension $n - d + 1$ passing through x and transverse to $L(p)$; we have $x + \text{Span}_{\mathbb{R}}(1, \dots, 1) = L(p) \cap_{\text{st}} L(p'')$. By adding a constant to all of the p'_I , we may assume that $x_j = \min_{I \cap I'' = \{j\}} (p_I + p''_{I''})$. (A priori, we only know this equality up to adding a common scalar to both sides.) Let x' be given by the formula $x'_j = \min_{I' \cap I'' = \{j\}} (p'_{I'} + p''_{I''})$. We have

$$x'_j \in x'_j + \text{Span}_{\mathbb{R}}(1, \dots, 1) = L(p') \cap_{\text{st}} L(p'') \subseteq L(p') \cap L(p'') \subseteq L(p').$$

We now check that $d(x, x')$ is sufficiently small. Choose an index j in $[n]$. Let (I, I'') be where the minimum in the equation $x_j = \min_{I \cap I'' = \{j\}} (p_I + p''_{I''})$ is achieved. Then we have

$$x_j - x'_j = (p_I + p''_{I''}) - \min_{K' \cap K'' = \{j\}} (p'_{K'} + p''_{K''}) \leq (p_I + p''_{I''}) - (p'_I + p''_{I''}) = p_I - p'_I \leq \delta,$$

and similarly $x'_j - x_j \leq \delta$. So we see that $d(x, x') = \max_{j \in [n]} |x_j - x'_j| \leq \delta$ as desired.

We have $p_I(L' + v) = p_I(L') + \sum_{i \in I} v_i$ so the tropical Plücker coordinates of $L' + v$ vary continuously with v . The tropical Plücker coordinates of $L \cap_{\text{st}} (L' + v)$ similarly vary continuously with v . As $L(p)$ is a continuous function of p , this means that $L \cap_{\text{st}} (L' + v)$ varies continuously with v . When v is chosen generically, L and $L' + v$ meet transversely so $L \cap (L' + v) = L \cap_{\text{st}} (L' + v)$. Take limits of both sides as $v \rightarrow 0$ and use the preceding continuity arguments to conclude that $\lim_{v \rightarrow 0} (L \cap (L' + v)) = L \cap_{\text{st}} L'$. $\square$

The notion of the stable intersection of two polyhedral complexes, defined by the formula $\lim_{v \rightarrow 0} (L \cap (L' + v))$, was introduced in [16] and shown to be well defined in the case of tropical hypersurfaces (defined in that paper). This operation for fans was described earlier, without this name, in [12] in the course of giving a combinatorial rule for multiplication in the cohomology ring of a toric variety.

5. Series-parallel matroids. Recall that we define a tropical linear space to be *constructible* if it can be built from hyperplanes (tropical linear spaces of dimension $n - 1$ in n -space) by successive dualization and transverse intersection. Let L be a constructible tropical linear space of dimension d in n -space, with $\mathcal{D}$ the corresponding division of $\Delta(d, n)$. Then every face of $\mathcal{D}$ is of the form Poly_M , where M is built from matroids of corank 1 by dualization and parallel connection. (We will check this in section 6.) It is therefore of interest to understand the class of matroids which can be built in this way. A connected matroid can be built in this way if and only if it is series-parallel. In general, a matroid can be built in this way if and only if its connected components are series-parallel matroids, loops, and coloops. In this section, we review the definition of series-parallel matroids and review several key lemmas about them. We will present a very streamlined version of this theory, ignoring the connections to graphs, electrical networks, and trees. The reader wanting more background on series-parallel matroids should consult [3]. We note that several of the references we cite in this section are written in the language of graph theory rather than that of matroid theory; for the connections between the two subjects, see [22, Chapter 6].

Let M be a matroid on the ground set E , and let e be an element of E . The *parallel extension* of M at e denoted $P(M, e)$ is a matroid on the ground set $\hat{E} := E \setminus \{e\} \cup \{e_1, e_2\}$. The bases of $P(M, e)$ are the subsets I of $\hat{E}$ such that either I does not contain either e_1 or e_2 and I is a basis of M , or I contains exactly one of e_1 and e_2 and $I \setminus \{e_1, e_2\} \cup \{e\}$ is a basis of M . Similarly, the *serial extension* of M at e denoted $S(M, e)$ is also a matroid on the ground set $\hat{E}$. The bases of $S(M, e)$ are the subsets I of $\hat{E}$ such that either I contains both e_1 and e_2 and $I \setminus \{e_1, e_2\} \cup \{e\}$ is a basis of M , or I contains precisely one of e_1 and e_2 , and $I \setminus \{e_1, e_2\}$ is a basis of M . We will want to know how series and parallel extensions effect the properties of being connected and loop-free. We leave the proof to the reader.

LEMMA 5.1. *Let M be a matroid with e an element of the ground set of M . If M has at least two elements, then M is connected if and only if $P(M, e)$ is connected if and only if $S(M, e)$ is connected. If any of these equivalent conditions hold, then M , $P(M, e)$, and $S(M, e)$ are all loop-free. We now describe the cases where M has one element. If M is a loop, then $S(M, e)$ is connected and loop-free, while $P(M, e)$ is neither. If M is a coloop, then $P(M, e)$ is connected and loop-free, while $S(M, e)$ is loop-free but disconnected.*

By definition, a *series-parallel* matroid is a matroid which can be produced from $\text{Uniform}(1, 2)$ by the repeated use of the operations of series and parallel extension. In this section, we prove several results on series-parallel matroids for future use.

PROPOSITION 5.2. *The dual of a series-parallel matroid is series-parallel.*

Proof. See [22, Proposition 6.4.5] for a proof in the language of graph theory. $\square$

PROPOSITION 5.3. *The parallel connection of two series-parallel matroids is series-parallel.*

Proof. In section 7 of [3], Brylawski gives a definition of “series-parallel network” which is tautologically closed under taking parallel connections. Brylawski’s definition clearly includes ours, as serial and parallel extensions are special cases of series and parallel connection. After Theorem 7.6 of [3], Brylawski notes that any matroid which is series-parallel by his definition can be built from $\text{Uniform}(1, 2)$ by repeated parallel extension and dualization. Since the dual of a parallel extension is a series extension and $\text{Uniform}(1, 2)$ is self-dual, this is equivalent to saying that every series-parallel network in Brylawski’s sense can be built from $\text{Uniform}(1, 2)$ by series and parallel extensions. This is our definition. $\square$

LEMMA 5.4. *Let M be a series-parallel matroid with at least three elements, and let f be an element of M . Then either M/f is connected and $M \setminus f$ is not, or vice versa.*

Proof. For the claim that at least one of M/f and $M \setminus f$ is connected, see “Lemma to Theorem II” in [4]. For the claim that at most one is, see Condition (6) in Theorem 7.6 of [3]. $\square$

PROPOSITION 5.5. *Let M be a series-parallel matroid, and let Poly_N be a face of Poly_M . Then the connected summands of N are all series-parallel, loops, or coloops.*

Proof. From Proposition 2.4, N is of the form $\text{gr}(M, F_\bullet)$ for some filtration F of M . By definition, $\text{gr}(M, F_\bullet)$ is a direct sum of the minors of M . By Lemma 7.7 of [3] and its dual, every minor of a series-parallel matroid is a direct sum of the matroids of the required forms. $\square$

Let M be a connected loop-free matroid. Following a suggestion of Sturmfels, we refer to proper, nonempty flats F of M such that $M|_F$ and M/F are both connected as *flacets*. With some redundancy, we can define a flacet as a proper, nonempty subset F of M so that both $M|_F$ and M/F are connected and loop-free. This is redundant (but correct) because F is a flat if and only if M/F is loop-free, while $M|_F$ never has loops because M doesn’t. The characteristic vectors of the flacets of M are the rays of the Bergman fan of M , as described in [2]. In the following straightforward, but tedious, lemma, we describe the effects of series and parallel extension on the set of flacets of a matroid.

LEMMA 5.6. *Let M be a connected loop-free matroid on the ground set E , with E of size at least two, and let e be an element of E . Let $\hat{E} = E \setminus \{e\} \cup \{e_1, e_2\}$. Let π be the function $\hat{E} \rightarrow E$ defined by $\pi(e_1) = \pi(e_2) = e$ and $\pi(e') = e'$ in all other cases. The flacets of $P(M, e)$ are precisely the sets $\pi^{-1}(F)$, where F is a flacet of M . Except for a few special cases which we will state shortly, a subset $\hat{F}$ of $\hat{E}$ is a flacet of $S(M, e)$ if and only if the set $\hat{F}$ is of the form $\pi^{-1}(F)$, where F is a flacet of M . The exceptions to this claim are the following: the singletons $\{e_1\}$ and $\{e_2\}$ are flacets of $\hat{M}$, the pair $\{e_1, e_2\}$ is not, and if $M \setminus e$ is connected, then $\hat{E} \setminus \{e_1, e_2\}$ is a flacet of $\hat{M}$.*

We use Lemma 5.1 repeatedly.

Proof. We treat the case of $P(M, e)$ first. Since e_1 is in the closure of e_2 and vice versa, every flat of $P(M, e)$ contains either both M_1 and M_2 or neither. Let $\hat{F}$ be a subset of $\hat{E}$ which contains either both e_1 and e_2 or neither; we will describe the circumstances under which $\hat{F}$ is a flacet of $P(M, e)$. First, suppose that $\hat{F}$ does not contain e_1 or e_2 . Then set $F = \hat{F}$ and observe that $\hat{M}|_{\hat{F}} = M|_F$ and $\hat{M}/\hat{F} = P(M/F, e)$, so $\hat{M}|_{\hat{F}}$ and $\hat{M}/\hat{F}$ are connected and loop-free if and only if $M|_F$ and M/F are. Alternatively, suppose that $\hat{F} = F \setminus \{e\} \cup \{e_1, e_2\}$ for a subset F of E containing e . Then $\hat{M}|_{\hat{F}} = P(M|_F, e)$ and $\hat{M}/\hat{F} = M/F$, so again $\hat{M}|_{\hat{F}}$ and $\hat{M}/\hat{F}$ are connected and loop-free if and only if $M|_F$ and M/F are.

Now, we consider the case of $S(M, e)$. If $\hat{F}$ is any subset of $\hat{E}$ which contains e_1 and not e_2 , then e_1 is a coloop of $\hat{M}|_{\hat{F}}$. So, in this case, the only way that $\hat{M}|_{\hat{F}}$ could be connected is if $\hat{F} = \{e_1\}$, and, on the other hand, it is easy to check in this case that $\{e_1\}$ is a flacet. Similarly, $\{e_2\}$ is the only flacet that contains e_2 and not e_1 . We now consider the case that $\hat{F}$ contains neither e_1 nor e_2 . Set $F = \hat{F}$. We have $\hat{M}|_{\hat{F}} = M|_F$ and $\hat{M}/\hat{F} = S(M/F, e)$. So $\hat{M}|_{\hat{F}}$ is connected and loop-free if and only if $M|_F$ is. The situation for $\hat{M}/\hat{F}$ is a little trickier: $\hat{M}/\hat{F}$ is connected and loop-free if and only if either $\hat{M}/\hat{F}$ is connected and loop-free or else if M/F is a loop. (It is impossible that M/F is a coloop, as then M would have a coloop, contradicting that

it is a connected matroid with at least two elements.) So, when $\hat{F}$ contains neither e_1 nor e_2 , we see that $\hat{F}$ is a facet if and only if either F is a facet or else $F = E \setminus \{e\}$ and $M|_F$ is connected. Finally, we consider the case where $\hat{F}$ contains both e_1 and e_2 . Set $F = \pi(\hat{F})$. Then $\hat{M}|_{\hat{F}} = S(M|_F, e)$ and $\hat{M}/\hat{F} = M/F$. This time, $\hat{M}/\hat{F}$ is connected and loop-free if and only if M/F and the difficulties come with $\hat{M}|_{\hat{F}}$. Specifically, $\hat{M}|_{\hat{F}}$ is loop-free and connected as long as $M|_F$ is loop-free and connected and $M|_F$ is not a coloop. The last criterion simply rules out the case $F = \{e\}$. (It is impossible that $M|_F$ is a loop, as that would imply that M had a loop, contradicting that M is connected and has multiple elements.) So, when $\hat{F}$ contains both e_1 and e_2 , then $\hat{F}$ is a facet if and only if F is a facet other than $\{e\}$. $\square$

LEMMA 5.7. *Let M be a series-parallel matroid, with f and g distinct elements of the ground set of M . Let $F_1, F_2, \dots, F_{d(f,g,M)}$ be the set of facets of M which contain f but not g . Then, after reordering, these facets form a nested chain $F_1 \subsetneq F_2 \subsetneq \dots \subsetneq F_{d(f,g,M)}$. For any $i < j$, the quotient F_j/F_i is connected. Furthermore, $d(f, g, M) = d(g, f, M)$.*

For any matroid M with elements f and g , we will define $d(f, g, M)$ to be the number of facets of M containing f and not g , even when M is not series-parallel.

Proof. Our proof is by induction on the cardinality of the ground set of M ; the base case where M has two elements is clear. So, consider a series-parallel matroid $\hat{M}$ on $\hat{E}$, with $\hat{M}$ equal to either $S(M, e)$ or $P(M, e)$ for some smaller series-parallel matroid M . By induction, the lemma has already been proven for M . We continue to use the notations e, e_1 , and e_2 as usual. We also write π for the function $\hat{E} \rightarrow E$ defined by $\pi(e_1) = \pi(e_2) = e$ and $\pi(e') = e'$ in all other cases. We break into several cases.

Case 1. The matroid $\hat{M}$ is a parallel extension of M . In this case, once again Lemma 5.6 shows that F is a facet of M containing f and not g if and only if $\pi^{-1}(F)$ is a facet of $\hat{M}$ doing the same. Taking inverse images under π preserves the property of being nested and preserves the length of nested chains. Furthermore, $\pi^{-1}(F_j)/\pi^{-1}(F_i)$ is either isomorphic to F_j/F_i or to a series or parallel extension thereof.

Case 2. The elements f, g, e_1 , and e_2 are all distinct, and $\hat{M} = S(M, e)$. Then Lemma 5.6 gives the same conclusion as in Case 1: F is a facet of M containing f and not g if and only if $\pi^{-1}(F)$ is a facet of $\hat{M}$ doing the same. We complete the argument as before.

Case 3. The matroid $\hat{M}$ is $S(M, e)$, and $(f, g) = (e_1, e_2)$. Then the only facet containing f and not g is $\{e_1\}$, and the only facet containing g and not f is $\{e_2\}$. Since there is only one facet separating f from g , the condition on quotients is empty.

Case 4. The matroid $\hat{M}$ is $S(M, e)$, with $e_1 = f$ and $g \neq e_2$. This is the only interesting case. Let $F_1 \subsetneq F_2 \subsetneq \dots \subsetneq F_{d(e,g,M)}$ be the chain of facets in M containing e and not g , while $G_1 \subsetneq G_2 \subsetneq \dots \subsetneq G_{d(g,e,M)}$ is the chain of facets in M containing g but not e . Now, by Lemma 5.4, either M/e is connected and $M \setminus e$ is not, or vice versa. We split into subcases.

Case 4a. The matroid M/e is connected and $M \setminus e$ is not. In this case, $\{e\}$ is a facet of M and is necessarily equal to F_1 . Consulting Lemma 5.6, the facets of $\hat{M}$ containing f and not g are

$$\{f\} = \{e_1\} \subsetneq \pi^{-1}(F_2) \subsetneq \dots \subsetneq \pi^{-1}(F_{d(e,g,M)}).$$

On the other hand, we also know in this case that $\hat{E} \setminus \{e_1, e_2\}$ is not a facet of $\hat{M}$,

so, consulting Lemma 5.6 again, the facets of $\hat{M}$ containing g and not f are

$$\pi^{-1}(G_1) \subsetneq \pi^{-1}(G_2) \subsetneq \cdots \subsetneq \pi^{-1}(G_{d(g,e,M)}).$$

We see that we have two nested chains of length $d(e, g, M) = d(g, e, M)$. We must check the condition on quotients: For $2 \leq i < j$, we have $\pi^{-1}(F_j)/\pi^{-1}(F_i) \cong F_j/F_i$, which is connected by the inductive hypothesis, and similarly $\pi^{-1}(G_j)/\pi^{-1}(G_i) \cong G_j/G_i$ is connected. Also, $\pi^{-1}(F_j)/e_1 \cong F_j$, which is connected by the definition of a facet.

Case 4b. The matroid M/e is not connected and $M \setminus e$ is. In this case, $\{e\}$ is not a facet of M , so the facets of $\hat{M}$ containing f and not g are

$$\{f\} = \{e_1\} \subsetneq \pi^{-1}(F_1) \subsetneq \pi^{-1}(F_2) \subsetneq \cdots \subsetneq \pi^{-1}(F_{d(e,g,M)}).$$

On the other hand, we also know in this case that $\hat{E} \setminus \{e_1, e_2\}$ is a facet of $\hat{M}$, while $E \setminus \{e\}$ is certainly not a facet of M . So the facets of $\hat{M}$ containing g and not f are

$$\pi^{-1}(G_1) \subsetneq \pi^{-1}(G_2) \subsetneq \cdots \subsetneq \pi^{-1}(G_{d(g,e,M)}) \subsetneq \hat{M} \setminus \{e_1, e_2\}.$$

We see that we have two nested chains of length $d(e, g, M) + 1 = d(g, e, M) + 1$. Once again, we must check the condition on quotients. The quotients $\pi^{-1}(F_j)/\pi^{-1}(F_i)$, $\pi^{-1}(F_j)/e_1$, and $\pi^{-1}(G_j)/\pi^{-1}(G_i)$ are all connected by the arguments in Case 4a. Finally, we must consider $(\hat{M} \setminus \{e_1, e_2\})/\pi^{-1}(G_i)$. First, note that $(\hat{M} \setminus \{e_1, e_2\})/\pi^{-1}(G_i)$ is isomorphic to $M \setminus e/G_i = (M/G_i) \setminus e$. So we must show that $(M/G_i) \setminus e$ is connected.

Assume for the sake of contradiction that $(M/e)/G_i$ is connected. We are currently assuming that M/e is disconnected so if $(M/e)/G_i$ is connected, then G_i must contain a connected component K of M/e . The closure of K , taken in M , contains e . (Otherwise, M would also be disconnected.) So e is in the closure of G_i (but not in G_i), contradicting that G_i is a flat of M . So we have a contradiction, and $(M/e)/G_i$ is, in fact, disconnected. Now, M/G_i is connected (because G_i is a facet), so, by Proposition 5.5, the quotient M/G_i is series-parallel. We have just shown that $(M/G_i)/e$ is disconnected, so, by Lemma 5.4, $(M/G_i) \setminus e$ is connected. This is what we wanted to show. $\square$

6. Proof of Theorem 1.3. We now have enough background to prove Theorem 1.3, which states that every constructible tropical linear space is series-parallel. We recall the definition of these concepts—a tropical linear space is called series-parallel if every facet of the corresponding subdivision of the hypersimplex is Poly_M for some series-parallel M . A tropical linear space is called constructible if it is built from tropical hyperplanes by the repeated use of the operations of orthogonal complement and transverse intersection. As the definition of constructibility suggests, we will prove Theorem 1.3 by showing that the orthogonal complement of a series-parallel linear space, or the transverse intersection of two series-parallel linear spaces, is series-parallel. Clearly, $L^\perp$ is series-parallel if L is, since the dual of a series-parallel matroid is series-parallel. So it is enough to show that if L and L' are two series-parallel tropical linear spaces that meet transversely, then $L \cap L'$ is series-parallel as well.

LEMMA 6.1. *If L is a series-parallel tropical linear space corresponding to the matroidal subdivision $\Delta(d, n)$, then, for every face Poly_M of $\mathcal{D}$, each connected component of M is series-parallel, a loop, or a coloop.*

Proof. Every face Poly_M of $\mathcal{D}$ is the face of some facet Poly_N of $\mathcal{D}$, where N is series-parallel by assumption. Now apply Proposition 5.5. $\square$

FIG. 2. A 3-simplicial division of a hexagon.

We now prove Theorem 1.3.

Proof of Theorem 1.3. Let L and L' be two series-parallel tropical linear spaces of dimensions d and d' in n -space which meet transversely at a point w . Let $\mathcal{D}$ and $\mathcal{D}'$ be the appropriate subdivisions of $\Delta(d, n)$ and $\Delta(d', n)$, respectively. Let $M^\vee$ and $(M')^\vee$ be the faces of $\mathcal{D}^\vee$ and $(\mathcal{D}')^\vee$ whose relative interiors contain w , then (by Corollary 4.3) $(M \wedge M')^\vee$ is the face of $L \cap L'$ containing w . Let $M = \bigoplus_{i \in I} M_i$ and $M' = \bigoplus_{i \in I'} M'_i$ be the connected components of M and M' ; note that none of the M_i or M'_i is a loop, so, by Lemma 6.1, the M_i and M'_i are series-parallel or coloops. By Lemma 4.6, the connected components of $M \wedge M'$ are built out of the M_i by a sequence of parallel connections. The parallel connection of N to a coloop is N again, and the parallel connection of two series-parallel matroids is series-parallel (Proposition 5.3), so we see that every component of N is series-parallel as desired. $\square$

7. A polyhedral lemma. The goal of this section is to prove the following lemma, which we will need in section 8.

LEMMA 7.1. *Let P be an N -dimensional polyhedron. Let $P_1, P_2, \dots, P_D$ be the facets of a polyhedral subdivision $\mathcal{E}$ of P . Suppose that, for every subset K of $[D]$, the intersection $\bigcap_{k \in K} P_k$ is a nonempty polytope of dimension at least $N - |K| + 1$. Then the number of $(N - g + 1)$ -dimensional faces of $\mathcal{E}$ whose relative interiors lie in $\text{Int}(P)$ is $\binom{D}{g}$.*

We will call a subdivision $\mathcal{E}$ as in Lemma 7.1 a D -simplicial subdivision. (The motivation for this terminology is that the neighborhood of the unique face of dimension $N - D + 1$ is the normal fan to a simplex of dimension $D - 1$.) Figure 2 shows a 3-simplicial division of a hexagon.

Some geometric experimentation should convince the reader that this lemma is extremely plausible. We will use a spherical variant of Helly's Theorem, due to Molnár. Recall that a convex cone is a subset C of $\mathbb{R}^N$ which is closed under addition, under multiplication by positive scalars, and contains the origin. A pointed convex cone is a convex cone C such that 0 can not be written as a positive combination of nonzero elements of C .

THEOREM 7.2. *Let $C_1, C_2, \dots, C_r$ be a collection of pointed convex cones of $\mathbb{R}^N$, with $r \geq N + 1$. Suppose that the intersection of any N of these cones contains a point other than the origin, and that the union of any $N + 1$ of these cones is not all of $\mathbb{R}^N$. Then the intersection of all of these cones contains a point other than the origin.*

Proof. For a proof in the case $N = 3$, see [15]. There is no difficulty in adapting Molnár's proof to arbitrary dimensions. The reader may also want to consult the survey article [5], which states this result in section 9 and sketches a proof. $\square$

We now prove Lemma 7.1. Recall from section 1 the notations $T(P, Q)$ and $T_0(P, Q)$.

Proof of Lemma 7.1. Without loss of generality, we may assume that the ambient space in which P lives is $\mathbb{R}^N$.

We first establish the following claim: for every nonempty subset K of $[D]$, the intersection $\bigcap_{k \in K} P_k$ has dimension $N - |K| + 1$ and meets $\text{Int}(P)$. We prove this

claim by induction on the cardinality of a subset K . When K is a singleton $\{k\}$, this is obvious as P_k is assumed to be a facet in a subdivision of P . Now, consider some K of cardinality greater than 1, and set $Q = \bigcap_{k \in K} P_k$. Let K' be a subset of K which contains one element less than K does. Since $Q \subseteq \bigcap_{k \in K'} P_k$ and since $P_1, \dots, P_D$ are faces of a subdivision, we know that Q is a face of $\bigcap_{k \in K'} P_k$. Since, by induction, $\bigcap_{k \in K'} P_k$ has dimension $N - |K'| + 2$ and, by hypothesis, Q has dimension at least $N - |K| + 1$, we know that Q has dimension either $N - |K| + 2$ or $N - |K| + 1$. We consider each case in turn.

First, suppose that Q has dimension $N - |K| + 2$. Consider the set of pointed cones $T_0(P_k, Q)$. Note that these cones live in a vector space of dimension $N - (N - |K| + 2) = |K| - 2$. We apply Theorem 7.2 to the cones $T_0(P_k, Q)$. For any $(|K| - 2)$ -element subset L of K , we know that $\bigcap_{\ell \in L} P_\ell$ has dimension $N - |L| + 2$, which is greater than that of Q , so $\bigcap_{\ell \in L} T_0(P_\ell, Q) = T_0(\bigcap_{\ell \in L} P_\ell, Q)$ has positive dimension and is not just the origin. Also, for any $(|K| - 1)$ -element subset $K \setminus \{x\}$ of K , we know that $\bigcup_{k \in K \setminus \{x\}} T_0(P_k, Q)$ can not be all of $(|K| - 2)$ -space, as it does not contain any points in $\text{Int}(T_0(P_x, Q))$. Thus, the hypotheses of Theorem 7.2 apply, and we conclude that $\bigcap_{k \in K} T_0(P_k, Q)$ contains a point other than the origin. But $\bigcap_{k \in K} T_0(P_k, Q) = T_0(\bigcap_{k \in K} P_k, Q) = T_0(Q, Q)$, which is just the origin. This is a contradiction.

So, we deduce that Q has dimension $N - |K| + 1$. If we can show that Q meets $\text{Int}(P)$ we are done, so assume for the sake of contradiction that Q lies in the boundary of P . Then there is some half-space H containing Q whose boundary contains P . Again, we consider the cones $T(Q, P_k)$, which we now know to lie in a space of dimension $|K| - 1$. Let L be any $(|K| - 1)$ -element subset of K . Then, by induction, $\bigcap_{\ell \in L} P_\ell$ has dimension $N - |L| + 2$ and hence is not Q . So $\bigcap_{\ell \in L} T_0(P_\ell, Q) = T_0(\bigcap_{\ell \in L} P_\ell, Q)$ is not just the origin. Also, it is impossible that $\bigcup_{k \in K} T_0(P_k, Q)$ is all of $(|K| - 1)$ -space, as every cone $T_0(P_k, Q)$ lies in $H/\mathbb{R}Q$. So Theorem 7.2 applies again, and we deduce that $\bigcap_{k \in K} T_0(P_k, Q)$ contains a point other than the origin. As before, this yields a contradiction. Thus, we conclude that Q has dimension $N - |K| + 1$ and meets $\text{Int}(P)$, as desired. This completes the inductive proof of the claim.

We now complete the proof. Every face of $\mathcal{E}$ whose relative interior lies in $\text{Int}(P)$ is of the form $\bigcap_{k \in K} P_k$ for some subset K of $[D]$. Our claim shows that every such intersection does meet the relative interior of P . Suppose two of these intersections are equal, let's say, $\bigcap_{k \in K} P_k = \bigcap_{k \in K'} P_k$. Then both these intersections are equal to $\bigcap_{k \in K \cup K'} P_k$. So, by our claim, the dimension of this intersection is equal to $N - |K| + 1$, $N - |K'| + 1$ and $N - |K \cup K'| + 1$. So $|K| = |K'| = |K \cup K'|$, and we deduce that $K = K'$. We have thus shown that all of the intersections $\bigcap_{k \in K} P_k$ give distinct faces whose relative interiors lie in $\text{Int}(P)$. So the number of such faces of dimension $N - g + 1$ is the number of g -element subsets of $[D]$. $\square$

8. Perturbing nearly transverse intersections. Our remaining goal is to prove Theorem 1.2—every constructible space achieves the f -vector of the f -vector conjecture. Our strategy is as follows: A constructible space is made by successive dualization and transverse intersection. From Proposition 2.12, the bounded parts of L and $L^\perp$ are negatives of each other, so they have the same f -vector. Thus, if L obeys the f -vector conjecture, so does $L^\perp$. So our main goal is to understand the effect of transverse intersection.

In this section, we will prove (Theorem 8.1) that, if L and L' are series-parallel tropical linear spaces and $v \in \mathbb{R}^n$, then the f -vector of $L \cap (L' + v)$ is independent of v as long as L and $L' + v$ meet transversely. The most technical part of this proof is the analysis of perturbing L' slightly when L and L' are almost transverse; this is

carried out in Lemma 8.4. Our result ultimately relies on a previously proven lemma (Lemma 5.7) about chains of flats in series-parallel matroids. In the next section, we will use Theorem 8.1 to prove Theorem 1.2. First, let us set out our goal for this section.

THEOREM 8.1. *Let L and L' be two series-parallel tropical linear spaces in n -space, of dimensions d and d' . Let a and $b \in \mathbb{R}^n$ be such that L meets $L' + a$ and $L' + b$ transversely. Then $L \cap (L' + a)$ and $L \cap (L' + b)$ have the same bounded f -vector.*

We first must prove some technical lemmas describing what happens when we perturb an intersection of two tropical linear spaces. We need to introduce a fair amount of notation. Let L and L' be tropical linear spaces of dimensions d and d' in n -space, with $0 < d, d' < n$ and $d + d' > n$. Let $\mathcal{D}$, $\mathcal{D}'$, and $\mathcal{E}$ be the regular subdivisions of $\Delta(d, n)$, $\Delta(d', n)$, and $\Delta(d + d' - n, n)$ corresponding to L , L' , and $L \cap_{\text{st}} L'$. Let v be a generic vector in $\mathbb{R}^n$, and consider $L \cap (L' + \epsilon v)$ for a ϵ sufficiently small positive number. Let $\mathcal{E}_v$ be the corresponding subdivision of $\Delta(d + d' - n, n)$, so $\mathcal{E}_v$ refines $\mathcal{E}$. For every face A of $\mathcal{E}_v$, there is a unique face B of $\mathcal{E}$ such that $\text{Int}(B) \supseteq \text{Int}(A)$. We will say that B is the face which *internally contains* A . We will focus on a particular face $\text{Poly}_{M \wedge M'}$ of $\mathcal{E}$ and try to determine how this face is subdivided in $\mathcal{E}_v$.

Let w be a point of $L \cap_{\text{st}} L'$, and let $M^\vee$ and $(M')^\vee$ be the faces of L and L' in whose relative interior w lies. So w lies in the face $\text{Int}((M \wedge M')^\vee)$ of $L \cap_{\text{st}} L'$. If $\mathbb{R}M^\vee + \mathbb{R}(M')^\vee = \mathbb{R}^n$, i.e., if $M^\vee$ and $(M')^\vee$ are transverse, then $M^\vee$ and $(M')^\vee + \epsilon v$ also meet for sufficiently small ϵ , so $\text{Poly}_{M \wedge M'}$ is a face of $\mathcal{E}_v$ as well as $\mathcal{E}$.

We will spend most of the rest of this section in a detailed analysis of the case where $M^\vee$ and $(M')^\vee$ are not transverse, but are nearly so. More specifically, suppose that $\mathbb{R}M^\vee + \mathbb{R}(M')^\vee$ has dimension $n - 1$. By Lemma 4.10, this means that $\Gamma(M, M')$ has first betti number 1. Let $c_1, c_2, \dots, c_{2r}$ be the vertices of this cycle, with $c_1, c_3, c_5, \dots$ indexing connected components of M and $c_2, c_4, c_6, \dots$ indexing connected components of M' . Let e_s be the edge joining c_s to c_{s+1} .¹ For future use, we define $\sigma := \sum_{j=1}^{2r} (-1)^j v_{e_j}$. The sign of σ will control the combinatorics of $\mathcal{E}_v$. We will use these notations throughout the section.

Now that $M^\vee$ and $(M')^\vee$ are not transverse, the polytopes $M^\vee$ and $(M')^\vee + \epsilon v$ will not meet for generic v . The faces of $\mathcal{E}_v$ which $\text{Poly}_{M \wedge M'}$ internally contains will all arise as $\text{Poly}_{N \wedge N'}$ where $N^\vee$ and $(N')^\vee$ are faces of L and L' containing $M^\vee$ and $(M')^\vee$ such that $N^\vee$ and $(N')^\vee + \epsilon v$ do meet (for ϵ a sufficiently small positive number.) If $N^\vee$ and $(N')^\vee + \epsilon v$ meet,² then $\text{Poly}_{N \wedge N'}$ is a face of $\mathcal{E}_v$ contained in $\text{Poly}_{M \wedge M'}$, but whether or not $\text{Poly}_{N \wedge N'}$ is internally contained in $\text{Poly}_{M \wedge M'}$ can be subtle.

We pause to introduce more notation. Let $M = \bigoplus_{c \in C} M_c$ and $M' = \bigoplus_{c' \in C'} M'_{c'}$ be the decompositions of M and M' into connected components, so the vertex set of $\Gamma(M, M')$ is $C \sqcup C'$. We will write S_c and S'_c for the elements of M_c and M'_c . Occasionally, we will write $M_c^{(\cdot)}$ or $S_c^{(\cdot)}$ when we don't want to state whether c lies in C or in C' .

We first wish to consider those faces internally contained in $\text{Poly}_{M \wedge M'}$ which are of the same dimension as $\text{Poly}_{M \wedge M'}$. Such faces must be of the form $N \wedge N'$, where either $N = M$ and $(N')^\vee$ has dimension one larger than $(M')^\vee$ or else $N' = M'$ and $N^\vee$ has dimension one larger than $M^\vee$. In the first case, $N' = \bigoplus_{d \neq c} M'_d \oplus M'_c|_V \oplus M'_c/V$ for

¹The indices on the c_i and the e_i are cyclic modulo $2r$.

²We will now begin to omit the statement “for ϵ a sufficiently small positive number” for brevity’s sake when it should be clear.

some component $c \in C'$ and some facet V of M'_c . Similarly, in the second case, N is described by giving a component c in C and a facet V of M_c . So, in general, we can describe a potential pair (N, N') by giving a vertex c of $\Gamma(M, M')$ and a facet V of $M_c^{(\cdot)}$. With this terminology, we can describe when $N^\vee$ and $(N')^\vee + \epsilon v$ meet.

LEMMA 8.2. *Let M and M' obey the above hypotheses and continue the above notation. Let N and N' be as above, with corresponding c and V . If σ is positive, then $\text{Int}(N^\vee)$ and $\text{Int}((N')^\vee) + \epsilon v$ meet if and only if c is in $\{c_1, c_2, \dots, c_{2r}\}$, with V containing e_{s-1} but not e_s . If σ is negative, then $\text{Int}(N^\vee)$ and $\text{Int}((N')^\vee) + \epsilon v$ meet if and only if c is in $\{c_1, c_2, \dots, c_{2r}\}$, with V containing e_s but not e_{s-1} .*

We first need the following general description of perturbed intersections.

LEMMA 8.3. *Let P and P' be two polytopes in $\mathbb{R}^n$, with $w \in P \cap P'$. Let Q and Q' be the faces of P and P' in whose relative interiors w lies. Let v be a vector in $\mathbb{R}^n$, and let $\bar{v}$ be the image of v in $\mathbb{R}^n/(\mathbb{R}Q + \mathbb{R}Q')$. Then $\text{Int}(P)$ and $\text{Int}(P') + \epsilon v$ meet if and only if $\bar{v}$ is in $\text{Int}((T(P, Q) - T(P', Q'))/(\mathbb{R}Q + \mathbb{R}Q'))$.*

Proof. Note that $\text{Int}(P)$ and $\text{Int}(P')$ lie in $w + \text{Int}(T(P, Q))$ and $w + \text{Int}(T(P', Q'))$, respectively. So if $\text{Int}(P)$ and $\text{Int}(P') + \epsilon v$ meet, then $\text{Int}(T(P, Q))$ and $\text{Int}(T(P', Q')) + \epsilon v$ meet implying that ϵv lies in $\text{Int}(T(P, Q)) - \text{Int}(T(P', Q'))$. As $\text{Int}(T(P, Q))$ and $\text{Int}(T(P', Q'))$ are cones, this means that v lies in $\text{Int}(T(P, Q)) - \text{Int}(T(P', Q'))$. This is equivalent to stating that $\bar{v}$ is in $\text{Int}((T(P, Q) - T(P', Q'))/(\mathbb{R}Q + \mathbb{R}Q'))$.

Now for the converse direction. Suppose that $v = x - x'$, with x and x' in $\text{Int}(T(P, Q))$ and $\text{Int}(T(P', Q'))$. Then, for ϵ sufficiently small, the points $w + \epsilon x$ and $w + \epsilon x'$ are in $\text{Int}(P)$ and $\text{Int}(P')$, respectively. So $w + \epsilon x = (w + \epsilon x') + \epsilon v$ is in the relative interiors of both P and $P' + \epsilon v$. $\square$

We now apply this description to the situation of Lemma 8.2.

Proof of Lemma 8.2. By assumption, $\mathbb{R}M^\vee + \mathbb{R}(M')^\vee$ has dimension $n - 1$, so the vector space $\mathbb{R}^n/(\mathbb{R}M^\vee + \mathbb{R}(M')^\vee)$ is one-dimensional. Let λ be the linear function $(x_1, x_2, \dots, x_n) \mapsto \sum_{j=1}^{2r} (-1)^j x_{e_j}$. We claim that λ is zero on $(\mathbb{R}M^\vee + \mathbb{R}(M')^\vee)$. The vector space $\mathbb{R}M^\vee$ is spanned by the characteristic vectors of the connected components of M . For any connected component M_c of M other than M_{c_1} , M_{c_3} , $\dots$, $M_{c_{2r-1}}$, none of the e_j lie in M_c , so λ is zero on the characteristic vector of M_c . Similarly, $M_{c_{2k-1}}$ contains e_{2k-1} , e_{2k} and none of the other e_j lie in $M_{c_{2k-1}}$, so λ is $1 - 1 = 0$ on the characteristic vector of $M_{c_{2k-1}}$. Thus, λ is zero on $\mathbb{R}M^\vee$. Similarly, λ is zero on $\mathbb{R}(M')^\vee$ and thus on $(\mathbb{R}M^\vee + \mathbb{R}(M')^\vee)$. So we can identify $\mathbb{R}^n/(\mathbb{R}M^\vee + \mathbb{R}(M')^\vee)$, with $\mathbb{R}$ by mapping every point x in $\mathbb{R}^n$ to $\lambda(x)$. Under this identification, $\bar{v}$ is identified, with $\lambda(v) = \sigma$. By Lemma 8.3, we need to determine whether or not σ is in the relative interior of $\lambda(T(N^\vee, M^\vee) - T((N')^\vee, (M')^\vee))$. For brevity, we abbreviate $\lambda(T(N^\vee, M^\vee))$ and $\lambda(T((N')^\vee, (M')^\vee))$ to K and K' .

From now on, we will consider the case where σ is positive. The case where σ is negative is precisely analogous. So, we need to determine the images of $T(N^\vee, M^\vee)$ and $-T((N')^\vee, (M')^\vee)$ under λ . Let us first consider the case where $c = c_{2j+1}$. Then $N' = M'$, while $T_0(N^\vee, M^\vee)$ is a ray spanned by the image in $\mathbb{R}^n/\mathbb{R}M^\vee$ of $\sum_{f \in V} e_f$. So K' is $\{0\}$, while K is spanned by $\mu(V) := \lambda(\sum_{f \in V} e_f)$. So σ is in $K - K'$ if and only if $\mu(V)$, like σ , is positive. This happens if and only if e_{2j} is in V and e_{2j+1} is not. Next, let us consider the case where $c = c_{2j}$. Then K is $\{0\}$, and K' is spanned by $\mu(V)$. So we see that, this time, σ is in $K - K'$ if and only if $\mu(V)$ is negative. This happens only if e_{2j-1} is in V and e_{2j} is not. In both cases, when $c = c_s$, we have that σ is in $K - K'$ if and only if e_{s-1} is in V and e_s is not. Finally, we need to consider the case where c is not one of $c_1, c_2, \dots, c_{2r}$. In this case, $\mu(V) = 0$, and both K and K' are $\{0\}$. So, in this case, σ is not in $K - K'$. $\square$

Recall from section 5 the notation $d(f, g, M)$ for the number of the facets of M containing f and not g . So we see that, when σ is positive, there are $\sum_{j=1}^{2r} d(e_{j-1}, e_j, M_{c_j}^{(\prime)})$ faces of $\mathcal{E}_v$, which are internally contained in and of the same dimension as $\text{Poly}_{M \wedge M'}$. Similarly, when σ is negative, there are $\sum_{j=1}^{2r} d(e_j, e_{j-1}, M_{c_j}^{(\prime)})$ such faces. In particular, assume that L and L' are series-parallel, so that each $M_i^{(\prime)}$ is series-parallel (by Lemma 6.1). Then, by Proposition 5.7, $d(e_{j-1}, e_j, M_{c_j}^{(\prime)}) = d(e_j, e_{j-1}, M_{c_j}^{(\prime)})$ for each j from 1 to $2r$. So $\sum_{j=1}^{2r} d(e_{j-1}, e_j, M_{c_j}^{(\prime)}) = \sum_{j=1}^{2r} d(e_j, e_{j-1}, M_{c_j}^{(\prime)})$, we define D to be the common value of these sums.

PROPOSITION 8.4. *Let L and L' be series-parallel linear spaces and continue the preceding assumptions and notation. For generic v , the subdivision of $\text{Poly}_{M \wedge M'}$ in $\mathcal{E}_v$ is D -simplicial.*

Proof. Since v is generic, σ is not zero. Our goal is to apply Lemma 7.1. Let $P_1, P_2, \dots, P_D$ be the maximal faces of the subdivision of $\text{Poly}_{M \wedge M'}$, with $P_k = \text{Poly}_{N(k) \wedge N'(k)}$. Our goal is to show that $\bigcap_{k \in K} P_k$ has dimension at least $\dim \text{Poly}_{M \wedge M'} - |K| + 1$. We first introduce some notation. Look at a particular index k . Suppose that $N'(k) = M'$ and $N = \bigoplus_{i \neq c_{2j+1}} M_i \oplus M_{c_{2j+1}}|_V \oplus M_{c_{2j+1}}/V$. In this case, we define $c(k) = c_{2j+1}$ and $V(k) = V$. Similarly, if $N(k) = M$ and $N' = \bigoplus_{i \neq c_{2j}} M_i \oplus M_{c_{2j}}|_V \oplus M_{c_{2j}}/V$, then we set $c(k) = c_{2j}$ and $V(k) = V$. Finally, we introduce the notation p for the number of connected components of $\Gamma(M, M')$, so $\text{Poly}_{M \wedge M'}$ has dimension $n - p$ (by Lemma 4.7).

Fix a particular nonempty set K of indices. Look at a particular component $M_c^{(\prime)}$ of $M^{(\prime)}$. (Throughout this paragraph, $(\prime)$ will either always denote a prime or always denote the absence of a prime.) Let $K_c = \{k \in K : c(k) = k\}$. Then, by Proposition 5.7, the set of facets $\{V(k)\}_{k \in K_c}$ forms a nested chain in $M_c^{(\prime)}$. Add the $\emptyset$ and $S_c^{(\prime)}$ to the ends of this chain to form a filtration on M_c . Define $N_c^{(\prime)}$ to be the associated graded matroid of $M_c^{(\prime)}$ with respect to this filtration. Set $\mathcal{N}^{(\prime)}(K) = \bigoplus_{c \in C^{(\prime)}} N_c^{(\prime)}$.

Consider the graph $\Gamma(\mathcal{N}(K), \mathcal{N}'(K))$. This graph is formed by taking $\Gamma(M, M')$ and separating each vertex c_j in the cycle of Γ into $|K_c| + 1$ vertices. So $\Gamma(\mathcal{N}(K), \mathcal{N}'(K))$ has $\sum_{c \in C \cup C'} |K_c| = |K|$ more vertices than $\Gamma(M, M')$ and has the same number of edges. Also, $\Gamma(\mathcal{N}(K), \mathcal{N}'(K))$ is a forest. (At least one K_{c_j} is nonempty and, for this j , the edges e_{j-1} and e_j of $\Gamma(\mathcal{N}(K), \mathcal{N}'(K))$ are connected to different vertices, splitting open the cycle of $\Gamma(M, M')$.) So $\Gamma(\mathcal{N}(K), \mathcal{N}'(K))$ is a forest, with $p + |K| - 1$ connected components. By Lemma 4.6, we know that $\mathcal{N}(K) \wedge \mathcal{N}'(K)$ has rank $d + d' - n$ and that $\text{Poly}_{\mathcal{N}(K) \wedge \mathcal{N}'(K)}$ has dimension $n - (p + |K| - 1) = \dim \text{Poly}_{M \wedge M'} - |K| + 1$.

For every k in K , every basis of $\mathcal{N}^{(\prime)}(K)$ is a basis of $N'(k)$. So $\text{Poly}_{\mathcal{N}^{(\prime)}(K)} \subseteq \text{Poly}_{N'(k)}$ and $\text{Poly}_{\mathcal{N}(K) \wedge \mathcal{N}'(K)} \subseteq \text{Poly}_{N(k) \wedge N'(k)} = P_k$. (We are using that we know $\mathcal{N}(K) \wedge \mathcal{N}'(K)$ has rank $d + d' - n$.) We deduce that $\text{Poly}_{\mathcal{N}(K) \wedge \mathcal{N}'(K)} \subseteq \bigcap_{k \in K} P_k$. So $\bigcap_{k \in K} P_k$ contains a polytope of dimension $\dim \text{Poly}_{M \wedge M'} - |K| + 1$. We have now checked the conditions of Lemma 7.1, and it follows that $\mathcal{E}_v$ is D -simplicial. $\square$

We now prove Theorem 8.1.

Proof of Theorem 8.1. Let $U_i \subseteq \mathbb{R}^n$ be the set of v such that, for any two faces F and F' of L and L' , either the relative interiors of F and $F' + v$ are disjoint or they span an affine linear space of dimension at least $n - i$. Thus, L and $L' + v$ meet transversely if and only if v is in U_0 and $\mathbb{R}^n \setminus U_i$ is a polyhedral complex of dimension at most $n - i - 1$. In particular, we see that U_1 is path connected. We may therefore join a and b by a path through U_1 . It is thus enough to show that if $w \in U_1 \setminus U_0$

and we perturb w into U_0 , then the f -vector we get is independent of the choice of perturbation. With loss of generality, we may take $w = 0$. Let $\mathcal{E}$ be the regular subdivision of $\Delta(d + d' - n, n)$ corresponding to $L \cap_{\text{st}} L'$, and let $\mathcal{E}_{\epsilon v}$ be the regular subdivision corresponding to $L \cap_{\text{st}} (L' + \epsilon v)$. Also, write $\mathcal{D}$ and $\mathcal{D}'$ for the subdivisions of $\Delta(d, n)$ and $\Delta(d', n)$. For ϵ small enough, $\mathcal{E}_{\epsilon v}$ refines $\mathcal{E}$. Let's focus on a face R of $\mathcal{E}$ and ask what faces of $\mathcal{E}_{\epsilon v}$ are internally contained in R .

The face R is of the form $\text{Poly}_{N \wedge N'}$ for Poly_N and $\text{Poly}_{N'}$ faces of $\mathcal{D}$ and $\mathcal{D}'$. If $N^\vee$ and $(N')^\vee$ are transverse, then $N^\vee$ and $(N')^\vee + \epsilon v$ will also meet, so R is also a face of $\mathcal{E}_{\epsilon v}$. If $N^\vee$ and $(N')^\vee$ are not transverse, then Lemma 8.4 applies. So there is an integer D so that, in $\mathcal{E}_{\epsilon v}$, there are $\binom{D}{i}$ faces of $\mathcal{E}_{\epsilon v}$ which have dimension $\dim R - i + 1$ and are internally contained in R . In particular, this number does not depend on the choice of v . Since each internal face of $\mathcal{E}_{\epsilon v}$ is internally contained in exactly one internal face of $\mathcal{E}$, this shows that the number of internal faces of $\mathcal{E}_{\epsilon v}$ is independent of v . $\square$

9. Proof of Theorem 1.2. We now are ready to begin our final assault on Theorem 1.2: that all constructible tropical linear spaces have the f -vector predicted by the f -vector conjecture. Our basic strategy is to use Theorem 8.1 to reduce to a particularly nice case. Our proof involves several binomial coefficient identities.

We will first need to study how the various faces of $\Delta(d, n)$ are subdivided in a constructible decomposition. Let S and T be disjoint subsets of $[n]$. Write $\Delta(d, n) \setminus S/T$ for the face of $\Delta(d, n)$ given by the equations $x_i = 0$ for $i \in S$ and $x_i = 1$ for $i \in T$. If p is a tropical Plücker vector, then define $p \setminus S/T$ to be the function on the vertices of $\Delta(d - |T|, n - |S| - |T|)$ given by $(p \setminus S/T)_I = p_{I \cup T}$. It is clear that $p \setminus S/T$ obeys the tropical Plücker relations (equation (1)), as they are a subset of the tropical Plücker relations for p . So $p \setminus S/T$ corresponds to a tropical $d - |T|$ plane in $n - |S| - |T|$ space. If $L = L(p)$, then we write $L \setminus S/T$ for the tropical linear space $L(p \setminus S/T)$.

LEMMA 9.1. *If L is a constructible d -plane in n -space and S and T are disjoint subsets of $[n]$, then $L \setminus S/T$ is also constructible.*

Proof. If L is a hyperplane, then every $L \setminus S/T$ is either a hyperplane or the whole space in which it sits and hence is constructible. Now suppose that the lemma holds for L . Then it holds for $L^\perp$ as $L^\perp \setminus S/T = (L \setminus T/S)^\perp$. Suppose that the lemma holds for L and L' and that L and L' meet transversely. Then it holds for $L \cap L' = L \cap_{\text{st}} L'$ as $(L \cap_{\text{st}} L') \setminus S/T = (L \setminus \emptyset / (S \cup T)) \cap_{\text{st}} (L' \setminus S/T)$. $\square$

We now begin to prove Theorem 1.2. Our proof is by induction, first on n and then on the number of steps used to construct L . We set

$$f_{i,d,n} = \frac{(n-i-1)!}{(i-1)!(d-i)!(n-d-i)!}.$$

First, suppose that the theorem is true for L . The bounded f -vectors of $L^\perp$ and L are the same by Proposition 2.12, so the theorem for $L^\perp$ follows from the symmetry $f_{i,d,n} = f_{i,n-d,n}$. For the rest of the proof, suppose that L and L'' are a constructible d -plane and d' plane in n -space which meet transversely and for which we know the theorem to hold. In addition, we know that the theorem holds for every $L \setminus S/T$ and $L'' \setminus S/T$ by our inductive hypotheses. Our aim will be to prove the theorem for $L \cap L''$.

By Theorem 8.1, it is enough to prove the result for $L \cap (L'' + w)$, where w is chosen generically enough. We will take a w for which $w_1 \gg w_2 \gg \cdots \gg w_n$ and which is otherwise generic. We will call such a w “large enough.” Set $L' = L'' + w$. Every face of $L \cap L'$ can be uniquely written as $(M^\vee) \cap ((M')^\vee)$ for some faces $M^\vee$ and $(M')^\vee$ which meet transversely. Our strategy will be to use the assumption

that w is large enough to figure out which pairs of faces meet in a bounded face of $L \cap L'$. We will need to consider the possibility that a bounded face of $L \cap L'$ is the intersection of unbounded faces of L and of L' ; to handle this situation we use the $L \setminus S/T$ construction to reduce enumerating unbounded faces of L (subject to certain restrictions) to enumerating bounded faces of tropical linear spaces for smaller n . By Lemma 9.1, all of these smaller tropical linear spaces will also be constructible, so our inductive hypotheses will apply.

Consider any face $M^\vee$ of L . We know M is loop-free; let T be the set of coloops of M so that Poly_M lies in the relative interior of $\Delta(d, n) \setminus \emptyset/T$. Then $M^\vee/(1, \dots, 1)$ is the product of $\mathbb{R}_{\geq 0}^T$ and a bounded polytope. Let $(M'')^\vee$ be a face of L'' and define T' similarly. We write $(M')^\vee = (M'')^\vee + w$, so M' and M'' are the same matroid.

Define an ordered pair (T, T') of the subsets of $[n]$ to be *facing* if, for all $1 \leq i < j \leq n$, either $i \in T$ or $j \in T'$.

LEMMA 9.2. *For $w_1 \gg w_2 \gg \dots \gg w_n$, the faces $M^\vee$ and $(M')^\vee$ meet if and only if (T, T') is facing. The intersection $M^\vee \cap (M')^\vee$ is bounded if and only if $T \cap T' = \emptyset$.*

Proof. First, suppose that (T, T') is not facing, so there exists some $i < j$, with $i \notin T$ and $j \notin T'$. On $M^\vee$, the function $x_i - x_j$ is bounded above (as $i \notin T$). On $(M'')^\vee$, $x_i - x_j$ is similarly bounded below. The value of $x_i - x_j$ on $(M')^\vee$ is $w_i - w_j$ larger than on $(M'')^\vee$ so if $w_j - w_i$ is large enough, then the values of $x_i - x_j$ on $M^\vee$ and $(M')^\vee$ will be disjoint. Thus, $M^\vee$ and $(M')^\vee$ will not meet.

Now suppose that (T, T') is facing. Let $(x_i) \in M^\vee$ and $(x'_i) \in (M'')^\vee$, set $x'_i = x''_i + w_i$, and set $d_i = x'_i - x_i$. For w large enough, we have $d_1 > d_2 > \dots > d_n$. Let b be the smallest element of $[n] \setminus T$, or let $b = n$ if $[n] = T$. Then, since (T, T') is facing, $j \in T'$ for every $j > b$ and, by construction, i is in T for every $i < b$. After translating (x_i) by $(1, \dots, 1)$, which will not change the assumption that $(x_i) \in M^\vee$, we may assume that $x_b = x'_b$, so $d_b = 0$. Consider the point

$$\begin{aligned} z &:= (x_1 + d_1, \dots, x_{b-1} + d_{b-1}, x_b, x_{b+1}, \dots, x_n) \\ &= (x'_1, \dots, x'_{b-1}, x'_b, x'_{b+1} - d_{b+1}, \dots, x'_n - d_n). \end{aligned}$$

Clearly, $z \in (x_i) + \mathbb{R}_{\geq 0}^T$ and $z \in (x'_i) + \mathbb{R}_{\geq 0}^{T'}$, so $z \in M^\vee \cap (M')^\vee$. We have now proved the first claim.

Now assume that (T, T') is facing, so there is some point $z = (z_i) \in M^\vee \cap (M')^\vee$. Suppose that $i \in T \cap T'$. Then $z + ue_i \in M^\vee \cap (M')^\vee$ for every $u > 0$ and $M^\vee \cap (M')^\vee$ is unbounded.

Suppose, on the other hand, that $T \cap T' = \emptyset$. Consider any distinct elements i and j , with $i < j$ in $[n]$. If neither i nor j is in T , then $x_i - x_j$ is bounded on $M^\vee$; if neither i nor j is in T' , then $x_i - x_j$ is bounded on $(M')^\vee$; if $i \notin T'$ and $j \notin T$, then $x_i - x_j$ is bounded below on $M^\vee$ and above on $(M')^\vee$. Given that (T, T') is facing and $T \cap T' = \emptyset$, it must be true that one of these three cases holds. We see that, in every case, $x_i - x_j$ is bounded on $M^\vee \cap (M')^\vee$. So all of the $x_i - x_j$ are bounded on $M^\vee \cap (M')^\vee$, which implies that $(M^\vee \cap (M')^\vee)/(1, \dots, 1)$ is bounded. $\square$

Keeping the above notation, $M^\vee$ corresponds to a bounded face of $L \setminus \emptyset/T$. If this bounded face is j -dimensional, then $M^\vee$ is $(j + t)$ -dimensional, where $t = |T|$. Similarly, let $t' = |T'|$, and let j' be the dimension of the face of $L \setminus \emptyset/T'$ corresponding to $(M')^\vee$, then the dimension of $(M')^\vee$ is $j' + t'$. The dimension of $M^\vee \cap (M')^\vee$ is then $j + j' + t + t' - n$. We thus see that the number of i -dimensional bounded faces of $L \cap L'$ is

$$\sum_{\substack{(T, T') \text{ facing} \\ T \cap T' = \emptyset}} \sum_{j+j'+t+t'-n=i} f_{j,d-t,n-t} f_{j',d'-t',n-t'}.$$

We have used our inductive assumption to know that all of the constructible tropical linear spaces $L \setminus \emptyset / T$ and $L' \setminus \emptyset / T'$ have the correct f -vector as they live either in a smaller ambient space, or if T or T' is empty, are constructed using a smaller number of steps.

The only facing pairs (T, T') , with $T \cap T' = \emptyset$ are $(\{1, \dots, b-1\}, \{b+1, \dots, n\})$ and $(\{1, \dots, b\}, \{b+1, \dots, n\})$. So we can write our sum as

$$\sum_b \left(\sum_{j+j'=i+1} f_{j,d-b+1,n-b+1} f_{j',d'-n+b,b} + \sum_{j+j'=i} f_{j,d-b,n-b} f_{j',d'-n+b,b} \right).$$

We will now show that this sum is $f_{i,D,n}$, where D is $d + d' - n$.

We work with the first sum first. Plugging in $f_{i,d,n} = \binom{n-d-1}{i-1} \binom{n-i-1}{n-d-1}$ and exchanging the order of summation, we have

$$\sum_{j+j'=i+1} \binom{n-d-1}{j-1} \binom{n-d'-1}{j'-1} \left(\sum_b \binom{n-b-j}{n-d-1} \binom{b-j'-1}{n-d'-1} \right).$$

Using the identity $\sum_{k+k'=p} \binom{k}{q} \binom{k'}{r} = \binom{p+1}{q+r+1}$, (see [14, equation (5.26)]) the inner sum evaluates to $\binom{n-i-1}{2n-d-d'-1} = \binom{n-i-1}{n-D-1}$. We are reduced to evaluating the sum

$$\binom{n-i-1}{n-D-1} \sum_{j+j'=i+1} \binom{n-d-1}{j-1} \binom{n-d'-1}{j'-1}.$$

The remaining sum can be evaluated by Vandermonde's convolution (see [14, equation (5.22)]) $\sum_{j+j'=r} \binom{p}{j} \binom{q}{j'} = \binom{p+q}{r}$. We get $\binom{n-i-1}{D-i} \binom{n-D-2}{i-1}$.

A similar argument shows that the second sum is $\binom{n-i-1}{D-i} \binom{n-D-2}{i-2}$. Adding these together, we get

$$\binom{n-i-1}{D-i} \left[\binom{n-D-2}{i-1} + \binom{n-D-2}{i-2} \right] = \binom{n-i-1}{D-i} \binom{n-D-1}{i-1} = f_{i,D,n}.$$

This concludes the proof of Theorem 1.2.

Acknowledgments. Much of this material originally appeared in my dissertation, [18], and I am grateful to my advisor Bernd Sturmfels for his guidance on this project. In addition, I have benefitted from conversations with many mathematicians; foremost among them Federico Ardila, Mike Develin, Michael Joswig, Frank Sottile, and Josephine Yu. I was supported by a research fellowship from the Clay Mathematics Institute for much of the writing of this paper.

BOUNDS FOR THE REAL NUMBER GRAPH LABELLINGS AND APPLICATION TO LABELLINGS OF THE TRIANGULAR LATTICE*

DANIEL KRÁL'[†] AND PETR ŠKODA[‡]

Abstract. We establish new lower and upper bounds for the real number graph labelling problem. As an application, we consider a problem of Griggs to determine the optimum spans of $L(p, q)$ -labellings of the infinite triangular plane lattice and find (using a computer) the optimum spans for all p and q .

Key words. real number graph labelling, channel assignment problem, graph labelling with distance conditions

AMS subject classification. 05C15

DOI. 10.1137/07068552X

1. Introduction. One of the important applications of graph colorings lies in the area of the channel assignment problem. The significance of results on the channel assignment problem has increased with development of mobile phone networks—large activity in this area yielding numerous results is documented in several recent surveys: an excellent survey [1] is focused on applications, a broad overview of the mathematical models can be found in [5], and some more specific results can be found in [19].

One of the well-established models for the channel assignment problem is the distance constrained graph labelling, introduced by Griggs and Yeh [12]. This notion can be treated in a more general setting of real number graph labellings and λ -graphs introduced in a series of papers of Griggs and Jin [8, 9, 10] and further developed in [2, 15]. The reader can check a recent survey [13] for more details.

Throughout this paper, we will use the concept of λ -graphs. A λ -graph G is a graph with k types of edges; two vertices of G could be joined by several edges of different types. Given the parameters $x_1, \dots, x_k$, a labelling f of vertices of G by nonnegative real numbers is called *proper* if the labels of every two vertices u and v joined by an edge of type i differ by at least x_i . The *span* of the labelling f is the supremum of the labels of all vertices (note at this point that it can always be assumed that the infimum of the used labels is equal to zero). The infimum of the spans of proper labellings of G is denoted by $\lambda(G; x_1, \dots, x_k)$. The values of $\lambda(G; x_1, \dots, x_k)$ interpreted as a k -parameter function form the λ -function of G .

Note that throughout the article we often assume implicitly that for every choice of parameters $x_1, \dots, x_k$ the value of $\lambda(G; x_1, \dots, x_k)$ is finite. This is equivalent to the statement that G viewed as an ordinary graph can be colored by a finite number of colors.

Let us now recall the notion of *distance constrained labellings*. For a graph G and nonnegative integers $p_1, \dots, p_k$, an $L(p_1, \dots, p_k)$ -labelling of G is a labelling of the vertices of G with nonnegative integers such that vertices at distance i , $1 \leq i \leq k$, receive labels that differ by at least p_i . This notion can be relaxed from integer labellings to real number graph labellings yielding a special class of λ -graphs: the corresponding λ -graph is the graph with the same vertex set where the vertices at distance i are connected by an edge of type x_i .

The most studied case both in the settings of λ -graphs and distance constrained labellings is $k = 2$. Since the so-called scaling property [8, 13] asserts that

$$\alpha\lambda(G; x_1, \dots, x_k) = \lambda(G; \alpha x_1, \dots, \alpha x_k)$$

for all $\alpha \geq 0$, the λ -function could be viewed as a one parameter function $\lambda(G; x, 1)$ if $k = 2$. In section 3, we prove several lemmas that allow us to derive (matching) upper and lower bounds on $\lambda(G; x, 1)$ from the knowledge of the values of $\lambda(G; x, 1)$ for specific values of x . To the best of our knowledge, these bounds are the first general bounds that can be used to deduce upper and lower bounds on $\lambda(G; x, 1)$ besides a direct application of the scaling property (see [8, 9] for an example of such an application). As an application of our bounds, we were able to find optimal $L(p, q)$ -labellings of the infinite triangular lattice, which is a known open problem for which we now give more details.

In practical applications, infinite graphs often provide a convenient model for the underlying topology of the network: instead of considering a finite graph, one can model a network as an infinite regular tiling of the plane. Hence, the infinite triangular lattice, the infinite square lattice, and the infinite hexagonal lattice naturally appear in such applications. The optimum spans of $L(p, q)$ -labellings of the infinite square and hexagonal lattices have been determined by Griggs and Jin [9]; cf. Calamoneri [4]. The case of the infinite triangular lattice seems to be more difficult.

The problem of determining the values of the λ -function for infinite triangular lattice Γ_Δ was posed by Griggs [11] in the 2000 International Math Contest in Modeling (MCM). Five teams proved new results for particular choices of parameters [3, 6, 7, 17, 18]. In particular, Goodwin, Johnston, and Marcus [7] determined the value of $\lambda(\Gamma_\Delta; x, 1)$ for $x \geq 4$. Jin and Yeh [14], Zhu and Shi [20], and Calamoneri [5] studied further the values of $\lambda(\Gamma_\Delta; x, 1)$ for $x \geq 1$. Finally, Griggs and Jin [9] managed to determine the values of $\lambda(\Gamma_\Delta; x, 1)$ for all $x \notin (1/3, 4/5)$.

As we have already said, we apply our bounds to complete the behavior of the function $\lambda(\Gamma_\Delta; x, 1)$ —the reader can find the whole function $\lambda(\Gamma_\Delta; x, 1)$ in Figure 1. Our argument is computer assisted, which is also the case of some earlier bounds on $\lambda(\Gamma_\Delta; x, 1)$; see, e.g., [9]. Of course, it would be interesting to determine the function $\lambda(\Gamma_\Delta; x, 1)$ avoiding the use of computers.

2. Preliminary results. In this section, we recall basic results on λ -functions mainly from [2, 8, 15].

The results of Griggs and Jin [8] and Král' [15] characterize the general behavior of the λ -function that could be summarized in the following theorem.

THEOREM 2.1. *Let G be a (possibly infinite) λ -graph with k types of edges. The λ -function of G is a continuous, nondecreasing, and piecewise linear function of $x_1, \dots, x_k$ on $[0, \infty)$ with finitely many linear parts.*

Additionally, the values of the λ -function are restricted to a subset $D(x_1, \dots, x_p)$

FIG. 1. The optimal value of $\lambda(\Gamma_\Delta; x, 1)$. Note that some parts of the graph are enlarged to reflect the behavior $\lambda(\Gamma_\Delta; x, 1)$ in more detail.

of real numbers defined as follows: $D(x_1, \dots, x_p)$ is a set of all linear combinations $\sum_{i=1}^p \alpha_i x_i$, where α_i are nonnegative integers. A theorem of Griggs and Jin [8] states that there exists a finite optimal labelling that uses only labels from set $D(x_1, \dots, x_p)$.

THEOREM 2.2 (Griggs and Jin [8]). *Let G be a λ -graph, possibly infinite, with k types of edges. For all nonnegative real numbers $x_1, \dots, x_k$, there is an optimal labelling f for the parameters $x_1, \dots, x_k$ such that $f(v) \in D(x_1, \dots, x_k)$ for each vertex v of G . In particular, $\lambda(G; x_1, \dots, x_k)$ belongs to the set $D(x_1, \dots, x_k)$.*

As we explained in section 1, the infinite coverings of the plane play a special role in the channel assignment problem. By the compactness principle, every λ -graph G contains a finite subgraph with the same λ -function.

THEOREM 2.3 (Král' [16]). *Every λ -graph G with k types of edges and a finite chromatic number contains a finite subgraph H such that $\lambda(G; x_1, \dots, x_k) = \lambda(H; x_1, \dots, x_k)$ for all $(x_1, \dots, x_k) \in [0, \infty)^k$.*

Note that it is easy to derive the existence of a subgraph H for a fixed k -tuple $(x_1, \dots, x_k)$ such that $\lambda(G; x_1, \dots, x_k) = \lambda(H; x_1, \dots, x_k)$, but this fact itself does not imply the existence of a universal subgraph H for all choices of $x_1, \dots, x_k$, which is claimed in Theorem 2.3.

Griggs and Jin [9] studied the function $\lambda(G; x, y)$ for G being a λ -graph obtained from the infinite triangular lattice Γ_Δ by connecting neighbors with edges of the first type and vertices at distance exactly two with edges of the second type. For the sake of simplicity, only the edges of the first type will be drawn in our figures. Griggs and Jin [9] determined $\lambda(\Gamma_\Delta; x, 1)$ for $x \in [0, 1/3] \cup [4/5, \infty)$.

THEOREM 2.4 (Griggs and Jin [9]). *For $k \geq 0$ the minimum span of any $L(x, 1)$ -labelling of triangular lattice is given by*

$$\lambda(\Gamma_{\Delta}; x, 1) \begin{cases} = 2x + 3 & \text{if } 0 \leq x \leq 1/3, \\ \in [2x + 3, 11x] & \text{if } 1/3 \leq x \leq 9/22, \\ \in [2x + 3, \frac{9}{2}] & \text{if } 9/22 \leq x \leq 3/7, \\ \in [9x, \frac{9}{2}] & \text{if } 3/7 \leq x \leq 1/2, \\ \in [\frac{9}{2}, \frac{16}{3}] & \text{if } 1/2 \leq x \leq 2/3, \\ \in [\frac{16}{3}, \frac{23}{4}] & \text{if } 2/3 \leq x \leq 3/4, \\ \in [\frac{23}{4}, 6] & \text{if } 3/4 \leq x \leq 4/5, \\ = 6 & \text{if } 4/5 \leq x \leq 1, \\ = 6x & \text{if } 1 \leq x \leq 4/3, \\ = 8 & \text{if } 4/3 \leq x \leq 2, \\ = 4x & \text{if } 2 \leq x \leq 11/4, \\ = 11 & \text{if } 11/4 \leq x \leq 3, \\ = 3x + 2 & \text{if } 3 \leq x \leq 4, \\ = 2x + 6 & \text{if } x \geq 4. \end{cases}$$

We complete the behavior of the function $\lambda(\Gamma_{\Delta}; x, 1)$ for $x \in [1/3, 4/5]$.

3. General bounds. In this section, we prove several bounds on $\lambda(G; x, 1)$ of the following type: given the values of $\lambda(G; x, 1)$ at two points x_1 and x_2 , we estimate the values of $\lambda(G; x, 1)$ in the whole interval (x_1, x_2) .

Since the λ -function $\lambda(G; x, 1)$ is a piecewise linear function of x , it is easy to complete the function inside the interval if there is only one acceptable linear function connecting the two known points of the function. One such case is described in the next lemma ($\mathbb{Z}^+$ stands for the set of nonnegative integers).

LEMMA 3.1. *Let G be a λ -graph and assume that $\lambda(G; x_i, 1) = \alpha + \beta x_i$ for $x_1, x_2 \in [0, \infty)$, $x_1 < x_2$, and $i = 1, 2$. If $\beta' \geq \beta$ whenever $\alpha + \beta x = \alpha' + \beta' x$ for $\alpha', \beta' \in \mathbb{Z}^+$ and $x \in [x_1, x_2]$, then $\lambda(G; x, 1) = \alpha + \beta x$ for all $x \in [x_1, x_2]$.*

Proof. By Theorem 2.1, the function $\lambda(G; x, 1)$ is a continuous piecewise linear function of x . It follows from Theorem 2.2 that the value of $\lambda(G; x, 1)$ is equal to an element of $D(x, 1)$.

Suppose that $\lambda(G; x, 1)$ is strictly greater than $\alpha + \beta x_0$ for some $x_0 \in (x_1, x_2)$. Since the function $\lambda(G; x, 1)$ is equal to $\alpha + \beta x$ for x_2 , there exists a linear function $\alpha' + \beta' x$ and $y_1, y_2 \in [x_1, x_2]$, $y_1 < y_2$, such that

- $\lambda(G; x, 1) = \alpha' + \beta' x$ for $x \in [y_1, y_2]$,
- $\alpha + \beta y_1 < \alpha' + \beta' y_1$, and
- $\alpha + \beta y_2 = \alpha' + \beta' y_2$.

Hence, $\beta'(y_2 - y_1)$ is strictly smaller than $\beta(y_2 - y_1)$, and thus $\beta' < \beta$, which is excluded by the assumptions of the lemma. We conclude that there is no $x_0 \in (x_1, x_2)$ such that $\lambda(G; x_0, 1) > \alpha + \beta x_0$.

An analogous argument yields that $\lambda(G; x_0, 1) < \alpha + \beta x_0$ for no $x_0 \in (x_1, x_2)$. We infer that $\lambda(G; x, 1)$ is equal to $\alpha + \beta x$ for all $x \in [x_1, x_2]$. $\square$

There is a variant of Lemma 3.1 where all the linear functions have a smaller slope than the segment connecting the two known points. The proof is analogous to that of Lemma 3.1.

LEMMA 3.2. *Let G be a λ -graph and assume that $\lambda(G; x_i, 1) = \alpha + \beta x_i$ for $x_1, x_2 \in [0, \infty)$, $x_1 < x_2$, and $i = 1, 2$. If $\beta' \leq \beta$ whenever $\alpha + \beta x = \alpha' + \beta' x$ for $\alpha', \beta' \in \mathbb{Z}^+$ and $x \in [x_1, x_2]$, then $\lambda(G; x, 1) = \alpha + \beta x$ for all $x \in [x_1, x_2]$.*

For every linear function $f(x) = \alpha + \beta x$, $\alpha, \beta \in \mathbb{Z}^+$, there exist intervals I where no linear function with a nonnegative integer offset and a nonnegative integer slope smaller than β is equal to $f(x)$ for any $x \in I$. We utilize this fact in our further considerations. For an interval $I \subseteq [0, \infty)$, $\xi(I)$ denotes the smallest positive integer q such that $p/q \in I$ for $p \in \mathbb{Z}$; i.e., $\xi(I)$ is the smallest denominator of a fraction with integral numerator and denominator contained in I .

PROPOSITION 3.3. *Let $I \subseteq [0, \infty)$ be an interval and α, β, α' , and β' nonnegative integers. If $\beta' < \beta < \xi(I)$, then $\alpha + \beta x \neq \alpha' + \beta' x$ for every $x \in I$.*

Proof. Assume the contrary; i.e., there exist nonnegative integers α, β, α' , and β' such that $\alpha + \beta x_0 = \alpha' + \beta' x_0$ for $x_0 \in I$ and $\beta' < \beta < \xi(I)$. A simple computation yields that

$$x_0 = -\frac{\alpha - \alpha'}{\beta - \beta'} = \frac{|\alpha - \alpha'|}{|\beta - \beta'|} \in I.$$

Hence, x_0 is a rational number with the denominator $|\beta - \beta'| \leq \beta$, which is impossible since $\beta < \xi(I)$. $\square$

Proposition 3.3 immediately yields the next simple lemma.

LEMMA 3.4. *Let $\lambda(G; x, 1) = \alpha + \beta x$ for $x = x_1, x_2 \in [0, \infty)$, $x_1 < x_2$. If $\xi([x_1, x_2]) > \beta$, then $\lambda(G; x, 1) = \alpha + \beta x$ for all $x \in [x_1, x_2]$.*

Proof. By Proposition 3.3, there is no linear function with nonnegative integer coefficients and a slope smaller than β that is equal to $\alpha + \beta x$ for $x \in [x_1, x_2]$. Therefore, the statement follows from the Lemma 3.1. $\square$

Lemma 3.1 handles the case when the interval contains no function with a smaller slope. The counterpart, Lemma 3.2, can be applied, too. It is enough to assume that the left endpoint of the interval is sufficiently large, as stated in the next lemma.

LEMMA 3.5. *Let $\lambda(G; x, 1) = \alpha + \beta x$ for $x = x_1, x_2 \in [0, \infty)$, $x_1 < x_2$. If x_1 is greater than $\frac{\alpha}{\xi([x_1, x_2])}$, then $\lambda(G; x, 1) = \alpha + \beta x$ for all $x \in [x_1, x_2]$.*

Proof. We want to apply Lemma 3.2. Assume that there is a linear function $\alpha' + \beta' x$, $\alpha', \beta' \in \mathbb{Z}^+$, that is equal to $\alpha + \beta x$ at $x_0 \in [x_1, x_2]$ and such that the slope β' is greater than β . A simple computation yields that

$$x_0 = -\frac{\alpha' - \alpha}{\beta' - \beta} = \frac{|\alpha' - \alpha|}{|\beta' - \beta|}.$$

Since $|\beta' - \beta| \geq \xi([x_1, x_2])$, it holds that

$$x_0 \leq \frac{|\alpha - \alpha'|}{\xi([x_1, x_2])} \leq \frac{\alpha}{\xi([x_1, x_2])} < x_1.$$

This implies that $x_0 < x_1$, contrary to the choice of x_0 . Therefore, all linear functions $\alpha' + \beta' x$ equal to $\alpha + \beta x$ for some $x \in [x_1, x_2]$ have a slope smaller than or equal to β . The statement of the lemma now follows from Lemma 3.2. $\square$

Consider an optimal labelling f of a λ -graph G for $x_1 = x_0$ and $x_2 = 1$. As we have explained in section 2, we can assume that $f(v) \in D(x_0, 1)$ for every vertex v . It is often the case that the labelling defined by considering the same integer combinations that appears in f is optimal for some $x_1 < x_0$ (and $x_2 = 1$). In the next lemma, we find an estimate of the interval to which the labelling f can be extended.

LEMMA 3.6. Let x_0 be a point equal to p_0/q_0 for some positive integers p_0 and q_0 that are relatively prime. If $\lambda(G; x_0, 1) = \alpha + \beta x_0$ and $\beta < q_0$, then

$$\lambda(G; x, 1) \leq \alpha + \beta x \quad \text{for all } x \in \left[\frac{\tilde{p}}{\tilde{q}}, x_0 \right],$$

where $\tilde{p}$ and $\tilde{q}$ are integers such that $\frac{\tilde{p}}{\tilde{q}} < \frac{p_0}{q_0}$, $1 \leq \tilde{q} \leq q_0$, and $\frac{\tilde{p}}{\tilde{q}}$ is maximal among all fractions formed by such a pair of integers $\tilde{p}$ and $\tilde{q}$.

Proof. Let $\tilde{x} = \tilde{p}/\tilde{q}$. By the choice of $\tilde{p}$ and $\tilde{q}$, $\xi((\tilde{x}, x_0])$ is equal to q_0 . By Proposition 3.3, there is no linear function with nonnegative integer coefficients and slope β' smaller than β that is equal to $\alpha + \beta x$ for $x \in (\tilde{x}, x_0]$.

Let x' be the smallest number such that $\lambda(G; x, 1) \leq \alpha + \beta x$ for all $x \in [x', x_0]$. Note that x' could be equal to x_0 . If $x' \leq \tilde{x}$, the statement of the lemma is true. Assume that $x' > \tilde{x}$. By the choice of x' , $\lambda(G; x, 1) = \alpha' + \beta' x$ for some integers α' and $\beta' < \beta$ (otherwise, the function $\lambda(G; x, 1)$ would not cross the function $f(x) = \alpha + \beta x$ at $x = x'$, and x' could be chosen smaller). Consequently, the choice of x' and the continuity of the function $\lambda(G; x, 1)$ imply that $\alpha + \beta x' = \alpha' + \beta' x'$, which is excluded by Proposition 3.3, as explained in the first paragraph. $\square$

In the rest of the paper, we will apply the bounds obtained in this section to complete the behavior of the function $\lambda(\Gamma_\Delta; x, 1)$.

4. Upper bounds for triangular lattice. The simplest way of obtaining an upper bound is a construction of a labelling. Let us start with introducing some additional notation related to the description of the lattice Γ_Δ . First, choose an arbitrary vertex of the lattice Γ_Δ to be the origin. The lattice contains two naturally defined axes (see Figure 2). This gives every vertex unique coordinates, as shown in the figure.

Our construction of labellings of Γ_Δ is similar to the technique of matrix labelling used in [9]. However, in addition, the patterns used to label the lattice can be “shifted” in the way described further.

A matrix M of size $n \times m$ specifies the labelling of nm vertices of Γ_Δ . We say that M is *placed* at coordinates $[a, b]$ if a vertex with coordinates $[a + i, b + j]$, $i \in \{0, \dots, m - 1\}$, $j \in \{0, \dots, n - 1\}$, is labelled with $M_{n-j, i+1}$. The labelling is produced with “horizontal offset” o if the matrix M is placed at all coordinates $[c \cdot m, d \cdot n + c \cdot o]$ for all integers c and d . The labelling constructed could also be created by the original matrix labelling technique, but our method allows using smaller matrices to describe the labelling.

FIG. 2. The infinite triangular lattice Γ_Δ with an origin and two axes.

FIG. 3. A part of the labelling of the infinite triangular lattice.

The next lemma uses shifted matrix labelling to construct proper labellings of Γ_Δ for $x \in [3/8, 2/5]$.

LEMMA 4.1. *The value of $\lambda(\Gamma_\Delta; x, 1)$ for $x \in [3/8, 2/5]$ is at most $3 + 3x$.*

Proof. The labelling of the infinite triangular lattice Γ_Δ will be obtained through the matrix labelling technique with horizontal offsets.

The matrix M we use is the following:

$$\begin{bmatrix} 2 & 0 & x & 2+3x \\ 3x & 3+2x & 3+3x & 2+x \\ x & 3 & 3+x & 4x \\ 3+3x & 1+3x & 1+4x & 2x \\ 2+3x & 1+x & 1+2x & 0 \\ 2+x & x & 1 & 3+2x \\ 4x & 3+3x & 0 & 2+2x \\ 2x & 3+x & 3+2x & 2 \\ 0 & 1+4x & 3 & 3x \\ 3+2x & 1+2x & 1+3x & x \\ 2+2x & 1 & 1+x & 3+3x \end{bmatrix}.$$

The horizontal offset of the matrix labelling is 9 (see Figure 3 for a part of the labelling of Γ_Δ obtained). The reader is kindly asked to verify that the labelling produced assigns neighboring vertices labels that differ by at least x and those at distance two labels that differ by at least one. Since the span of the labelling of Γ_Δ constructed is equal to $3 + 3x$, the statement of the lemma follows. $\square$

5. Lower bounds. Our lower bound proofs are partly computer assisted. By the compactness principle, if Γ_Δ does not have a labelling with a certain span, then there exists a finite subgraph of Γ_Δ that does not have a labelling of that span either. We have independently prepared two programs that test all labellings of finite parts of the

triangular lattice Γ_Δ by brute force to reveal specific values of x ; one of the programs can be downloaded at <http://kam.mff.cuni.cz/~kral/lattice.c>. Both programs use the same coordinate system as we define in the proof of Lemma 4.1. Finally, for an integer n , $\Gamma_{\Delta,n}$ denotes the subgraph of Γ_Δ induced by the vertices with coordinates $[x, y]$ from set $\{0 \leq x \leq n, 0 \leq y \leq n\}$.

In order to decrease the running time, our program does not try to assign all values of the set $D(x, 1)$ to the points of the lattice, but it assigns only labels contained in a set $\tilde{D}_m(x) \subset D(x, 1)$. The set $\tilde{D}_m(x)$ is defined recursively. We start with $\tilde{D}_m^0(x)$, which is equal to the set of labels contained in $D(x, 1)$ smaller than or equal to m . If $\tilde{D}_m^i(x)$ contains two numbers a and b , $a < b$, such that for every label $c \in \tilde{D}_m^i(x)$ it holds that

- if $c \geq a + x$, then $c \geq b + x$, and
- if $c \geq a + 1$, then $c \geq b + 1$,

then we set $\tilde{D}_m^{i+1}(x) = \tilde{D}_m^i(x) \setminus \{a\}$. We proceed in this way while $\tilde{D}_m^i(x)$ contains a pair a and b of such labels. The final set $\tilde{D}_m^i(x)$ is denoted by $\tilde{D}_m(x)$.

The input of our programs is the size of the lattice n , the value of x , and the maximal label m . The programs return whether $\Gamma_{\Delta,n}$ can be labelled by $\tilde{D}_m(x)$. However, it remains to verify that restricting the set of possible labels to $\tilde{D}_m(x)$ does not affect the correctness of our algorithm. We do so in the next lemma.

LEMMA 5.1. *Let G be a λ -graph. If G has a proper labelling for $x_1 = x$ and $x_2 = 1$ of span at most m , then it has a proper labelling of span at most m that uses only the labels contained in the set $\tilde{D}_m(x)$.*

Proof. Assume that G has a proper labelling of span at most m . By Theorem 2.2, there also exists a proper labelling f that uses only the labels contained in the set $D(x, 1)$.

We now prove by induction on i that for every $i \geq 0$ there exists a proper labelling f_i that uses only labels from $\tilde{D}_m^i(x)$. Consider the pair of numbers a and b such that a was removed from $\tilde{D}_m^i(x)$ at the i th step. We claim that changing the labels of all the vertices labelled by f_i with a to b yields a proper labelling of G . Let f_{i+1} be the resulting labelling. If f_{i+1} is not proper, then there exist a vertex v such that $f_i(v) = a$ (and thus $f_{i+1}(v) = b$) and a vertex u adjacent to v such that the labels $f_{i+1}(v)$ and $f_{i+1}(u)$ are too close. Let $c = f_i(u) = f_{i+1}(u)$.

If $c < a$, then the difference between the labels of u and v increases after relabelling. Hence, we can assume $c > a$ since $c \neq a$ by the constraints on the labelling. If u and v are joined by an x_1 -edge, then $c \geq a + x$ (recall that $x_1 = x$). Consequently, by the choice of a and b , $c \geq b + x$. An analogous argument applies when u and v are joined by an x_2 -edge. Hence, we have inferred from the fact that f_i is a proper labelling of G that f_{i+1} is also a proper labelling of G .

We eventually conclude that there is a proper labelling of G that uses only the labels contained in $\tilde{D}_m(x)$. $\square$

The following four lemmas have been established using our computer-assisted technique.

LEMMA 5.2. *The optimal span $\lambda(\Gamma_\Delta; x, 1)$ of the infinite triangular lattice Γ_Δ is at least $4 + x$ for $x = 3/7$.*

Proof. We have verified by a computer that $\lambda(\Gamma_{\Delta,9}; x, 1) > 3 + 3x$ for $x = 3/7$; i.e., $\Gamma_{\Delta,9}$ has no labellings of span $30/7$ for $x = 3/7$. Therefore, $\lambda(\Gamma_\Delta; 3/7, 1) > 30/7$. By Theorem 2.2, the value of $\lambda(\Gamma_\Delta; 3/7, 1)$ is contained in the set $D(3/7, 1)$. The smallest element of $D(3/7, 1)$ greater than $30/7$ is $4 + 3/7$. This yields the statement of the lemma. $\square$

LEMMA 5.3. *The optimal span $\lambda(\Gamma_\Delta; x, 1)$ of the infinite triangular lattice Γ_Δ is at least $3 + 3x$ for $x = 3/8$ and $x = 2/5$.*

Proof. We proceed similarly as in Lemma 5.2. Again, we have verified using a computer that $\lambda(\Gamma_{\Delta,10}; x, 1) > 4$ for $x = 3/8$. Hence, $\lambda(\Gamma_\Delta; 3/8, 1) > 4$. Since the optimal span is a nondecreasing function of x , it holds that $\lambda(\Gamma_\Delta; 2/5, 1) > 4$. Again, by Theorem 2.2, $\lambda(\Gamma_\Delta; 3/8, 1) \in D(3/8, 1)$ and $\lambda(\Gamma_\Delta; 2/5, 1) \in D(2/5, 1)$. The smallest elements greater than 4 are $3 + 3 \cdot 3/8$ for $x = 3/8$ and $3 + 3 \cdot 2/5$ for $x = 2/5$. We conclude that $\lambda(\Gamma_\Delta; x, 1) \geq 3 + 3x$ for $x = 3/8$ and $x = 2/5$. $\square$

LEMMA 5.4. *The optimal span $\lambda(\Gamma_\Delta; x, 1)$ of the infinite triangular lattice Γ_Δ is at least $4 + 2x$ for $x = 4/7$ and $x = 3/5$.*

Proof. Using a computer, we have found out that $\lambda(\Gamma_{\Delta,13}; x, 1) > 5$ for $x = 4/7$. Therefore, $\lambda(\Gamma_\Delta; 4/7, 1) > 5$. It follows from the fact that the optimal span is a nondecreasing function that also satisfies $\lambda(\Gamma_\Delta; 3/5, 1) > 5$. By Theorem 2.2, the value of $\lambda(\Gamma_\Delta; 4/7, 1)$ is contained in the set $D(4/7, 1)$. The smallest element greater than 5 is $4 + 2x$ for both $x = 4/7$ and $x = 3/5$. The assertion of the lemma follows. $\square$

LEMMA 5.5. *The optimal span $\lambda(\Gamma_\Delta; x, 1)$ of the infinite triangular lattice Γ_Δ is at least $5 + x$ for $x = 5/7$.*

Proof. Again, we have verified that $\lambda(\Gamma_{\Delta,15}; x, 1) > 2 + 5x$ for $x = 5/7$. Therefore, the value of $\lambda(\Gamma_\Delta; 5/7, 1)$ is greater than $5 + 4/7$. By Theorem 2.2, the value of $\lambda(\Gamma_\Delta; 5/7, 1)$ is contained in $D(5/7, 1)$. The smallest element of $D(5/7, 1)$ greater than $5 + 4/7$ is $5 + 5/7 = 5 + x$, which yields the lemma. $\square$

6. Optimal labellings of triangular lattice. In this section we prove our main theorem, filling in the values of $\lambda(\Gamma_\Delta; x, 1)$ for $x \in [1/3, 4/5]$.

THEOREM 6.1. *The following values are the spans of optimal labelling of the infinite triangular lattice Γ_Δ :*

$$\lambda(\Gamma_\Delta; x, 1) = \begin{cases} 3 + 2x & \text{if } 0 \leq x \leq 1/3, \\ 11x & \text{if } 1/3 \leq x \leq 3/8, \\ 3 + 3x & \text{if } 3/8 \leq x \leq 2/5, \\ 1 + 8x & \text{if } 2/5 \leq x \leq 3/7, \\ 4 + x & \text{if } 3/7 \leq x \leq 1/2, \\ 9x & \text{if } 1/2 \leq x \leq 4/7, \\ 4 + 2x & \text{if } 4/7 \leq x \leq 2/3, \\ 8x & \text{if } 2/3 \leq x \leq 5/7, \\ 5 + x & \text{if } 5/7 \leq x \leq 3/4, \\ 2 + 5x & \text{if } 3/4 \leq x \leq 4/5, \\ 6 & \text{if } 4/5 \leq x \leq 1, \\ 6x & \text{if } 1 \leq x \leq 4/3, \\ 8 & \text{if } 4/3 \leq x \leq 2, \\ 4x & \text{if } 2 \leq x \leq 11/4, \\ 11 & \text{if } 11/4 \leq x \leq 3, \\ 3x + 2 & \text{if } 3 \leq x \leq 4, \\ 2x + 6 & \text{if } x \geq 4. \end{cases}$$

Proof. The values of $\lambda(\Gamma_\Delta; x, 1)$ for $x \in [0, 1/3] \cup [4/5, \infty)$ were determined by Griggs and Jin [9] (see Theorem 2.4). For $x \in [1/3, 4/5]$, we split the proof into

several parts dealing with subintervals of $[1/3, 4/5]$ separately. We do not consider the subintervals of $[1/3, 4/5]$ from left to right since some of the values we compute are used in our further considerations for neighboring subintervals.

- The interval $[3/8, 2/5]$.
It follows from Lemmas 5.3 and 4.1 that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $3 + 3x$ for $x = 3/8$ and $x = 2/5$. Since $\xi([3/8, 2/5]) = 5$, Lemma 3.4 implies that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $3 + 3x$ for all $x \in [3/8, 2/5]$.
- The interval $[1/3, 3/8]$.
By Theorem 2.4, the value of $\lambda(\Gamma_\Delta; 1/3, 1)$ is equal to $3 + 2/3$. Therefore, $\lambda(\Gamma_\Delta; x, 1)$ is equal to $11x$ for $x = 1/3$ and $x = 3/8$. Since $1/3$ is greater than 0, Lemma 3.5 asserts the value of $\lambda(\Gamma_\Delta; x, 1)$ being equal to $11x$ for all $x \in [1/3, 3/8]$.
- The interval $[3/7, 1/2]$.
By Theorem 2.4, $\lambda(\Gamma_\Delta; x, 1) = 4 + x$ for $x = 1/2$. It follows from Lemma 3.6 that the value of $\lambda(\Gamma_\Delta; x, 1)$ is less than or equal to $4 + x$ for $x \in [0, 1/2]$. On the other hand, by Lemma 5.2, the value of $\lambda(\Gamma_\Delta; x, 1)$ is greater than or equal to $4 + x$ for $x = 3/7$. Therefore, $\lambda(\Gamma_\Delta; 3/7, 1) = 4 + 3/7$. Since $\xi([3/7, 1/2]) = 2$, Lemma 3.4 yields that $\lambda(\Gamma_\Delta; x, 1) = 4 + x$ for all $x \in [3/7, 1/2]$.
- The interval $[2/5, 3/7]$.
We have shown above that $\lambda(\Gamma_\Delta; x, 1)$ is equal to $1 + 8x$ for $x = 2/5$ and $x = 3/7$. Since $\xi([2/5, 3/7]) = 5$ and $2/5$ is greater than $1/5$, Lemma 3.5 implies that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $1 + 8x$ for all $x \in [2/5, 3/7]$.
- The interval $[4/7, 2/3]$.
By Theorem 2.4, the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $4 + 2x$ for $x = 2/3$. We infer from Lemma 3.6 that the value of $\lambda(\Gamma_\Delta; x, 1)$ is less than or equal to $4 + 2x$ for $x \in [1/2, 2/3]$. On the other hand, by Lemma 5.4, the value of $\lambda(\Gamma_\Delta; x, 1)$ is greater than or equal to $4 + 2x$ for $x = 4/7$. Therefore, $\lambda(\Gamma_\Delta; 4/7, 1)$ is equal to $4 + 2 \cdot 4/7$. Since $\xi([4/7, 2/3]) = 3$, we derive from Lemma 3.4 that $\lambda(\Gamma_\Delta; x, 1) = 4 + 2x$ for all $x \in [4/7, 2/3]$.
- The interval $[1/2, 4/7]$.
We have established that $\lambda(\Gamma_\Delta; x, 1) = 9x$ for $x = 1/2$ and $x = 4/7$. Since $1/2$ is greater than 0, Lemma 3.5 asserts that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $9x$ for all $x \in [1/2, 4/7]$.
- The interval $[5/7, 3/4]$.
By Theorem 2.4, $\lambda(\Gamma_\Delta; x, 1)$ is equal to $5 + x$ for $x = 3/4$. We infer from Lemma 3.6 that $\lambda(\Gamma_\Delta; x, 1)$ is less than or equal to $5 + x$ for $x \in [2/3, 3/4]$. On the other hand, by Lemma 5.5, the value of $\lambda(\Gamma_\Delta; x, 1)$ is greater than or equal to $5 + x$ for $x = 5/7$. Therefore, $\lambda(\Gamma_\Delta; 5/7, 1)$ equals $5 + 5/7$. Since $\xi([5/7, 3/4]) = 4$, Lemma 3.4 implies that $\lambda(\Gamma_\Delta; x, 1)$ is equal to $5 + x$ for all $x \in [5/7, 3/4]$.
- The interval $[2/3, 5/7]$.
We have shown that $\lambda(\Gamma_\Delta; x, 1)$ is equal to $8x$ for $x = 2/3$ and $x = 5/7$. Since $2/3$ is greater than 0, Lemma 3.5 yields that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $8x$ for all $x \in [2/3, 5/7]$.
- The interval $[3/4, 4/5]$.
By Theorem 2.4, $\lambda(\Gamma_\Delta; x, 1)$ is equal to $2 + 5x$ for $x = 3/4$ and $x = 4/5$. Since $\xi([3/4, 4/5]) = 4$ and $3/4$ is greater than $2/4$, we infer from Lemma 3.5 that the value of $\lambda(\Gamma_\Delta; x, 1)$ is equal to $2 + 5x$ for all $x \in [3/4, 4/5]$.

Since we have analyzed all subintervals of $[1/3, 4/5]$, the proof of the theorem is finished. $\square$

ORTHOGONAL DRAWINGS OF SERIES-PARALLEL GRAPHS WITH MINIMUM BENDS*

XIAO ZHOU[†] AND TAKAO NISHIZEKI[†]

Abstract. In an orthogonal drawing of a planar graph G , each vertex is drawn as a point, each edge is drawn as a sequence of alternate horizontal and vertical line segments, and any two edges do not cross except at their common end. A bend is a point where an edge changes its direction. A drawing of G is called an optimal orthogonal drawing if the number of bends is minimum among all orthogonal drawings of G . In this paper we give an algorithm to find an optimal orthogonal drawing of any given series-parallel graph of the maximum degree at most three. Our algorithm takes linear time, while the previously known best algorithm takes cubic time. Furthermore, our algorithm is much simpler than the previous one. We also obtain a best possible upper bound on the number of bends in an optimal drawing.

Key words. orthogonal drawing, bend, series-parallel graph, planar graph

1. Introduction. Automatic graph drawings have numerous applications in VLSI circuit layouts, networks, computer architecture, circuit schematics, etc. [3, 11]. Many graph drawing styles have been introduced [1, 3, 9, 11, 15, 17]. Among them, an “orthogonal drawing” has attracted much attention due to its various applications, especially in circuit schematics, entity relationship diagrams, data flow diagrams, etc. [14, 16, 19, 20]. An *orthogonal drawing* of a planar graph G is a drawing of G such that each vertex is mapped to a point, each edge is drawn as a sequence of alternate horizontal and vertical line segments, and any two edges do not cross except at their common end. A point where an edge changes its direction in a drawing is called a *bend* of the drawing. Figure 1.1(a) depicts an orthogonal drawing of the planar graph in Figure 1.1(b); the drawing has exactly one bend on the edge joining vertices g and t . If a planar graph G has a vertex of degree five or more, then G has no orthogonal drawing. On the other hand, if G has no vertex of degree five or more, that is, the maximum degree Δ of G is at most four, then G has an orthogonal drawing, but may need bends. If a planar graph represents a VLSI routing, then one may be interested in an orthogonal drawing such that the number of bends is as small as possible, because bends increase the manufacturing cost of a VLSI chip. An orthogonal drawing of a planar graph G is called an *optimal* orthogonal drawing if it has the minimum number of bends among all possible orthogonal drawings of G .

The problem of finding an optimal orthogonal drawing is one of the most famous problems in the graph drawing literature [3, 11] and has been studied both in the fixed embedding setting [7, 14, 16, 18, 20] and in the variable embedding setting [5, 6, 8, 12, 13]. A planar graph with a fixed embedding is called a *plane graph*. As a result in the fixed embedding, Tamassia [20] presented an algorithm to find an optimal orthogonal drawing of a plane graph G in time $O(n^2 \log n)$, where n is the

FIG. 1.1. (a) An optimal orthogonal drawing with one bend, (b), (c) two embeddings of the same planar graph, and (d) an orthogonal drawing with three bends.

number of vertices in G ; he reduced the optimal drawing problem to a min-cost flow problem. Then Garg and Tamassia improved the complexity to $O(n^{7/4}\sqrt{\log n})$ [7]. As a result in the variable embedding setting, Garg and Tamassia showed that the problem is NP-complete for planar graphs of $\Delta \leq 4$ [8]. However, Di Battista, Liotta, and Vargiu [5] showed that the problem can be solved in polynomial time for a planar graph G of $\Delta \leq 3$. Their algorithm finds an optimal orthogonal drawing among all possible plane embeddings of G . They use the properties of “spirality,” min-cost flow techniques, and a data structure, call a SPQ*R tree that implicitly represents all of the plane embeddings of G . The algorithm is complicated and takes time $O(n^5 \log n)$ for a planar graph of $\Delta \leq 3$. Using the algorithm, one can find more efficiently an optimal orthogonal drawing for a biconnected series-parallel simple graph; it takes time $O(n^4)$ if $\Delta \leq 4$ [5] and takes time $O(n^3)$ if $\Delta \leq 3$ [4, 5]. Note that every series-parallel graph is planar. Series-parallel graphs arise in a variety of problems such as scheduling, electrical networks, data-flow analysis, database logic programs, and circuit layout [21]. On the other hand, Garg and Liotta give an algorithm to find a nearly optimal orthogonal drawing for a biconnected planar graph of $\Delta \leq 3$ [6]. Their algorithm finds a drawing having at most three more bends than the optimal one in time $O(n^2)$. The complexities $O(n^5 \log n)$, $O(n^4)$, and $O(n^3)$ above for an exact algorithm in the variable embedding setting are very high, and it is expected to obtain an efficient algorithm for a particular class of planar graphs of $\Delta \leq 3$ [2].

In this paper we deal with the class of series-parallel (multi)graphs of $\Delta \leq 3$ and give a simple linear algorithm to find an optimal orthogonal drawing in the variable embedding setting. The graph G in Figure 1.1 is series-parallel and has various plane embeddings; two of them are illustrated in Figures 1.1(b) and (c); there is no plane embedding having an orthogonal drawing with no bend; however, the embedding in Figure 1.1(b) has an orthogonal drawing with one bend, as illustrated in Figure 1.1(a), and hence the drawing is optimal; the embedding in Figure 1.1(c) needs three bends, as illustrated in Figure 1.1(d); given G , our algorithm finds an optimal drawing in Figure 1.1(a). Our algorithm works well even if G has multiple edges or is not biconnected and is much simpler and faster than the algorithms for biconnected series-parallel simple graphs in [4, 5]; we use neither the min-cost flow technique nor the SPQ*R tree, but uses some structural features of series-parallel graphs, which have not been exploited in [21]. We furthermore obtain a best possible upper bound on the minimum number of bends. An early version of the paper has been presented at [22].

The rest of the paper is organized as follows. In section 2 we present some definitions and our main idea. In section 3 we present an algorithm and an upper

bound for biconnected series-parallel graphs. In section 4 we present an algorithm and an upper bound for nonbiconnected series-parallel graphs. Finally section 5 is a conclusion.

2. Preliminaries. In this section we present some definitions and our main idea.

Let $G = (V, E)$ be an undirected graph, with vertex set V and edge set E . We denote the number of vertices in G by $n(G)$ or simply by n . For a vertex $v \in V$, we denote by $G - v$ the graph obtained from G by deleting v . An edge joining vertices u and v is denoted by uv . We denote by $G - uv$ the graph obtained from G by deleting uv . We denote the degree of a vertex v in G by $d(v, G)$ or simply by $d(v)$. We denote the maximum degree of G by $\Delta(G)$ or simply by Δ . A connected graph is *biconnected* if there is no vertex whose removal results in a disconnected graph or a single-vertex graph K_1 . A *plane graph* is a fixed embedding of a planar graph.

Let G be a planar graph with $\Delta \leq 3$. We denote by $bend(G)$ the number of bends of an optimal orthogonal drawing of G in the variable embedding setting. (Thus $bend(G) = 1$ for the graph G in Figure 1.1.) Let D be an orthogonal drawing of G . The number of bends in D is denoted by $bend(D)$. Of course, $bend(G) \leq bend(D)$. Let $G(D)$ be a plane graph obtained from a drawing D by replacing each bend in D with a new vertex. Figures 2.1(a) and (b) depict $G(D)$ for the drawings D in Figures 1.1(a) and (d), respectively. An angle formed by two edges e and e' incident to a vertex v in $G(D)$ is called an *angle of vertex v* if e and e' appear consecutively around v . An angle of a vertex in $G(D)$ is called an *angle of the plane graph $G(D)$* . In an orthogonal drawing, every angle is $\pi/2$, π , $3\pi/2$, or 2π . Consider a labeling l , which assigns a label 1, 0, -1 , or -2 to every angle of $G(D)$. Labels 1, 0, -1 , and -2 correspond to angles $\pi/2$, π , $3\pi/2$, and 2π , respectively. We call l a *regular labeling* of $G(D)$ if l satisfies the following three conditions (a)–(c) [11, 20]:

- (a) for each vertex v of $G(D)$,
 - (a-1) if $d(v) = 1$, then the label of the angle of v is -2 ;
 - (a-2) if $d(v) = 2$, then the labels of the two angles of v total to 0; and
 - (a-2) if $d(v) = 3$, then the labels of the three angles of v total to 2;
- (b) the sum of the labels of each inner face is 4; and
- (c) the sum of the labels of the outer face is -4 .

Figures 2.1(a) and (b) illustrate regular labelings for the orthogonal drawings in Figures 1.1(a) and (d), respectively. If D is an orthogonal drawing of G , then clearly $G(D)$ has a regular labeling. Conversely, every regular labeling of $G(D)$ corresponds to an orthogonal drawing of G [20]. An orthogonal (geometric) drawing of G can be obtained from a regular labeling of $G(D)$ in linear time, that is, in time $O(n(G) + bend(D))$ [11, 20]. Therefore, from now on, we call a regular labeling of $G(D)$ an *orthogonal*

FIG. 2.1. Regular labelings of $G(D)$ corresponding to the drawings D in Figures 1.1(a) and (d), respectively.

FIG. 2.2. (a) K_2 , (b) series, and (c) parallel connections.

drawing of a planar graph G or simply, a drawing of G , and obtain a regular labeling of G in place of an orthogonal (geometric) drawing of G .

For a drawing D of a planar graph G and for a subgraph G' of G , we denote by $D|G'$ the drawing of G' in D . Clearly

$$(2.1) \quad \text{bend}(G') \leq \text{bend}(D|G') \leq \text{bend}(D).$$

Let $\overline{G'}$ be the complement of G' , that is, the subgraph of G induced by all of the edges that are not contained in G' . Then

$$(2.2) \quad \text{bend}(D) = \text{bend}(D|G') + \text{bend}(D|\overline{G'}).$$

A series-parallel graph (with terminals s and t) is recursively defined as follows:

- (a) A graph G of a single edge is a series-parallel graph. The ends s and t of the edge are called the *terminals* of G . (See Figure 2.2(a).)
- (b) Let G_1 be a series-parallel graph with terminals s_1 and t_1 , and let G_2 be a series-parallel graph with terminals s_2 and t_2 .
 - (i) A graph G obtained from G_1 and G_2 by indentifying vertex t_1 with vertex s_2 is a series-parallel graph, whose terminals are $s = s_1$ and $t = t_2$. Such a connection is called a *series connection*. (See Figure 2.2(b).)
 - (ii) A graph G obtained from G_1 and G_2 by indentifying s_1 with s_2 and t_1 with t_2 is a series-parallel graph, whose terminals are $s = s_1 = s_2$ and $t = t_1 = t_2$. Such a connection is called a *parallel connection*. (See Figure 2.2(c).)

For example, the graph in Figure 1.1 is series-parallel.

Throughout the paper we assume that the maximum degree of a given series-parallel graph G is at most three, that is, $\Delta \leq 3$. We may assume without loss of generality that G is a simple graph, that is, G has no multiple edges, as follows. If a series-parallel multigraph G consists of exactly three multiple edges, then G has an optimal drawing of four bends; otherwise, insert a dummy vertex of degree two into an edge of each pair of multiple edges in G , and let G' be the resulting series-parallel simple graph, then an optimal drawing of the multigraph G can be immediately obtained from an optimal drawing of the simple graph G' by replacing each dummy vertex with a bend.

A drawing D of a series-parallel graph G is *outer* if the two terminals s and t of G are drawn on the outer face of D . A drawing D is called an *optimal outer drawing* of G if D is outer and $\text{bend}(D) = \text{bend}(G)$. The graph in Figure 1.1 has an optimal outer drawing, as illustrated in Figure 1.1(a). On the other hand, the graph in Figure 2.3(a) has no optimal outer drawing for the specified terminals s and t ; the no-bend drawing

FIG. 2.3. (a) A biconnected series-parallel graph G , (b) an optimal drawing D , and (c) an outer drawing D^0 .

FIG. 2.4. (a)–(c) I-, L-, and U-shaped drawings, and (d)–(f) their schematic representations.

D in Figure 2.3(b) is optimal but is not outer, because s is not on the outer face; and the drawing D^0 with one bend in Figure 2.3(c) is outer but is not optimal.

Our main idea is to notice that a series-parallel graph G has an optimal outer drawing if G is “2-legged.” We say that G is 2-legged if $n(G) \geq 3$ and $d(s) = d(t) = 1$ for the terminals s and t of G . The edge incident to s or t is called a *leg* of G , and the neighbor of s or t is called a *leg-vertex*. For example, the series-parallel graphs in Figures 2.4(a)–(c) are 2-legged.

We will show in section 3 that every 2-legged series-parallel graph G has an optimal outer drawing, and the drawing has one of the three shapes: “I-shape,” “L-shape,” and “U-shape,” defined as follows. An outer drawing D of G is *I-shaped* if D intersects neither the north side of terminal s nor the south side of terminal t after rotating the drawing and renaming the terminals if necessary, as illustrated in Figure 2.4(a). D is *L-shaped* if D intersects neither the north side of s nor the east side of t after rotating the drawing and renaming the terminals if necessary, as illustrated in Figure 2.4(b). D is *U-shaped* if D does not intersect the north sides of s and t after rotating the drawing and renaming the terminals if necessary, as illustrated in Figure 2.4(c). In Figures 2.4(a)–(c) each side is shaded. The north side and the south side of a terminal contain the horizontal line passing through the terminal, while the east side of a terminal contains the vertical line passing through the terminal. The schematic representations of I-, L-, and U-shaped drawings are depicted in Figures 2.4(d), (e), and (f), respectively. D is called an *optimal X-shaped drawing*, $X = \text{I, L and U}$, if D is X-shaped and $\text{bend}(D) = \text{bend}(G)$.

More precisely, we will show in section 3 that every 2-legged series-parallel graph G , with $n(G) \geq 3$ has both an optimal I-shaped drawing and an optimal L-shaped drawing and that G has an optimal U-shaped drawing, too, unless G is a “diamond graph,” defined as follows. A *diamond graph* is either a graph in Figure 2.5(a) or obtained from two diamond graphs G' and G'' by connecting them in parallel and adding two legs, as illustrated in Figures 2.5(b) and (c).

For example, the 2-legged series-parallel graph in Figure 2.6(a) is a diamond graph and has both an optimal (no-bend) I-shaped drawing and an optimal (no-bend) L-

FIG. 2.5. Recursive definition of a diamond graph.

FIG. 2.6. (a) Diamond graph, (b) I-shaped drawing, (c) L-shaped drawing, (d) nondiamond graph, and (e) U-shaped drawing.

shaped drawing, as illustrated in Figures 2.6(b) and (c), but does not have an optimal (no-bend) U-shaped drawing. On the other hand, the 2-legged series-parallel graph in Figure 2.6(d) is obtained from the diamond graph in Figure 2.6(a) simply by inserting a new vertex of degree two in an edge and is not a diamond graph anymore. It has an optimal (no-bend) U-shaped drawing, too, as illustrated in Figure 2.6(e). Thus the diamond graph in Figure 2.6(a) has a U-shaped drawing with one bend.

3. Optimal drawing of biconnected series-parallel graph. In this section we give a linear algorithm to find an optimal drawing of a biconnected series-parallel graph G of $\Delta \leq 3$. We first give an algorithm for 2-legged series-parallel graphs in subsection 3.1. Using the algorithm, we then give an algorithm for biconnected series-parallel graphs in subsection 3.2.

3.1. 2-legged series-parallel graph. We first have the following lemma on a diamond graph.

LEMMA 3.1. *If G is a diamond graph, then*

- G has both a no-bend I-shaped drawing D_I and a no-bend L-shaped drawing D_L ;*
- D_I and D_L can be found in linear time; and*
- every no-bend drawing of G is either I-shaped or L-shaped, and hence G does not have a no-bend U-shaped drawing.*

FIG. 3.1. Illustration of the proof of Lemma 3.1.

Proof. We prove the lemma by induction on the number $n(G)$ of vertices of G . Since G is a diamond graph, G has at least three vertices. If $n(G) = 3$, as illustrated in Figure 2.5(a), then (a), (b), and (c) trivially hold true. One may thus assume that $n(G) \geq 4$, and inductively assume that (a), (b), and (c) hold for every diamond graph of at most $n(G) - 1$ vertices.

We first prove that (a) holds for G . The definition of a diamond graph implies that one can obtain two diamond subgraphs G' and G'' from G by deleting the two terminals of G and splitting each of the two leg-vertices into two vertices, as illustrated in Figures 2.5(b) and (c). By the inductive hypothesis, (a) holds for G' , and hence G' has a no-bend L-shaped drawing D'_L . Similarly, G'' has a no-bend L-shaped drawing D''_L . Combining a flipped drawing of D'_L with the drawing D''_L and drawing the two legs appropriately, one can construct a no-bend I-shaped drawing D_I and a no-bend L-shaped drawing D_L of G , as illustrated in Figures 3.1(a) and (b), respectively. Thus (a) holds true.

One can obtain (regular labelings of) D_I and D_L from (those of) D'_L and D''_L in constant time by deciding the labels of the angles of the terminals and leg vertices of G . Thus (b) holds true for G .

We now prove that (c) holds for G . Let D^* be an arbitrary no-bend drawing of G . Then both the drawing $D^*[G']$ of G' in D^* and the drawing $D^*[G'']$ of G'' in D^* are no-bend drawings. By the inductive hypothesis, each of $D^*[G']$ and $D^*[G'']$ is either I-shaped or L-shaped. Since D^* is a no-bend drawing, both $D^*[G']$ and $D^*[G'']$ must be L-shaped and D^* must be either I-shaped or L-shaped. Thus (c) holds true. $\square$

The proof of Lemma 3.1 immediately yields a linear algorithm **Diamond**(G, D_I, D_L), which recursively finds both a no-bend I-shaped drawing D_I and a no-bend L-shaped drawing D_L of a given diamond graph G .

The following lemma holds for a 2-legged series-parallel graph G which is not a diamond graph.

LEMMA 3.2. *The following (a), (b), and (c) hold for a 2-legged series-parallel graph G , with $n(G) \geq 3$ unless G is a diamond graph:*

- (a) G has three optimal I-, L-, and U-shaped drawings D_I, D_L , and D_U ;
- (b) D_I, D_L , and D_U can be found in linear time; and
- (c) $\text{bend}(G) \leq (n(G) - 2)/3$.

Proof. We prove the lemma by induction on the number $n(G)$ of vertices of G . Assume that G is a 2-legged series-parallel graph, with $n(G) \geq 3$, and G is not a diamond graph. Then $n(G) \geq 4$. If $n(G) = 4$, that is, G is a path of four vertices, then the lemma trivially holds true, as illustrated in Figure 3.2. One may thus assume $n(G) \geq 5$, and inductively assume that the lemma holds for every 2-legged

FIG. 3.2. Optimal I-, L-, and U-shaped drawings of a path of four vertices.

FIG. 3.3. Illustration of the proof of Lemma 3.2.

series-parallel graph of at most $n(G) - 1$ vertices. We now prove that the lemma holds for G .

(a) We first prove that (a) holds for G . Let s and t be the terminals of G , then $d(s) = d(t) = 1$. Since G is a 2-legged series-parallel graph, the graph $G - s - t$ obtained from G by deleting vertices s and t is a series-parallel graph having the leg-vertices as the terminals, and hence $G - s - t$ is either a series connection or a parallel connection of two subgraphs.

Consider first the case where $G - s - t$ is a series connection of two subgraphs. In this case, since $\Delta(G) \leq 3$, G has a bridge $e = uv$ other than the two legs, that is, $G - e$ is disconnected, as illustrated in Figure 3.3(a). Then G contains two subgraphs G' and G'' ; G' is a 2-legged series-parallel graph with terminals s and v , and G'' is a 2-legged series-parallel graph with terminals u and t , as illustrated in Figure 3.3(b). If G' is not a diamond graph, then $4 \leq n(G') < n(G)$, and hence by the inductive hypothesis, G' has three optimal drawings of I-, L-, and U-shapes. If G' is a diamond graph, then by Lemma 3.1(a), G' has two optimal (no-bend) drawings of I- and L-shapes. Hence, in either case, G' has two optimal drawings of I- and L-shapes. Similarly, G'' has two optimal drawings of I- and L-shapes. Combining these drawings of G' and G'' , one can easily construct three optimal drawings D_I , D_L , and D_U of G , as illustrated in Figures 3.3(c), (d), and (e). Thus (a) holds true.

Consider next the case where $G - s - t$ is a parallel connection of two subgraphs. Then G has exactly one biconnected component, and the degrees of the leg-vertices are three, as illustrated in Figure 3.4(a). Deleting the terminals of G and splitting the two leg-vertices of G , one can obtain two edge-disjoint 2-legged series-parallel

FIG. 3.4. Illustration of the proof of Lemma 3.2.

subgraphs G' and G'' , as illustrated in Figure 3.4(b). Since $n(G'), n(G'') \geq 2$, there are the following two cases to consider.

Case 1: Either $n(G') = 2$ or $n(G'') = 2$.

One may assume that $n(G'') = 2$, and hence G'' consists of a single edge. Since G is a simple graph, we have $n(G') \geq 3$.

Consider first the case where G' is not a diamond graph. Then $4 \leq n(G') < n(G)$, and hence by the inductive hypothesis, G' has an optimal U-shaped drawing D'_U . From a flipped drawing of D'_U , one can easily construct three optimal drawings D_I , D_L , and D_U of G , as illustrated in Figure 3.4(c).

Consider next the case where G' is a diamond graph. Then by Lemma 3.1(a), G' has a no-bend L-shaped drawing D'_L . From a flipped drawing of D'_L , one can easily construct three drawings D_I , D_L , and D_U of G , with one bend, as illustrated in Figure 3.4(d). Since G' is a diamond graph, by Lemma 3.1(c), every no-bend drawing of G' is either I-shaped or L-shaped. Therefore, we have $bend(G) \geq 1$; if G had a no-bend drawing D , then $D|G'$ would be I- or L-shaped, and hence D would have one or more bends on the edge in G'' , a contradiction. Thus the constructed drawings D_I , D_L , and D_U having exactly one bend are optimal.

Case 2: $n(G'), n(G'') \geq 3$.

Since G is not a diamond graph, either G' or G'' is not a diamond graph. One may assume without loss of generality that G' is not a diamond graph. Then $4 \leq n(G') < n(G)$, and hence by the inductive hypothesis, G' has an optimal U-shaped drawing D'_U . On the other hand, G'' has an optimal I-shaped drawing D'_I ; if G'' is a diamond graph, then by Lemma 3.1(a), G'' has an optimal (no-bend) I-shaped drawing D'_I ; otherwise, by the inductive hypothesis, G'' has an optimal I-shaped drawing D'_I . From the U-shaped drawing D'_U and the I-shaped drawing D'_I , one can easily construct I-, L-, and U-shaped drawings D_I , D_L , and D_U of G without introducing any new bends, as illustrated in Figure 3.4(e). Since D_I has no bend on the legs, by (2.1) and (2.2) we have

$$bend(D_I) = bend(D'_U) + bend(D'_I).$$

Since D'_U and D'_I are optimal drawings of G' and G'' , respectively,

$$bend(D'_U) = bend(G')$$

FIG. 3.5. A graph attaining the bound in Lemma 3.2(c).

and

$$\text{bend}(D_1'') = \text{bend}(G'').$$

Let D^* be an arbitrary optimal drawing of G , then clearly

$$\begin{aligned} \text{bend}(G') &\leq \text{bend}(D^*|G'), \\ \text{bend}(G'') &\leq \text{bend}(D^*|G''), \end{aligned}$$

and

$$\text{bend}(D^*|G') + \text{bend}(D^*|G'') \leq \text{bend}(D^*) = \text{bend}(G).$$

From these six equations we have $\text{bend}(D_I) \leq \text{bend}(G)$, and hence D_I is an optimal drawing of G . Similarly, D_L and D_U are optimal drawings of G . Thus (a) holds true.

(b) We now prove (b). One can construct the (regular labeling of) drawings D_I , D_L , and D_U above from the (regular labeling of) drawings of G' and G'' simply by deciding the labels of the terminals and leg-vertices in G ; this can be done in constant time. Thus (b) holds true for G .

(c) We finally prove (c). If a new bend is produced in a construction of G , as illustrated in Figures 3.3 and 3.4, then the construction is one in Figure 3.4(d), $n(G) \geq 5$, and $\text{bend}(G) = \text{bend}(G') + 1 = 1 \leq (n(G) - 2)/3$. In any other construction, no new bend is produced. Noting this fact, one can inductively prove that $n(G) \leq (n(G) - 2)/3$. $\square$

We denote by K_n a complete graph of $n(\geq 1)$ vertices. Let G be a 2-legged series-parallel graph obtained from copies of K_2 and K_3 by connecting them alternately in series, as illustrated in Figure 3.5. Then $\text{bend}(G) = (n(G) - 2)/3$. Thus the bound in Lemma 3.2(c) is best possible.

The proof of Lemma 3.2 immediately yields a linear algorithm **NonDiamond**(G, D_I, D_L, D_U), which recursively finds three optimal I-, L-, and U-shaped drawings D_I , D_L , and D_U of a given 2-legged series-parallel graph G unless G is a diamond graph. By algorithms **Diamond** and **NonDiamond**, one can find an optimal drawing of a 2-legged series-parallel graph G . Note that **NonDiamond** may call **Diamond**.

For a series-parallel graph G with $d(s), d(t) \leq 2$, one can easily find an optimal outer drawing D of G , as follows. Add to G a dummy edge $s's$ for a new vertex s' if $d(s) = 2$, and add to G a dummy edge tt' for a new vertex t' if $d(t) = 2$. Then the resulting graph G' is a 2-legged series-parallel graph, and $\Delta(G') \leq 3$. Find an optimal drawing D' of G' by **Diamond** or **NonDiamond** and delete the dummy edges from D' . Then the resulting drawing D of G is clearly optimal and outer.

3.2. Biconnected series-parallel graphs. A biconnected series-parallel graph G can be defined (without specifying terminals) as a biconnected graph which has no K_4 as a minor. For every edge uv in G , G is a series-parallel graph with terminals u and v .

A cycle C of four vertices in a graph G is called a *diamond* if two nonconsecutive vertices of C have degree two in G and the other two vertices of C have degree three

FIG. 3.6. Substructures contained in a biconnected series-parallel graph of $\Delta \leq 3$.FIG. 3.7. Smaller graphs G' .

and are not adjacent in G , as illustrated in Figure 3.6(a). We denote by G/C the graph obtained from G by contracting C to a new single vertex v_C , as illustrated in Figure 3.7(a). (Note that $G_C = G/C$ is series-parallel if G is series-parallel. One can observe that, from every diamond graph, one can obtain a graph in Figure 2.5(a) by repeatedly contracting a diamond.)

Noting that every biconnected series-parallel graph G has a vertex of degree two, one can easily observe that the following Lemma 3.3 holds. (Lemma 3.3 is also an immediate consequence of Lemma 2.1 in [10] on a general series-parallel graph.)

LEMMA 3.3. *Every biconnected series-parallel graph G of $\Delta \leq 3$ has, as a subgraph, one of the following three substructures (a)–(c) illustrated in Figure 3.6:*

- (a) a diamond C ;
- (b) two adjacent vertices u and v such that $d(u) = d(v) = 2$; and
- (c) a complete graph K_3 of three vertices u , v , and w such that $d(v) = 2$.

Our idea is to reduce the optimal drawing problem for a biconnected series-parallel graph G to that for a smaller graph G' illustrated in Figure 3.7, as in the following Lemmas 3.4 and 3.5.

LEMMA 3.4. *If a biconnected series-parallel graph G , with $n(G) \geq 6$ has a diamond C , then $\text{bend}(G) = \text{bend}(G')$ for $G' = G/C$.*

Proof. Assume that a biconnected series-parallel graph G has a diamond C and that s' and t' are the two vertices of C having degree three in G , as illustrated in Figure 3.8(a). Let $G' = G/C$ be the graph obtained from G by contracting C to a new single vertex v_C , as illustrated in Figure 3.8(b). Since $n(G) \geq 6$ and G is biconnected, the neighbor of s' outside C is different from that of t' . Therefore, G' is a biconnected series-parallel (simple) graph. Let D'^* be an optimal drawing of G' , then $\text{bend}(D'^*) = \text{bend}(G')$. (See Figure 3.8(e).) Replace the vertex v_C in D'^* with a rectangular drawing of C , and let D be the resulting drawing of G , as illustrated in Figure 3.8(d). We claim that D is an optimal drawing of G , and hence $\text{bend}(G) = \text{bend}(G')$.

FIG. 3.8. Illustration for the proof of Lemma 3.4.

The (regular labeling of) drawing D is constructed from the (regular labeling of) optimal drawing D'^* of G' without introducing any new bend, and hence we have $\text{bend}(D) = \text{bend}(D'^*) = \text{bend}(G')$. Let D^* be an arbitrary optimal drawing of G , then $\text{bend}(D^*) = \text{bend}(G)$. If

$$(3.1) \quad \text{bend}(G') \leq \text{bend}(D^*),$$

then $\text{bend}(D) = \text{bend}(G') \leq \text{bend}(D^*) = \text{bend}(G)$, and hence D is an optimal drawing of G . It thus suffices to verify (3.1). There are the following two cases to consider.

Case 1: $\text{bend}(D^*|C) = 0$.

In this case, $D^*|C$ is a rectangle, as illustrated in Figure 3.8(d). Contracting C in D^* to a single vertex v_C and appropriately deciding the two labels of v_C , one can obtain (a regular labeling of) a drawing D' of $G' = G/C$ from D^* without introducing any new bend, as illustrated in Figure 3.8(e). We thus have $\text{bend}(G') \leq \text{bend}(D') = \text{bend}(D^*)$.

Case 2: $\text{bend}(D^*|C) \geq 1$.

In this case, $D^*|C$ is a rectilinear polygon having five or more (geometric) vertices including at least one bend. Delete from G the two vertices of C having degree two, and let G'' be the resulting graph, as illustrated in Figure 3.8(c). Since G is biconnected, G'' is a 2-legged series-parallel graph with terminals s' and t' . (Note that every biconnected series-parallel graph is a series-parallel graph having the ends of an arbitrary edge as terminals, and that a graph obtained from a series-parallel graph by contracting an edge is series-parallel.) Since G'' is the complement of C in G , by (2.2) we have

$$(3.2) \quad \text{bend}(D^*|G'') + \text{bend}(D^*|C) = \text{bend}(D^*).$$

There are the following two subcases to consider.

Case 2.1: G'' is not a diamond graph.

Since $n(G) \geq 6$, $n(G'') = n(G) - 2 \geq 4$. Since G'' is not a diamond graph, by Lemma 3.2(a), G'' has an optimal U-shaped drawing D''^* , as illustrated in Figure 3.8(f). D''^* can be modified to a drawing D' of G' by identifying s' with t' as a single vertex v_C and introducing a new bend, as illustrated in Figure 3.8(g), and

FIG. 3.9. An optimal drawing D^* of G such that $D^*[G'']$ is I-shaped in (a) or L-shaped in (b).

hence by (3.2),

$$\begin{aligned}
 \text{bend}(G') &\leq \text{bend}(D') \\
 &= \text{bend}(D''^*) + 1 \\
 &= \text{bend}(G'') + 1 \\
 &\leq \text{bend}(D^*[G'']) + \text{bend}(D^*[C]) \\
 &= \text{bend}(D^*).
 \end{aligned}$$

Case 2.2: G'' is a diamond graph.

Since $\text{bend}(D^*[C]) \geq 1$, by (2.1) we have $\text{bend}(D^*) \geq \text{bend}(D^*[C]) \geq 1$. We now claim that

$$(3.3) \quad \text{bend}(D^*) \geq 2.$$

Suppose for a contradiction that $\text{bend}(D^*) = 1$. Since $\text{bend}(D^*[C]) \geq 1$, by (3.2) we have $\text{bend}(D^*[C]) = 1$ and $\text{bend}(D^*[G'']) = 0$, and hence $D^*[G'']$ is a no-bend drawing of G'' . Then by Lemma 3.1(c), $D^*[G'']$ is either I-shaped or L-shaped, as illustrated in Figures 3.9(a) and (b), respectively. In either case, the drawing of C needs two or more bends in D^* , that is, $\text{bend}(D^*[C]) \geq 2$, as illustrated in Figure 3.9, where C is drawn by thick lines. This is contrary to $\text{bend}(D^*[C]) = 1$.

Since G'' is a diamond graph, by Lemma 3.1(a) G'' has a no-bend L-shaped drawing D'' , as illustrated in Figure 3.8(h). The drawing D'' can be modified to a drawing D' of $G' = G/C$ by identifying the two vertices s' and t' as a single vertex v_C and introducing two new bends, as illustrated in Figure 3.8(g), and hence we have

$$(3.4) \quad \text{bend}(G') \leq \text{bend}(D') = \text{bend}(D'') + 2 = 2.$$

By (3.3) and (3.4) we have $\text{bend}(G') \leq 2 \leq \text{bend}(D^*)$. $\square$

LEMMA 3.5. Assume that a biconnected series-parallel graph G , with $n(G) \geq 6$ has no diamond. If G has a substructure of type (b) in Figure 3.6(b), then $\text{bend}(G) = \text{bend}(G')$ for $G' = G - uv$. If G has a substructure of type (c) in Figure 3.6(c), then $\text{bend}(G) = \text{bend}(G') + 1$ for $G' = G - v - uw$. (See Figures 3.7(b) and (c).)

Proof. Since G has no diamond, by Lemma 3.3, G has either a substructure (b) or (c).

Suppose first that G has a substructure (b). Let $G' = G - uv$, as illustrated in Figure 3.7(b). Then G' is a 2-legged series-parallel graph with terminals u and v . Clearly $n(G') = n(G) \geq 6$. Since G has no diamond, the subgraph G' of G has no diamond. Therefore G' is not a diamond graph, and hence by Lemma 3.2(a), G' has

 FIG. 3.10. Construction of D from D'_U .

an optimal U-shaped drawing D'_U . D'_U can be extended to a drawing D of G simply by drawing uw as a straight line segment. Since $\text{bend}(D) = \text{bend}(D'_U) = \text{bend}(G') \leq \text{bend}(G)$, D is an optimal drawing of G . Thus $\text{bend}(G) = \text{bend}(D) = \text{bend}(G')$.

Suppose next that G has a substructure (c). Let $G' = G - v - uw$, as illustrated in Figure 3.7(c). Then G' is a 2-legged series-parallel graph with terminals u and w and is not a diamond graph. Therefore, by Lemma 3.2(a), G' has an optimal U-shaped drawing D'_U . D'_U can be extended to a drawing D of G by drawing the complete graph K_3 of three vertices u, v, w as a rectangle with one bend, as illustrated in Figure 3.10. Any orthogonal drawing of K_3 needs a bend, and hence $\text{bend}(D) = \text{bend}(D'_U) + 1 = \text{bend}(G') + 1 \leq \text{bend}(G)$. Thus D is an optimal drawing of G , and hence $\text{bend}(G) = \text{bend}(G') + 1$. $\square$

From the proofs of Lemmas 3.4 and 3.5 we have the following algorithm **Biconnected**(G, D) to find an optimal drawing D of a biconnected series-parallel graph G .

Biconnected(G, D);

begin

One may assume that $n(G) \geq 6$ (otherwise, one can easily find an optimal drawing D of G in linear time);

{By Lemma 3.3, G has one of the three substructures (a)–(c) in Figure 3.6.}

Case 1: G has a diamond C ;

Let $G' = G/C$; { G' is a biconnected series-parallel graph.}

Biconnected(G', D');

Extend an optimal drawing D' of G' to an optimal drawing D of G simply by replacing v_C by a rectangular drawing of C , as illustrated in

Figures 3.8(d) and (e); {cf. Lemma 3.4}

Case 2: G has no diamond but has a substructure (b);

Let $G' = G - uv$;

{ G' is a 2-legged series-parallel graph with terminals u and v and is not a diamond graph.}

Find an optimal U-shaped drawing D'_U of G' by **NonDiamond**;

{cf. Lemma 3.2}

Extend D'_U to an optimal drawing D of G by drawing uv as a straight line segment;

{cf. Lemma 3.5}

Case 3: G has neither a diamond nor a substructure (b) but has a substructure (c);

Let $G' = G - v - uw$;

{ G' is a 2-legged series-parallel graph with terminals u and w and is not a diamond graph.}

Find an optimal U-shaped drawing D'_U of G' by **NonDiamond**;

FIG. 3.11. Biconnected series-parallel graphs with $n = 4$ or $n = 5$.

Extend D'_U to an optimal drawing D of G by drawing $K_3 = uvw$ as a rectangle with one bend, as illustrated in Figure 3.10; {cf. Lemma 3.5}

end.

All substructures (a)–(c) can be found total in time $O(n)$ by a standard bookkeeping method to maintain all degrees of vertices together with all paths of length two with an intermediate vertex of degree two. One can thus observe that **Biconnected** can be executed in linear time.

We thus have the following theorem.

THEOREM 3.6. *An optimal orthogonal drawing of a series-parallel biconnected graph G of $\Delta \leq 3$ can be found in linear time.*

It should be noted that the (original) terminals s and t of G are not always on the outer face of a drawing D obtained by **Biconnected**, and hence D is not always an outer drawing, as known from the example in Figure 2.3.

Di Battista, Liotta, and Vargiu gave an $O(n^3)$ algorithm for biconnected series-parallel simple graphs using a min-cost flow technique and a data structure called an SPQ*R tree [4, 5]. Our linear algorithm is much simpler and faster than their algorithm.

We have the following lemma on the minimum number of bends.

LEMMA 3.7. *If a series-parallel graph G is biconnected and $\Delta \leq 3$, then*

$$(3.5) \quad \text{bend}(G) \leq \lceil n(G)/3 \rceil.$$

Proof. We prove (3.5) by induction on $n(G)$. Since G is biconnected, $n(G) \geq 3$.

1°. We first show that (3.5) holds if $3 \leq n(G) \leq 5$. If $n(G) = 3$, then $G = K_3$ and $\text{bend}(G) = 1 = \lceil n(G)/3 \rceil$. If $n(G) = 4$ and $\text{bend}(G) \geq 1$, then $G = K_4 - e$ in Figure 3.11(a), and hence $\text{bend}(G) = 2 \leq \lceil n(G)/3 \rceil$, where $K_4 - e$ is a graph obtained from K_4 by deleting an edge. If $n(G) = 5$ and $\text{bend}(G) \geq 1$, then G is one of the two graphs in Figure 3.11(b), and hence $\text{bend}(G) \leq 2 \leq \lceil n(G)/3 \rceil$.

2°. Assume that $n(G) \geq 6$, and assume inductively that (3.5) holds for every series-parallel biconnected graph of at most $n(G) - 1$ vertices.

3°. We then show that (3.5) holds for G . There are the following three cases to consider.

Case 1: G has a diamond C .

By Lemma 3.4 we have $\text{bend}(G) = \text{bend}(G')$ for $G' = G/C$. Since $n(G') = n(G) - 3$ and G' is a series-parallel biconnected graph, by the inductive hypothesis we have $\text{bend}(G') \leq \lceil n(G')/3 \rceil$. We thus have $\text{bend}(G) = \text{bend}(G') < \lceil n(G)/3 \rceil$.

Case 2: G has no diamond but has a substructure (b) in Figure 3.6(b).

By Lemma 3.5 we have $\text{bend}(G) = \text{bend}(G')$ and $n(G) = n(G')$ for $G' = G - uv$. Since G' is a 2-legged series-parallel graph and is not a diamond graph, by Lemma 3.2(c) we have $\text{bend}(G') \leq (n(G') - 2)/3$. We thus have $\text{bend}(G) = \text{bend}(G') \leq \lceil n(G)/3 \rceil$.

Case 3: G has neither a diamond nor a substructure (b) but has a substructure (c) in Figure 3.6(c).

By Lemma 3.5 we have $\text{bend}(G) = \text{bend}(G') + 1$ and $n(G) = n(G') + 1$ for $G' = G - v - uw$. Since G' is a 2-legged series-parallel and is not a diamond graph, by Lemma 3.2(c) we have $\text{bend}(G') \leq (n(G') - 2)/3$. We thus have

$$\begin{aligned} \text{bend}(G) &\leq (n(G') - 2)/3 + 1 \\ &= n(G)/3 \\ &\leq \lceil n(G)/3 \rceil. \quad \square \end{aligned}$$

4. Optimal drawing of nonbiconnected series-parallel graph. It has been left as open by Di Battista, Liotta, and Vargiu [4, 5] to obtain an algorithm for nonbiconnected series-parallel graphs G . In section 4.1 we give a linear algorithm for G , and in section 4.2 we give a best possible upper bound on $\text{bend}(G)$.

4.1. Algorithm. By Lemma 3.1, Lemma 3.2, and Theorem 3.6, one may assume that G is neither 2-legged nor biconnected. Therefore either $d(s) \geq 2$ or $d(t) \geq 2$, and hence one may assume without loss of generality that $d(s) \geq 2$.

We now claim that one may further assume that $d(t) \geq 2$, and hence G consists of biconnected components $B_1, B_2, \dots, B_p$, $p \geq 2$, and $p - 1$ copies of K_2 , alternately connected in series, as illustrated in Figure 4.1(a), after replacing each induced path contained in none of the biconnected components by a single edge. Suppose that $d(t) = 1$, as illustrated in Figure 4.1(b). Then $G' = G - t$ is a series-parallel graph with terminals s and t_p , and takes the form in Figure 4.1(a). Since $d(t_p, G') = d(t_p, G) - 1 = 2$, there is an angle of π or $3\pi/2$ around vertex t_p in any optimal drawing D' of G' . An optimal drawing D of G can be obtained from D' simply by inserting the edge $t_p t$ in the angle. One may thus assume that $d(t) \geq 2$.

For a series-parallel graph G in Figure 4.1(a), each biconnected component B_i , $1 \leq i \leq p$, is a series-parallel graph with terminals s_i and t_i , where $s_1 = s$ and $t_p = t$. Clearly

$$(4.1) \quad \sum_{i=1}^p \text{bend}(B_i) \leq \text{bend}(G).$$

However, (4.1) does not always hold with equality, as follows. Consider the series-parallel graph G in Figure 4.2(a); G has two biconnected components B_1 and B_2 , and hence $p = 2$. B_1 and B_2 have no-bend (optimal) drawings D_1 and D_2 , as illustrated in Figures 4.2(b) and (c), respectively. Thus $\text{bend}(B_1) = \text{bend}(B_2) = 0$, and hence $\text{bend}(B_1) + \text{bend}(B_2) = 0$. However, terminal t_1 of B_1 is not on the outer face of any no-bend drawing of B_1 . Similarly, s_2 is not on the outer face of any no-bend drawing of B_2 . Therefore, one cannot connect t_1 in D_1 and s_2 in D_2 by an edge without edge-crossing. Thus G does not have a no-bend drawing. On the other hand, B_2 has a drawing D_2' with one bend in which s_2 is on the outer face, as illustrated in Figure 4.2(d). Combining D_1 and D_2' , one can construct a drawing D of G with one bend, as illustrated in Figure 4.2(e). Thus $\text{bend}(G) = 1$, and hence

$$\text{bend}(B_1) + \text{bend}(B_2) < \text{bend}(G).$$

In section 4.3, we will prove

$$(4.2) \quad \text{bend}(G) = \sum_{i=1}^p \text{bend}(B_i) \quad \text{or} \quad \sum_{i=1}^p \text{bend}(B_i) + 1.$$

(a) G with $d(s), d(t) \geq 2$ (b) G with $d(t) = 1$ (c) G_{int}

FIG. 4.1. Nonbiconnected series-parallel graphs.

(a) G (b) D_1 (c) D_2 (d) D_2^o (e) D FIG. 4.2. Construction of an optimal drawing D of G for a case $p = 2$.

Delete from a series-parallel graph G in Figure 4.1(a) all vertices in B_1 and B_p except t_1 and s_p , and let G_{int} be the resulting series-parallel graph with terminals t_1 and s_p , as illustrated in Figure 4.1(c). Then we claim that G_{int} has an optimal I-shaped drawing. If $p = 2$, then $G_{\text{int}} = K_2$, and hence G_{int} has an optimal (no-bend) I-shaped drawing D_{intI} . If $p \geq 3$, then G is 2-legged, and hence by Lemmas 3.1 and 3.2, G_{int} has an optimal I-shaped drawing D_{intI} , in which both terminals t_1 and s_p are on the outer face.

 FIG. 4.3. Two alternative drawings D_a and D_b of G .

 FIG. 4.4. Three kinds of the outer angle of s_p in D_p^o .

As known from the example in Figure 4.2, we have the following lemma.

LEMMA 4.1. Let G be a series-parallel graph taking the form in Figure 4.1(a). Then an arbitrary drawing D of G has one of the following two alternatives forms:

- (a) the terminal s_p of B_p is on the outer face of the drawing $D_p^o = D|B_p$ of B_p (see Figure 4.3(a), for example); and
- (b) the terminal t_1 of B_1 is on the outer face of the drawing $D_1^o = D|B_1$ of B_1 (see Figure 4.3(b), for example).

In (a) above, the *outer angle* of s_p , that is, the angle around s_p in the outer face of D_p^o , must be either $3\pi/2$ or π , as illustrated in Figures 4.4(a) and (b); if it were $\pi/2$, as illustrated in Figure 4.4(c), then the edge $t_{p-1}s_p$ could not be drawn in the outer angle. Since $d(t_1, B_1) = 2$, one of the two angles of t_1 in any drawing of B_1 has an angle of $3\pi/2$ or π . Of course, in an arbitrary drawing D of G , both G_{int} and B_p are drawn in the same face F_1 of $D_1 = D|B_1$ having such an angle of t_1 , as illustrated in Figure 4.3(a). Note that face F_1 may be outer although it is drawn as an inner face in Figure 4.3(a). Similarly, in (b) above, both G_{int} and B_1 are drawn in the same face F_p of $D_p = D|B_p$, as illustrated in Figure 4.3(b).

Let B be a biconnected series-parallel graph, and let v be a vertex of degree two in B . A drawing D of B is (α, v) -*outer* if v is on the outer face of D and the outer angle of v is α , where $\alpha = \pi/2, \pi$, or $3\pi/2$. An (α, v) -outer drawing D is *optimal* if D has the minimum number of bends among all possible (α, v) -outer drawings of B . The minimum number of bends is denoted by $\text{bend}(B, \alpha, v)$. Clearly $\text{bend}(B) \leq \text{bend}(B, \alpha, v)$. However, the equation does not always hold with equality. For example, $\text{bend}(B_2) = 0 < 1 = \text{bend}(B_2, 3\pi/2, s_2)$ for B_2 in Figure 4.2(a).

Lemma 4.1 and the arguments above imply that we shall find optimal (α, t_1) -outer drawings of B_1 and optimal (α, s_p) -outer drawings of B_p for both $\alpha = 3\pi/2$ or $\alpha = \pi$. However, it suffices to find them only for $\alpha = 3\pi/2$, because $\text{bend}(B_1, 3\pi/2, t_1) \leq \text{bend}(B_1, \pi, t_1)$ and $\text{bend}(B_p, 3\pi/2, s_p) \leq \text{bend}(B_p, \pi, s_p)$ as known from the following, Lemma 4.2(a), whose proof will be given in section 4.3.

LEMMA 4.2. *If a biconnected series-parallel graph B has a vertex v of degree two, then*

(a)

$$(4.3) \quad \text{bend}(B, 3\pi/2, v) \leq \min\{\text{bend}(B, \pi/2, v), \text{bend}(B, \pi, v)\};$$

(b)

$$\text{bend}(B, 3\pi/2, v) = \text{bend}(B) \quad \text{or} \quad \text{bend}(B) + 1;$$

and

(c) *an optimal $(3\pi/2, v)$ -outer drawing of B can be found in linear time.*

The proof of Lemma 4.2 yields a linear algorithm **OuterDrawing** (B, v, D) to find an optimal $(3\pi/2, v)$ -outer drawing of B . Thus one can easily observe that the following algorithm **NonBiconnected** (G, D) finds an optimal drawing of G .

NonBiconnected (G, D) ;

begin

Find an optimal drawing D_1 of B_1 and an optimal drawing D_p of B_p
by **Biconnected**;

Find an optimal $(3\pi/2, t_1)$ -outer drawing D_1° of B_1 and an optimal $(3\pi/2, s_p)$ -outer drawing D_p° of B_p by **OuterDrawing**;

Find an optimal I-shaped drawing D_{intI} of G_{int} ; {cf. Lemmas 3.1 and 3.2}

Let F_1 be a face of D_1 such that the angle of t_1 in F_1 is π or $3\pi/2$, insert D_{intI} and D_p° in F_1 , and let D_a be the resulting drawing of G , as illustrated in Figure 4.3(a);

Similarly construct a drawing D_b of G , as illustrated in Figure 4.3(b);

if $\text{bend}(D_a) \leq \text{bend}(D_b)$, **then return** D_a as D

else return D_b as D ;

end.

One can easily observe that **NonBiconnected** finds an optimal drawing of G in linear time. We thus have the following theorem.

THEOREM 4.3. *An optimal orthogonal drawing of a series-parallel graph G of $\Delta \leq 3$ can be found in linear time.*

4.2. Upper bounds on bends. In this subsection we prove the following theorem.

THEOREM 4.4. *If G is a series-parallel graph of $\Delta \leq 3$, then $\text{bend}(G) \leq (n + 4)/3$.*

The bound in Theorem 4.4 is best possible, because $\text{bend}(G) = (n + 4)/3$ for a series-parallel graph G consisting of two copies of $K_4 - e$ and several copies of K_2 and K_3 connected in series, as illustrated in Figure 4.5, where $K_4 - e$ is a graph obtained from K_4 by deleting an edge e .

We first have the following lemma.

LEMMA 4.5. *If a biconnected series-parallel graph B has a vertex v of degree two, then*

$$\text{bend}(B, 3\pi/2, v) \leq (n(B) + 2)/3.$$

 FIG. 4.5. A series-parallel graph G with $(n+4)/3$ bends.

Proof. Since B is biconnected, we have $n(B) \geq 3$. Split the vertex v into two vertices s' and t' , and let B_v be the resulting 2-legged series-parallel graph, as illustrated in Figure 4.6.

Consider first the case where B_v is a diamond graph. Then clearly $n(B) \geq 6$. By Lemma 3.1(a), B_v has a no-bend L-shaped drawing D_{vL} . From D_{vL} , one can construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with two bends. (See Figures 3.8(g) and (h).) Therefore $\text{bend}(B, 3\pi/2, v) \leq \text{bend}(D_{3\pi/2}) = 2 \leq (n(B) + 2)/3$.

Consider next the case where B_v is not a diamond graph. By Lemma 3.2(a), B_v has an optimal U-shaped drawing D_{vU} , and $\text{bend}(D_{vU}) = \text{bend}(B_v)$. From D_{vU} , one can construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with a new bend, and hence $\text{bend}(D_{3\pi/2}) = \text{bend}(D_{vU}) + 1$. (See Figures 3.8(e) and (f).) By Lemma 3.2(c), $\text{bend}(B_v) \leq (n(B_v) - 2)/3$. Clearly $n(B) = n(B_v) - 1$. We thus have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D_{vU}) + 1 \\ &= \text{bend}(B_v) + 1 \\ &\leq (n(B_v) - 2)/3 + 1 \\ &= (n(B) + 2)/3. \quad \square \end{aligned}$$

We are now ready to present a proof of Theorem 4.4.

Proof of Theorem 4.4. By Lemma 3.7, $\text{bend}(G) \leq \lceil n/3 \rceil < (n+4)/3$ for every series-parallel biconnected graph G . We may thus assume that G is not biconnected. Then one may assume that G consists of biconnected components $B_1, B_2, \dots, B_p$, $p \geq 2$, and several copies of K_2 , alternately connected in series, as illustrated in Figure 4.1(a). **NonBiconnected** finds an optimal drawing D of G such that $\text{bend}(D) \leq \text{bend}(D_a) \leq \text{bend}(B_1) + \text{bend}(G_{\text{int}}) + \text{bend}(B_p, 3\pi/2, s_p)$.

By Lemma 3.7 we have $\text{bend}(B_1) \leq \lceil n(B_1)/3 \rceil \leq (n(B_1) + 2)/3$. We have $\text{bend}(G_{\text{int}}) \leq (n(G_{\text{int}}) - 2)/3$; if $n(G_{\text{int}}) = 2$, then $\text{bend}(G_{\text{int}}) = 0 = (n(G_{\text{int}}) - 2)/3$; if $n(G_{\text{int}}) \geq 3$ and G_{int} is a diamond graph, then by Lemma 3.1(a) $\text{bend}(G_{\text{int}}) = 0 < (n(G_{\text{int}}) - 2)/3$; if $n(G_{\text{int}}) \geq 3$ and G_{int} is not a diamond graph, then by Lemma 3.2(c) $\text{bend}(G_{\text{int}}) \leq (n(G_{\text{int}}) - 2)/3$. By Lemma 4.5 we have $\text{bend}(B_p, 3\pi/2, s_p) \leq (n(B_p) + 2)/3$. Clearly $n(G) = n(B_1) + n(G_{\text{int}}) + n(B_p) - 2$. We thus have

$$\begin{aligned} \text{bend}(G) &\leq (n(B_1) + 2)/3 + (n(G_{\text{int}}) - 2)/3 + (n(B_p) + 2)/3 \\ &\leq (n(G) + 4)/3. \quad \square \end{aligned}$$

One can easily observe that each edge has at most one bend in a drawing found by our algorithm.

4.3. Proof of Lemma 4.2. In this subsection, we first give a proof of Lemma 4.2, then present algorithm **OuterDrawing** to find an optimal $(3\pi/2, v)$ -outer drawing, and finally prove (4.2).

FIG. 4.6. (a) Biconnected graph B , (b) 2-legged graph B_v , and (c) graph $B - v$.

Let B be a biconnected series-parallel graph with $\Delta(B) \leq 3$, and let v be a vertex of degree two in B , as illustrated in Figure 4.6(a). Split the vertex v into two vertices s' and t' , and let B_v be the resulting 2-legged series-parallel graph with terminals s' and t' , as illustrated in Figure 4.6(b).

Consider first the case where B_v is a diamond graph. Then we have the following lemma.

LEMMA 4.6. *If B_v is a diamond graph, then $\text{bend}(B, 3\pi/2, v) = \text{bend}(B) = 2$.*

Proof. Since B_v is a diamond graph, by Lemma 3.1 B_v has a no-bend L-shaped drawing D_L , from which one can construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with two bends (see Figures 3.8(g) and (h)), and hence

$$\text{bend}(B) \leq \text{bend}(B, 3\pi/2, v) \leq \text{bend}(D_{3\pi/2}) = 2.$$

Thus it suffices to verify $2 \leq \text{bend}(B)$.

Let D^* be an arbitrary optimal drawing of B . Let D_v be a drawing of B_v obtained from D^* without introducing any new bend as follows: erase, from D^* , point v together with very short segments of two edges incident to vertex v , and regard the ends of the erased segments other than v as vertices s' and t' of B_v . We then have

$$(4.4) \quad \text{bend}(D_v) = \text{bend}(D^*) = \text{bend}(B).$$

The construction of D_v implies that D_v has none of I-, L-, and U-shapes. We now claim $2 \leq \text{bend}(D_v)$; if $\text{bend}(D_v) = 0$, then by Lemma 3.1(c), D_v must be I-shaped or L-shaped, a contradiction; if $\text{bend}(D_v) = 1$, then one can easily observe from the example in Figure 2.6 that D_v is I-, L-, or U-shaped, a contradiction. Thus we have $2 \leq \text{bend}(D_v) = \text{bend}(B)$. $\square$

The proof of Lemma 4.6 immediately yields the following linear algorithm **OuterDiamond**(B, v, D) to find an optimal $(3\pi/2, v)$ -outer drawing D of B , with $\text{bend}(D) = \text{bend}(B) = 2$ if B_v is a diamond graph.

OuterDiamond(B, v, D);

begin

Find a no-bend L-shaped drawing D_{vL} of B_v by **Diamond**;

Construct from D_{vL} a $(3\pi/2, v)$ -outer drawing D of B with two bends;

(See Figures 3.8(g) and (h).)

end.

Consider next the case where $B - v$ is a series connection of subgraphs. We then have the following lemma.

LEMMA 4.7. *If $B - v$ is a series connection of subgraphs, then $\text{bend}(B, 3\pi/2, v) = \text{bend}(B)$.*

Proof. Since $\Delta(B) \leq 3$ and $B - v$ is a series connection of subgraphs, B_v has a bridge e other than the two legs, as illustrated in Figure 4.7(a). B_v has two subgraphs

FIG. 4.7. Illustration of the proof of Lemma 4.7.

B' and B'' , each of which is a 2-legged series-parallel graph and has e as a leg, as illustrated in Figure 4.7(b). Clearly $n(B'), n(B'') \geq 3$.

Consider first the case where both B' and B'' are diamond graphs. Then by Lemma 3.1(a), B' and B'' have no-bend L-shaped drawings D'_L and D''_L , respectively. Merging D'_L and D''_L , one can construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with one bend, as illustrated in Figure 4.7(c), and hence $\text{bend}(B, 3\pi/2, v) \leq 1$. By Lemma 3.1(c), any no-bend drawings of B' and B'' are not U-shaped but are I-shaped or L-shaped. Therefore, B does not have a no-bend drawing. Thus $D_{3\pi/2}$ is an optimal drawing of B , and hence $\text{bend}(B) = \text{bend}(B, 3\pi/2, v) = 1$.

Consider next the case of either B' or B'' is not a diamond graph. Assume without loss of generality that B' is not a diamond graph. Then by Lemma 3.2(a), B' has an optimal U-shaped drawing D'_U . On the other hand, B'' has an optimal L-shaped drawing D''_L ; if B'' is a diamond graph, then by Lemma 3.1(a), B'' has an optimal (no-bend) L-shaped drawing; otherwise, by Lemma 3.2(a), B'' has an optimal L-shaped drawing. Merging D'_U and D''_L , one can construct an optimal $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B without introducing any new bend, as illustrated in Figure 4.7(d). Clearly $D_{3\pi/2}$ is an optimal drawing of B , and hence $\text{bend}(B, 3\pi/2, v) = \text{bend}(B)$. $\square$

The proof of Lemma 4.7 immediately yields the following linear algorithm **OuterSeries**(B, v, D) to find an optimal $(3\pi/2, v)$ -outer drawing D of B , with $\text{bend}(D) = \text{bend}(B)$ if $B - v$ is a series connection of subgraphs.

OuterSeries(B, v, D);

begin

 Define B' and B'' as in Figures 4.7(a) and (b);

if both B' and B'' are diamond graphs,

then

 Find no-bend L-shaped drawings D'_L of B' and D''_L of B'' by **Diamond**;

 Construct a drawing D with one bend from D'_L and D''_L as in Figure 4.7(c);

else

 Assume that B' is not a diamond graph;

 Find an optimal U-shaped drawing D'_U of B' by **NonDiamond**;

 Find an optimal L-shaped drawing D''_L of B'' by **Diamond**

or NonDiamond;

 Construct D from D'_U and D''_L as in Figure 4.7(d);

end.

We shall thus consider the remaining case where $B - v$ is a parallel connection of subgraph. Roughly speaking, for the case, we reduce the problem of finding an optimal $(3\pi/2, v)$ -outer drawing of B to those for smaller graphs B'_{id} and B''_{id} illustrated in Figure 4.8. The detail is given in the following proof of Lemma 4.2(a).

FIG. 4.8. Illustration of the proof of Lemma 4.2.

Proof of Lemma 4.2(a). We prove (4.3) by induction on the number $n(B)$ of vertices of B . If $n(B) = 3$, that is, $B = K_3$, then $\text{bend}(B, 3\pi/2, v) = 1$, $\text{bend}(B, \pi, v) = 2$, and $\text{bend}(B, \pi/2, v) = 3$, and hence (4.3) holds. One may thus assume that $n(B) \geq 4$, and inductively assume that (4.3) holds for every biconnected series-parallel graph of at most $n(B) - 1$ vertices. We now prove (4.3) for B . By Lemmas 4.6 and 4.7, one may assume that B_v is not a diamond graph and $B - v$ is a parallel connection of subgraphs. Then $B - v$ is biconnected, and the two vertices v_1 and v_2 that are adjacent to v in B have degree three in B , as illustrated in Figure 4.8(a). Splitting vertices v_1 and v_2 of $B - v$, one can obtain two edge-disjoint series-parallel subgraphs B' and B'' of B , as illustrated in Figure 4.8(c). Clearly $n(B'), n(B'') \geq 2$.

We prove only $\text{bend}(B, 3\pi/2, v) \leq \text{bend}(B, \pi, v)$, because one can similarly prove $\text{bend}(B, 3\pi/2, v) \leq \text{bend}(B, \pi/2, v)$. Let D_π^* be an optimal (π, v) -outer drawing of B , then $\text{bend}(D_\pi^*) = \text{bend}(B, \pi, v)$. It suffices to prove that $\text{bend}(B, 3\pi/2, v) \leq \text{bend}(D_\pi^*)$. There are the following three cases to consider.

Case 1: D_π^* has a bend on edge vv_1 or vv_2 .

Erasing from D_π^* a line segment connecting v and a bend in the edge, one can obtain a drawing D_v of B_v . Since a bend in D_π^* is regarded as a vertex in D_v , we have $\text{bend}(B_v) \leq \text{bend}(D_v) = \text{bend}(D_\pi^*) - 1$.

Since B_v is not a diamond graph, by Lemma 3.2(a) B_v has an optimal U-shape drawing D_{vU} . From D_{vU} , one can construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with a new bend. (See Figures 3.8(e) and (f).) Thus we have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D_{vU}) + 1 \\ &= \text{bend}(B_v) + 1 \\ &\leq \text{bend}(D_\pi^*). \end{aligned}$$

Case 2: D_π^* has no bend on edges vv_1 and vv_2 , and either $n(B') = 2$ or $n(B'') = 2$.

One may assume without loss of generality that $n(B') = 2$, and hence B' consists of a single edge v_1v_2 . Since D_π^* has no bend on the edges v_1v and vv_2 , they are drawn on the same straight line segment in D_π^* . Therefore the edge v_1v_2 in B' must have two or more bends in D_π^* , and hence $\text{bend}(D_\pi^*[B']) \geq 2$. Since B has no multiple edges, $n(B'') \geq 3$ and B'' is a 2-legged series-parallel graph.

If B'' is a diamond graph, then $\text{bend}(B'') = 0$ and B'' has a U-shaped drawing D_U'' with one bend as known from the example in Figure 2.6. If B'' is not a diamond graph, then by Lemma 3.2(a), B'' has an optimal U-shaped drawing D_U'' . In either case $\text{bend}(D_U'') \leq \text{bend}(B'') + 1$. One can easily extend D_U'' to a $(3\pi/2, v)$ -outer drawing

FIG. 4.9. (a)–(f) All of the possible (π, v) -outer drawings D_π^* , and (g), (h) constructions of $D_{3\pi/2}$.

$D_{3\pi/2}$ with a new bend. We thus have

$$\begin{aligned}
 \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\
 &= 1 + \text{bend}(D_U'') \\
 &\leq 1 + \text{bend}(B'') + 1 \\
 &\leq 2 + \text{bend}(D_\pi^*|B'') \\
 &\leq \text{bend}(D_\pi^*|B') + \text{bend}(D_\pi^*|B'') \\
 &= \text{bend}(D_\pi^*).
 \end{aligned}$$

Case 3: Otherwise.

In this case, $n(B'), n(B'') \geq 3$, and hence both B' and B'' are 2-legged series-parallel graphs. Identify v_1 with v_2 as a new vertex v^* in B' , and let B'_{id} be the resulting graph, as illustrated in Figure 4.8(d). Similarly define B''_{id} . Then both B'_{id} and B''_{id} are biconnected series-parallel graphs and have a vertex v^* of degree two. Since D_π^* has no bend on the two edges v_1v and vv_2 , all of the possible (π, v) -outer drawings of B are those illustrated in Figures 4.9(a)–(f) after interchanging the roles of B' and B'' and the roles of v_1 and v_2 , depending on the angles of v_1 and v_2 in D_π^* . There are the following two subcases to consider.

Case 3.1: D_π^* is a drawing illustrated in Figure 4.9(a) or (b).

In this case, one can construct from $D_\pi^*|B'$ a $(3\pi/2, v^*)$ -outer drawing of B'_{id} with no new bends, and hence $\text{bend}(B'_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(D_\pi^*|B')$. Let $D'_{\text{id}3\pi/2}$ be an optimal $(3\pi/2, v^*)$ -outer drawing of B'_{id} . Since B'' is 2-legged, B'' has an optimal L-shaped drawing D''_L . Merging $D'_{\text{id}3\pi/2}$ and D''_L , one can easily construct a $(3\pi/2, v)$ -

outer drawing $D_{3\pi/2}$ of B , as illustrated in Figure 4.9(g). We thus have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D'_{\text{id}3\pi/2}) + \text{bend}(D'_L) \\ &= \text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B'') \\ &\leq \text{bend}(D_\pi^*|B') + \text{bend}(D_\pi^*|B'') \\ &= \text{bend}(D_\pi^*). \end{aligned}$$

Case 3.2: D_π^* is a drawing illustrated in Figures 4.9(c)–(f).

We first prove that if D_π^* is a drawing in Figure 4.9(c) or (d), then

$$(4.5) \quad \text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(D_\pi^*|B'').$$

One can construct from $D_\pi^*|B''$ an (α, v^*) -outer drawing of B''_{id} with no new bend, where $\alpha = \pi$ for Figure 4.9(c) and $\alpha = \pi/2$ for Figure 4.9(d). We thus have $\text{bend}(B''_{\text{id}}, \alpha, v^*) \leq \text{bend}(D_\pi^*|B'')$. Since B''_{id} is a biconnected series-parallel graph with $d(v^*, B''_{\text{id}}) = 2$ and $n(B''_{\text{id}}) < n(B)$, by the inductive hypothesis we have $\text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(B''_{\text{id}}, \alpha, v^*)$. Thus we have (4.5).

We also have the following fact, whose proof will be given in section 4.4.

FACT 1. *If D_π^* is a drawing illustrated in Figures 4.9(e) and (f), then $\text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(D_\pi^*|B'')$.*

Let $D'_{\text{id}3\pi/2}$ be an optimal $(3\pi/2, v^*)$ -outer drawing of B''_{id} . Let D'_L be an optimal L-shaped drawing of B' . Merging D'_L and $D'_{\text{id}3\pi/2}$, one can easily construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B , as illustrated in Figure 4.9(h). Thus, using (4.5) and Fact 1 we have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D'_L) + \text{bend}(D'_{\text{id}3\pi/2}) \\ &= \text{bend}(B') + \text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \\ &\leq \text{bend}(D_\pi^*|B') + \text{bend}(D_\pi^*|B'') \\ &= \text{bend}(D_\pi^*). \quad \square \end{aligned}$$

We then have the following lemma.

LEMMA 4.8. *Suppose that B_v is not a diamond graph and that $B - v$ is a parallel connection of subgraphs. (See Figure 4.8.) Then the following (a) and (b) hold:*

- (a) *if $n(B') = 2$ or $n(B'') = 2$, then $\text{bend}(B, 3\pi/2, v) = \text{bend}(B_v) + 1$; and*
- (b) *if $n(B'), n(B'') \geq 3$, then*

$$(4.6) \quad \begin{aligned} \text{bend}(B, 3\pi/2, v) &= \min\{\text{bend}(B_v) + 1, \\ &\quad \text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B''), \\ &\quad \text{bend}(B') + \text{bend}(B''_{\text{id}}, 3\pi/2, v^*)\}. \end{aligned}$$

Proof. We first prove

$$(4.7) \quad \text{bend}(B, 3\pi/2, v) \leq \text{bend}(B_v) + 1.$$

Since $n(B) \geq 3$, $n(B_v) \geq 4$. Since B_v is not a diamond graph, by Lemma 3.2(a), B_v has an optimal U-shaped drawing D_{vU} . From D_{vU} , one can easily construct a

$(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with a new bend. (See Figures 3.8(e) and (f).) Therefore,

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D_{vU}) + 1 \\ &= \text{bend}(B_v) + 1. \end{aligned}$$

(a) We then prove (a). By (4.7), it suffices to prove

$$(4.8) \quad \text{bend}(B, 3\pi/2, v) \geq \text{bend}(B_v) + 1.$$

Since B has no multiple edges and either $n(B') = 2$ or $n(B'') = 2$, one may assume without loss of generality that $n(B') = 2$, and hence $n(B'') \geq 3$. Let $D_{3\pi/2}^*$ be an optimal $(3\pi/2, v)$ -outer drawing of B , then $\text{bend}(B, 3\pi/2, v) = \text{bend}(D_{3\pi/2}^*)$. If $D_{3\pi/2}^*$ has a bend on an edge incident to v , then $\text{bend}(D_{3\pi/2}^*) - 1 \geq \text{bend}(B_v)$, and hence $\text{bend}(B, 3\pi/2, v) = \text{bend}(D_{3\pi/2}^*) \geq \text{bend}(B_v) + 1$. One may thus assume that $D_{3\pi/2}^*$ has no bend on the two edges of B incident to v . Then $D_{3\pi/2}^*$ has one or more bends on the edge in B' , and hence $\text{bend}(D_{3\pi/2}^*) \geq 1$. Let $\overline{B''}$ be the complement of B'' in B . Then $\overline{B''}$ is $K_3 = v_1vv_2$, and hence

$$(4.9) \quad \text{bend}(B_{3\pi/2}^* | \overline{B''}) \geq \text{bend}(\overline{B''}) \geq 1.$$

By (2.2) we have

$$(4.10) \quad \text{bend}(D_{3\pi/2}^*) = \text{bend}(D_{3\pi/2}^* | B'') + \text{bend}(D_{3\pi/2}^* | \overline{B''}).$$

There are the following two cases to consider.

Case 1: B'' is a diamond graph.

We first claim that $\text{bend}(D_{3\pi/2}^*) \geq 2$. Suppose for a contradiction that $\text{bend}(D_{3\pi/2}^*) = 1$. Then by (4.9) and (4.10) we have

$$\text{bend}(D_{3\pi/2}^* | \overline{B''}) = 1$$

and

$$\text{bend}(D_{3\pi/2}^* | B'') = 0.$$

Therefore, by Lemma 3.1(c), the no-bend drawing $D_{3\pi/2}^* | B''$ of B'' must be I- or L-shaped. Since $D_{3\pi/2}^*$ has no bend on edges vv_1 and vv_2 , $D_{3\pi/2}^* | B''$ must be L-shaped. Then $D_{3\pi/2}^*$ must have three or more bends on the edge v_1v_2 in B' , and hence $\text{bend}(D_{3\pi/2}^* | \overline{B''}) \geq 3$, contrary to $\text{bend}(D_{3\pi/2}^* | \overline{B''}) = 1$.

Since B'' is a diamond graph, by Lemma 3.1(a), B'' has a no-bend L-shaped drawing D_L'' . From D_L'' , one can easily construct a drawing D_v of B_v with one bend, as illustrated in Figure 4.10(a), and hence $\text{bend}(B_v) \leq \text{bend}(D_v) = 1$. Thus we have $\text{bend}(B, 3\pi/2, v) = \text{bend}(D_{3\pi/2}^*) \geq 2 \geq \text{bend}(B_v) + 1$.

Case 2: B'' is not a diamond graph.

Since $\text{bend}(D_{3\pi/2}^* | B'') \geq \text{bend}(B'')$, by (4.9) and (4.10) we have

$$(4.11) \quad \text{bend}(D_{3\pi/2}^*) \geq \text{bend}(B'') + 1.$$

FIG. 4.10. Illustration for the proof of Lemma 4.8(a).

Since B'' is not a diamond graph, by Lemma 3.2(a), B'' has an optimal U-shaped drawing D''_U . From D''_U , one can easily construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with one new bend, as illustrated in Figure 4.10(b). We then have

$$\begin{aligned}
 \text{bend}(D_{3\pi/2}) &= \text{bend}(D''_U) + 1 \\
 (4.12) \qquad \qquad &= \text{bend}(B'') + 1.
 \end{aligned}$$

Erasing from $D_{3\pi/2}$ the line segment connecting v and a bend, one can obtain a drawing D_v of B_v , and hence

$$\begin{aligned}
 \text{bend}(B_v) &\leq \text{bend}(D_v) \\
 (4.13) \qquad \qquad &= \text{bend}(D_{3\pi/2}) - 1.
 \end{aligned}$$

By (4.11)–(4.13) we have

$$\begin{aligned}
 \text{bend}(B, 3\pi/2, v) &= \text{bend}(D_{3\pi/2}^*) \\
 &\geq \text{bend}(B'') + 1 \\
 &= \text{bend}(D_{3\pi/2}) \\
 &\geq \text{bend}(B_v) + 1.
 \end{aligned}$$

(b) We then prove (b). We first prove that

$$\begin{aligned}
 \text{bend}(B, 3\pi/2, v) &\leq \min\{\text{bend}(B_v) + 1, \\
 (4.14) \qquad \qquad &\text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B''), \\
 &\text{bend}(B') + \text{bend}(B''_{\text{id}}, 3\pi/2, v^*)\}.
 \end{aligned}$$

Since (4.7) holds, it suffices to prove that

$$(4.15) \qquad \text{bend}(B, 3\pi/2, v) \leq \text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B'')$$

and

$$(4.16) \qquad \text{bend}(B, 3\pi/2, v) \leq \text{bend}(B') + \text{bend}(B''_{\text{id}}, 3\pi/2, v^*).$$

We verify only (4.15), because one can similarly verify (4.16).

Let $D'_{\text{id}3\pi/2}$ be an optimal $(3\pi/2, v^*)$ -outer drawing of B'_{id} . Since $n(B'') \geq 3$, there is an optimal L-shaped drawing D''_L of B'' . Merging $D'_{\text{id}3\pi/2}$ and D''_L , one can

 FIG. 4.11. All of the possible $(3\pi/2, v)$ -outer drawings $D_{3\pi/2}^*$ of B .

easily construct a $(3\pi/2, v)$ -outer drawing $D_{3\pi/2}$ of B with no new bend, as illustrated in Figure 4.9(g). We thus have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D'_{\text{id}, 3\pi/2}) + \text{bend}(D''_{\text{L}}) \\ &= \text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B''). \end{aligned}$$

We next prove that

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &\geq \min\{\text{bend}(B_v) + 1, \\ &\quad \text{bend}(B'_{\text{id}}, 3\pi/2, v^*) + \text{bend}(B''), \\ &\quad \text{bend}(B') + \text{bend}(B'_{\text{id}}, 3\pi/2, v^*)\}. \end{aligned} \quad (4.17)$$

Let $D_{3\pi/2}^*$ be an optimal $(3\pi/2, v)$ -outer drawing of B , then $\text{bend}(B, 3\pi/2, v) = \text{bend}(D_{3\pi/2}^*)$. If $D_{3\pi/2}^*$ has a bend on an edge incident to v , then $\text{bend}(D_{3\pi/2}^*) - 1 \geq \text{bend}(B_v)$, and hence $\text{bend}(B, 3\pi/2, v) = \text{bend}(D_{3\pi/2}^*) \geq \text{bend}(B_v) + 1$ and (4.17) holds. One may thus assume that $D_{3\pi/2}^*$ has no bend on the two edges of B incident to v . Then all of the possible $(3\pi/2, v)$ -outer drawings of B are those illustrated in Figures 4.11(a)–(f) after interchanging the roles of B' and B'' and the roles of v_1 and v_2 .

We now claim

$$\text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(D_{3\pi/2}^*|B''). \quad (4.18)$$

If $D_{3\pi/2}^*$ is a drawing illustrated in Figure 4.11(f), then from $D_{3\pi/2}^*|B''$, one can easily construct a $(3\pi/2, v^*)$ -outer drawing of B''_{id} with no new bend, and hence (4.18) holds. One may thus assume that $D_{3\pi/2}^*$ is a drawing illustrated in Figures 4.11(a)–(e). Then one can construct from $D_{3\pi/2}^*|B''$ an (α, v^*) -outer drawing of B''_{id} with no new bend, where $\alpha = \pi/2$ for Figures 4.11(a)–(c) and $\alpha = \pi$ for Figures 4.11(d) and (e). We thus

have $\text{bend}(B''_{\text{id}}, \alpha, v^*) \leq \text{bend}(D^*_{3\pi/2}|B'')$. By Lemma 4.2(a), $\text{bend}(B''_{\text{id}}, 3\pi/2, v^*) \leq \text{bend}(B''_{\text{id}}, \alpha, v^*)$. These two equations imply (4.18).

By (4.18) we have

$$\begin{aligned} \text{bend}(B, 3\pi/2, v) &= \text{bend}(D^*_{3\pi/2}) \\ &= \text{bend}(D^*_{3\pi/2}|B') + \text{bend}(D^*_{3\pi/2}|B'') \\ &\geq \text{bend}(B') + \text{bend}(B''_{\text{id}}, 3\pi/2, v^*), \end{aligned}$$

and hence (4.17) holds true. $\square$

By Lemmas 4.6, 4.7, and 4.8 and the proofs of (4.7) and (4.14) we have the following recursive algorithm **OuterDrawing**($B, v, D, D_{vI}, D_{vL}, D_{vU}$) to find an optimal $(3\pi/2, v)$ -outer drawing D of a biconnected series-parallel graph B with a vertex v of degree two. It finds an optimal I-shaped drawing D_{vI} , an optimal L-shaped drawing D_{vL} , and an optimal U-shaped drawing D_{vU} of B_v , too.

OuterDrawing($B, v, D, D_{vI}, D_{vL}, D_{vU}$);

begin

Case 1: B_v is a diamond graph.

OuterDiamond(B, v, D); {cf. Lemma 4.6}

Find a no-bend I-shaped drawing D_{vI} and a no-bend L-shaped drawing D_{vL} of B_v by **Diamond**;

Insert a dummy vertex of degree two in an edge of B_v , as illustrated in Figure 2.6(e);

Obtain a U-shaped drawing D_{vU} of B_v with one bend by regarding the dummy vertex as a bend;

Case 2: B_v is not a diamond graph, and $B - v$ is a series connection of subgraphs.

OuterSeries(B, v, D); {cf. Lemma 4.7}

Find an optimal I-shaped drawing D_{vI} , an optimal L-shaped drawing D_{vL} , and an optimal U-shaped drawing D_{vU} of B_v by **NonDiamond**;

Case 3: B_v is not a diamond graph, and $B - v$ is a parallel connection of subgraphs.

{cf. the proofs of (4.7) and (4.14).}

Case 3.1: Either $n(B') = 2$ or $n(B'') = 2$.

Find an optimal I-shaped drawing D_{vI} , an optimal L-shaped drawing D_{vL} , and an optimal U-shaped drawing D_{vU} of B_v by **NonDiamond**;

Extend D_{vU} to a $(3\pi/2, v)$ -outer drawing D of B with a new bend;

{See Figures 3.8(e) and (f).}

Case 3.2: $n(B'), n(B'') \geq 3$.

{One may assume without loss of generality that B' is not a diamond graph.}

OuterDrawing($B'_{\text{id}}, v^*, D'_{\text{id}}, D'_{v^*I}, D'_{v^*L}, D'_{v^*U}$);

OuterDrawing($B''_{\text{id}}, v^*, D''_{\text{id}}, D''_{v^*I}, D''_{v^*L}, D''_{v^*U}$);

Combine a U-shaped drawing D'_{v^*U} of $B' (= B'_{\text{id}v^*})$ and an I-shaped drawing D''_{v^*I} of $B'' (= B''_{\text{id}v^*})$ to an optimal I-shaped drawing D_{vI} , an optimal L-shaped drawing D_{vL} , and an optimal U-shaped drawing D_{vU} of B_v , as illustrated in Figure 3.4(e);

{cf. Lemma 3.2}

Let $x = \min\{\text{bend}(D_{vU}) + 1, \text{bend}(D'_{\text{id}}) + \text{bend}(D''_{\text{L}}), \text{bend}(D'_{\text{L}}) + \text{bend}(D''_{\text{id}})\}$, where $D'_{\text{L}} = D'_{v^*L}$ and $D''_{\text{L}} = D''_{v^*L}$ are optimal L-shaped drawings of $B' = B'_{\text{id}v^*}$ and $B'' = B''_{\text{id}v^*}$, respectively;

Case 3.2.1: $x = \text{bend}(D_{vU}) + 1$.

Extend D_{vU} to a $(3\pi/2, v)$ -outer drawing D of B with a new bend;

{See Figure 3.8(e).}

Case 3.2.2: $x = \text{bend}(D'_{id}) + \text{bend}(D''_L)$.

Construct a $(3\pi/2, v)$ -outer drawing D of B by merging D'_{id} and D''_L , as illustrated in Figure 4.9(g);

Case 3.2.3: $x = \text{bend}(D'_L) + \text{bend}(D''_{id})$.

Construct a $(3\pi/2, v)$ -outer drawing D of B by merging D'_L and D''_{id} , as illustrated in Figure 4.9(h);

end.

Clearly **OuterDrawing** correctly finds an optimal $(3\pi/2, v)$ -outer drawing D of B . We now show that **OuterDrawing** runs in linear time. Let $T(B)$ be the execution time of **OuterDrawing** $(B, v, D, D_{vI}, D_{vL}, D_{vU})$. Let $T_1(B)$ be the execution time of **OuterDrawing** when **Case 1** occurs, that is, B_v is a diamond graph. We similarly define $T_2(B)$, $T_{3.1}(B)$, and $T_{3.2}(B)$ for **Cases 2, 3.1, and 3.2**, respectively. Then clearly

$$T(B) = \max\{T_1(B), T_2(B), T_{3.1}(B), T_{3.2}(B)\},$$

$$T_1(B), T_2(B), T_{3.1}(B) = O(n(B)),$$

$$T_{3.2}(B) = T(B'_{id}) + T(B''_{id}) + O(1),$$

and

$$n(T(B'_{id})) + n(T(B''_{id})) < n(B).$$

We hence have $T(B) = O(n(B))$. We have thus completed a proof of Lemma 4.2(c).

Since $\text{bend}(B_v) \leq \text{bend}(B)$, by Lemmas 4.6, 4.7, and 4.8, we immediately have $\text{bend}(B, 3\pi/2, v) \leq \text{bend}(B) + 1$, completing a proof of Lemma 4.2(b).

Let a series-parallel graph G take the form in Figure 4.1(a), and let D_a be a drawing of G , as illustrated in Figure 4.3(a). Then we have

$$\begin{aligned} \text{bend}(G) &\leq \text{bend}(D_a) \\ &= \text{bend}(B_1) + \text{bend}(G_{\text{int}}) + \text{bend}(B_p, 3\pi/2, s_p). \end{aligned}$$

Clearly

$$\begin{aligned} \text{bend}(G_{\text{int}}) &= \text{bend}(D_{\text{intI}}) \\ &= \sum_{i=2}^{p-1} \text{bend}(B_i) \end{aligned}$$

and

$$\text{bend}(B_p, 3\pi/2, s_p) \leq \text{bend}(B_p) + 1.$$

We thus have

$$(4.19) \quad \text{bend}(G) \leq \sum_{i=1}^p \text{bend}(B_i) + 1.$$

FIG. 4.12. Biconnected graph H , 2-legged graph H_u , and C-shaped drawing D_u .

Equations (4.1) and (4.19) immediately imply (4.2).

Omitting the operations in Cases 3.2.2 and 3.2.3 in **OuterDrawing**, one can obtain a nonrecursive algorithm **ApproOuterDrawing** to find a $(3\pi/2, v)$ -outer drawing D of B such that D is not always an optimal $(3\pi/2, v)$ -outer drawing, but $\text{bend}(D) \leq \text{bend}(B) + 1$. Replacing **OuterDrawing** in **NonBiconnected** by **ApproOuterDrawing** and finding only the drawing D_a in Figure 4.3, one can obtain a simple linear algorithm to find a drawing D of G such that

$$\text{bend}(D) \leq \sum_{i=1}^p \text{bend}(B_i) + 1.$$

4.4. Proof of Fact 1. In this subsection we give a proof of Fact 1 in Case 3.2 of the proof of Lemma 4.2(a).

A 2-legged series-parallel graph B'' and a biconnected series-parallel graph B''_{id} in Fact 1 are illustrated in Figures 4.8(c) and (d), respectively. B'' can be obtained from B''_{id} by splitting a vertex v^* of degree two to two vertices v_1 and v_2 . The drawing D_π^* in Fact 1 is illustrated in Figure 4.9(e) or (f). We call a drawing of a 2-legged series-parallel graph illustrated in Figure 4.12(c) a *C-shaped drawing*. Then $D_\pi^*[B''$ in Figure 4.9(e) or (f) is a C-shaped drawing of B'' . Thus it suffices to prove the following fact. (Regard B''_{id} as H , B'' as H_u , and v^* as u .)

FACT 2. Let H be a biconnected series-parallel graph with a vertex u of degree two, let H_u be a 2-legged series-parallel graph obtained from H by splitting u to two vertices u_1 and u_2 . If D_u is a C-shaped drawing of H_u , then

$$(4.20) \quad \text{bend}(H, 3\pi/2, u) \leq \text{bend}(D_u).$$

(See Figure 4.12.)

Proof. We prove (4.20) by induction on the number $n(H)$ of vertices of H . If $n(H) = 3$, that is, $H = K_3$, then $\text{bend}(H, 3\pi/2, v) = 1$, $\text{bend}(D_u) \geq 4$, and hence (4.20) holds true. One may thus assume that $n(H) \geq 4$, and inductively assume that (4.20) holds for every biconnected series-parallel graph of at most $n(H) - 1$ vertices. We now prove that (4.20) holds for H . There are the following two cases to consider.

Case 1: $H - u$ is a series connection of subgraphs.

In this case, H_u has a bridge e , and has two subgraphs H' and H'' , each of which is a 2-legged series-parallel graph and has e as a leg. (See Figures 4.7(a) and (b).) Then we have the following two subcases to consider.

Case 1.1: Both H' and H'' are diamond graphs.

In this case, H' and H'' have no-bend L-shaped drawings D'_L and D''_L , respectively. Merging D'_L and D''_L , one can easily construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}^*$ of H with one bend, and hence $\text{bend}(D_{3\pi/2}^*) = 1$. (See Figure 4.7(c).) Since both H' and H'' are diamond graphs, one can easily observe that $D_{3\pi/2}^*$ is an optimal $(3\pi/2, u)$ -outer drawing of H and that a C-shaped drawing D_u of H_u needs one or more bends. We thus have $\text{bend}(H, 3\pi/2, u) = \text{bend}(D_{3\pi/2}^*) = 1 \leq \text{bend}(D_u)$.

Case 1.2: Either H' or H'' is not a diamond graph.

In this case, one may assume without loss of generality that H' is not a diamond graph. Then H' has an optimal U-shaped drawing D'_U . H'' has an optimal L-shaped drawing D''_L . Merging D'_U and D''_L , one can easily construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H with no new bends. (See Figure 4.7(d).) Thus

$$\begin{aligned} \text{bend}(H, 3\pi/2, u) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D'_U) + \text{bend}(D''_L) \\ &= \text{bend}(H') + \text{bend}(H'') \\ &\leq \text{bend}(D_u|H') + \text{bend}(D_u|H'') \\ &= \text{bend}(D_u). \end{aligned}$$

Case 2: $H - u$ is a parallel connection of subgraphs.

Consider first the case where H_u is a diamond graph. By Lemma 4.6, $\text{bend}(H, 3\pi/2, u) = \text{bend}(H)$. Since H_u has a U-shaped drawing with one bend, we have $\text{bend}(H) \leq 2$. Since D_u is a C-shaped drawing of a diamond graph H_u , one can easily observe that $\text{bend}(D_u) \geq 2$. We thus have

$$\text{bend}(H, 3\pi/2, u) = \text{bend}(H) \leq 2 \leq \text{bend}(D_u).$$

Consider next the case where H_u is not a diamond graph. Regarding H as B in Figure 4.8, we define H' , H'' , H'_{id} , and H''_{id} , as illustrated in Figure 4.8. Then we have the following three subcases.

Case 2.1: D_u has a bend on a leg of H_u .

In this case, erasing a line segment connecting a terminal and a bend from D_u , one can obtain a drawing $\widetilde{D}_u$ of H_u such that $\widetilde{D}_u$ is not always C-shaped and $\text{bend}(H_u) \leq \text{bend}(\widetilde{D}_u) = \text{bend}(D_u) - 1$. Since H_u is not a diamond graph, H_u has an optimal U-shape drawing D_{uU} . From D_{uU} , one can construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H with a new bend. (See Figures 3.8(e) and (f).) We thus have

$$\begin{aligned} \text{bend}(H, 3\pi/2, u) &\leq \text{bend}(D_{3\pi/2}) \\ &= \text{bend}(D_{uU}) + 1 \\ &= \text{bend}(H_u) + 1 \\ &\leq \text{bend}(\widetilde{D}_u) + 1 \\ &= \text{bend}(D_u). \end{aligned}$$

Case 2.2: D_u has no bend on the two legs of H_u , and either $n(H') = 2$ or $n(H'') = 2$.

One may assume without loss of generality that $n(H') = 2$, and hence H' consists of a single edge. Then H'' is a 2-legged series-parallel graph. Since the C-shaped drawing D_u has no bend on the two legs of H_u , we have $\text{bend}(D_u|H') \geq 4$.

FIG. 4.13. (a)–(f) All of the possible C-shaped drawings D_u of H_u , and (g) construction of a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H .

Consider first the case where H'' is a diamond graph. Then H_u has a U-shaped drawing D_{uU} with one bend. From D_{uU} , one can construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H with two bends. Thus $\text{bend}(H, 3\pi/2, u) \leq \text{bend}(D_{3\pi/2}) = 2 < \text{bend}(D_u|H') \leq \text{bend}(D_u)$.

Consider next the case where H'' is not a diamond graph. Then by Lemma 3.2(a), H'' has an optimal U-shaped drawing D''_U . From D''_U , one can construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H with a new bend. We thus have

$$\begin{aligned}
 \text{bend}(H, 3\pi/2, u) &\leq \text{bend}(D_{3\pi/2}) \\
 &= 1 + \text{bend}(D''_U) \\
 &= 1 + \text{bend}(H'') \\
 &< \text{bend}(D_u|H') + \text{bend}(D_u|H'') \\
 &= \text{bend}(D_u).
 \end{aligned}$$

Case 2.3: D_u has no bend on the two legs of H_u , and $n(H'), n(H'') \geq 3$.

In this case H' and H'' are 2-legged series-parallel graphs. All of the possible C-shaped drawings D_u of H_u for this case are those illustrated in Figures 4.13(a)–(f).

Let $D'_{\text{id}3\pi/2}$ be an optimal $(3\pi/2, u^*)$ -outer drawing of H'_{id} . Let D''_L be an optimal L-shaped drawing of H'' . Merging $D'_{\text{id}3\pi/2}$ and D''_L , one can easily construct a $(3\pi/2, u)$ -outer drawing $D_{3\pi/2}$ of H , as illustrated in Figure 4.13(g). We thus have

$$\begin{aligned}
 \text{bend}(H, 3\pi/2, u) &\leq \text{bend}(D_{3\pi/2}) \\
 &= \text{bend}(D'_{\text{id}3\pi/2}) + \text{bend}(D''_L) \\
 (4.21) \quad &= \text{bend}(H'_{\text{id}}, 3\pi/2, u^*) + \text{bend}(H'').
 \end{aligned}$$

We now claim

$$(4.22) \quad \text{bend}(H'_{\text{id}}, 3\pi/2, u^*) \leq \text{bend}(D_u|H').$$

If D_u is a drawing illustrated in Figure 4.13(f), then $D_u|H'$ is a C-shaped drawing of H' , and hence the inductive hypothesis of the proof of Fact 2 implies (4.22). One

may thus assume that D_u is a drawing illustrated in Figures 4.13(a)–(e). Then one can construct from $D_u|H'$ an (α, u^*) -outer drawing with no new bend, where $\alpha = \pi$ for Figures 4.13(a)–(c) and $\alpha = \pi/2$ for Figures 4.13(d) and (e). Hence

$$(4.23) \quad \text{bend}(H'_{\text{id}}, \alpha, u^*) \leq \text{bend}(D_u|H').$$

Since $n(H'_{\text{id}}) < n(B)$ for the graph B in Fact 1, by the inductive hypothesis of the proof of Lemma 4.2(a) we have

$$(4.24) \quad \text{bend}(H'_{\text{id}}, 3\pi/2, u^*) \leq \text{bend}(H'_{\text{id}}, \alpha, u^*).$$

Equations (4.23) and (4.24) imply (4.22).

By (4.21) and (4.22) we have

$$\begin{aligned} \text{bend}(H, 3\pi/2, u) &\leq \text{bend}(D_u|H') + \text{bend}(D_u|H'') \\ &= \text{bend}(D_u). \quad \square \end{aligned}$$

5. Conclusions. In this paper, we gave a linear algorithm to find an optimal orthogonal drawing of a series-parallel graph G of $\Delta \leq 3$ in the variable embeddings setting. Our algorithm works well even if G has multiple edges or is not biconnected and is simpler and faster than the previously known one for biconnected series-parallel simple graphs [4, 5]. One can easily extend our algorithm so that it finds an optimal orthogonal drawing of a partial 2-tree of $\Delta \leq 3$. Note that the so-called block-cutvertex graph of a partial 2-tree is a tree although the block-cutvertex graph of a series-parallel graph is a path. We gave a best possible bound on $\text{bend}(G)$: $\text{bend}(G) \leq (n(G) + 4)/3$.

In an *orthogonal grid drawing*, every vertex has an integer coordinate. The *size* of an orthogonal grid drawing is the sum of the width and height of the minimum axis-parallel rectangle enclosing the drawing. Using an argument which is similar to that in sections 3 and 4 but is more lengthy, one can prove that every series-parallel graph G of $\Delta \leq 3$ has an optimal orthogonal grid drawing of size $\leq 3N/4$, and every biconnected series-parallel graph G of $\Delta \leq 3$ has an optimal orthogonal grid drawing of size $\leq 2N/3 + 1$, where $N = n(G) + \text{bend}(G)$. The proof is omitted in the paper.

It is left as a future work to obtain a linear algorithm for a larger class of planar graphs.

Acknowledgment. We thank Dr. Md. Saidur Rahman for fruitful discussions.

HOW MANY POINTS CAN BE RECONSTRUCTED FROM k PROJECTIONS?*

JIRÍ MATOUŠEK[†], ALEŠ PRÍVĚTIVÝ[‡], AND PETR ŠKOVROŇ[‡]

Abstract. Let A be an n -point set in the plane. A *discrete X-ray* of A in direction u gives the number of points of A on each line parallel to u . We define $F(k)$ as the maximum number n such that there exist k directions $u_1, \dots, u_k$ such that every set of at most n points in the plane can be uniquely reconstructed from its discrete X-rays in these directions. A simple “cube” construction shows $F(k) \leq 2^{k-1}$. We establish the lower bound $F(k) \geq 2^{\Omega(k/\log k)}$ by reducing the problem through linear algebra to a graph-theoretic question, for which we then obtain an almost tight bound. As a part of the proof we establish a result in extremal theory that allows one to conclude that, under certain conditions, a graph has only at most a logarithmic density, which may be of independent interest. We also improve the upper bound to $F(k) \leq O(1.81712^k)$ (or $O(1.79964^k)$ if we allow A to be a multiset).

1. Introduction. Let A be a finite set of points in the plane. We consider A to be chosen by an adversary and inaccessible by itself, and the information available to us consists only of k discrete X-rays of A . The *discrete X-ray of A in direction u* specifies the number of points of A on every line parallel to u (this convenient terminology is borrowed from the field of geometric tomography). We say that A is *uniquely reconstructible for directions $u_1, u_2, \dots, u_k$* if there is no $B \neq A$ such that, for all $i = 1, 2, \dots, k$, the X-rays of A and B in direction u_i are identical.

It is not hard to see that every set A of $k - 1$ or fewer points is uniquely reconstructible for *any* k distinct directions. (To see this, we suppose that some $A \neq B$ have the same X-rays in directions $u_1, \dots, u_k$, we fix a point $a \in A \setminus B$, and we note that each line through a parallel to some u_i has to contain a point of B , forcing $|B| \geq k$.) This has been observed many times; the earliest reference seems to be Rényi [12]. If the directions are chosen by an adversary, then we cannot do any better in general: Figure 1 shows directions u_1, u_2 , and u_3 and two distinct point sets A and B (the black points and the white points, respectively) that cannot be distinguished. This can be generalized to any number k of equally spaced directions, where A and B are obtained by coloring the vertices of a regular $2k$ -gon alternately black and white.

Intuition suggests that the equally spaced directions in this example are “exceptionally bad” and that other sets of directions should allow for unique reconstruction of much larger sets. For given directions $u_1, u_2, \dots, u_k$ let us define

$$f(u_1, \dots, u_k) := \max\{n : \text{every } n\text{-point set is uniquely reconstructible for } u_1, \dots, u_k\}$$

FIG. 2. A construction of two sets with identical X-rays in given directions.

and

$$F(k) := \max_{u_1, u_2, \dots, u_k} f(u_1, \dots, u_k).$$

We have just noted that $f(u_1, \dots, u_k) \geq k - 1$ for all k -tuples of distinct $u_1, \dots, u_k$.

The following simple construction (also rediscovered several times) shows that, perhaps counterintuitively, $F(k)$ is finite for every k ; see Figure 2. Let $u_1, u_2, \dots, u_k$ be given distinct directions. For suitable nonzero scalars $\alpha_1, \dots, \alpha_k$ we set $v_i := \alpha_i u_i$, and we define

$$(1) \quad A := \{v(I) : I \subseteq [k], |I| \text{ even}\}, \quad B := \{v(I) : I \subseteq [k], |I| \text{ odd}\},$$

where we use the notation $[k] := \{1, 2, \dots, k\}$ and $v(I) := \sum_{i \in I} v_i$. First, it is easy to see that almost all choices of the α_i guarantee that all of the 2^k points $v(I)$, $I \subseteq [k]$, are distinct, and thus $|A| = |B| = 2^{k-1}$. Second, for every $i \in [k]$, each point $v(I) \in A$ can be paired with the point $v(I \triangle \{i\}) = v(I) \pm v_i \in B$ (where $\triangle$ denotes symmetric difference), and this shows that A and B have identical X-rays in direction u_i . Thus $F(k) \leq 2^{k-1} - 1$.

The only published lower bound on $F(k)$ we could find is roughly $k + \Omega(\sqrt{k})$, due to Bianchi and Longinetti [3]. After we started working on the problem, we learned from Pór that Tóth [13] announced an $\Omega(k^{3/2})$ lower bound, which has remained unpublished.

We have the following lower bound.

THEOREM 1.1. *There are constants $c > 0$ and k_0 such that*

$$F(k) > 2^{ck/\log k}$$

for all $k \geq k_0$. Moreover, for every $k \geq k_0$ there exists a finite set $\mathcal{P}_k$ of nonzero polynomials in $2k$ variables and with integer coefficients such that if $u_1 = (x_1, y_1), \dots, u_k = (x_k, y_k)$ are directions with $f(u_1, \dots, u_k) \leq 2^{ck/\log k}$, then $(x_1, x_2, \dots, x_k, y_1, \dots, y_k)$ is in the zero set of some polynomial in $\mathcal{P}_k$. Consequently, almost all (in the sense of measure) k -tuples of directions $u_1, \dots, u_k$ satisfy the stated lower bound.

Thus, the true order of magnitude of $F(k)$ is between $2^{ck/\log k}$ and 2^{k-1} . We don't have any good guess of what it might be, but at least we can improve the upper bound from 2^{k-1} to C^k for a suitable $C < 2$.

To prove an upper bound we need to construct, for any k -tuple $u_1, \dots, u_k$, two sets A and B with identical X-rays in these directions. It seems technically much easier to construct examples if we allow for *multisets* A and B (formally, an n -point multiset A can be regarded as an arbitrary mapping $[n] \rightarrow \mathbb{R}^2$, and in an X-ray of A , the points are counted with the appropriate multiplicities). We thus define $f_{\text{mult}}(u_1, \dots, u_k)$ as the largest n such that every n -point multiset is uniquely reconstructible for $u_1, \dots, u_k$, and $F_{\text{mult}}(k) := \max_{u_1, \dots, u_k} f_{\text{mult}}(u_1, \dots, u_k)$. Let us remark that the proof of the lower bound in Theorem 1.1 applies equally well to F_{mult} .

THEOREM 1.2. *We have $F(k) \leq O(C^k)$ for $C = 6^{1/3} \approx 1.81712$ and $F_{\text{mult}}(k) \leq O(C_1^k)$ for $C_1 = 198^{1/9} \approx 1.79964$.*

Higher dimensions. The reconstruction problem can naturally be generalized to point sets in $\mathbb{R}^d$. There are actually several possible generalizations, since we can x-ray the point set with lines as we did in the plane, but also with k -flats for some k between 1 and $d-1$. Here we comment only on the case of line X-rays, for which some simple observations below show that it is not too different from the planar case.

We thus say that $A, B \subset \mathbb{R}^d$ have the same X-rays in direction u if $|A \cap \ell| = |B \cap \ell|$ for every line ℓ parallel to u , and we define the function $F_d(k)$ analogous to $F(k)$.

The simple construction above for the upper bound on $F(k)$ works in any dimension, so $F_d(k) \leq 2^{k-1} - 1$ for all $d \geq 2$ and all k . By the method explained in section 4 below, it can be shown that for every fixed d there exists $\delta_d > 0$ with $F_d(k) = O((2 - \delta_d)^k)$.

On the other hand, we have $F_d(k) \geq F(k)$ for all d and k with $d \geq 2$. Indeed, let $u_1, \dots, u_k$ be directions in $\mathbb{R}^2$ with $f(u_1, \dots, u_k) = F(k)$. We identify $\mathbb{R}^2$ with a (2-dimensional) plane ρ in $\mathbb{R}^d$, so that we can consider the u_i as directions in $\mathbb{R}^d$. Now if $A, B \subset \mathbb{R}^d$ are distinct sets with identical X-rays in directions $u_1, \dots, u_k$, then for every plane σ parallel to ρ the sets $A \cap \sigma$ and $B \cap \sigma$ have identical X-rays in directions $u_1, \dots, u_k$ as well, and they have to be distinct for at least one σ . For such a σ we get $|A \cap \sigma| = |B \cap \sigma| > F(k)$ by the choice of $u_1, \dots, u_k$, and this concludes the proof of $F_d(k) \geq F(k)$.

Related work. Problems similar to those investigated in the present paper have been studied in a lively area called *geometric tomography*; see, e.g., the book by Gardner [8]. The classical tomography problem deals with reconstructing a set, or more generally a density function, from X-rays in all directions. *Discrete tomography* investigates the reconstruction problem for a finite (discrete) set of X-ray directions. Since reconstructing an arbitrary set is generally impossible, most of the work deals with special sets, say, convex ones.

For reconstructing finite sets A , most of the results in the literature concern the case where A is a lattice set, $A \subseteq \mathbb{Z}^2$, and the directions of the X-rays are integer vectors. A seminal paper by Gardner and Gritzmann [6] thoroughly examines the case where A is guaranteed to be a convex lattice set (that is, the intersection of $\mathbb{Z}^2$ with a convex set). In this case, they show that any 7 lattice directions suffice for unique reconstruction of every convex lattice set, while 6 directions need not suffice. Dulio, Gardner, and Peri [5] studied a variant of the problem ("point X-rays"): Instead of k directions, we have k points $p_1, \dots, p_k$, and we obtain the number of points of A on every line passing through one of the p_i . They show, for example, that the analogue of

our function $F(k)$ is unbounded in their setting. A few other papers with somewhat related results are [9], [7], [2].

2. A reduction of the lower bound to a combinatorial problem. This section contains the first part of the proof of the lower bound for $F(k)$. Given two sets A and B with identical X-rays in given k directions, we construct a graph with edges colored by k colors, and we show that for a generic choice of the directions this colored graph satisfies a combinatorial condition; namely, it doesn't contain two color-disjoint spanning trees. The subsequent section then deals with the resulting graph-theoretic problem.

The interchange graph. Let $u_1, \dots, u_k$ be fixed direction vectors, and let $A \subset \mathbb{R}^2$ be a set with the minimum number of points n that is not uniquely reconstructible for $u_1, \dots, u_k$. Thus there exists another set $B \subset \mathbb{R}^2$ with the same X-rays in these directions. We note that $A \cap B = \emptyset$ (if not, $A \setminus B$ and $B \setminus A$ would be smaller indistinguishable sets).

For each $i = 1, 2, \dots, k$, we construct a perfect matching E_i between A and B in such a way that, for each edge $\{a, b\} \in E_i$, the points $a \in A$ and $b \in B$ lie on the same line parallel to u_i . Thus, if a line ℓ in direction u_i contains a single point of A , and hence also a single point of B , these two points necessarily form an edge of E_i . If ℓ contains several points of A , these are matched arbitrarily, in a one-to-one fashion, to the points of $\ell \cap B$ (hence E_i need not be determined uniquely, but if there are several choices, we fix one once and for all). We note that $E_i \cap E_j = \emptyset$ for $i \neq j$.

We call the bipartite graph H with vertex set $A \cup B$ and with edge set $E(H) = E_1 \cup \dots \cup E_k$ an *interchange graph for directions* $u_1, \dots, u_k$. It has $2n$ vertices and kn edges.

For our exposition it will be convenient to consider the edges of an interchange graph to have colors: We say that an edge $e \in E_i$ has *color* i , and we write $c(e) = i$.

2.1. An algebraic necessary condition for interchange graphs. We begin by recalling several notions from algebraic graph theory.

Let $\vec{G} = (V, \vec{E})$ be a directed graph. For an edge $e = (u, v) \in \vec{E}$, we write $u = \text{tail}(e)$ and $v = \text{head}(e)$. The *incidence matrix* $D = D_{\vec{G}}$ is a $V \times \vec{E}$ matrix, with rows indexed by vertices of $\vec{G}$ and columns indexed by edges, given by

$$d_{v,e} := \begin{cases} +1 & \text{if } v = \text{head}(e), \\ -1 & \text{if } v = \text{tail}(e), \text{ and} \\ 0 & \text{otherwise.} \end{cases}$$

A *circulation* in $\vec{G}$ is any vector in $\ker D$, that is, a vector $\xi \in \mathbb{R}^{\vec{E}}$ with $D\xi = 0$.

Further we recall that an *orientation* of an undirected graph $G = (V, E)$ is a directed graph $(V, \vec{E})$ obtained by choosing, for every undirected edge $\{u, v\} \in E$, one of its vertices as a head and one as a tail (more formally, for every $\{u, v\} \in E$ we have exactly one of the directed edges (u, v) and (v, u) in $\vec{E}$). For notational convenience we will use the same letter for an undirected edge $e = \{u, v\}$ and for a directed version (u, v) of it.

We begin with the following necessary condition for interchange graphs.

LEMMA 2.1. *Let $H = (V, E)$ be a subgraph of an interchange graph for directions $u_1, u_2, \dots, u_k$, and let $\vec{H}$ be an arbitrary orientation of H . Then there exist reals α_e ,*

$e \in E$, all of them nonzero, such that for every circulation ξ in $\vec{H}$ we have

$$\sum_{e \in E} \alpha_e \xi_e x(u_{c(e)}) = 0,$$

and for every circulation ψ in $\vec{H}$ we have

$$\sum_{e \in E} \alpha_e \psi_e y(u_{c(e)}) = 0.$$

Here $c(e)$ denotes the color of the edge e (inherited from the interchange graph), and $x(u)$ and $y(u)$ denote the x -coordinate and y -coordinate, respectively, of a vector $u \in \mathbb{R}^2$.

Proof. First we note that if $G = (V, \vec{E})$ is a directed graph, ξ is a circulation in it, and $z \in \mathbb{R}^V$ is a vector indexed by the vertices of G , we have

$$(2) \quad \sum_{e \in \vec{E}} (z_{\text{head}(e)} - z_{\text{tail}(e)}) \xi_e = 0.$$

This is immediate by using $D\xi = 0$, because the sum equals $z^T D\xi$. (Or, perhaps more intuitively, the equality is obvious if ξ is an elementary circulation along a cycle, and the general case follows since every circulation is a linear combination of elementary circulations.)

Next, let us consider $\vec{H}$ as in the lemma, and let ξ be a circulation in it. The vertices of H are points in the plane, and for every edge $e \in E$ we have $(\text{head}(e) - \text{tail}(e)) = \alpha_e u_{c(e)}$ for some $\alpha_e \neq 0$, since the segment with end points $\text{head}(e)$ and $\text{tail}(e)$ is parallel to $u_{c(e)}$. Then the first equality in the claim of the lemma follows by applying (2) with $z_v := x(v)$ for all vertices v , while the second equality is obtained similarly by using the y -coordinates. $\square$

Let D be the incidence matrix of a directed graph. By D^- we denote D with the last row deleted. We note that since every column of D has one $+1$ and one -1 , the sum of all rows of D is the zero vector, and thus each row is a linear combination of the others. Consequently, we have $\ker D^- = \ker D$, and thus it suffices to “test” circulations by using D^- .

Let $H = (V, E)$ be a graph with n vertices and m edges and with edges colored by k colors. We define a polynomial matrix $P_H = P_H(x_1, \dots, x_k, y_1, \dots, y_k)$ with $m + 2n - 2$ rows and $2m$ columns, where the x_i and the y_i are variables:

$$P_H := \begin{pmatrix} X & Y \\ D^- & 0 \\ 0 & D^- \end{pmatrix},$$

where X is an $E \times E$ diagonal matrix with the entry (e, e) equal to $x_{c(e)}$, Y is defined analogously with $y_{c(e)}$, and D is the incidence matrix of some orientation of H (thus, P_H is not defined uniquely, since it depends on the orientation).

Here is an algebraic condition for certain subgraphs of interchange graphs.

LEMMA 2.2. *Let $H = (V, E)$ be a subgraph of an interchange graph for directions $u_1, \dots, u_k$. Let us assume that $|E| = 2n - 2$, where $n = |V|$. Then P_H is a square matrix and*

$$\det(P_H(x(u_1), \dots, x(u_k), y(u_1), \dots, y(u_k))) = 0$$

(we substitute the coordinates of the directions $u_1, \dots, u_k$ for the variables in the matrix P_H).

Proof. Let us write $\tilde{P}_H = P_H(x(u_1), \dots, x(u_k), y(u_1), \dots, y(u_k))$. By supposing for contradiction that $\det(\tilde{P}_H) \neq 0$, we get that the linear system $\tilde{P}_H q = b$ has a (unique) solution q for every right-hand side $b \in \mathbb{R}^{2m}$. Let us choose, in particular, $b = \begin{pmatrix} w \\ 0 \end{pmatrix}$, where $w \in \mathbb{R}^E$ is arbitrary (and 0 stands for an m -component zero vector), and let us also write $q = \begin{pmatrix} \xi \\ \psi \end{pmatrix}$, with $\xi, \psi \in \mathbb{R}^E$. By using the definition of P_H , we get that the system $\tilde{P}_H q = b$ is then equivalent to

$$D^- \xi = 0, \quad D^- \psi = 0, \quad x(u_{c(e)})\xi_e + y(u_{c(e)})\psi_e = w_e \quad \text{for all } e \in E.$$

The first two equations say that ξ and ψ are circulations.

Lemma 2.1 tells us that there exist nonzero α_e , $e \in E$, such that for every two circulations ξ, ψ we have

$$\sum_{e \in E} \alpha_e \left(x(u_{c(e)})\xi_e + y(u_{c(e)})\psi_e \right) = 0.$$

However, in view of the previous paragraph, for every $w \in \mathbb{R}^E$ we can choose circulations ξ, ψ with $x(u_{c(e)})\xi_e + y(u_{c(e)})\psi_e = w_e$ for all $e \in E$, and thus we have $\sum_{e \in E} \alpha_e w_e = 0$ for all w . This forces $\alpha_e = 0$ for all e , though—a contradiction proving the lemma. $\square$

In order that the last lemma provide a nontrivial condition for the directions u_i , we need that the determinant of the matrix $P_H(x_1, \dots, x_k, y_1, \dots, y_k)$ is not the zero polynomial. The following section provides a sufficient combinatorial condition for this.

2.2. A combinatorial necessary condition for interchange graphs.

LEMMA 2.3. *Let $H = (V, E)$ be a subgraph of an interchange graph for directions $u_1, \dots, u_k$, and suppose that H has two color-disjoint spanning trees T_1 and T_2 (that is, $c(e_1) \neq c(e_2)$ for all $e_1 \in E(T_1)$, $e_2 \in E(T_2)$). Then $(x(u_1), \dots, x(u_k), y(u_1), \dots, y(u_k))$ is in the zero set of a nonzero polynomial with integer coefficients (depending on H).*

Proof. Without loss of generality we may assume that $E = E(T_1) \cup E(T_2)$. By writing $n = |V|$, we have $|E| = 2n - 2$, and so Lemma 2.2 tells us that the vector of the coordinates of the u_i is in the zero set of $\det(P_H)$. It remains to check that $\det(P_H)$ is not identically 0. To this end, we verify that the monomial

$$\mu := \left(\prod_{e \in E(T_1)} x_{c(e)} \right) \left(\prod_{e \in E(T_2)} y_{c(e)} \right)$$

appears in $\det(P_H)$ with coefficient ± 1 . Indeed, let us consider the expansion of $\det(P_H)$ according to the definition of the determinant as a sum over all permutations of products. Since T_1 and T_2 are color-disjoint, if such a product should be a nonzero multiple of the monomial μ , it must use all of the entries $x_{c(e)}$ of the diagonal matrix X for $e \in E(T_1)$ and also all of the entries $y_{c(e)}$ of the diagonal matrix Y for $e \in E(T_2)$; see Figure 3. This uniquely determines which entries are used from the top m rows of P_H . In the next $n - 1$ rows, the entries must be taken from the submatrix D_2^- of D^- corresponding to $E(T_2)$, and in the last $n - 1$ rows the entries must be taken from the submatrix D_1^- of D^- corresponding to $E(T_1)$. Hence the coefficient of μ in $\det(P_H)$ equals $\det(D_1^-) \det(D_2^-)$. By a standard fact (a special case of the matrix-tree theorem; see, e.g., Biggs [4]), the incidence matrix of any directed tree has determinant ± 1 , and the lemma follows. $\square$

FIG. 3. Terms in $\det(\tilde{P}_H)$ contributing to the monomial μ .

3. Existence of two color-disjoint spanning trees. The last building block in the proof of our lower bound for $F(k)$ is a result stating that every sufficiently dense graph has a subgraph with two color-disjoint spanning trees.

The graphs that we will deal with throughout the proof will be disjoint unions of perfect matchings, so it is convenient to introduce the following terminology. A *DUPM-graph* is a graph $G = (V, E)$ together with a fixed partition $E = E_1 \cup \dots \cup E_k$ of the edge set into perfect matchings on V (we also keep referring to *colors* of edges as in the previous sections). In particular, we note that each vertex is incident to edges of all colors in a DUPM-graph. For an index set $I \subseteq [k]$ and a subset $W \subseteq V$, we write $G[I, W]$ for the subgraph induced by W on edges with colors in I , that is, $G[I, W] = (W, \binom{W}{2} \cap \bigcup_{i \in I} E_i)$ (instead of $G[I, V]$ we write just $G[I]$). This $G[I, W]$ need not be a DUPM-graph in general, but in our considerations we will choose I and W so that we do get DUPM-graphs.

Before proving the result needed for the proof of Theorem 1.1, we first establish a quantitatively weaker result with a simpler proof (section 3.1), which can serve as a gradual introduction to the subsequent more involved proof of the stronger result.

3.1. A weaker bound. The weaker result with the simpler proof is the following.

PROPOSITION 3.1. *Let $G = (V, E_1 \cup \dots \cup E_k)$ be a DUPM-graph on $n \geq 2$ vertices. If $k \geq 5 \log_2^3 n$, then there exist disjoint index sets $I_1, I_2 \subset [k]$ and a subset $W \subseteq V$, $|W| \geq 2$, such that the graphs $G[I_1, W]$ and $G[I_2, W]$ are both connected.*

The construction of the desired two subgraphs proceeds in two stages. In the first stage, captured by the next lemma, we find a DUPM-subgraph of G in which every edge cut has sufficiently many colors.

LEMMA 3.2. *Let G and k be as in Proposition 3.1. Then there exist nonempty $J \subseteq [k]$ and $W \subseteq V$, $|W| \geq 2$, such that $H := G[J, W]$ is a DUPM-graph in which every edge cut has edges of at least $r := 5 \log_2^2 n$ colors. That is, for every partition of W into nonempty sets A and B , the edges in $E(H; A, B) := \{e \in E(H) : e \cap A \neq \emptyset \neq e \cap B\}$ have at least r distinct colors.*

The proof proceeds by a recursive partitioning: As long as we can find an edge cut F with fewer than r colors in the current graph, we discard the *larger* of the two pieces defined by F , together with all edges that do not have both end points in the new vertex set or whose color appears in F . We repeat this step as long as we can. Since the size of the vertex set is halved (at least) in each iteration, the number of iterations is at most $\log_2 n$. The key observation is that, since we started with $5 \log_2^3 n$ colors and we lose fewer than r colors in every iteration, we must finish with a nontrivial graph satisfying the required condition. A more formal proof follows.

Proof. We start with $J_1 = [k]$, $V_1 = V$, and $G_1 = G$, and for $j = 1, 2, \dots$ we repeat the following step:

(Step j) We have a current DUPM-graph G_j on vertex set V_j with edge colors in J_j . If there is a partition $V_j = A \cup B$ such that the edges in $E(G_j; A, B)$ have fewer than r colors, we construct J_{j+1} , V_{j+1} , G_{j+1} as follows:

- V_{j+1} is the smaller of the sets A and B (a possible tie broken arbitrarily);
- J_{j+1} is J_j minus all colors appearing on edges in $E(G_j; A, B)$;
- $G_{j+1} = G_j[V_{j+1}, J_{j+1}]$.

Otherwise, if $E(G_j; A, B)$ has at least r colors for every partition $V_j = A \cup B$, then we set $W = V_j$, $J = J_j$ and finish.

It is clear that the resulting $H = G[J, W]$ is a DUPM-graph, and actually that every vertex of H is incident to $|J|$ edges, and also that every edge cut has at least r colors. It remains to check that $J \neq \emptyset$. As we have observed, the algorithm must finish in at most $\log_2 n$ steps since $|V_{j+1}| \leq \lfloor \frac{1}{2} |V_j| \rfloor$ for all j . In each step the number of colors in J_j decreases by less than r , and hence $|J| > k - r \log_2 n \geq 0$. The lemma is proved. $\square$

In the second stage of the proof of Proposition 3.1, having a subgraph where every edge cut has at least r colors, we exhibit two color-disjoint connected subgraphs. To build the first connected subgraph, we start with an empty edge set and add the edge sets E_i one by one, always taking one that decreases the current number of components the most. Since every edge cut contains at least about a $1/\log n$ fraction of all colors, it can be shown that adding a random color decreases the current number of component by a factor of at least roughly $(1 - 1/\log n)$. Consequently, after adding $s = O(\log^2 n)$ colors we obtain a connected graph. By setting the constants so that $s < r$, the remaining colors form a graph where every edge cut still has at least one color, and hence the graph is connected. As was pointed to us by Alon, this stage of our proof resembles his proof in [1].

The next lemma formalizes this second stage.

LEMMA 3.3. *Let H be a DUPM-graph on $m \leq n$ vertices and with $k \leq 6 \log_2^3 n$ colors in which every edge cut has edges of at least $r := 5 \log_2^2 n$ colors. Then there exists a set I of at most $s := 4 \log_2^2 n$ colors such that $H[I]$ is connected.*

Proof. We set $I_0 = \emptyset$, and for $j = 0, 1, 2, \dots$, we do the following: If $H[I_j]$ is connected, we set $I := I_j$ and finish. Otherwise, we let i_j be a color i maximizing $\text{cc}(H[I_j]) - \text{cc}(H[I_j \cup \{i\}])$, where $\text{cc}(G)$ denotes the number of connected components of a graph G . Then we set $I_{j+1} := I_j \cup \{i_j\}$, and we continue with the next step.

We need to show that we obtain a connected graph before exhausting more than the claimed number of colors.

Let $m_j = \text{cc}(H[I_j])$. We have $m_1 = m \leq n$, and we claim that

$$m_{j+1} \leq m_j \left(1 - \frac{r}{2k}\right)$$

whenever $m_j \geq 2$. To see this, let $K_1, K_2, \dots, K_{m_j}$ be the connected components of $H[I_j]$. Let us say that K_ℓ gets connected by color i if there is an edge of color i connecting K_ℓ to the rest of H . Since the edge cut $E(H; V(K_\ell), W \setminus V(K_\ell))$ contains at least r colors (none of them in I_j , since K_ℓ is a connected component of $H[I_j]$), the probability that any particular K_ℓ gets connected by a randomly chosen color i is at least r/k . Hence in expectation at least $q := m_j r/k$ components get connected, and thus there is a particular color i by which at least q components get connected. It is not difficult to check that by adding such a color i to I_j the number of components decreases by at least $q/2$, and thus $m_{j+1} \leq m_j - q/2 = m_j(1 - r/2k)$ as claimed.

Applying this inequality inductively gives $m_j \leq n(1 - r/2k)^j \leq ne^{-jr/2k}$. This is at most 1 for $j = 2k(\ln n)/r \leq 2 \cdot 6 \log_2^3 n \cdot \log_2 e \cdot (\log_2 n)/(5 \log_2^2 n) \leq s = 4 \log_2^2 n$, and the lemma is proved. $\square$

Proof of Proposition 3.1. Given a DUPM-graph $G = (V, E_1 \cup \dots \cup E_k)$ as in the proposition, we first discard colors if needed so that the remaining number of colors is between $5 \log_2^3 n$ and $6 \log_2^3 n$ (we'd actually like to say that we may assume that there are exactly $5 \log_2^3 n$ colors, but that need not be an integer). Then we use Lemma 3.2 and obtain a DUPM-graph $H = G[J, W]$ where every edge cut contains at least r colors (and, of course, H has at most n vertices and at most $6 \log_2^3 n$ colors). We apply Lemma 3.3, and we obtain a set I_1 of at most $s = 4 \log_2^2 n < r$ colors with $H[I_1]$ connected. In the DUPM-graph induced in H by colors not belonging to I_1 , every edge cut still has at least one color (since we have removed fewer than r colors), and hence this DUPM-graph is connected as well. We can thus set $I_2 := J \setminus I_1$. This proves the proposition. $\square$

3.2. An improved bound. Here we improve the bound of $\log^3 n$ from Proposition 3.1 to $\log n \log \log n$. The improvement is based on two observations, which are more or less independent (applying each of them alone would save a factor of roughly $\log n$).

The first observation is that in the first stage, i.e., in the proof of Lemma 3.2, we can force unbalanced cuts (with A much smaller than B) to have considerably more colors than balanced ones (with A and B of roughly equal size). Indeed, if we encounter highly unbalanced cuts in most steps of the algorithm, then the algorithm has to finish considerably sooner than after $\log_2 n$ steps, and as a result fewer colors get discarded. This is expressed quantitatively in Lemma 3.6 below.

In the second stage we build a connected graph by iteratively merging components. Here we note that at the beginning, when the components are small, the property “cuts having sufficiently many colors” is applied with very much unbalanced cuts. Only as the typical size of the current components grows do we have to deal with more balanced cuts. As a result, if we know that unbalanced cuts are richer in colors than balanced ones, the merging procedure progresses faster at the beginning than towards the end. Technically, we are going to divide the merging procedure into roughly $\log \log n$ phases. In each phase, the number of components is typically reduced to approximately its square root (except for the last phase, where the number of components is reduced to 1).

This first improvement alone would bring the original $\log^3 n$ factor down to $\log^2 n \log \log n$, where the $\log \log n$ factor arises because the contribution of each of the $\log \log n$ phases turns out to be roughly the same.

We now turn to the second improvement. The procedure for selecting colors and merging components in the proof of Lemma 3.3 can conceptually be regarded as a randomized algorithm that selects colors one by one at random. (We phrased

it deterministically, by saying that we always pick a color that reduces the number of components as much as possible, but the reason why this worked was that the expected number of components merged by adding a *random* color is sufficiently large.) Instead of picking the colors one by one, we can think of this as selecting a random subset of s colors, with a suitable s . If we can show that such a random set of colors induces a connected subgraph with a probability strictly greater than $\frac{1}{2}$, we can use the following simple observation to assert the existence of *two disjoint* sets of s colors, each inducing a connected subgraph.

OBSERVATION 3.4. *Let s and n be natural numbers, $1 \leq s \leq n/2$, and let $\mathcal{P}$ be a property of s -element subsets of $[n]$. If a random s -element subset of $[n]$ (where all s -element subsets are chosen with equal probability) has property $\mathcal{P}$ with probability $p > \frac{1}{2}$, then there exist two disjoint s -element subsets of $[n]$ with property $\mathcal{P}$.*

This observation, as well as the following neat proof, may very well be folklore.

Proof. Let us choose a random permutation of $[n]$. Let S_1 consist of the first s elements in this permutation, and let S_2 consist of the next s elements. We have $S_1 \cap S_2 = \emptyset$, and both S_1 and S_2 can be regarded as random s -element subsets of $[n]$ (not independent, of course). The probability that either of S_1 and S_2 fails to have $\mathcal{P}$ is, by the union bound, at most $2(1 - p) < 1$. $\square$

Using this observation appropriately will allow us to save another $\log n$ factor in the number of colors.

Here is a formal statement of the improved version of Proposition 3.1.

PROPOSITION 3.5. *There exists a constant C such that the following holds. Let $G = (V, E_1 \cup \dots \cup E_k)$ be a DUPM-graph on $n \geq 4$ vertices.¹ If $k \geq \lfloor C \log_2 n \log_2 \log_2 n \rfloor$, then there exist disjoint index sets $I_1, I_2 \subset [k]$ and a subset $W \subseteq V$, $|W| \geq 2$, such that the graphs $G[I_1, W]$ and $G[I_2, W]$ are both connected.*

We begin with the first stage of the proof—a refined version of Lemma 3.2. For a partition of a vertex set into two nonempty subsets A and B , we define the *imbalance* of (A, B) as

$$\text{imb}(A, B) := \frac{|A| + |B|}{\min(|A|, |B|)},$$

and we set

$$\gamma(n, k, A, B) := \frac{k}{2 \log_2 n} \cdot \log_2 \text{imb}(A, B);$$

this is going to be the lower bound on the number of colors in every edge cut $E(H; A, B)$.

LEMMA 3.6. *Let $G = (V, E_1 \cup \dots \cup E_k)$ be a DUPM-graph on $n \geq 2$ vertices. Then there exist $J \subseteq [k]$, $|J| \geq k/2$, and $W \subseteq V$, $|W| \geq 2$, such that $H := G[J, W]$ is a DUPM-graph in which every edge cut $E(H; A, B)$ has edges of at least $\gamma(n, k, A, B)$ colors (note that n is the number of vertices of G , not of H).*

Proof. The proof is a simple modification of that for Lemma 3.2, so we proceed quickly. We assume $k > 0$. We start with $J_1 = [k]$, $V_1 = V$, and $G_1 = G$. If a current DUPM-graph G_j on vertex set V_j with edge colors in J_j has already been constructed and if there is a partition $V_j = A \cup B$ where $E(G_j; A, B)$ has fewer than $\gamma(n, k, A, B)$ colors, we let V_{j+1} be the smaller of the sets A and B , we let J_{j+1} be J_j minus all colors appearing in $E(G_j; A, B)$, and we set $G_{j+1} = G_j[V_{j+1}, J_{j+1}]$. If there is no such partition, we set $W = V_j$, $J = J_j$, $t = j$ and finish.

¹We assume that $n \geq 4$ so that $\log_2 \log_2 n \geq 1$ and the $C \log_2 n \log_2 \log_2 n$ term can absorb additive constants, for example, if C is chosen sufficiently large.

The only condition whose checking needs some work is $|J| \geq k/2$. In the j th step the number of colors in J_j decreases by less than

$$\gamma(n, k, V_{j+1}, V_j \setminus V_{j+1}) = \frac{k}{2\log_2 n} \log_2 \frac{|V_j|}{|V_{j+1}|},$$

and hence

$$\begin{aligned} |J| &\geq k - \sum_{j=1}^{t-1} \frac{k}{2\log_2 n} (\log_2 |V_j| - \log_2 |V_{j+1}|) \\ &= k - \frac{k}{2\log_2 n} (\log_2 |V_1| - \log_2 |V_t|) \\ &\geq k - \frac{k}{2\log_2 n} \log_2 n = \frac{k}{2}. \end{aligned}$$

The lemma is proved. $\square$

Next, we state a counterpart of Lemma 3.3.

LEMMA 3.7. *Let H be a DUPM-graph on $m \leq n$ vertices and with k colors, where $k_0/2 \leq k \leq k_0$ for $k_0 := \lfloor C \log_2 n \log_2 \log_2 n \rfloor$. Let us suppose that every edge cut $E(H; A, B)$ has at least $\gamma(n, k_0, A, B)$ colors. Then a set I of $s := \lfloor \frac{1}{4}k_0 \rfloor$ colors chosen uniformly at random from $[k]$ guarantees $H[I]$ to be connected with probability at least $\frac{3}{4}$.*

It is easy to derive Proposition 3.5 from Lemma 3.7.

Proof of Proposition 3.5. Given a DUPM-graph as in the proposition, we may assume (after deleting colors) that the number of colors is exactly k_0 . Lemma 3.6 yields a DUPM-subgraph H with at most n vertices, a number of colors between $k_0/2$ and k_0 , and every edge cut $E(H; A, B)$ having at least $\gamma(n, k_0, A, B)$ colors. Lemma 3.7 shows that a random subset of s colors induces a connected subgraph in H with a probability of at least $\frac{3}{4}$, and Observation 3.4 thus yields the existence of two disjoint sets of colors inducing connected subgraphs. $\square$

Now we start working towards the proof of Lemma 3.7. Instead of choosing the random set I of colors all at once, we think of picking the colors one by one. So we set $I_0 = \emptyset$, and, for $j = 1, 2, 3, \dots$, we choose a color $i_j \in [k] \setminus I_{j-1}$ uniformly at random and set $I_j := I_{j-1} \cup \{i_j\}$.

Moreover, for the purposes of the analysis, we conceptually divide the choice of I into *phases*. We set $b := \lceil 64 \log_2 n \rceil$, and, for $i = 0, 1, 2, \dots$, we let the sets $I_{ib}, I_{ib+1}, \dots, I_{(i+1)b-1}$ belong to the i th phase.

Let $X_j := \text{cc}(H[I_j])$ be the number of connected components of the graph $H[I_j]$; this is a random variable. The next lemma wants to claim that each phase is reasonably likely to reduce the current number of connected components to no more than its square root. However, if the number of components is already rather small, concretely, below 2^4 , we require the phase to finish with a connected graph. So let us call the i th phase *successful* if either $X_{ib} \geq 2^4$ and $X_{(i+1)b} \leq \sqrt{X_{ib}}$, or $2 \leq X_{ib} < 2^4$ and $X_{(i+1)b} = 1$.

LEMMA 3.8. *For every i we can estimate the conditional probability of the i th phase being successful, conditioned on $X_{ib} \geq 2$, as follows:*

$$\text{Prob}[\textit{ith phase is successful} \mid X_{ib} \geq 2] \geq \frac{1}{2}.$$

Proof. Let us assume that the set I_{ib} is fixed in such a way that $x := X_{ib} \geq 2$. Let $p^* = p^*(I_{ib})$ be the probability that the i th phase is *unsuccessful*, conditioned on I_{ib} fixed as above.² It suffices to prove that $p^* \leq \frac{1}{2}$ for every I_{ib} with $X_{ib} \geq 2$.

For contradiction, let us assume that $p^* > \frac{1}{2}$. We will show that this implies that

$$\mathbb{E}[\log_2 X_{(i+1)b} \mid I_{ib}] < 0,$$

which is a contradiction, since obviously $X_{(i+1)b} \geq 1$ always. To this end, we define $D_j := \log_2(X_j/X_{j+1})$, and we establish the following.

Claim. For all $j = ib, ib+1, \dots, (i+1)b-1$ we have

$$\mathbb{E}[D_j \mid I_{ib}] > \frac{1}{64} \frac{\log_2 x}{\log_2 n}.$$

First, assuming this claim, we can finish the proof of the lemma quickly. We calculate

$$\begin{aligned} \mathbb{E}[\log_2 X_{(i+1)b} \mid I_{ib}] &= \log_2 x - \mathbb{E}[\log_2(X_{ib}/X_{(i+1)b}) \mid I_{ib}] \\ &= \log_2 x - \sum_{j=ib}^{(i+1)b-1} \mathbb{E}[D_j \mid I_{ib}] \\ &< \log_2 x - \sum_{j=ib}^{(i+1)b-1} \frac{1}{64} \frac{\log_2 x}{\log_2 n} \\ &\leq (\log_2 x) \left(1 - \frac{b}{64 \log_2 n}\right) \leq 0 \end{aligned}$$

since $b = \lceil 64 \log_2 n \rceil$. We have shown $\mathbb{E}[\log_2 X_{(i+1)b} \mid I_{ib}] < 0$, which is the contradiction announced above.

Proof of the claim. Let us define y as the desired target value of $X_{(i+1)b}$ making the phase successful; that is, $y := \sqrt{x}$ for $x \geq 2^4$ and $y := 1$ for $2 \leq x < 2^4$. We have

$$\begin{aligned} \mathbb{E}[D_j \mid I_{ib}] &= \mathbb{E}[D_j \mid I_{ib} \text{ and } X_j > y] \cdot \text{Prob}[X_j > y \mid I_{ib}] \\ &\quad + \mathbb{E}[D_j \mid I_{ib} \text{ and } X_j \leq y] \cdot (1 - \text{Prob}[X_j > y \mid I_{ib}]) \\ (3) \quad &\geq \mathbb{E}[D_j \mid I_{ib} \text{ and } X_j > y] \cdot p^*, \end{aligned}$$

since $\mathbb{E}[D_j \mid I_{ib} \text{ and } X_j \leq y] \cdot (1 - \text{Prob}[X_j > y \mid I_{ib}]) \geq 0$ and $\text{Prob}[X_j > y \mid I_{ib}] \geq \text{Prob}[X_{(i+1)b} > y \mid I_{ib}] = p^*$.

We now want to bound below $\mathbb{E}[D_j \mid I_{ib} \text{ and } X_j > y]$. Let W denote the vertex set of H , and let us recall that $m = |W|$. Let us fix I_j such that $X_j > y$, and, for every color $\ell \in [k] \setminus I_j$, let $a_\ell := X_j - \text{cc}(H[I_j \cup \{\ell\}])$ be the decrease in the number of connected components caused by adding color ℓ .

For each component A of $H[I_j]$, the number of colors in the complement of I_j that connect A to the rest of the graph is at least

$$\gamma(n, k_0, A, W \setminus A) = \frac{k_0}{2 \log_2 n} \log_2 \text{imb}(A, W \setminus A),$$

²More precisely, we should say that we first fix an ib -element set $J \subset [k]$ with $\text{cc}(H[J]) \geq 2$, set $x := \text{cc}(H[J])$, and then condition on $I_{ib} = J$. However, we allow ourselves the luxury of the more concise notation.

and hence

$$(4) \quad \sum_{\ell \in [k] \setminus I_j} a_\ell \geq \frac{1}{2} \cdot \frac{k_0}{2 \log_2 n} \sum_A \log_2 \text{imb}(A, W \setminus A),$$

where the sum is over all components A of $H[I_j]$.

Now for the case $2 \leq x < 2^4$, we simply use $\text{imb}(A, W \setminus A) \geq 2$ for every A , and (4) yields

$$(5) \quad \sum_{\ell \in [k] \setminus I_j} a_\ell \geq \frac{1}{4} X_j \frac{k_0}{\log_2 n}.$$

To derive a similar inequality for $x \geq 2^4$ as well, we note that the number of components of $H[I_j]$ of size exceeding some threshold t is at most m/t , and, by setting $t = 2m/\sqrt{x}$, we find that if $X_j > \sqrt{x}$, then at least $\frac{1}{2}X_j$ of the components have size at most t . For each such component A , we have $\text{imb}(A, W \setminus A) \geq m/t = \frac{1}{2}\sqrt{x}$, and so

$$(6) \quad \sum_{\ell \in [k] \setminus I_j} a_\ell \geq \frac{k_0}{4 \log_2 n} \cdot \frac{1}{2} X_j \cdot \log_2(\sqrt{x}/2) \geq \frac{1}{32} X_j \frac{k_0 \log_2 x}{\log_2 n},$$

where we have used $\log_2(\sqrt{x}/2) \geq \frac{1}{4} \log_2 x$, which is valid for all $x \geq 2^4$.

In the case $2 \leq x < 2^4$, we have $\log_2 x \leq 4$, and so (5) shows that (6) holds in this case, too.

Now we can calculate

$$\begin{aligned} \mathbb{E}[D_j | I_j] &= \mathbb{E}[\log_2(X_j/X_{j+1}) | I_j] \\ &= \sum_{\ell \in [k] \setminus I_j} \frac{1}{k-j} \log_2 \frac{X_j}{X_j - a_\ell} \\ &\geq \frac{1}{k_0} \sum_{\ell \in [k] \setminus I_j} \log_2 \frac{1}{1 - a_\ell/X_j} \\ &\geq \frac{1}{k_0} \sum_{\ell \in [k] \setminus I_j} \frac{a_\ell}{X_j}, \end{aligned}$$

where we have used the inequality $\ln(1+z) \leq z$, with $z = -a_\ell/X_j$. By using (6), we arrive at $\mathbb{E}[D_j | I_j] \geq \frac{1}{32} \frac{\log_2 x}{\log_2 n}$, and averaging over all choices of $I_j \supseteq I_{ib}$ and plugging into (3) finally lead to the inequality in the claim. This also concludes the proof of the lemma. $\square$

Proof of Lemma 3.7. Let us put $q := \lceil \log_2 \log_2 n \rceil + 1$. First we note that there cannot be more than q successful phases in the algorithm. Indeed, each successful phase starting with at least 2^4 components reduces the current number of components to at most its square root, so there can't be more than $\log_2 \log_2 n$ such phases, and, after the number of components drops below 2^4 , there can be at most one additional successful phase.

Let Y_i be the indicator variable of the event that the i th phase is successful, and let $p_i := \text{Prob}[X_{ib} \geq 2]$. We have

$$\mathbb{E}[Y_i] = \text{Prob}[Y_i = 1 | X_{ib} \geq 2] p_i \geq \frac{1}{2} p_i$$

by Lemma 3.8.

Let us consider the first $8q$ phases, and let $p := p_{8q}$. For proving the lemma it suffices to show that $p \leq \frac{1}{4}$. Indeed, then after $8q$ phases we have $X_{8q} = 1$ with probability at least $\frac{3}{4}$.

For contradiction we thus assume that $p > \frac{1}{4}$. Since $p_i \geq p > \frac{1}{4}$ for all $i < 8q$, we have $\mathbb{E}[Y_0 + Y_1 + \dots + Y_{8q-1}] > 8q \cdot \frac{1}{8} = q$. But this contradicts the fact noted above, namely, that at most q of the Y_i can be 1. This finishes the proof. $\square$

3.3. Proof of Theorem 1.1. Theorem 1.1 is now a simple consequence of Lemma 2.3 and Proposition 3.5. Given directions $u_1, \dots, u_k$, we let $n := 2f(u_1, \dots, u_k)$. Assuming $k \geq \lfloor C \log_2 n \log_2 \log_2 n \rfloor$, where C is as in Proposition 3.5, we consider an interchange graph G on n vertices for $u_1, \dots, u_k$. By Proposition 3.5 it has a subgraph H possessing two color-disjoint connected subgraphs and hence two color-disjoint spanning trees. Then by Lemma 2.3 the vector of the coordinates of the u_i has to be in the zero set of a nonzero polynomial (depending on H). $\square$

3.4. A limitation of the proof method. Our strategy for finding the two color-disjoint spanning trees was to reduce the graph as long as possible by partitioning along “few-colored” cuts and then to choose two random disjoint sets of colors. Here we present an example showing that our version of the second part of this strategy, namely, Lemma 3.7, is not far from optimal.

PROPOSITION 3.9. *For infinitely many values of n , there exists a DUPM-graph H on n vertices and with k colors, where $k \geq \frac{1}{2} \log n \log \log n / \log^{(3)} n$ (with $\log^{(3)} n = \log \log \log n$), such that every edge cut $E(H; A, B)$ has at least $\gamma(n, k, A, B)$ colors and the probability that $H[I]$ is connected, where $I \subset [k]$ is a random subset of colors obtained by picking each color of $[k]$ independently with probability $\frac{1}{2}$, tends to 0 as $n \rightarrow \infty$. (There is nothing special about probability $\frac{1}{2}$; a similar construction with parameters slightly adjusted works for any constant probability $p < 1$.)*

Let us remark that the graph H that we construct in the proof of this proposition does have two color-disjoint spanning trees. Hence the proposition shows only that, in a setting as in Lemma 3.7 but with considerably fewer than $\log n \log \log n$ colors, we cannot get the desired trees by a purely random choice of colors—it might still be that they could be obtained by some more clever strategy.

One might also wonder whether the initial reduction, partitioning the graph along few-colored cuts, couldn't be improved. We believe that an improvement cannot be achieved in this way either, but we prefer not to formalize our heuristic reasoning here, since it doesn't seem to bring anything useful towards resolving the problem (while the example in Proposition 3.9 might give some inspiration for future research).

Sketch of proof of Proposition 3.9. We recall that the Cartesian product (or graph product) $G_1 \square G_2$ of two graphs has vertex set $V(G_1) \times V(G_2)$, and two vertices (v_1, v_2) and (v'_1, v'_2) in this product are connected by an edge if $v_1 = v'_1$ and $\{v_2, v'_2\} \in E(G_2)$ or if $v_2 = v'_2$ and $\{v_1, v'_1\} \in E(G_1)$. (So the d -dimensional cube is the d th Cartesian power of an edge.)

We assume n to be sufficiently large, and we set (ignoring integrality issues) $b := \frac{1}{2} \log \log n$, assuming b even, and $d := \log n / \log b$. We let H be the d -fold Cartesian product $H_1 \square H_2 \square \dots \square H_d$, where each H_i is a complete DUPM-graph on b vertices such that the sets of colors for H_i and H_j are disjoint for $i \neq j$. Then H is a DUPM-graph on $b^d = 2^{d \log b} = n$ vertices with $k = d(b - 1) \in [\frac{1}{2} \log n \log \log n / \log^{(3)} n, \log n \log \log n / \log^{(3)} n]$ colors (each edge in the product “comes from” a particular edge of a particular H_i , and it inherits the color of that edge).

If $I \subset [k]$ is a random set of colors as in the proposition, then with probability larger than 2^{-b} the set I contains no color among those used on H_i , and these events for $i = 1, 2, \dots, d$ are independent.³ Hence $H[I]$ is connected with probability at most $(1 - 2^{-b})^d \leq \exp(-2^{-b}d) = o(1)$ as $n \rightarrow \infty$.

It remains to verify that all cuts in H have sufficiently many colors. To this end, we show that any subgraph of H on a set $A \subseteq V(H)$ of m vertices has an average degree of at most $((b-1)/\log b) \log m$, generalizing the well-known isoperimetric inequality for the cube corresponding to the case $b = 2$ (then the average number of edges going from a vertex of A to the complement of A , $|A| \leq \frac{1}{2}|V(H)|$, is at least $d(b-1) - ((b-1)/\log b) \log |A| = ((b-1)/\log b) \log(n/|A|) \geq \gamma(n, k, A, V(H) \setminus A)$). This can be proved by induction; namely, by induction on i we prove that any subgraph on at most m vertices of $H_1 \square \dots \square H_i$ has an average degree of at most $((b-1)/\log b) \log m$. For $i = 1$ this holds because the average degree is at most $m-1$, and for $1 \leq m \leq b$ we have $(m-1)/\log m \leq (b-1)/\log b$. For $i > 1$ we consider the partition $A = A_1 \dot{\cup} \dots \dot{\cup} A_b$ of a set $A \subseteq V(H_1 \square \dots \square H_i)$ according to the projection on the last coordinate, we estimate the number of edges on each A_j by induction, and we add the edges among distinct A_j , whose number is at most $\sum_{j_1 < j_2} \min(|A_{j_1}|, |A_{j_2}|)$. Elementary calculations, which we omit, finish the inductive step. $\square$

4. The upper bound. Here we are going to prove Theorem 1.2. In order to prove an upper bound for $F(k)$, we need to construct, for any given k -tuple of distinct directions $u_1, u_2, \dots, u_k$, two point sets A and B with identical X-rays in all of these directions.

The basic approach. All of the constructions are modifications of the basic example mentioned in the introduction, which provides the upper bound $F(k) < 2^{k-1}$. Given $u_1, u_2, \dots, u_k$, we choose suitable nonzero scalars $\alpha_1, \alpha_2, \dots, \alpha_k$, and we define the multisets A', B' as follows:

$$A' := \left\{ v(I) : I \subseteq [k], |I| \text{ even} \right\}, \quad B' = \left\{ v(I) : I \subseteq [k], |I| \text{ odd} \right\},$$

where $v(I) = \sum_{i \in I} v_i$ and $v_i = \alpha_i u_i$. For easier exposition we will call the points of A' *black* and the points of B' *white*. We have $|A'| = |B'| = \frac{1}{2}2^k$ (where each point is counted with multiplicity), and, as was discussed in the introduction, A' and B' have identical X-rays in each of the directions u_i .

In order to improve the upper bound of 2^{k-1} , we try to choose the α_i so that A' and B' have many points in common. After removing the common points the resulting multisets still have identical X-rays, but they are smaller. More precisely, when a black point coincides with a white point, they cancel each other out (so we have to respect multiplicities; if, say, five black points and three white points all occupy the same location, after cancellation we obtain two black points at that location). The resulting multisets after the cancellation will be denoted by A and B .

An example for $k = 3$. The simplest nontrivial example, with $k = 3$, is depicted in Figure 4, and it shows that $F(3) < 3$ (the circled point in the middle is in both A' and B' , and thus it cancels out).

To make this construction work, we need to choose nonzero $\alpha_1, \alpha_2, \alpha_3$ so that $v_1 + v_2 = v_3$, and we should check that this is possible for any triple of distinct directions

³Here the model of picking the colors independently is convenient; if we fixed the number of colors picked, we would not get independence, and the calculations would become more complicated.

FIG. 4. A construction for $k = 3$, using $v_1 + v_2 = v_3$.

u_1, u_2, u_3 . This is easy: Since the vectors u_1 and u_2 define distinct directions, they are linearly independent, and each vector in the plane is a linear combination of them. In particular, we can write $u_3 = \alpha_1 u_1 + \alpha_2 u_2$, and neither of α_1 and α_2 can be 0, for otherwise, u_3 would define the same direction as u_2 or u_1 .

We should also note that A' and B' are always sets (no multiple points) in this particular construction, and hence the upper bound holds for $F(3)$ and not only for $F_{\text{mult}}(3)$. Indeed, if two black points were equal or two white points were equal, then there would be two distinct sets $I, J \subseteq [3]$ with $|I| \equiv |J| \pmod{2}$ and with $v(I) = v(J)$. This yields a linear combination of the u_j equal to 0 and supported on the symmetric difference $I \Delta J$. But we necessarily have $|I \Delta J| = 2$, which would mean that one of the u_j is a multiple of another, which is excluded.

A product argument. Before considering more involved constructions of the type just described, we present a general “product” trick.

LEMMA 4.1. *Let us set $G(k) := 2(F(k) + 1)$. Then we have $G(k + \ell) \leq G(k)G(\ell)$ for any $k, \ell \geq 1$, and in particular, $F(mk) \leq \frac{1}{2}(2F(k) + 2)^m - 1$. An analogous statement holds for F_{mult} .*

Proof. Let $u_1, \dots, u_k$ and $w_1, \dots, w_\ell$ be directions, all of them distinct. Let A_u and B_u be sets of $F(k) + 1$ points each, $A_u \cap B_u = \emptyset$, that have identical X-rays in each of the directions u_i , and, similarly, A_w and B_w are disjoint $(F(\ell) + 1)$ -point sets with identical X-rays in each of the directions w_j .

We choose a sufficiently large real number t and set

$$A := (A_u + tA_w) \dot{\cup} (B_u + tB_w), \quad B := (A_u + tB_w) \dot{\cup} (B_u + tA_w),$$

where “+” represents the Minkowski addition, i.e., $X + Y = \{x + y : x \in X, y \in Y\}$ (and $X + Y$ is understood as a multiset). We have $|A|, |B| = 2(F(k) + 1)(F(\ell) + 1)$, and it is easy to check that A and B have identical X-rays in each of the directions u_i and w_j . Indeed, for the direction u_1 , for example, let $\varphi : A_u \rightarrow B_u$ be a bijection assigning to each point of A_u a point of B_u lying on the same line parallel to u_1 . Each point $a \in A$ can be written as $a_u + ta_w$, $a_u \in A_u$, $a_w \in A_w$, or as $b_u + tb_w$, $b_u \in B_u$, $b_w \in B_w$. Then we define a bijection $\psi : A \rightarrow B$ by $\psi(a_u + ta_w) := \varphi(a_u) + ta_w$, $\psi(b_u + tb_w) := \varphi^{-1}(b_u) + tb_w$, and it is immediate that a and $\psi(a)$ lie on the same line parallel to u_1 .

It remains to verify that, with an appropriate choice of t , A and B are sets and $A \cap B = \emptyset$. We choose t so large that the diameter of $A_u \cup B_u$ is smaller than the distance of any two points in $t(A_w \cup B_w)$. Then if two points $a, a' \in A \cup B$ coincide, we can write $a = x + ty$, $a' = x' + ty'$, $x, x' \in A_u \cup B_u$, $y, y' \in A_w \cup B_w$, and by the choice of t we obtain $y = y'$ and $x = x'$. $\square$

Proof of Theorem 1.2 for sets. By combining Lemma 4.1 with the example above showing $F(3) \leq 2$, we have $F(3m) \leq \frac{1}{2}6^m - 1$, and by monotonicity of F we then

FIG. 5. Sets A and B with the same X -rays in 9 directions, with $|A| = |B| = 99$. Dotted circles denote points that have been cancelled out.

obtain $F(k) = O((6^{1/3})^k)$ for all k . This proves the claim in Theorem 1.2 concerning sets. $\square$

A better construction for multisets. Here we return to the basic construction, depending on a good choice of the α_i . We consider the case $k = 9$. We set $\alpha_9 = 1$, say, and we choose nonzero α_3 and α_6 so that $v_9 = v_3 + v_6$ (by the same argument as in the example for $k = 3$). Then we set the remaining α_i so that $v_1 + v_2 = v_3$, $v_4 + v_5 = v_6$, and $v_7 + v_8 = v_9$.

As we have verified by a computer, in this way 157 pairs of points always cancel out, and we are left with $|A| = |B| \leq 99$ (see Figure 5). Hence $F_{\text{mult}}(9) < 99$, and by Lemma 4.1 we then have $F_{\text{mult}}(k) = O((198^{1/9})^k)$, which verifies the part of Theorem 1.2 concerning F_{mult} .

An example where the construction gives multisets. It can easily be shown that, for a generic choice of $u_1, \dots, u_9$, the construction just given produces sets A' and B' (no two black points and no two white points coincide). However, it turns out that if we insist on the particular dependences among the v_i used in the construction, i.e., on the relations $v_9 = v_3 + v_6$, $v_3 = v_1 + v_2$, $v_4 + v_5 = v_6$, and $v_7 + v_8 = v_9$, then for some choices of the u_i multiple points in A or B cannot be avoided. Indeed, let us consider the following 9 distinct directions:

$$\begin{aligned} u_1 &= (-1, 4), & u_2 &= (2, 3), & u_3 &= (1, 7), & u_4 &= (-1, 5), & u_5 &= (2, 1), \\ u_6 &= (1, 6), & u_7 &= (1, 1), & u_8 &= (1, 12), & u_9 &= (2, 13). \end{aligned}$$

Up to scaling, the only choice of the α_i providing the desired relations among the v_i is $\alpha_1 = \alpha_2 = \dots = \alpha_9 = 1$. But then we also have $u_1 + u_3 = (0, 13) = u_4 + u_6$; i.e., two points in A' coincide. We have also checked that these two black points don't cancel out with any white points, and so A also has multiple points

It seems that, for the choices of u_i that lead to multiple points in this particular construction, we can use alternative constructions, obtained from the present construction by a suitable renumbering of the u_i . But so far we have no systematic approach to such problems.

Concluding remarks. It is clear that the upper bound for F_{mult} can be improved further, by using a larger number of directions in the basic construction. For example, we can take $k = 27$, divide the 27 vectors u_i into 3 groups by 9, apply the choice of the α_i as in the construction for $k = 9$ for each of these groups separately, and then force the additional relation $v_{27} = v_9 + v_{18}$, say. We can then continue and get better and better constructions for k 's of the form 3^m .

But analyzing these constructions seems demanding; already the case $k = 27$ looks challenging even with the help of a computer. Moreover, it appears that the improvements get very small as m grows. There might be a nice theory hiding behind such constructions, but, since this is only one particular class of examples, it is not clear whether understanding them better would be of much help for estimating the functions F and F_{mult} , which was our main objective in this paper.

5. Open problems. Our work was motivated by a question of Holub [11], which in our language can be reformulated as estimating $f(u_1, \dots, u_k)$ for $u_i = (1, i)$ (i.e., u_i is the direction with slope i). The problem emerged in a study of certain systems of equations over free semigroups; originally it deals with a set $F = \{x \mapsto a_i x + b_i : i = 1, 2, \dots, n\}$ of n linear functions, and it asks for what k we can be sure that every F is uniquely determined by the multiset of its values for $x = 1, 2, \dots, k$. An almost identical question appeared a few years later as a problem by Hillar and Levine in the American Mathematical Monthly [10]. In our geometric context, these special directions $(1, i)$ do not seem to have any special significance; yet, even disregarding the algebraic motivation, it would be interesting to have a simple explicit set of directions that allows unique reconstruction of large sets.⁴ Unfortunately, our current methods are unlikely to yield any nontrivial lower bound in this case.

Acknowledgments. We thank Štěpán Holub for raising a problem that brought us to the research reported here, Attila Pór for fruitful discussions concerning the upper bounds, Géza Tóth for the idea of considering the interchange graph, and Noga Alon for pointing out [1].

MINIMUM COST HOMOMORPHISMS TO SEMICOMPLETE BIPARTITE DIGRAPHS*

GREGORY GUTIN[†], ARASH RAFIEY[‡], AND ANDERS YEO[§]

Abstract. For digraphs D and H , a mapping $f : V(D) \rightarrow V(H)$ is a homomorphism of D to H if $uv \in A(D)$ implies $f(u)f(v) \in A(H)$. If, moreover, each vertex $u \in V(D)$ is associated with costs $c_i(u)$, $i \in V(H)$, then the cost of the homomorphism f is $\sum_{u \in V(D)} c_{f(u)}(u)$. For each fixed digraph H , we have the *minimum cost homomorphism problem for H* . The problem is to decide, for an input graph D with costs $c_i(u)$, $u \in V(D)$, $i \in V(H)$, whether there exists a homomorphism of D to H and, if one exists, to find one of minimum cost. Minimum cost homomorphism problems encompass (or are related to) many well-studied optimization problems. We describe a dichotomy of the minimum cost homomorphism problem for semicomplete bipartite digraphs H . This solves an open problem from an earlier paper. To obtain the dichotomy of this paper, we introduce and study a new notion, a k -Min-Max ordering of digraphs.

Key words. homomorphisms, minimum cost homomorphisms, semicomplete bipartite digraphs

1. Introduction.

Motivation. We consider only directed (undirected) graphs that have neither loops nor multiple arcs (edges). In this paper we solve a problem raised in [6] to find a dichotomy for the computational complexity of the minimum cost homomorphism problem (MCH) for semicomplete bipartite digraphs (we define this problem below). In fact, our result leads to a complete dichotomy for the computational complexity of MCH for semicomplete k -partite digraphs ($k \geq 2$) as a (much simpler) dichotomy for the case $k \geq 3$ was obtained in [6] (see also section 5). Our result uses and significantly extends a dichotomy for the computational complexity of MCH for bipartite undirected graphs obtained in [4].

In our previous papers we used properties of an important notion of Min-Max ordering of digraphs. To obtain the dichotomy of this paper, we introduce and study a new notion, a k -Min-Max ordering of digraphs. We believe that properties of this notion and, in particular, Theorem 2.2 can be used to obtain further results on MCH and its special cases. Recent results obtained in [3, 7] and other papers led us to conjecture in [7] that, unless $P=NP$, MCH is polynomial time solvable only when H admits either a Min-Max ordering or a k -Min-Max ordering for some $k \geq 2$.

The MCH was introduced in [8], where it was motivated by a real-world problem in defense logistics. We believe it offers a practical and natural model for the optimization of weighted homomorphisms. MCH's special cases include the well-known

list homomorphism problem [10, 12] and the general optimum cost chromatic partition problem, which has been intensively studied [9, 13, 14] and has a number of applications, [16, 17]. A problem more general than MCH was considered in [2].

Minimum cost homomorphisms. For directed or undirected graphs G and H , a mapping $f : V(G) \rightarrow V(H)$ is a *homomorphism of G to H* if $uv \in E(G)$ implies $f(u)f(v) \in E(H)$. The recent treatments of homomorphisms in directed and undirected graphs can be found in [10, 12]. Let H be a fixed directed or undirected graph. The *homomorphism problem* for H asks whether a directed or undirected input graph G admits a homomorphism to H . The *list homomorphism problem* for H asks whether a directed or undirected input graph G with lists (sets) $L_u \subseteq V(H)$, $u \in V(G)$ admits a homomorphism f to H in which $f(u) \in L_u$ for each $u \in V(G)$.

Suppose G and H are directed (or undirected) graphs, and $c_i(u)$, $u \in V(G)$, $i \in V(H)$ are nonnegative *costs*. The *cost of a homomorphism f* of G to H is $\sum_{u \in V(G)} c_{f(u)}(u)$. If H is fixed, the *MCH for H* $\text{MinHOM}(H)$ is the following optimization problem. Given an input graph G , together with costs $c_i(u)$, $u \in V(G)$, $i \in V(H)$, we wish to find a minimum cost homomorphism of G to H or state that none exists.

A bipartite digraph is *semicomplete* if there is at least one arc between every two vertices belonging to different partite sets. In this paper, we study the *MCH for semicomplete bipartite digraphs*, i.e., $\text{MinHOM}(H)$ when H is a *semicomplete bipartite digraph*. Observe that MCH for semicomplete bipartite digraphs extends MCH for bipartite undirected graphs. Indeed, let B be a semicomplete bipartite digraph, with partite sets U, V and arc set $A(B) = A_1 \cup A_2$, where $A_1 = \{uv : u \in U, v \in V\}$ and $A_2 \subseteq \{vu : v \in V, u \in U\}$. Let B' be a bipartite graph, with partite sets U, V and edge set $E(B') = \{uv : vu \in A_2\}$. Notice that $\text{MinHOM}(B)$ is equivalent to $\text{MinHOM}(B')$.

Min-Max ordering. Let H be a digraph. We say that an ordering $v_1, v_2, \dots, v_p$ of $V(H)$ is a *Min-Max ordering* of H if $v_i v_r, v_j v_s \in A(H)$ implies $v_{\min\{i,j\}} v_{\min\{s,r\}} \in A(H)$ and $v_{\max\{i,j\}} v_{\max\{s,r\}} \in A(H)$. One can easily see that $v_1, v_2, \dots, v_p$ of $V(H)$ is a Min-Max ordering of H if $i < j$, $s < r$ and $v_i v_r, v_j v_s \in A(H)$, then $v_i v_s \in A(H)$ and $v_j v_r \in A(H)$. We can define a Min-Max ordering for a bipartite undirected graph G , with partite sets V and U as follows: We orient all edges from V to U and apply the above definition for digraphs. The importance of Min-Max ordering for $\text{MinHOM}(H)$ is indicated in the following two theorems.

THEOREM 1.1 (see [5]). *Let a digraph H have a Min-Max ordering. Then $\text{MinHOM}(H)$ is polynomial time solvable.*

A bipartite graph H with vertices $x_1, x_2, x_3, x_4, y_1, y_2, y_3$ is called

- (a) a *bipartite claw* if its edge set $E(H) = \{x_4 y_1, y_1 x_1, x_4 y_2, y_2 x_2, x_4 y_3, y_3 x_3\}$;
- (b) a *bipartite net* if its edge set $E(H) = \{x_1 y_1, y_1 x_3, y_1 x_4, x_3 y_2, x_4 y_2, y_2 x_2, y_3 x_4\}$;
- (c) a *bipartite tent* if its edge set $E(H) = \{x_1 y_1, x_1 y_2, x_1 y_3, x_2 y_1, x_2 y_3, x_3 y_1, x_4 y_1, x_4 y_2\}$.

See Figure 1.

THEOREM 1.2 (see [4]). *Let H be an undirected bipartite graph. If H contains a cycle C_{2k} , $k \geq 3$ or a bipartite claw or a bipartite net or a bipartite tent as an induced subgraph, then $\text{MinHOM}(H)$ is NP-hard.*

Assume that $P \neq \text{NP}$. Then the following three assertions are equivalent:

- (i) H has a Min-Max ordering;
- (ii) $\text{MinHOM}(H)$ is polynomial time solvable;

FIG. 1. A bipartite claw (a), a bipartite net (b), and a bipartite tent (c).

- (iii) H does not contain a cycle C_{2k} , $k \geq 3$, a bipartite claw, a bipartite net, or a bipartite tent as an induced subgraph.

Additional terminology and notation. For a graph H , $V(H)$ and $E(H)$ denote its vertex and edge sets, respectively. For a digraph H , $V(H)$ and $A(H)$ denote its vertex and arc sets, respectively. For a pair X, Y of vertex sets of a digraph, H , $(X, Y)_H$ denotes the set of all arcs of the form xy , where $x \in X, y \in Y$. We omit the subscript when it is clear from the context. Also, $X \times Y = \{xy : x \in X, y \in Y\}$. For a set $X \subseteq V(H)$, let $N^+(X) = \{y : \exists x \in X \text{ with } xy \in A(H)\}$ and $N^-(X) = \{y : \exists x \in X \text{ with } yx \in A(H)\}$.

If xy is an arc of a digraph H , we will say that y is an *out-neighbor* of x , and x is an *in-neighbor* of y . We also denote it by $x \rightarrow y$. For disjoint sets $X, Y \subseteq V(H)$, $X \rightarrow Y$ means that $x \rightarrow y$ for each $x \in X$ and $y \in Y$.

An *extension* of a digraph G is a digraph D obtained from G by replacing each vertex u of G by a set of independent vertices $u_1, u_2, \dots, u_{n(u)}$ such that, for a pair u, v of vertices in G , $u_i \rightarrow v_j$ in D if and only if $u \rightarrow v$ in G .

For a bipartite digraph $H = (V, U; A)$, where V and U are its partite sets, $H^{\rightarrow}$ is the subdigraph induced by all arcs directed from V to U , $H^{\leftarrow}$ is the subdigraph induced by all arcs directed from U to V , and $H^{\leftrightarrow}$ is the subdigraph induced by all 2-cycles of H , i.e., by the set $\{xy : xy \in A, yx \in A\}$. A digraph H is an *oriented graph* if it does not contain a 2-cycle, i.e., if $H^{\leftrightarrow}$ is empty. The *converse* of H is the digraph obtained from H by replacing every arc xy with the arc yx .

We denote a directed cycle with p vertices by $\vec{C}_p$. For a set X of vertices of a digraph H , $D[X]$ denotes the subdigraph of H induced by X . For a digraph H , $\text{UN}(H)$ denotes the *underlying graph* of H , i.e., an undirected graph obtained from H by disregarding all orientations and deleting multiple edges.

A digraph D is *strong* (or, *strongly connected*) if there is a directed path from x to y and a directed path from y to x for every pair x, y of vertices of D . A *strong component* of a digraph D is a strong maximal induced subdigraph of D .

Forbidden family. Let us introduce five special digraphs for which, as we will see later, the minimum homomorphism problem is NP-hard. The digraphs are depicted in Figures 2 and 3.

The digraph C'_4 has vertices $\{x_1, x_2, y_1, y_2\}$ and arcs $\{x_1y_1, y_1x_2, x_2y_2, y_2x_1, y_1x_1\}$. The digraph C''_4 has the same vertex set, but its arc set is $A(C'_4) \cup \{x_2y_1\}$. The digraph H^* has vertex set $\{x_1, x_2, y_1, y_2, y_3\}$ and arc set $\{x_1y_1, y_1x_2, x_2y_2, y_2x_1, x_1y_3, x_2y_3\}$.

Let N_1 be a digraph, with $V(N_1) = \{x_1, x_2, x_3, y_1, y_2, y_3\}$ and

$$A(N_1) = \{x_1y_1, y_1x_1, x_2y_2, y_2x_2, x_3y_3, y_3x_3, y_1x_2, y_1x_3, x_1y_2, x_1y_3, x_3y_2, x_2y_3\}.$$

 FIG. 2. The digraphs C'_4 , C''_4 , and H^* .

 FIG. 3. The digraphs N_1 and N_2 .

Let N_2 be a digraph, with $V(N_2) = \{x_1, x_2, x_3, y_1, y_2, y_3\}$ and

$$A(N_2) = \{x_1y_1, x_2y_2, y_2x_2, x_3y_3, y_3x_3, y_1x_2, y_1x_3, x_1y_2, x_1y_3, x_3y_2, x_2y_3\}.$$

A digraph H belongs to the family $\mathcal{HFORB}$ if H or its converse is isomorphic to one of the five digraphs above or $\text{UN}(H^s)$ is isomorphic to bipartite claw, bipartite net, bipartite tent, or even cycle with at least 6 vertices, where $s \in \{\rightarrow, \leftarrow, \leftrightarrow\}$.

k -Min-Max ordering. A collection $V_1, V_2, \dots, V_k$ of subsets of a set V is called a k -partition of V if $V = V_1 \cup V_2 \cup \dots \cup V_k$, $V_i \cap V_j = \emptyset$ provided $i \neq j$.

DEFINITION 1.3. Let $H = (V, A)$ be a digraph, and let $k \geq 2$ be an integer. We say that H has a k -Min-Max ordering if there is a k -partition of V into subsets $V_1, V_2, \dots, V_k$ and there is an ordering $v_1^i, v_2^i, \dots, v_{\ell(i)}^i$ of V_i for each i such that

- (i) Every arc of H is an (V_i, V_{i+1}) -arc for some $i \in \{1, 2, \dots, k\}$,
- (ii) $v_1^i, v_2^i, \dots, v_{\ell(i)}^i, v_1^{i+1}, v_2^{i+1}, \dots, v_{\ell(i+1)}^{i+1}$ is a Min-Max ordering of the subdigraph $H[V_i \cup V_{i+1}]$ for all $i \in \{1, 2, \dots, k\}$,

where all indices $i+1$ are taken modulo k . We call the ordering

$$v_1^1, v_2^1, \dots, v_{\ell(1)}^1, v_1^2, v_2^2, \dots, v_{\ell(2)}^2, \dots, v_1^k, v_2^k, \dots, v_{\ell(k)}^k$$

a k -Min-Max ordering of H .

Note that, if H is a strong digraph in which the greatest common divisor of all cycle lengths is k , then $V(H)$ has a k -partition, $k \geq 2$, satisfying (i) (see Theorem 10.5.1 in [1]). A simple example of a digraph having a k -Min-Max ordering is an extension of $\vec{C}_k$.

Dichotomy and paper organization. The main result of this paper is the following.

THEOREM 1.4. *Let H be an semicomplete bipartite digraph. If H contains a digraph from $\mathcal{HFORB}$ as an induced subdigraph, then $\text{MinHOM}(H)$ is NP-hard.*

Assume that $P \neq \text{NP}$. Then the following three assertions are equivalent:

- (i) *$\text{MinHOM}(H)$ is polynomial time solvable;*
- (ii) *H does not contain a digraph from $\mathcal{HFORB}$ as an induced subdigraph;*
- (iii) *Each component of H has a k -Min-Max ordering for $k = 2$ or 4 .*

Theorem 1.4 follows from Corollaries 3.5 and 4.6.

The rest of the paper is organized as follows. In section 2, we study properties of k -Min-Max orderings. In section 3, we prove polynomial cases of $\text{MinHOM}(H)$, when H is a semicomplete bipartite digraph. In section 4, we establish NP-hard cases of the problem. In section 5 we formulate a dichotomy for the computational complexity of $\text{MinHOM}(H)$, when H is a semicomplete multipartite digraph. Section 6 provides a short discussion of further research.

2. Properties of k -Min-Max orderings. Digraphs having k -Min-Max ordering have a very special structure as described in the following lemma.

LEMMA 2.1. *If a digraph $H = (V, A)$ has a k -Min-Max ordering as described in Definition 1.3 and $I = \{x \in V : d^-(x) = 0\}$, then we can define $0 \leq L(i, j) < R(i, j) \leq \ell(j) + 1$ for all i and j such that the following holds:*

- (a) *We have $N^+(v_i^j) = \{v_{L(i,j)+1}^{j+1}, v_{L(i,j)+2}^{j+1}, \dots, v_{R(i,j)-1}^{j+1}\} \setminus I$ for each $v_i^j \in V$ with positive out-degree, where all superscripts are taken modulo k ;*
- (b) *For all j and $i < i'$, we have $R(i, j) \leq R(i', j)$ and $L(i, j) \leq L(i', j)$.*

Proof. If $d_H^+(v_i^j) > 0$, then let $L(i, j)$ be the maximum number such that $N^+(v_i^j) \cap \{v_1^{j+1}, v_2^{j+1}, \dots, v_{L(i,j)}^{j+1}\} = \emptyset$, and let $R(i, j)$ be the minimum number such that $N^+(v_i^j) \cap \{v_{R(i,j)}^{j+1}, v_{R(i,j)+1}^{j+1}, \dots, v_{\ell(j)}^{j+1}\} = \emptyset$. If $d_H^+(v_i^j) = 0$, then if $i = 1$, we let $L(i, j) = 1 = R(i, j) - 1$ and if $i > 1$, we let $L(i, j) = L(i-1, j)$ and $R(i, j) = R(i-1, j)$.

Suppose that, for some m and $p \geq 2$, we have $v_m^j v_m^{j+1}, v_i^j v_{m+p}^{j+1} \in A$, but $v_i^j v_{m+1}^{j+1}, \dots, v_i^j v_{m+p-1}^{j+1} \notin A$ and $v_{m+s}^{j+1} \notin I$, where $1 \leq s \leq p-1$. Since $v_m^{j+s} \notin I$, there is an arc $v_i^j v_m^{j+s}$ in H . By the definition of a k -Min-Max ordering $v_i^j v_m^{j+1} \in A$, a contradiction that proves (a).

We now prove (b). If $d^+(v_i^j) > 0$ and $d^+(v_{i'}^j) > 0$, then this follows from the k -Min-Max ordering using an analogous argument as above. If $i = 1$ and $d^+(v_i^j) = 0$, then we also see that (b) holds. We now prove the remaining cases by induction on $i + i'$. If $d^+(v_i^j) = 0$, consider $i-1$ instead of i and if $d^+(v_{i'}^j) = 0$, then consider $i'-1$ instead of i' . If the new i and i' are equal, then (b) holds, and otherwise we are done by induction. $\square$

The construction used in the following theorem was inspired by somewhat similar constructions in [15] and [2].

THEOREM 2.2. *If a digraph H has a k -Min-Max ordering, then $\text{MinHOM}(H)$ is polynomial time solvable.*

Proof. Let H have a k -Min-Max ordering. Let $V_1, V_2, \dots, V_k$ be defined as in Definition 1.3. If there is a homomorphism h of D to H , then each $h^{-1}(V_i)$, $i = 1, 2, \dots, k$ is an independent set. Thus, we may say that the vertices of $h^{-1}(V_i)$ are of color i . We may assume that $\text{UN}(D)$ is connected, as otherwise we consider a minimum cost homomorphism of each component of D (corresponding to a component of $\text{UN}(D)$) separately.

Let $z \in V(D)$ be an arbitrary vertex. We will show how to decide whether there is a homomorphism f of D to H such that $f(z) \in V_i$ for each $i \in \{1, 2, 3, \dots, k\}$. If such a homomorphism exists for a given i , then we will furthermore show how to find a minimum cost homomorphism of D to H such that $f(z) \in V_i$. We may assume without loss of generality that $i = 1$.

Now assign color 1 to z . Assign every out-neighbor of z color 2 and each in-neighbor of z color k . For every vertex z' with color i , we assign every out-neighbor of z' color $i + 1$ modulo k and every in-neighbor of z' color $i - 1$ modulo k . If some vertex of D is assigned different colors, then clearly there is no homomorphism of D to H , so assume that this is not the case.

Consider the k -partition $G_1, G_2, \dots, G_k$ of $V(D)$ such that all vertices of G_j were assigned color j for each $j \in \{1, 2, \dots, k\}$. Clearly, all arcs in D are (G_j, G_{j+1}) -arcs, where all indices are taken modulo k and $j \in \{1, 2, 3, \dots, k\}$. Note that, if f is a homomorphism of D to H such that $f(z) \in V_1$, then for all $y_j \in G_j$, we must have $f(y_j) \in V_j$.

We will build a weighted digraph (network) $\mathcal{L}$, with vertex set $\cup_{j=1}^k (G_j \times V_j)$ together with two other vertices denoted by s and t . We will also denote t by $(x, v_{\ell(j)+1}^j)$ for every $j \in \{1, 2, \dots, k\}$. The weighted arcs of $\mathcal{L}$ are as follows, where M is any constant greater than the cost of a minimum cost homomorphism of D to H .

- An arc from s to (x, v_1^j) , of weight ∞ , for each $x \in G_j$.
- An arc, $e_{i,j}^x$, from (x, v_i^j) to (x, v_{i+1}^j) , for each $x \in G_j$ and $i \in \{1, 2, \dots, \ell(j)\}$. Recall that, when $i = \ell(j)$, the arc enters t . We define the weight of $e_{i,j}^x$ as follows. If $d_D^-(x) > 0$ and $d_H^-(v_i^j) = 0$, then the weight is ∞ . If $d_D^+(x) > 0$ and $d_H^+(v_i^j) = 0$, then the weight is ∞ . Otherwise, the weight is $c_{v_i}(x) + M$.
- An arc from (x, v_i^j) to $(y, v_{L(i,j)+1}^{j+1})$ and an arc from $(y, v_{R(i,j)}^{j+1})$ to (x, v_{i+1}^j) for every $xy \in A(D)$, with $x \in G_j$ and every $i = 1, 2, \dots, \ell(j)$. Furthermore the weight of these arcs are ∞ .

A *cut* in $\mathcal{L}$ is a partition of the vertices into two sets S and T such that $s \in S$ and $t \in T$ and the weight of a cut is the sum of the weights of all arcs going from a vertex of S to a vertex of T . We will show that a minimum weight cut in $\mathcal{L}$ has weight equal to the minimum cost homomorphism f of D to H such that $f(z) \in V_1$ plus $|V(D)|M$, if such a homomorphism exists. Otherwise, a minimum weight cut in $\mathcal{L}$ is of weight at least $|V(D)|M + M$.

Assume f is a minimum cost homomorphism of D to H such that $f(z) \in V_1$, and assume that $f(x) = v_{a(x)}^j$ for each $x \in G_j$ and for all $j = 1, 2, \dots, k$. Define a cut in $\mathcal{L}$ as follows: $S = \{(x, v_i^j) : i \leq a(x), j = 1, 2, \dots, k\} \cup \{s\}$ and $T = V(\mathcal{L}) - S$. Since f is a homomorphism of D to H , we note that, if $d_D^-(x) > 0$ then $d_H^-(v_{a(x)}^j) > 0$ and if $d_D^+(x) > 0$, then $d_H^+(v_{a(x)}^j) > 0$. Therefore the arcs from $(x, v_{a(x)}^j)$ to $(x, v_{a(x)+1}^j)$ belong to the cut and contribute $c_{f(x)}(x) + M$ to the weight of the cut (and not ∞). We will now show that there are no arcs of infinite weight in the cut, which would imply that the weight of S is exactly the cost of a minimum cost homomorphism from D to H plus $|V(D)|M$.

Clearly no arc out of s belongs to the cut S . Assume for the sake of contradiction that the arc (x, v_i^j) to $(y, v_{L(i,j)+1}^{j+1})$ belongs to the cut S for some $xy \in A(D)$, with $x \in G_j$. This implies that $a(x) \geq i$ (as $(x, v_i^j) \in S$) and $a(y) < L(i, j) + 1$ (as $(y, v_{L(i,j)+1}^{j+1}) \notin S$). By Lemma 2.1(b), this implies that $a(y) \leq L(i, j) \leq L(a(x), j)$. Thus, there is no arc from $v_{a(x)}^j$ to $v_{a(y)}^{j+1}$ in H , by the definition of $L(i, j)$. This is a contradiction to f being a homomorphism.

Now assume for the sake of contradiction that the arc $(y, v_{R(i,j)}^{j+1})$ to (x, v_{i+1}^j) belongs to the cut S for some $xy \in A(D)$, with $x \in G_j$. This implies that $a(x) < i+1$ (as $(x, v_{i+1}^j) \notin S$) and $a(y) \geq R(i, j)$ (as $(y, v_{R(i,j)}^{j+1}) \in S$). By Lemma 2.1(b), this implies that $a(y) \geq R(i, j) \geq R(a(x), j)$. Thus, there is no arc from $v_{a(x)}^j$ to $v_{a(y)}^{j+1}$ in H , by the definition of $R(i, j)$. This is a contradiction to f being a homomorphism. We have now proved that the cut S has the stated weight when there is a homomorphism of D to H , with $f(z) \in V_1$.

Assume that S' is a cut of weight less than $M + |V(D)|M$, and note that the cut S' contains exactly one arc of the form $(x, v_i^j)(x, v_{i+1}^j)$ for each $x \in V(D)$. Therefore we may define a mapping f' from $V(D)$ to $V(H)$ by letting $f'(x) = v_i^j$ if and only if $(x, v_i^j) \in S'$ and $(x, v_{i+1}^j) \notin S'$. We will now show that f' is a homomorphism of D to H of cost equal to the weight of the cut S' minus $|V(D)|M$.

Let xy be any arc in D , and assume without loss of generality that $x \in G_j$. Let i_x and i_y be defined such that $(x, v_{i_x}^j) \in S'$ and $(x, v_{i_x+1}^j) \notin S'$ (i.e., $f'(x) = v_{i_x}^j$) and $(y, v_{i_y}^{j+1}) \in S'$ and $(y, v_{i_y+1}^{j+1}) \notin S'$ (i.e., $f'(y) = v_{i_y}^{j+1}$). As the arc $(x, v_{i_x}^j)(y, v_{L(i_x,j)+1}^{j+1})$ is not in the cut, we must have $(y, v_{L(i_x,j)+1}^{j+1}) \in S$, which implies that $i_y \geq L(i_x, j) + 1$. Furthermore as the arc $(y, v_{R(i_x,j)}^{j+1})(x, v_{i_x+1}^j)$ is not in the cut, we must have $(y, v_{R(i_x,j)}^{j+1}) \notin S$, which implies that $i_y < R(i_x, j)$. We have now shown that $L(i_x, j) + 1 \leq i_y < R(i_x, j)$. Since $xy \in A(D)$ and the arc $(x, v_{i_x}^j)(x, v_{i_x+1}^j)$ has finite weight, we observe that $d_H^+(v_{i_x}^j) > 0$ and $v_{i_y}^{j+1} \notin I$, where I is defined in Lemma 2.1. Lemma 2.1 now implies that $v_{i_x}^j v_{i_y}^{j+1}$ is an arc in H . Therefore f' is a homomorphism. It is not difficult to see that the cost of f' is indeed equal to weight of the cut S' minus $|V(D)|M$.

It remains to recall that a minimum weight cut in a network can be found in polynomial time [1]. $\square$

3. Polynomial cases. We start from a special case which is of importance when H contains no induced $\vec{C}_4$.

LEMMA 3.1. *Let $H = (V, U; A)$ be a semicomplete bipartite digraph, which does not contain an induced subdigraph belonging to $\mathcal{HFORB}$. Suppose for every $v, v' \in V$, we have $N^+(v) \subseteq N^+(v')$ or $N^+(v') \subseteq N^+(v)$. Then H has a 2-Min-Max ordering.*

Proof. We say that vertices $v_i, v_j \in V$ are *similar* if $N^+(v_i) = N^+(v_j)$. Consider similarity classes $V_1, V_2, \dots, V_s$ of V . Moreover, assume that $N^+(V_i) \subset N^+(V_j)$ for $i < j$. Set $U_1 = N^+(V_1)$ and $U_i = N^+(V_i) - \bigcup_{j=1}^{i-1} U_j$ for each $i > 1$. If $s = 1$, then $\text{UN}(H^{\rightarrow})$ is a complete bipartite graph. By Theorem 1.2, $H^{\leftarrow}$ has a Min-Max ordering π . Observe that the orderings of vertices in V and U given by the relative order of vertices in π generate a 2-Min-Max ordering of H . Assume $s > 1$. We prove the following two claims:

- (1) Let $u_i \in U_i$, $v_j \in V_j$, $j > i$, and $u_i v_j \in A$. Then $U_r \rightarrow v_j$ for each $r > i$ and $u_i \rightarrow V_t$ for each $t < j$.

Proof of (1). By the definition of U_i and V_i , if $r > j$, then $U_r \rightarrow v_j$. Now suppose that $i < r \leq j$ and $u_r v_j \notin A$ for some $u_r \in U_r$. Let $v_i \in V_i$ be arbitrary, and note that $H[\{u_i, v_i, u_r, v_j\}]$ is isomorphic to C'_4 or C''_4 , a contradiction. So $u_r v_j \in A$.

By the definition of U_i and V_i , if $t < i$, then $u_i \rightarrow V_t$. Now suppose that $i \leq t < j$ and that $u_i v_t \notin A$ for some $v_t \in V_t$. Let $u_j \in U_j$ be arbitrary, and note that $H[\{u_i, v_t, u_j, v_j\}]$ is isomorphic to C'_4 or C''_4 , a contradiction.

- (2) If $u, u' \in U$, then $N^+(u) \subseteq N^+(u')$ or $N^+(u') \subseteq N^+(u)$.

Proof of (2). Assume that this is not the case, and there exist $v \in N^+(u) - N^+(u')$ and $v' \in N^+(u') - N^+(u)$. This implies that $u \neq u', v \neq v', uv, u'v' \in A$, and $uv', u'v \notin A$. If $u \in U_i$ and $u' \in U_j$ and $i < j$, then by (1) we note that $u'v \in A$, a contradiction. So, for some i , we must have $\{u, u'\} \subseteq U_i$. Analogously, if $v \in V_a$ and $v' \in V_b$ and $a < b$, then by (1) we note that $u'v \in A$, a contradiction. So, for some j , we must have $\{v, v'\} \subseteq V_j$. If $i > j$, then $U_i \rightarrow V_j$, which is a contradiction, so we must have $i \leq j$.

If $i < j$, then let $u'' \in U_j$ and $v'' \in V_i$ be arbitrary. Note that by (1) we must have the arcs $u''v, u''v', uv'', u'v''$ in H . By the construction of the sets U_i, U_j, V_i, V_j we now note that the underlying graph of $H[\{u, u', u'', v, v', v''\}]^{\leftrightarrow}$ is the 6-cycle $v''uvu''v'u'v''$, a contradiction.

Therefore we must have $i = j$. First assume that $i < s$. Now consider $v_s \in V_s$ and $u_s \in U_s$. By (1) there is no arc from $\{u, u'\}$ to v_s . However, $H[\{u, u', v, v', v_s, u_s\}]$ is either N_1 or N_2 , a contradiction.

Similarly, for the case $i = s$, we derive a contradiction.

Now consider an ordering $u_1, u_2, \dots, u_a$ of the vertices in U and an ordering $v_1, v_2, \dots, v_b$ of the vertices in V , defined as follows. If $i < j$, then $d^+(v_i) \leq d^+(v_j)$ and if $d^+(v_i) = d^+(v_j)$, then $d^-(v_i) \geq d^-(v_j)$. Furthermore when $i < j$, then $d^+(u_i) \leq d^+(u_j)$ and if $d^+(u_i) = d^+(u_j)$, then $d^-(u_i) \geq d^-(u_j)$. Note that the ordering $v_1, v_2, \dots, v_b$ first contains vertices from V_1 , then from V_2 , etc.

We will now show that, for every $i \in \{1, 2, \dots, b\}$, there exists an integer α_i such that $N^+(u_i) = \{v_1, v_2, \dots, v_{\alpha_i}\}$. Suppose this is not the case. Then there exists an arc $u_i v_j$ in H such that $u_i v_{j-1}$ is not an arc in H . Thus, both v_j and v_{j-1} belong to some V_k , as otherwise we have a contradiction to (1). This implies that $d^+(v_j) = d^+(v_{j-1})$ and $d^-(v_{j-1}) \geq d^-(v_j)$. Note that every vertex $u \in N^-(v_{j-1})$ has $N^+(u_i) \subseteq N^+(u)$, by (2). Therefore $u \rightarrow v_j$. However, this implies that $d^-(v_{j-1}) < d^-(v_j)$ (as $u_i \rightarrow v_j$ but $u_i v_{j-1} \notin A(H)$), a contradiction.

Using the fact that $N^+(u_i) = \{v_1, v_2, \dots, v_{\alpha_i}\}$ for each $i \in \{1, 2, \dots, b\}$ and that $\alpha_i \geq \alpha_{i-1}$ for each $i \in \{2, 3, \dots, b\}$ (as $d^+(u_i) \geq d^+(u_{i-1})$) and the similar relations for the vertices of V , we can readily conclude that H has a 2-Min-Max ordering. $\square$

The *distance* $\text{dist}(x, y)$ between a pair x, y of vertices in an undirected graph G is the length of the shortest path between x and y . The *diameter* of G is the maximal distance between a pair of vertices in G .

The following theorem shows when $\text{MinHOM}(H)$ is polynomial time solvable if H is strong and does not contain $\tilde{C}_4$ as an induced subdigraph.

THEOREM 3.2. *Let H be a strongly connected semicomplete bipartite digraph. Assume that H does not contain a digraph from $\mathcal{HFORB}$ or $\tilde{C}_4$ as an induced subdigraph. Then H has a 2-Min-Max ordering, and $\text{MinHOM}(H)$ is polynomial time solvable.*

Furthermore, either $\text{UN}(H^{\rightarrow})$ or $\text{UN}(H^{\leftarrow})$ are complete bipartite graphs, or the following holds. For every pair u, u' of distinct vertices of U , we have $N^+(u) \subseteq N^+(u')$ or $N^+(u') \subseteq N^+(u)$ and for every pair v, v' of distinct vertices of V , we have $N^+(v) \subseteq N^+(v')$ or $N^+(v') \subseteq N^+(v)$.

Proof. By Theorem 2.2, to prove the first part of this theorem (before “Furthermore”), it suffices to show that H has a 2-Min-Max ordering. Let V and U be partite sets of H . Denote $H_1 = H^{\rightarrow}$ and $H_2 = H^{\leftarrow}$. It follows from Theorem 1.2 that $\text{UN}(H_1)$ and $\text{UN}(H_2)$ have Min-Max orderings and so do H_1 and H_2 .

Let d_i be the diameter of $\text{UN}(H_i)$, $i = 1, 2$. Observe that if $\text{UN}(H_1)$ ($\text{UN}(H_2)$) is a complete bipartite graph, then, as in the proof of Lemma 3.1, a Min-Max ordering of

$H_2(H_1)$ generates a 2-Min-Max ordering of H . Therefore, $\text{MinHOM}(H)$ is polynomial time solvable by Theorem 2.2. Notice that $\text{UN}(H_i)$ is complete bipartite if and only if $d_i = 2$. Thus, we may assume that both $d_1 \geq 3$ and $d_2 \geq 3$.

We consider the following cases for the value of $d_1 \geq 3$.

Case 1: $d_1 > 4$.

We will show that $\text{UN}(H_2)$ is a complete bipartite graph, or equivalently, $d_2 = 2$. Assume that d_1 is odd, as the case of d_1 even can be considered similarly. Let $P = v_1 u_1 v_2 u_2 \dots v_{k-1} u_{k-1} v_k u_k$ be a shortest path of length d_1 between v_1 and u_k in $\text{UN}(H_1)$. Let $\hat{U} = \{u_1, u_2, \dots, u_k\}$, and $\hat{V} = \{v_1, v_2, \dots, v_k\}$. We will first prove that $\hat{U} \rightarrow \hat{V}$. Since P is a shortest path, we have $u_i \rightarrow v_j$ for each $u_i \in \hat{U}$ and $v_j \in \hat{V}$ provided $j \notin \{i, i+1\}$. Thus, it sufficient to prove

$$(1) \quad u_i \rightarrow v_i \ (i = 1, 2, \dots, k) \text{ and } u_i \rightarrow v_{i+1} \ (i = 1, 2, \dots, k-1).$$

Consider the subdigraph H' of H induced by four vertices $v_i, u_i, v_{i+2}, u_{i+1}$, where $i \in \{1, 2, \dots, k-2\}$. By the definition of P (including the fact that P is a shortest path), we have $v_i u_i, v_{i+2} u_{i+1}, u_{i+1} v_i, u_i v_{i+2} \in A(H)$, but $v_i u_{i+1}, v_{i+2} u_i \notin A(H)$. Since H' is not isomorphic to either $\vec{C}_4$ or C'_4 , we have $u_i v_i, u_{i+1} v_{i+2} \in A(H)$. This proves that $u_i \rightarrow v_i$ provided $i = 1, 2, \dots, k-2$ and $u_i \rightarrow v_{i+1}$ provided $i = 2, 3, \dots, k-1$. Thus, to prove (1) it remains to show that

$$(2) \quad u_{k-1} \rightarrow v_{k-1}, \ u_k \rightarrow v_k, \ u_1 \rightarrow v_2.$$

Consider the subdigraph H'' of H induced by four vertices $v_{k-1}, u_{k-1}, v_k, u_k$. By the definition of P , we have $v_{k-1} u_{k-1}, v_k u_k, v_k u_{k-1}, u_k v_{k-1} \in A(H)$, but $v_{k-1} u_k \notin A(H)$. We have proved that $u_{k-1} \rightarrow v_k$. Since H'' is not isomorphic to C'_4 or C''_4 , we have $u_{k-1} v_{k-1}, u_k v_k \in A(H)$.

Consider $H[\{v_2, v_3, u_1, u_2\}]$. By the definition of P , we have $v_2 u_1, v_2 u_2, v_3 u_2, u_1 v_3 \in A(H)$, but $v_3 u_1 \notin A(H)$. We have proved that $u_2 \rightarrow v_2$. Since $H[\{v_2, v_3, u_1, u_2\}]$ is not isomorphic to C'_4 or C''_4 , we have $u_1 v_2, u_2 v_3 \in A(H)$. This implies that (2), and thus (1), has been proved.

Consider vertex $u \in U - \hat{U}$; we will show that $u \rightarrow \hat{V}$. Suppose this is not true. Let j be the smallest index such that $uv_j \notin A(H)$. We have $v_j u \in A(H)$. Suppose $j > 1$. Since $H[\{u, v_1, u_1, v_j\}]$ is not isomorphic to C'_4 or C''_4 , we have $v_j u_1, v_1 u \in A(H)$. Since P is a shortest path, we have $j = 2$, as otherwise $v_1 u v_j u_{j+1} \dots v_j u_k$ is shorter than P . We have $v_3 u \notin A(H)$, as otherwise $v_1 u v_3 u_3 \dots v_k u_k$ is shorter than P . However, C'_4 is isomorphic to $H[\{v_2, u, v_3, u_3\}]$, a contradiction.

Now assume that $j = 1$. We have $v_3 u \notin A(H)$, as otherwise we have a shorter path. Since H is semicomplete bipartite, we have $uv_3 \in A(H)$. However, $H[\{v_1, u, v_3, u_2\}] \cong C'_4$, a contradiction.

Analogously we can prove that $\hat{U} \rightarrow v$ for every $v \in V - \hat{V}$. Consider $u \in U - \hat{U}$, $v \in V - \hat{V}$. We show that $uv \in A(H)$. Suppose this is not true. We have $vu \in A(H)$. Since $H[\{v, u, v_1, u_1\}]$ is not isomorphic to $\vec{C}_4$, C'_4 , or C''_4 , we have $v_1 u, v u_1 \in A(H)$. Since $H[\{v, u, v_k, u_k\}]$ is not isomorphic to C'_4 or C''_4 , we have $v_k u, v u_k \in A(H)$. But now $\text{dist}(v_1, u_k) = 3$ in $\text{UN}(H_1)$, a contradiction.

Case 2: $d_1 = 4$.

We will show that again $\text{UN}(H_2)$ is a complete bipartite graph. Assume that $v_1 u'_1 v'_2 u'_2 v'_3$ is a shortest path between a pair $v_1 \in V$ and $v'_3 \in U$ in $\text{UN}(H_1)$. Let $U_1 = N^+(v_1)$, $V_2 = N^-(U_1) - \{v_1\}$, $U_2 = N^+(V_2) - U_1$, and $V_3 = N^-(U_2) - V_2$. By the definitions, $V = \{v_1\} \cup V_2 \cup V_3$ and $U = U_1 \cup U_2$. Observe also that $(U_1, V_3) = U_1 \times V_3$,

$(V_3, U_1) = \emptyset$, $(U_2, \{v_1\}) = U_2 \times \{v_1\}$, and $(\{v_1\}, U_2) = \emptyset$. Let $u_1 \in U_1$, $u_2 \in U_2$, $v_2 \in V_2$, and $v_3 \in V_3$ be arbitrary. If $u_2v_3 \notin A(H)$, then $v_3u_2 \in A(H)$, and now $H[\{u_1, v_3, u_2, v_1\}]$ is either $\vec{C}_4$ or C'_4 , a contradiction. Therefore, we have $u_2v_3 \in A(H)$, and consequently $(U_2, V_3) = U_2 \times V_3$. Consider v_3, u_2 , where $v_3u_2 \in A(H)$. Since $H[\{u_1, v_3, u_2, v_1\}]$ is not C'_4 or $\vec{C}_4$, we conclude that $u_1v_1 \in A(H)$, and consequently $(U_1, \{v_1\}) = U_1 \times \{v_1\}$.

Note that we have already proved that the underlying graph of $H_2[U_1 \cup U_2 \cup V_3 \cup \{v_1\}]$ is a complete bipartite graph. Suppose $u_1v_2 \in A(H)$. Then $u_2v_2 \in A(H)$, as otherwise $H[\{u_1, v_1, u_2, v_2\}]$ is isomorphic to C'_4 or C''_4 , a contradiction. Therefore, if $u_1v_2 \in A(H)$, then $(U_2, \{v_2\}) = U_2 \times \{v_2\}$. Thus, to show that $(U_2, V_2) = U_2 \times V_2$, it suffices to prove that every vertex in V_2 has an in-neighbor in U_1 . Suppose this is not true, and let X_2 be the set of all vertices in V_2 that does not have an in-neighbor in U_1 . Let Y_2 be the set of all vertices in U_2 that have an arc into X_2 . As H is strong, some vertex in H must have an arc into X_2 , which implies that $Y_2 \neq \emptyset$.

If there is an arc v_3y_2 from V_3 to Y_2 , then let x_2 be an out-neighbor of y_2 in X_2 , and let $u_1 \in U_1$ be arbitrary. However, this is a contradiction to $H[\{v_3, y_2, x_2, u_1\}]$ not being isomorphic to C'_4 and C''_4 , which implies that there is no arc from V_3 to Y_2 .

As H is strong and there is no arc from V_3 into U_1 or Y_2 , there must be an arc, say v_3u_2 , from V_3 into $U_2 - Y_2$. As H is strong, there must also be an arc from $V(H) - X_2 - Y_2$ into $X_2 \cup Y_2$. By the above this arc, say v_2y_2 , must be from $V_2 - X_2$ to Y_2 . As y_2 belongs to Y_2 , there must be a vertex, say $x_2 \in X_2$, such that $y_2x_2 \in A(H)$. As $v_2 \notin X_2$, we note that there is a vertex, say $u_1 \in U_1$, such that $u_1v_2 \in A(H)$. As $u_1x_2 \notin A(H)$ and $H[\{v_2, x_2, u_1, y_2\}]$ is not isomorphic to C'_4 and C''_4 , we note that $x_2y_2, v_2u_1 \in A(H)$. If $u_2v_2 \notin A(H)$, then $H[\{v_1, v_2, u_1, u_2\}]$ is isomorphic to C'_4 and C''_4 (as $v_1u_2 \notin A(H)$), a contradiction. As $u_2v_2 \in A(H)$ and $H[\{v_2, v_3, u_2, y_2\}]$ is not isomorphic to C'_4 and C''_4 , we note that $y_2v_2 \in A(H)$ (as $v_3y_2 \notin A(H)$). As $H[\{v_2, x_2, u_2, y_2\}]$ is not isomorphic to C'_4 and C''_4 , we note that $v_2u_2 \in A(H)$ (as $u_2x_2 \notin A(H)$). However, the underlying graph of $H[v_1, u_1, v_2, v_3, x_2, y_2, u_2]^{\leftrightarrow}$ is now a bipartite claw, with edges $\{v_2u_1, v_2y_2, v_2u_2, u_1v_1, y_2x_2, u_2v_3\}$, a contradiction. Therefore $U_2 \rightarrow V_2$.

We show that $u_1v_2 \in A(H)$ for every $u_1 \in U_1$ and $v_2 \in V_2$. Suppose this is not true for some $v_2 \in V_2$ and $u_1 \in U_1$. Then we have $v_2u_1 \in A(H)$. Let $v_3 \in V_3$ be arbitrary, and $u_2 \in U_2 \cap N^+(v_3)$. Then $H[\{u_1, v_3, u_2, v_2\}]$ is isomorphic to C'_4 or C''_4 . This completes our proof that $\text{UN}(H_2)$ is a complete bipartite graph.

Case 3: $d_1 = 3$.

Consider a Min-Max ordering π for H_1 . Define vertices x, t, y , and z as follows. Let $\pi(x) = \min\{\pi(x') : x' \in V\}$, $\pi(t) = \max\{\pi(t') : t' \in U\}$, $\pi(y) = \max\{\pi(y') : y' \in U, x \rightarrow y'\}$, and $\pi(z) = \min\{\pi(z') : z' \in V, z' \rightarrow t\}$.

Let $T = N^-(t)$. Since H is strong, every vertex of V has an out-neighbor. Since π is a Min-Max ordering, $z' \rightarrow t$ for each $z' \in V$, with $\pi(z') \geq \pi(z)$. Thus, $T = \{z' \in V : \pi(z') \geq \pi(z)\}$. Let $X = N^+(x)$. Since H is strong, every vertex of U has an in-neighbor. Since π is a Min-Max ordering, $x \rightarrow y'$ for each $y' \in U$, with $\pi(y') \leq \pi(y)$. Thus, $X = \{y' \in U : \pi(y') \leq \pi(y)\}$.

Since $\text{dist}(x, z) = 2$ in $\text{UN}(H_1)$, we have $z \rightarrow y'$ for some $y' \in N^+(x)$. Since π is a Min-Max ordering, $z \rightarrow y$ (consider the arcs zy' and xy). Now, for every $z'' \in V$ with $\pi(z'') \leq \pi(z)$, we have $z'' \rightarrow y$ (as π is a Min-Max ordering). Similarly, for every $y'' \in U$ with $\pi(y'') \geq \pi(y)$, we have $z \rightarrow y''$.

Let $\pi(w) = \min\{\pi(w') : w' \in U\}$. Notice that $\text{dist}(w, t) = 2$ in $\text{UN}(H_1)$. Thus, for some $z' \in T$, we have $z' \rightarrow w$. Hence, $z \rightarrow w$ and $z \rightarrow X$ (as π is a Min-Max ordering). We conclude that $z \rightarrow U$. Similarly, we can obtain that $V \rightarrow y$.

Let $Y = V - T$, and $Z = U - X$. Let $x' \in X$, $y' \in Y$. We have $z \rightarrow x'$ and $y' \rightarrow y$. Hence (as π is a Min-Max ordering), $y' \rightarrow x'$. Thus, $Y \rightarrow X$. Analogously, we can prove that $T \rightarrow Z$.

Let $x' \in X$, $t' \in T$, $y' \in Y$, and $x' \rightarrow t'$. Then $t't$, ty' , $y'x' \in A(H)$. Since $H[\{x', t, t', y'\}]$ is not isomorphic to $\vec{C}_4$, C'_4 , or C''_4 , we have $x' \rightarrow y'$ and $t \rightarrow t'$. Thus, if $x' \rightarrow t'$, we have $x' \rightarrow Y$. Analogously, if $x' \rightarrow t'$, we have $Z \rightarrow t'$. Hence,

$$(3) \quad x' \rightarrow t' \text{ implies } x' \rightarrow Y \text{ and } Z \rightarrow t'.$$

We will now prove the following: for a pair u, u' of distinct vertices of U , we have $N^+(u) \subseteq N^+(u')$ or $N^+(u') \subseteq N^+(u)$. By Lemma 3.1, this implies that H has a 2-Min-Max ordering, and we are done. Suppose that we have neither $N^+(u) \subseteq N^+(u')$ nor $N^+(u') \subseteq N^+(u)$. Thus, there is a pair v, v' of vertices in V such that $u \rightarrow v$, $u' \rightarrow v'$, but uv' and $u'v$ are not arcs in H . Since $H[\{u, u', v, v'\}]$ is not isomorphic to $\vec{C}_4$, C'_4 , and C''_4 , we have $v \rightarrow u$ and $v' \rightarrow u'$. Now consider four cases.

Case 3.1: $v, v' \in Y$. Let $t' \in T$. By the definition of t , $t \notin \{u, u'\}$. If $u' \rightarrow t'$, then $H[\{t, t', v, u'\}]$ is isomorphic to $\vec{C}_4$, C'_4 , or C''_4 , which is impossible. Thus, $u't' \notin A(H)$, and $t' \rightarrow u'$. Analogously, $ut' \notin A(H)$, and $t' \rightarrow u$. By the fact that $t' \rightarrow t$ and the existence and nonexistence of previously considered arcs, we conclude that $H[\{v, v', u, u', t, t'\}]$ is isomorphic to N_1 or N_2 , which is impossible.

Case 3.2: $u, u' \in Z$. We can show that this case is impossible similarly to Case 3.1 but considering x, w instead of t, t' .

Case 3.3: $v \in Y$, $v' \in T$. By (3), $u' \in Z$. By Case 3.2, we may assume that $u \in X$. Then $H[\{v, v', u', t\}]$ is isomorphic to $\vec{C}_4$, C'_4 , or C''_4 , which is impossible.

Case 3.4: $v, v' \in T$. By Case 3.2, we may assume that $u \in X$. By (3), $Z \rightarrow v$, and thus $u' \in X$. By (3), we conclude that uxu , $u'xu'$, vtv , and $v'tv'$ are 2-cycles. Notice that $t \rightarrow x$, but $xt \notin A(H)$. Now it follows that $H[\{x, v, v', u, u', t\}]^{\leftrightarrow}$ is isomorphic to C_6 , a contradiction.

It follows from Cases 1, 2, and 3 that if neither $\text{UN}(H_1)$ nor $\text{UN}(H_2)$ are complete bipartite graphs, then we must have $d_1 = d_2 = 3$. In this case we have shown that, for every pair u, u' of distinct vertices of U , we have $N^+(u) \subseteq N^+(u')$ or $N^+(u') \subseteq N^+(u)$. However, by swapping the roles of U and V , we also get that, for every pair v, v' of distinct vertices of V , we have $N^+(v) \subseteq N^+(v')$ or $N^+(v') \subseteq N^+(v)$. $\square$

The following theorem shows when $\text{MinHOM}(H)$ is polynomial time solvable for the case when H is not strong and does not contain $\vec{C}_4$ as an induced subdigraph.

THEOREM 3.3. *Let $H = (V, U; A)$ be a semicomplete bipartite digraph, with strong components $C_1, C_2, \dots, C_p$ ($p \geq 2$) satisfying the following:*

- *There is no arc from C_i to C_j for $i > j$;*
- *H does not contain an induced subdigraph belonging to $\mathcal{HFORB}$ or an induced directed 4-cycle.*

Then H has a 2-Min-Max ordering, and $\text{MinHOM}(H)$ is polynomial time solvable.

Proof. If there are no $v, v' \in V$ and $u, u' \in U$ such that $A(H^{\rightarrow}[\{v, v', u, u'\}]) = \{vu, v'u'\}$, then $H^{\rightarrow}$ satisfies the condition of Lemma 3.1. Therefore H has a 2-Min-Max ordering.

Thus, we may assume that there exist $v, v' \in V$ and $u, u' \in U$ such that $A(H^{\rightarrow}[\{v, v', u, u'\}]) = \{vu, v'u'\}$. Note that $\{v, v', u, u'\}$ belong to a strong component of H as they are contained in a 4-cycle. Let $\{v, v', u, u'\} \subseteq V(C_t)$ for some t , and let $V_1 = \{x \in V \mid x \in C_i, i < t\}$, $U_1 = \{y \in U \mid y \in C_i, i < t\}$, $V_2 = V \cap C_t$, $U_2 = U \cap C_t$, $V_3 = V - V_1 - V_2$, and $U_3 = U - U_1 - U_2$.

If there is a $w' \in U_3$ and $w \in V_3$, such that $w' \rightarrow w$, then $H[\{u, v, u', v', w, w'\}]$ is the converse of either N_1 or N_2 . Therefore we must have $A(H[U_3 \cup V_3]) = V_3 \times U_3$. Analogously we must have $A(H[U_1 \cup V_1]) = V_1 \times U_1$. Consider $H' = H[U_2 \cup V_2]$, and note that H' is strong and does not contain a digraph from $\mathcal{HFORB}$ or $\vec{C}_4$ as an induced subdigraph. Therefore Theorem 3.2 implies that $U_2 \rightarrow V_2$ (as $V_2 \rightarrow U_2$ is not true), which furthermore implies that $(U_1 \cup U_2) \rightarrow (V_2 \cup V_3)$.

Let π be a Min-Max ordering of $H^\rightarrow$. Let $uv \in A(H)$ and $u'v' \in A(H)$ be two distinct arcs from U to V . As $d^+(u) > 0$, we note that $u \in U_1 \cup U_2$, by the above. Analogously we note that $u' \in U_1 \cup U_2$, $v \in V_2 \cup V_3$ (as $d^-(v) > 0$), and $v' \in V_2 \cup V_3$. By the above, we therefore have $uv', u'v \in A(H)$. As u, u', v, v' were chosen arbitrarily, this implies that π is a 2-Min-Max ordering. $\square$

The following theorem shows when $\text{MinHOM}(H)$ is polynomial time solvable for the case when H does contain $\vec{C}_4$ as an induced subdigraph.

THEOREM 3.4. *Let H be a semicomplete bipartite digraph. Assume that H does not contain a digraph from $\mathcal{HFORB}$ as an induced subdigraph but contains $\vec{C}_4$ as an induced subdigraph. Then H is an extension of a $\vec{C}_4$, and $\text{MinHOM}(H)$ is polynomial time solvable.*

Proof. Observe that an extension L of any cycle $\vec{C}_p$, $p \geq 2$, has a p -Min-Max ordering. Thus, $\text{MinHOM}(L)$ is polynomial time solvable by Theorem 2.2. Let $C = v_1u_1v_2u_2v_1$ be an induced 4-cycle of H . It suffices to prove that H is an extension of C .

For $i = 1, 2$, let $M^+(v_i) = \{u \in U : v_iu \in A(H), uv_i \notin A(H)\}$, $M^-(v_i) = \{u \in U : uv_i \in A(H), v_iu \notin A(H)\}$, and $M(v_i) = \{u \in U : uv_i, v_iu \in A(H)\}$. We have $M^+(v_1) \cap M^+(v_2) = \emptyset$, as otherwise $H[\{v_1, v_2, u_1, u_2, u_3\}] \cong H^*$, where $u_3 \in M^+(v_1) \cap M^+(v_2)$. We have $M^-(v_1) \cap M^-(v_2) = \emptyset$, as otherwise $H[\{v_1, v_2, u_1, u_2, u_3\}] \cong H^{**}$, where $u_3 \in M^-(v_1) \cap M^-(v_2)$ and H^{**} is the converse of H^* .

We have $M(v_1) \cap (M^+(v_2) \cup M^-(v_2)) = \emptyset$, as otherwise $H[\{v_1, u_1, v_2, u\}] \cong C'_4$, where $u \in M(v_1) \cap M^+(v_2)$ or $H[\{v_1, u_2, v_2, u\}] \cong C'_4$, where $u \in M(v_1) \cap M^-(v_2)$. Moreover, $M(v_1) \cap M(v_2) = \emptyset$, as otherwise $H[\{v_1, u_1, v_2, u\}] \cong C''_4$, where $u \in M(v_1) \cap M(v_2)$. The arguments above imply that $M(v_1) = M(v_2) = \emptyset$, $M^+(v_1) = M^-(v_2)$, and $M^-(v_1) = M^+(v_2)$.

Similarly, we can define $M^+(u_i)$, $M^-(u_i)$, and $M(u_i)$, $i = 1, 2$, and prove the relations analogous to those for $M^+(v_i)$, $M^-(v_i)$, and $M(v_i)$, $i = 1, 2$.

Let $v \in V - \{v_1, v_2\}$ and $u \in U - \{u_1, u_2\}$ be arbitrary. Without loss of generality, assume that $u \in M^+(v_1) = M^-(v_2)$ and $v \in M^+(u_2) = M^-(u_1)$ (all other cases can be treated similarly). To show that H is an extension of C , it suffices to prove that $v \rightarrow u$, but $uv \notin A(H)$. Suppose first that $u \rightarrow v$ and $v \rightarrow u$. Then $H[\{v, u, v_2, u_2\}] \cong C'_4$, a contradiction. Now suppose that $u \rightarrow v$, but $vu \notin A(H)$. Then $H[\{v, v_1, v_2, u, u_2\}] \cong H^*$, a contradiction. Thus, $v \rightarrow u$, but $uv \notin A(H)$, and we are done. $\square$

The three theorems of this section and the fact that $\vec{C}_4$ has a 4-Min-Max ordering imply the following.

COROLLARY 3.5. *Let H be a semicomplete bipartite digraph not containing a digraph from $\mathcal{HFORB}$ as an induced subdigraph. Then $\text{MinHOM}(H)$ is polynomial time solvable, and H has a k -Min-Max ordering for $k = 2$ or 4 .*

4. NP-hardness cases. It is well known that the problem of finding a maximum size independent set in an undirected graph G is NP-hard. We say that a set I in a digraph D is *independent* if no vertices in I are adjacent. Clearly, the problem of finding a maximum size independent set in an oriented graph D (MISO) is NP-hard.

LEMMA 4.1. *$\text{MinHOM}(C'_4)$ is NP-hard.*

Proof. Let H be isomorphic to C'_4 as follows:

$$V(H) = \{1, 2, 3, 4\}, \quad A(H) = \{12, 21, 23, 34, 41\}.$$

Let D be an arbitrary oriented graph. We replace every arc uv of D by the digraph G_{uv} , with $V(G_{uv}) = \{u, v, x_{uv}, y_{uv}, z_{uv}\}$ and $A(G_{uv}) = \{ux_{uv}, x_{uv}y_{uv}, y_{uv}z_{uv}, vz_{uv}\}$. Here $x_{uv} \neq x_{u'v'}$, $y_{uv} \neq y_{u'v'}$, and $z_{uv} \neq z_{u'v'}$ for each $uv \neq u'v'$. Let D' be the obtained oriented graph. Define the cost function as follows: $c_1(w) = 1$, $c_2(w) = 1$, $c_3(w) = 0$, and $c_4(w) = 1$ for each $w \in V(D)$, and $c_i(t) = 0$ for each $t \in V(D') \setminus V(D)$ and $i \in \{1, 2, 3, 4\}$.

Let g be a homomorphism of D' to H , and let $S = \{s \in V(D) : g(s) = 3\}$. Observe that the cost of g is $|V(D)| - |S|$, and S is an independent set in D . Indeed, suppose that $uv \in A(D)$ and $\{u, v\} \subseteq S$. Then $g(y_{uv}) = 1$ and $g(z_{uv}) = 4$, a contradiction to the fact that g is a homomorphism of D' to H .

Let I be an independent set in D of maximum size. Set $f(w) = 3$ for each $w \in I$, and $f(w) = 1$ for each $w \in V(D) \setminus I$. For each $uv \in A(D)$, set

- (a) $f(x_{uv}) = 2, f(y_{uv}) = 1$ and $f(z_{uv}) = 2$ if $\{u, v\} \cap I = \emptyset$;
- (b) $f(x_{uv}) = 4, f(y_{uv}) = 1$ and $f(z_{uv}) = 2$ if $u \in I$ and $v \notin I$;
- (c) $f(x_{uv}) = 2, f(y_{uv}) = 3$ and $f(z_{uv}) = 4$ if $u \notin I$ and $v \in I$.

Observe that f is a homomorphism of D' to H , and the cost of f is $|V(D)| - |I|$. By the arguments above, f is a homomorphism of D' to H of minimum cost. Thus, we have reduced MISO to MinHOM(H). $\square$

LEMMA 4.2. *MinHOM(C''_4) is NP-hard.*

Proof. Let H be isomorphic to C''_4 as follows:

$$V(H) = \{1, 2, 3, 4\}, \quad A(H) = \{12, 21, 23, 32, 34, 41\}.$$

Let D be an arbitrary oriented graph. We replace every arc uv of D by the digraph G_{uv} , with $V(G_{uv}) = \{u, v, x_{uv}\}$ and $A(G_{uv}) = \{ux_{uv}, x_{uv}v\}$. Here $x_{uv} \neq x_{u'v'}$ for each $uv \neq u'v'$. Let D' be the obtained oriented graph. Define the cost function as follows: $c_1(w) = 1$, $c_2(w) = 1$, $c_3(w) = 1$, and $c_4(w) = 0$ for each $w \in V(D)$, and $c_i(x) = 0$ for each $x \in V(D') \setminus V(D)$ and $i = 1, 2, 3, 4$.

Let g be a homomorphism of D' to H , and let $S = \{s \in V(D) : g(s) = 4\}$. Observe that the cost of g is $|V(D)| - |S|$, and S is an independent set in D .

Let I be an independent set in D of maximum size. Set $f(w) = 4$ for each $w \in I$, $f(w) = 2$ for each $w \in V(D) \setminus I$, $f(x_{uv}) = 3$ if $v \in I$ and $f(x_{uv}) = 1$, otherwise, for each $uv \in A(D)$. Observe that f is a homomorphism of D' to H , and the cost of f is $|V(D)| - |I|$. By the arguments above, f is a homomorphism of D' to H of minimum cost. Thus, we have reduced MISO to MinHOM(H). $\square$

The following lemma was stated in [6]. We give a proof here for the sake of completeness.

LEMMA 4.3. *MinHOM(H^*) is NP-hard.*

Proof. Let H be isomorphic to H^* as follows:

$$V(H) = \{1, 2, 3, 4, 5\}, \quad A(H) = \{12, 23, 34, 41, 15, 35\}.$$

We replace every arc uv of an oriented graph D by the digraph G_{uv} , with $V(G_{uv}) = \{v_1, v_2, v_3, v_4, v_5, v_6, v_7\}$, where $u = v_6$ and $v = v_7$, and

$$A(G_{uv}) = \{v_1v_2, v_2v_3, v_3v_4, v_4v_1, v_5v_6, v_5v_7, v_1v_6, v_3v_7\}.$$

Let D' be the obtained oriented graph. Define the cost function as follows: $c_4(w) = 0$ and $c_i(w) = 1$ for each $w \in V(D)$ and $i \in \{1, 2, 3, 5\}$, and $c_i(t) = 0$ for each $t \in V(D') \setminus V(D)$ and $i \in \{1, 2, 3, 4, 5\}$.

Let g be a homomorphism of D' to H , and let $S = \{s \in V(D) : g(s) = 4\}$. Observe that the cost of g is $|V(D)| - |S|$, and S is an independent set in D . Indeed, suppose that $uv \in A(D)$ and $\{u, v\} \subseteq S$. Then $g(v_1) = g(v_3) = 3$, and $g(v_2)$ cannot be given any value in $V(H)$ since g is a homomorphism.

Let I be an independent set in D of maximum size. Set $f(w) = 4$ for each $w \in I$ and $f(w) = 5$ for each $w \in V(D) \setminus I$. For each $uv \in A(D)$, set

- (a) $f(v_5) = 3$ and $f(v_i) = i$ for every $i = 1, 2, 3, 4$ if $u \notin I$,
- (b) $f(v_5) = 3$ and $f(v_i) = i + 2$ for every $i = 1, 2, 3, 4$, where $i + 2$ is taken modulo 4, if $u \in I$.

Observe that f is a homomorphism of D' to H , and the cost of f is $|V(D)| - |I|$. By the arguments above, f is a homomorphism of D' to H of minimum cost. Thus, we have reduced MISO to MinHOM(H). $\square$

LEMMA 4.4. *MinHOM(N_1) is NP-hard.*

Proof. Let H be the following digraph isomorphic to N_1 : $V(H) = \{1, 2, 3, 4, 5, 6\}$ and

$$A(H) = \{12, 21, 34, 43, 56, 65, 23, 25, 14, 16, 54, 36\}.$$

Let D be an arbitrary oriented graph. We replace every arc uv of D with the digraph G_{uv} , with $V(G_{uv}) = \{x, y, z, u, v\}$ and $A(G_{uv}) = \{ux, vz, xy, yz\}$. Consider the following cost function: $c_2(u) = c_2(v) = 1$, $c_6(u) = c_6(v) = 0$, $c_i(u) = c_i(v) = M + 1$ for $i \neq 2, 6$ and $c_6(y) = M + 1$, where $M = |V(D)|$. In all remaining cases the cost is zero.

Let D' be the obtained oriented graph, let f be a mapping from $V(D')$ to $V(H)$, and let uv be an arc in D . Assume that $f(u) = f(v) = 2$. Then with $f(x) = f(z) = 1$ and $f(y) = 2$, we obtain a homomorphism from G_{uv} to H of cost 2. This implies that there is a homomorphism of D' to H of cost $M < M + 1$, and thus every vertex of D in D' must be colored either 2 or 6 in any minimum cost homomorphism of D' to H . Let f be a homomorphism of D' to H , and let us consider the remaining options for coloring the vertices of D in D' .

Assume that $f(v) = 6$ and $f(u) = 2$. Then with $f(z) = 5$, $f(y) = 2$, and $f(x) = 1$, we obtain a homomorphism from G_{uv} to H of cost 1. Assume that $f(v) = 2$ and $f(u) = 6$. Then with $f(x) = 5$, $f(y) = 4$, and $f(z) = 3$, we obtain a homomorphism from G_{uv} to H of cost 1. Note that if $f(u) = f(v) = 6$, then $f(x) = f(z) = 5$ and $f(y) = 6$. Then the cost of f will be at least $M + 1$ implying we cannot color both vertices u and v in color 6 in any minimum cost homomorphism of D' to H .

Now let f be a minimum cost homomorphism, let S be the vertices of D in D' colored 6, and let $T = V(D) \setminus S$. Recall that the vertices of T are colored 2. Notice that S is an independent set, and the cost of f equals $|T|$. Thus, S is an independent set of maximum size, and we have reduced MISO to MinHOM(H). $\square$

LEMMA 4.5. *MinHOM(N_2) is NP-hard.*

Proof. Let H be the following digraph isomorphic to N_2 : $V(H) = \{1, 2, 3, 4, 5, 6\}$ and

$$A(H) = \{12, 34, 43, 56, 65, 23, 25, 14, 16, 54, 36\}.$$

Let D be an arbitrary oriented graph. We replace every arc uv of D by the digraph G_{uv} , with $V(G_{uv}) = \{x, y, z, u, v\}$ and $A(G_{uv}) = \{ux, vz, xy, zy\}$. We introduce the following cost function: $c_1(u) = c_1(v) = 1$, $c_5(u) = c_5(v) = 0$, $c_i(u) = c_i(v) = M + 1$ for $i \neq 1, 5$ and $c_4(x) = c_6(z) = M + 1$, where $M = |V(D)|$. In any other cases the

cost is zero. Let D' be the obtained oriented graph, let f be a mapping from $V(D')$ to $V(H)$, and let uv be an arc in D .

Assume that $f(u) = f(v) = 1$. With $f(x) = f(z) = 2$ and $f(y) = 3$, we obtain a homomorphism from H' to H with cost 2. Thus, there is a homomorphism of D' to H of cost at most M (assign all vertices of D in D' color 1), and no vertex of D in D' must not be assigned any color other than 1 and 5.

Let f be a homomorphism of D' to H , and let us consider the remaining options for coloring the vertices of D in D' . Assume that $f(v) = 1$ and $f(u) = 5$. With $f(z) = 2$, $f(x) = 6$, and $f(y) = 5$, we obtain a homomorphism of G_{uv} to H of cost 1. Assume that $f(v) = 5$ and $f(u) = 1$. With $f(x) = 2$, $f(z) = 4$, and $f(y) = 3$, we obtain a homomorphism of G_{uv} to H of cost 1. Note that if $f(u) = f(v) = 5$, then $f(x) \in \{4, 6\}$ and $f(z) \in \{4, 6\}$. Thus, f has cost at least $M + 1$ implying that a minimum cost homomorphism of D' to H does not assign adjacent vertices of D color 5 (in D').

Now let f be a minimum cost homomorphism, let S be the vertices of D in D' colored 5 and $T = V(D) \setminus S$. Recall that the vertices of T are colored 1. Notice that S is an independent set, and the cost of f equals $|T|$. Thus, S is an independent set of maximum size, and we have reduced MISO to MinHOM(H). $\square$

COROLLARY 4.6. *MinHOM(H) is NP-hard for every $H \in \mathcal{HFORB}$.*

Proof. If H is isomorphic to C'_4 , C''_4 , H^* , N_1 or N_2 , or the converse of one of the five digraphs, then MinHOM(H) is NP-hard due to the lemmas of this section and the simple fact that if MinHOM(H) is NP-hard and H' is the converse of H , then MinHOM(H') is NP-hard as well.

Let $\mathcal{B}$ be the set consisting of the following bipartite graphs: bipartite claw, bipartite net, bipartite tent, and every even cycle with at least 6 vertices. If $\text{UN}(H^s)$, where $s \in \{\rightarrow, \leftarrow\}$, is isomorphic to a graph in $\mathcal{B}$, then MinHOM(H) is NP-hard due to Theorem 1.2 and the transformation from a bipartite undirected graph to a semi-complete bipartite digraph described in the last paragraph of subsection “Minimum Cost Homomorphisms” of section 1. If $\text{UN}(H^{\leftrightarrow})$ is isomorphic to a graph in $\mathcal{B}$, then MinHOM(H) is NP-hard as, for each bipartite undirected graph L , MinHOM(L) is equivalent to MinHOM(L^+), where L^+ is the digraph obtained from L by replacing every edge xy with two arcs xy and yx . $\square$

5. Dichotomy for semicomplete multipartite digraphs. A digraph D is called *semicomplete k -partite* if D can be obtained from a complete k -partite (undirected) graph G by replacing every edge xy of G by either the arc xy or the arc yx or the pair xy, yx of arcs. Let TT_p denote the acyclic tournament on $p \geq 1$ vertices. Let $p \geq 3$, and let TT_p^- be a digraph obtained from TT_p by deleting the arc from the vertex of in-degree zero to the vertex of out-degree zero. Combining the main result of this paper with the main result of [6], we obtain the following.

THEOREM 5.1. *Let H be a semicomplete k -partite digraph. If $k = 2$ and H does not contain a digraph from $\mathcal{HFORB}$ as an induced subdigraph or if $k \geq 3$ and H is an extension of either TT_k or TT_{k+1}^- or $\vec{C}_3$, then MinHOM(H) is polynomial time solvable. Otherwise, MinHOM(H) is NP-hard.*

6. Further research. In the case of undirected graphs H , the well-known theorem of Hell and Nešetřil [11] on the homomorphism problem implies that MinHOM(H) is NP-hard for each nonbipartite graph H . The authors of [4] obtained a complete dichotomy of the computational complexity of MinHOM(H) when H is undirected. The dichotomy obtained in this paper significantly extends the dichotomy of [4]. This indicates that the problem of obtaining a dichotomy for the computational complex-

ity of $\text{MinHOM}(H)$ when H is a bipartite digraph is a very difficult problem. Note that $\text{MinHOM}(H)$ is polynomial time solvable for some nonbipartite digraphs, for example, for acyclic tournaments [6]. Thus, a dichotomy for the bipartite-directed case does not coincide with a dichotomy for the general-directed case. The problem of obtaining dichotomy for both cases is a very interesting open problem.

Acknowledgments. We are grateful to Pavol Hell and Eun Jung Kim for several useful discussions.

ON THE POLYTOPE OF THE (1,2)-SURVIVABLE NETWORK DESIGN PROBLEM*

MOHAMED DIDI BIHA[†], HERVÉ KERIVIN[‡], AND A. RIDHA MAHJOUB[§]

Abstract. This paper deals with the survivable network design problem where each node v has a connectivity type $r(v)$ equal to 1 or 2, and the survivability conditions require the existence of at least $\min\{r(s), r(t)\}$ edge-disjoint paths for all distinct nodes s and t . We consider the polytope given by the trivial and cut inequalities together with the partition inequalities. More precisely, we study some structural properties of this polytope which leads us to give some sufficient conditions for this polytope to be integer in the class of series-parallel graphs. With both separation problems for the cut and partition inequalities being polynomially solvable, we then obtain a polynomial time algorithm for the (1,2)-survivable network design problem in a subclass of series-parallel graphs including the outerplanar graph class. We also introduce a new class of facet-defining inequalities for the polytope associated to the (1,2)-survivable network design problem.

Key words. survivable network, cut and partition inequalities, polytope, facet, series-parallel graphs

1. Introduction. In order to protect telecommunication networks from equipment failures, one must maintain the survivability of networks when links are severed or nodes fail. As failures are not very common, robust networks are designed to withstand a single network equipment failure. Moreover, in practice a node usually fails completely because of major incidents (e.g., power outages), and thus it is more frequent to encounter link interface failures or severed links than node failures. Therefore, one of the main concerns when designing telecommunication networks is to devise network topologies that provide protection against single-link failures. The network topology problem is usually the first stage of the overall network design optimization process, and the second one involves traffic and routing issues.

Furthermore, some network nodes may be more important than others because of their specific functions. This fact thus leads to considering two kinds of nodes: the *specific nodes*, also called *terminals*, for which a “high” degree of survivability has to be guaranteed, and the *ordinary nodes*, which simply have to be connected to the network. The network topology problem then consists of selecting links such that the sum of their cost is minimized and the failure of any single link does not disconnect any two terminal nodes.

More precisely, based on a model first introduced by Grötschel and Monma [8] (see also Stoer [19]), this problem can be stated as follows. Consider an undirected graph $G = (V, E)$ where V represents the node set and E represents the set of edges or potential links. The set V is partitioned into two subsets T and O corresponding, respectively, to the terminal and ordinary node sets. By associating to each node $u \in V$ a *connectivity type* $r(u)$ which is equal to 1 if u is an ordinary node and to 2 if u is a terminal, we have $O = \{u \in V : r(u) = 1\}$, $T = \{u \in V : r(u) = 2\}$, and $V = O \cup T$. A subgraph H of G fulfills the survivability conditions if there exist at least $\min\{r(s), r(t)\}$ edge-disjoint paths (i.e., paths sharing no edges) in H for any pair of nodes $s, t \in V$. Such a subgraph is then called *survivable*. Suppose that each edge $e \in E$ has a certain cost $c(e) \in \mathbb{R}_+$. Our network topology problem, called the *(1,2)-survivable network design problem* (SNDP), then consists of finding a survivable subgraph of G with minimum total cost. (The cost of a subgraph of G is equal to the sum of its edge costs.)

The optimization problem SNDP is NP-hard since it includes as a special case the 2-edge connected network problem (i.e., $r(u) = 2$ for all $u \in V$), which has been extensively studied in the past. Some heuristics have thus been devised such as the one of Monma and Shallcross [18] which was used to obtain near optimal solutions to both real-world and randomly generated problems. The SNDP has also been proved to be polynomially solvable in special cases. Particularly, if $T = \emptyset$ (i.e., $r(u) = 1$ for all $u \in V$, and r is then called a *unit connectivity type vector*), then the SNDP is nothing but the minimum-cost spanning tree problem which is well known to be polynomially solvable [15]. Furthermore, if the underlying graph G is series-parallel and $O = \emptyset$ (i.e., $r(u) = 2$ for all $u \in V$), then we have a linear time algorithm for the SNDP devised by Winter [20]. Many survivability problems related to the SNDP have received particular attention and complete surveys over the existing approaches can be found in Grötschel, Monma, and Stoer [11], Stoer [19], and Kerivin and Mahjoub [13].

Grötschel, Monma, and Stoer [9] studied the general model related to the SNDP from a polyhedral point of view. (They consider $r(u) \in \mathbb{Z}_+$ for all $u \in V$.) They introduced several families of valid inequalities for the polytope associated with this problem. They also derived some necessary and/or sufficient conditions under which these inequalities are facet-defining. Among all of the inequalities considered in [9], the so-called partition inequalities are of interest for solving the SNDP as pointed out in [10, 14]. Kerivin and Mahjoub [12] actually showed that the separation problem for the partition inequalities is polynomially solvable for the SNDP, even though this separation problem is NP-hard for general connectivity type vectors $r \in \mathbb{Z}_+^V$. Furthermore, Grötschel and Monma [8] showed that the partition inequalities together with the trivial lower-bound and upper-bound inequalities suffice to describe the polytope associated with the SNDP when $r(u) = 1$ for all $u \in V$. When the underlying graph G is series-parallel, Mahjoub [17] described the polytope associated with the 2-edge connected network problem by the trivial inequalities and the cut ones, the latter being a special case of the partition inequalities.

Let $\text{SNDP}(G, r)$ be the convex hull of incidence vectors of all survivable subgraphs. This polytope is called the *survivable network polytope*. In this paper, we are interested in the polytope $\text{CPP}(G, r)$ given by the trivial lower-bound and upper-bound inequalities and the so-called partition inequalities for connectivity type vectors $r \in \{1, 2\}^V$. This polytope is a strengthened linear relaxation of $\text{SNDP}(G, r)$. Here, we give sufficient conditions for the $\text{CPP}(G, r)$ to be an integer on series-parallel graphs. This

study leads us to give a polynomial-time algorithm for solving the $(1, 2)$ -survivable network design problem on a class of graphs including the outerplanar ones.

This paper is organized as follows. In the next section, we formulate the problem SNDP as an integer linear program and introduce its associated polytope $\text{SNDP}(G, r)$ as well as the polytope $\text{CPP}(G, r)$. Section 3 is devoted to the study of some structural properties of the polytope $\text{CPP}(G, r)$. In section 4, we consider the $\text{CPP}(G, r)$ when G can be decomposed by one-node cutsets. We show in section 5 that the polytope $\text{CPP}(G, r)$ may have noninteger extreme points even if the underlying graph G is series-parallel, and give sufficient conditions which make the $\text{CPP}(G, r)$ integer on series-parallel graphs. In section 6, we prove this last result. A new class of facet-defining inequalities for the $\text{SNDP}(G, r)$ is introduced in section 7. Finally, some concluding remarks are given in section 8.

The rest of this section is devoted to more definitions and notation. Throughout this paper, the graphs are undirected, finite, loopless, and connected. We consider a graph $G = (V, E)$ and denote by n the number of nodes of G , that is, $n = |V|$. For $W \subseteq V$, let $\bar{W} = V \setminus W$, and for $F \subseteq E$, let $\bar{F} = E \setminus F$. Given two distinct nodes u and v of V , an edge between u and v is denoted by uv . For a nonempty node subset $W \subsetneq V$, the set of edges having exactly one endnode in W is called a *cut* and is denoted by $\delta_G(W)$. If $W = \{u\}$, we then write $\delta_G(u)$ for $\delta_G(\{u\})$. A *partition* of V is a collection of disjoint subsets of V with union V . The elements of the partition are called its *classes*. Given a partition $\{V_1, \dots, V_p\}$ of the node set V , we denote by $\delta_G(V_1, \dots, V_p)$ the set of edges with endnodes in two different classes. Given a collection $(W_1, \dots, W_q)$ of node subsets, we write $[W_1, \dots, W_q]_G$ for the set of edges with endnodes in two different subsets. We notice that if $(W_1, \dots, W_q)$ is a partition of V , then we have $[W_1, \dots, W_q]_G = \delta_G(W_1, \dots, W_q)$. If u and v are two distinct nodes of V , we then write $[u, v]_G$ for $\{u\}, \{v\}_G$. For all of our notation, we don't use the subscript G whenever the graph G can be deduced from the context. For $F \subseteq E$, we denote by $V(F)$ the set of nodes which are spanned by the edges in F . For $W \subseteq V$, we denote by $E(W)$ the set of edges with both endnodes in W , and $G(W) = (W, E(W))$ is called the *subgraph induced by W* . A maximal connected non-empty subgraph of G is called a *connected component*. (Here, "maximal" is taken with respect to inclusion.) A graph G is called *2-node-connected* if for any node $u \in V$, the subgraph $G - u$ induced by $V \setminus \{u\}$ is connected. Given a ground set S , a set-function $f : 2^S \rightarrow \mathbb{R} \cup \{\infty\}$ is called *fully submodular* if

$$(1.1) \quad f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$$

for all $A, B \subseteq S$. A pair of subsets A and B of S is said to be *crossing* if none of $A \setminus B$, $B \setminus A$, $A \cap B$, $S \setminus (A \cup B)$ is empty. A set-function f is called *submodular on crossing pairs* if the inequality (1.1) is required only for crossing pairs. Moreover, if f satisfies the inequality (1.1) with equality for crossing pairs, then f is called *modular on crossing pairs*. For a vector $x \in \mathbb{R}^S$ and a subset $A \subseteq S$, we denote $\sum_{a \in A} x(a)$ by $x(A)$. For $F \subseteq E$, its *incidence vector* $x^F \in \mathbb{R}^S$ is defined by $x^F(e) = 1$ if $e \in F$, and $x^F(e) = 0$ if $e \in S \setminus F$. An *integer vector* is a vector with all entries integer. A polytope $P \subseteq \mathbb{R}^S$ is *integer* if and only if each extreme point of P is integer. An inequality $a^T x \geq \alpha$, where $a \in \mathbb{R}^S$ and $\alpha \in \mathbb{R}$, is *tight* for a point x^* if $a^T x^* = \alpha$. If $a^T x \geq \alpha$ is induced by a cut (respectively, a partition), we equivalently say that the cut (respectively, partition) is tight for x^* .

2. The $(1, 2)$ -survivable network design problem and some related polytopes. Let $G = (V, E)$ be an undirected graph and $r \in \{1, 2\}^V$ be a connectiv-

ity type vector. Without loss of generality, we may assume throughout this paper that there exist at least two nodes having the largest connectivity type (i.e., $|T| \geq 2$). For a nonempty node subset $W \subsetneq V$, let $r(W) = \max\{r(u) : u \in W\}$ and $\text{con}(W) = \min\{r(W), r(V \setminus W)\}$. Given an edge subset $F \subseteq E$, if (V, F) is a survivable subgraph of G , then its incidence vector x^F satisfies

$$\begin{aligned} (2.1) \quad & x(e) \geq 0 && \text{for all } e \in E, \\ (2.2) \quad & x(e) \leq 1 && \text{for all } e \in E, \\ (2.3) \quad & x(\delta(W)) \geq \text{con}(W) && \text{for all } \emptyset \neq W \subsetneq V, \\ (2.4) \quad & x(e) \in \{0, 1\} && \text{for all } e \in E. \end{aligned}$$

The inequalities (2.1) and (2.2) are, respectively, called *lower-bound* and *upper-bound trivial inequalities* (or more generally *trivial inequalities*), and inequalities (2.3) are called *cut inequalities*.

For a class of inequalities, the separation problem is as follows: given a vector y , find a violated inequality in the class or prove that none exists. An algorithm for the separation problem associated with a class of inequalities is a key ingredient for being able to use those inequalities within a branch-and-cut algorithm. The separation problem for the cut inequalities (2.3) is polynomially solvable using a polynomial-time maximum flow algorithm (e.g., preflow-push algorithm of Goldberg and Tarjan [6] running in $O(n^3)$ time).

In [9], Grötschel, Monma, and Stoer introduced a class of valid inequalities for the polytope $\text{SNDP}(G, r)$ which can be stated as follows. Let $\{V_1, \dots, V_p\}$, $p \geq 2$, be a partition of V . Let $I_2 = \{i : \text{con}(V_i) = 2, i = 1, \dots, p\}$ be the set of subscripts whose corresponding classes of the partition contain at least one terminal. The *partition inequalities* induced by $\{V_1, \dots, V_p\}$ is

$$(2.5) \quad x(\delta(V_1, \dots, V_p)) \geq \begin{cases} p-1 & \text{if } I_2 = \emptyset, \\ p & \text{otherwise.} \end{cases}$$

The inequalities (2.5) are a generalization of the cut inequalities (2.3). (The latter correspond to the case where $p = 2$.) Therefore, if we do not specify $p \geq 3$, then a partition inequality (2.5) may be a cut inequality (2.3). In the remainder of this paper, a partition of V with $I_2 = \emptyset$ (respectively, $I_2 \neq \emptyset$) will be called a *partition of type 1* (respectively, *partition of type 2*), and the inequality (2.5) induced by it will be called a *partition inequality of type 1* (respectively, a *partition inequality of type 2*). Grötschel, Monma, and Stoer [9] gave sufficient conditions and necessary conditions for the inequalities (2.5) to define facets of $\text{SNDP}(G, r)$.

In [12], Kerivin and Mahjoub showed that the separation problem for the partition inequalities (2.5) reduces to minimizing a particular submodular function, and then is polynomially solvable. Later, Barahona and Kerivin [2] reduced the separation problem for those inequalities to a sequence of $O(n^4)$ minimum cut problem.

Let $\text{CPP}(G, r)$ be the polytope given by the inequalities (2.1), (2.2), (2.3), and (2.5). This polytope, called the *cut and partition inequalities polytope*, is the linear relaxation of $\text{SNDP}(G, r)$ strengthened by the partition inequalities (2.5). As we mentioned above, the separation problems for both cut and partition inequalities are polynomially solvable, and then this implies by the ellipsoid method [7] that the (1,2)-survivable network design problem can be solved in polynomial time on graphs for which $\text{SNDP}(G, r) = \text{CPP}(G, r)$.

The definition of the connectivity type of node subsets implies the following remarks.

Remark 2.1. The function $r : 2^V \longrightarrow \{1, 2\}$ is nondecreasing, that is, r satisfies $r(A) \leq r(B)$ for all $A \subseteq B \subseteq V$.

Remark 2.2. Let $A \subseteq V$ such that $r(A) = 1$. Then, we have

(a) $r(A \cup B) = r(B)$ for any $B \subseteq V$, and

(b) $\text{con}(A \cup B) = \text{con}(B)$ for any $B \subseteq V$ such that $A \cup B \neq V$.

PROPOSITION 2.3. *The function $\text{con} : 2^V \longrightarrow \{1, 2\}$ is submodular on crossing pairs.*

Proof. Let $A, B \subseteq V$ such that $A \cap B \neq \emptyset$, $A \setminus B \neq \emptyset$, $B \setminus A \neq \emptyset$, and $\overline{A \cup B} \neq \emptyset$. We must show that

$$(2.6) \quad \text{con}(A) + \text{con}(B) \geq \text{con}(A \cap B) + \text{con}(A \cup B).$$

If $\text{con}(A) + \text{con}(B) = 4$, then it is obvious that inequality (2.6) holds.

If $\text{con}(A) = \text{con}(B) = 1$, then $\text{con}(A \cap B) = \text{con}(A \cup B) = 1$ and hence, inequality (2.6) is satisfied.

Suppose now that $\text{con}(A) + \text{con}(B) = 3$. Without loss of generality, we may assume that $\text{con}(A) = 1$ and $\text{con}(B) = 2$. Consider first the case $r(A) = 1$. From Remark 2.1, we then have $r(A \cap B) = r(A)$. By the definition of the function con , we thus obtain $\text{con}(A \cap B) = \text{con}(A) = 1$. From Remark 2.2(b), we have $\text{con}(A \cup B) = \text{con}(B)$. Thus, inequality (2.6) holds. If $r(A) = 2$, then $r(A \cap B) = r(A \setminus B) = 2$ and $r(B \setminus A) = r(\overline{A \cup B}) = 1$ and hence, inequality (2.6) is satisfied. $\square$

From the proof of Proposition 2.3, we deduce the remark below.

Remark 2.4. The function $\text{con} : 2^V \longrightarrow \{1, 2\}$ is modular on crossing pairs $A, B \subseteq V$ if one of the two following properties hold:

(a) $\text{con}(A) + \text{con}(B) \leq 3$, or

(b) $\text{con}(A) = \text{con}(B) = 2$ and $r(A \cap B) = r(\overline{A \cup B}) = 2$.

To conclude this section, we define the connectivity type vectors associated with the subgraphs of G obtained by contractions or deletions of edges. For any subset F of E , deleting F gives rise to the graph $G - F = (V(\overline{F}), \overline{F})$. The connectivity type vector $r_F^d \in \{1, 2\}^{V(\overline{F})}$ is then obviously the restriction of $r \in \{1, 2\}^V$ on $V(\overline{F})$, that is,

$$(2.7) \quad r_F^d(u) = r(u) \quad \text{for all } u \in V(\overline{F}).$$

Given an edge $e = uv \in E$, contracting e means deleting e and identifying u and v . If $F \subseteq E$ induces a connected subgraph of G , then G/F denotes the graph obtained from G by contracting F , that is, by contracting all of the edges in F . Let w be the node that arises from the contraction of F . The connectivity type vector $r_F^c \in \{1, 2\}^{V'}$ associated with the node set $V' = (V \setminus V(F)) \cup \{w\}$ is defined as follows:

$$(2.8) \quad r_F^c(u) = \begin{cases} r(u) & \text{if } u \in V' \setminus \{w\}, \\ \text{con}_G(V(F)) & \text{if } u = w. \end{cases}$$

A couple (H, r_H) is called a *minor* of (G, r) if H arises from G by a series of deletions and contractions of edges. The vector r_H is the connectivity type vector associated with H , and it is obtained from r by applying at each deletion/contraction the corresponding (2.7)/(2.8). This notion of minor will be important in section 5. In the next section, we study some structural properties of the $\text{CPP}(G, r)$ which will be also useful later on.

3. Structural properties of the polytope $\text{CPP}(G, r)$. One way to solve the (1,2)-survivable network design problem is to use a branch-and-cut framework. In such an approach, one may first consider a linear program whose constraints are given by $\text{CPP}(G, r)$ which is a relaxation of $\text{SNDP}(G, r)$. This linear program provides a lower bound for the SNDP , and in some special cases an optimal solution. This linear program has an exponential number of constraints, and one needs to use a cutting-plane algorithm to solve it. The knowledge of structural properties of the points (especially the extreme points) of $\text{CPP}(G, r)$ may provide useful information which is important in order to determine violated inequalities more efficiently. The structural properties established in this section may also be used to characterize the polytope $\text{SNDP}(G, r)$ on certain classes of graphs (see section 5).

Let us consider a point $\bar{x}$ of $\text{CPP}(G, r)$.

PROPOSITION 3.1. *Let $F \subseteq E$ be an edge subset of E that induces a connected subgraph of G . Then $\bar{x}' \in \mathbb{R}^{E \setminus F}$, the restriction of $\bar{x}$ on $E \setminus F$, is a point of $\text{CPP}(G/F, r_F^c)$.*

Proof. The result comes directly from the fact that any inequality of $\text{CPP}(G/F, r_F^c)$ is also an inequality of $\text{CPP}(G, r)$. $\square$

Let us denote by π a partition $\{V_1, \dots, V_p\}$ of V , $p \geq 2$, which is tight for $\bar{x}$.

PROPOSITION 3.2. *Suppose $p \geq 3$. Consider $i, j \in \{1, \dots, p\}$ such that $i < j$. Let $\pi' = \{V'_1, \dots, V'_{p-1}\}$ be the partition defined below*

$$\begin{aligned} V'_t &= V_t, & t &= 1, \dots, i-1, i+1, \dots, j-1, \\ V'_i &= V_i \cup V_j, \\ V'_t &= V_{t+1}, & t &= j, \dots, p-1. \end{aligned}$$

- (a) *If π is of type 1, then $\bar{x}[V_i, V_j] \leq 1$.*
- (b) *If π is of type 2 and π' is of type 1, then $\bar{x}[V_i, V_j] \leq 2$.*
- (c) *If π and π' are of type 2, then $\bar{x}[V_i, V_j] \leq 1$.*

Moreover, if $\bar{x}[V_i, V_j] = 1$ (cases (a) and (c)) or $\bar{x}[V_i, V_j] = 2$ (case (b)), then the partition π' is also tight for $\bar{x}$.

Proof. We are going to prove (a). (The proofs of (b) and (c) are similar.) Since π is of type 1, then clearly π' is also of type 1. Hence, we have

$$\bar{x}(\delta(V'_1, \dots, V'_{p-1})) \geq p-2.$$

We thus obtain

$$\begin{aligned} \bar{x}[V_i, V_j] &= \bar{x}(\delta(V_1, \dots, V_p)) - \bar{x}(\delta(V'_1, \dots, V'_{p-1})) \\ &\leq p-1 - (p-2) \\ &= 1. \end{aligned}$$

Moreover, if $\bar{x}[V_i, V_j] = 1$, then the above inequalities are all satisfied as equalities, and we get $\bar{x}(\delta(V'_1, \dots, V'_{p-1})) = p-2$. $\square$

PROPOSITION 3.3. *Consider a partition $\{V_i^1, V_i^2\}$ of V_i for some $i \in \{1, \dots, p\}$. Let $\pi' = \{V'_1, \dots, V'_{p+1}\}$ be the partition of V given by*

$$\begin{aligned} V'_j &= V_j, & j &= 1, \dots, i-1, \\ V'_i &= V_i^1, \\ V'_{i+1} &= V_i^2, \\ V'_j &= V_{j-1}, & j &= i+2, \dots, p+1. \end{aligned}$$

- (a) If π and π' are of type 1, then $\bar{x}[V_i^1, V_i^2] \geq 1$.
- (b) If π is of type 1 and π' is of type 2, then $\bar{x}[V_i^1, V_i^2] \geq 2$.
- (c) If π is of type 2, then $\bar{x}[V_i^1, V_i^2] \geq 1$.

Moreover, if $\bar{x}[V_i^1, V_i^2] = 1$ (cases (a) and (c)) or $\bar{x}[V_i^1, V_i^2] = 2$ (case (b)), then the partition π' is also tight for $\bar{x}$.

Proof. The proof is omitted because of its similarity with the one of Proposition 3.2. $\square$

An immediate consequence of Proposition 3.3 is the following.

Remark 3.4. The subgraphs $G(V_i)$ for $i = 1, \dots, p$ are all connected.

We notice that the two previous propositions could be generalized as described in the remark below.

Remark 3.5. In Proposition 3.2, we may consider a subscript subset $I \subsetneq \{1, \dots, p\}$ with $|I| \geq 2$ (instead of only two distinct subscripts i and j), and in Proposition 3.3, we may partition the node subset V_i into at least (rather than exactly) two subsets.

PROPOSITION 3.6. *Let $\delta(W_1)$ and $\delta(W_2)$ be two cuts tight for $\bar{x}$ such that W_1 and W_2 are two crossing subsets of V . Then, $\delta(W_1 \cap W_2)$ and $\delta(\overline{W_1 \cup W_2})$ are tight for $\bar{x}$, and $\bar{x}[W_1 \setminus W_2, W_2 \setminus W_1] = 0$ if one of the two following properties holds:*

- (a) $\text{con}(W_1) + \text{con}(W_2) \leq 3$, or
- (b) $\text{con}(W_1) = \text{con}(W_2) = 2$ and $r(W_1 \cap W_2) = r(\overline{W_1 \cup W_2}) = 2$.

Proof. We have

$$\begin{aligned} \bar{x}(\delta(W_1)) + \bar{x}(\delta(W_2)) &= \text{con}(W_1) + \text{con}(W_2) \\ &= \bar{x}(\delta(W_1 \cap W_2)) + \bar{x}(\delta(\overline{W_1 \cup W_2})) + 2\bar{x}[W_1 \setminus W_2, W_2 \setminus W_1] \\ &\geq \text{con}(W_1 \cap W_2) + \text{con}(\overline{W_1 \cup W_2}), \end{aligned}$$

where the last inequality follows from $\bar{x} \in \text{CPP}(G, r)$. Since one of the properties (a) and (b) holds and $\text{con}(\overline{W_1 \cup W_2}) = \text{con}(W_1 \cup W_2)$, by Remark 2.4 we have $\text{con}(W_1) + \text{con}(W_2) = \text{con}(W_1 \cap W_2) + \text{con}(\overline{W_1 \cup W_2})$. We then obtain the result. $\square$

PROPOSITION 3.7. *Let $\pi_1 = \{V_1, \dots, V_p\}$ and $\pi_2 = \{W_1, \dots, W_q\}$, $p \geq 2$ and $q \geq 2$, be two partitions of V which are tight for $\bar{x}$. Consider two distinct subscripts $i, j \in \{1, \dots, p\}$.*

- (a) *If π_1 is of type 1 or π_1 is of type 2 with $p \geq 3$ and $r(\overline{V_i \cup V_j}) = 2$, then at most one class of π_2 only intersects both V_i and V_j .*
- (b) *If π_1 is of type 2 with either $p = 2$ or $r(\overline{V_i \cup V_j}) = 1$, then at most two classes of π_2 only intersect both V_i and V_j .*

Proof. Assume that π_1 is a partition of type 1. (The proofs for the other cases are similar.) Let $K \subseteq \{1, \dots, q\}$, $|K| > 1$, be the set of subscripts such that $W_k \cap V_i \neq \emptyset$, $W_k \cap V_j \neq \emptyset$, and $W_k = (W_k \cap V_i) \cup (W_k \cap V_j)$ for all $k \in K$. From Proposition 3.3, we have

$$\bar{x}[W_k \cap V_i, W_k \cap V_j] \geq 1 \quad \text{for all } k \in K.$$

These last inequalities together with Proposition 3.2(a) lead to

$$\begin{aligned} 1 &\geq \bar{x}[V_i, V_j] \geq \sum_{k \in K} \bar{x}[W_k \cap V_i, W_k \cap V_j] \\ &\geq |K| \\ &> 1, \end{aligned}$$

a contradiction. $\square$

We remark that if we have $p = 2$ in Proposition 3.7, then at most $\text{con}(V_1)$ classes of the partition π_2 intersect both V_1 and V_2 .

PROPOSITION 3.8. *Let $\pi_1 = \{V_1, \dots, V_p\}$ and $\pi_2 = \{W_1, \dots, W_q\}$, $p \geq 2$ and $q \geq 3$, be two partitions of V which are tight for $\bar{x}$. Given a subscript $i \in \{1, \dots, p\}$, define $J = \{j_1, \dots, j_k\} = \{j \in \{1, \dots, q\} \mid V_i \cap W_j \neq \emptyset\}$. Assume $2 \leq k < q$. We then have*

- (a) $\bar{x}[V_i \cap W_{j_1}, \dots, V_i \cap W_{j_k}] = \bar{x}[W_{j_1}, \dots, W_{j_k}] = k - 1$, if π_1 is of type 1, and one of the following conditions hold:
 - (a.1) π_2 is of type 1, or
 - (a.2) π_2 is of type 2, $r(V_1) = 1$ and $r(V \setminus \bigcup_{j \in J} W_j) = 2$.
- (b) $\bar{x}[V_i \cap W_{j_1}, \dots, V_i \cap W_{j_k}] = \bar{x}[W_{j_1}, \dots, W_{j_k}] = k$, if π_1 and π_2 are of type 2 and $r(V_i) = 2$.

Proof. We are going to prove the case (a.1). (The proofs for the other cases use similar arguments.) Without loss of generality, we suppose $J = \{1, \dots, k\}$. Since $[V_i \cap W_1, \dots, V_i \cap W_k] \subseteq [W_1, \dots, W_k]$ and $\bar{x} \geq 0$, we have

$$(3.1) \quad \bar{x}[V_i \cap W_1, \dots, V_i \cap W_k] \leq \bar{x}[W_1, \dots, W_k].$$

From the definition of J and the fact that π_2 is a partition of V , $\{V_i \cap W_1, \dots, V_i \cap W_k\}$ is a partition of V_i . By Proposition 3.3(a) and Remark 3.5, we have

$$(3.2) \quad \bar{x}[V_i \cap W_1, \dots, V_i \cap W_k] \geq k - 1.$$

Furthermore, as π_2 is of type 1, the partition $\{\bigcup_{j \in J} W_j, W_{k+1}, \dots, W_q\}$ is also of type 1. From Proposition 3.2(a) and Remark 3.5, we have

$$\bar{x}[W_1, \dots, W_k] \leq k - 1.$$

This last inequality combined with the inequalities (3.1) and (3.2) gives $\bar{x}[V_i \cap W_1, \dots, V_i \cap W_k] = \bar{x}[W_1, \dots, W_k] = k - 1$. $\square$

We remark that in Proposition 3.8, if we do not fulfill the conditions (a) and (b), we still have $k - 1 \leq \bar{x}[V_i \cap W_{j_1}, \dots, V_i \cap W_{j_k}] \leq \bar{x}[W_{j_1}, \dots, W_{j_k}] \leq k$.

PROPOSITION 3.9. *Let $\pi = \{V_1, \dots, V_p\}$, $p \geq 2$, be a partition of V which is tight for $\bar{x}$. Consider two distinct subscripts $i, j \in \{1, \dots, p\}$ such that $i < j$, $|V_i| \geq 2$, and $|V_j| \geq 2$. Given a nonempty node set $W \subsetneq V_i$ and a partition $\{V_j^1, \dots, V_j^q\}$, $q \geq 2$, of V_j , let $\pi' = \{V'_1, \dots, V'_{p'}\}$ be the following partition of V :*

$$\begin{aligned} V'_t &= V_t, & t &= 1, \dots, i-1, \\ V'_i &= V_i \setminus W, \\ V'_t &= V_t, & t &= i+1, \dots, j-1, \\ V'_j &= V_j^1 \cup W, \\ V'_{t+j} &= V_j^{t+1}, & t &= 1, \dots, q-1, \\ V'_{t+q-1} &= V_t, & t &= j+1, \dots, p, \end{aligned}$$

where $p' = p + q - 1$.

- (a) *If π and π' are of the same type, then $\bar{x}[V_j^1, \dots, V_j^q] \geq q - 1 + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$.*
- (b) *If π is of type 1 and π' is of type 2, then $\bar{x}[V_j^1, \dots, V_j^q] \geq q + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$.*

(c) If π is of type 2 and π' is of type 1, then $\bar{x}[V_j^1, \dots, V_j^q] \geq q - 2 + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$.

Moreover, if $\bar{x}[V_j^1, \dots, V_j^q] = q - 1 + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$ (case (a)), $\bar{x}[V_j^1, \dots, V_j^q] = q + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$ (case (b)) or $\bar{x}[V_j^1, \dots, V_j^q] = q - 2 + \bar{x}[W, V_j^1] - \bar{x}[W, V_i \setminus W]$ (case (c)), then the partition π' is also tight for $\bar{x}$.

Proof. Using $\bar{x}(\delta(V'_1, \dots, V'_{p'})) = \bar{x}(\delta(V_1, \dots, V_p)) + \bar{x}[V_j^1, \dots, V_j^q] - \bar{x}[W, V_j^1] + \bar{x}[W, V_i \setminus W]$, the proof is similar to the one of Proposition 3.2, and thus it is omitted. $\square$

In the remainder of this section, let us assume that $\bar{x}$ is an extreme point of $\text{CPP}(G, r)$. We denote by $E_0(\bar{x})$, $E_1(\bar{x})$ and $E_f(\bar{x})$ the set of edges $e \in E$ such that $\bar{x}(e) = 0$, $\bar{x}(e) = 1$ and $0 < \bar{x}(e) < 1$, respectively. Let $P_1(\bar{x})$ and $P_2(\bar{x})$ be the sets of partitions of type 1 and 2, respectively, which are tight for $\bar{x}$.

Since $\bar{x}$ is an extreme point of $\text{CPP}(G, r)$, there exist $P_1^*(\bar{x}) \subseteq P_1(\bar{x})$ and $P_2^*(\bar{x}) \subseteq P_2(\bar{x})$ such that $\bar{x}$ is the unique solution of the system

$$S(\bar{x}) \begin{cases} x(e) = 0 & \text{for all } e \in E_0(\bar{x}), \\ x(e) = 1 & \text{for all } e \in E_1(\bar{x}), \\ x(\delta(V_1, \dots, V_p)) = p - 1 & \text{for all } \{V_1, \dots, V_p\} \in P_1^*(\bar{x}), \\ x(\delta(W_1, \dots, W_q)) = q & \text{for all } \{W_1, \dots, W_q\} \in P_2^*(\bar{x}), \end{cases}$$

where $|E_0(\bar{x})| + |E_1(\bar{x})| + |P_1^*(\bar{x})| + |P_2^*(\bar{x})| = |E|$. Since the system $S(\bar{x})$ is not unique, we give the following remarks which will be useful later.

Remark 3.10. From any system of equations, induced by inequalities of $\text{CPP}(G, r)$ and whose unique solution is $\bar{x}$, we may extract a nonsingular subsystem having exactly $|E|$ equations.

Remark 3.11. For any $e \in E$, there exists at least one equation of $S(\bar{x})$ which contains $x(e)$ with a nonzero coefficient.

PROPOSITION 3.12. *If $\bar{x}$ is fractional, then $|E_f(\bar{x})| \geq 2$.*

Proof. Every equation of the system $S(\bar{x})$ has coefficients equal to 0 or 1 and an integer right-hand side. Since $\bar{x}$ is fractional, Remark 3.11 then implies that $\bar{x}$ must contain at least two fractional components. $\square$

PROPOSITION 3.13. *For any edge pair of $E_f(\bar{x})$, there exists at least one equation of $S(\bar{x})$ which contains exactly one of the two edges.*

Proof. Suppose that there exist two edges $e_1, e_2 \in E_f(\bar{x})$ such that any equation of $S(\bar{x})$ contains either both or none of them. Let $x' \in \mathbb{R}^E$ be the point such that

$$x'(e) = \begin{cases} \bar{x}(e) + \epsilon & \text{if } e = e_1, \\ \bar{x}(e) - \epsilon & \text{if } e = e_2, \\ \bar{x}(e) & \text{if } e \in E \setminus \{e_1, e_2\}, \end{cases}$$

where $\epsilon \neq 0$. The point x' is also a solution of $S(\bar{x})$, which contradicts the extremality of $\bar{x}$. $\square$

A direct consequence of the previous proposition is the following.

Remark 3.14. If u, v are two nodes of V , then $[u, v]$ contains at most one edge in $E_f(\bar{x})$.

PROPOSITION 3.15. *Let $W \subsetneq V$ be a nonempty node subset such that $\bar{x}(\delta(W)) = 1$. We then have $\bar{x}(e) \in \{0, 1\}$ for all $e \in \delta(W)$.*

Proof. Suppose there exists $e \in \delta(W) \cap E_f(\bar{x})$. Since $\bar{x}(\delta(W)) = 1$, there must exist another edge $f \in \delta(W) \cap E_f(\bar{x})$. We are going to prove that the system $S(\bar{x})$ can

be chosen such that any of its equations contains either e and f or none of them. Let $\{V_1, \dots, V_p\}$ be a partition of V inducing an equation of the system $S(\bar{x})$. Assume that there exist two distinct subscripts $i, j \in \{1, \dots, p\}$ such that $V_i \cap W \neq \emptyset \neq V_j \cap W$. From Proposition 3.3, we obtain $\bar{x}[V_i \cap W, V_i \setminus W] \geq 1$ and $\bar{x}[V_j \cap W, V_j \setminus W] \geq 1$ which give $\bar{x}(\delta(W)) \geq \bar{x}[V_i \cap W, V_i \setminus W] + \bar{x}[V_j \cap W, V_j \setminus W] \geq 2$, a contradiction. Therefore, we have $W \subseteq V_k$ for some $k \in \{1, \dots, p\}$. If $W \neq V_k$, then from Proposition 3.3 and $\bar{x}(\delta(W)) = 1$ we must have $\delta(W) = [W, V_k \setminus W]$. We thus conclude that any equation of $S(\bar{x})$ contains either e and f or none of them. But this contradicts Proposition 3.13. $\square$

PROPOSITION 3.16. *Let $W \subsetneq V$ be a nonempty node subset such that $\text{con}(W) = 2$. If $\bar{x}(\delta(W)) = 2$, then the system $S(\bar{x})$ can be chosen such that $P_1^*(\bar{x}) = \emptyset$.*

Proof. Suppose there exists a partition $\{V_1, \dots, V_p\} \in P_1^*(\bar{x})$. Without loss of generality, we suppose that V_1 contains all the terminals. Since $\text{con}(W) = 2$, we obtain that $V_1 \cap W \neq \emptyset \neq V_1 \cap \bar{W}$. From Proposition 3.3(b), we have $\bar{x}[V_1 \cap W, V_1 \cap \bar{W}] \geq 2$ which implies $\delta(W) = [V_1 \cap W, V_1 \cap \bar{W}]$. Therefore by Proposition 3.2, we deduce that either W or $\bar{W}$ is a subset of V_1 . Without loss of generality, we assume that $W \subset V_1$. The partition $\{W, V_1 \cap \bar{W}, V_2, \dots, V_p\}$ is of type 2, then since $\bar{x}[W, V_1 \cap \bar{W}] = 2$ Proposition 3.3 gives $\{W, V_1 \cap \bar{W}, V_2, \dots, V_p\} \in P_2^*(\bar{x})$.

We can thus replace in the system $S(\bar{x})$ the partition $\{V_1, \dots, V_p\}$ by the partitions $\{W, \bar{W}\}$ and $\{W, V_1 \cap \bar{W}, V_2, \dots, V_p\}$. The obtained system may have more than $|E|$ equations, yet from Remark 3.10 we can choose $|E|$ equations of this system whose unique solution is $\bar{x}$. $\square$

PROPOSITION 3.17. *Let $W \subsetneq V$ be a nonempty node subset such that $\text{con}(W) = 2$. If $\bar{x}(\delta(W)) = 2$, then the system $S(\bar{x})$ can be chosen such that at most one class of any partition of $P_2^*(\bar{x})$ intersects both W and $\bar{W}$.*

Proof. From Proposition 3.7(b), any partition of $P_2^*(\bar{x})$ has at most two classes which intersect both W and $\bar{W}$. Suppose that there exists a partition $\{V_1, \dots, V_p\}$ of $P_2^*(\bar{x})$ such that, without loss of generality, V_1 and V_2 intersect both W and $\bar{W}$. Proposition 3.3(c) then states that the partition $\{V_1 \cap W, V_1 \cap \bar{W}, V_2 \cap W, V_2 \cap \bar{W}, V_3, \dots, V_p\}$ belongs to $P_2(\bar{x})$. We can thus replace in the system $S(\bar{x})$ the partition $\{V_1, \dots, V_p\}$ by the partitions $\{W, \bar{W}\}$ and $\{V_1 \cap W, V_1 \cap \bar{W}, V_2 \cap W, V_2 \cap \bar{W}, V_3, \dots, V_p\}$. The result thus follows from Remark 3.10. $\square$

PROPOSITION 3.18. *Let u, v be two distinct nodes such that $\bar{x}[u, v] \geq 1$. The system $S(\bar{x})$ can thus be chosen such that*

- (a) $\delta(V_1, \dots, V_p) \cap [u, v] = \emptyset$, for all $\{V_1, \dots, V_p\} \in P_1^*(\bar{x})$, and
- (b) if $\{V_1, \dots, V_p\} \in P_2^*(\bar{x})$ with $p \geq 3$ and $[u, v] \subseteq [V_i, V_j]$ for some distinct subscripts $i, j \in \{1, \dots, p\}$, then $r(V \setminus (V_i \cup V_j)) = 1$.

Proof. We will prove (a). (The proof of (b) uses similar arguments.) Let $\pi = \{V_1, \dots, V_p\}$, $p \geq 2$, be a partition of type 1, tight for $\bar{x}$ and such that without loss of generality, $[u, v] \subseteq [V_1, V_2]$. If $p = 2$, then from Proposition 3.15, we have $\bar{x}(e) \in \{0, 1\}$ for all $e \in [u, v]$. The equation induced by π can thus be obtained from the equations $x(e) = 0$ for all $e \in [u, v] \cap E_0(\bar{x})$, and $x(e) = 1$ for all $e \in [u, v] \cap E_1(\bar{x})$.

Suppose now that $p \geq 3$. From Proposition 3.2, we have $\bar{x}[V_1, V_2] \leq 1$. Since $[u, v] \subseteq [V_1, V_2]$ and $\bar{x}[u, v] \geq 1$, we then obtain $\bar{x}[u, v] = 1$. Therefore, the partition $\pi' = \{V_1 \cup V_2, V_3, \dots, V_p\}$ is also tight for $\bar{x}$. Moreover, by Remark 3.14, $\bar{x}(e) \in \{0, 1\}$ for all $e \in [u, v]$. The equation induced by π can thus be obtained from the one induced by π' together with the equations $x(e) = 0$ for all $e \in [u, v] \cap E_0(\bar{x})$ and $x(e) = 1$ for all $e \in [u, v] \cap E_1(\bar{x})$. $\square$

PROPOSITION 3.19. *Let u be a node having exactly two neighbors, namely u_1*

and u_2 . The system $S(\bar{x})$ can then be chosen such that any partition $\{V_1, \dots, V_p\} \in P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ with $p \geq 3$ and $[u, u_1] \subset \delta(V_1, \dots, V_p)$ has the following property:

$$|V_i \cap \{u_1, u_2\}| \leq 1 \text{ for all } i \in \{1, \dots, p\}.$$

Moreover, if $\bar{x}[u, u_2] < 1$, then we also have

$$|V_i \cap \{u, u_2\}| \leq 1 \text{ for all } i \in \{1, \dots, p\}.$$

Proof. Let $\pi = \{V_1, \dots, V_p\} \in P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ with $p \geq 3$ and $[u, u_1] \subset \delta(V_1, \dots, V_p)$. Without loss of generality, we assume $u \in V_1$ and $u_1 \in V_2$. Suppose $u_2 \in V_2$. By Remark 3.4, we have $V_1 = \{u\}$. If $\bar{x}(\delta(u)) > r(u)$, by considering the partition $\{V_1 \cup V_2, V_3, \dots, V_p\}$, we then contradict Proposition 3.2. Hence, we have $\bar{x}(\delta(u)) = r(u)$. Let π' be the partition $\{V_1 \cup V_2, V_3, \dots, V_p\}$. If $r(u) = 2$, then either $\bar{x}[u, u_1]$ or $\bar{x}[u, u_2]$ is greater than 1, and by Proposition 3.18, we have $\pi \in P_2^*(\bar{x})$, $r(V \setminus (V_1 \cup V_2)) = 1$, and then $\pi' \in P_1(\bar{x})$. If $r(u) = 1$, then we clearly have $\pi' \in P_1(\bar{x}) \cup P_2(\bar{x})$. We can thus replace in the system $S(\bar{x})$ the partition π by the partition π' and the cut $\delta(u)$. The obtained system may have more than $|E|$ equations, yet from Remark 3.10 we can choose $|E|$ equations of this system whose unique solution is $\bar{x}$. Therefore, the system $S(\bar{x})$ can be chosen such that no partition has one class containing u and a different one containing both u_1 and u_2 .

We now suppose that $\bar{x}[u, u_2] < 1$. If $u_2 \in V_1$, we then have $\bar{x}[u, V_1 \setminus \{u\}] = \bar{x}[u, u_2] < 1$, a contradiction with Proposition 3.3. $\square$

PROPOSITION 3.20. Let u, v be two distinct nodes such that $\bar{x}[u, v] \geq 2$. We have the following:

- (a) the system $S(\bar{x})$ can be chosen such that the variables $x(e)$, for all $e \in [u, v]$, only appear in equations induced by $E_0(\bar{x}) \cup E_1(\bar{x})$ with a nonzero coefficient, and
- (b) $\bar{x}(e) \in \{0, 1\}$ for all $e \in [u, v]$.

Proof. Using the same arguments as in the proof of Proposition 3.18, we get (a). Consequently, from Remark 3.11, we obtain $\bar{x}(e) \in \{0, 1\}$ for all $e \in [u, v]$. $\square$

4. Composition of G by one-node cutset and the $\text{CPP}(G, r)$. Given a graph $G = (V, E)$ and two subgraphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ of G , if $V = V_1 \cup V_2$ and $|V_1 \cap V_2| = 1$, then $G = (V, E_1 \cup E_2)$ is called the 1-sum of G_1 and G_2 . In that case, the singleton $V_1 \cap V_2$ is called a *one-node cutset* of G .

LEMMA 4.1. Let $G = (V, E)$ be a graph and $r \in \{1, 2\}^V$ be a connectivity type vector. Suppose that G is the 1-sum of the graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$. Let u be the only node of $V_1 \cap V_2$. For $i = 1, 2$, let $r_i \in \{1, 2\}^{V_i}$ be the connectivity type vector such that $r_i(v) = r(v)$ if $v \in V_i \setminus \{u\}$ and $r_i(u) = \max\{r(u), r(V \setminus V_i)\}$. If $\bar{x}$ is an extreme point of $\text{CPP}(G, r)$, then the restriction $\bar{x}_i$ of $\bar{x}$ on G_i is also an extreme point of $\text{CPP}(G_i, r_i)$ for $i = 1, 2$.

Proof. First, when we write $\bar{x}_i$, we refer to one of the two restrictions $\bar{x}_1$ and $\bar{x}_2$, and then the subscript i may be either 1 or 2 in the proof. From Proposition 3.1, $\bar{x}_i \in \text{CPP}(G_i, r_i)$. (We remark that the couples (G_1, r_1) and (G_2, r_2) are nothing but the couples $(G/E_2, r_{E_2}^c)$ and $(G/E_1, r_{E_1}^c)$, respectively.) To prove that $\bar{x}_i$ is an extreme point of $\text{CPP}(G_i, r_i)$, it suffices to show that we can choose the system $S(\bar{x})$ such that for any pair of edges $e_1 \in E_1$ and $e_2 \in E_2$, none of its equations involves both $x(e_1)$ and $x(e_2)$ with nonzero coefficients.

Let $\pi = \{W_1, \dots, W_p\}$ be a partition which is tight for $\bar{x}$. Suppose $u \in W_q$ for some $q \in \{1, \dots, p\}$. Since $\{u\}$ is a one-node cutset, by Remark 3.4 W_q is the only

class which may intersect both V_1 and V_2 . Without loss of generality, we can assume that $W_j \subseteq V_1$ for all $j \in \{1, \dots, q-1\}$ and $W_k \subseteq V_2$ for all $k \in \{q+1, \dots, p\}$.

Consider the two partitions $\pi_1 = \{W_1, \dots, W_{q-1}, W_q^1\}$ and $\pi_2 = \{W_q^2, W_{q+1}, \dots, W_p\}$ of V , where

$$W_q^1 = \bigcup_{j \geq q} W_j \quad \text{and} \quad W_q^2 = \bigcup_{k \leq q} W_k.$$

We clearly have

$$(4.1) \quad \bar{x}(\delta(W_1, \dots, W_p)) = \bar{x}(\delta(W_1, \dots, W_{q-1}, W_q^1)) + \bar{x}(\delta(W_q^2, W_{q+1}, \dots, W_p)).$$

We remark that we cannot have both π_1 and π_2 of type 2. The partition π would be of type 2 otherwise, and then (4.1) would give

$$\begin{aligned} p &= \bar{x}(\delta(W_1, \dots, W_p)) \\ &\geq q + (p - q + 1) \\ &= p + 1, \end{aligned}$$

which is impossible.

Without loss of generality, we now suppose that π_1 is of type 1. We notice that, in this case, π and π_2 have the same type. Assume that π_2 is of type 2. (The case where π_2 is of type 1 is similar.) The inequality (4.1) then gives

$$\begin{aligned} p &= \bar{x}(\delta(W_1, \dots, W_p)) \\ &\geq (q-1) + (p - q + 1) \\ &= p. \end{aligned}$$

We thus have that both partitions π_1 and π_2 are tight for $\bar{x}$. Hence, we can replace in the system $S(\bar{x})$ the partition π by the two partitions π_1 and π_2 , and we then get a new system $S'(\bar{x})$. By Remark 3.10, there is a nonsingular subsystem of $S'(\bar{x})$ with exactly $|E|$ equations and whose solution is $\bar{x}$. Since $\delta(W_1, \dots, W_{q-1}, W_q^1) \subseteq E_1$ and $\delta(W_q^2, W_{q+1}, \dots, W_p) \subseteq E_2$, any equation of this subsystem only contains variables induced by edges from either E_1 or E_2 . The proof is thus complete. $\square$

Using the same notations as those introduced in Lemma 4.1, the following is an immediate consequence of this lemma.

COROLLARY 4.2. *If $CPP(G_1, r_1)$ and $CPP(G_2, r_2)$ are integer, then so is $CPP(G, r)$.*

Suppose that G is decomposable by one-node cutsets into $G_1, G_2, \dots, G_t$ with $t \geq 2$. Let $r_i, i = 1, \dots, t$, be the connectivity type vector associated to G_i , defined as in Lemma 4.1. A direct consequence of Corollary 4.2 is that if $CPP(G_i, r_i)$ is integer for all $i \in \{1, \dots, t\}$, then so is $CPP(G, r)$.

5. The polytope $CPP(G, r)$ on series-parallel graphs. In this section, we are interested in the cut and partition inequalities polytope $CPP(G, r)$ on series-parallel graphs. A graph is called *series-parallel* if and only if it does not contain K_4 (i.e., the complete graph with 4 nodes) as a minor [4]. We are going to give sufficient conditions for this polytope to be an integer on this class of graphs, that is, sufficient conditions for the polytope $SNDP(G, r)$ to be completely described by the trivial inequalities (2.1) and (2.2) together with the partition inequalities (2.5). (We recall that the cut inequalities (2.3) are partition inequalities induced by partitions having exactly two classes.)

We can remark that if the graph G contains at most one terminal (i.e., $|T| \leq 1$), then the SNDP is nothing but the spanning tree problem. In this case and for general graphs G , Fulkerson [5] completely described the polytope $\text{SNDP}(G, r)$ by the trivial inequalities and the inequalities (2.5) induced by partitions of type 1. For general graphs G , we then have the following.

THEOREM 5.1 (see [5]). *If $|T| \leq 1$, then $\text{CPP}(G, r)$ is integer.*

On the other hand, Mahjoub [17] showed that the polytope $\text{SNDP}(G, r)$ is completely described by the trivial inequalities (2.1) and (2.2), and the cut inequalities (2.3) on series-parallel graphs when $r(u) = 2$ for all $u \in V$. We notice that for such connectivity type vectors, the partition inequalities (2.5) are dominated by the cut inequalities (2.3). Therefore we have the following theorem.

THEOREM 5.2 (see [17]). *If G is series-parallel and $T = V$, then $\text{CPP}(G, r)$ is integer.*

In the remainder of this paper, we are going to restrict our attention to graphs G having at least one ordinary node and two terminals. We remark that according to the definition of the survivability conditions, the case with exactly one terminal can be trivially reduced to the one with $T = \emptyset$.

In view of Theorems 5.1 and 5.2, one would have expected the integrality of the polytope $\text{CPP}(G, r)$ if G is series-parallel and $r \in \{1, 2\}^V$. Unfortunately, it turns out that this result does not hold. In fact, let us consider the two graphs $G_p^1 = (V_p^1, E_p^1)$ and $G_p^2 = (V_p^2, E_p^2)$ of Figure 5.1, where the terminals are represented by black circles. (G_p^1 has three terminals $\{u_1, u_2, u_3\}$ and two ordinary nodes $\{v_1, v_2\}$, while G_p^2 has four terminals $\{u_1, u_2, u_3, u_4\}$ and one ordinary node $\{v_1\}$.) These two graphs are clearly series-parallel. Moreover, the fractional solutions of $\frac{1}{2}$ for all of the dashed edges and 1 for all of the solid ones are extreme points of the corresponding polytopes $\text{CPP}(G_p^1, r_p^1)$ and $\text{CPP}(G_p^2, r_p^2)$, where $r_p^1 \in \{1, 2\}^{V_p^1}$ and $r_p^2 \in \{1, 2\}^{V_p^2}$ are the connectivity type vectors associated to G_p^1 and G_p^2 , respectively. This implies that the partition inequalities (2.5) together with the trivial ones (2.1) and (2.2) do not suffice to completely describe the survivable network design polytope $\text{SNDP}(G, r)$ on series-parallel graphs.

FIG. 5.1. Fractional extreme points of $\text{CPP}(G_p^1, r_p^1)$ and $\text{CPP}(G_p^2, r_p^2)$.

Let us now consider the following inequalities:

$$(5.1) \quad x(E_p^i) + x(\delta(v_1)) \geq 8 \quad \text{for } i = 1, 2.$$

It is not hard to see that the inequality (5.1) for $i = 1$ (respectively, $i = 2$) should be satisfied by any point of the polytope $\text{SNDP}(G_p^1, r_p^1)$ (respectively, $\text{SNDP}(G_p^2, r_p^2)$). Moreover, this inequality cuts off the fractional extreme point of $\text{CPP}(G_p^1, r_p^1)$ (respectively, $\text{CPP}(G_p^2, r_p^2)$) given above. We will see in section 7 that inequalities (5.1) are actually special cases of a more general class of facet-defining inequalities of $\text{SNDP}(G, r)$.

In the next theorem, we give sufficient conditions based on both graphs (G_p^1, r_p^1) and (G_p^2, r_p^2) for the cut and partition inequalities polytope $\text{CPP}(G, r)$ to be an integer on series-parallel graphs.

THEOREM 5.3. *Let $G = (V, E)$ be a series-parallel graph and $r \in \{1, 2\}^V$ be its associated connectivity type vector. If (G, r) does not have either (G_p^1, r_p^1) or (G_p^2, r_p^2) as a minor, then $\text{CPP}(G, r)$ is integer.*

Before giving the proof of the theorem, let us first note that its converse does not hold as shown by the following example. (The black circles still depict the terminal nodes.)

FIG. 5.2. Counterexample for the converse of Theorem 5.3.

Let $G_0 = (V_0, E_0)$ be the graph given in Figure 5.2 and $r_0 \in \{1, 2\}^{V_0}$ its associated connectivity type vector. The polytope $\text{CPP}(G_0, r_0)$ is integer. In fact it is reduced to the point with all components equal to 1. The couple (G_0, r_0) clearly has (G_p^1, r_p^1) as a minor, proving that the converse of Theorem 5.3 is not true.

Proof of Theorem 5.3. The proof is by induction on the number of edges. It is not hard to see that the statement holds for any graph with no more than two edges. Suppose that for any series-parallel graph G having no more than m edges and any connectivity type vector $r \in \{1, 2\}^V$ such that (G, r) has neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor, we have that $\text{CPP}(G, r)$ is integer. Let us consider a series-parallel graph $G = (V, E)$ and a connectivity type vector $r \in \{1, 2\}^V$ such that G has $m+1$ edges, (G, r) has neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor and $\text{CPP}(G, r)$ is not integer. There thus exists a fractional extreme point $\bar{x}$ of $\text{CPP}(G, r)$. We can choose $\bar{x}$ among all the fractional extreme points of $\text{CPP}(G, r)$ such that $|E_0(\bar{x}) \cup E_1(\bar{x})|$ is maximum. (Associated with $\bar{x}$, we consider the system $S(\bar{x})$ as well as the sets $E_0(\bar{x})$, $E_1(\bar{x})$ and $E_f(\bar{x})$ as defined in section 3.)

If $r(v) = 2$ for all $v \in V$, then from Theorem 5.2 the polytope $\text{CPP}(G, r)$ is integer. Therefore, without loss of generality, we can also suppose that the cardinality of the terminal set T is maximum. It means that for any series-parallel graph $G' = (V', E')$ and any connectivity type vector $r' \in \{1, 2\}^{V'}$ such that $|E'| = m + 1$, (G', r') has neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor and $|\{v \in V' : r'(v) = 2\}| > |T|$, the polytope $\text{CPP}(G', r')$ is integer.

From the induction hypothesis, it follows that

$$(5.2) \quad \bar{x}(e) > 0 \quad \text{for all } e \in E,$$

that is, $E_0(\bar{x}) = \emptyset$.

CLAIM 1. *Any variable $x(e)$, $e \in E$, has a nonzero coefficient in at least two equations of $S(\bar{x})$.*

Proof. Let us consider an edge $f = uv$ of E , and denote $F = [u, v]$. From Remark 3.11, there exists at least one equation of $S(\bar{x})$ which contains $x(f)$ with a nonzero coefficient. Assume that there is exactly one such equation. Let $S'(\bar{x})$ be the system obtained from $S(\bar{x})$ by deleting all of the equations involving $x(e)$ for $e \in F$. We notice that the system $S'(\bar{x})$ contains exactly $|E| - |F|$ equations. Let x' be the restriction of $\bar{x}$ on $E \setminus F$. By Proposition 3.1, $x' \in \text{CPP}(G/F, r_F)$. Furthermore, x' is a solution of the system $S'(\bar{x})$. Since $S'(\bar{x})$ is nonsingular and its equations come from constraints of $\text{CPP}(G/F, r_F)$, this implies that x' is an extreme point of $\text{CPP}(G/F, r_F)$. By Proposition 3.12 and Remark 3.14, the point x' is fractional. As $(G/F, r_F)$ is a series-parallel graph having neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor, this contradicts the induction hypothesis. $\square$

CLAIM 2. *The graph G is 2-node connected.*

Proof. Suppose the graph G is not 2-node connected. There then exists a node $u \in V$ defining a one-node cutset of G . Let $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ be the two subgraphs of G such that $V_1 \cap V_2 = \{u\}$ and G is the 1-sum of G_1 and G_2 . For $i = 1, 2$ we associate with G_i the connectivity type vector $r_i \in \{1, 2\}^{V_i}$ such that $r_i(v) = r(v)$ if $v \in V_i \setminus \{u\}$, and $r_i(u) = \text{con}_G(V \setminus V_i)$. Let $\bar{x}_1$ and $\bar{x}_2$ be the two restrictions of $\bar{x}$ on E_1 and E_2 , respectively. From Lemma 4.1, both $\bar{x}_1$ and $\bar{x}_2$ are extreme points of $\text{CPP}(G_1, r_1)$ and $\text{CPP}(G_2, r_2)$, respectively. Since $E_f(\bar{x}) \neq \emptyset$, at least one among both restrictions is clearly fractional. Without loss of generality, we assume that $\bar{x}_1$ is fractional. We point out that (G_1, r_1) is nothing but the minor of (G, r) obtained by the contraction of E_2 . Therefore, since the couple (G, r) has neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor, then neither does (G_1, r_1) . The latter combined with $|E_1| < |E|$ and $\bar{x}_1$ fractional contradicts the induction hypothesis. $\square$

The proof now proceeds by successively establishing a sequence of claims which build on each other. Therefore, for the sake of clarity, we only mention the highlights of our argument, and the detailed sequences and proofs are deferred to section 6.

Let $u \in V$ be a node having exactly two neighbors, say u_1 and u_2 . Since G is series-parallel, such a node u must exist [4]. Let us denote by F_1 and F_2 the set of edges between u and u_1 , and u and u_2 , respectively. Without loss of generality, we suppose

$$(5.3) \quad \bar{x}(F_1) \geq \bar{x}(F_2).$$

Suppose that $\bar{x}(F_1) < 1$. From the inequality (5.3), we also have $\bar{x}(F_2) < 1$, and then, by Remark 3.14, we obtain $F_1 = \{f_1 = uu_1\}$ and $F_2 = \{f_2 = uu_2\}$. From Proposition 3.13, there exists a partition $\{V_1, \dots, V_p\}$ of $P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ such that $|\delta(V_1, \dots, V_p) \cap \{f_1, f_2\}| = 1$. Without loss of generality, assume that $f_1 \in \delta(V_1, \dots, V_p)$, and then $\{u, u_2\} \subseteq V_i$ for some $i \in \{1, \dots, p\}$. Hence, we obtain $\bar{x}[u, V_i \setminus \{u\}] = \bar{x}(f_2) < 1$, which contradicts Proposition 3.3. Therefore, $\bar{x}(F_1) \geq 1$.

CLAIM 3. $r(u) = 2$.

CLAIM 4. $r(u_2) = 1$.

CLAIM 5. *There does not exist a node of degree 2.*

CLAIM 6. $1 < \bar{x}(F_1) < 2$.

Let $F_1 = \{e_1, f_1\}$ with $\bar{x}(e_1) = 1$ and $0 < \bar{x}(f_1) < 1$. From Claims 3, 4, 5, 6, we can make the following remarks.

Remark 5.4. If v is a terminal adjacent to exactly two nodes, then between v and one of its neighbors there are exactly two edges.

Remark 5.5. Given two nodes v_1 and v_2 , then any path P between v_1 and v_2 , whose internal nodes have exactly two neighbors in G , satisfies the following.

- (a) All of the internal nodes of P are terminals.
- (b) P has at most two internal nodes.

Since $G = (V, E)$ is series-parallel and 2-connected, there is a 2-node cutset $\{v_1, v_2\}$ such that G decomposes with respect to $\{v_1, v_2\}$ into two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, where $\{v_1, v_2\} = V_1 \cap V_2$ and G_1 is a cycle, possibly with parallel edges (see Figure 5.3). Let L_1 and L_2 be the two walks of G_1 having only v_1 and v_2 in common. (In our context, a walk is a path between v_1 and v_2 , possibly with parallel edges.) We remark that if $|V| \geq 3$, then there exists such a decomposition with $|V_1| \geq 3$.

FIG. 5.3. Decomposition of G by the 2-node cutset $\{v_1, v_2\}$.

By Remark 5.5, all of the internal nodes of L_1 and L_2 are terminals and both L_1 and L_2 have each at most two internal nodes. Throughout the rest of the proof, we only consider the case where both L_1 and L_2 have each at most one internal node. The case of two internal nodes in L_1 or L_2 can be handled using the same arguments.

Without loss of generality, we can consider that L_1 has an internal node, say v . Under the induction assumptions, we remark that the claims 3, 4, and 6 are the results of the fact that u has exactly two neighbors. From now on, we consider $u = v$, $u_1 = v_1$, and $u_2 = v_2$.

CLAIM 7. $|F_2| = 1$

Let $F_2 = \{f_2 = uu_2\}$.

CLAIM 8. $\bar{x}(f_2) < 1$

CLAIM 9. L_2 contains an internal node.

Let $W = V \setminus \{u, u_1, u_2, u'\}$, where u' is an internal node in L_2 . We can suppose, without loss of generality, that $|\delta(u)| \leq |\delta(u')|$. From Remark 5.5(a), we have $r(u') = 2$. To finish the proof of our theorem, we give the following three claims.

CLAIM 10. $||u', u_1|| > ||u', u_2||$.

From Claims 6 and 7, we obtain $|\delta(u')| = |\delta(u)| = 3$. Using similar arguments for u' as those used for u , we have $F'_1 = \{e'_1, f'_1\}$ and $F'_2 = \{f'_2\}$ with $\bar{x}(e'_1) = 1$, $0 < \bar{x}(f'_1) < 1$, and $0 < \bar{x}(f'_2) < 1$.

CLAIM 11. $\bar{x}(f_1) = \bar{x}(f_2) = \bar{x}(f'_1) = \bar{x}(f'_2) = \frac{1}{2}$.

CLAIM 12. The couple (G, r) has the following properties:

- (a) $W \cap T \neq \emptyset$. (We recall that $T = \{u \in V : r(u) = 2\}$.)
- (b) $||S, u_1|| \geq 2$ and $||S, u_2|| \geq 1$ for every $S \subseteq W$ such that $G(S)$ is a connected component of $G(W)$ and $S \cap T \neq \emptyset$.

Among the series-parallel graphs, the class of outerplanar graphs has received particular attention (see, for instance, [3, 20]). A graph is called *outerplanar* if it can be embedded in the plane such that all nodes lie on the boundary of its exterior region. In order to give a complete linear description of the survivable network polytope on

outerplanar graphs, we give this second characterization devised from Kuratowski's theorem [16]. A graph is outerplanar if and only if it does not contain K_4 or $K_{2,3}$ as a minor. (We recall that $K_{2,3}$ is the complete bipartite graph having its node set decomposed into V_1 and V_2 with $|V_1| = 2$, $|V_2| = 3$, and $E(V_1) = E(V_2) = \emptyset$.)

First of all, we remark that the graph G_p of Figure 5.1 contains $K_{2,3}$ as a minor. In fact, $K_{2,3}$ can be obtained from G_p by deleting the three solid edges. Therefore, from the second definition of outerplanar graphs and Theorems 5.1, 5.2, and 5.3, we can deduce the following result.

THEOREM 5.6. *Let $G = (V, E)$ be an outerplanar graph and $r \in \{1, 2\}^V$ be an associated connectivity type vector. The survivable network polytope $SNDP(G, r)$ is then completely described by the trivial inequalities (2.1) and (2.2) together with the partition inequalities (2.5).*

We notice that there exist some series-parallel graphs which are not outerplanar and for which the polytope $CPP(G, r)$ is integer. For instance, from Theorem 5.3, we know that the cut and partition inequalities polytope is an integer for $K_{2,3}$ with exactly three terminals, and clearly, $K_{2,3}$ is not outerplanar. Therefore, the class of outerplanar graphs is strictly included in the subclass of series-parallel graphs implying an integer cut and partition inequalities polytope.

Since the separation problem for the partition inequalities (2.5) is polynomially solvable, a direct consequence of Theorem 5.6 is the following corollary.

COROLLARY 5.7. *The (1, 2)-survivable network design problem can be solved in polynomial time on outerplanar graphs.*

6. Proof of Theorem 5.3. In order to allow a better understanding of the proof of Theorem 5.3, we have just presented its main ideas. This section is thus devoted to give the details of the proof.

Proof of Claim 3. Suppose that $r(u) = 1$ and the system $S(\bar{x})$ satisfies Proposition 3.18. Consider a partition $\pi = \{V_1, \dots, V_p\}$ of $P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ such that $F_1 \subseteq \delta(V_1, \dots, V_p)$. From Claim 1, we know that such a partition exists. Since $\bar{x}(F_1) \geq 1$, by Proposition 3.18(a), we have $\pi \in P_2^*(\bar{x})$. Without loss of generality, assume $u \in V_1$ and $u_1 \in V_2$. From Proposition 3.18(b) and the assumption $r(u) = 1$, we obtain $r(V_1 \setminus \{u\}) = 2$. We can then deduce from Remark 3.4 that $u_2 \in V_1$. With π , we associate the partition $\pi_a = \{V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p\}$ which clearly is of type 2. Since $\bar{x}(\delta(V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p)) \geq p$, we then obtain $\bar{x}(F_2) \geq \bar{x}(F_1)$. This last inequality combined with inequality (5.3) gives $\bar{x}(F_2) = \bar{x}(F_1)$, and thus, $\pi_a \in P_2(\bar{x})$.

Let $S_{F_1}(\bar{x})$ be the system arisen from $S(\bar{x})$ when we delete every equation induced by $e \in E_1(\bar{x}) \cap F_1$ and the ones induced by the partitions π containing F_1 , and we add the equations induced by the associated partitions π_a . (We remark that π_a might already belong to $P_2^*(\bar{x})$.) From Proposition 3.1, the restriction $\bar{x}_{F_1}$ of $\bar{x}$ on G/F_1 belongs to $CPP(G/F_1, r_{F_1})$. Moreover, the couple $(G/F_1, r_{F_1})$ clearly has neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor. Since G/F_1 has less edges than G , by the induction hypothesis, the polytope $CPP(G/F_1, r_{F_1})$ is an integer. Therefore $\bar{x}_{F_1}$, which is clearly fractional, is not an extreme point of $CPP(G/F_1, r_{F_1})$. There must thus exist an extreme point $y \in CPP(G/F_1, r_{F_1})$ which is also a solution of $S_{F_1}(\bar{x})$. Let $\bar{y} \in \mathbb{R}^E$ be the unique point such that $\bar{y}(e) = y(e)$ if $e \in E \setminus F_1$, $\bar{y}(e) = 1$ if $e \in E_1(\bar{x}) \cap F_1$, and $\bar{y}(F_1) = y(F_2)$. We clearly have $\bar{y} \neq \bar{x}$. Moreover, it is obvious that $\bar{y}$ is also a solution of the system $S(\bar{x})$. This contradicts the fact that the system $S(\bar{x})$ is nonsingular. $\square$

Proof of Claim 4. Assume on the contrary that $r(u_2) = 2$. Let us consider a partition $\pi = \{V_1, V_2, \dots, V_p\}$ of $P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ such that $u \in V_1$ and $u_1 \in V_2$.

From Claim 1, such a partition must exist and from Proposition 3.18, $\pi \in P_2^*(\bar{x})$. We claim that this partition exists providing $\bar{x}(F_1) = \bar{x}(F_2)$. In fact, suppose that $\bar{x}(F_1) > \bar{x}(F_2)$. Since $\bar{x}(\delta(u)) = \bar{x}(F_1) + \bar{x}(F_2) \geq 2$, we clearly get $\bar{x}(F_1) > 1$. If $u_2 \notin V_1 \cup V_2$, Remark 3.4 implies that the class V_1 is then reduced to the single node u . The partition $\pi_1 = \{V_1 \cup V_2, V_3, \dots, V_p\}$ is of type 2 because of $u \in V_1 \cup V_2$, $r(u) = 2$, $u_2 \notin V_1 \cup V_2$, and $r(u_2) = 2$. We then have

$$\begin{aligned}\bar{x}(\delta(V_1 \cup V_2, V_3, \dots, V_p)) &= \bar{x}(\delta(V_1, V_2, \dots, V_p)) - \bar{x}(F_1) \\ &= p - \bar{x}(F_1) \\ &< p - 1,\end{aligned}$$

which contradicts $\bar{x} \in \text{CPP}(G, r)$.

If $u_2 \in V_1$, the partition $\pi_2 = \{V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p\}$ is obviously of type 2. We then get

$$\begin{aligned}\bar{x}(\delta(V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p)) &= \bar{x}(\delta(V_1, V_2, \dots, V_p)) - \bar{x}(F_1) + \bar{x}(F_2) \\ &= p - \bar{x}(F_1) + \bar{x}(F_2) \\ &< p,\end{aligned}$$

which contradicts $\bar{x} \in \text{CPP}(G, r)$. We therefore deduce that the node u_2 belongs to V_2 , and thus $V_1 = \{u\}$. From Proposition 3.19, we could have chosen the system $S(\bar{x})$ such that $p = 2$, and thus partition π is nothing but the cut $\delta(u)$. Since $\bar{x}(F_1) > 1$, $\bar{x}(F_2) > 0$, and $\bar{x}(\delta(u)) = 2$, we clearly deduce that there exists $f_1 \in F_1 \cap E_f(\bar{x})$. This edge belongs to exactly one equation of $S(\bar{x})$, contradicting Claim 1. Therefore $\bar{x}(F_1) = \bar{x}(F_2)$.

We still consider the partition π introduced at the beginning of this proof. If $p = 2$, then we have $\bar{x}(F_1) = \bar{x}(F_2) = 1$ which implies that the equation induced by π is redundant with respect to $\bar{x}(e_1) = \bar{x}(e_2) = 1$, where $F_1 = \{e_1\}$ and $F_2 = \{e_2\}$. Hence, we can consider $p \geq 3$. From Proposition 3.19, we have either $u_2 \notin V_1 \cup V_2$ or $u_2 \in V_1$. If $u_2 \notin V_1 \cup V_2$ (respectively, $u_2 \in V_1$), then by considering the partition π_1 (respectively, π_2) previously defined, we obtain $\bar{x}(F_1) = 1$ and $\pi_1 \in P_2(\bar{x})$ (respectively, $\pi_2 \in P_2(\bar{x})$). Using the same arguments as the ones of the proof of Claim 3, we can exhibit a vector $\bar{y} \neq \bar{x}$ which is also a solution of $S(\bar{x})$. This contradiction completes our proof. $\square$

Proof of Claim 5. Suppose that the statement does not hold. Let v be a node of degree 2 adjacent to exactly two different nodes, say v_1 and v_2 . (Remark that the 2-node connectivity of G implies the existence of v_1 and v_2 .) Without loss of generality, we may suppose that $\bar{x}(vv_1) \geq \bar{x}(vv_2)$. By Claims 3 and 4, it then follows that $r(v) = 2$ and $r(v_2) = 1$. Let $r^* \in \mathbb{R}^V$ be the connectivity type vector such that $r^*(w) = r(w)$ if $w \neq v_2$, and $r^*(w) = 2$ if $w = v_2$. We claim that (G, r^*) contains neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor. In fact, suppose, on the contrary, that (G, r^*) contains one of these minors, and let us denote that (H, r_H) contains one of these minors. Let $\pi = (S_1, \dots, S_5)$ be the partition of V that induces H , where S_1 corresponds to the ordinary node of H of degree 3, S_2, S_3, S_4 to the terminal nodes of H of degree 3, and S_5 to the node of H of degree 6. As $r^*(v_2) = 2$, v_2 belongs to a class S_i of connectivity type 2, that is, $i \neq 1$. If S_i contains a node $w \neq v_2$ with $r^*(w) = 2$, then (H, r_H) would also be a minor of (G, r) , a contradiction. Therefore $S_i \setminus \{v_2\}$ only contains nodes of connectivity type 1 with respect to r^* . In consequence, v belongs to S_j with $j \neq i$ and $j \neq 1$. Note that $v_1 \in S_j$. Otherwise as $G(S_j)$ is

connected, one would have $S_j = \{v\}$, and thus, H would contain a node of degree 2. Since neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) has a node of degree 2, this is impossible.

If $i = 5$, then (H, r_H) is nothing but (G_p^2, r_p^2) . Since $r^*(S_i) = 2$ and $r^*(S_i \setminus \{v_2\}) = 1$, we have $r(S_i) = 1$, and (G_p^1, r_p^1) is a minor of (G, r) . This contradicts our hypothesis on (G, r) . Therefore $2 \leq i \leq 4$.

If $j = 5$, let us consider the partition $\pi' = (S'_1, \dots, S'_5)$ such that

$$\begin{aligned} S'_t &= S_t & t \in \{1, \dots, 4\} \setminus \{i\}, \\ S'_i &= S_i \cup \{v\}, \\ S'_5 &= S_5 \setminus \{v\}. \end{aligned}$$

We can easily see that the partition π' induces either (G_p^1, r_p^1) or (G_p^2, r_p^2) with respect to r . This yields to a contradiction, and then $2 \leq j \leq 4$.

Since $i \neq j$, $v \in S_j$, and $v_2 \in S_i$, we have $[S_i, S_j] \neq \emptyset$. Therefore, G is not series-parallel.

Consequently, (G, r^*) contains neither (G_p^1, r_p^1) nor (G_p^2, r_p^2) as a minor. Let us now prove that $\bar{x}$ is an extreme point of $\text{CPP}(G, r^*)$. We first show that $\bar{x}$ belongs to $\text{CPP}(G, r^*)$. Let $\pi = (V_1, V_2, \dots, V_p)$ be a partition of V . It is obvious that if v and v_2 are in the same class of π or if π is of type 2 with respect to r , then the type of π doesn't change by considering r^* instead of r . The inequality induced by π with respect to r^* is then satisfied by $\bar{x}$. Therefore, we only have to focus on the case where π is a partition of type 1 with respect to r and $e_2 \in \delta(V_1, V_2, \dots, V_p)$. Without loss of generality, suppose that $v \in V_1$ and $v_2 \in V_2$. Since π is of type 1 with respect to r , all of the nodes u with $r(u) = 2$ belong to V_1 . (We recall that (G, r) has at least two terminals which implies that $|V_1| \geq 2$.) The partition $(\{v\}, V_1 \setminus \{v\}, V_2, \dots, V_p)$ is of type 2 with respect to r , and hence, we have

$$\begin{aligned} \bar{x}(\delta(\{v\}, V_1 \setminus \{v\}, V_2, \dots, V_p)) &= \bar{x}(\delta(V_1, V_2, \dots, V_p)) + \bar{x}[\{v\}, V_1 \setminus \{v\}] \\ &\geq p + 1. \end{aligned}$$

Since $\bar{x}[\{v\}, V_1 \setminus \{v\}] \leq 1$, we obtain $\bar{x}(\delta(V_1, V_2, \dots, V_p)) \geq p$. Therefore, $\bar{x}$ belongs to $\text{CPP}(G, r^*)$. Using similar arguments, we can prove that $S(\bar{x})$ is a system of tight inequalities of $\text{CPP}(G, r^*)$. Thus, $\bar{x}$ is an extreme point of $\text{CPP}(G, r^*)$. As (G, r^*) has more terminals than (G, r) , this contradicts the maximality of T . $\square$

Proof of Claim 6. From Claim 5, we have $\bar{x}(F_1) > 1$. If $\bar{x}(F_1) \geq 2$, then by Proposition 3.20(a), the variable $x(e)$ belongs to exactly one equation of the system $S(\bar{x})$ with a nonzero coefficient, for all $e \in F_1$. Yet, this contradicts Claim 1. $\square$

Since by Claim 6, $1 < \bar{x}(F_1) < 2$, it follows from Remark 3.14 that there exist two edges $e_1, f_1 \in E$ such that $F_1 = \{e_1, f_1\}$, $e_1 \in E_1(\bar{x})$, and $f_1 \in E_f(\bar{x})$, that is, $\bar{x}(e_1) = 1$ and $0 < \bar{x}(f_1) < 1$.

Proof of Claim 7. Suppose that $|F_2| = 2$. We then have $F_2 = \{e_2, f_2\}$ with $\bar{x}(e_2) = 1$ and $0 < \bar{x}(f_2) < 1$. A consequence of Proposition 3.18(b) is that F_1 and F_2 cannot belong to a same partition inducing an equation of $S(\bar{x})$. Let $F_0 = [u_1, u_2]$. We are going to consider two cases. We first consider $F_0 \neq \emptyset$. Using Proposition 3.2(b) and the previous remark about F_1 and F_2 , we obtain $\bar{x}(F_0) < 1$. We then have $F_0 = \{f_0 = u_1 u_2\}$. Let $y \in \mathbb{R}^E$ be the point defined as follows:

$$y(e) = \begin{cases} \bar{x}(e) & \text{if } e \in E \setminus \{f_0, f_1, f_2\}, \\ \bar{x}(f_0) - \epsilon & \text{if } e = f_0, \\ \bar{x}(f_1) + \epsilon & \text{if } e = f_1, \\ \bar{x}(f_2) + \epsilon & \text{if } e = f_2, \end{cases}$$

where ϵ is any arbitrary scalar. The point y is also a solution of $S(\bar{x})$. In fact, any partition inducing an equation of $S(\bar{x})$ contains either none of the edges in $\{f_0, f_1, f_2\}$, or f_0 and exactly one among f_1 and f_2 . Since $y \neq \bar{x}$, this contradicts the extremality of $\bar{x}$.

We now suppose that $F_0 = \emptyset$. Let us denote by u^* the internal node in L_2 . Without loss of generality, we can suppose that $|\delta(u)| \leq |\delta(u^*)|$, which makes us deduce that $||[u^*, u_1]| = |[u^*, u_2]| = 2$. Proposition 3.2(b) then implies that there is no partition of $P_1(\bar{x}) \cup P_2(\bar{x})$ containing an edge in $\delta(u)$. This is a contradiction with Claim 1. $\square$

Proof of Claim 8. Let us suppose that $\bar{x}(f_2) = 1$. From Proposition 3.2(b) and $\bar{x}(F_1) > 1$, the system $S(\bar{x})$ can be chosen such that any of its equations containing $x(f_1)$ with a nonzero coefficient does not contain $x(f_2)$. In fact, suppose that there is a partition $\pi = \{V_1, \dots, V_p\}$ of $S(\bar{x})$ such that $\delta(u) \subset \delta(V_1, \dots, V_p)$. Thus, π is of type 2. Since $\bar{x}(\delta(u)) > 2$, we have $p \geq 3$. Without loss of generality, suppose that $V_1 = \{u\}$. If u_1 and u_2 are both in the same class of π , say V_2 , then $\bar{x}(\delta(V_1 \cup V_2, V_3, \dots, V_p)) = p - \bar{x}(\delta(u)) < p - 2$, which is a contradiction. Now suppose, without loss of generality, that $u_1 \in V_2$ and $u_2 \in V_3$. Since $\bar{x}[V_1, V_2] > 1$, then by Proposition 3.2, the partition $\{V_1 \cup V_2, V_3, \dots, V_p\}$ is of type 1. Thus, the partition $\pi' = \{V_1 \cup V_3, V_4, \dots, V_p\}$ is of type 1. Moreover, π' is tight for $\bar{x}$. We can thus replace in the system $S(\bar{x})$ the partition π by the partition π' and the equation $x(f_2) = 1$.

Let $\pi^1 = \{V_1, V_2, \dots, V_p\}$ be a partition of $S(\bar{x})$ such that $F_1 \subseteq \delta(V_1, \dots, V_p)$. We thus have $f_2 \notin \delta(V_1, V_2, \dots, V_p)$. By Proposition 3.18, we have $\pi^1 \in P_2^*(\bar{x})$. Without loss of generality, we suppose $\{u, u_2\} \subseteq V_1$ and $u_1 \in V_2$.

From Claim 1, there also exists a partition $\pi^2 = \{W_1, \dots, W_q\}$ inducing an equation of $S(\bar{x})$ such that $f_2 \in \delta(W_1, \dots, W_q)$. We are going to prove that the system $S(\bar{x})$ can be chosen such that $q \geq 3$. From above, we clearly have $F_1 \cap \delta(W_1, \dots, W_q) = \emptyset$. Suppose that $q = 2$. Without loss of generality, we assume that $u_2 \in W_1$. We then have $\{u, u_1\} \subseteq W_2$. From $\bar{x}(f_2) = 1$, it is obvious that $\text{con}(W_1) = 2$. Proposition 3.17 then implies that at most one class of the partition π^1 intersects both W_1 and W_2 . From the definition of π^1 , we have $V_1 \cap W_1 \neq \emptyset$ and $V_1 \cap W_2 \neq \emptyset$. We then obtain $V_2 \subseteq W_2$. Since $r(V \setminus (V_1 \cup V_2)) = 1$ and $\text{con}(W_1) = 2$, we get $r(V_1 \setminus \{u\}) = 2$. Thus, the partition $\{V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p\}$ is clearly of type 2, and from Claim 7, we have

$$\begin{aligned} \bar{x}(\delta(V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p)) &= \bar{x}(\delta(V_1, \dots, V_p)) - \bar{x}(F_1) + \bar{x}(f_2) \\ &= p - \bar{x}(F_1) + \bar{x}(f_2) \\ &< p, \end{aligned}$$

a contradiction.

Without loss of generality, we suppose $\{u, u_1\} \subseteq W_1$ and $u_2 \in W_2$. Since $\bar{x}(f_2) = 1$, Proposition 3.18 implies that $\pi^2 \in P_2^*(\bar{x})$ and $r(V \setminus (W_1 \cup W_2)) = 1$. Without loss of generality, let us assume that $W_i \cap V_2 \neq \emptyset$ for $i = 1, \dots, k$, and $W_i \cap V_2 = \emptyset$ for $i = k + 1, \dots, q$. In fact, we have $u_1 \in W_1$ and $u_1 \in V_2$. Moreover, since $\bar{x}(f_2) < \bar{x}(F_1)$ by Claim 7, the partition $\{V_1 \setminus \{u\}, V_2 \cup \{u\}, V_3, \dots, V_p\}$ must be of type 1, and then $r(V_1 \setminus \{u\}) = 1$. As $\pi^2 \in P_2^*(\bar{x})$ and $r(V \setminus (W_1 \cup W_2)) = 1$, we have $r(W_2) = 2$, which, combined with $r(V \setminus (V_1 \cup V_2)) = 1$ and $u \notin W_2$, implies that $W_2 \cap V_2 \neq \emptyset$. Let $\{U_1, \dots, U_k\}$ be the partition of V_2 such that $U_i = W_i \cap V_2$ for $i = 1, \dots, k$. It comes directly from the previous argument that $r(U_1) = r(U_2) = 2$. Therefore, by Proposition 3.9(a), we have $\bar{x}[U_1, \dots, U_k] \geq k - 1 + \bar{x}(F_1) - \bar{x}(f_2)$. Since

$\bar{x}(F_1) = \bar{x}(e_1) + \bar{x}(f_1) = 1 + \bar{x}(f_1)$, we obtain

$$(6.1) \quad \bar{x}[U_1, \dots, U_k] \geq k + \bar{x}(f_1) - \bar{x}(f_2).$$

Furthermore, we notice that $F_2 \cap [U_1, \dots, U_k] = \emptyset$. Hence, from (5.2), we have

$$(6.2) \quad \bar{x}[U_1, \dots, U_k] \leq \bar{x}(\delta(W_1, \dots, W_q)) - \bar{x}(f_2).$$

If $k = q$, by the inequalities (6.1) and (6.2), we then obtain $k + \bar{x}(f_1) - \bar{x}(f_2) \leq k - \bar{x}(f_2)$. This implies that $\bar{x}(f_1) \leq 0$ which contradicts (5.2). Suppose now that $k < q$. Since $r(V \setminus (W_1 \cup W_2)) = 1$ and $k \geq 2$, it is straightforward that the partition $\{Z_1, \dots, Z_{q-k+1}\}$ defined as

$$\begin{aligned} Z_1 &= \bigcup_{i=1}^k W_i, \\ Z_i &= W_{i+k-1}, \quad i = 2, \dots, q-k+1, \end{aligned}$$

is of type 1. We then have

$$\begin{aligned} \bar{x}(\delta(W_1, \dots, W_q)) - \bar{x}[U_1, \dots, U_k] - \bar{x}(f_2) &\geq \bar{x}(\delta(Z_1, \dots, Z_{q-k+1})) \\ &\geq q - k + 1 - 1 \\ &= q - k. \end{aligned}$$

Thus, we obtain $\bar{x}[U_1, \dots, U_k] + \bar{x}(f_2) \leq k$. From this last inequality combined with (6.1), we then get $\bar{x}(f_1) \leq 0$. This contradicts (5.2). Consequently, we obtain $\bar{x}(f_2) < 1$. $\square$

Proof of Claim 9. Suppose that $F_0 = [u_1, u_2] \neq \emptyset$. Suppose that $\bar{x}(F_0) \geq 1$. Let be $\pi = \{V_1, \dots, V_p\} \in S(\bar{x})$ such that $F_1 \in \delta(V_1, \dots, V_p)$. Since $\bar{x}(F_1) = \bar{x}[u, u_1] > 1$, by Proposition 3.18(a), π is of type 2. Since $\bar{x}(F_0) \geq 1$, by Proposition 3.18(b), u and u_2 are in the same class of π , say V_1 . Suppose, without loss of generality, that $u_1 \in V_2$. Since $F_0 \cup F_1 \in \delta(V_1, \dots, V_p)$ and $\bar{x}(F_0 \cup F_1) > 2$, we then have $p \geq 3$ and $\bar{x}(\delta(V_1 \cup V_2, V_3, \dots, V_p)) = p - \bar{x}(\delta(u)) < p - 2$, a contradiction. We therefore obtain $\bar{x}(F_0) < 1$. Let $F_0 = \{f_0 = u_1 u_2\}$. Let $y \in \mathbb{R}^E$ be the point defined as follows:

$$y(e) = \begin{cases} \bar{x}(e) & \text{if } e \in E \setminus \{f_0, f_2\}, \\ \bar{x}(f_0) - \epsilon & \text{if } e = f_0, \\ \bar{x}(f_2) + \epsilon & \text{if } e = f_2, \end{cases}$$

where $\epsilon = \min\{\bar{x}(f_0), 1 - \bar{x}(f_2)\}$. We first remark that any partition of $P_1(\bar{x}) \cup P_2(\bar{x})$, different from $\{\{u\}, V \setminus \{u\}\}$, contains either both f_0 and f_2 or none of them. If the partition $\{\{u\}, V \setminus \{u\}\}$ doesn't belong to $P_2(\bar{x})$, then the point y is a solution of $S(\bar{x})$ which is different to $\bar{x}$. This is a contradiction with the extremality of $\bar{x}$.

We suppose now that $\{\{u\}, V \setminus \{u\}\}$ belongs to $P_2(\bar{x})$. We first show that y is a point of $\text{CPP}(G, r)$. To obtain that, we only need to prove that for any partition $\pi = \{V_1, V_2, \dots, V_p\}$ with $f_0 \in \delta(V_1, V_2, \dots, V_p)$ and $f_2 \notin \delta(V_1, V_2, \dots, V_p)$, we have $y(\delta(V_1, V_2, \dots, V_p)) \geq t$, where $t = p - 1$ if π is of type 1 and $t = p$ otherwise. Without loss of generality, we suppose that $u \in V_1$. Let us consider the partition $\{\{u\}, V_1 \setminus \{u\}, V_2, \dots, V_p\}$. Note that this partition is of the same type as $\{V_1, V_2, \dots, V_p\}$.

Hence we have

$$\begin{aligned}\bar{x}(\delta(\{u\}, V_1 \setminus \{u\}, V_2, \dots, V_p)) &= y(\delta(\{u\}, V_1 \setminus \{u\}, V_2, \dots, V_p)) \\ &= y(\delta(V_1, V_2, \dots, V_p)) + y(f_2) \\ &= y(\delta(V_1, V_2, \dots, V_p)) + \bar{x}(f_2) + \epsilon \\ &\geq t + 1.\end{aligned}$$

This implies that

$$\begin{aligned}y(\delta(V_1, V_2, \dots, V_p)) &\geq t + 1 - (\bar{x}(f_2) + \epsilon) \\ &\geq t + 1 - 1 = t.\end{aligned}$$

From the definition of ϵ , we clearly have $0 \leq y(f_0) \leq 1$ and $0 \leq y(f_2) \leq 1$. Therefore, y belongs to $\text{CPP}(G, r)$.

We remark that $|E_f(y)| < |E_f(\bar{x})|$ since at least one variable among $y(f_0)$ and $y(f_2)$ is an integer. Moreover, as $0 < y(f_1) < 1$, y is fractional. By the induction hypothesis, y isn't an extreme point of $\text{CPP}(G, r)$. Hence, there exist $t \geq 2$ extreme points $y^1, \dots, y^t$ of $\text{CPP}(G, r)$ and t scalars $0 < \alpha_i < 1$, $i = 1, \dots, t$, such that

$$y = \sum_{i=1}^t \alpha_i y^i \quad \text{and} \quad \sum_{i=1}^t \alpha_i = 1.$$

It is clear that $|E_f(y^i)| < |E_f(\bar{x})|$ for $i = 1, \dots, t$. From the extremality of the y^i and the induction hypothesis on $\bar{x}$, we obtain that the points y^i are integer. All of the constraints that are tight for y are also tight for y^i . Moreover, since $y(\delta(u)) = 2 + \epsilon < 3$, there exists $i_0 \in \{1, \dots, t\}$ such that $y^{i_0}(\delta(u)) < 3$. The integrality of y^{i_0} then implies that $y^{i_0}(\delta(u)) = 2$. Therefore, the point y^{i_0} is also a solution of $S(\bar{x})$ which contradicts the extremality of $\bar{x}$. We then conclude that $F_0 = \emptyset$. $\square$

Proof of Claim 10. Denote $F'_1 = [u', u_1]$ and $F'_2 = [u', u_2]$. Suppose that $|F'_2| \geq 2$. From (5.2) and Remark 3.14, we have $\bar{x}(F'_2) > 1$. Let $\pi = \{V_1, \dots, V_p\}$ be a partition of $P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ different from $\{\{u\}, V \setminus \{u\}\}$. By Claim 1, such a partition exists. Moreover, Claim 8 together with Proposition 3.3 implies that $p \geq 3$. From Proposition 3.19, u , u_1 , and u_2 belong to three different classes of π . Without loss of generality, suppose that $u \in V_1$, $u_1 \in V_2$, and $u_2 \in V_3$. We remark that $V_1 = \{u\}$. Using Proposition 3.18, we obtain that $u' \in V_3$. Therefore, π is a partition of type 2. The partition $\pi' = \{V_1 \cup V_2, V_3, \dots, V_p\}$ is of type 2, and is such that

$$\begin{aligned}\bar{x}(\delta(V_1 \cup V_2, V_3, \dots, V_p)) &= \bar{x}(\delta(V_1, \dots, V_p)) - \bar{x}(F_1) \\ &< p - 1.\end{aligned}$$

The last inequality comes from $\bar{x}(F_1) > 1$. We then get a contradiction. We conclude that $|F'_2| = 1$. By Claims 5 and 6, we have $|F'_1| = 2$. $\square$

To make the proofs of the next two claims clearer and shorter, we introduce additional notation. Given an edge subset $F \subseteq E$, we denote by $P(\bar{x}, F)$ the subset of partitions $\pi = \{V_1, \dots, V_p\} \in P_1^*(\bar{x}) \cup P_2^*(\bar{x})$ such that $p \geq 3$ and $F \subseteq \delta(V_1, \dots, V_p)$.

Proof of Claim 11. In order to prove the result, it is enough to prove that $\bar{x}(F_1) = \bar{x}(F'_1)$, $\bar{x}(\delta(u)) = \bar{x}(\delta(u')) = 2$, and $\bar{x}(f_2) + \bar{x}(f'_2) = 1$.

We first prove that $\bar{x}(F_1) = \bar{x}(F'_1)$. Without loss of generality, we suppose $\bar{x}(F_1) \geq \bar{x}(F'_1)$. Since $0 < \bar{x}(f_1) < 1$, by Claim 1, there must exist a partition $\pi = \{V_1, \dots, V_p\}$ such that $\pi \in P(\bar{x}, F_1)$. By Proposition 3.18(a), $\pi \in P_2^*(\bar{x})$. Without loss of generality,

assume $u \in V_1$ and $u_1 \in V_2$. From $\bar{x}(F_2) < 1$ and Proposition 3.3(c), we obtain $V_1 = \{u\}$. Since $\bar{x}[u, u_1] > 1$, by Proposition 3.18(b), we have $r(V \setminus (V_1 \cup V_2)) = 1$, and then $u' \in V_2$. Consider then the partition $\{\{u'\}, (V_2 \setminus \{u'\}) \cup \{u\}, V_3, \dots, V_p\}$. It clearly is a partition of type 2, and then we have

$$\begin{aligned} \bar{x}(\delta(\{u'\}, (V_2 \setminus \{u'\}) \cup \{u\}, V_3, \dots, V_p)) &= \bar{x}(\delta(V_1, \dots, V_p)) + \bar{x}(F'_1) - \bar{x}(F_1) \\ &= p + \bar{x}(F'_1) - \bar{x}(F_1) \\ &\geq p. \end{aligned}$$

We get $\bar{x}(F_1) \leq \bar{x}(F'_1)$, and consequently $\bar{x}(F_1) = \bar{x}(F'_1)$.

Now we are going to prove that $\bar{x}(\delta(u)) = \bar{x}(\delta(u')) = 2$. Since $0 < \bar{x}(f_1) < 1$, as we have shown in the proof of Claim 10, the system $S(\bar{x})$ can be chosen such that there exists a partition $\pi^0 = \{V_1^0, \dots, V_{p_0}^0\} \in P(\bar{x}, F_1)$ such that u, u_1 , and u_2 belong to three different classes of π_0 . Without loss of generality, suppose that $V_1^0 = \{u\}$, $u_1 \in V_2^0$, and $u_2 \in V_3^0$. Since $r(u') = 2$, Proposition 3.18(b) implies $u' \in V_2^0$. Let $\pi'_0 = \{V'_1, V'_2, V'_3, \dots, V'_{p_0}\}$, where $V'_1 = \{u'\}$ and $V'_2 = (V_2^0 \setminus \{u'\}) \cup \{u\}$. This partition clearly is of type 2, and since $\bar{x}(F_1) = \bar{x}(F'_1)$, we get

$$\begin{aligned} \bar{x}(\delta(V'_1, V'_2, V'_3, \dots, V'_{p_0})) &= \bar{x}(\delta(V_1^0, \dots, V_{p_0}^0)) + \bar{x}(F'_1) - \bar{x}(F_1) \\ &= p_0 + \bar{x}(F'_1) - \bar{x}(F_1) \\ &= p_0. \end{aligned}$$

Let π be any partition of $P(\bar{x}, F_1) \setminus \{\pi_0\}$. The partition π' obtained from π by switching u and u' , as π'_0 was obtained above from π_0 , belongs to $P_2(\bar{x})$. Consider the system $S'(\bar{x})$ obtained from $S(\bar{x})$ by adding the equation induced by π'_0 and replacing those induced by $\pi \in P(\bar{x}, F_1) \setminus \{\pi_0\}$ by the ones induced by π' . This system is nonsingular, and $\bar{x}$ is its unique solution. The system $S(\bar{x})$ can then be chosen such that $P(\bar{x}, F_1) = \{\pi_0\}$. Since $0 < \bar{x}(f_1) < 1$, Claim 1 implies $\bar{x}(\delta(u)) = 2$, and thus, $\bar{x}(\delta(u')) = 2$. Moreover, we have $\bar{x}(F_1) = \bar{x}(F'_1)$, and we then get $\bar{x}(f_2) = \bar{x}(f'_2)$.

Finally, we prove that $\bar{x}(f_2) + \bar{x}(f'_2) = 1$. Suppose that $\bar{x}(f_2) + \bar{x}(f'_2) > 1$. (The case $\bar{x}(f_2) + \bar{x}(f'_2) < 1$ is similar.) Let $S_{F_1}(\bar{x})$ be the system obtained from $S(\bar{x})$ by removing the equations $x(e_1) = 1$, $x(\delta(u)) = 2$, and the one induced by π_0 . Let $\bar{x}_1$ be the restriction of $\bar{x}$ on G/F_1 . By the induction hypothesis, the polytope $\text{CPP}(G/F_1, r_{F_1})$ is an integer. Since $\bar{x}_1$ is fractional, it is not an extreme point of $\text{CPP}(G/F_1, r_{F_1})$. Hence, there exist $k \geq 2$ extreme points $y^1, \dots, y^k$ of $\text{CPP}(G/F_1, r_{F_1})$ and k scalars $0 < \alpha_i < 1$, $i = 1, \dots, k$, such that

$$\bar{x}_1 = \sum_{i=1}^k \alpha_i y^i \quad \text{and} \quad \sum_{i=1}^k \alpha_i = 1.$$

By the integrality of $\text{CPP}(G/F_1, r_{F_1})$, the points y^i , $i = 1, \dots, k$, are integer. Since $\bar{x}$ is a solution of $S_{F_1}(\bar{x}_1)$ and is a convex combination of the points y^i , $i = 1, \dots, k$, it is clear that y^i is also a solution of $S_{F_1}(\bar{x}_1)$ for all $i \in \{1, \dots, k\}$. There must then exist some $j \in \{1, \dots, k\}$ such that $y^j(f_2) + y^j(f'_2) > 1$. Since y^j is integer, we have $y^j(f_2) + y^j(f'_2) \geq 2$, which gives $y^j(f_2) = y^j(f'_2) = 1$. Let $\bar{y} \in \mathbb{R}^E$ be the point defined below

$$\bar{y}(e) = \begin{cases} y^j(e) & \text{if } e \in E \setminus F_1, \\ 1 & \text{if } e = e_1, \\ 0 & \text{if } e = f_1. \end{cases}$$

This point is also a solution of $S(\bar{x})$. In fact, additionally, to be a solution of $S_{F_1}(\bar{x})$, y^j clearly satisfies the equations $x(e_1) = 1$, $x(\delta(u)) = 2$, and $x(\delta(V_1^0, \dots, V_{p_0}^0)) = p_0$, which are the only three equations removed from $S(\bar{x})$ to get $S_{F_1}(\bar{x})$. Since $\bar{y} \neq \bar{x}$, this contradicts the fact that $\bar{x}$ is an extreme point of $\text{CPP}(G, r)$. $\square$

Proof of Claim 12. We first prove (a), that is, $W \cap T \neq \emptyset$. From Claim 4 we know that $u_2 \notin T$. Suppose now that $T \subseteq \{u, u', u_1\}$. Let $G^* = (V^*, E^*)$ be the graph obtained from G by contracting F_1 and F'_1 , and deleting f_2 as well. Let $w \in V^*$ be the node arising from the contraction, that is, $V^* \setminus V = \{w\}$. We have $r(v) = 1$ for all $v \in V \setminus \{u, u', u_1\}$ and therefore, the connectivity type vector r^* associated with V^* can be defined such that $r^*(v) = 1$ for all $v \in V^*$. Let x^* be the restriction of $\bar{x}$ on E^* .

We are going to show that $x^* \in \text{CPP}(G^*, r^*)$. Consider a partition $\pi^* = \{V_1^*, \dots, V_p^*\}$, $p \geq 2$, of V^* . (We remark that any partition of V^* is obviously of type 1 with respect to r^* .) Without loss of generality, we suppose $w \in V_1^*$. Let $\{U_1, \dots, U_p\}$ be the partition of V such that $U_1 = (V_1^* \setminus \{w\}) \cup \{u, u', u_1\}$ and $U_i = V_i^*$ for all $i = 2, \dots, p$. This partition clearly is of type 1 with respect to r . If $f'_2 \notin \delta(V_1^*, \dots, V_p^*)$, then we get

$$\begin{aligned} x^*(\delta(V_1^*, \dots, V_p^*)) &= \bar{x}(\delta(U_1, \dots, U_p)) \\ &\geq p - 1. \end{aligned}$$

If $f'_2 \in \delta(V_1^*, \dots, V_p^*)$, we suppose, without loss of generality, that $u_2 \in V_2^*$. By considering the partition $\{\{u\}, U_1 \setminus \{u\}, U_2, \dots, U_p\}$ of V which is of type 2 with respect to r , we then have

$$\begin{aligned} x^*(\delta(V_1^*, \dots, V_p^*)) &= \bar{x}(\delta(\{u\}, U_1 \setminus \{u\}, U_2, \dots, U_p)) - \bar{x}(\delta(u)) \\ &\geq p + 1 - 2 \\ &= p - 1. \end{aligned}$$

Therefore, we conclude that $x^* \in \text{CPP}(G^*, r^*)$.

Proposition 3.16 and $\bar{x}(\delta(u)) = 2$ imply that the system $S(\bar{x})$ can be chosen such that $P_1^*(\bar{x}) = \emptyset$. Let $\pi_0^* = \{U_1^0, \dots, U_{p_0-1}^0\}$ be the partition of V^* such that $U_1^0 = (V_2^0 \setminus \{u', u_1\}) \cup \{w\}$ and $U_i^0 = V_{i+1}^0$ for all $i = 2, \dots, p_0 - 1$, where $\pi^0 = \{V_1^0, \dots, V_{p_0}^0\}$ is the unique partition in $P(\bar{x}, F_1)$. (See the proof of Claim 11 for the definition of π^0 .) We then get

$$\begin{aligned} x^*(\delta(U_1^0, \dots, U_{p_0-1}^0)) &= \bar{x}(\delta(V_1^0, \dots, V_{p_0}^0)) - \bar{x}(\delta(u)) \\ &= p_0 - 2. \end{aligned}$$

Let $\pi_1 = \{V_1, \dots, V_p\}$ be a partition in $P(\bar{x}, F'_1)$ and then, in $P_2^*(\bar{x})$ too. We suppose, without loss of generality, that $\{u, u_1\} \subseteq V_1$ and $V_2 = \{u'\}$. Let $\pi_1^* = \{V'_1, \dots, V'_{p-1}\}$ be the partition of V^* such that $V'_1 = (V_1 \setminus \{u, u_1\}) \cup \{w\}$ and $V'_i = V_{i+1}$ for all $i = 2, \dots, p - 1$. This partition clearly is of type 1 with respect to r^* , and then

$$\begin{aligned} x^*(\delta(V'_1, \dots, V'_{p-1})) &= \bar{x}(\delta(V_1, \dots, V_p)) - (\bar{x}(f_2) + \bar{x}(F'_1)) \\ &= p - \left(\frac{1}{2} + \frac{3}{2}\right) \\ &= p - 2. \end{aligned}$$

Let $Q^*(F'_1) = \{\pi_1^* : \pi_1 \in P(\bar{x}, F'_1)\}$ be the set of partitions of V^* obtained from the partitions in $P(\bar{x}, F'_1)$ as described above. The point x^* is a solution of the following

system:

$$S(x^*) \begin{cases} x(e) = 1 & \text{for all } e \in E_1(\bar{x}) \setminus \{e_1, e'_1\}, \\ x(\delta(U_1^0, \dots, U_{p_0-1}^0)) = p_0 - 2, \\ x(\delta(V_1^*, \dots, V_p^*)) = p - 2 & \text{for all } \{V_1^*, \dots, V_p^*\} \in Q^*(F'_1). \end{cases}$$

Since x^* is fractional, from Theorem 5.1, it cannot be an extreme point of $\text{CPP}(G^*, r^*)$. There must then exist an extreme point y^* of $\text{CPP}(G^*, r^*)$ such that y^* is a solution of $S(x^*)$ and $y^*(f_2^*) > 0$. By Theorem 5.1, y^* is an integer, and thus, $y^*(f_2^*) = 1$. Let $\bar{y} \in \mathbb{R}^E$ be the point defined as

$$\bar{y}(e) = \begin{cases} y^*(e) & \text{if } e \notin \delta(u) \cup F'_1, \\ 1 & \text{if } e \in \{e_1, e'_1, f_2\}, \\ 0 & \text{if } e \in \{f_1, f'_1\}. \end{cases}$$

The point $\bar{y}$ clearly satisfies the two equations $x(\delta(u)) = 2$ and $x(\delta(u')) = 2$. Therefore, since $P_2^*(\bar{x}) = P(\bar{x}, F_1) \cup P(\bar{x}, F'_1)$ and y^* is a solution of $S(x^*)$, the point $\bar{y}$ is also a solution of $S(\bar{x})$. This leads to a contradiction, and we conclude that $W \cap T \neq \emptyset$.

To prove (b), we consider a node subset $S \subseteq W$ such that $G(S)$ is a connected component of $G(W)$ and $S \cap T \neq \emptyset$. Suppose that $[S, u_1] = \emptyset$. (The proof for the case $[S, u_2] = \emptyset$ is similar.) The node u_2 then defines a one-node cutset of G which contradicts Claim 2. Therefore $|[S, u_1]| \geq 1$.

Suppose that $|[S, u_1]| = 1$. From Proposition 3.18(b), we have $r(V \setminus (V_1^0 \cup V_2^0)) = 1$, where $\pi_0 = \{V_1^0, \dots, V_{p_0}^0\}$ is the only partition in $P(\bar{x}, F_1)$ as previously defined. We then have $(W \cap T) \subset V_2^0$. Thus, $S \cap T \subset V_2^0$. Let $S^0 = S \cap V_2^0$. We obviously have $r(S^0) = 2$. Since $|[S, u_1]| = 1$, we get $\bar{x}[S^0, u_1] \leq 1$. By considering the partition $\{S^0, (V_2^0 \setminus S^0) \cup \{u\}, V_3^0, \dots, V_{p_0}^0\}$ which is of type 2, we have

$$\begin{aligned} \bar{x}(\delta(S^0, (V_2^0 \setminus S^0) \cup \{u\}, V_3^0, \dots, V_{p_0}^0)) &= \bar{x}(\delta(V_1^0, \dots, V_{p_0}^0)) - \bar{x}(F_1) + \bar{x}[S^0, u_1] \\ &\leq p_0 - \frac{3}{2} + 1 \\ &= p_0 - \frac{1}{2}. \end{aligned}$$

This leads to a contradiction with $\bar{x} \in \text{CPP}(G, r)$. Consequently, we have $|[S, u_1]| \geq 2$. $\square$

7. New facet-defining inequalities for the polytope $\text{SNDP}(G, r)$. In this section, we introduce a new family of facet-defining inequalities of the polytope $\text{SNDP}(G, r)$. Given a graph $G = (V, E)$, not necessarily series-parallel, and a connectivity type vector $r \in \{1, 2\}^V$, let $\{V_0, V_1, \dots, V_t, V_{t+1}\}$ be a partition of V such that $t \geq 2$ and

- (a) $r(V_0) = 1$,
- (b) $r(V_i) = 2$ for $i = 1, 2, \dots, t$,
- (c) $[V_i, V_j] = \emptyset$ for $i = 1, 2, \dots, t-1$ and $j = i+1, \dots, t$.

Consider the inequality

$$(7.1) \quad x(\delta(V_0, V_1, \dots, V_t, V_{t+1})) + x(\delta(V_0)) \geq 2t + 2$$

THEOREM 7.1. *Inequality (7.1) is valid for the polytope $\text{SNDP}(G, r)$.*

Proof. Let $H = (V, F)$ be a survivable subgraph of G . Let $F' = F \cap \delta(V_0, V_1, \dots, V_t, V_{t+1})$. It suffices to prove that $|F'| + |F' \cap \delta(V_0)| \geq 2t + 2$. Since $r(V_0) = 1$, we have $|F' \cap \delta(V_0)| \geq 1$. If $|F' \cap \delta(V_0)| = 1$, let $i_0 \in \{1, \dots, t\}$ such that $F' \cap \delta(V_0) = [V_0, V_{i_0}]$. Since H is survivable, we have $|F' \cap \delta(V_0 \cup V_{i_0})| \geq 2$ and $|F' \cap \delta(V_i)| \geq 2$ for all $i \in \{1, \dots, t\} \setminus \{i_0\}$. We then obtain that $|F' \setminus \delta(V_0)| \geq 2t$. From $|F' \setminus \delta(V_0)| + 2|F' \cap \delta(V_0)| = |F'| + |F' \cap \delta(V_0)|$, we get $|F'| + |F' \cap \delta(V_0)| \geq 2t + 2$. If $|F' \cap \delta(V_0)| \geq 2$, by summing up the $t + 1$ inequalities $|F' \cap \delta(V_i)| \geq 2$ for all $i \in \{0, 1, \dots, t\}$, we obtain $|F'| + |F' \cap \delta(V_0)| \geq 2t + 2$. $\square$

We call inequalities of type (7.1) *spinning-top inequalities*. In the next theorem, we give necessary and sufficient conditions for spinning-top inequalities to define facets of $\text{SNDP}(G, r)$ when $G(V_{t+1})$ is 2-edge connected. We denote by $\mathcal{F}$ the face of $\text{SNDP}(G, r)$ induced by a spinning-top inequality. From the proof of Theorem 7.1, we give the following remark which is useful to prove the theorem.

Remark 7.2. Let (V, F) be a survivable subgraph of G . If $|F \cap \delta(V_0)| \geq 3$ or $|F \cap \delta(V_0)| \geq 4$ for some $i \in \{1, \dots, t\}$, then $x^F \notin \mathcal{F}$.

THEOREM 7.3. Suppose that $G(V_{t+1})$ is 2-edge connected. Inequality (7.1) then defines a facet of the polytope $\text{SNDP}(G, r)$ if and only if the following holds:

- (a) $G(V_i)$ is 2-edge connected for $i = 0, 1, \dots, t$,
- (b) $|[V_0, V_i]| \geq 1$ for $i = 1, \dots, t$, and
- (c) $|[V_i, V_{t+1}]| \geq 2$ for $i = 1, \dots, t$.

Proof. The proof uses Remark 7.2 and standard polyhedral techniques. $\square$

A direct consequence of Theorem 7.3 is that for a general couple (G, r) , inequality (7.1) must be considered to obtain a complete linear description of the polytope $\text{SNDP}(G, r)$. The previous statement remains true even when G is a series-parallel graph, as we showed in section 5.

8. Final remarks. In this paper, we studied the polytope $\text{CPP}(G, r)$ given by the trivial inequalities and the partition ones. We first gave some structural properties of the extreme points of $\text{CPP}(G, r)$. Using these, we proved that the polytope $\text{CPP}(G, r)$ is an integer on a nontrivial subclass of series-parallel graphs, which includes the outerplanar graph class. This result leads to a polynomial-time algorithm, based on the ellipsoid method, for solving the (1, 2)-survivable network design problem in that class of graphs. To the best of our knowledge, the complete linear description of $\text{SNDP}(G, r)$ given in this paper is the first one which combines even and odd connectivity types for an important class of graphs. We also introduced a new family of facet-defining inequalities for the polytope $\text{SNDP}(G, r)$, called the *spinning-top inequalities*. This class of inequalities must be considered in linear descriptions of the survivable network polytope $\text{SNDP}(G, r)$.

From Theorem 5.3, we can deduce that $\text{CPP}(G, r)$ is an integer when G is a series-parallel graph and $|T| \leq 2$. (We remind that T is the set of terminal nodes, that is, nodes u such that $r(u) = 2$.) For a general graph G and $|T| \leq 1$, we know that $\text{SNDP}(G, r) = \text{CPP}(G, r)$ [5]. Moreover, for a general graph G , a positive cost function, and $|T| = 2$, the survivable network design problem can be solved in polynomial time, since Arkin and Hassin [1] have shown that this special case of the SNDP can be reduced to the matroid intersection problem. In view of the previous discussion, we give the following conjecture.

CONJECTURE 8.1. Let $G = (V, E)$ be a graph and $r \in \{1, 2\}^V$ its connectivity type vector such that $|\{u \in V : r(u) = 2\}| = 2$. The polytope $\text{SNDP}(G, r)$ is then completely described by both the trivial and the partition inequalities (i.e., $\text{CPP}(G, r)$ is an integer).

An important problem which deserves to be addressed is to study the separation problem of the spinning-top inequalities. We think that this problem is polynomial on series-parallel graphs and NP-hard in general.

Our work has started with the objective of giving a linear description of the polytope $\text{SNDP}(G, r)$ on series-parallel graphs. Our study then leads us to give the following conjecture.

CONJECTURE 8.2. *Let $G = (V, E)$ be a series-parallel graph and $r \in \{1, 2\}^V$ its connectivity type vector. The polytope $\text{SNDP}(G, r)$ is then completely described by the trivial, partition, and spinning-top inequalities.*
