Proof. The proof is by induction on the size of T . When $|V(T)| = 1$ the result is trivial. Otherwise deleting v from T partitions the remaining vertices into a collection of disjoint subtrees $T_1, T_2, \dots, T_j$. For $i = 1, 2, \dots, j$, let $r(T_i)$ denote the unique neighbor of v in T_i . Let $\Gamma_1(T_i)$ (respectively, $\Gamma_2(T_i)$) denote the guessing strategy applied in T_i when the color of v is c_1 (respectively, c_2). Note that $\Gamma_1(T_i)$ and $\Gamma_2(T_i)$ differ only in the function which $r(T_i)$ uses to guess its color based on the colors of its neighbors in T_i . Let $B_1(T_i)$ denote the set of “bad colorings” for guessing strategy $\Gamma_1(T_i)$, i.e., the colorings which cause every node of T_i to guess its color incorrectly. Let $C_1(T_i)$ denote the set of colors assigned to $r(T_i)$ by colorings in $B_1(T_i)$. Define sets $B_2(T_i), C_2(T_i)$ similarly, but use the guessing strategy $\Gamma_2(T_i)$ in place of $\Gamma_1(T_i)$. The induction hypothesis implies that $C_1(T_i)$ and $C_2(T_i)$ each have at least $k - 1$ elements. (If not, then the complement of one of these sets, say $C_1(T_i)$, contains at least 2 colors, say c_3, c_4 . Applying the induction hypothesis with tree T_i , guessing strategy $\Gamma_1(T_i)$, node $r(T_i)$, and color pair c_3, c_4 would lead to an element of $B_1(T_i)$ in which the color of $r(T_i)$ is either c_3 or c_4 , contradicting the assumption that c_3 and c_4 are both in the complement of $C_1(T_i)$.) Having established that $C_1(T_i)$ and $C_2(T_i)$ each have at least $k - 1$ elements, it follows (from the fact that $k > 2$) that the intersection of $C_1(T_i)$ and $C_2(T_i)$ is nonempty. Choose a color c_i from the intersection of these two sets and assign it to $r(T_i)$. Do this for each i in $\{1, 2, \dots, j\}$. Having

assigned a color to each neighbor of v , the guess of node v is now determined. At least one of the colors c_1 and c_2 differs from this guess, so we may assign this color to node v and thereby ensure that it guesses incorrectly. Assume without loss of generality that color c_1 is assigned to v . For each subtree T_i , the set $B_1(T_i)$ contains a coloring which satisfies that

- the color of $r(T_i)$ is c_i ;
- every node guesses its color incorrectly using guessing strategy $\Gamma_1(T_i)$.

We choose one such coloring and use it to assign colors to the nodes of T_i . Doing this for every i in $\{1, 2, \dots, j\}$ yields a coloring of T which satisfies the two properties in the statement of the lemma. $\square$

COROLLARY 9. *If G is an undirected tree and $k > 2$, then $H_k(G) = 0$.*

2.4. Generalized guessing graphs. In this section we consider a variation in which players are not necessarily trying to guess their own hat colors. Instead there is a set P (“players”), a set H (“hats”), and two directed graphs, G_v (“visibility graph”) and G_g (“guessing graph”). Both graphs have a vertex set which is the union of P and H . Every edge of G_v has its tail in P and its head in H ; we think of edge (u, v) as indicating that person u can see the color of hat v . Every edge of G_g has its tail in H and its head in P ; we think of edge (v, u) as indicating that person u must guess the color of hat v . (Note that the orientation of these edges is from hats to people, the reverse of the orientation convention used in G_v . This orientation convention is adopted because it will be convenient later on.) The hat problem considered in earlier sections corresponds to the case when there is a bijection $\phi : H \rightarrow P$ and the edge set of G_g is $\{(v, \phi(v)) : v \in H\}$.

A “guessing strategy” is a set of functions, one for each edge in G_g . Each such function maps the set of k -colorings of H to the set of colors and has the property that the value of the function corresponding to edge $e = (v, u)$ depends only on the colors of the elements of H which are adjacent to u in G_v . Given a k -coloring of H and a guessing strategy, we say that edge $e = (v, u)$ of G_g gives a correct answer if its function evaluates to the color which was assigned to v . We define $H_k(G_v, G_g)$ to be the maximum number of correct guesses that the players can guarantee using an optimal strategy when there are k colors of hats.

THEOREM 10. *When $k = 2$, $H_k(G_v, G_g) > 0$ if and only if at least one of the following properties holds:*

- There is a vertex of G_g whose out-degree is greater than 1.*
- There is a directed cycle in the union of G_v and G_g .*

Proof. Identify the set of colors with the set $\{0, 1\}$. If property (a) is satisfied and G_g contains edges (v, u) and (v, u') for some v in H and u, u' in P , then assign the constant function 0 to edge (v, u) and the constant function 1 to edge (v, u') . Clearly, on every input, at least one of these edges gives a correct answer.

If property (b) is satisfied, let the vertices of the cycle be

$$v_1 \rightarrow u_1 \rightarrow v_2 \rightarrow u_2 \rightarrow \dots \rightarrow v_n \rightarrow u_n$$

and adopt the following guessing strategy. For $i = 1, 2, \dots, n - 1$, player u_i guesses that the color of v_i is different from the color of v_{i+1} . Player u_n guesses that the color of v_n is the same as the color of v_1 . Observe that this is a legal guessing strategy since each of the edges $(u_1, v_2), (u_2, v_3), \dots, (u_n, v_1)$ belongs to G_v . Also, for any input on which none of $u_1, u_2, \dots, u_{n-1}$ guess correctly, it must be the case that $v_1, v_2, \dots, v_n$ are all assigned the same color. But then (u_n, v_1) guesses correctly.

Finally, suppose neither (a) nor (b) is satisfied; we must prove that for every guessing strategy there exists an input on which every edge guesses incorrectly. We will only sketch this part of the proof. Let G be the union of G_v and G_g , and let G' be the directed graph obtained from G by contracting the edges of G_g . If G' contains a directed cycle, then G must also contain a directed cycle. (In fact, our assumption that property (a) is not satisfied implies that every edge of G' corresponds to a 2-hop path between two elements of P in G .) Since we are assuming G contains no directed cycles, it follows that G' is acyclic. An elementary induction argument, using a topological sort of G' , produces a coloring of H which causes every edge to guess incorrectly. $\square$

Question. Above we characterize visibility and guessing graphs for which we can guarantee at least one correct answer. It would be nice if we could determine exactly how much more information in the guessing graph we can obtain by adding a particular edge to the visibility graph. More generally, given m , G_v , and G_g determine the smallest value j such that there exists a graph G'_v consisting of G_v with j additional edges such that the hat number $H_2(G'_v, G_g)$ is at least m .

The above question can be loosely considered along the same lines as the Aanderaa–Rosenberg conjecture [7] which asks for the minimum number of edges of a graph that should be revealed in order to determine whether the graph has a given monotone property P or not (see also [5]).

3. Using hypercubes to approach the game. One of the interesting connections between hat guessing games and applications lies in interpreting the game in terms of various structure restrictions on hypercubes (the restriction depending on the rule of the particular game). In this section we will consider several questions for which we can use hypercubes to give an answer. One drawback to using hypercubes is that the number of vertices is exponential in the number of players and so many of the constructions are not polynomial in n . Nevertheless, insight into the game can be achieved by considering hypercubes (see, for example, Proposition 13).

Recall that the n -cube has as vertices all 2^n binary words of length n . This has a natural connection with the possible placements of hats. The edges of the n -cube join two vertices which differ by one letter. As an example, in the 4-cube there is an edge between 1011 and 1010; we can represent this in shorthand as 101* where * indicates an indeterminate bit which is either 0 or 1. The edges of the n -cube represent the decisions which must be made in forming the strategy. So 101* indicates that the fourth player (the *) sees 1, 0, and 1 on the first, second, and third players, respectively. In this situation they must guess either 0 or 1. To indicate his/her guess we will “orient” the edge in the direction of the guess. So for instance, if the player guesses 0 in this case, then we will have 1011→1010.

The original version of the game reduces to finding an orientation on the edges of the n -cube to maximize the minimum in-degree.

3.1. Balanced strategies. We now return to the original game. In Theorem 2 we gave one example of how to construct a strategy to guarantee $\lfloor n/k \rfloor$ guesses. This strategy is far from unique and may not have some desired property. For example, while that strategy is easy to implement, the correct guesses are not reflective of the actual hats that are placed on the players. For 2 colors of hats we will show how to construct different strategies, and in particular how to construct a balanced strategy.

LEMMA 11. *If there are n players and 2 different hat colors, then there exists a strategy which is balanced. That is, if there are b blue hats and r red hats placed on*

FIG. 2.

the players ($r + b = n$), then at least $\lfloor b/2 \rfloor$ of the people wearing blue guess correctly and $\lfloor r/2 \rfloor$ of the people wearing red guess correctly.

We first approach the problem by using hypercubes. To construct a balanced strategy we will group the vertices of the hypercube in i levels, where a vertex is at level i if the word indexing the vertex has Hamming weight i . The up-degree (respectively, down-degree) at a vertex in level i will be the number of edges between that vertex and vertices in level $i + 1$ (respectively, $i - 1$). If we consider how directing the edges corresponds to guesses, we have the picture shown in Figure 2.

We now see that the balanced strategy in Lemma 11 would correspond to an orientation on the edges of the hypercube so that at each node the number of directed edges from level $i + 1$ to that node is $\lfloor \text{up-degree}/2 \rfloor$ while the number of directed edges from level $i - 1$ to that node is $\lfloor \text{down-degree}/2 \rfloor$.

Proof. Construction of Lemma 11. For n even we start with any edge and orient it arbitrarily and then continue to lengthen the directed path to be as long as possible by continually directing an undirected edge, which is incident with the current terminal vertex. The only restriction is that if an edge is between level i and level $i + 1$, then if possible the next edge will also be between level i and level $i + 1$. When the path can no longer be extended, if we have not oriented all the edges, then we pick an unoriented edge and repeat the process.

When n is odd a similar construction works, with the only caveat being that we must be careful in selecting our initial edges. Now an initial edge cannot be chosen arbitrarily but must be directed up from a vertex of odd up-degree or down from a vertex of odd down-degree.

It is easy to see that the strategy we construct is balanced, since at each vertex we pair directed in- and out-edges in such a way that every edge coming in from below (respectively, above) is paired, if possible, with an edge going down (respectively, up). $\square$

Using a different technique based on network flow, it is possible to construct balanced strategies for every k ; see [1] for details.

THEOREM 12 (see [1]). *If there are n players and k different hat colors, then there exists a strategy which is balanced. That is, if a_i of the players are wearing hats of color i ($1 \leq i \leq k$), then at least $\lfloor a_i/k \rfloor$ of the people wearing color i guess correctly for each value of i .*

3.2. Optimal strategies are unbiased. If one constructs many optimal strategies for the 2-color game when n is even, one starts to see a pattern emerge. Namely, each player is as likely to guess one hat color as to guess the other. We give a short proof that uses hypercubes.

PROPOSITION 13. *Suppose the set of hat colors is $\{0, 1\}$ and there are n players playing an optimal strategy, where n is even. For any fixed player i , looking over all*

FIG. 3.

possible hat placements, we have that the number of times that player i guesses 0 is the same as the number of times that player i guesses 1.

Proof. When n is even an optimal strategy corresponds to an orientation on the edges of the n -cube with the in-degree equal to the out-degree at each vertex. In particular, the strategy corresponds to some Eulerian walk on the n -cube. We now redraw the n -cube as in Figure 3.

Then note that the number of edges in the center that point up is the number of times the i th player guesses 1, and the number of edges that point down is the number of times that the i th player guesses 0. Since we have an Eulerian walk the number of up-edges equals the number of down-edges. $\square$

Proposition 13 can be generalized to games with more than 2 colors.

PROPOSITION 14. *Suppose that n players are playing an optimal strategy of the k -color game, where k is a divisor of n . If the players' hat colors are drawn independently from the uniform distribution on $\{1, 2, \dots, k\}$, then for each player i and each hat color c ,*

$$\Pr(i \text{ guesses } c) = 1/k.$$

Equivalently, in an optimal strategy each player guesses each hat color an equal number of times.

Proof. Let X denote the random variable which counts the number of correct answers provided by the players. Our assumption that the players use an optimal guessing strategy means that $X \geq n/k$ at every point of the sample space. Now let $\mathcal{E}(i, c)$ denote the event that player i is assigned hat color c . We have

$$\begin{aligned} (1) \quad \mathbf{E}[X \mid \mathcal{E}(i, c)] &= \sum_{j=1}^n \Pr(j \text{ guesses correctly} \mid \mathcal{E}(i, c)) \\ (2) \quad &= \frac{n-1}{k} + \Pr(i \text{ guesses } c \mid \mathcal{E}(i, c)) \\ (3) \quad &= \frac{n-1}{k} + \Pr(i \text{ guesses } c). \end{aligned}$$

Here (1) follows from linearity of expectation, and (2) follows from the fact that, conditional on $\mathcal{E}(i, c)$, every player except i has a hat color which is uniformly distributed and is independent of its own guess. Finally, (3) follows from the fact that player i 's guess is independent of its own hat color.

Recalling now that $X \geq n/k$ at every point of the sample space, we see that

$$\mathbf{E}[X \mid \mathcal{E}(i, s)] \geq n/k,$$

and according to (3) this implies $\Pr(i \text{ guesses } c) \geq 1/k$. Since this inequality applies to every hat color c , it must be the case that $\Pr(i \text{ guesses } c) = 1/k$ for every color c . $\square$

3.3. The limited hats game. We now consider another variation on the original hats game. The setup is as before, but now the adversary has a limited supply of hats to choose from. We will let $H(n; a_1, a_2, \dots, a_k)$ denote the maximum number of correct guesses that we can guarantee when there are n players and a_1 hats of the first color, a_2 hats of the second color, and so on up through a_k hats of the k th color. We need $a_1 + a_2 + \dots + a_k \geq n$ (to ensure that we have enough hats for the players) and without loss of generality we can assume that $0 < a_i \leq n$ for all i .

Example 15. Suppose that there are three players and the adversary has two blue hats and two red hats. The players can choose to ignore this information and use the same strategy as in Theorem 2, guaranteeing one correct guess. However, if they modify their strategy, then they can guarantee 2 correct guesses. If the players are a, b, c , then such a strategy would be for a to guess the opposite of what b is wearing, b to guess the opposite of what c is wearing, and c to guess the opposite of what a is wearing. So $H(3; 2, 2) = 2$. (More generally, it was shown in [3] that $H(4k - 1; 2k, 2k) = 3k - 1$.)

THEOREM 16. *We have the following properties:*

(i)

$$H(n; \underbrace{n, n, \dots, n}_{k \text{ times}}) = \lfloor n/k \rfloor.$$

(ii) *If $a_1 + a_2 + \dots + a_k = n$, then $H(n; a_1, a_2, \dots, a_k) = n$.*

(iii) *If m is even or k is odd (or both), then*

$$H(mk - 1; \underbrace{m, \dots, m}_{k \text{ times}}) = \frac{mk + m - 2}{2}.$$

(iv) *$H(n; a_1, a_2, \dots, a_k) = H(n; a_{\sigma(1)}, a_{\sigma(2)}, \dots, a_{\sigma(k)})$ for any permutation σ .*

(v) *If $b_i \leq a_i$ for all $i = 1, 2, \dots, k$, then $H(n; a_1, a_2, \dots, a_k) \leq H(n; b_1, b_2, \dots, b_k)$.*

(vi)

$$H(n; a_1, a_2, \dots, a_k) \leq \left\lfloor \sum_{\substack{b_i \leq a_i, 1 \leq i \leq k \\ b_1 + \dots + b_k = n-1}} n \binom{n-1}{b_1, \dots, b_k} \right\rfloor / \sum_{\substack{b_i \leq a_i, 1 \leq i \leq k \\ b_1 + \dots + b_k = n}} \binom{n}{b_1, \dots, b_k}.$$

Proof. Item (i) is Theorem 2. Item (ii) is obvious because the strategy is to have each player guess the hat not seen. Item (iv) says we can permute the hat colors. Item (v) follows by noting that the optimal strategy for the $H(n; a_1, a_2, \dots, a_k)$ game is also a (not necessarily optimal) strategy for the $H(n; b_1, b_2, \dots, b_k)$ game.

To prove item (vi) we first give a hyper-hypercube interpretation of the game. The k^n vertices are words of length n from the alphabet $\{0, \dots, k-1\}$ and correspond to the k^n possible placements of hats. The tuples (i.e., edges) represent the decisions which must be made in deciding a strategy. So, for example, if $n = 5$ and $k = 3$, then one tuple would be $210*1 = \{21001, 21011, 21021\}$, representing the situation when the fourth player (the $*$) sees 2, 1, 0, and 1 on the first, second, third, and fifth players, respectively. A strategy corresponds to marking one vertex on each tuple,

the marking indicating the guess that the player will make. Note each marking is one correct guess.

We now use an averaging argument similar to that given in Theorem 2.

$$\begin{aligned} H(n; a_1, a_2, \dots, a_k) &\leq \left\lfloor \frac{\# \text{ of correct guesses}}{\# \text{ of possible hat placements}} \right\rfloor \\ &= \left\lfloor \frac{\# \text{ of tuples available for marking}}{\# \text{ of vertices to be marked}} \right\rfloor \\ &= \left\lfloor \frac{\sum_{\substack{b_i \leq a_i, 1 \leq i \leq k \\ b_1 + \dots + b_k = n-1}} n \binom{n-1}{b_1, \dots, b_k}}{\sum_{\substack{b_i \leq a_i, 1 \leq i \leq k \\ b_1 + \dots + b_k = n}} \binom{n}{b_1, \dots, b_k}} \right\rfloor \end{aligned}$$

The numerator is the n possible positions of the $*$ along with the allowable combinations of the remaining $n-1$ entries. The denominator is the number of ways to place the n hats in allowable combinations.

For item (iii) we have that $H(mk-1; m, \dots, m) \leq (mk+m-2)/2$ from (vi). So it suffices to show that we can construct a strategy guaranteeing at least $(mk+m-2)/2$ correct guesses. There are two types of tuples; those which involve only one markable vertex and those that involve two. The first kind is for players who see a full set of all but one type of hat and so automatically know their hats. The second kind is for players who see a full set of all but two types of hats and so have to make one of two choices.

Every vertex will be associated with $m-1$ tuples of the first type (one for each hat of the deficient color in the placement); we mark these tuples and put them aside. We now construct a bipartite graph with the remaining edges and tuples as follows: The vertex set is $S \cup T$, where S is the set of tuples we have not yet marked and T is the set of vertices to be marked; there is an edge between an element in S and an element in T if the corresponding vertex can be marked by the corresponding tuple.

Every element in S has degree 2 and every element in T has degree $mk-m$, which by assumption is even. We now split the elements in T by duplicating each element $(mk-m)/2$ times and then distributing the edges of the original element so that each resulting piece has degree 2. It is easy to now construct a perfect matching between S and T (for example, start with any edge and going through a cycle alternatively include/not include the edges). This perfect matching gives a marking on the tuples so that each of the vertices is marked $(mk-m)/2$ times.

In total each vertex was marked $(m-1) + (mk-m)/2 = (mk+m-2)/2$ times, giving our desired strategy. $\square$

Questions. What is $H(n; a_1, a_2, \dots, a_k)$? Is the upper bound given in Theorem 16 tight? (Note that items (i), (ii), and (iii) in Theorem 16 are examples where the bound is tight.)

As a warmup to the above question, the interested reader might enjoy showing that $H(5; 4, 3) = 3$ (an upper bound of 3 immediately follows from Theorem 16 so it suffices to find a strategy guaranteeing at least three correct guesses).

4. Summary and open questions. In this paper we considered hat guessing games in which players wearing hats of various colors use deterministic strategies to guess the color of some hats (usually their own) with the goal of maximizing the number of correct answers in the worst case. In this section we summarize our main results, and we list the open questions which are scattered throughout this paper.

Focusing on hat games with a *sight graph* that specifies the set of hats visible to each player, we defined the *hat number* $H_k(G)$ to be the number of correct answers

provided in the worst case by an optimal strategy for players guessing their own hat color, when the sight graph is G and there are k colors of hats. We proved that for two colors and undirected sight graphs, the hat number equals the cardinality of a maximum matching in the sight graph. For a directed graph G and two hat colors, we provided lower and upper bounds on the hat number; these bounds suffice to distinguish graph families with a bounded hat number from those with an unbounded hat number. For three or more colors, we proved that the hat number of a tree is zero and that there are bipartite graphs with a nonzero hat number. When there are two hat colors and there is a *guessing graph* which specifies the set of hat colors which each player must guess, we provided necessary and sufficient conditions for the existence of a strategy which guarantees at least one correct answer.

Turning to questions about the distribution of guesses and of correct guesses, we introduced a hypercube interpretation of the game which permitted us to prove that when there are two colors of hats and players can see all hats except their own, there is a guessing strategy which guarantees that roughly half of the players wearing each type of hat guess correctly. (This result was also proved in [1], which contains a generalization to more than two colors.) We also proved that optimal strategies are unbiased, i.e., when the number of hat colors is a divisor of the number of players, each player guesses each hat color with equal probability when the colors are assigned independently and uniformly at random. Finally, turning to a version in which the players are given an a priori upper bound on the number of hats of each color, we exhibited some bounds on the number of correct answers provided by the optimal strategy in the worst case.

In presenting these results, we also introduced many open questions inspired by them. Here we recapitulate the open questions presented earlier.

Complexity of computing hat numbers and optimal strategies. What is the computational complexity of determining $H_k(G)$, given k and G ? There is a polynomial-time algorithm when $k = 2$ and G is undirected (because a maximum matching can be computed in polynomial time), but for all other cases the best known algorithm requires nondeterministic exponential time. On the other hand, we do not know if the problem is NP-hard.

How much computational power is required to implement an optimal guessing strategy? For $k = 2$, can the optimal guessing strategy for a directed sight graph G always be implemented by players using Boolean circuits of size polynomial in the size of G ?

Graphs with positive hat numbers. Is there a bipartite graph G satisfying $H_k(G) > 0$ whose size is polynomial in k ? What if, instead of bipartite, we consider k -clique-free graphs? Are there infinitely many graphs G such that $H_k(G) > 0$ but $H_k(G') = 0$ for every proper subgraph $G' \subset G$?

Augmenting sight graphs to improve hat numbers. Given a positive number m and two graphs G_v, G_g (the sight graph and guessing graph of a hat guessing game), determine the smallest value j such that one can add j additional edges to G_v to obtain a graph G'_v satisfying $H_2(G'_v, G_g) \geq m$.

The limited hats game with unrestricted vision. Suppose players can see every hat color except their own and must guess their own hat color. When there are k hat colors and at most a_i hats in color class i ($1 \leq i \leq k$), compute the maximum number of correct answers that can be guaranteed by a guessing strategy given this limitation on the placement of hats. Is the upper bound in part (vi) of Theorem 16 tight?

Acknowledgments. We thank Joe Buhler, Kevin Costello, Harvey Friedman, and Ron Graham for interesting and helpful discussions on this subject.

THE WINDY GENERAL ROUTING POLYHEDRON: A GLOBAL VIEW OF MANY KNOWN ARC ROUTING POLYHEDRA*

ANGEL CORBERÁN[†], ISAAC PLANA[‡], AND JOSÉ M. SANCHIS[§]

Abstract. The windy postman problem consists of finding a minimum cost traversal of all of the edges of an undirected graph with two costs associated with each edge, representing the costs of traversing it in each direction. In this paper we deal with the windy general routing problem (WGRP), in which only a subset of edges must be traversed and a subset of vertices must be visited. This is also an *NP*-hard problem that generalizes many important arc routing problems (ARPs) and has some interesting real-life applications. Here we study the description of the WGRP polyhedron, for which some general properties and some large families of facet-inducing inequalities are presented. Moreover, since the WGRP contains many well-known routing problems as special cases, this paper also provides a global view of their associated polyhedra. Finally, for the first time, some polyhedral results for several ARPs defined on mixed graphs formulated by using two variables per edge are presented.

1. Introduction. Arc routing problems (ARPs) have their origin in the celebrated Königsberg bridge problem solved by Euler. They basically consist of finding a traversal on a graph satisfying some conditions related to the links of the graph. ARPs have been studied in depth during the past 40 years due to the large number of real situations that can be modeled in this way: collection or delivery of goods, mail distribution, network maintenance (electrical lines or gas main inspection), snow removal, garbage collection, etc. The book edited by Dror [15] summarizes the state-of-the-art and real-life applications of the ARPs. Other interesting papers are those by Assad and Golden [1] and Eiselt, Gendreau, and Laporte [17, 18].

The first ARP presented in the literature is the well-known Chinese postman problem (CPP) [22]. It consists of finding a shortest tour (closed walk) traversing all of the *links* of a given graph G . Since then, this problem has been generalized in several aspects. Orloff [29] proposed the rural postman problem (RPP), in which not all of the links of the graph have to be traversed by the tour but only those in a given subset of “required” links. Orloff also proposed the general routing problem (GRP), in which the graph has a given set of required links to be traversed and a given set of required vertices to be visited. The GRP can also be considered as a generalization of the graphical traveling salesman problem (GTSP), studied by Cornuéjols, Fonlupt, and Naddef [14], Fleischmann [19], and Naddef and Rinaldi [27]. The GTSP consists of finding a shortest tour visiting all of the vertices of a given graph G at least once.

All of these problems were defined on *undirected* graphs, where all of the links are *edges* that can be traversed in both directions with the same cost. These four problems are shown in Figure 1 (box labeled “undirected”), where an arc between two problems means that the first one is generalized by the second one.

Alternatively, the CPP can be defined on a *directed* graph, where all of the links are *arcs* that must be traversed in a given direction. This problem is known as the directed Chinese postman problem (DCPP) [16]. Obviously the RPP and the GRP can also be defined on a *directed* graph to obtain their “directed” versions, the DRPP [5, 33, 24] and the DGRP. The GTSP on a directed graph is known as the graphical asymmetric TSP (GATSP) [3]. These four problems are also represented in Figure 1 (box labeled “directed”).

A graph G is called a *mixed* graph if it has edges and arcs simultaneously. The CPP on a mixed graph, the mixed Chinese postman problem (MCP) [16, 4, 21, 28] is then a generalization of both the CPP and the DCPP. Note that any routing problem defined on a mixed graph generalizes the corresponding problems defined on undirected and directed graphs. This is the case for the mixed RPP (MRPP) [32, 11] and for the mixed GRP (MGRP) [6]. Note that since the GTSP is a pure node routing problem, the GTSP defined on a mixed graph is equivalent to the GATSP. These four “mixed” problems are also shown in Figure 1 (box labeled “mixed”). An arc between two “boxes” means that each problem in the first box is generalized by the corresponding problem in the second box.

Finally, we have the windy postman problem (WPP), proposed by Minieka [26] and also studied by Guan [23], Win [34], and Grötschel and Win [20, 21]. This problem consists of finding a minimum cost traversal of all of the edges of an undirected graph in which the cost of traversing an edge (i, j) in a given direction, c_{ij} , can be different from the cost of traversing it in the opposite direction, c_{ji} . Obviously, the WPP

FIG. 1. Relationship among routing problems.

generalizes the undirected CPP (when $c_{ij} = c_{ji}$), but also the DCP (each arc (i, j) with cost c can be modeled as an edge with costs $c_{ij} = c$ and $c_{ji} = \infty$) and therefore the MCP. As before, windy routing problems are also represented in Figure 1 (box labeled “windy”). As for the mixed case, the windy version of the GTSP is equivalent to the GATSP.

In this paper we deal with the windy general routing problem (WGRP). This is the most general routing problem among those represented in Figure 1 and contains all of the other problems as special cases. Consequently, most of the theoretical results obtained for the WGRP and the algorithms designed for its approximate or exact resolution can be applied to many other ARPs.

Except for the CPP and the DCP, which can be solved in polynomial time, all of the other problems in Figure 1 are *NP*-hard problems and therefore the WGRP is also *NP*-hard. The most successful approach to optimally solving these difficult routing problems is polyhedral combinatorics. It is based on the description of the polyhedron defined by the convex hull of all of the solutions associated with a formulation of the problem. This approach has recently been used by Corberán, Plana, and Sanchis [9] to optimally solve WGRP instances of large size, and its success is mostly due to the partial description of the WGRP polyhedron we present here. This description is the subject of this paper.

On the other hand, all of the formulations proposed in the literature for ARPs defined on undirected or directed graphs use only one variable per link. This variable represents, in the directed case, the number of times its associated arc is traversed (in the fixed direction), while, in the undirected case, it represents only the number of times the edge is traversed in either of the two possible directions. All windy problems are formulated by using two variables associated with each edge, representing the number of times the edge is traversed in each direction. However, ARPs defined on mixed graphs can be formulated by using either one variable per edge [28, 11, 6] or two variables [4, 31]. Although the polyhedra associated with ARPs defined on mixed graphs and formulated by using only one variable per edge have already been studied [11, 6], this is not the case when these problems are formulated by using two variables per edge. Then, as a by-product of the polyhedral study of the WGRP presented here, we also obtain some results on the polyhedra associated with ARPs defined on mixed graphs whose formulation uses two variables per edge.

Although the facet-inducing inequalities presented in this paper are associated with a formulation with two variables per edge, they can be easily transformed into facets of the polyhedra of the ARPs shown in Figure 1. Hence, a final contribution of this work is that it also gives a global view of the polyhedra associated with many well-known ARPs.

More specifically, the WGRP is formally defined and some notation is presented in section 2. Section 3 introduces the WGRP polyhedron and presents some results characterizing its facet-defining inequalities. In section 4 several families of valid inequalities and their facet-defining property are described. Section 5 discusses the application of these results to mixed ARPs formulated with two variables per edge. Finally, section 6 presents the conclusions.

2. Problem definition and notation. The WGRP can be defined as follows. Let $G = (V, E)$ be an undirected and connected graph with two nonnegative costs c_{ij} and c_{ji} associated with each edge $(i, j) \in E$, corresponding to the costs of traversing it from i to j and from j to i , respectively. Given a subset $E_R \subseteq E$ of required edges and a subset $V_R \subseteq V$ of required vertices, the problem is to find a minimum cost tour

(closed walk) on G traversing each required edge and visiting each required vertex at least once.

Note that the vertices incident with required edges can also be considered as required vertices and then included in V_R . Without loss of generality, we will assume that the original graph has been transformed to satisfy $V = V_R$. This is not a serious restriction as it is easy to transform WGRP instances which do not satisfy the assumption into equivalent instances which do. Hence, we will assume, in what follows, that we are working with a connected graph $G = (V, E) := (V_R, E_R \cup E_{NR})$.

If we remove all of the nonrequired edges from graph $G = (V, E)$, the resulting graph $G_R = (V, E_R)$ is, in general, not connected. Let p be the number of connected components of graph G_R , and let $V_1, V_2, \dots, V_p$ denote the vertex sets of these connected components, which will be called *R-sets*. We will call the subgraphs $G(V_i)$ of G *R-connected components*. Note that each isolated required vertex itself defines an *R-set*.

If S_1 and S_2 are two vertex sets, (S_1, S_2) represents the set of edges with an end point in S_1 and another end point in S_2 , while $(S_1, S_2)_R$ and $(S_1, S_2)_{NR}$ represent, respectively, the sets of required and nonrequired edges in (S_1, S_2) . Given a vertex subset S , $\delta(S)$ denotes the cutset $(S, V \setminus S)$, i.e., the set of edges with an end point in S and another end point not in S , while $E(S)$ denotes the set of edges with both end points in S . A vertex is called *R-even* (*R-odd*) if it is incident with an even (odd) number of required edges, and a subset of vertices $S \subseteq V$ is *R-even* (*R-odd*) if it contains an even (odd) number of *R-odd* vertices.

A tour for the WGRP is a closed walk on the edges of G traversing each required edge and visiting each required vertex at least once. Each tour is represented by an incidence vector $x \in \mathbb{R}^{2|E|}$ with two variables x_{ij}, x_{ji} associated with each edge $e = (i, j) \in E$ representing the number of times e is traversed in each direction. Given an edge set $F \subseteq E$, $x(F)$ denotes the sum of the variables in x corresponding to the edges in F , i.e., $x(F) := \sum_{(i,j) \in F} (x_{ij} + x_{ji})$. Moreover, a tour for the WGRP can be represented by a directed graph (V, A) , where A contains as many copies of arc (i, j) as the number of times the original edge (i, j) has been traversed from i to j . In a similar way to that given in [2] for the WRPP, the WGRP can be formulated as follows:

$$\begin{aligned}
 & \text{Minimize} && \sum_{(i,j) \in E} (c_{ij}x_{ij} + c_{ji}x_{ji}) \\
 & \text{subject to} \\
 (1) & && x_{ij} + x_{ji} \geq 1 \quad \forall (i, j) \in E_R, \\
 (2) & && \sum_{(i,j) \in \delta(i)} (x_{ij} - x_{ji}) = 0 \quad \forall i \in V, \\
 (3) & && \sum_{i \in S, j \notin S} x_{ij} \geq 1 \quad \forall S = \bigcup_{k \in Q} V_k, \quad Q \subset \{1, \dots, p\}, \\
 (4) & && x_{ij}, x_{ji} \geq 0 \quad \forall (i, j) \in E, \\
 (5) & && x_{ij}, x_{ji} \text{ integer} \quad \forall (i, j) \in E.
 \end{aligned}$$

Traversing inequalities (1) force the tour x to traverse each required edge at least once (in any direction). *Symmetry* equations (2) force the tour x to depart from each vertex as many times as it arrives at it. Given any edge cutset of G , $(S, V \setminus S)$, by

combining some of the equations (2),

$$\sum_{i \in S, j \notin S} x_{ij} = \sum_{i \in S, j \notin S} x_{ji}$$

is obtained. *Connectivity* inequalities (3) prevent the formation of subtours. Since inequalities (1) guarantee that x traverses each edge cutset containing required edges, inequalities (3) are needed only for edge cutsets joining different R -sets. Finally, (4) and (5) assure that all of the variables are nonnegative and integer.

3. The WGRP polyhedron. Let $\text{WGRP}(G)$ denote the convex hull of all of the tours for the WGRP on graph G , i.e., all of the integer vectors $x \in \mathbb{R}^{2|E|}$ satisfying (1)–(4). $\text{WGRP}(G)$ is an unbounded polyhedron which has the following properties.

THEOREM 1. *If G is a connected graph, the dimension of $\text{WGRP}(G)$ is $2|E| - |V| + 1$.*

Proof. The matrix defined by the coefficients of (2) has rank $|V| - 1$, and therefore it follows that $\dim(\text{WGRP}(G)) \leq 2|E| - (|V| - 1)$. On the other hand, it is not difficult to see that $\text{aff}(\text{WGRP}(G)) = \{x \in \mathbb{R}^{2|E|} : x \text{ satisfies (2)}\}$. Therefore, $\dim(\text{WGRP}(G)) \geq 2|E| - |V| + 1$, and the result follows. $\square$

Note that $\text{WGRP}(G)$ is not of full dimension, and different inequalities can induce the same facet of it. Such inequalities are called equivalent. In this section we show that inequalities (4), (1), and (3) from the formulation of the problem are facet-inducing for $\text{WGRP}(G)$.

THEOREM 2. *If edge $e = (i, j) \in E$ is not a bridge of G , then inequalities $x_{ij} \geq 0$ and $x_{ji} \geq 0$ are facet-inducing for $\text{WGRP}(G)$. If in addition $e = (i, j) \in E_R$, then inequality $x_{ij} + x_{ji} \geq 1$ is facet-inducing for $\text{WGRP}(G)$.*

Proof. We will study only the case when $e \in E_R$. If e is not a bridge of G , graph $G \setminus \{e\}$ is connected, and there are $K - 1$ affinely independent tours for the WGRP on $G \setminus \{e\}$, $x^1, x^2, \dots, x^{K-1}$, where $K = \dim(\text{WGRP}(G))$. All of these tours are not tours for the WGRP on G because they do not traverse the required edge e . Let C^1 be a cycle on G traversing e once from j to i . Then $x^1 + C^1, x^2 + C^1, \dots, x^{K-1} + C^1, x^1 + 2C^1$ are K affinely independent tours for the WGRP on G satisfying $x_{ij} = 0$. Hence, inequality $x_{ij} \geq 0$ is facet-inducing for $\text{WGRP}(G)$.

Consider now the inequality $x_{ij} + x_{ji} \geq 1$, and let C^2 be a cycle on G traversing e once from i to j . Then $x^1 + C^1, x^2 + C^1, \dots, x^{K-1} + C^1, x^1 + C^2$ are K affinely independent tours for the WGRP on G satisfying $x_{ij} + x_{ji} = 1$. $\square$

Before discussing the facet-defining property of connectivity and other families of inequalities, we will present some properties that are common to all of them in what follows.

3.1. Weak configuration inequalities. The polyhedra based on standard formulations using only one variable per edge corresponding to the routing problems in Figure 1 satisfy the following property. All of the facet-inducing inequalities (except the trivial ones) are *configuration inequalities* [27]. An inequality $F(x) \geq b_0$ is a configuration inequality if there is a partition $\mathcal{B} = \{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_r\}$ of V such that the subgraphs $G(\mathcal{B}_k)$ are connected, the variables associated with links in the sets $E(\mathcal{B}_k)$ have coefficient zero in the inequality, and the variables associated with links from a given set $\mathcal{B}_p$ to another given set $\mathcal{B}_q$ have the same coefficient in the inequality.

It is easy to see that $\text{WGRP}(G)$ does not satisfy the above property. Connectivity inequalities (3), for example, are configuration inequalities with $\mathcal{B} = \{S, V \setminus S\}$, while traversing inequalities (1), and others that will be presented later, are not configuration inequalities. In what follows we will show that all of the facet-inducing

inequalities for $\text{WGRP}(G)$, except the trivial and the traversing ones, share some of the properties described above for the configuration inequalities. This will allow us to define a new wider class, the *weak configuration inequalities*.

LEMMA 3. *Let $F(x) \geq b_0$ be a facet-inducing inequality for $\text{WGRP}(G)$ different from the trivial and the traversing ones.*

(a) *For each variable x_{ij} there is a tour x satisfying $F(x) = b_0$ and $x_{ij} \geq 1$.*

(b) *For each required edge $e = (i, j) \in E_R$ there is a tour x satisfying $F(x) = b_0$ and $x_{ij} + x_{ji} \geq 2$.*

Proof. If (a) is not satisfied, every tour x such that $F(x) = b_0$ satisfies $x_{ij} = 0$. Then

$$\{x \text{ WGRP tour on } G : F(x) = b_0\} \subseteq \{x \text{ WGRP tour on } G : x_{ij} = 0\},$$

and, hence, either $F(x) \geq b_0$ is equivalent to a trivial inequality or it is not facet-inducing. In a similar way, if (b) is not satisfied, every tour x such that $F(x) = b_0$ satisfies $x_{ij} + x_{ji} = 1$, and either $F(x) \geq b_0$ is equivalent to a traversing inequality or it is not facet-inducing. $\square$

Part (a) in Lemma 3 implies that, for each variable x_{ij} associated with a *nonrequired* edge (i, j) , there is a tour x such that $F(x) = b_0$ and uses x_{ij} *an extra time*. This means that if a copy of the arc (i, j) is removed from the directed graph associated with x and is replaced by any other path from i to j , another WGRP tour is obtained. Part (a) also implies that, for each variable x_{ij} associated with a *required* edge (i, j) , there is a tour x such that $F(x) = b_0$ and uses x_{ij} at least once, although not necessarily *an extra time*. Finally, part (b) implies that, at least for one variable of each pair x_{ij}, x_{ji} associated with a *required* edge (i, j) , there is a tour x such that $F(x) = b_0$ and uses it *an extra time*.

An inequality $F(x) \geq b_0$ will be called a *weak configuration inequality* if there is a partition $\mathcal{B} = \{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_r\}$ of V such that the subgraphs $G(\mathcal{B}_k)$ are connected, the variables associated with edges in the sets $E(\mathcal{B}_k)$ have coefficient zero in the inequality, and the variables associated with *nonrequired* edges from a given set $\mathcal{B}_p$ to another given set $\mathcal{B}_q$ have the same coefficient in the inequality. Note that if, in addition, the variables associated with *required* edges from $\mathcal{B}_p$ to $\mathcal{B}_q$ also have the same coefficient in the inequality, we have a (strong) configuration inequality.

THEOREM 4. *All of the facet-inducing inequalities for the $\text{MGRP}(G)$, except those equivalent to the trivial or the traversing ones, are weak configuration inequalities.*

Proof. Let $F(x) := \sum_{(i,j) \in E} (a_{ij}x_{ij} + a_{ji}x_{ji}) \geq b_0$ be such an inequality, and let $E^0 = \{e = (i, j) \in E : a_{ij} = a_{ji} = 0\}$. Let S be the node set of a connected component of $G^0 = (V, E^0)$.

Assume that there is an edge $e = (i, j) \in E(S)$ with $a_{ij} \neq 0$ (necessarily $a_{ij} > 0$). Let x^* be a tour for the WGRP on G such that $F(x^*) = b_0$ and $x_{ij}^* \geq 1$ (it exists from Lemma 3). Let us replace in x^* arc (i, j) by a path from i to j in $E^0(S)$. If x^* uses x_{ij} an extra time, we obtain a tour x^{**} for the WGRP on G satisfying $F(x^{**}) < b_0$, which is a contradiction. From Lemma 3, this is true for all of the variables associated with nonrequired edges and for one variable of each pair associated with a required edge. Then, if x^* does not use x_{ij} an extra time, we add to x^* the arcs in a cycle formed by the arc from j to i (whose associated variable x_{ji} , which is used an extra time, has coefficient zero) and a path in E^0 from i to j , obtaining a tour for the WGRP on G violating the inequality. Therefore, if $\mathcal{B} = \{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_r\}$ are the vertex sets of the connected components of G^0 , the induced graphs $G(\mathcal{B}_k)$ are connected and $a_{ij} = a_{ji} = 0$, for all $e = (i, j) \in E(\mathcal{B}_k)$, $k = 1, 2, \dots, r$.

Let us suppose now that there are two nonrequired edges $e=(i, j)$, $f=(u, v)$ with $i, u \in \mathcal{B}_p$ and $j, v \in \mathcal{B}_q$ such that $a_{ij} > a_{uv}$. Let x^* be a tour for the WGRP on G using x_{ij} an extra time and $F(x^*) = b_0$. Replace in x^* arc (i, j) by a path in $G(\mathcal{B}_p)$ from i to u , the edge f traversed from u to v , and a path in $G(\mathcal{B}_q)$ from v to j . This way, a tour violating the inequality is obtained, which is a contradiction. $\square$

Then, associated with each facet-inducing inequality for the WGRP(G), we have a *configuration graph* $G_C = (V^C, E^C)$. This is the graph resulting from shrinking vertex sets $\mathcal{B}_k$, $k = 1, \dots, r$, into a single vertex each and, after that, shrinking each set of nonrequired parallel edges into one single nonrequired edge but keeping all of the required edges. If two costs equal to the coefficients of the corresponding variables in the inequality are associated with each edge in G_C , this graph keeps all of the information about the inequality, since b_0 is the length of the shortest tour for the WGRP on graph G_C . Hence, each facet-inducing inequality for the WGRP(G) can be represented by means of its corresponding configuration graph G_C . The following theorem implies that, in order to show that a given inequality is facet-inducing for WGRP(G), it will suffice to prove it for the polyhedron associated with the configuration graph, which is simpler in general.

THEOREM 5. *If a weak configuration inequality is facet-inducing for WGRP(G_C), it is also facet-inducing for WGRP(G).*

Proof. It suffices to prove the result for a graph G obtained from G_C by replacing vertex $\mathcal{B}_1$ (for example) by a connected graph $G(\mathcal{B}_1) = (V^{\mathcal{B}_1}, E^{\mathcal{B}_1})$. For simplicity, $F(x) \geq b_0$ will denote both the inequality on G and the inequality on G_C . Note that, given a tour x for the WGRP on G , by shrinking $G(\mathcal{B}_1)$ into a single vertex we obtain a tour x^* for the WGRP on G_C satisfying $F(x) = F(x^*) \geq b_0$.

Let $K = \dim(\text{WGRP}(G_C))$, and let us suppose that $b_0 \neq 0$. Then there are K linearly independent tours for the WGRP on G_C satisfying $F(x) = b_0$, say, $x^1, x^2, \dots, x^K$. After replacing $\mathcal{B}_1$ by the graph $G(\mathcal{B}_1)$, some nonrequired edges may appear between the vertices of $G(\mathcal{B}_1)$ and nodes $\mathcal{B}_i$, $i \neq 1$. Let us call G'_C the graph obtained from G_C by adding Q nonrequired edges $e'_1, e'_2, \dots, e'_Q$, where each e'_i is parallel to a nonrequired edge (not necessarily distinct) e_j of G_C .

For each e'_i , $i = 1, 2, \dots, Q$, we will construct two tours in G'_C . Let $e_j = (\mathcal{B}_1, \mathcal{B}_q)$ be the original edge of G_C to which e'_i is parallel. From Lemma 3, there is a tour in G_C satisfying $F(x) = b_0$ and that traverses e_j from $\mathcal{B}_1$ to $\mathcal{B}_q$ and another one that traverses it in the opposite direction. By replacing the edge e_j by the edge e'_i in these two tours, we obtain two new tours on G'_C satisfying $F(x) = b_0$. Then we have $K+2Q$ linearly independent tours on G'_C satisfying $F(x) = b_0$. These tours can be completed with edges of $G(\mathcal{B}_1)$ to obtain $K+2Q$ tours on G , $x^1, x^2, \dots, x^{K+2Q}$, also satisfying $F(x) = b_0$ because the variables associated with the edges of $G(\mathcal{B}_1)$ do not appear in the inequality.

Consider now the WGRP defined on graph $G(\mathcal{B}_1)$. Let $M = \dim(\text{WGRP}(G(\mathcal{B}_1)))$, and let $y^1, y^2, \dots, y^M$ be M linearly independent tours for the WGRP on $G(\mathcal{B}_1)$. Then $x^1 + y^1, x^1 + y^2, \dots, x^1 + y^M$ are also tours for the WGRP on G satisfying $F(x) = b_0$. By expressing the $K+2Q+M$ tours as rows of a matrix and subtracting the first row x^1 from the last M rows, we obtain a full rank matrix. Then, since $K = 2|E^C| - |V^C| + 1$ and $M = 2|E^{\mathcal{B}_1}| - |V^{\mathcal{B}_1}| + 1$, we have $K+2Q+M = 2(|E^C| + |E^{\mathcal{B}_1}| + Q) - (|V^C| - 1 + |V^{\mathcal{B}_1}|) + 1 = \dim(\text{WGRP}(G))$ linearly independent tours satisfying $F(x) = b_0$. $\square$

As mentioned before, strong and weak configuration inequalities differ only in the fact that, in the first one, “parallel” variables (variables x_{ij} , x_{km} associated with edges in $(\mathcal{B}_p, \mathcal{B}_q)$, with $i, k \in \mathcal{B}_p$ and $j, m \in \mathcal{B}_q$) have equal coefficients, while the

last one can have parallel variables with different coefficients. By arguing as in the proof of Theorem 4 above, it can be shown that, if for each variable x_{ij} there is a tour satisfying $F(x) = b_0$ and using x_{ij} an extra time, then $F(x) \geq b_0$ is a strong configuration inequality, with all of the variables in $(\mathcal{B}_p, \mathcal{B}_q)$ having a coefficient equal to a_{pq} or a_{qp} . A variable with a different coefficient in a weak configuration inequality is then a variable x_{ij} associated with a required edge $(i, j) \in (\mathcal{B}_p, \mathcal{B}_q)$ such that there is no tour satisfying $F(x) = b_0$ which uses x_{ij} an extra time. It can be seen that, in this case, the coefficients of variables x_{ij} and x_{ji} are, respectively, $a_{pq} + k$ and a_{qp} , for some k satisfying $0 < k \leq a_{pq} + a_{qp}$.

Therefore, if a given facet-inducing inequality $F(x) \geq b_0$ for $\text{WGRP}(G)$ is not a strong configuration inequality, then there is at least one variable x_{ij} (associated with a required edge) such that every tour x satisfying $F(x) = b_0$ also satisfies either $x_{ij} = 0$ or $x_{ij} + x_{ji} = 1$. In other words, if a given facet $\mathcal{F}$ of $\text{WGRP}(G)$ is not induced by a strong configuration inequality, then every tour for the WGRP on G which lies in $\mathcal{F}$ also lies either in a trivial facet or in a traversing facet of $\text{WGRP}(G)$. Hence, we think that there must be relatively few such facets in $\text{WGRP}(G)$. In fact, the only inequalities of this type that we have found are a subset of the class of zigzag inequalities. All of the other inequalities presented in the following sections are strong configuration inequalities.

3.2. Connectivity inequalities. To finish this section, we will study the conditions under which connectivity inequalities (3) are facet-inducing for $\text{WGRP}(G)$. Furthermore, the proof of Theorem 6 shows the usefulness of the configuration issue and illustrates the use of Theorem 5 above.

THEOREM 6. *Connectivity inequalities (3) are facet-inducing for $\text{WGRP}(G)$ if subgraphs $G(S)$ and $G(V \setminus S)$ are connected.*

Proof. The configuration graph G_C associated with connectivity inequalities has only two nodes, say, 1 and 2, corresponding to S and to $V \setminus S$, respectively, joined by a single nonrequired edge. Therefore, $\dim(\text{WGRP}(G_C)) = 1$, and, since the tour $x_{12} = x_{21} = 1$ satisfies $\sum_{i \in S, j \notin S} x_{ij} = x_{12} = 1$, the inequality is facet-inducing for $\text{WGRP}(G_C)$. By applying Theorem 5, connectivity inequalities (3) are facet-inducing for $\text{WGRP}(G)$. $\square$

4. Other facets of the WGRP polyhedron. In the presence of the integrality conditions (5), equations (2) and inequalities (4), (1), and (3) in the formulation are enough to describe all of the tours for the WGRP on G . Nevertheless, this is not the case when the integrality conditions are relaxed. In this section we study some other families of inequalities which are facet-inducing for $\text{WGRP}(G)$.

We first obtain valid inequalities for the WGRP from known valid inequalities for the undirected GRP. Let $G = (V, E)$ be an undirected graph, and let $\text{GRP}(G)$ be the polyhedron associated with the formulation of the undirected GRP using one variable y_e per edge $e = (i, j) \in E$, representing the number of times the edge is traversed in any direction. Consider now the same graph $G = (V, E)$ but with two nonnegative costs associated with each edge, and let $\text{WGRP}(G)$ be the polyhedron studied in this paper. In [2] it is shown that, if $\sum_{e \in E} \beta_e y_e \geq b_0$ is a valid inequality for $\text{GRP}(G)$, the inequality $\sum_{e=(i,j) \in E} \beta_e (x_{ij} + x_{ji}) \geq b_0$ is valid for $\text{WGRP}(G)$. Therefore, the R -odd cut, K-C, path-bridge, and honeycomb inequalities presented in what follows are valid inequalities for the $\text{WGRP}(G)$.

4.1. R -odd cut inequalities. An edge cutset $\delta(S)$ is called R -odd if it contains an odd number of required edges. Given that any tour must cross any given edge cutset

FIG. 2. K -C and K -C₀₂ configuration graphs.

an even number of times, the R -odd cut inequalities

$$(6) \quad x(\delta(S)) \geq |\delta_R(S)| + 1 \quad \forall S \subset V \quad \text{such that } \delta(S) \text{ is } R\text{-odd}$$

are valid for $\text{WGRP}(G)$. It can be proved [30] that they are facet-inducing for $\text{WGRP}(G)$ if subgraphs $G(S)$ and $G(V \setminus S)$ are connected.

4.2. K-C inequalities. K-C inequalities were introduced in [12] for the undirected RPP, and in [11] they were generalized to the mixed GRP in two families, the K-C and the K-C₀₂ inequalities. In this section we will study their generalization to the WGRP.

Consider a partition of V into $K+1$ subsets $\{M_0, M_1, M_2, \dots, M_{K-1}, M_K\}$, $K \geq 3$, such that each R -set V_i is contained by one of the node sets $M_0 \cup M_K, M_1, M_2, \dots, M_{K-1}$, the induced subgraphs $G(M_i)$, $i = 0, 1, 2, \dots, K$, are connected, and (M_0, M_K) contains a positive and even number of required edges. Furthermore, we will assume that sets (M_i, M_{i+1}) are nonempty, $i = 0, 1, \dots, K-1$. Such a partition defines the configuration graph shown in Figure 2(a), where the costs of its edges are $c(M_0, M_K) = c(M_K, M_0) = K-2$ and $c(M_i, M_j) = |i-j|$ for all i, j such that $\{i, j\} \neq \{0, K\}$. These costs, shown in Figure 2(a), correspond to the coefficients of the variables in the inequality. Each number represents the coefficient of the variable associated with the traversal of the edge from the nearest node to the farthest one. The K -C inequality is then

$$(7) \quad (K-2) x(M_0, M_K) + \sum_{\substack{0 \leq i < j \leq K \\ \{i, j\} \neq \{0, K\}}} |i-j| x(M_i, M_j) \geq 2(K-1) + (K-2)|(M_0, M_K)_R|.$$

Since K-C inequalities are a particular case of path-bridge inequalities, which will be presented later, the proof that K-C inequalities are facet-inducing is omitted here.

4.3. K-C₀₂ inequalities. With the same underlying configuration graph, K-C₀₂ inequalities differ from the standard ones in that integer K can now take value 2 and in that the coefficients of the variables and the right-hand side (RHS) change as follows:

- $c(M_0, M_K) = c(M_K, M_0) = K-1$;
- $c(M_0, M_1) = 0$, $c(M_1, M_0) = 2$;
- $c(M_i, M_{i+1}) = c(M_{i+1}, M_i) = 1$, $i = 1, 2, \dots, K-1$;

- otherwise, $c(M_i, M_j)$ is the shortest path cost from M_i to M_j in G_C , i.e.,
 - $c(M_0, M_j) = j - 1$, $1 \leq j \leq K - 1$,
 - $c(M_j, M_0) = j + 1$, $1 \leq j \leq K - 1$,
 - $c(M_i, M_j) = |i - j|$, $1 \leq i, j \leq K$.

The corresponding K -C₀₂ inequality is then

$$(8) \quad \sum_{(i,j) \in E} (a_{ij}x_{ij} + a_{ji}x_{ji}) \geq 2(K-1) + (K-1)|(M_0, M_K)_R|,$$

where $a_{ij} = c(M_p, M_q)$ if $i \in M_p$ and $j \in M_q$. These inequalities are also a special case of the path-bridge₀₂ inequalities presented next.

4.4. Path-bridge inequalities. Path-bridge (PB) inequalities were introduced by Letchford [25] for the undirected GRP and are based on the path inequalities for the GTSP proposed by Cornuéjols, Fonlupt, and Naddef [14]. In this section we study their extension to the WGRP. Let $P \geq 1$ and $B \geq 0$ be integers such that $P + B \geq 3$ is an odd number, and let $n_i \geq 2$, $i = 1, \dots, p$, be integer numbers. Let us define a partition $\{A, Z, \{V_j^i\}_{j=1, \dots, n_i}^{i=1, \dots, P}\}$ of V satisfying that each R -set is contained either in $A \cup Z$ or in a set V_j^i , the induced subgraphs $G(V_j^i)$ are connected, $i = 1, 2, \dots, P$, $j = 0, 1, 2, \dots, n_i + 1$ (where for the sake of simplicity we identify A with V_0^i and Z with $V_{n_i+1}^i$ for all i), and (A, Z) contains a number B of required edges. Furthermore, we will suppose that sets (V_j^i, V_{j+1}^i) are nonempty. Then the configuration graph has P paths from A to Z , each of them with $n_i + 2$ vertices and $n_i + 1$ edges. The edges joining the sets A and Z form the *bridge*. This configuration graph is shown in Figure 3, where only one number near an edge means that the coefficients of its two corresponding variables are equal. These coefficients are

- $c(A, Z) = c(Z, A) = 1$,
- $c(V_j^i, V_k^i) = \frac{|j-k|}{n_i-1}$ for all $j, k \in \{0, 1, \dots, n_i+1\}$, $i \in \{1, \dots, P\}$,
- $c(V_j^i, V_k^r) = \frac{1}{n_i-1} + \frac{1}{n_r-1} + \left| \frac{j-1}{n_i-1} - \frac{k-1}{n_r-1} \right|$ for all $i \neq r \in \{1, \dots, P\}$, $j \in \{1, \dots, n_i\}$, $k \in \{1, \dots, n_r\}$.

The PB inequality is then

$$(9) \quad \sum_{(i,j) \in E} (a_{ij}x_{ij} + a_{ji}x_{ji}) \geq 1 + \sum_{i=1}^P \frac{n_i + 1}{n_i - 1} + |(A, Z)_R|,$$

where, again, $a_{ij} = c(V_p^k, V_q^l)$ if $i \in V_p^k$ and $j \in V_q^l$.

A PB inequality is called n -regular if all of the paths have the same length n . In this case, by multiplying it by $n-1$, the inequality (9) can be rewritten in an easier way. Note that a K-C inequality is a particular case of a PB inequality with $P = 1$ and that PB inequalities reduce to the s -path inequalities for the GATSP, introduced by Chopra and Rinaldi [3], when there are no required links crossing from A to Z .

THEOREM 7. *PB inequalities (9) are facet-inducing for WGRP(G).*

Proof. Let us first suppose that the number B of required edges joining A and Z is even. Then the number P of paths from A to Z is odd. If we consider in G_C all of the required edges as nonrequired and we replace each edge by a pair of opposite arcs, we obtain an instance G'_C of the GATSP. By subtracting $|(A, Z)_R|$ from the RHS of the PB inequality, an s -path inequality is obtained, which is facet-inducing for GATSP(G'_C) (see [3]). The dimension of this polyhedron is $2|E_C| - |V_C| + 1$, and there is this number of affinely independent tours for the GATSP on G'_C satisfying the inequality as an equality. Each one of these tours can be easily transformed into

FIG. 3. *PB configuration graph.*

tours for the WGRP on G_C (by adding to them one arc per each required edge in (A, Z) , half of them directed from A to Z and the other half from Z to A) satisfying the PB inequality (9) as an equality. Hence, PB inequalities are facet-inducing for $\text{WGRP}(G_C)$ and, from Theorem 5, for $\text{WGRP}(G)$.

Let us now suppose that B is odd and P is even. Let $\bar{e}$ be a given required edge in (A, Z) . We construct the tour x^1 as the one traversing edge $\bar{e}$ once in each direction, half of the edges in $(A, Z)_R \setminus \{\bar{e}\}$ from A to Z and the other half from Z to A . Tour x^1 traverses half of the paths from A to Z and the other half from Z to A . From x^1 we construct the following tours:

- (a) For each edge $e \in (A, Z) \setminus \{\bar{e}\}$ we define a tour traversing e from A to Z once more than tour x^1 does and traversing $\bar{e}$ only from Z to A . All of the other edges are traversed as in x^1 . Another similar tour traversing e from Z to A and $\bar{e}$ from A to Z is considered. Then we have $2|(A, Z)| - 2$ tours.
- (b) For each edge $e = (V_i^k, V_{i+1}^k)$, we construct a tour x that traverses all of the edges in the path k , except e , in both directions. Edge $\bar{e}$ is traversed by x in the same direction as path k is traversed by x^1 . All of the other edges are traversed by x as they are traversed by x^1 . Then we have $\sum_{i=1}^P (n_i + 1)$ tours.
- (c) For each path k , it is possible to build $n_i + 1$ different tours by using the opposite orientations to those used in (b) for the other $P - 1$ paths. From among them we select, for each path k , only the tour that does not traverse the edge (V_0^k, V_1^k) , and we then have P tours.
- (d) For each of the remaining edges (if any) there are always two tours for the

	$\bar{e}$	$(A, Z) \setminus \{\bar{e}\}$	Paths	E'
(a)	*	I	0	0
(b)+(c)	*	0	B	0
(d)	*	*	*	I

FIG. 4. Matrix appearing in the proof of Theorem 7.

WGRP in G_C satisfying (9) as an equality, traversing this edge exactly once in one direction each, edges in (A, Z) and edges in the P paths. Then, if E' is the set of such remaining edges, we have obtained $2|E'|$ tours.

By including x^1 we have $1+2|(A, Z)|-2+\sum_{i=1}^P(n_i+1)+P+2|E'|$ tours, all of them satisfying the PB inequality as an equality. Hence we have $2|E_C| - \sum_{i=1}^P n_i - 1 = \dim(\text{WGRP}(G_C))$ tours. If we subtract x^1 from all of the other tours and express them as the rows of a matrix (sorted as (a), (b)+(c), and (d) above) and the variables associated with the edges as columns (sorted as $\bar{e}$, $(A, Z) \setminus \{\bar{e}\}$, (V_i^k, V_{i+1}^k) for all i, k , and E'), we obtain the matrix shown in Figure 4. Submatrix B is a full rank matrix (see [30] for details) and, hence, also the complete matrix in Figure 4. Therefore, the PB inequality is facet-inducing for $\text{WGRP}(G_C)$, and then it is also facet-inducing for $\text{WGRP}(G)$. $\square$

4.5. Path-bridge₀₂ inequalities. Path-bridge₀₂ inequalities were presented in [6] for the MGRP. The configuration graph corresponding to a path-bridge₀₂ inequality is similar to the previous one except that integers n_i can now take value 1 and the paths are classified into two types: AZ paths and ZA paths. The associated configuration graph is shown in Figure 5, where the two coefficients associated with an edge are represented only if they are different.

The coefficients are

- $c(A, Z) = c(Z, A) = 1$,
- $c(V_0^i, V_1^i) = 0$ and $c(V_1^i, V_0^i) = \frac{2}{n_i}$ for each AZ path i ,
- $c(V_0^i, V_1^i) = \frac{2}{n_i}$ and $c(V_1^i, V_0^i) = 0$ for each ZA path i ,
- $c(V_j^i, V_{j+1}^i) = c(V_{j+1}^i, V_j^i) = \frac{1}{n_i}$,
- $c(V_j^i, V_k^i)$, with $|j-k| > 1$, is the shortest path cost from V_j^i to V_k^i using edges of the path i , i.e.,
 - $c(V_j^i, V_k^i) = \frac{|j-k|}{n_i}$ for all $j \neq k \in \{1, 2, \dots, n_i+1\}$,
 - $c(V_0^i, V_k^i) = \frac{k-1}{n_i}$ and $c(V_k^i, V_0^i) = \frac{k+1}{n_i}$ if path i is of type AZ , $1 \leq k \leq n_i$,
 - $c(V_0^i, V_k^i) = \frac{k+1}{n_i}$ and $c(V_k^i, V_0^i) = \frac{k-1}{n_i}$ if path i is of type ZA , $1 \leq k \leq n_i$.
- Order the remaining edges (edges in (V_j^i, V_l^k) , $i \neq k$, if any) in an arbitrary way $e_1, e_2, \dots, e_h$. For $i=1$ to h , if $e_i = (u, v)$, we assign to c_{uv} the maximum value such that there is a WGRP tour on G_C with cost $P+1+|(A, Z)_R|$ traversing e_i just from u to v but not traversing the edges $\{e_{i+1}, \dots, e_h\}$. Similarly, we assign to c_{vu} the maximum value such that there is a tour of c -length $P+1+|(A, Z)_R|$ traversing e_i from v to u (perhaps also from u to v) but not traversing the edges $\{e_{i+1}, \dots, e_h\}$ (sequential lifting).

FIG. 5. PB_{02} configuration graph.

The path-bridge $_{02}$ inequality PB_{02} is then

$$(10) \quad \sum_{(i,j) \in E} (a_{ij}x_{ij} + a_{ji}x_{ji}) \geq P + 1 + |(A, Z)_R|.$$

Note that the main difference between PB_{02} and PB inequalities is that variables in sets (A, V_1^i) have different coefficients for its two associated variables. One of these coefficients is $\frac{2}{n_i}$, twice the cost of the other edges in path i , while the other coefficient is 0 (see Figure 5). The direction represented by the variable with coefficient 0 in each path determines whether the path is of type AZ or ZA . In a path-bridge $_{02}$ configuration graph, the pair of asymmetric coefficients $(\frac{2}{n_i}, 0)$ for each path i can be associated with any edge (V_j^i, V_{j+1}^i) in the path, thus obtaining different but equivalent inequalities (given the same ordering in the sequential lifting process). Finally, when $P=1$, the path-bridge $_{02}$ inequality (10) reduces to a $K-C_{02}$ inequality.

THEOREM 8. *Path-bridge $_{02}$ inequalities (10) are valid for $WGRP(G)$.*

Proof. The proof is similar to that in [6] for the MGRP and is omitted here for the sake of brevity. $\square$

THEOREM 9. *Let $F(x) \geq b_0$ be a path-bridge $_{02}$ inequality (10), and let P_{AZ} and P_{ZA} be the number of paths of types AZ and ZA , respectively. Then $F(x) \geq b_0$ is facet-inducing of $WGRP(G)$ if $|(A, Z)_R| \geq |P_{AZ} - P_{ZA}| + 1$.*

Proof. The proof is similar to that of Theorem 7 and is omitted here. Note only that condition $|(A, Z)_R| \geq |P_{AZ} - P_{ZA}| + 1$ is needed in order to construct $WGRP$ tours traversing the paths of type AZ (type ZA) from A to Z (from Z to A) and

satisfying $F(x) = b_0$. $\square$

As for the (standard) PB inequalities, when all of the paths are of the same length n , we obtain the n -regular PB₀₂ inequalities, which can be written in an easier way.

4.6. Honeycomb inequalities. Honeycomb inequalities were first proposed by Corberán and Sanchis [13] for the undirected GRP and by Corberán, Mejía, and Sanchis [6] for the MGRP. These inequalities also generalize the K-C inequalities. Consider a partition $\{A_1, A_2, \dots, A_L, A_{L+1}, \dots, A_K\}$ of V , $3 \leq K \leq p$, $1 \leq L \leq K$, such that each R -set is contained by one A_i and the induced subgraphs $G(A_i)$ are connected. Each set A_i , $i = 1, 2, \dots, L$, is divided into $\gamma_i \geq 2$ subsets, $A_i = B_i^1 \cup B_i^2 \cup \dots \cup B_i^{\gamma_i}$, satisfying that each B_i^j contains an even number of R -odd nodes and the induced subgraphs $G(B_i^j)$ are connected, $j = 1, 2, \dots, \gamma_i$, and the graph defined by nodes $B_i^1, B_i^2, \dots, B_i^{\gamma_i}$ and the required edges (B_i^j, B_i^k) is connected (and even).

Note that, when A_i consists of several R -sets, the last condition implies that the partition of A_i into the B_i^j is made by cutting the R -sets. For notational convenience, we denote $B_i^0 = A_i$, $i = L+1, \dots, K$. Therefore we have the following partition of V :

$$\mathcal{B} = \{B_1^1, B_1^2, \dots, B_1^{\gamma_1}, B_2^1, B_2^2, \dots, B_2^{\gamma_2}, \dots, B_L^1, B_L^2, \dots, B_L^{\gamma_L}, B_{L+1}^0, \dots, B_K^0\}.$$

This partition $\mathcal{B}$ defines the configuration graph $G_C = (\mathcal{B}, \mathcal{E})$. Let T be a set of nonrequired edges in G_C joining nodes corresponding to different A_j such that $(\mathcal{B}, T)$ is a spanning tree (see Figure 6, where the arcs in T are represented by thin lines and the required links by bold lines). Then, for each pair of nodes B_i^j, B_p^q in $\mathcal{B}$, let $d(B_i^j, B_p^q)$ denote the number of edges in the unique path in $(\mathcal{B}, T)$ joining B_i^j to B_p^q . We will also assume that $d(B_i^j, B_i^q) \geq 3$ for all $i = 1, \dots, L$ and for all $j \neq q$.

We divide the set $\mathcal{E}$ into 3 subsets: the set $\mathcal{C}$ formed by the edges joining nodes B_i^p, B_i^q , with $p, q \neq 0$ (the nodes obtained by “cutting” the sets A_i , $i = 1, \dots, L$), the set of edges in T , and the set formed by the remaining edges, which will be called $\mathcal{I}n$. The costs of the edges of graph $G_C = (\mathcal{B}, \mathcal{E})$ are (see Figure 6) the following:

- (I) For the edges $(B_q^i, B_q^j) \in \mathcal{C}$ such that the path in $(\mathcal{B}, T)$ joining B_q^i and B_q^j does not contain more than one node related to the same A_s (except the nodes B_q^i and B_q^j), $c(B_q^i, B_q^j) = c(B_q^j, B_q^i) = d(B_q^i, B_q^j) - 2$.

FIG. 6. Honeycomb configuration graph.

- (II) For the edges $(B_r^i, B_q^j) \in T \cup \mathcal{I}n$, $r \neq q$, such that the path in $(\mathcal{B}, T)$ joining B_r^i and B_q^j does not contain more than one node related to the same A_s , $c(B_r^i, B_q^j) = c(B_q^j, B_r^i) = d(B_r^i, B_q^j)$.
- (III) For the remaining edges (if any), we compute their two costs with a process of sequential lifting such as the one described for PB_{02} inequalities.

The corresponding *honeycomb inequality* is then

$$(11) \quad \sum_{(i,j) \in E} (a_{ij}x_{ij} + a_{ji}x_{ji}) \geq 2(K-1) + \sum_{(B_q^i, B_q^j) \in \mathcal{E}_R} c(B_q^i, B_q^j),$$

where $a_{ij} = c(B_r^i, B_q^j)$ if $i \in B_r^i$ and $j \in B_q^j$.

Note that, when the configuration graph has no edges of type III, all of the coefficients in the honeycomb inequality can be computed in terms of the shortest distances in the graph $(\mathcal{B}, T)$. This occurs, for example, when every node B_q^i , $i \neq 0$, has degree 1 in $(\mathcal{B}, T)$. Given that the sequential lifting process for a set of edges guarantees the validity of an inequality if it is valid without this set of edges, and that this is also true for the facet-inducing property, in what follows we will assume that the honeycomb configuration has no edges of type III.

Before proving that the honeycomb inequalities are facet-inducing for $WGRP(G)$, let us show how to build tours for the WGRP on $G_C = (\mathcal{B}, \mathcal{E})$ satisfying the honeycomb inequality $F(x) \geq b_0$ as an equality. Let $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ denote the graph with node set $\bar{\mathcal{A}} = \{A_1, A_2, \dots, A_L, A_{L+1}, \dots, A_K\}$ and having an edge (A_i, A_j) for each edge (B_i^p, B_j^q) in T (Figure 7(a)). Then, by traversing all of the $K-1$ edges of any spanning tree of $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ once in each direction, and each required edge in G_C once, we obtain a tour of cost b_0 (Figure 7(b)).

THEOREM 10. *Honeycomb inequalities (11) are facet-inducing of $WGRP(G)$ if the shrunk graph $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ is 2-connected.*

Proof. The dimension of $WGRP(G_C)$ is $2|\mathcal{E}| - |\mathcal{B}| + 1 = 2|\mathcal{E}| - |T| = 2|\mathcal{C}| + 2|\mathcal{I}n| + |T|$, and this is the number of linear independent WGRP tours x satisfying the inequality as an equality that we build in what follows. Let x^d be the incidence vector of a set of L cycles traversing each required edge exactly once (such cycles exist since the required edges in G_C form even graphs).

For each variable x_{uv} associated with an edge in $\mathcal{C} \cup \mathcal{I}n$, consider the tour that uses x_{uv} exactly once, the path in T from v to u , and the required edges as in x^d . The nodes still not visited are connected with edges in T used once in each direction. Then we have $2|\mathcal{C}| + 2|\mathcal{I}n|$ tours.

FIG. 7. Graph $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ and a WGRP tour on G_C satisfying (11) as an equality.

Since the graph $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ is 2-connected, it can be proved that the only equation satisfied by the incidence vectors of all its spanning trees is $\sum_{e \in T_{\bar{\mathcal{A}}}} x_e = |\bar{\mathcal{A}}| - 1$. Hence, $|T_{\bar{\mathcal{A}}}| = |T|$ different spanning trees can be selected in such a way that their incidence vectors are linearly independent. For each spanning tree of graph $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ we can define a WGRP tour, such as the one shown in Figure 7(b), which uses each edge in the tree once in each direction and the required edges as in x^d .

If we subtract x^d from the $2|\mathcal{C}| + 2|\mathcal{I}n| + |T|$ tours above and we express them as rows of a matrix, then we obtain a full rank matrix. Hence, the honeycomb inequality is facet-inducing for $\text{WGRP}(G_{\mathcal{C}})$, and, by applying Theorem 5, it is facet-inducing for $\text{WGRP}(G)$. $\square$

4.7. Honeycomb₀₂ inequalities. As for K-C and PB inequalities, there is another version of the honeycomb inequalities in which some edges have coefficients 0 and 2. Honeycomb₀₂ inequalities were presented in [6] for the MGRP. As in that paper, we consider here only the case $L = 1$, i.e., when only one R -set (or cluster of R -sets) is divided into γ_1 parts. We have not studied the general case because it is quite a bit more complicated. The reason is that, after replacing some pairs of coefficients (1, 1) in a honeycomb configuration with $L > 1$ by coefficients (0, 2), a nonvalid inequality can be obtained.

With a similar configuration graph $G_{\mathcal{C}} = (\mathcal{B}, \mathcal{E})$ and tree T (see Figure 8), the nodes in set A_1 are classified into two types, nodes of type $\mathcal{O}$ (those that will be incident with edges in T with coefficients 0 and 2) and nodes of type $\mathcal{I}$, in such a way that there is at least one node of each type. We will assume that $d(B_1^i, B_1^j) \geq 3$ if B_1^i, B_1^j are nodes of the same type, while $d(B_1^i, B_1^j) \geq 2$ if B_1^i, B_1^j are of different types. The coefficients are defined as

- $c(B_1^i, B_1^j) = d(B_1^i, B_1^j) - 2$ if B_1^i, B_1^j are nodes of the same type;
- $c(B_1^i, B_1^j) = d(B_1^i, B_1^j) - 1$ if B_1^i, B_1^j are nodes of different types;
- $c(B_1^i, B_q^0) = 0$ and $c(B_q^0, B_1^i) = 2$ if B_1^i is of type $\mathcal{O}$ and $(B_1^i, B_q^0) \in T$;
- for the remaining edges in T , $c(B_q^i, B_r^j) = c(B_r^j, B_q^i) = 1$;
- otherwise, $c(B_q^i, B_r^j)$ is the shortest path cost in T from B_q^i to B_r^j .

With these coefficients, the honeycomb₀₂ inequality is expressed as in (11).

THEOREM 11. *Honeycomb₀₂ inequalities are valid for $\text{WGRP}(G)$.*

Proof. The proof is similar to that in [6] for the MGRP and is omitted here for the sake of brevity. $\square$

THEOREM 12. *Honeycomb₀₂ inequalities are facet-inducing for $\text{WGRP}(G)$ if the shrunk graph $(\bar{\mathcal{A}}, T_{\bar{\mathcal{A}}})$ is 2-connected.*

FIG. 8. Honeycomb₀₂ configuration graph with $L = 1$.

Proof. The proof is similar to that of Theorem 10, and the details can be found in [30]. The main difference is the way the tours associated with variables that correspond to traversing an edge $e = (u, v)$ in $\mathcal{C}$ from a node u of type $\mathcal{O}$ to a node v of type $\mathcal{I}$ are defined. If (u, v) is required, we construct a tour traversing each edge in the path in T from u to v twice and some edges in T once in each direction to connect those nodes B_i^0 that have still not been visited. In this case not all of the required edges can be traversed as in x^d , and some of them are redirected to obtain a symmetric graph. If e is not required, the tour is constructed in a similar way. $\square$

4.8. Zigzag inequalities. Zigzag inequalities were introduced in [8]. Here we first describe two families of zigzag inequalities: the even and odd zigzag inequalities. Consider a partition of set V into 4 subsets: M^1 , M^2 , M^3 , and M^4 . Let α_{ij} denote the number of required edges in (M^i, M^j) , and suppose that one of the following conditions is satisfied:

- *Even case:* M^1 , M^2 , M^3 , and M^4 are R -even and $\alpha_{12} = \alpha_{34} = \alpha_{14} = \alpha_{23} = 0$.
- *Odd (simple) case:* M^1 , M^2 , M^3 , and M^4 are R -odd and $\alpha_{12} + \alpha_{34} = \alpha_{14} + \alpha_{23}$.

The configuration graphs $G_{\mathcal{C}}$ associated with even and odd (simple) zigzag inequalities are shown in Figures 9(a) and 9(b) (where the required edges are represented in bold lines) and are defined by the partition of V above and by the following coefficients:

$$c(M^1, M^2) = c(M^3, M^4) = 0, \quad c(M^2, M^1) = c(M^4, M^3) = 2, \quad c(M^i, M^j) = 1 \text{ otherwise.}$$

Then the even and odd (simple) zigzag inequalities can be expressed as

$$(12) \quad x(\delta(M^1 \cup M^2)) + 2x(M^2 : M^1) + 2x(M^4 : M^3) \geq \alpha_{13} + \alpha_{24} + \alpha_{14} + \alpha_{23} + 2,$$

where, given any set of edges (S_1, S_2) , $x(S_1 : S_2) = \sum_{(i,j): i \in S_1, j \in S_2} x_{ij}$.

In the above-mentioned paper it is shown that even and odd (simple) zigzag inequalities (12) are valid and facet-inducing for $\text{WGRP}(G)$ if the following conditions hold: If $G_{\mathcal{C}}$ is a complete graph and $\alpha_{13}, \alpha_{24} \geq 2$ (even case) or $\alpha_{13} \geq |\alpha_{12} - \alpha_{14}| + 1$ and $\alpha_{24} \geq |\alpha_{12} - \alpha_{23}| + 1$ (odd case). All of these inequalities are strong configuration inequalities. Furthermore, it is also proved that odd (simple) zigzag inequalities are equivalent to 3-wheel inequalities for the WPP [34].

FIG. 9. Zigzag configuration graphs.

Condition $\alpha_{12} + \alpha_{34} = \alpha_{14} + \alpha_{23}$ for the odd (simple) case above is very strong and can be relaxed as follows to obtain a more general version of odd zigzag inequalities. Let M^1, M^2, M^3 , and M^4 be a partition of V into R -odd sets. Let us represent the horizontal edges by $\mathcal{H} = (M^1, M^2) \cup (M^3, M^4)$ and the diagonal ones by $\mathcal{D} = (M^2, M^3) \cup (M^1, M^4)$, and note that $\mathcal{H} \cup \mathcal{D} = \delta(M^1 \cup M^3)$. Let $\mathcal{F} \subset (\mathcal{H} \cup \mathcal{D})_R$ be a subset of required edges (shown as bold lines in Figure 9(c), where all of the edges are required) satisfying

$$(13) \quad |\mathcal{H}_R \setminus \mathcal{F}| + |\mathcal{D}_R \cap \mathcal{F}| = |\mathcal{D}_R \setminus \mathcal{F}| + |\mathcal{H}_R \cap \mathcal{F}|.$$

The more general odd zigzag inequality is

$$(14) \quad \begin{aligned} & x(\delta(M^1 \cup M^2)) + 2x(M^2 : M^1) + 2x(M^4 : M^3) + 2x(F_{zz}) \\ & \geq \alpha_{13} + \alpha_{24} + \alpha_{14} + \alpha_{23} + 2|\mathcal{H} \cap \mathcal{F}| + 2, \end{aligned}$$

where $x(F_{zz})$ denotes the variables associated with the edges in $\mathcal{F}$ in the direction given by the zigzag, i.e., $M^1 \rightarrow M^2 \rightarrow M^3 \rightarrow M^4 \rightarrow M^1$. The pairs of coefficients associated with each edge are shown in Figure 9(c). Odd zigzag inequalities (14) are valid and facet-inducing for $\text{WGRP}(G)$ if $G_C \setminus \mathcal{F}$ is a complete graph, there are two required edges $e_{13} \in (M^1, M^3)$ and $e_{24} \in (M^2, M^4)$, and the remaining required edges in G_C can be oriented to induce a symmetric graph satisfying that all of the edges in $(\mathcal{H} \cup \mathcal{D})_R \setminus \mathcal{F}$ are oriented in the direction of the zigzag and all of the edges in $\mathcal{F}$ are oriented in the opposite direction.

Odd zigzag inequalities (14) are weak configuration inequalities when $\mathcal{F} \neq \emptyset$. If $\mathcal{F} = \emptyset$, they reduce to inequalities (12), and condition (13) becomes $\alpha_{12} + \alpha_{34} = \alpha_{14} + \alpha_{23}$.

In the odd zigzag inequalities, the direction of the zigzag is $M^1 \rightarrow M^2 \rightarrow M^3 \rightarrow M^4 \rightarrow M^1$ and is determined by the orientation of some edges whose associated variables take fractional values in the linear program (LP) solution. More recently, in [10], two more versions of zigzag inequalities have been described for the WPP, the even-even, and the odd-odd zigzag inequalities. These two kinds of inequalities are designed to cut fractional LP solutions in which some edges in the zigzag have a different orientation, $M^1 \rightarrow M^2 \rightarrow M^3$ and $M^1 \rightarrow M^4 \rightarrow M^3$ for the even-even zigzag inequalities and $M^1 \rightarrow M^2 \rightarrow M^3 \rightarrow M^4$ and $M^1 \rightarrow M^4$ for the odd-odd zigzag inequalities. The name of the inequalities also refers to the degree of the two shores of the edge cutset $\delta(M^1 \cup M^3)$ (see Figures 10(a) and 10(b), where all of the edges are required and a set M^i represented with a double circle is R -odd). These two last types of inequalities are proved to be facet-inducing for the WPP polyhedron under mild conditions. In what follows we describe the generalization of these inequalities to the WGRP.

For the even-even zigzag inequalities, sets M^2 and M^4 are R -odd, sets M^1 and M^3 are R -even, and $\mathcal{F}$ is a subset of required edges $\mathcal{F} \subset \delta_R(M^1 \cup M^3)$ (shown as bold lines in Figure 10(a)), satisfying

$$(15) \quad \begin{aligned} & |(M^1, M^2 \cup M^4)_R \setminus \mathcal{F}| + |(M^2 \cup M^4, M^3)_R \cap \mathcal{F}| \\ & = |(M^1, M^2 \cup M^4)_R \cap \mathcal{F}| + |(M^2 \cup M^4, M^3)_R \setminus \mathcal{F}|. \end{aligned}$$

The corresponding even-even zigzag inequality is

$$(16) \quad \begin{aligned} & x(\delta(M^3)) + 2x(M^2, M^4) + 2x(M^2 : M^1) + 2x(M^4 : M^1) + 2x(F_{zz}) \\ & \geq \alpha_{13} + 2\alpha_{24} + \alpha_{23} + \alpha_{34} + 2|\delta(M^1) \cap \mathcal{F}| + 2, \end{aligned}$$

FIG. 10. Even-even and odd-odd zigzag configurations, with sets $\mathcal{F}$ in bold lines.

where $x(F_{zz})$ denotes the variables associated with the edges in $\mathcal{F}$ in the direction of the zigzag, i.e., $M^1 \rightarrow M^2 \rightarrow M^3$ and $M^1 \rightarrow M^4 \rightarrow M^3$. The coefficients of the variables are also shown in Figure 10(a).

For the odd-odd zigzag inequalities (see Figure 10(b)), sets M^2 and M^3 are R -odd, sets M^1 and M^4 are R -even, set $\mathcal{F} \subset \delta_R(M^1 \cup M^3)$ satisfies the condition

$$(17) \quad \begin{aligned} & |(M^1, M^2 \cup M^4)_R \setminus \mathcal{F}| + |(M^3, M^4)_R \setminus \mathcal{F}| + |(M^2, M^3)_R \cap \mathcal{F}| + 1 \\ & = |(M^1, M^2 \cup M^4)_R \cap \mathcal{F}| + |(M^3, M^4)_R \cap \mathcal{F}| + |(M^2, M^3)_R \setminus \mathcal{F}|, \end{aligned}$$

and the corresponding odd-odd zigzag inequality is

$$(18) \quad \begin{aligned} & x(M^2 \cup M^4 : M^1 \cup M^3) + x(M^1, M^3) + x(M^2, M^4) + x(M^3 : M^2) + x(F_{zz}) \\ & \geq \alpha_{13} + \alpha_{24} + |(M^2, M^3) \setminus \mathcal{F}| + |\mathcal{F}| + 1, \end{aligned}$$

where, again, $x(F_{zz})$ denotes the variables associated with the edges in $\mathcal{F}$ in the direction of the zigzag, i.e., $M^1 \rightarrow M^2 \rightarrow M^3 \rightarrow M^4$ and $M^1 \rightarrow M^4$.

The proofs of the following two theorems are similar to those for the WPP in [10] and are omitted here.

THEOREM 13. *Even-even zigzag inequalities (16) are valid for $WGRP(G)$. They are facet-inducing for $WGRP(G)$ if $G_C \setminus \mathcal{F}$ is a complete graph, there are three edges $e_{13}, f_{13} \in (M^1, M^3)_R$ and $e_{24} \in (M^2, M^4)_R$, and the remaining required edges in G_C can be oriented to induce a (directed) symmetric graph where all of the edges in $\delta_R(M^1 \cup M^3) \setminus \mathcal{F}$ are oriented in the direction of the zigzag and all of the edges in $\mathcal{F}$ are oriented in the opposite direction.*

THEOREM 14. *Odd-odd zigzag inequalities (18) are valid for $WGRP(G)$. They are facet-inducing for $WGRP(G)$ if $G_C \setminus \mathcal{F}$ is a complete graph, there are three edges $e_{13} \in (M^1, M^3)_R$, $e_{24} \in (M^2, M^4)_R$, and $e_{14} \in (M^1, M^4)_R \cap \mathcal{F}$, and the remaining required edges in G_C can be oriented to induce a (directed) symmetric graph where all of the edges in $\delta_R(M^1 \cup M^3) \setminus \mathcal{F}$ are oriented in the direction of the zigzag and all of the edges in $\mathcal{F}$ are oriented in the opposite direction.*

5. The mixed GRP polyhedron. As mentioned in the introduction, the MGRP is the general routing problem defined on a mixed graph $G = (V, E, A)$, where V is the set of vertices, E is the set of edges, and A is the set of arcs, and the MCP is a special case of it.

Nobert and Picard [28] proposed a formulation for the MCPP using only one variable per edge expressing the number of times a given edge is traversed in any direction. Such an approach has been also used for the MGRP in [11] and [6], where a wide polyhedral study is carried out. We call this kind of formulation F1. On the other hand, different formulations using two variables per edge were proposed for the MCPP by Christofides et al. [4] and Ralphs [31]. They will be called F2 formulations. A theoretical and computational comparison of both formulations for ARPs on mixed graphs can be found in [7]. Although formulation F2 is perhaps a more intuitive approach to a problem defined on a mixed graph, polyhedral investigations on it have not been presented up to now. That is the subject of this section, where we will take advantage of the previous WGRP study.

As for the WGRP, we will assume again that the original graph has been transformed to satisfy $V = V_R$. In addition, it can also be assumed that $E \setminus E_R = \emptyset$, because each nonrequired edge can be replaced by a pair of opposite nonrequired arcs [11]. Although this last transformation is not as important for formulation F2 as it is for F1, in what follows we suppose that we are working on a strongly connected graph $G = (V, E, A) := (V_R, E_R, A_R \cup A_{NR})$.

An MGRP instance can be transformed into a WGRP instance in which the cost of traversing the edges in the forbidden directions are set to infinity. Then the variables associated with the forbidden directions can be removed from the WGRP formulation, thus obtaining an MGRP formulation with just one variable associated with each arc and two variables associated with each edge. Hence, formulation F2 for the MGRP is exactly the one presented for the WGRP in section 2 except that some variables do not exist (all of the variables x_{ji} associated with arcs (i, j)). Therefore, constraints (1) and (4) are replaced by

$$(19) \quad x_{ij} + x_{ji} \geq 1 \quad \forall (i, j) \in E (= E_R),$$

$$(20) \quad x_{ij} \geq 1 \quad \forall (i, j) \in A_R,$$

$$(21) \quad x_{ij} \geq 0 \quad \text{otherwise.}$$

Let $\text{MGRP}(G)$ represent the convex hull of all of the feasible solutions of the F2 formulation for the MGRP on $G = (V, E, A)$ (MGRP tours). From the results obtained for the WGRP polyhedron, it can be shown that, if G is a strongly connected graph, the dimension of $\text{MGRP}(G)$ is $2|E| + |A| - |V| + 1$. Furthermore, *traversing* and *trivial* inequalities are facet-inducing for $\text{MGRP}(G)$ if the corresponding link (edge or arc) $e = (i, j)$ satisfies that $G \setminus \{e\}$ is a strongly connected graph. All other facet-inducing inequalities for the $\text{MGRP}(G)$ are *weak configuration inequalities*, and their associated configuration graphs can have parallel variables with different coefficients associated with their edges.

Obviously any valid inequality for the WGRP is also a valid inequality for the MGRP. Furthermore, the facet-inducing inequalities for $\text{WGRP}(G)$ described in this paper are also facet-inducing for $\text{MGRP}(G)$ if the arcs in G have the “appropriate direction,” i.e., if the removed variables do not avoid the existence of all of the tours needed to define a facet. Before presenting the following inequalities, we need some more notation. If $G = (V_R, E_R, A_R \cup A_{NR})$ is a mixed graph and S_1, S_2 are two vertex sets, we denote

$$E(S_1, S_2) = \{e = (i, j) \in E : i \in S_1, j \in S_2 \text{ or } j \in S_1, i \in S_2\},$$

$$A(S_1, S_2) = \{a = (i, j) \in A : i \in S_1, j \in S_2\},$$

$$A_R(S_1, S_2) = \{a = (i, j) \in A_R : i \in S_1, j \in S_2\}.$$

A mixed graph is called *balanced* if, for every $S \subset V$, the difference between the number of arcs leaving S and the number of arcs entering S is less than or equal to the number of edges in $E(S, V \setminus S)$.

It can be shown that the following inequalities are facet-inducing for $\text{MGRP}(G)$:

- Connectivity inequalities (3), if graphs $G(S)$ and $G(V \setminus S)$ are strongly connected.
- R -odd cut inequalities (6), if $G(S)$ and $G(V \setminus S)$ are strongly connected and $\epsilon > |\alpha - \beta|$, where $\epsilon = |E(S, V \setminus S)|$, $\alpha = |A_R(S, V \setminus S)|$, and $\beta = |A_R(V \setminus S, S)|$.
- K-C inequalities (7), if $\epsilon \geq |\alpha - \beta|$, and K-C₀₂ inequalities (8), if $\epsilon \geq |\alpha + 1 - \beta| + 1$, where $\epsilon = |E(M_0, M_K)|$, $\alpha = |A_R(M_0, M_K)|$, and $\beta = |A_R(M_K, M_0)|$. Here we assume that all of the sets $A(M_i, M_{i+1})$, $A(M_{i+1}, M_i)$ are nonempty.
- PB inequalities (9), if $\epsilon \geq |\alpha - \beta|$ for P odd and $\epsilon \geq |\alpha - \beta| + 1$ for P even, and path-bridge₀₂ inequalities (10), if $\epsilon \geq |\alpha + P_{AZ} - \beta - P_{ZA}| + 1$, where P_{AZ} and P_{ZA} are the number of paths of types AZ and ZA , respectively, $\epsilon = |E(A, Z)|$, $\alpha = |A_R(A, Z)|$, and $\beta = |A_R(Z, A)|$. The existence of all of the pairs of opposite (nonrequired) arcs forming the P paths is assumed here.
- Honeycomb inequalities (11), if the subgraph of G_C induced by the required links $E \cup A_R$ is balanced and the graph $(\bar{A}, T_{\bar{A}})$ is 2-connected. Honeycomb₀₂ inequalities if, in addition, for each edge or arc (u, v) , with node u of type $\mathcal{O}$ and node v of type $\mathcal{I}$, the subgraph of G_C induced by the required links plus two extra arcs from u to v is a balanced graph. We assume the existence of all of the pairs of opposite (nonrequired) arcs forming the tree T .
- Zigzag inequalities (12) and (14), if there are 4 links defining a zigzag $M^1 \rightarrow M^2 \rightarrow M^3 \rightarrow M^4 \rightarrow M^1$ and,
 - (a) for the even case, the subgraph of G_C induced by the required links is balanced;
 - (b) for the odd case, there are two required edges $e_{13} \in (M^1, M^3)$ and $e_{24} \in (M^2, M^4)$, and the remaining required edges in G_C can be oriented in such a way that, together with the required arcs in G_C , they induce a symmetric graph in which all of the links in $(\mathcal{H} \cup \mathcal{D})_R \setminus \mathcal{F}$ are oriented in the direction of the zigzag and all of the links in $\mathcal{F}$ are oriented in the opposite direction.
- Even-even zigzag inequalities (16) and odd-odd zigzag inequalities (18), under conditions similar to those above for the odd zigzag inequalities.

Given that the MCP and MRPP are special cases of the MGRP, the above inequalities are also facet-inducing for the polyhedra associated with these problems when they are formulated with two variables.

6. Conclusions. Given a “windy” graph (an undirected graph with two costs associated with each edge, representing the costs of traversing it in each direction) and given a subset of “required” edges and a subset of required vertices, the windy general routing problem consists of finding a minimum cost tour traversing each required edge and visiting each required vertex at least once. Since undirected, directed, and mixed graphs can be modeled with a windy graph, and the GRP generalizes the CPP, RPP, and GTSP, all of the routing problems represented in Figure 1 are special cases of the WGRP. Therefore, most of the theoretical and practical results obtained for the WGRP can be applied to these important problems.

In this paper we have presented a polyhedral study of the WGRP. In addition to describing some basic properties of its associated polyhedron $\text{WGRP}(G)$, we have shown that all of its facet-inducing inequalities, except those equivalent to the trivial or

the traversing ones, are *weak* configuration inequalities. This is a generalization of the (strong) configuration property related to the polyhedra associated with the problems in Figure 1. Then each facet-inducing inequality can be represented by means of a configuration graph, and we have proved that, if a given inequality is facet-inducing for the polyhedron defined on this simple configuration graph, it is also facet-inducing for the whole polyhedron $\text{WGRP}(G)$.

We have also described wide families of facet-inducing inequalities. This partial description of $\text{WGRP}(G)$ has been recently used in [9] to develop a branch and cut algorithm capable of solving WGRP instances of large size and other difficult instances of some of the problems shown in Figure 1. Although slightly different versions of most of these inequalities were already known for other routing problems polyhedra, it is in this paper that they have been generalized for the WGRP and proved to be facet-inducing of $\text{WGRP}(G)$.

On the other hand, a partial description of the polyhedra associated with ARPs defined on mixed graphs whose formulation uses two variables per edge has also been obtained. This polyhedral study had not been done before.

A final contribution of this paper is that it also provides a global view of most of the known facet-inducing inequalities for the polyhedra associated with the problems in Figure 1, since versions of facet-inducing inequalities for other problems with formulations using only one variable per link are very similar.

ON COMPLEXITY OF THE SUBPATTERN PROBLEM*

SHLOMO AHAL[†] AND YURI RABINOVICH[‡]

Abstract. We study various computational aspects of the problem of determining whether, given a (fixed) permutation π on k elements and an input permutation σ on $n > k$ elements, π can be *embedded* in σ in an order-preserving manner. Formally, the goal is to determine whether there exists a strictly increasing function f from $[1, k]$ to $[1, n]$ which is order preserving, i.e., f satisfies $\sigma(f(i)) > \sigma(f(j))$ whenever $\pi(i) > \pi(j)$. We call this decision problem the *subpattern problem*. The study falls into two parts. In the first part we develop and analyze an algorithmic paradigm for this problem. We introduce two naturally defined (related) permutation-complexity measures $C(\pi)$ and a somewhat finer $C^T(\pi)$, and, we show that our algorithms run in time $O(n^{1+C(\pi)})$ and $O(n^{2 \cdot C^T(\pi)})$, respectively; i.e., the hardness of the problem crucially depends on the structure of π , as measured by $C(\pi)$ or by $C^T(\pi)$. In the second part of the paper we study the above complexity measures. In particular, we show that in the general case, $C(\pi) \leq 0.47k + o(k)$. Thus, the time complexity of the subpattern problem is at most $O(n^{0.47k+o(k)})$, improving over the trivial $O(n^k)$. Unfortunately, it turns out that for most permutations $C^T(\pi) = \Omega(k)$, and thus, in general, the upper bound on the running time cannot be significantly improved using this approach. Yet, for many natural classes of permutations the complexity of $C(\pi)$ is sublinear in k . To demonstrate this, we study two interesting classes of “linear” permutations and show that their complexity is $C(\pi) = O(\sqrt{k})$. In addition, we study some structural properties of the complexity measures, show that $C^T(\pi) \leq C(\pi) \leq O(\log k) \cdot C^T(\pi)$, and relate $C(\pi)$ and $C^T(\pi)$ to the pathwidth and the treewidth of a certain graph G_π defined by the permutation π .

1. Introduction. The question studied in this paper belongs to a vast family of questions dealing with finding a specified substructure within a given (large) structure. Our structures here are permutations, viewed as order types of finite sequences of distinct numbers. The key relation between two such sequences is *embeddability*. We say that π is embeddable in σ if there exists a subsequence σ' of σ (i.e., a sequence obtained by erasing some of σ 's entries) that has the same order type as π . The embeddability of π in σ will be denoted by $\pi \hookrightarrow \sigma$. Formally, we have the following definition.

DEFINITION 1.1. Let σ, π be permutations of fully ordered sets of sizes n and k , respectively ($n \geq k$). A function $f : [1, k] \rightarrow [1, n]$ (mapping indices to indices, not values to values!) will be called a (π, σ) -legal mapping, or alternatively, an embedding of π into σ , if it is

1. strictly increasing, i.e., $f(i) > f(j)$ whenever $i > j$;
2. order preserving, i.e., $\sigma(f(i)) > \sigma(f(j))$ whenever $\pi(i) > \pi(j)$.

For a subset $A \subset [1, k]$, a function $f : A \rightarrow [1, n]$ will be called a partial (π, σ) -legal mapping if the above two conditions hold for all $i, j \in A$.

For example, the permutation $\pi = (213)$ can be embedded in $\sigma = (124536)$, with

f being, e.g., $f(1) = 3$, $f(2) = 5$, $f(3) = 6$. The corresponding subsequence σ' is (436).

Families of permutations of the type $S_n(\pi) = \{\sigma \in S_n \mid \pi \not\prec \sigma\}$ occur naturally, e.g., in the study of stack-sortable permutations, or, more notably, in the well-known, recently confirmed [9] Stanley–Wilf conjecture, claiming that for a fixed π the size of $S_n(\pi)$ grows at most exponentially in n . The main obstacle for proving this conjecture was a poor understanding of the structure of $S_n(\pi)$. This structure, however, is clearly present and easily detectable for special π 's. This suggests that some (and, in particular, random) permutations are more complex in this respect than the others. The present paper can be viewed as an attempt to quantify this complexity.

We study the following algorithmic problem, to be called the *subpattern (SP) problem*:

Let $\pi \in S_k$ be fixed. Given an input $\sigma \in S_n$, determine whether the relation $\pi \hookrightarrow \sigma$ holds.

To distinguish between π and σ , we shall call the former a *pattern* and the latter an *input* permutation. The SP problem is, of course, polynomially tractable, and the brute-force approach (checking all the subpatterns of σ of size k) gives an $O(n^k)$ upper bound. A closer look soon reveals that the complexity of the SP problem crucially depends on the structure of the pattern π , and while, for instance, for $\pi = (12 \dots k)$ the problem can be solved in time $\approx n \cdot \log k$ (using, e.g., the patience sorting), there is no obvious way to substantially improve upon the brute-force upper bound for a random $\pi \in S_k$. Possible evidence for the hardness of this problem is the following fact from [5]. When π is *not* fixed, but comes as a part of the input, the problem of deciding whether $\pi \hookrightarrow \sigma$ holds is NP-complete. In our SP problem, however, only the exponent of n (asymptotically) matters, while the dependence on k can be exponential and beyond, as k is constant. This is a typical situation in the parameterized complexity theory (see, e.g., [6]).

How then does the complexity of the SP problem depend on π ? The question has been addressed before only for a special class of *separable* permutations (see [5] and the bibliography therein), but, to our best knowledge, the general case has not been studied so far. We introduce two suitable related notions of *complexity* of a pattern π , a $C(\pi)$, and a somewhat finer (and smaller) $C^{\mathbf{T}}(\pi)$, and show that the SP problem for π can be solved in time $O(n^{1+C(\pi)})$, and also in time $O(n^{\alpha_\pi \cdot C^{\mathbf{T}}(\pi)})$, where $1 \leq \alpha_\pi \leq 2$ is a constant depending on π . This is the main algorithmic contribution of the paper.

We go on to study the two complexity measures. The good news is that $C(\pi)$, and hence $C^{\mathbf{T}}(\pi)$, never exceeds $0.47k + o(k)$. Unfortunately, for most $\pi \in S_k$, $C^{\mathbf{T}}(\pi) = \Omega(k)$. However, this is not *always* the case, and many nonrandom classes of patterns have much smaller complexity; e.g., the separable patterns studied in [5] have complexity $C^{\mathbf{T}}(\pi) \leq 4$ (see the remark at the end of section 3.3). To stress this point, we present two other naturally defined classes of patterns π for which $C(\pi) = O(\sqrt{k})$.

We establish some general structural properties of the two permutation-complexity measures. In particular, we show that $C^{\mathbf{T}}(\pi) \leq C(\pi) \leq O(\log k) \cdot C^{\mathbf{T}}(\pi)$. It also turns out that $C(\pi)$ and $C^{\mathbf{T}}(\pi)$ are closely related to the pathwidth and the treewidth of a graph G_π defined by the permutation π . We show also that there exist $\pi, \rho \in S_k$ with $C(\pi), C(\rho) \leq 6$, while $C(\pi \circ \rho) = \Omega(\sqrt{k})$.

While the exact computation of $C(\pi)$ appears to be computationally difficult (it probably requires time exponential in k , and thus is not practical for, say, $k = 30$), an $O(\log k)$ -approximation of $C(\pi)$ can be obtained in time polynomial in k , yielding

a reasonably good practical algorithm for the SP problem with low-complexity π 's. The same holds for $C^{\mathbf{T}}(\pi)$. In fact, due to relation to the treewidth of G_π , it can be approximated even better, within a factor of $O(\sqrt{\log C^{\mathbf{T}}(\pi)})$ (by [7]).

To sum up, in this paper we take the first steps in the study of the asymptotic complexity of the SP problem and its dependence on the properties of the (fixed) pattern $\pi \in S_k$. A natural question arising from the present work is whether the parameterization of π 's by $C^{\mathbf{T}}(\pi)$ is the correct one. Or, phrasing it more concretely, *Can the SP problem be solved in time $O(n^{o(C^{\mathbf{T}}(\pi))})$ for any infinite family of patterns $\{\pi\}$?*

2. The algorithms. We shall be mainly interested here in either finding a (single) embedding $\pi \hookrightarrow \sigma$ or concluding that no such embedding exists. The approach is basically that of dynamic programming. The pattern π will be gradually *exposed*, and at each stage the corresponding tables will be suitably refined.

Consider a chain of subsets of $[1, k]$ (i.e., the indices), $\emptyset = A_0 \subset A_1 \subset \dots \subset A_k = [1, k]$, such that each $A_i \setminus A_{i-1}$ consists of a single element. Setting $\tau(i) = A_i \setminus A_{i-1}$, we get a 1-1 function $\tau : [1, k] \rightarrow [1, k]$, to be called the *order of exposure*, defined by (and defining) the chain of subsets. The restrictions $\pi_i = \pi|_{A_i}$ form a chain of subsequences $\emptyset = \pi_0 \hookrightarrow \pi_1 \hookrightarrow \dots \hookrightarrow \pi_k = \pi$. For example, let $\pi = (35412)$, and consider the chain of subsets

$$\emptyset \subset \{4\} \subset \{2, 4\} \subset \{2, 4, 5\} \subset \{2, 3, 4, 5\} \subset \{1, 2, 3, 4, 5\}.$$

The corresponding exposure order is (42531). The corresponding chain of subsequences is

$$\emptyset \hookrightarrow (1) \hookrightarrow (51) \hookrightarrow (512) \hookrightarrow (5412) \hookrightarrow (35412) = \pi.$$

Roughly speaking, our strategy is to create tables $T_0, T_1, \dots, T_k$, where T_i will store partial (π, σ) -legal mappings $f_i : A_i \rightarrow [1, n]$. Equivalently, each $f_i \in T_i$ describes an embedding $\pi_i \hookrightarrow \sigma$. The last table T_k will contain (π, σ) -legal mappings, if they exist.

In order to obtain T_i , we take the partial (π, σ) -legal mappings $\{f_{i-1}\}$ stored in T_{i-1} , and extend, if possible, each $f_{i-1} \in T_{i-1}$ to a set of (π, σ) -legal mappings $\{f_i\}$ to be stored in T_i . Extending an f_{i-1} means assigning a value to $\tau(i) = A_i \setminus A_{i-1}$.

Storing in T_i all possible partial (π, σ) -legal mappings is infeasible: the size of T_i can get as large as $\Omega(n^i)$ (e.g., for a random σ), and one gains little compared to the brute-force algorithm. The goal then is to condense the content of T_i without incurring an information loss.

Let us first examine the situation in a particularly clear and simple case when $\pi = (123 \dots k)$, and the exposure order τ is also $(123 \dots k)$. Equivalently, $A_i = \{1, 2, \dots, i\}$ for $i = 1, \dots, k$. Clearly, the *only* information about any particular f_i to be used in the subsequent extensions is solely the value of $f_i(i)$. Thus, storing in T_i just the values $\{f_i(i)\}$, a row per value, we get tables of size at most $O(n)$ that succinctly represent all possible embeddings of π_i into σ ; different partial (π, σ) -legal f_i 's may of course have the same representative in T_i . This leads to an algorithm of complexity $O(n^2)$, improving on $O(n^k)$.

For a better understanding of the nature of the gain in the above example, let us return to the general case and have a closer look on the structure of legal extensions $\{f_i\}$ of some f_{i-1} . Since any such f_i must agree with f_{i-1} on A_{i-1} , the only question is where the new index $\tau(i)$ can be mapped. In view of Definition 1.1, the obvious restrictions on the value of $j = f_i(\tau(i))$ are the following.

Monotonicity: Let $p_i^- \in A_{i-1}$ and $p_i^+ \in A_{i-1}$ be, respectively, the largest element in A_i smaller than $\tau(i)$, and the smallest element in A_i larger than $\tau(i)$. Then, in order to maintain the monotonicity property, it must hold that

$$f_{i-1}(p_i^-) < j < f_{i-1}(p_i^+) .$$

Order preservation: Let $x_i \in \pi_{i-1}$ be the largest element smaller than $\pi(\tau(i))$ appearing in the subpattern π_{i-1} , and let $y_i \in \pi_{i-1}$ be the smallest element larger than $\pi(\tau(i))$ appearing in π_{i-1} . Let $q_i^- \in A_{i-1}$ and $q_i^+ \in A_{i-1}$ be the indices of x_i and y_i , respectively, i.e., $\pi(q_i^-) = x_i$ and $\pi(q_i^+) = y_i$. Then, in order to maintain the order preservation property, it must hold that

$$\sigma(f_{i-1}(q_i^-)) < \sigma(j) < \sigma(f_{i-1}(q_i^+)) .$$

Call $\{p_i^-, p_i^+, q_i^-, q_i^+\} \subseteq A_{i-1}$ the *significant* elements for the i th stage. (Note that this set may contain less than four elements; e.g., for $i = 1$, it is empty.)

EXAMPLE. Consider, e.g., the pattern $\pi = (318257946)$ and the exposure order $\tau = (742936518)$. Then $A_5 = \{7, 4, 2, 9, \underline{3}\} = \{2, \underline{3}, 4, 7, 9\}$ and $\pi_5 = (18296)$ (the underlined index/element is the one last exposed). Respectively, $p_5^- = 2$, $p_5^+ = 4$, $x_5 = 6$, $y_5 = 9$, $q_5^- = 9$, $q_5^+ = 7$.

In the simple case when $\pi = (123456789)$ and $\tau = (123456789)$, $p_5^- = q_5^- = 4$, while p_5^+ and q_5^+ do not exist.

PROPOSITION 2.1. Let π, σ, τ be as above. Let f_{i-1} be a partial (π, σ) -legal mapping. Then, the extension f_i of f_{i-1} obtained by setting $f_i(\tau(i)) = j$ is a partial (π, σ) -legal mapping if and only if the above monotonicity and the order preservation restrictions are met. Consequently, the set of all possible values $\{f_i(\tau(i))\}$ for any legal extension of f_{i-1} is fully determined by the values of f_{i-1} on the i th stage significant elements.

Proof. The necessity is obvious. The sufficiency is also rather obvious. Since f_{i-1} is legal, if the extended f_i is not strictly increasing as required by Definition 1.1, then either $f_{i-1}(p^-) \geq j$ or $f_{i-1}(p^+) \leq j$ must hold. Also if f_i is not order preserving, then either $\sigma(f_{i-1}(q^-)) \geq \sigma(j)$ or $\sigma(f_{i-1}(p^+)) \leq \sigma(j)$. $\square$

Next, we define for each $i = 0, 1, \dots, k-1$ the set $U_i \subseteq [1, k]$ of *unforgettable* elements:

$$U_i = \cup_{j=i+1}^k \{p_j^-, p_j^+, q_j^-, q_j^+\} .$$

A corollary to Proposition 2.1 is the following.

COROLLARY 2.2. For any partial (π, σ) -legal mapping $f_i : A_i \rightarrow [1, n]$, the only elements of A_i whose value will ever be significant for the subsequent extensions are $U_i \cap A_i$. In other words, in order to determine whether or not a partial (π, σ) -legal f_i can be extended to an entire (π, σ) -legal mapping, it suffices to know $f_i|_{U_i \cap A_i}$.

Before going on with the formal description of the emerging algorithm, let us have a different, clearer look at the system of sets $\{U_i \cap A_i\}_{i=1, \dots, k}$.

DEFINITION 2.3. Let $\pi \in S_k$ be a pattern. The incidence graph G_π is an undirected multigraph on vertices $[1, k]$ with two types of edges: blue ones and red ones. The blue edges are $E^{\text{blue}}(G_\pi) = \{(i, j) \mid |i - j| = 1\}$. The red edges are $E^{\text{red}}(G_\pi) = \{(i, j) \mid |\pi(i) - \pi(j)| = 1\}$; i.e., G_π is a union of two Hamiltonian paths, blue: $(1 - 2 - 3 - \dots - n)$, and red: $(\pi^{-1}(1) - \pi^{-1}(2) - \pi^{-1}(3) - \dots - \pi^{-1}(n))$. Curiously, G_π is almost identical to the breakpoint graph of π as defined by Bafna and Pevzner [2] for completely different purposes.

DEFINITION 2.4. For $A \subseteq [1, n]$ define $\partial_\pi A \subseteq A$, the boundary of A in G_π , as the set of all elements in A that have a neighbor (in G_π) outside of A . For future use,

we refine $\partial_\pi A$ to $\partial_\pi^{\text{blue}} A$ and $\partial_\pi^{\text{red}} A$ (which may or may not be disjoint) according to the color of the edge between the element and its external neighbor.

PROPOSITION 2.5. $U_i \cap A_i = \partial_\pi A_i$.

Proof. Let $v \in \partial_\pi A_i$; this means that v possesses a neighbor $u \notin A_i$. Let $\tau^{-1}(u) > i$ be the stage when u is first exposed by τ . It is readily checked that v is a significant element for this stage, and therefore $v \in U_i$.

Conversely, assume that $v \in A_i$ does not belong to $\partial_\pi A_i$. This means that $v \pm 1$ (the blue neighbors) and $\pi^{-1}(\pi(v) \pm 1)$ (the red neighbors) have already been exposed or do not exist. But then v cannot possibly become significant at any stage in the future because its exposed neighbors will prevent it. Thus, $v \notin U_i$. $\square$

From now on, we shall use $\partial_\pi A_i$ for $U_i \cap A_i$. Returning to our algorithmic strategy, we follow the minimalistic logic of dynamic programming (preserve only what is essential for the future) and observe that for every $f_i \in T_i$ it suffices to store only the values of f_i on $\partial_\pi A_i$. This leads to the following algorithm for the SP problem. Consider (for now, fixed) exposure order τ . Compute offline all $\{\partial_\pi A_i\}_{i=1, \dots, k-1}$. This takes constant (more precisely, $O(k^2)$) time. The data structure of the main procedure is a sequence of tables $\{T_i\}_{i=0}^k$. The rows of each T_i will contain a numerical field per each element of $\partial_\pi A_i$ and an additional single field for a pointer to a row of T_{i-1} . A row represents a partial (π, σ) -legal f_i on A_i by its values on $\partial_\pi A_i$, and it also keeps a pointer to some $f_{i-1} \in T_{i-1}$ whose legal extension resulted in the present f_i . It is required that no two rows of T_i will be identical with respect to the numerical fields. Observe that T_k has a single row containing only the pointer, and T_0 is empty.

ALG1-SP $_{\pi, \tau}(\sigma)$:

INPUT: $\sigma \in S_n$ - an input permutation;

$\pi \in S_k$ - a pattern; (* fixed *)

$\tau \in S_k$ - an exposure order; (* for now fixed *)

OUTPUT: an embedding of π into σ , or a message “NONE”;

```

set  $T_0 = \text{EMPTY ROW}$ ;
for  $i = 1$  to  $k$  do {
  set  $T_i = \emptyset$ ;
  for each row of  $T_{i-1}$  (* corresponding to some  $f_{i-1}$  *) do
    (* create all legal extensions *) {
      for  $j = 1$  to  $n$  do {
        (* check whether  $j$  is a legitimate value for  $f_i(\tau(i))$  *)
        check whether  $f_{i-1}(p_i^-) < j < f_{i-1}(p_i^+)$ ; (* Monotonicity *)
        check whether  $\sigma(f_{i-1}(q_i^-)) < \sigma(j) < \sigma(f_{i-1}(q_i^+))$ ; (* Order Preservation *)
        if both checks succeeded, do {
          create a new row of  $T_i$ ;
          extend  $f_{i-1}$  by setting  $f(\tau(i)) = j$ ;
          fill the numerical fields with the values of the extended  $f_{i-1}$  on  $\partial_\pi A_i$ ;
          if the new row does not already occur in  $T_i$ ,
            add it to  $T_i$ , and direct its pointer to the current row in  $T_{i-1}$ ;
        }
      }
    }
}
}
if  $T_k$  is empty return “NONE”;
else, using the back pointers, retrieve an actual embedding  $f_k$ , and print it.
```

The correctness of the algorithm follows from Corollary 2.2. The time complexity is governed by $\max_i |T_i|$, the size of the largest table. Indeed, at every stage $i > 2$, $O(n)$ operations are performed per each row of T_{i-1} . In addition, one must take care not to create identical rows in T_i ; this can be achieved by, e.g., an online bucket sort. In total, we have $O(|T_i| + n \cdot |T_{i-1}|)$ operations for stage i . In the end, the reconstruction of the resulting f_k may require an additional time $O(kn)$. Combining all this, and ignoring the additive and multiplicative factors depending solely on k , we get $O(\sum_{i=0}^k n \cdot |T_i|) = O(n \cdot \max_i |T_i|)$. Now, by its definition, $|T_i| \leq \binom{n}{|\partial_\pi A_i|} = O(n^{|\partial_\pi A_i|})$. Setting $C_\tau(\pi) = \max_i |\partial_\pi A_i|$, we conclude that the time complexity of **ALG1-SP** $_{\pi,\tau}(\sigma)$ is $O(n^{1+C_\tau(\pi)})$.

Observe that the exposure order does not have to be fixed and that it makes good sense to choose the best possible τ for the given π . Thus, we have naturally arrived at the suitable notion of permutation complexity as follows.

DEFINITION 2.6. Define $C(\pi)$, the complexity of a permutation $\pi \in S_k$, as

$$C(\pi) = \min_{\tau} C_\tau(\pi).$$

Our discussion so far can be summarized by the following theorem.

THEOREM 2.7. The SP problem for a pattern $\pi \in S_k$ can be solved in time $O(n^{1+C(\pi)})$.

Next, we present a generalization of **ALG1-SP** $_{\pi,\tau}$. The basic idea is simple: instead of extending the partial embeddings by a single element, one can *merge* partial embeddings of (almost) disjoint sets. The following lemma, a generalization of Proposition 2.1, provides the basis for this approach.

LEMMA 2.8. Let A, B be subsets of $[1, k]$ satisfying $A \cap B \subseteq \partial_\pi A \cap \partial_\pi B$. Let also f_A and f_B be partial (π, σ) -legal mappings of A and B , respectively, into $[1, k]$. Denote by $f_{A \cup B} : A \cup B \rightarrow [1, k]$ their common extension, possibly ill-defined (this happens when f_A and f_B disagree on $A \cap B$). Then, $f_{A \cup B}$ is well-defined partial (π, σ) -legal if and only if its restriction to $\partial_\pi A \cup \partial_\pi B$ is such.

Proof. The well-definedness is obvious, as $A \cap B \subseteq \partial_\pi A \cap \partial_\pi B$. Assuming $f_{A \cup B}$ is well defined, we address (π, σ) -legality. The necessity is obvious: any restriction of a partial (π, σ) -legal mapping is legal as well. For the sufficiency part, assume, e.g., that $f_{A \cup B}$ violates the monotonicity requirement of Definition 1.1. It is, however, strictly increasing on A and B separately. Assume that the violation $f_A(i) \geq f_B(j)$ occurs on a pair $i < j$ where, w.l.o.g., $i \in A$ and $j \in B$. Let i_+ be the largest element in A such that $[i, i_+] \subseteq A$, and let j_- be the smallest element in B such that $[j_-, j] \subseteq B$. Clearly, $i_+ \in \partial_\pi^{\text{blue}} A$ and $j_- \in \partial_\pi^{\text{blue}} B$. (Recall that the blue path represents $[1, k]$ in the natural order.) By the assumptions on A, B there are two possibilities: either $[i, i_+] = [j_-, j]$, or $i_+ \leq j_-$, implying $f_A(i_+) > f_B(j_-)$. In both cases we conclude that a violation must occur on $\partial_\pi^{\text{blue}} A \cup \partial_\pi^{\text{blue}} B$.

By the same argument, if $f_{A \cup B}$ violates the order-preservation requirement, the violation must occur on $\partial_\pi^{\text{red}} A \cup \partial_\pi^{\text{red}} B$, as the red path represents $[1, k]$ in the order of increasing value of π . $\square$

A rooted binary tree T directed towards the root, with leaves labeled by elements of $[1, k]$ (a unique element per leaf, all the elements appearing, and possibly more than once), will be called an *exposure tree* of π provided it satisfies the following additional requirement. A vertex $v \in T$ *dominates* another vertex u if there is a directed path from u to v in T . Let $S_v^T \subseteq [1, k]$ denote the set of the labels on the leaves of T dominated by v . In particular, if v is the root of T , then $S_v^T = [1, k]$. The additional requirement on T is that if u_l, u_r are the parents of some $u \in T$, then the sets $S_{u_l}^T, S_{u_r}^T$ must satisfy the requirements of Lemma 2.8. As we shall see in section 3.3, this

requirement turns out to be quite natural. Observe, e.g., that when each label from $[1, k]$ appears exactly once, the requirement is automatically satisfied.

We now present the second algorithm. To avoid confusion about the meaning of the T_v 's, let us denote here (and only here) the exposure tree by Z rather than by T . Given an exposure tree Z , compute first, as a part of preprocessing, all S_v^Z 's and $\partial_\pi S_v^Z$'s. The data structure for the main procedure is a set of tables $\{T_v\}_{v \in Z}$, logically organized in some postorder of Z ; the root is the last. The rows of T_v will contain a numerical field per each element of $\partial_\pi S_v^Z$, and two additional fields for pointers to rows of the tables corresponding to v 's two parents. We require that no two rows of T_v are identical with respect to the numerical fields. As before, the rows of T_v represent partial (π, σ) -legal mappings $f_{S_v^Z} : S_v^Z \rightarrow [1, n]$ by storing their values on $\partial_\pi S_v^Z$. The pointers are used to keep track of the two mappings whose merge (i.e., the common extension) yielded the current $f_{S_v^Z}$.

ALG2-SP $_{\pi, Z}(\sigma)$:

INPUT: $\sigma \in S_n$ - an input permutation;

$\pi \in S_k$ - a pattern; (* fixed *)

Z - a tree as above; (* for now fixed *)

OUTPUT: an embedding of π into σ , or a message "NONE";

process the nodes v of Z in some order consistent with the partial order induced by Z {

if v is a leaf, set $T_v = [1, n]$, and set all pointers to NULL;

else (* $T_v = \text{Merge}(T_u, T_w)$, where u and w are the parents of v *)

for each $r_u \in T_u$, $r_w \in T_w$ (* merge the two rows *) {

unite the domains of the corresponding partial mappings

to get a partial mapping f^* of $\partial_\pi S_u^Z \cup \partial_\pi S_w^Z$;

verify that f^* is well-defined partial (π, σ) -legal;

if yes, create a new row by assigning the numerical fields

the values of f^* on $\partial_\pi(S_u^Z \cup S_w^Z)$;

check whether there is no such row in T_v already;

if not, add it to T_v , and direct its pointers to r_u and r_w ;

}

}

if T_{root} is empty return "NONE";

else, using the back pointers, retrieve an actual embedding f , and print it.

(* this is done by running a DFS from the root according to the back pointers,

and retrieving $f(S_v^T)$ upon blackening v . *)

The correctness of **ALG2-SP $_{\pi, Z}$** follows from Lemma 2.8, as representing each legal $f_{S_v^Z}$ by its values on $\partial_\pi S_v^Z$ preserves all the information about $f_{S_v^Z}$ that will be needed in the future.

The time complexity of the algorithm depends on the implementation of the procedure **Merge**(T_u, T_w). The trivial implementation compares each row in T_u to each row in T_w . Ignoring the additive and multiplicative factors depending solely on k , we see that with this implementation, for inner vertex v of Z with parents u and w , one performs $O(|T_u| \cdot |T_w|)$, i.e., $O(n^{|\partial_\pi S_u^Z| + |\partial_\pi S_w^Z|})$ operations. In addition, the online bucket sorting (needed to ensure the uniqueness of a row) costs $O(n^{|\partial_\pi S_v^Z|})$, which is dominated by the previous term. Thus, the time complexity in this case can be as large as

$$O\left(n^{\max_{v \in Z} |\partial_\pi S_u^Z| + |\partial_\pi S_w^Z|}\right).$$

Let us outline a slightly improved implementation, starting with an explanation of its logic. An uninterested reader can safely skip this part.

For brevity, set $\Delta_z = \partial_\pi S_z^Z$ for $z \in Z$. Consider the legality comparisons performed while creating r from r_u and r_w . There are at most $\min\{|\Delta_u|, |\Delta_w|\}$ comparisons of the type “ $r_u[i] ? r_w[j]$ ” (for monotonicity) and at most the same number of comparisons of the type “ $\sigma(r_u[i]) ? \sigma(r_w[j])$ ” (for order preservation). Since all the relevant indices $i \in \Delta_u$ and $j \in \Delta_w$ are fixed and known in advance, there are two simple (linear) transformations $r_u \mapsto R_u$ and $r_w \mapsto R_w$, such that the corresponding r is legal if and only if R_u strictly dominates R_w on all coordinates. These transformations can be specified in terms of π and σ alone; the specification can be done in advance, prior to starting with the main algorithm. The vectors R_u and R_w have the same length, being the number of legality comparisons as above. It is at most $2 \cdot \min\{|\Delta_u|, |\Delta_w|\} < 2k$. The entries of R_u are $\pm r_u[i]$ or $\pm \sigma(r_u[i])$; the entries of R_w are $\pm r_w[j]$ or $\pm \sigma(r_w[j])$.

Given two sets of vectors $X, Y \subset \mathbb{R}^d$, finding a single pair $x \in X, y \in Y$ such that y strictly dominates x on all coordinates, or deciding that no such pair exists, can be done in time $\tilde{O}(|X| + |Y|) = O((|X| + |Y|) \cdot \log^{d-1}(|X| + |Y|))$, which is much better than the trivial $O(|X| \cdot |Y|)$.¹

Since the table T_v should represent all possible partial (π, σ) -legal mappings of S_v^Z , producing a single such mapping will not help. Observe, however, that in creating a row r of T_v from $r_u \in T_u$ and $r_w \in T_w$, only the numerical values on D_v will be stored in r , while the rest of the values are needed only for the current step legality comparisons. Thus, it makes sense to bucket the rows of T_u according to their value on $\Delta_u \cap \Delta_v$, and the rows T_w according to their value on $\Delta_w \cap \Delta_v$. Instead of comparing the rows of T_u and T_w in a pairwise manner, let us compare them bucketwise. Now, in comparing two such buckets, it is enough to get a *single* legal pair, or decide that there is none. Thus, the above idea applies to bucket-comparison, improving the overall complexity of the stage v from $O(n^{|\Delta_u|+|\Delta_w|})$ to

$$\tilde{O} \left(n^{\max_{v \in T} \{ |\Delta_u| + |\Delta_w \cap \Delta_v|, |\Delta_w| + |\Delta_u \cap \Delta_v| \}} \right).$$

We omit the straightforward calculation.

To simplify the presentation, we define the second natural notion of permutation complexity as follows.

DEFINITION 2.9. *For a permutation $\pi \in S_k$ and a fixed exposure tree T , define $C_T = \max_{v \in T} |\partial_\pi S_v^T|$. The tree-complexity $C^{\mathbf{T}}(\pi)$ of π is the minimum of $C_T(\pi)$ over all T 's.*

The above discussion can be summarized by the following theorem.

THEOREM 2.10. *The SP problem for a pattern $\pi \in S_k$ can be solved in time $O(n^{\alpha_\pi \cdot C^{\mathbf{T}}(\pi)})$, where $1 \leq \alpha_\pi \leq 2$.*

Observe that $C(\pi) \geq C^{\mathbf{T}}(\pi)$. Indeed, let τ be the optimal exposure order, and let T_τ be the following rooted caterpillar tree: the root's left son is a leaf labeled $\tau(k)$, right-left grandson is a leaf labeled $\tau(k-1)$, right-right-left grandson is a leaf labeled $\tau(k-2)$, and so on, with $\tau(1)$ and $\tau(2)$ being brothers at the lowest level. Direct the edges towards the root to obtain an exposure tree T_τ . Clearly, it holds that $C_{T_\tau}(\pi) = C_\tau(\pi)$. Moreover, the running time of **ALG2-SP** $_{\pi, T_\tau}$ with the trivial implementation is precisely $O(n^{1+C(\pi)})$, the optimal running time of the first algorithm.

The complexity measures $C(\pi)$ and $C^{\mathbf{T}}(\pi)$ are natural graph-theoretic parameters

¹Bernard Chazelle, private communication.

of the graph G_π . Their general properties and interrelations, and their relations to standard graph-theoretic parameters, are studied in the next section.

3. Complexity of permutations.

3.1. A general upper bound. The first natural question to ask is how well a fixed exposure order τ can perform for $\pi \in S_k$. The answer is given by the following proposition.

PROPOSITION 3.1. *For the identity exposure order Id , $C_{Id}(\pi) \leq \frac{2}{3} \cdot k + 1$. This is essentially best possible for a fixed exposure order, as for every τ there exists π' such that $C_\tau(\pi') \geq \lfloor \frac{2}{3} \cdot k \rfloor$.*

Proof. Clearly, $|\partial_\pi^{\text{blue}} A_i| = 1$ for all i . For the red boundary, consider any $A \subseteq [1, k]$. Since the red degree of a vertex $v \in V(G_\pi)$ is at most 2, $|\partial_\pi^{\text{red}} A| \leq \min\{2|A|, |A|\} \leq \frac{2}{3} \cdot k$. This establishes the first part of the proposition.

For the second part, consider first $\tau = Id$. Assume for convenience that $k = 3q$. It suffices to find a pattern $\pi_k \in S_{3q}$ such that $\partial_\pi^{\text{red}} A_{2q} = A_{2q}$. A generic construction of such an A is exemplified for $k = 9$: $\pi_9 = (1\ 3\ 4\ 6\ 7\ 9\ 2\ 5\ 8)$; i.e., 2, 5, 8, ... are removed and placed at the end in this order. For an arbitrary τ , observe that exposing the permutation $\rho = \pi \circ \tau^{-1}$ according to exposure order τ yields exactly the same values, and hence the same red boundaries, as in exposing π according to Id . $\square$

REMARKS.

1. *So far we have treated τ as the exposure order, but in fact τ is also a permutation in S_k , and from now it often will be treated as such.*
2. *The complexity $C(\pi_k)$ of the above generic “hard” permutation π_k is just 4 for all k ’s.*

The next natural question is how well a random exposure order behaves. The answer is as follows.

THEOREM 3.2. *For any pattern $\pi \in S_k$, almost all exposure orders τ satisfy $C_\tau(\pi) \leq 0.54 \cdot k + o(k)$.*

Proof. The proving mechanism to be used here and in the following theorem is as follows.

1. Given a pattern $\pi \in S_k$, define a random process $\mathcal{P}$ which produces the exposure order $\tau \in S_k$ by exposing $[1, k]$ an index at a time. The process $\mathcal{P}$ will be described by specifying the conditional distribution according to which the next step is performed.
2. For each $i \leq k$, consider a random variable $X_i = |\partial_\pi A_i|$ defined by τ . Compute its expectation $E[X_i]$, and show that X_i is well concentrated, i.e., that for some function $g(k) = o(k)$ it holds that

$$\Pr[X_i - E[X_i] \geq g(k)] = o(1/k).$$

To show this, a standard martingale technique is used (see, e.g., [1] and [10] for a detailed discussion of it). For each i and $t = 0, 1, \dots, k$ define a random variable Y_i^t as the expected value of X_i conditional on the values of $\tau([1, t])$. Clearly, $E[X_i] = Y_i^0$ and $\{Y_i^t\}_{t=0}^k$ form a martingale, i.e., $E[Y_i^{t+1} | Y_i^t] = Y_i^t$. The next step is to establish the bounded differences property, i.e., show that there exists a constant L such that $|Y_i^{t+1} - Y_i^t| \leq L$ for all i and t . Finally, employing the Azuma inequality, conclude that

$$\Pr[X_i - E[X_i] \geq 2L\sqrt{k \ln k}] \leq 1/k^2 = o(1/k).$$

3. Having achieved this, we conclude that a random permutation τ drawn according to $\mathcal{P}$ almost surely satisfies $C_\tau(\pi) = \max_i X_i \leq \max_i \mathbb{E}[X_i] + o(k)$.

This is all we need.

Let us see how the above strategy works for analyzing a random uniform $\tau \in S_k$. It will be convenient to use G_π and speak of vertices instead of indices. Thus, $\mathcal{P}$ at each stage will expose a random uniformly chosen previously unexposed vertex.

First we estimate $\mathbb{E}[X_i]$. What is the probability that vertex $v \in V(G)$ belongs to $\partial_\pi A_i$? A simple combinatorial argument shows that if v has degree 4, then

$$\Pr[v \in \partial_\pi A_i] = \frac{i}{k} \left[1 - \frac{i-1}{k-1} \cdot \frac{i-2}{k-2} \cdot \frac{i-3}{k-3} \cdot \frac{i-4}{k-4} \right] \leq h\left(\frac{i}{k}\right) + o(1),$$

where h is a real valued function $h(x) = x(1-x^4)$. If the degree of v is less than 4, the above probability only decreases. Thus, by linearity of expectation, $\mathbb{E}[X_i] = k \cdot h(\frac{i}{k}) + o(k)$. To show that X_i are concentrated as required, it suffices to verify that the exposure martingale $\{Y_i^t\}_{i=0}^k$ has the bounded differences property. But this is easy: since the exposure of the vertex $\tau(i)$ can influence no more than four vertices besides itself, $L = |Y_i^{t+1} - Y_i^t| \leq 1 + 4 = 5$.

We conclude that almost surely,

$$\max_i X_i \leq \left(\max_{x \in [0,1]} h(x) \right) \cdot k + o(k) + O(\sqrt{k \ln k}) = 0.54 \cdot k + o(k). \quad \square$$

How can the constant 0.54 of Theorem 3.2 be improved? Clearly, the process $\mathcal{P}$ should be more “sensitive” to the current boundary and not attempt to increase it needlessly. A natural improvement on $\mathcal{P}$ would be to fill up the “holes” (i.e., the unexposed vertices, all of whose neighbors are exposed) upon their creation. Such an operation can only be beneficial for the size of the boundaries, and there is no gain in delaying it. Therefore, the improved $\mathcal{P}$ would at each “long step” randomly expose a vertex and then deterministically fill the holes it created. Call the new process $\mathcal{P}_1$.

THEOREM 3.3. *Almost all exposure orders $\tau \in S_k$ produced by $\mathcal{P}_1$ satisfy $C_\tau(\pi) \leq 0.47 \cdot k + o(k)$.*

Proof (sketch). Define the *closure* of a set $A \subset V(G_\pi)$ as the set obtained from A by filling all its holes, i.e., $A \cup \{u \in \bar{A} \mid \Gamma(u) \subseteq A\}$, where $\Gamma(u)$ is the set of u ’s neighbors in G_π . Notice that filling a hole cannot create a new hole. Let $\{A_i\}$ be the sets produced by $\mathcal{P}$ as before, and let $\{B_i\}$ be their respective closures (some of the B_i ’s may be identical). It is easy to be convinced that the system of sets produced by the “long steps” of process $\mathcal{P}_1$ under the same random choices as in $\mathcal{P}$ is precisely $\{B_i\}$. In addition, there will be intermediate sets created during the “short” steps of $\mathcal{P}_1$, i.e., the random exposure and the subsequent deterministic hole filling. Since the size of the boundary of any intermediate set created during the “long step” $B_i \rightarrow B_{i+1}$ is at most $|\partial_\pi B_i| + 1$, it suffices to analyze $\{\partial_\pi B_i\}$. From here, we follow closely the proof scheme of Theorem 3.2. Let $X_i = |\partial_\pi B_i|$. We start with estimating $\mathbb{E}[X_i]$. What is the probability that vertex $v \in V(G)$ belongs to $\partial_\pi B_i$? Clearly, this happens when $v \in A_i$, while at least one of v ’s neighbors is not in A_i and has at least one neighbor which is not in A_i as well. The probability of this event is determined by the local structure of G_π in the vicinity of v . There are numerous cases to consider, each quite simple in itself. We shall discuss in detail here only the typical (and the worst) case, which is when the 2-neighborhood of v is a 4-regular tree. Then, $\Pr[v \in \partial_\pi B_i] \leq h_1(|A_i|/k) + o(1)$, where $h_1(x)$ is a sum of terms corresponding to

the number of neighbors of v in the compliment of A_i :

$$h_1(x) = x \cdot \sum_{j=1}^4 \binom{4}{j} (1-x)^j x^{4-j} (1-x^{3j}).$$

Since the maximum value of $h_1(x)$ on $[0, 1]$ is less than 0.47, by linearity of expectation we get

$$\max_i \mathbb{E}[X_i] \leq k \left(o(1) + \max_{x \in [0,1]} h_1(x) \right) \leq 0.47 \cdot k + o(k).$$

As before, in order to complete the proof it remains to verify that the exposure martingale $\{Y_i^t\}$ has the bounded differences property. It is easy to verify that an exposure of an extra vertex v at any particular moment may influence at most the 2-ball of v , i.e., at most $1 + 4 + 3 \cdot 4 = 17$ vertices, and thus $|Y_i^{t+1} - Y_i^t| \leq 17$. $\square$

The process $\mathcal{P}_1$ can be further improved. Besides holes filling, there is another beneficial operation: if the exposure of a vertex does not increase the size of the current boundary, there is definitely no damage in exposing it. This defines a new process $\mathcal{P}_2$. The analysis of the latter process presents some difficulties, since now an exposure of a single vertex may cause a cascading effect, destabilizing the process. We shall not attempt to carry out an analysis of $\mathcal{P}_2$ here (although it is not out of hand). Let us just mention that for all (large) π 's we have checked, the numerical simulations show that for the random τ created by $\mathcal{P}_2$, $C_\tau(\pi)$ is bounded by $0.35 \cdot k$.

Before concluding this section, we would like to mention an entirely different approach for finding a good exposure order τ for the given π . Take the Laplacian matrix of G_π , find its eigenvector corresponding to the first positive eigenvalue, and expose the vertices in increasing order of their value in the eigenvector. Numerical simulations seem to indicate that this method is superior to the other methods described so far, yielding a constant of about 0.22. While there are good intuitive reasons why this approach should work (see, e.g., [12] for a related discussion), we have at the moment no rigorous results in this direction.

3.2. General lower bound. Next, we show that there exist patterns with $C^T(\pi) = \Omega(k)$. In fact, almost all permutations $\pi \in S_k$ have this property.

THEOREM 3.4. *Let $\pi \in S_k$ be a random, uniformly chosen permutation. Then there exists a universal constant $c > 0.036$ such that*

$$\Pr [C^T(\pi) \leq c \cdot k] = o(1).$$

Proof. The reason the theorem holds is that for a random π , the graph G_π is almost surely an edge-expander with some universal constant $c_1 > 0$. From here the road is short. Consider any exposure tree T . Since it is binary, there exists a vertex $v \in D$ such that $\frac{2}{3}k \geq |S_v^T| \geq \frac{1}{3}k$. The edge-boundary of S_v^T in G_π must be at least $\frac{c_1}{3} \cdot k$, and hence $|\partial_\pi S_v^T| \geq \frac{c_1}{12} \cdot k$.

Establishing the edge-expansion of a random G_π can be done with “bare hands” or using the available master-tools. Since the latter path is both shorter and more instructive, we shall follow it here. Observe that in the proofs of Theorems 3.2 and 3.3 the only structural property of G_π exploited was that it has degree at most 4. Did we lose much by making this simplification? It turns out that, at least for a random π , nothing was lost! More precisely, the model of a uniformly random 4-regular graph on $[1, n]$ is *contiguous* to the model of a graph obtained by taking the union of two

random independent Hamiltonian cycles on $[1, n]$ (see [13] and Theorem 4.15 there for a clear and detailed discussion of this and related issues). In particular, the expansion ratio of a random graph in the first model is (asymptotically) the same as that in the second model. Clearly, the expansion ratio of a graph obtained by taking one fixed and one uniformly random Hamiltonian path on $[1, n]$, i.e., our G_π for a random π , has this property as well.

Now, by a well-known result of Bollobas [4], the edge-expansion ratio c_1 for a uniformly random 4-regular graph is at least 0.44. Hence, $c \geq 0.036$. $\square$

3.3. The two complexity measures: $C(\pi)$ and $C^T(\pi)$. Since $C(\pi)$ and $C^T(\pi)$ are purely graph-theoretic parameters of a special graph G_π , it is natural to extend their definitions (in an obvious manner) to arbitrary graphs G . Thus we arrive (with a slight abuse of notation) at graph-theoretic parameters $C(G)$ and $C^T(G)$. As we shall see, these parameters are closely related to *pathwidth* and *treewidth* of G , respectively.

The pathwidth of G is defined as follows. An *interval representation* of G is a mapping $v \mapsto I_v$ of vertices v of G to closed intervals $I_v \subseteq \mathbb{R}$ such that whenever $(u, v) \in E(G)$, the corresponding intervals I_v and I_u have a nonempty intersection. The *width* of such a representation is the maximum over $x \in \mathbb{R}$ of $|\{v \in V(G) \mid x \in I_v\}|$. The pathwidth of G , $\text{pw}(G)$, is the minimum possible width over all interval representations of G minus 1. The treewidth $\text{tw}(G)$ is defined similarly, only the vertices of G are mapped to subtrees of an (arbitrary) host tree T . The width is optimized over all subtree-representations and all host trees T .

PROPOSITION 3.5. $C(G) = \text{pw}(G)$.

Proof (sketch). Consider an optimal interval representation of G . Sort the intervals $\{I_v\}$ by their starting points $\{s_v\}$ and expose the vertices according to this order. Clearly, at the time of exposure of a vertex v , the current boundary, i.e., the set of already exposed vertices that have not-yet-exposed neighbors, is a subset of $\{u \mid s_v \in I_u\}$. In particular, the size of the current boundary is at most the width of the representation at s_v . Hence, $C(G) \leq \text{pw}(G) + 1$. To refine the argument, assume that our optimal representation of G is also minimal, i.e., no interval in the set can be shortened without harming the representation. Then, every s_v is also the endpoint t_u of some interval I_u of the representation. Let the maximum width be attained at a point t_u . Observe that the vertex u will not contribute to the boundary at the moment when the last of the v 's with $s_v = t_u$ is exposed, and hence $C(G) \leq \text{pw}(G)$.

For the other direction, consider the optimal exposure order τ . For each $v \in V(G)$, let $s_v = \tau^{-1}(v)$, i.e., the moment when v is exposed by τ , and let t_v be the smallest $j \geq s_v$ such that $v \notin \partial_G A_j$, i.e., the first moment when both v and all its neighbors are exposed. Map $v \mapsto [s_v, t_v] \subset \mathbb{R}$. It is readily checked that this is an interval representation of G . Indeed, if $(v, u) \in E(G)$, and, w.l.o.g., $s_u > s_v$, then $t_v \geq s_u$, since up to the moment s_u the exposed vertex v has a nonexposed neighbor u . Hence $s_u \in [s_v, t_v]$.

The maximum width of this representation is attained, as one can easily check, at a moment t_v for some $v \in G$. At this moment, v does not contribute to the present boundary. Hence, $\text{pw}(G) \leq C(G)$. $\square$

Returning for a moment to permutations, we observe that the complexity measure $C(\pi)$ is equal, within a multiplicative factor in $[\frac{1}{4}, 1]$, to the *minimum cut linear arrangement*, also called the *cutwidth*, of G_π . This is due to the fact that G_π has degree bounded by 4. While finding the best τ apparently requires time exponential in k , a suboptimal $\tilde{\tau}$ can be found in time polynomial in k by using Rao and Richa's [11]

$O(\log(k))$ -factor approximation algorithm for the minimum cut linear arrangement.

Next, we turn to $C^T(G)$ and relate it to $\text{tw}(G)$. We assume for simplicity that G is connected.

PROPOSITION 3.6. $C^T(G) \leq \text{tw}(G) + 1 \leq 2 \cdot C^T(G)$.

Proof (sketch). Consider an optimal subtree-representation of G , and let T be its host tree. Choose an arbitrary vertex $r \in T$, and make it the root of T . For each of the subtrees $\{T_v\}_{v \in V(G)}$ of the representation, let r_v be the vertex in T_v closest to r . Performing a series of simple local modifications without ever increasing the width, one can arrive at a representation of G with the following special properties. The rooted tree T is a binary tree. Each leaf of T belongs to a unique subtree T_v of the representation, and, moreover, the leaves of any subtree T_v of the representation (with a possible exception of r_v) are also leaves of T ; besides, no T_v is a single vertex. Now, assigning to each leaf of T the label v of the unique subtree T_v that contains it, we obtain a candidate for an exposure tree for G . It remains to verify that the additional requirement on exposure trees (as in Lemma 2.8) holds for T . Clearly, it suffices to show that for each $v \in V(G)$, $\{x \in T \mid v \in \partial_G S_x^T\} = V(T_v) - \{r_v\}$.

We claim that unless the representation is redundant, this is indeed the case. Observe that $\{x \in T \mid v \in S_x^T\}$ is precisely T_v plus the path from r_v to r , the root of T . Since the T_v 's constitute a subtree-representation of G in T , it follows that $v \notin \partial_G S_{r_v}^T$. The same applies, of course, to the vertices on the path from r_v to r . Consider now any vertex $x \in T_v$ different from r_v , and assume that $v \notin \partial_G S_x^T$. This means that the part of T_v dominated by x in T has already met all T_u 's such that $(v, u) \in E(G)$. Thus, T_v can be reduced to this subtree without causing any harm. Therefore, taking the most "economical" optimal special subtree representation of G , we conclude that T is indeed an exposure tree for G , and, moreover, it holds that $C^T(G) \leq \text{tw}(G) + 1$.

For the other direction, consider an optimal exposure tree T for G . For $v \in V(G)$, let r_v be a vertex in T such that $v \in S_{r_v}^T$ but $v \notin \partial_G S_{r_v}^T$, while this fails for any ancestor x of r_v (i.e., a vertex dominated by r_v in T). The additional requirement on exposure trees implies that r_v is uniquely defined, and that it dominates all the leaves of T labeled v . Let T_v be a subtree of T rooted at r_v , whose vertices are all $x \in T$ lying on a path from a leaf labeled v to r_v . We claim that $\{T_v\}_{v \in G}$ is a tree representation of G in T . Indeed, let $(v, u) \in E(G)$, and assume that r_u is at least as low (i.e., far from the root) as r_v in T . Since $u \notin \partial_G S_{r_u}^T$, r_u must dominate some leaf l labeled v . Thus, r_u lies on a path from l to r_v , i.e., $r_u \in T_v$.

What is the width of this representation? For $x \in T$ with parents z, y , the width at x is

$$|\partial_G S_x^T| + |\{v \mid x = r_v\}| \leq |\partial_G S_y^T| + |\partial_G S_z^T|.$$

Hence, $\text{tw}(G) + 1 \leq 2 \cdot C_T(G)$. $\square$

Our next goal is to show that $C^T(G)$ cannot be much smaller than $C(G)$, and that $C(G) \leq O(\log k) \cdot C^T(G)$ holds, where $k = |V(G)|$. In fact, this relation between $\text{tw}(G)$ and $\text{pw}(G)$ is well known (see, e.g., Bodlaender et al. [3]). We give here a different, direct and simple proof of this fact, phrased in the terms of this paper. Then, we show that the factor $O(\log k)$ is tight even for G_π 's, which are the incidence graphs of permutations and the primary concern of this paper, by presenting and analyzing an explicit family of permutations $\{\pi^\tau\}$.

THEOREM 3.7. $\log_2 k \cdot C^T(\pi) \geq C(\pi)$.

Proof. To draw a tree T means to specify for each inner vertex v of T the left and the right parents. Each drawing of T defines the exposure order τ : traverse the

leaves of the drawing from left to right, and expose at each step the corresponding label (i.e., vertex of G), unless it has already been exposed. Given a drawing of T , for each inner vertex $v \in T$, in addition to S_v^T define also Q_v^T , the set of all labels exposed by τ prior to getting to the first leaf of T_v , the (complete) subtree of T rooted at v .

Let T be the optimal exposure tree of G . Draw it so that for *each* inner vertex v it holds that $|S_l^T \setminus Q_v^T| \geq |S_r^T \setminus Q_v^T|$, where l and r are, respectively, the left and the right parents of v . We claim that for the resulting τ , $C_\tau(G) \leq \log_2 k \cdot C_T(G)$.

Indeed, consider the first moment when $C_\tau(G)$ is attained, i.e., when the current exposed set A has the maximum boundary, $|\partial_G A| = C_\tau(\pi)$. Let K denote the set of traversed leaves of T . Call a vertex $v \in T$ *maximal* if all the leaves of T_v belong to K , but v 's son (i.e., the neighbor closer to the root) in T does not have this property. Let $\{v_1, v_2, \dots, v_q\}$ be the set of maximal vertices. Clearly, $A = \cup_{i=1}^q S_{v_i}^T$. The exposure order τ on A defines a total order on maximal vertices: for (maximal) v_i and v_j , we say that v_i precedes v_j if the leaves of T_{v_i} are traversed prior to the leaves of T_{v_j} . Assume that the maximal vertices are numbered according to this order. Now, on one hand, it holds that

$$|\partial_G A| \leq |\partial_G S_{v_1}^T| + |\partial_G S_{v_2}^T| + \dots + |\partial_G S_{v_q}^T|,$$

and hence $C_\tau(G) \leq q \cdot C^T(G)$.

On the other hand, q can be upper-bounded as follows. For each v_i , let u_i be its (right) brother. A simple check shows that u_i is well defined, even for $i = q$ (as $A \neq [1, k]$), and that for each $j > i$, v_j must be an ancestor of u_i . Let $n_i = |S_{v_i}^T \setminus Q_{v_i}^T|$ and $m_i = |S_{u_i}^T \setminus Q_{u_i}^T|$. By our construction, $n_i \geq m_i$ for $i = 1, \dots, q$, and, moreover, by the above observation, $m_i \geq n_{i+1} + m_{i+1}$ for $i = 1, \dots, q-1$. Consequently, $m_i \geq 2m_{i+1}$ for $i = 1, \dots, q-1$, and $m_1 \geq 2^{q-1} \cdot m_q$. Since $m_1 \leq k/2$ and $m_q \geq 1$, we conclude that $q \leq \log_2 k$. $\square$

To argue that the bound of Theorem 3.7 is tight for incidence graphs G_π , let us define the following family of patterns $\{\pi^r \in S_{3^r}\}$. For $r = 0$, $\pi^1 = (1)$. For $r > 1$, define $\pi^r = (\pi^{r-1}, \pi^{r-1} + 2 \cdot 3^{r-1}, \pi^{r-1} + 3^{r-1})$, where by $\pi + x$ we mean the pattern obtained by taking π and adding x to each of its entries. Thus, $\pi^1 = (132)$, $\pi^2 = (132798465)$, etc. We claim that for this family the gap of Theorem 3.7 is indeed attained up to a multiplicative factor.

PROPOSITION 3.8. $C^T(\pi^r) \leq 4$, while $C(\pi^r) > r$.

Proof. For the first statement, we recursively construct an exposure tree T^r for π^r with the property that each label appears at a unique leaf of T^r . We need to specify the tree structure and the labels on the leaves. In what follows, we describe a drawing of an unlabeled T^r , i.e., for each node we specify the left and the right sons. The drawing defines a total (left-to-right) order on the leaves; the labels of the leaves, 1 to 3^r , left to right, are assigned accordingly.

For $r = 0$, T^r is just a single node. For $r > 0$, the right son of the root is (isomorphic to) T^{r-1} ; the left son has two sons, each (isomorphic to) T^{r-1} .

An easy check shows that for each vertex $v \in T^r$ as above, the set $S_v^{T^r}$ of labels constitutes an interval in both the blue and red paths, and therefore has boundary of size at most $2 + 2 = 4$. Thus, $C_{T^r}(\pi^r)$ is at most 4.

The second statement is proved by induction. For $r = 0$ it is obviously true. For $r > 0$, we claim that $C_\tau(\pi^r) \geq 1 + C(\pi^{r-1})$ for any τ . Let K_1 , K_2 , and K_3 denote, respectively, the first, second, and third groups of indices in $[1, 3^r]$. By definition of π^r , its restriction to each K_i is equivalent to π^{r-1} and constitutes an interval in both the blue and the red paths. Therefore, the exposure order τ must proceed as follows.

First, at some moment t_1 the relative boundary of the exposed set with respect to some K_x (i.e., the neighbors lying outside this third are ignored) must become as large as $C(\pi^{r-1})$. At some later moment t_2 this happens for another K_y , and, finally, this happens for the remaining K_z . Let us have a closer look at the actual boundary at the moment t_2 . Clearly, $|\partial_{\pi^r} A_{t_2}| = \sum_{j=1}^3 |K_j \cap \partial_{\pi^r} A_{t_2}|$, and each $|K_j \cap \partial_{\pi^r} A_{t_2}|$ is at least as big as the current relative boundary with respect to K_j . Thus, the only possibility for $|\partial_{\pi^r} A_{t_2}|$ not to exceed $C(\pi^{r-1})$ may occur when the contributions of K_x and K_z are null, while the contribution of K_y is $C(\pi^{r-1})$. That is, K_x must be entirely exposed, while K_z must be entirely unexposed. However, a trivial case analysis shows that in this situation, no matter how K_x, K_y , and K_z are situated, K_x must contain an element with a neighbor (either blue or red) in K_z . Thus, even if the favorable possibility does occur, still the total size of the boundary at this moment must be at least $1 + C(\pi^{r-1})$. $\square$

REMARK. The patterns $\{\pi^r\}$ used in the proof of Proposition 3.8 belong to a larger family of separable permutations, characterized (using our terminology) by the existence of a suitable read-once (i.e., each label appears on a unique leaf) exposure tree T , such that all S_v^T constitute a contiguous interval in both the red and the blue paths. Such patterns were treated in [5], and, in particular, it is shown there that for this family of patterns the SP problem can be solved in time $O(n^6)$. The method, specific to this family, uses dynamic programming in a manner somewhat different than, yet reminiscent of **ALG2-SP**. The bound was further improved to $O(n^4)$ in [8]. For comparison, our results imply that the separable π 's have complexity $C^T(\pi) \leq 4$, and the running time of **ALG2-SP** $_{\pi,T}$ with the improved implementation is $O(n^6 \log n)$.

3.4. Special families: Complexity of the linear permutations. In this section we study in detail two special families of patterns and demonstrate that for such patterns $C(\pi_k) = O(\sqrt{k})$. Throughout this section, for technical reasons we treat the patterns of length k and their exposure orders as permutations of $[0, k-1]$ rather than the usual $[1, k]$; e.g., the pattern $\pi = (201)$ denotes the function $\pi(0) = 2$, $\pi(1) = 0$, $\pi(2) = 1$.

The first family is the set of patterns corresponding to invertible linear transformations of the ring $\mathbb{Z}_k$ to itself, i.e., transformations of the form $\pi(x) = ax + b \bmod k$, where $\text{GCD}(a, k) = 1$.

DEFINITION 3.9. For an invertible $a \in \mathbb{Z}_k$, define $R(a, k) \in \mathbb{N}$ as the smallest natural number R such that there exist $x, y \in [-R, R] \setminus \{0\}$ satisfying $ax + y = 0 \bmod k$.

THEOREM 3.10. Let π be of the form $\pi(x) = ax + b \bmod k$, where $\text{GCD}(a, k) = 1$. Then,

$$R(a, k) - 4 \leq C(\pi) \leq 4 \cdot R(a, k) + 4.$$

Proof. It will be convenient to work in $\mathbb{Z}_k$ under a natural identification between $\mathbb{Z}_k$ and $[0, k-1]$. In what follows, all operations (except square root) are mod k , and so are the intervals $[i, j] = [i, i+1, \dots, j]$.

The lower bound follows from the fact that for a linear π the graph G_π is locally a grid. The upper bound is implied by the manner in which these grid patches overlap. We start with the easier lower bound. Observe that $(i, i + a^{-1})$ is always a red edge except when $i = \pi^{-1}(k-1)$. Let $I = [0, r-1]$, where $r = R(a, k)$. Let $I_x = x \cdot a^{-1} + I$. Consider the restriction of G_π to the vertices in $I_0 \cup I_1 \cup I_2 \cup \dots \cup I_{(r-1)}$. The definition of $R(a, k)$ implies that these intervals are disjoint. It is easy to verify that the induced subgraph contains the $r \times r$ grid with blue horizontal and red vertical edges. One vertical and one horizontal edge may be missing. Exposing G_π is at least as hard as

exposing its subgraph. It is a simple (folklore) exercise to show that any set of size about $\lfloor r^2/2 \rfloor$ in the $r \times r$ grid ($r > 1$) has boundary of size at least r . Subtracting 4 in order to compensate the 2 possibly missing edges, we arrive at the lower bound.

For the upper bound, it will be convenient to consider G_π augmented by a blue edge $(k-1, 0)$ and by a red edge $(\pi^{-1}(k-1), \pi^{-1}(0))$. Let $J = [0, r]$ and $J_x = x \cdot a^{-1} + J$. The exposure order is defined as follows. First, expose J_0 (according to the natural order on it), then J_1 , J_2 , and so on. If the current index/vertex has already been exposed previously, skip to the next one. It is clear that at any moment the set of the exposed indices constitutes a union of at most $r+1$ intervals in the red path, and thus the size of the red boundary never exceeds $2(r+1)$. In order to analyze the blue boundary, observe that by definition of $R(a, k)$, the first $r+1$ (blue) intervals J_x cannot be disjoint. Since $J_s \cap J_t \neq \emptyset$ implies $J_{s+1} \cap J_{t+1} \neq \emptyset$, we conclude that for every $t \geq r$, the interval J_t intersects one or more of the previously exposed intervals. This implies that at any moment the exposed set has at most $r+1$ connected components in the blue path, and thus its blue boundary is of size at most $2(r+1)$. $\square$

COROLLARY 3.11. *For any linear permutation π as above, $C(\pi) \leq 4\sqrt{k} + O(1)$. The upper bound is tight; for instance, when $a = \lfloor \sqrt{k} \rfloor$, it holds that $C(\pi) \geq \sqrt{k} + O(1)$.*

Proof. For the upper bound, divide the domain $[0, k-1]$ into $\lfloor \sqrt{k} \rfloor$ disjoint intervals of length at most $\lceil \sqrt{k} \rceil + 2$. By the pigeonhole principle, some two elements of $\{0, a, 2a, \dots, \lceil \sqrt{k} \rceil \cdot a\}$ must fall into the same interval; subtracting one such element from another yields a pair x, y in the interval $[-\lceil \sqrt{k} \rceil - 1, \lceil \sqrt{k} \rceil + 1] \setminus \{0\}$ satisfying $ax + b = 0$. Thus, $R(a, k) \leq \sqrt{k} + 2$.

The lower bound for the special a is obvious. $\square$

The second family of linear permutations that we would like to discuss corresponds to the family of invertible linear transformations $A : \mathbb{Z}_2^m \rightarrow \mathbb{Z}_2^m$. Let $k = 2^m$. The value $\pi(i)$ of a number $i \in [0, k-1]$ is obtained by taking the binary representation of i (with leading zeroes!), interpreting it as a vector $v \in \mathbb{Z}_2^m$, applying A_π to v to get $u = A_\pi(v)$, and interpreting u as the binary presentation of another number in $[0, k-1]$. Formally, let $e_1, \dots, e_m$ be the vectors of the standard basis of $\mathbb{Z}_2^m$. The correspondence between $\mathbb{Z}_2^m$ and $[0, 2^m - 1]$ is given by $\sum_{i=1}^m b_i e_i \mapsto (b_m \dots b_2 b_1)_2$, a number in the binary representation.

Let $V_i = \text{span}\{e_1, e_2, \dots, e_i\}$. Call a linear transformation $A : \mathbb{Z}_2^m \rightarrow \mathbb{Z}_2^m$ *semi-triangular* if for every $i = 1, 2, \dots, m$ it holds that $A(V_i) \supseteq V_{\lfloor i/2 \rfloor}$.

LEMMA 3.12. *Let A be invertible and semitriangular, and let $\pi \in S_k$ be the corresponding permutation. Then, $C_{Id}(\pi) = O(2^{\frac{m}{2}})$.*

Proof. To start with, observe that there is a natural 1-1 correspondence between the affine subspaces of $\mathbb{Z}_2^m$ of the form $(u + V_i)$ and the subintervals of $[0, 2^m - 1]$ of the form $x \cdot 2^i + [0, 2^i - 1]$, where $x \in [0, 2^{m-i} - 1]$. By definition of A , the image $A(p + V_i)$ of any affine subspace of the form $(p + V_i)$ is a disjoint union of affine subspaces of the form $(u + V_{\lfloor i/2 \rfloor})$. Moreover, by a size argument, it is a union of $2^{\lceil \frac{i}{2} \rceil}$ such subspaces. Keeping in mind the correspondence between subspaces and subintervals, we conclude that the image of an interval $J_i \subseteq [0, 2^m - 1]$ of the above form under π consists of at most $2^{\lceil \frac{i}{2} \rceil}$ intervals.

Consider now the image of $[0, t]$ under π . Observe that for every $0 \leq t \leq 2^m - 1$, the interval $[0, t]$ can be (uniquely) represented as $\cup_{i=0}^{m-1} J_i$, where the J_i 's are of the above form. For example,

$$[0, 54] = [0, 31] \cup 32 + [0, 15] \cup 48 + [0, 3] \cup 52 + [0, 1] \cup 54 + [0].$$

Since $[0, t]$ can be represented as $\cup_{i=0}^{m-1} J_i$, we conclude that $\pi([0, t])$ is a union of at most $2 \sum_{i=0}^{m-1} 2^{\frac{i}{2}} = O(2^{\frac{m}{2}})$ intervals. Hence, the red boundary of $[0, t]$ in G_π is at most $O(2^{\frac{m}{2}})$. The blue boundary is 1, and the lemma follows. $\square$

REMARK. A similar argument implies that for a triangular A , i.e., when $A(V_i) = V_i$ for all i , $C_{Id}(\pi) = O(\log n)$. It is also not hard to see that in this case $C^T(\pi) = 3$. The corresponding exposure tree is a complete binary tree of height m , and the leaves are labeled 0 to $2^m - 1$ in this order, starting from the leftmost leaf and ending at the rightmost one.

In order to upper-bound $C(\pi)$ for π originating in a general linear transformation, we need the following two propositions.

PROPOSITION 3.13. For any pair of permutations $\tau, \pi \in S_k$ it holds that

$$C_\tau(\pi) \leq C_{Id}(\tau) + C_{Id}(\pi \circ \tau).$$

Proof. Let us first establish two simple inequalities. The first is

$$(3.1) \quad C_{Id}(\gamma) \geq C_\gamma(Id).$$

Indeed, it is easy to verify that at every step i , a vertex j belongs to the current red boundary in G_γ if and only if $\gamma(j)$ belongs to the current blue boundary in G_{Id} . Since in G_{Id} the blue and the red boundaries are identical, the inequality holds.

Second, we claim that for any $A \subseteq [0, k-1]$, it holds that

$$(3.2) \quad |\partial_\pi A| \leq |\partial_{Id} A| + |\partial_{Id}(\pi(A))|.$$

Indeed, $\partial_{Id} A = \partial_\pi^{\text{blue}} A$, while the second term $\partial_{Id}(\pi(A))$ is, by the previous argument, in a 1-1 correspondence with $\partial_\pi^{\text{red}} A$.

Now we are ready to prove the proposition. Let $A_i = [0, i-1]$. Using (3.2), we conclude that

$$\begin{aligned} C_\tau(\pi) &= \max_i |\partial_\pi(\tau(A_i))| \leq \max_i |\partial_{Id}(\tau(A_i))| + \max_i |\partial_{Id}(\pi \circ \tau(A_i))| \\ &= C_\tau(Id) + C_{\pi \circ \tau}(Id). \end{aligned}$$

Applying (3.1), we conclude the proof. $\square$

In view of Proposition 3.13, our next goal is to show the following fact from linear algebra.

PROPOSITION 3.14. For any invertible $A : \mathbb{Z}_2^m \rightarrow \mathbb{Z}_2^m$ there exists an invertible semitriangular $D : \mathbb{Z}_2^m \rightarrow \mathbb{Z}_2^m$ such that $A \circ D$ is also invertible semitriangular.

Proof. Restating the problem, we need to construct an invertible D such that for every $k \leq \frac{m}{2}$, $V_k \subset D(V_{2k})$, and also $V_k \subset A \circ D(V_{2k})$. Or, combining the two conditions,

$$\begin{aligned} \text{for } k = 1, 2, \dots, \left\lfloor \frac{m}{2} \right\rfloor, \\ \text{span}\{e_1, A^{-1}(e_1), e_2, A^{-1}(e_2), \dots, e_k, A^{-1}(e_k)\} \subseteq D(\text{span}\{e_1, e_2, \dots, e_{2k}\}). \end{aligned}$$

For k as above, define $u_{2k-1} = e_k$ and $u_{2k} = A^{-1}(e_k)$. D is defined as follows. For $i = 1, \dots, m$, set $D(e_i) = u_i$ unless $u_i \in D(\text{span}\{e_1, \dots, e_{i-1}\})$; in the latter case assign to $D(e_i)$ an arbitrary vector not in $D(\text{span}\{e_1, \dots, e_{i-1}\})$. It is a simple matter to verify that D is well defined, and that it indeed satisfies the requirements. $\square$

Combining Propositions 3.13 and 3.14 we conclude the following.

THEOREM 3.15. *For any permutation $\pi \in S_k$ ($k = 2^m$) associated with an invertible linear transformation $A : \mathbb{Z}_2^m \rightarrow \mathbb{Z}_2^m$, it holds that $C(\pi) = O(\sqrt{k})$.*

The upper bound is tight. Consider, e.g., the following simple transformation inverting the binary representation: $\pi^m(b_m b_{m-1} \dots b_1)_2 = (b_1 b_2 \dots b_m)_2$.

PROPOSITION 3.16. $C^T(\pi^m) \geq 2^{\lfloor \frac{m-1}{2} \rfloor}$.

Proof. It is a simple matter to verify that π^m has the following recursive structure. For any natural $r \in [1, m-1]$,

$$\pi^m = (\pi^{m-r}(0) + 2^r \cdot \pi^r, \pi^{m-r}(1) + 2^r \cdot \pi^r, \dots, \pi^{m-r}(2^{m-r} - 1) + 2^r \cdot \pi^r),$$

where the operations of addition and multiplication of a pattern by a scalar are performed entrywise. For example,

$$\begin{aligned} \pi^4 &= (0, 8, 4, 12, 2, 10, 6, 14, 1, 9, 5, 13, 3, 11, 7, 15) \\ &= (0 + 4 \cdot (0213), 2 + 4 \cdot (0213), 1 + 4 \cdot (0213), 3 + 4 \cdot (0213)). \end{aligned}$$

Assume for simplicity $m = 2r$, and let $J_i = i \cdot 2^r + [0, 2^r - 1]$, $i = 0, 1, \dots, 2^r - 1$, denote subintervals of $[0, 2^m - 1]$. For $q \in [0, 2^r - 1]$, let $J_i(q) = i \cdot 2^r + q$, i.e., the q th position in J_i . Observe that $J_a(q)$ and $J_b(q)$ are red neighbors in G_{π^m} if and only if a and b are red neighbors in G_{π^r} . This means that G_{π^m} contains a $2^r \times 2^r$ grid with blue horizontal and red vertical edges. The rows are the J_a 's, and their order of appearance (top to bottom) is as in the red path of G_{π^r} . We had already encountered a similar situation in the course of the proof of Theorem 3.10. Essentially, we are done. A standard technical argument follows.

Let T be any exposure tree, and let $v \in T$ be a vertex such that $S = S_v^T$ intersects at least half of the intervals $\{J_i\}$, but not all of them. Such a vertex must exist. We claim that $|\partial_{\pi^m} S| \geq 2^{r-1}$. Call an interval J_i *white* if $J_i \cap S = \emptyset$, *black* if $J_i \subseteq S$, and *gray* otherwise. By our assumption, there is at least one white interval. Since each gray interval contributes at least 1 to the blue boundary, either there exists a black interval, or the blue boundary is as large as 2^{r-1} , and we are done. Assume we are in the former case. Then, there exists a chain of intervals $\{J_{a_i}\}_{i=0}^t$ such that J_{a_0} is black, J_{a_t} is white, and $\{a_i, a_{i+1}\}$ are red neighbors in G_{π^r} for $i = 0, 1, \dots, t-1$. Let $K_i = J_i \cap S - i \cdot 2^r$. By the previous discussion,

$$|\partial_{\pi^m}^{\text{red}}(S)| \geq |K_0 \setminus K_1| + |K_1 \setminus K_2| + \dots + |K_{t-1} \setminus K_t| \geq |K_0 \setminus K_t| = 2^r. \quad \square$$

3.5. Permutation complexity and operations on strings. In this last section we would like to make a number of observations about the effect of some standard edit and group theoretic operations on the permutation complexity. All arguments below equally apply to $C(\pi)$ and $C^T(\pi)$. To avoid repetition, we shall restrict the discussion to $C(\pi)$.

CLAIM 3.17. *For a subpattern $\pi' = \pi|_S$ of π , it holds that $C(\pi') \leq 2C(\pi)$.*

Proof. The key point is that for any $A \subseteq [1, k]$ it holds that $|\partial_{\pi'}^{\text{blue}}(A \cap S)| \leq |\partial_{\pi}^{\text{blue}}(A)|$ and also that $|\partial_{\pi'}^{\text{red}}(A \cap S)| \leq |\partial_{\pi}^{\text{red}}(A)|$. Let τ' be the exposure order induced on S by the optimal exposure order τ for π . Comparing the boundaries of $\{A_i\}$ exposed by τ with the S -boundaries of the corresponding $\{S \cap A_i\}$ exposed by τ' , we arrive at the desired conclusion. $\square$

Next, let us consider the edit operations *block reversal* and *block move*. Instead of formal definitions, we provide generic examples of these operations:

$$\text{block reversal: } (156 \underline{2497} 83) \rightarrow (156 \underline{7942} 83);$$

$$\text{block move: } (156 \underline{249} \overline{78} 3) \rightarrow (156 \overline{78} \underline{249} 3).$$

Another operation of interest is *split*, $\pi \rightarrow (\pi|_S, \pi|_{\bar{S}})$ for some $S \subseteq [1, k]$. For example, $(\overline{1} \ 5 \ 6 \ 2 \ 4 \ 9 \ 7 \ 8 \ 3) \rightarrow (12473 \ 5698)$. All these operations correlate well with permutation complexity.

CLAIM 3.18. *Let π' be a pattern obtained from π by one of the above operations. Then, $C(\pi')$ is at most $C(\pi) + 2$ for block reversals, at most $C(\pi) + 4$ for block moves, and at most $2C(\pi) + 1$ for splits.*

Proof (sketch). Let τ denote the optimal exposure order for π . The exposure order τ' (in all three cases) is defined by following requirement: $\pi \circ \tau(i) = \pi' \circ \tau'(i)$ for $i = 1, 2, \dots, n$; i.e., at every given moment i , the same *value* is exposed in π and π' . Let A_i and A'_i denote the corresponding stage- i exposed sets. Then, $\pi'(A'_i) = \pi(A_i)$ and $\pi'(\partial_{\pi'}^{\text{red}}(A'_i)) = \pi(\partial_{\pi}^{\text{red}}(A_i))$. It remains to estimate the blue boundaries.

It is a simple matter to verify that the size of $\partial_{\pi'}^{\text{blue}}(A'_i) \setminus \partial_{\pi}^{\text{blue}}(A_i)$ is at most 2 for a block reversal, and at most 4 for a block move, implying the statement for these operations.

For a split $\pi' = (\pi|_S, \pi|_{\bar{S}})$, observe that the exposure orders induced by τ' on S and $\bar{S}$ coincide with those induced on S and $\bar{S}$, respectively, by τ . Arguing as in the proof of Claim 3.17, we conclude that $|\partial_{\pi'}^{\text{blue}}(A'_i)| \leq 2 \cdot |\partial_{\pi}^{\text{blue}}(A_i)| + 1$, and the statement follows. The factor of 2 is tight, since any pattern can be obtained from the identity by performing at most $\lceil \log_2 n \rceil$ splits. $\square$

Next, let us discuss the effect of group-theoretic operations. It clearly holds that $C(\pi) = C(\pi^{-1})$ since the graphs G_{π} and $G_{\pi^{-1}}$ are isomorphic. Viewing Claim 3.18 from a group-theoretic perspective, observe that π' is of the form $\pi \circ \gamma$, where γ is obtained from the identity permutation by a single block reversal, block move, or split, respectively. Thus, in all cases $C(\gamma)$ is low. This makes one wonder whether $C(\pi \circ \gamma)$ can always be upper-bounded in terms of $C(\pi)$ and $C(\gamma)$ alone. Our next (and last) goal is to provide a negative answer to this question.

Let $k = 2r$, and let $\rho_r, \zeta_r \in S_r$. We will be working with permutations of the form $\pi_k = (\rho_r, r + \zeta_r)$. The permutation π'_k is obtained from π_k by an operation of *shuffle* (an inverse operation of split) of a very special kind:

$$(3.3) \quad \pi_k = (\rho_r, r + \zeta_r) \mapsto (\rho_r(1), r + \zeta_r(1), \rho_r(2), r + \zeta_r(2), \dots, \rho_r(r), r + \zeta_r(r)) = \pi'_k.$$

For example, $(\overline{2431} \ 8756) \mapsto (\overline{2} \ 8 \ 4 \ 7 \ 3 \ 5 \ 1 \ 6)$. Thus, $\pi'_k = \pi_k \circ \gamma_k$, where γ_k is of (generic) form $(1 \ 5 \ 2 \ 6 \ 3 \ 7 \ 4 \ 8)$. Clearly, $C_{Id}(\gamma_k) \leq 4$ for all k .

In what follows, we use the notation $C^{\mathbf{T}}(G)$ introduced in section 3.3. Observe that if H is a minor of G , then $\text{tw}(G) \geq \text{tw}(H)$, and hence, by Proposition 3.6, $C^{\mathbf{T}}(G) \geq 0.5 \cdot C^{\mathbf{T}}(H)$.

CLAIM 3.19. *There exists an infinite family of permutations $\{\pi_k \in S_k\}$ as in (3.3), so that $C(\pi_k) \leq 5$, and yet for their shuffles $\{\pi'_k = \pi_k \circ \gamma_k\}$ as in (3.3) it holds that $C^{\mathbf{T}}(\pi'_k) = \Omega(\sqrt{k})$.*

Proof. In what follows, $k = 2r$, and r is a square of a natural number. For π_k as in (3.3) it holds that $C(\pi_k) \leq \max\{C(\rho_r), C(\zeta_r)\} + 2$, as one can first (optimally) expose ρ_r , and then (optimally) expose ζ_r . We shall construct ρ_r and ζ_r of complexity 3; the resulting π_{2r} will thus have complexity ≤ 5 .

To establish a lower bound on $C^{\mathbf{T}}(\pi'_k)$, we use the following line of reasoning. Observe that contracting the blue edges $\{(2i-1, 2i)\}_{i=1}^r$ of $G_{\pi'_k}$ results in a graph isomorphic to $G_{\{\rho_r, \zeta_r\}}$, the graph obtained from G_{ρ_r} and G_{ζ_r} by gluing them together along their blue Hamiltonian paths; i.e., $G_{\{\rho_r, \zeta_r\}}$ is a union of *three* Hamiltonian paths:

FIG. 3.1. The graphs $G_{\rho_{36}}$ and $G_{\zeta_{36}}$. Black is for blue, and gray is for red. Their union contains a 6×6 grid.

the joint blue one, ρ -red, and ζ -red. This graph, as we shall see, can be considerably more complex than either G_{ρ_r} or G_{ζ_r} . Also, by (rough) monotonicity with respect to taking minors, $C^{\mathbf{T}}(G_{\pi'_k}) \geq 0.5 \cdot C^{\mathbf{T}}(G_{\{\rho_r, \zeta_r\}})$.

It remains to construct the permutations $\{\rho_r, \zeta_r\}$ with the required properties. It is easier to describe such permutations by drawing the corresponding incidence graphs rather than by a formal description. Figure 3.1 provides the generic drawings of G_{ρ_r} and G_{ζ_r} for $r = 6^2$. Clearly, each of the patterns has complexity 3 (e.g., expose according to the red order), and hence, by the previous discussion, $C(\pi_{2r}) \leq 5$. However, $G_{\{\rho_r, \zeta_r\}}$ contains an $\sqrt{r} \times \sqrt{r}$ grid, and thus, as we have seen before (e.g., at the end of the proof of Proposition 3.16), $C^{\mathbf{T}}(G_{\{\rho_r, \zeta_r\}}) = \Omega(\sqrt{r})$. Therefore, $C^{\mathbf{T}}(\pi'_{2r}) = \Omega(\sqrt{r})$. $\square$

Acknowledgments. We are grateful to the anonymous referees for their helpful remarks and criticism.

CUBIC MONOMIAL BENT FUNCTIONS: A SUBCLASS OF $\mathcal{M}^*$

PASCALE CHARPIN[†] AND GOHAR M. KYUREGHYAN[‡]

Abstract. Based on a computer search, Anne Canteaut conjectured that the exponent $2^{2r} + 2^r + 1$ in $\mathbf{F}_{2^{6r}}$ and the exponent $(2^r + 1)^2$ in $\mathbf{F}_{2^{4r}}$ yield bent monomial functions. These conjectures are proved in [A. Canteaut, P. Charpin, and G. Kyureghyan, *A new class of monomial bent functions*, in Proceedings of the 2006 IEEE International Symposium on Information Theory, (ISIT 06 Seattle), IEEE Press, Piscataway, NJ, 2006, pp. 903–906] and [N. G. Leander, *IEEE Trans. Inform. Theory*, 52 (2006), pp. 738–743]. Both exponents are of binary weight 3 and define functions from the Maiorana–McFarland class $\mathcal{M}$ of bent functions to the subfield. In this paper we show that these are the only such exponents. Our proof is based on the classification of the permutation binomials $X^{2^k+2} + \nu X$ of finite fields of even characteristics. We also extend the result of Leander, determining all bent monomial functions with the exponent $(2^r + 1)^2$.

1. Introduction. A bent function is a Boolean function with an even number of variables which has the maximal possible Hamming distance from the set of affine Boolean functions. More precisely, a function $f : \mathbf{F}_2^n \rightarrow \mathbf{F}_2$ (n even) is called bent if

$$\sum_{x \in \mathbf{F}_2^{2t}} (-1)^{f(x) + \langle a, x \rangle} = \pm 2^{\frac{n}{2}}$$

for any $a \in \mathbf{F}_2^n$. Observe that the bent functions are defined in a vector space over $\mathbf{F}_2$ with an inner product. Sometimes it is more convenient to consider bent functions in the finite field $\mathbf{F}_{2^n}$ with the inner product taken to be the absolute trace function. Working in the finite field can be advantageous because of its additional multiplicative structure. The classification of the bent functions in finite fields and vector spaces is completely equivalent. Let us restate the definition of a bent function in $\mathbf{F}_{2^n}$, where n is even. A function $f : \mathbf{F}_{2^n} \rightarrow \mathbf{F}_2$ is called bent if

$$\sum_{x \in \mathbf{F}_{2^n}} (-1)^{f(x) + T_1^n(\alpha x)} = \pm 2^{\frac{n}{2}}$$

for any $\alpha \in \mathbf{F}_{2^n}$, where T_1^n is the absolute trace over $\mathbf{F}_{2^n}$.

Several recent papers are devoted to the study of bent functions which are *monomial*, i.e., which are of the form

$$x \in \mathbf{F}_{2^n} \mapsto f(x) = T_1^n(\lambda x^d) \text{ for some } \lambda \in \mathbf{F}_{2^n},$$

where d is said to be the *exponent of f* . One of the goals in this research is to find exponents d and the field elements λ defining a bent function. Also, some properties of bent functions are observed by studying monomial ones. For instance, the only known so-called nonnormal bent functions are constructed with monomial bent functions [3]. A further example is

$$\{ f_\lambda : \mathbf{F}_{2^{6r}} \rightarrow \mathbf{F}_2 \mid f_\lambda(x) = T_1^{6r}(\lambda x^{2^{2r}+2^r+1}), \lambda \in \mathbf{F}_{2^{3r}}^* \text{ and } T_r^{3r}(\lambda) = 0 \},$$

which is closed under the addition of different elements and consists of bent functions of degree 3 (see [1, 2]). To our knowledge, this is the first example of such a family of nonquadratic bent functions.

Based on a computer search carried out for $n \leq 24$, Anne Canteaut conjectured that the exponent $2^{2r} + 2^r + 1$ in $\mathbf{F}_{2^{6r}}$ and the exponent $2^{2r} + 2^{r+1} + 1$ in $\mathbf{F}_{2^{4r}}$ yield bent monomial functions. These conjectures are proved in [1, 10]. Both exponents are of binary weight 3 and define bent functions from the Maiorana–McFarland class $\mathcal{M}$ of bent functions. More precisely, the obtained bent functions are concatenations of affine Boolean functions of the subfield $\mathbf{F}_{2^{\frac{n}{2}}}$ or shifts of such functions. Using the techniques introduced in [1], this paper continues the study of cubic monomial functions. After introducing some preliminary definitions and results in section 2, in section 3 the cubic monomial functions, which can be represented as a concatenation of affine Boolean functions of the subfield $\mathbf{F}_{2^{\frac{n}{2}}}$, are classified. Furthermore, it is shown that among these functions only the ones with the exponents $2^{\frac{n}{2}+2^j+1}$ may define new bent functions. In section 4 the Walsh spectrum of the corresponding monomial functions are studied. It is shown that only exponent $2^{2r} + 2^{r+1} + 1$ for $n = 4r$ of that type defines a bent function. This uses the classification of all permutation polynomials $X^{2^k+2} + \nu X$ over a finite field of even characteristics obtained in section 5. Finally, the result of [10] is extended by determining all bent monomial functions with the exponent $2^{2r} + 2^{r+1} + 1$. In particular, all presently known (found by computer search) monomial bent functions are proved to belong to an infinite family of bent monomial functions. These families are as follows:

- $d = 2^i + 1$ and $\lambda \notin \{y^d \mid y \in \mathbb{F}_{2^n}\}$ (folklore).
- $d = (2^{\frac{n}{2}} - 1)\ell$, $\gcd(\ell, 2^{\frac{n}{2}} + 1) = 1$, and λ corresponds to a zero of the Kloosterman sum (Dillon [6], Lachaud and Wolfmann [9]).
- If n is not a multiple of 3 and $(i, n) = 1$, then $d = 2^{2i} - 2^i + 1$ and $\lambda \notin \{y^3 \mid y \in \mathbb{F}_{2^n}\}$ (Dillon and Dobbertin [7]).
- If $n = 4r$ and r is odd, then $d = 2^{2r} + 2^{r+1} + 1$ (Leander [10]) and $\lambda = \lambda' a^{2^{2r}+2^{r+1}+1}$, where $\lambda' \in \omega \mathbf{F}_{2^r}$, $\omega \in \mathbf{F}_4 \setminus \mathbf{F}_2$, and $a \in \mathbf{F}_{2^{4r}}$ (this paper).
- If $n = 6r$, then $d = 2^{2r} + 2^r + 1$ and $\lambda = \lambda' a^{2^{2r}+2^r+1}$, where $a \in \mathbf{F}_{2^{6r}}$ and $\lambda' \in \mathbf{F}_{2^{3r}}$ such that $T_r^{3r}(\lambda') = 0$ (Canteaut, Charpin, and Kyureghyan [1]).

2. Preliminaries. Let $\mathbf{F}_{2^n}$ be the finite field with 2^n elements. If $n = ms$, then T_m^n is the trace function from $\mathbf{F}_{2^n}$ onto $\mathbf{F}_{2^m}$ given by

$$T_m^n(x) = x + x^{2^m} + \cdots + x^{2^{m(s-1)}} \quad \text{for any } x \in \mathbf{F}_{2^n}.$$

Note that T_m^n is an $\mathbf{F}_{2^m}$ -linear function.

2.1. Boolean functions. Boolean functions on $\mathbf{F}_{2^n}$ are given by $T_1^n(p(x))$, where $p(x)$ is a polynomial over $\mathbf{F}_{2^n}$. Further, we will use the notation

$$\mathcal{F}(f) = \sum_{x \in \mathbf{F}_{2^n}} (-1)^{f(x)}$$

for a given Boolean function f . The weight of f , denoted $wt(f)$, is the number of x such that $f(x) = 1$ and it holds that

$$\mathcal{F}(f) = 2^n - 2wt(f).$$

Recall that f is said to be *balanced* when $wt(f) = 2^{n-1}$ or, equivalently, $\mathcal{F}(f) = 0$. For a given $u \in \mathbf{F}_{2^n}$, a linear Boolean function φ_u is defined by

$$\varphi_u(x) = T_1^n(ux) \text{ for any } x \in \mathbf{F}_{2^n},$$

and every linear Boolean function is of such form. The *Walsh spectrum* of f is the multiset

$$\{ \mathcal{F}(f + \varphi_u) \mid u \in \mathbf{F}_{2^n} \}.$$

Thus a Boolean function is bent if and only if its Walsh spectrum contains only values $\pm 2^{n/2}$. In particular, the weight of a bent function is $2^{n-1} \pm 2^{\frac{n-2}{2}}$.

2.2. The Maiorana–McFarland bent functions. The Maiorana–McFarland class of bent functions was introduced in [12] and extensively studied by Dillon [6, pp. 90–95]. It is usually called the *class* $\mathcal{M}$ of bent functions. The Maiorana–McFarland bent functions on $\mathbf{F}_{2^n}$, $n = 2t$, are the concatenation of 2^t different affine functions, defined on some fixed subspace of dimension t of $\mathbf{F}_{2^{2t}}$. We are interested in the subclass of $\mathcal{M}$, where the fixed subspace is the subfield $\mathbf{F}_{2^t}$. This subclass we denote by $\mathcal{M}(\mathbf{F}_{2^t})$ and define more accurately in Corollary 2.2.

PROPOSITION 2.1. *Let W be a subspace of $\mathbf{F}_{2^{2t}}$ such that $\mathbf{F}_{2^{2t}} = \mathbf{F}_{2^t} \oplus W$. Assume that a Boolean function $f : \mathbf{F}_{2^{2t}} \rightarrow \mathbf{F}_2$ can be expressed in the form*

$$(2.1) \quad f(x) = f(y + a) = T_1^t(y\pi(a) + h(a)),$$

where $x = y + a$, with $y \in \mathbf{F}_{2^t}$ and $a \in W$, and $\pi, h : W \rightarrow \mathbf{F}_{2^t}$. Let us define, for any $u \in \mathbf{F}_{2^{2t}}$,

$$W_u = \{ a \in W \mid \pi(a) = u + u^{2^t} \}.$$

Then

$$\mathcal{F}(f + \varphi_u) = \begin{cases} 0 & \text{if } W_u = \emptyset \\ 2^t \sum_{a \in W_u} (-1)^{T_1^t(h(a) + T_t^{2t}(ua))} & \text{otherwise.} \end{cases}$$

Proof. For any $u \in \mathbf{F}_{2^{2t}}$ it holds that

$$\begin{aligned} \mathcal{F}(f + \varphi_u) &= \sum_{x \in \mathbf{F}_{2^{2t}}} (-1)^{f(x) + T_1^{2t}(ux)} \\ &= \sum_{a \in W} \sum_{y \in \mathbf{F}_{2^t}} (-1)^{f(y+a) + T_1^{2t}(u(y+a))} \\ &= \sum_{a \in W} \sum_{y \in \mathbf{F}_{2^t}} (-1)^{T_1^t(y\pi(a) + h(a) + T_t^{2t}(u(y+a)))} \\ &= \sum_{a \in W} ((-1)^{T_1^t(h(a) + T_t^{2t}(ua))} \sum_{y \in \mathbf{F}_{2^t}} (-1)^{T_1^t(y(\pi(a) + T_t^{2t}(u)))}). \end{aligned}$$

The second sum over $\mathbf{F}_{2^t}$ is 0 unless $\pi(a) = u + u^{2^t}$; in this case it is equal to 2^t . Thus, this sum is 0 for all a if and only if W_u is empty. Otherwise we get

$$\mathcal{F}(f + \varphi_u) = 2^t \sum_{a \in W_u} (-1)^{T_1^t(h(a) + ua + (ua)^{2^t})},$$

completing the proof. $\square$

COROLLARY 2.2. *Let $W \subset \mathbf{F}_{2^{2t}}$ be such that $\mathbf{F}_{2^{2t}} = \mathbf{F}_{2^t} \oplus W$. Assume that a Boolean function $f : \mathbf{F}_{2^{2t}} \rightarrow \mathbf{F}_2$ can be expressed in the form*

$$f(x) = f(y + a) = T_1^t(y\pi(a) + h(a)),$$

where $x = y + a$, with $y \in \mathbf{F}_{2^t}$ and $a \in W$, and $\pi, h : W \rightarrow \mathbf{F}_{2^t}$. Then f is bent if and only if π is bijective. Such functions are said to be the elements of the subclass $\mathcal{M}(\mathbf{F}_{2^t})$ of $\mathcal{M}$.

Proof. Suppose that π is not a permutation. Then there is an element $b \in \mathbf{F}_{2^t}$ such that $\pi(a) \neq b$ for any $a \in W$. For every $u \in \mathbf{F}_{2^{2t}}$ with $u + u^{2^t} = b$ it holds that $W_u = \emptyset$, and thus Proposition 2.1 implies $\mathcal{F}(f + \varphi_u) = 0$, proving the necessity of the condition. To derive the sufficiency, note that in the case of bijective π the cardinality of W_u equals 1 for any $u \in \mathbf{F}_{2^{2t}}$. $\square$

3. Decomposable cubic monomial Boolean functions. In [1], it is shown that the monomial Boolean functions on $\mathbf{F}_{2^n}$ defined by the new bent exponents $2^{2r} + 2^r + 1$ (for $n = 6r$) and $(2^r + 1)^2$ (for $n = 4r$), can be decomposed in form (2.1). In this section we describe all cubic monomial Boolean functions possessing such a decomposition.

Let $0 \leq k \leq 2^n - 2$. We denote by C_k the cyclotomic coset modulo $2^n - 1$ containing k , i.e.,

$$C_k = \{k, 2k, \dots, 2^{n-1}k\} \pmod{2^n - 1}.$$

Recall that if $|C_k| = l$, then $\{x^k : x \in \mathbf{F}_{2^n}\} \subset \mathbf{F}_{2^l}$ and $\mathbf{F}_{2^l}$ is the smallest subfield of $\mathbf{F}_{2^n}$ with this property.

Let $d = 2^i + 2^j + 1$ and $\lambda \in \mathbf{F}_{2^{2t}}$. We consider the function $f : x \mapsto T_1^{2t}(\lambda x^d)$ on $\mathbf{F}_{2^{2t}}$. Taking the smallest representative of C_d , we may assume that

$$(3.1) \quad d = 2^i + 2^j + 1 \quad \text{with} \quad 0 < j < t, \quad i - j < t \quad \text{and} \quad j < i.$$

If $\mathbf{F}_{2^{2t}} = \mathbf{F}_{2^t} \oplus W$, then setting $x = y + a$ ($y \in \mathbf{F}_{2^t}$ and $a \in W$), we have

$$\begin{aligned} T_1^{2t}(\lambda x^d) &= T_1^{2t}(\lambda(y + a)^{2^i + 2^j + 1}) \\ &= T_1^{2t}(\lambda y^{2^i + 2^j + 1}) \\ &\quad + T_1^{2t}(\lambda a^{2^i} y^{2^j + 1} + \lambda a^{2^j} y^{2^i + 1} + \lambda a y^{2^i + 2^j}) \\ &\quad + T_1^{2t}(\lambda y^{2^i} a^{2^j + 1} + \lambda y^{2^j} a^{2^i + 1} + \lambda y a^{2^i + 2^j}) \\ &\quad + T_1^{2t}(\lambda a^{2^i + 2^j + 1}). \end{aligned}$$

Using the transitivity of the trace function we get that $T_1^{2t}(\lambda x^d)$ is equal to the

following sum:

$$\begin{aligned}
 (3.2) \quad & T_1^t \left(T_t^{2t}(\lambda) y^{2^i+2^j+1} \right) \\
 (3.3) \quad & + T_1^t \left(T_t^{2t}(\lambda a^{2^i}) y^{2^j+1} + T_t^{2t}(\lambda a^{2^j}) y^{2^i+1} + T_t^{2t}(\lambda a) y^{2^i+2^j} \right) \\
 & + T_1^t \left(T_t^{2t}(\lambda a^{2^j+1}) y^{2^i} + T_t^{2t}(\lambda a^{2^i+1}) y^{2^j} + T_t^{2t}(\lambda a^{2^i+2^j}) y \right) \\
 & + T_1^{2t} \left(\lambda a^{2^i+2^j+1} \right).
 \end{aligned}$$

Our goal is to describe the set of pairs (i, j) defining a function $T_1^{2t}(\lambda x^{2^i+2^j+1})$ of form (2.1). Equivalently, we are going to find i, j , and λ such that (3.2) and (3.3) are constant or linear on y for any $a \in W$. The following easy result will be used several times in what follows. We present a brief proof of it for the convenience of the reader.

LEMMA 3.1. *Consider the function on $\mathbf{F}_{2^n}$ given by $f(x) = T_1^n(\delta x^d)$, $\delta \in \mathbf{F}_{2^n}^*$. Assume that d is the smallest element of its cyclotomic coset.*

- (a) *Let $d = 2^i + 2^j + 1$. Then the function f is constantly c , $c \in \mathbf{F}_2$, if and only if $c = 0$ and*

$$n = 3\ell, \quad d = 2^{2\ell} + 2^\ell + 1, \quad \text{and} \quad \delta + \delta^{2^\ell} + \delta^{2^{2\ell}} = 0.$$

- (b) *Let $d = 2^i + 1$. Then the function f is constantly c , $c \in \mathbf{F}_2$, if and only if $c = 0$ and*

$$n = 2\ell, \quad i = \ell \quad \text{and} \quad \delta \in \mathbf{F}_{2^\ell}.$$

Proof. Assume that $f(x) = c$ for all x . Then $c = 0$ since $f(0) = 0$. So the polynomial

$$T_1^n(\delta x^d) = \delta x^d + (\delta x^d)^2 + \cdots + (\delta x^d)^{2^{n-1}}$$

is the null polynomial since it has degree less than 2^n . Hence the cyclotomic coset C_d has cardinality ℓ with $\ell < n$ and $n = k\ell$. Then $\{x^k : x \in \mathbf{F}_{2^n}\} \subset \mathbf{F}_{2^\ell}$ and we have

$$T_1^n(\delta x^d) = T_1^\ell(x^d T_1^n(\delta)).$$

To complete the proof we find the exponents d of binary weights 3 and 2 satisfying $2^\ell d \equiv d \pmod{2^n - 1}$.

- (a) $2^\ell(2^i + 2^j + 1) \equiv 2^i + 2^j + 1 \pmod{2^n - 1}$ if and only if $n - i = i - j = j = \ell$. Thus $n = 3\ell$, $i = 2\ell$, and $j = \ell$. In this case, to have $T_1^n(\delta x^d)$ constantly zero it must also hold that $\delta + \delta^{2^\ell} + \delta^{2^{2\ell}} = 0$.
- (b) $2^\ell(2^i + 1) \equiv 2^i + 1 \pmod{2^n - 1}$ if and only if $n - i = i = \ell$. Then $n = 2\ell$ and, moreover, $\delta + \delta^{2^\ell} = 0$. $\square$

We will also need the following observation.

LEMMA 3.2. *Let $n = 6j$ and $d = 2^{4j} + 2^{2j} + 1$. Let f_λ be the function on $\mathbf{F}_{2^n}$ defined by $f_\lambda(x) = T_1^n(\lambda x^d)$, $\lambda \in \mathbf{F}_{2^n}$. Then, f_λ is the null function when $T_{2^j}^{6j}(\lambda) = 0$. Otherwise the weight of f_λ is equal to $2^{2j-1}(2^{4j} + 2^{2j} + 1)$. In particular, f_λ cannot be bent.*

Proof. Recall that the weight of f_λ , say $wt(f_\lambda)$, is the number of x such that $f_\lambda(x) = 1$. Since $(2^{2j} - 1)d = 2^{6j} - 1$, the image set of $x \mapsto x^d$ is equal to $\mathbf{F}_{2^{2j}}$ and every nonzero element from $\mathbf{F}_{2^{2j}}$ has $2^{4j} + 2^{2j} + 1$ many preimages. Using

$$T_1^{6j}(\lambda x^{2^{4j}+2^{2j}+1}) = T_1^{2j} \left(T_{2^j}^{6j}(\lambda) x^{2^{4j}+2^{2j}+1} \right)$$

it is clear that $wt(f_\lambda) = 0$ when λ satisfies $T_{2^j}^{6j}(\lambda) = 0$ (see also Lemma 3.1). Otherwise

$$wt(f_\lambda) = (2^{4j} + 2^{2j} + 1) \# \{ y \in \mathbf{F}_{2^{2j}} \mid T_1^{2j}(T_{2^j}^{6j}(\lambda)y) = 1 \},$$

where $\#B$ denotes the cardinality of a set B . So we get $wt(f_\lambda) = 2^{2j-1}d$. The weights 0 and $2^{2j-1}d$ both do not correspond to a weight of a bent function, completing the proof. $\square$

THEOREM 3.3. *Let $n = 2t$ and $d = 2^i + 2^j + 1$, where d satisfies (3.1). Given $\lambda \in \mathbf{F}_{2^n}^*$, let us define*

$$f_\lambda : x \in \mathbf{F}_{2^n} \mapsto T_1^n(\lambda x^d).$$

Then f_λ can be represented in the form (2.1) exactly in one of the following cases:

- (i) The trivial case: $n = 6j$ and $d = 2^{4j} + 2^{2j} + 1$ with $\lambda + \lambda^{2^{2j}} + \lambda^{2^{4j}} = 0$ —in this case f_λ is the null function;
- (ii) $n = 6j$ and $d = 2^{2j} + 2^j + 1$ with $\lambda \in \mathbf{F}_{2^{3j}}$ satisfying $\lambda + \lambda^{2^j} + \lambda^{2^{2j}} = 0$;
- (iii) $d = 2^t + 2^j + 1$ with $\lambda \in \mathbf{F}_{2^t}$.

Proof. The function f_λ can be represented in the form (2.1) if and only if the sum of the summands in (3.2) and (3.3) is either constant or linear on y . Note that since $y \in \mathbf{F}_{2^t}$ we are interested in the behavior of $d \pmod{2^t - 1}$.

Let us consider (3.2). We want to determine d such that $c(y) = T_1^t(T_t^{2t}(\lambda)y^d)$ is of degree strictly less than 3. Because of the conditions on i, j , if $c(y)$ is not constantly zero, then i must be equal to t . We will consider the cases $i = t$ and $i \neq t$ separately.

Let $d = 2^t + 2^j + 1$. Then the sum of terms in (3.2) and (3.3) becomes

$$g(y) = T_1^t \left(T_t^{2t}(\lambda)y^{2^j+2} \right) + T_1^t \left(T_t^{2t}(\lambda)(a^{2^t} + a)y^{2^j+1} + T_t^{2t}(\lambda a^{2^j})y^2 \right).$$

Suppose that $\lambda \notin \mathbf{F}_{2^t}$. So the function g is of degree 2. Indeed, the integer $2^j + 1$ cannot be a power of 2 and it is not in the cyclotomic coset (modulo $2^t - 1$) of $2^j + 2$. We must have

$$(3.4) \quad T_1^t \left(T_t^{2t}(\lambda)(a^{2^t} + a)y^{2^j+1} \right) = 0,$$

for any $a \in W$, where $j < t$. By Lemma 3.1(b), (3.4) holds if and only if

$$t = 2\ell, \quad j = \ell \quad \text{and} \quad T_t^{2t}(\lambda)T_t^{2t}(a) \in \mathbf{F}_{2^\ell}.$$

But this last condition cannot hold for any $a \in W$, since the map $a \mapsto T_t^{2t}(a)$, from W to $\mathbf{F}_{2^t}$, is bijective. We conclude that we must have $T_t^{2t}(\lambda) = 0$. In this case, we get $g(y) = T_1^t(T_t^{2t}(\lambda a^{2^j})y^2)$, which proves case (iii).

Let $d = 2^i + 2^j + 1$ with $i \neq t$. Set $d' = d \pmod{2^t - 1}$, $0 < d' < 2^t - 1$. In this case $c(y)$ must be constantly zero, and thus applying Lemma 3.1(a), we get

$$t = 3k, \quad d' = 2^{2k} + 2^k + 1 \quad \text{and} \quad T_{3k}^{6k}(\lambda + \lambda^{2^k} + \lambda^{2^{2k}}) = T_k^{6k}(\lambda) = 0.$$

Hence there are two possibilities for d : either $d = d'$ or $d = 2^{4k} + 2^{2k} + 1$. Suppose $d = d'$. Then the sum in (3.3) is as follows:

$$\begin{aligned} & T_1^{3k} \left(T_{3k}^{6k}(\lambda a^{2^{2k}})y^{2^k+1} + T_{3k}^{6k}(\lambda a^{2^k})y^{2^{2k}(2^k+1)} + T_{3k}^{6k}(\lambda a)y^{2^{2k}(2^k+1)} \right) \\ &= T_1^{3k} \left(T_{3k}^{6k}((\lambda + \lambda^{2^k} + \lambda^{2^{2k}})a^{2^{2k}})y^{2^k+1} \right) \\ &= T_1^{3k} \left((\lambda + \lambda^{2^k} + \lambda^{2^{2k}})T_{3k}^{6k}(a^{2^{2k}})y^{2^k+1} \right), \end{aligned}$$

where the last equality follows from previously obtained condition $T_k^{6k}(\lambda) = 0$. Lemma 3.1(b), implies that $\lambda + \lambda^{2^k} + \lambda^{2^{2k}} = 0$, which is possible only for $\lambda \in \mathbf{F}_{2^{3k}}$, because the polynomial $X + X^{2^k} + X^{2^{2k}}$ divides $X^{2^{3k}} + X$. Hence we have proved case (ii).

The last possibility is $d = 2^{4k} + 2^{2k} + 1$. We apply Lemma 3.2. If f_λ is not the null function, then $\mathcal{F}(f_\lambda) = 2^n - 2^{2j}d$. Since $\mathcal{F}(f_\lambda)$ is not divisible by 2^{3j} , we deduce from Proposition 2.1 that f_λ cannot be represented in the form (2.1). Hence we obtain the trivial case (i). $\square$

Further, we want to see when the decomposable cubic monomial functions are bent. We have seen that the exponent $d = 2^{4j} + 2^{2j} + 1$ does not lead to a bent monomial function. The bent monomial functions with the exponent $2^{2j} + 2^j + 1$ are studied in [1], where the following result is proved.

THEOREM 3.4 (see [1]). *The monomial function $T_1^{6r}(\lambda'x^{2^{2r}+2^r+1})$ in $\mathbf{F}_{2^{6r}}$ is bent if and only if there are $\lambda \in \mathbf{F}_{2^{3r}}$ and $a \in \mathbf{F}_{2^{6r}}$ such that $T_r^{3r}(\lambda) = 0$ and $\lambda' = \lambda a^{2^{2r}+2^r+1}$. Moreover, all these bent functions are from the Maiorana–McFarland class.*

By Theorem 3.3 only the exponents $2^t + 2^j + 1$ may provide further examples of cubic monomial bent functions from $\mathcal{M}(\mathbf{F}_{2^t})$. The rest of this paper is devoted to the study of this exponent.

4. Exponent $2^t + 2^j + 1$. In the study of the Walsh spectrum of the monomial functions with exponents $2^t + 2^j + 1$, we may restrict ourselves to the elements λ from the subfield $\mathbf{F}_{2^t}$. This is a consequence of the following observation.

LEMMA 4.1. *Let b be such that $\gcd(b, 2^t + 1) = 1$. Then, for any $\mu \in \mathbf{F}_{2^{2t}}$, there are $\lambda \in \mathbf{F}_{2^t}$ and $\delta \in \mathbf{F}_{2^{2t}}$ such that $\mu = \lambda\delta^b$. Consequently, the Walsh spectrum of the monomial function $T_1^{2t}(\mu x^b)$ is the same as the one of $T_1^{2t}(\lambda x^b)$.*

Proof. Let α be a primitive element of $\mathbf{F}_{2^{2t}}$. Since $\gcd(2^t - 1, 2^t + 1) = 1$, any element $\mu \in \mathbf{F}_{2^{2t}}^*$ can be expressed as follows:

$$\mu = \alpha^{\ell(2^t-1)} \alpha^{k(2^t+1)}, \quad 0 \leq \ell \leq 2^t, \quad 0 \leq k \leq 2^t - 2.$$

Since b and $2^t + 1$ are coprime, it holds that $\mu = \lambda\delta^b$ with $\lambda = \alpha^{k(2^t+1)}$ and $\delta^b = \alpha^{\ell(2^t-1)}$. $\square$

The next proposition gives the explicit decomposition of the function

$$(4.1) \quad g_\lambda(x) = T_1^{2t}(\lambda x^{2^t+2^j+1}), \quad 0 < j < t, \quad \lambda \in \mathbf{F}_{2^t}^*.$$

PROPOSITION 4.2. *Let $W \subset \mathbf{F}_{2^{2t}}$ be such that $\mathbf{F}_{2^{2t}} = \mathbf{F}_{2^t} \oplus W$. Then the function g_λ defined in (4.1) can be written as follows:*

$$g_\lambda(y, a) = T_1^t(y\pi(a) + h(a)), \quad y \in \mathbf{F}_{2^t}, \quad a \in W,$$

where $\pi, h : W \rightarrow \mathbf{F}_{2^t}$ are given by

$$\pi(a) = \lambda^{2^{t-1}}(a + a^{2^t})^{2^{j-1}} + \lambda(a^{2^t} + a)^{2^j+1}$$

and

$$h(a) = \lambda a^{2^t+1}(a + a^{2^t})^{2^j}.$$

Proof. For any $y \in \mathbf{F}_{2^t}$ and $a \in W$, we compute

$$g_\lambda(y, a) = g_\lambda(y + a) = T_1^{2t}(\lambda(y + a)^d).$$

We have $T_1^{2t}(\lambda y^d) = 0$ since λ and y are in $\mathbf{F}_{2^t}$. The part which is (a priori) quadratic relative to y is

$$\begin{aligned} B &= T_1^{2t} \left(\lambda(y^{1+2^j}a + y^{2^j+1}a^{2^t} + y^2a^{2^j}) \right) \\ &= T_1^{2t} \left(\lambda y^{2^j+1}(a^{2^t} + a) + \lambda y^2a^{2^j} \right) \\ &= T_1^{2t}(\lambda y^2a^{2^j}) = T_1^t(\lambda y^2(a + a^{2^t})^{2^j}), \end{aligned}$$

since $\lambda y^{2^j+1}(a^{2^t} + a) \in \mathbf{F}_{2^t}$. Further, we compute the part which is linear relative to y :

$$\begin{aligned} C &= T_1^{2t} \left(y(\lambda(a^{2^t+2^j} + a^{2^j+1}) + \lambda^{2^{t-j}}a^{2^{t-j}(2^t+1)}) \right) \\ &= T_1^{2t} \left(y\lambda(a^{2^t+2^j} + a^{2^j+1}) \right) \\ &= T_1^t \left(y\lambda(a^{2^t} + a)^{2^j+1} \right), \end{aligned}$$

since $\lambda^{2^{t-j}}a^{2^{t-j}(2^t+1)} \in \mathbf{F}_{2^t}$. Finally,

$$g_\lambda(y, a) = T_1^t \left(y(\lambda^{2^{t-1}}(a + a^{2^t})^{2^j+1} + \lambda(a^{2^t} + a)^{2^j+1}) \right) + T_1^{2t}(\lambda a^d).$$

So, we have $g_\lambda(y, a) = T_1^t(y\pi(a) + h(a))$, where $\pi(a)$ is the coefficient of y above and

$$h(a) = \lambda T_1^{2t}(a^d) = \lambda a^{2^t+1}(a + a^{2^t})^{2^j},$$

since $d = 2^t + 2^j + 1$ and $2^t d \equiv 1 + 2^t + 2^{t+j}$. $\square$

The obtained decomposition allows us to get some information on the Walsh spectrum of g_λ in general. By Proposition 2.1 we obtain

$$(4.2) \quad \mathcal{F}(g_\lambda + \varphi_u) = 2^t \sum_{a \in W_u} (-1)^{T_1^t(h(a) + T_1^{2t}(ua))},$$

where $W_u = \{ a \in W \mid \pi(a) = u + u^{2^t} \}$ and, by convention, the sum above is null if $W_u = \emptyset$. Note that

$$W_u = W_{u+\beta} \quad \text{for all } \beta \in \mathbf{F}_{2^t}.$$

Recall that g_λ is bent if and only if π is a permutation (see Corollary 2.2).

As a direct consequence of (4.2) we get a lower bound on the multiplicity of the value 0 in the Walsh spectrum of g_λ . This is because $W_u = \emptyset$ when $u + u^{2^t}$ is not in the image of π .

PROPOSITION 4.3. *Let I be the cardinality of the image of π in $\mathbf{F}_{2^t}$. Then*

$$\#\{ v \in \mathbf{F}_{2^{2t}} \mid \mathcal{F}(g_\lambda + \varphi_v) = 0 \} \geq 2^t(2^t - I).$$

Equation (4.2) gives also an upper bound on the magnitude of the value of Walsh transform at u in terms of the cardinality of W_u .

PROPOSITION 4.4. *For any u , $\mathcal{F}(g_\lambda + \varphi_u) \equiv 0 \pmod{2^t}$. Moreover,*

$$|\mathcal{F}(g_\lambda + \varphi_u)| \leq 2^t \times \#W_u.$$

As we have seen, the Walsh spectrum of g_λ could be determined as soon as we know the set W_u , which describes the preimages of the mapping $\pi : W \rightarrow \mathbf{F}_{2^t}$. Recall that

$$\pi(a) = \lambda^{2^{t-1}}(a + a^{2^t})^{2^{j-1}} + \lambda(a^{2^t} + a)^{2^j+1}.$$

Since the mapping $a \mapsto a + a^{2^t}$ is a permutation from W to $\mathbf{F}_{2^t}$, we have $\pi(a) = \pi'(a + a^{2^t})$, where $\pi' : \mathbf{F}_{2^t} \rightarrow \mathbf{F}_{2^t}$ is given by

$$(4.3) \quad \pi'(y) = \lambda^{2^{t-1}}y^{2^{j-1}} + \lambda y^{2^j+1}, \quad y \in \mathbf{F}_{2^t}.$$

Hence our problem is linked with the one of determining the image of π' or, equivalently, of $(\pi')^2$.

PROBLEM 1. *Let $\lambda \in \mathbf{F}_{2^t}$. For any $\tau \in \mathbf{F}_{2^t}$, compute the number of $y \in \mathbf{F}_{2^t}$ such that*

$$\lambda^2 y^{2(2^j+1)} + \lambda y^{2^j} + \tau = 0.$$

This problem can be easily solved for $\tau = 0$, which yields information on $\mathcal{F}(g_\lambda + \varphi_u)$ for $u \in \mathbf{F}_{2^t}$ as in subsection 4.1 shown. Subsection 4.2 is devoted to the characterization of λ and j such that the equation of Problem 1 has exactly one solution.

4.1. The case $u \in \mathbf{F}_{2^t}$. Let $u \in \mathbf{F}_{2^t}$. Then $W_u = \{ a \in W \mid \pi(a) = 0 \}$ and $W_u = W_{u'}$ for all $u' \in \mathbf{F}_{2^t}$. Clearly, $\pi'(0) = 0$, where π' is given by (4.3). For nonzero y , it holds that

$$\pi'(y) = 0 \Leftrightarrow y^{2^{j-1}+1} = \lambda^{2^{t-1}-1} \Leftrightarrow y^{2^j+2} = \frac{1}{\lambda}.$$

Thus, for any $u \in \mathbf{F}_{2^t}$,

$$(4.4) \quad W_u = \left\{ a \in W \mid a = 0 \text{ or } (a + a^{2^t})^{2^j+2} = \frac{1}{\lambda} \right\}.$$

LEMMA 4.5. *Let $u \in \mathbf{F}_{2^t}$. Then the constant term of g_λ , given by*

$$h(a) = \lambda a^{2^t+1}(a + a^{2^t})^{2^j},$$

satisfies $T_1^t(h(a)) = 1$ for any nonzero $a \in W_u$.

Proof. Note that $h(0) = 0$ and assume now that $a \neq 0$. Using (4.4), we have $(a + a^{2^t})^{2^j+2} = \lambda^{-1}$. By replacing $(a + a^{2^t})^{2^j}$ in $h(a)$, we get

$$h(a) = \lambda a^{2^t+1} \lambda^{-1} (a + a^{2^t})^{-2} = \frac{a^{2^t+1}}{(a + a^{2^t})^2}.$$

The elements a and a^{2^t} are the solutions in $\mathbf{F}_{2^{2t}}$ of the equation

$$x^2 + (a + a^{2^t})x + a^{2^t+1} = 0,$$

while they do not belong to $\mathbf{F}_{2^t}$. This implies that the polynomial $X^2 + (a + a^{2^t})X + a^{2^t+1} \in \mathbf{F}_{2^t}[X]$ is irreducible over $\mathbf{F}_{2^t}$. Hence

$$T_1^t \left(\frac{a^{2^t+1}}{(a + a^{2^t})^2} \right) = T_1^t(h(a)) = 1. \quad \square$$

Now we can describe the values $\mathcal{F}(g_\lambda + \varphi_u)$ for $u \in \mathbf{F}_{2^t}$ more precisely. Notably, we compute the weight of each function g_λ .

PROPOSITION 4.6. *Let $u \in \mathbf{F}_{2^t}$ and W_u be given by (4.4). Set $s = \gcd(2^{j-1} + 1, 2^t - 1)$. Then we have the following:*

(i) *If $s = 1$ (i.e., $t/\gcd(j-1, t)$ odd) then $\#W_u = 2$ and*

$$\mathcal{F}(g_\lambda + \varphi_u) = \begin{cases} 0 & \text{if } T_1^t(u(a + a^{2^t})) = 0, \\ 2^{t+1} & \text{if } T_1^t(u(a + a^{2^t})) = 1, \end{cases}$$

where a is the unique element of W_u different from 0. Note that each value above occurs 2^{t-1} times. In particular, $\mathcal{F}(g_\lambda) = 0$.

(ii) *Set $S_s = \{u^s | u \in \mathbf{F}_{2^t}\}$. For $s > 1$ we have that*

- *if $\lambda \notin S_s$, then $\mathcal{F}(g_\lambda + \varphi_u) = 2^t$ for any u .*
- *if $\lambda \in S_s$, then $|\mathcal{F}(g_\lambda + \varphi_u)| \leq (s+1)2^t$. In particular, $\mathcal{F}(g_\lambda) = (1-s)2^t$.*

Consequently, if g_λ is bent then $s > 1$ and $\lambda \notin S_s$.

Proof. According to (4.4), we get from (4.2) and Lemma 4.5 that

$$\begin{aligned} \mathcal{F}(g_\lambda + \varphi_u) &= 2^t \sum_{a \in W_u} (-1)^{T_1^t(h(a) + u(a + a^{2^t}))} \\ &= 2^t - 2^t \sum_{a \in W_u, a \neq 0} (-1)^{T_1^t(u(a + a^{2^t}))}. \end{aligned}$$

(i) When $s = 1$ then W_u contains only 0 and a unique a such that $(a + a^{2^t})^{2^j+2} = \lambda^{-1}$. Consequently, $\mathcal{F}(g_\lambda + \varphi_u) = 0$ or 2^{t+1} depending on whether $T_1^t(u(a + a^{2^t})) = 0$ or 1. Since u runs through $\mathbf{F}_{2^t}$, each such case occurs 2^{t-1} times. In particular, for $u = 0$, we get $\mathcal{F}(g_\lambda) = 0$.

(ii) Now assume that $s > 1$. If $\lambda \notin S_s$, then $W_u = \{0\}$, implying $\mathcal{F}(g_\lambda + \varphi_u) = 2^t$ for any u .

Denote by G_s the subgroup of $\mathbf{F}_{2^t}^*$ of order s . If $\lambda \in S_s$, then

$$W_u = \{0\} \cup \{a \in W \mid a + a^{2^t} \in yG_s \text{ with } y^{2^j+2} = \lambda^{-1}\}$$

(where $y \in \mathbf{F}_{2^t}$). Using Proposition 4.4, we conclude that $|\mathcal{F}(g_\lambda + \varphi_u)| \leq (s+1)2^t$ when $\lambda \in S_s$. Finally, observe that for $u = 0$, we get $\mathcal{F}(g_\lambda) = (1-s)2^t$. $\square$

4.2. The bent functions. In this section we find all j and $\mu \in \mathbf{F}_{2^{2t}}$ defining bent monomial functions $x \mapsto T_1^{2t}(\mu x^{2^t+2^j+1})$. Remember that this is equivalent to describing those $\lambda \in \mathbf{F}_{2^t}$ for which π' , defined in (4.3), is a permutation. Consider

$$\begin{aligned} (\pi'(y))^2 &= \lambda y^{2^j} + \lambda^2 y^{2^j+1+2} \\ &= \lambda(y + \lambda^{2^t-j} y^{2^t-j(2^j+1)+2})^{2^j} \\ &= \lambda(y + \lambda^{2^t-j} y^{2^t-j+1+2})^{2^j} \\ &= \lambda^2(\lambda^{-2^t-j} y + y^{2^t-j+1+2})^{2^j}. \end{aligned}$$

Thus, the function g_λ is bent if and only if the mapping $\rho: \mathbf{F}_{2^t} \rightarrow \mathbf{F}_{2^t}$, given by

$$\rho(y) = y^{2^t-j+1+2} + \nu y,$$

where $\nu = \lambda^{-2^t-j}$, is a permutation. All such permutation polynomials are characterized in Theorem 5.1 of the next section. In particular, Theorem 5.1 implies the following proposition.

PROPOSITION 4.7. Let $g_\lambda = T_1^{2t}(\lambda x^{2^t+2^j+1})$, $0 < j < t$, $\lambda \in \mathbf{F}_{2^t}^*$. Then, g_λ can be bent only if $t = 2r$, r odd, and $j = r + 1$.

In [10] it is shown that the exponent $2^{2r} + 2^{r+1} + 1$ in $\mathbf{F}_{2^{4r}}$, r odd, yields a bent function if λ is chosen to be β^5 , where β is the root of the polynomial $X^4 + X + 1$. Theorem 5.1 allows us to extend this result.

THEOREM 4.8. Let $\omega \in \mathbf{F}_4 \setminus \mathbf{F}_2$. The monomial function $T_1^{4r}(\mu x^{2^{2r}+2^{r+1}+1})$ on $\mathbf{F}_{2^{4r}}$ is bent for some $\mu \in \mathbf{F}_{2^{4r}}$ if and only if r is odd and there are $\lambda \in \omega \mathbf{F}_{2^r}$ and $a \in \mathbf{F}_{2^{4r}}$ such that $\mu = \lambda a^{2^{2r}+2^{r+1}+1}$.

5. On some binomial quadratic permutations in $\mathbf{F}_{2^t}$. In this section we describe all permutation polynomials of type

$$X^{2^k+2} + \nu X$$

in a finite field of characteristics 2. More precisely, we will prove the next theorem.

THEOREM 5.1. Let $0 \leq k \leq t - 1$ and $\nu \neq 0$. Then the polynomial

$$\rho(X) = X^{2^k+2} + \nu X \quad \text{in } \mathbf{F}_{2^t}[X]$$

is a permutation polynomial of $\mathbf{F}_{2^t}$ if and only if t is even and

- either $k = 1$ and ν is not a third power in $\mathbf{F}_{2^t}$, or
- $t = 2r$, $r \geq 3$ with r odd, $k = r$, and $\nu \in \omega \mathbf{F}_{2^r}$, where $\omega \in \mathbf{F}_{2^2} \setminus \mathbf{F}_2$.

We will use some well-known facts about the quadratic monomial Boolean functions. Our main reference is [11, pp. 175–189]; we give only the idea of a proof of Proposition 5.2. The interested reader may see [8, 10] for these proofs and [5, 8] for some other properties of the quadratic monomial functions.

PROPOSITION 5.2. Let $\gcd(t, i) = s$ and $F: \mathbf{F}_{2^t} \rightarrow \mathbf{F}_{2^t}$ be given by $F(x) = x^{2^i+1}$. Let f_μ , $\mu \in \mathbf{F}_{2^t}^*$, be the Boolean function defined by $f_\mu(x) = T_1^t(\mu F(x))$. Then the following properties hold:

- (a) The function F is bijective if and only if t/s is odd.
- (b) If t/s is odd, then the Walsh transform of the Boolean function f_μ takes the values $\{0, \pm 2^{\frac{t+s}{2}}\}$. In particular, f_μ is never bent.
- (c) Assume that t/s is even. The function f_μ is bent if and only if μ is not a $(2^i + 1)$ th power in $\mathbf{F}_{2^t}$. Otherwise, its Walsh transform takes the values $\{0, \pm 2^{\frac{t+2s}{2}}\}$.

Proof. The function F is bijective if and only if $\gcd(2^i + 1, 2^t - 1) = 1$ which is equivalent to $s = \gcd(2i, t)$, i.e., t/s odd.

Set $S = \{y^{2^i+1} | y \in \mathbf{F}_{2^t}\}$. The function f_μ is bent if and only if t/s is even and $\mu \notin S$ (see [10, Thm. 2]). Otherwise the Walsh spectrum of f_μ is the same as that of the function $x \mapsto T_1^t(x^{2^i+1})$. The Walsh transform of this quadratic function takes the values

$$\begin{aligned} &\{0, \pm 2^{\frac{t+s}{2}}\} && \text{if } t/s \text{ is odd,} \\ &\{0, \pm 2^{\frac{t+2s}{2}}\} && \text{if } t/s \text{ is even and } \mu \in S. \end{aligned}$$

(see [11, Thm. 11.13]). $\square$

Further, we need also the following property of the Walsh transform of quadratic Boolean functions.

PROPOSITION 5.3. Let $\gcd(t, i) = s$, t/s be odd. Let f be the Boolean function on $\mathbf{F}_{2^t}$ defined by $f(x) = T_1^t(x^{2^i+1} + \beta x)$. Then f is balanced if and only if $T_s^t(\beta) \neq 1$.

Proof. Note that $T_s^t(1) = 1$ since $t = su$ with odd u . Such a function f is balanced if and only if there is $a \in \mathbf{F}_{2^t}^*$ such that the derivative of f with respect to a constantly equals 1, that is,

$$h_a(x) = f(x) + f(x+a) = 1 \quad \text{for all } x$$

(see a proof in [4, Prop. II-5]). We compute the derivative of f with respect to a :

$$h_a(x) = T_1^t(ax^{2^i} + a^{2^i}x + a^{2^i+1} + \beta a) = T_1^t\left(x(a^{2^{t-i}} + a^{2^i}) + a(a^{2^i} + \beta)\right).$$

Then h_a is constant if and only if $a^{2^{2i}} = a$, i.e., $a \in \mathbf{F}_{2^s}^*$. In this case,

$$h_a(x) = T_1^t(a + \beta a) = T_1^s(aT_s^t(1 + \beta)) = T_1^s(a(1 + T_s^t(\beta))).$$

So, there is $a \in \mathbf{F}_{2^s}^*$ such that $h_a = 1$ if and only if $T_s^t(\beta) \neq 1$. $\square$

Now we are going to prove Theorem 5.1 by means of the two following lemmas.

LEMMA 5.4. *Let $\nu \in \mathbf{F}_{2^t}$ and $\rho : \mathbf{F}_{2^t} \rightarrow \mathbf{F}_{2^t}$ be given by the polynomial*

$$(5.1) \quad \rho(X) = X^{2^k+2} + \nu X, \quad 2 \leq k \leq t-1.$$

Take $c = \gcd(t, k-1)$. Then ρ is a permutation polynomial of $\mathbf{F}_{2^t}$ if and only if

$$\frac{t}{c} \text{ is odd and } T_c^t(\gamma^{2^k+1}\nu) \neq 1 \quad \text{for every } \gamma \in \mathbf{F}_{2^t}.$$

In this case, t is even, $\frac{t}{\gcd(t,k)}$ is even, and k is odd.

Proof. It is well known that a mapping $g : \mathbf{F}_{2^t} \rightarrow \mathbf{F}_{2^t}$ is bijective if and only if

$$\sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(\beta g(x))} = 0$$

for any $\beta \in \mathbf{F}_{2^t}^*$. Consider the sum

$$S = \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(\beta x^{2^k+2} + \beta \nu x)} = \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(\beta^{2^{n-1}} x^{2^{k-1}+1} + \beta \nu x)}.$$

Suppose t/c is even; then by Proposition 5.2(c), there is a β such that the function $x \mapsto T_1^t(\beta^{2^{n-1}} x^{2^{k-1}+1})$ is bent. Clearly, $S \neq 0$ for such a β . Hence ρ defines a permutation only if t/c is odd.

We assume that t/c is odd, i.e., by Proposition 5.2(a), the mapping $x \mapsto x^{2^{k-1}+1}$ is a permutation on $\mathbf{F}_{2^t}$. Then $\beta^{2^{n-1}} = \gamma^{2^{k-1}+1}$ for some $\gamma \in \mathbf{F}_{2^t}$ and

$$\begin{aligned} S &= \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t((\gamma x)^{2^{k-1}+1} + \gamma^{2^k+2} \nu x)} \\ &= \sum_{z \in \mathbf{F}_{2^t}} (-1)^{T_1^t(z^{2^{k-1}+1} + \gamma^{2^k+1} \nu z)}, \end{aligned}$$

where $z = \gamma x$. Hence, we are interested in $\nu \in \mathbf{F}_{2^t}$ satisfying

$$(5.2) \quad \sum_{z \in \mathbf{F}_{2^t}} (-1)^{T_1^t(z^{2^{k-1}+1} + \gamma^{2^k+1} \nu z)} = 0 \quad \text{for every } \gamma \in \mathbf{F}_{2^t}.$$

By Proposition 5.3, condition (5.2) is satisfied if and only if

$$(5.3) \quad T_c^t(\gamma^{2^k+1}\nu) \neq 1 \quad \text{for every } \gamma \in \mathbf{F}_{2^t}.$$

Let $s = \gcd(t, k)$. If (5.3) holds, then t/s must be even because otherwise $x \mapsto x^{2^k+1}$ would be a permutation. Hence t must be even. Further, $k-1$ must be even when t/c is odd. $\square$

Now we are going to prove that condition (5.3) is generally impossible.

LEMMA 5.5. *Let $t = 2r$, $1 \leq k \leq r$, and $c = \gcd(t, k-1)$, where k is odd. Assume that there exists an element $\lambda \in \mathbf{F}_{2^t}^*$ satisfying*

$$T_c^t(\gamma^{2^k+1}\lambda) \neq 1 \quad \text{for every } \gamma \in \mathbf{F}_{2^t}.$$

Then $k = r$ and $c = 2$. In particular, r is odd.

Proof. Note that c is even, by hypothesis, and thus $c \geq 2$. Denote by N the number of $x \in \mathbf{F}_{2^t}$ satisfying

$$T_c^t(x^{2^k+1}\lambda) = 1.$$

We have

$$\begin{aligned} & \sum_{x \in \mathbf{F}_{2^t}} \sum_{a \in \mathbf{F}_{2^t}} (-1)^{T_1^t(a(T_c^t(x^{2^k+1}\lambda)+1))} \\ &= 2^t \times \#\{x \in \mathbf{F}_{2^t} \mid T_c^t(x^{2^k+1}\lambda) = 1\} \\ &= 2^t N. \end{aligned}$$

Hence we can use the results on the Walsh transform of quadratic monomial functions to bound N . Our goal is to show that $N \geq 1$, except for the case $k = r$. Setting $b = T_c^t(a)$, the above sum can be modified to

$$\begin{aligned} N &= \frac{1}{2^t} \sum_{b \in \mathbf{F}_{2^c}} 2^{t-c} (-1)^{T_1^c(b)} \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^c(b(T_c^t(x^{2^k+1}\lambda)))} \\ &= \frac{1}{2^c} \sum_{b \in \mathbf{F}_{2^c}} (-1)^{T_1^c(b)} \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(b\lambda x^{2^k+1})} \\ &= \frac{1}{2^c} \left(2^t + \sum_{b \in \mathbf{F}_{2^c}^*} (-1)^{T_1^c(b)} \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(b\lambda x^{2^k+1})} \right). \end{aligned}$$

Let $s = \gcd(t, k)$. Since t/s is even, we have, by Proposition 5.2,

$$\mathcal{F}(h) = \sum_{x \in \mathbf{F}_{2^t}} (-1)^{T_1^t(b\lambda x^{2^k+1})} \in \{0, \pm 2^{r+s}, \pm 2^r\}.$$

Thus,

$$N = \frac{1}{2^c} \left(2^t + \sum_{b \in \mathbf{F}_{2^c}^*} (-1)^{T_1^c(b)} \epsilon_b \right),$$

where $\epsilon_b \in \{0, \pm 2^r, \pm 2^{r+s}\}$. In particular,

$$(5.4) \quad N > \frac{1}{2^c} (2^t - 2^c 2^{r+s}) = 2^{t-c} - 2^{r+s} = 2^r (2^{r-c} - 2^s).$$

Let us prove that $r - c \geq s$ unless $k = r$. Recall that $c = \gcd(2r, k - 1)$ is even. Moreover, s is odd, $c < k \leq r$, and, clearly, $\gcd(s, c) = 1$.

First, note that $r - c \geq s$ for $s = 1$, since $r - c \geq 1$. So we assume that $s \geq 3$. Set $c = 2c'$ so that $r = sc'v$ for some c' and some $v \geq 1$. So we have

$$r - c = sc'v - 2c' = c'(sv - 2).$$

If $v > 1$, then for any c' ,

$$r - c = c'(sv - 2) = c'(s + (s(v - 1) - 2)) \geq s.$$

If $v = 1$, then $r = c's$ and we want to check when $c'(s - 2) \geq s$. Setting $s = 2 + \tau$ with τ odd, it holds if and only if $c'\tau \geq \tau + 2$. This last inequality is satisfied unless $c' = 1$ or $c' = 2$ and $\tau = 1$.

In the case where $c' = 2$ and $\tau = 1$, we have $r = 6$ and $s = 3$ so that $k = 3$, since $s = \gcd(r, k)$. Further, $c = 4$ and we get $k > c$, a contradiction.

Finally, it appears that $r - c \geq s$ unless $c' = 1$ and $v = 1$, the case where $r = s = k$. According to (5.4), we conclude that $N \geq 1$ unless $k = r$. In this case, we have $k = r = s$, which implies that r is odd and $c = 2$, completing the proof. $\square$

Now we are able to prove our main theorem.

Proof of Theorem 5.1. We are now able to determine which polynomials of type

$$\rho(X) = X^{2^k+2} + \nu X, \quad \rho \in \mathbf{F}_{2^t}[X],$$

with $0 \leq k \leq t - 1$, are permutations of $\mathbf{F}_{2^t}$. If $k = 0$, then $\rho(X) = X^3 + \nu X$. So ρ cannot be a permutation, since it has two roots in $\mathbf{F}_{2^t}$. For $k = 1$, we get

$$\rho(X) = X^4 + \nu X = X(X^3 + \nu),$$

which is a linearized polynomial. Thus, it is a permutation polynomial if and only if it has only one root, i.e., ν is never equal to x^3 when x runs through $\mathbf{F}_{2^t}^*$.

We now assume that $k > 1$. According to Lemmas 5.4 and 5.5, we know that ρ is a permutation only when $t = 2r$, with r odd, $k = r$, and $c = \gcd(2r, r - 1) = 2$. Moreover, those ν such that ρ is a permutation are the elements of $\mathbf{F}_{2^t}^*$ which satisfy

$$(5.5) \quad T_2^{2r}(\gamma^{2^r+1}\nu) \neq 1 \quad \text{for every } \gamma \in \mathbf{F}_{2^{2r}}.$$

Note that $\{\gamma^{2^r+1} | \gamma \in \mathbf{F}_{2^{2r}}\} = \mathbf{F}_{2^r}$, and therefore (5.5) is equivalent to

$$(5.6) \quad T_2^{2r}(\delta\nu) \neq 1 \quad \text{for every } \delta \in \mathbf{F}_{2^r}.$$

It remains to describe the set of suitable ν . Consider the map $\ell_\nu : \mathbf{F}_{2^r} \rightarrow \mathbf{F}_{2^2}$ defined by $\ell_\nu(z) = T_2^{2r}(\nu z)$. Note that ℓ_ν is $\mathbf{F}_2$ -linear and

$$\ell_\nu(z) = \nu z + \cdots + (\nu z)^{2^{r-1}} + \nu^{2^{r+1}} z^2 + \cdots + \nu^{2^{2(r-1)}} z^{2^{r-2}}.$$

So ℓ_ν cannot be constant.

Moreover, if also (5.6) holds, then

$$(5.7) \quad \{\ell_\nu(z) | z \in \mathbf{F}_{2^r}\} = \{0, \omega\}, \quad \text{where } \omega \in \mathbf{F}_{2^2} \setminus \mathbf{F}_2.$$

Assume that ℓ_ν satisfies (5.7) for such ω . We consider now the map $\ell_{\nu\omega^2}$. Since $\ell_{\nu\omega^2}(z) = \omega^2\ell_\nu(z)$, we have

$$(5.8) \quad \{\ell_{\nu\omega^2}(z) | z \in \mathbf{F}_{2^r}\} = \{0, 1\}.$$

From (5.8) it follows that $T_1^2(\ell_{\nu\omega^2}(z)) = 0$ for every $z \in \mathbf{F}_{2^r}$. Observe, that

$$T_1^2(\ell_{\nu\omega^2}(z)) = T_1^2(T_2^{2r}(\nu\omega^2 z)) = T_1^{2r}(\nu\omega^2 z) = T_1^r(T_r^{2r}(\nu\omega^2 z)).$$

But the function $z \mapsto T_1^r(T_r^{2r}(\nu\omega^2 z))$ is constantly zero if and only if $T_r^{2r}(\nu\omega^2)$ is zero, which is equivalent to $\nu\omega^2 \in \mathbf{F}_{2^r}$. To complete the proof, note that for any $\nu = \omega u$, with $u \in \mathbf{F}_{2^r}$, we have

$$\ell_{\nu\omega}(z) = \omega\ell_1(uz) = \omega T_1^r(uz),$$

implying (5.7). $\square$

Remark 1. Note that we have proved the following: There are $2(2^r - 1)$ permutations of $\mathbf{F}_{2^{2r}}$ with polynomial form $X^{2^r+2} + \nu X$. These correspond to

$$\nu \in (\omega\mathbf{F}_{2^r}^*) \cup (\omega^2\mathbf{F}_{2^r}^*)$$

with notation $\mathbf{F}_4 = \{0, 1, \omega, \omega^2\}$.

6. Conclusion. As one may see from the list of known monomial bent functions in the introduction, the quadratic monomial bent functions are easily characterized. The complete classification of the cubic monomial bent functions $T_1^{2^t}(\lambda x^{2^t+2^j+1})$ seems to be a difficult problem. In this paper all bent exponents $2^t + 2^j + 1$ are found. Further, it is shown that all cubic monomial bent functions from the Maiorana–McFarland family to the subfield are known. All known bent exponents (computer search for $n \leq 24$, exhaustive search for $n \leq 20$) are covered by the examples in the introduction. However, the following question remains open.

OPEN PROBLEM 1. *Are there cubic monomial bent functions besides those listed in the introduction of this paper?*

Acknowledgments. The authors thank Anne Canteaut for many helpful discussions along this work. They wish also to thank Gregor Leander for his valuable comments.

RANK-WIDTH AND WELL-QUASI-ORDERING*

SANG-IL OUM†

Abstract. Robertson and Seymour [*J. Combin. Theory Ser. B*, 48 (1990), pp. 227–254] proved that graphs of bounded tree-width are well-quasi-ordered by the graph minor relation. By extending their arguments, Geelen, Gerards, and Whittle [*J. Combin. Theory Ser. B*, 84 (2002), pp. 270–290] proved that binary matroids of bounded branch-width are well-quasi-ordered by the matroid minor relation. We prove another theorem of this kind in terms of *rank-width* and *vertex-minors*. For a graph $G = (V, E)$ and a vertex v of G , a *local complementation* at v is an operation that replaces the subgraph induced by the neighbors of v with its complement graph. A graph H is called a *vertex-minor* of G if H can be obtained from G by applying a sequence of vertex deletions and local complementations. Rank-width was defined by Oum and Seymour [*J. Combin. Theory Ser. B*, 96 (2006), pp. 514–528] to investigate clique-width; they showed that graphs have bounded rank-width if and only if they have bounded clique-width. We prove that graphs of bounded rank-width are well-quasi-ordered by the vertex-minor relation; in other words, for every infinite sequence $G_1, G_2, \dots$ of graphs of rank-width (or clique-width) at most k , there exist $i < j$ such that G_i is isomorphic to a vertex-minor of G_j . This implies that there is a finite list of graphs such that a graph has rank-width at most k if and only if it contains no one in the list as a vertex-minor. The proof uses the notion of *isotropic systems* defined by Bouchet.

1. Introduction. Oum and Seymour [12] defined *rank-width* in order to investigate *clique-width*, which was defined by Courcelle and Olariu [5]. Rank-width is a complexity measure of graph in a kind of tree structure, called a *rank-decomposition*. Oum and Seymour showed that graphs have bounded rank-width if and only if they have bounded clique-width and they used it to find an approximation algorithm for clique-width.

Later the author [11] showed that the notion of rank-width of graphs has an interesting intersection with the notion of *branch-width* of matroids. More specifically, the branch-width of a binary matroid is exactly one more than the rank-width of its fundamental graph.

The branch-width of matroids generalizes the branch-width of graphs, both defined by Robertson and Seymour [14]. Branch-width of graphs is approximately equal to *tree-width*, also defined by Robertson and Seymour. Informally speaking, tree-width is a measure describing how close a graph is to being a forest.

Both tree-width and branch-width are interesting with respect to the *graph minor* relation. A *contraction* of an edge e is an operation, that deletes e and identifies the ends of e . A graph H is a *minor* of a graph G if H can be obtained from G by a sequence of contractions, vertex deletions, and edge deletions. If H is a minor of G , then the tree-width of H is at most that of G and the same is true for branch-width. This implies that a set of graphs of bounded tree-width is closed under the graph minor relation.

†Department of Mathematical Sciences, KAIST, Daejeon, 305-701 Republic of Korea (sangil@kaist.edu).

In this paper, we consider vertex-minors of graphs, previously called *l-reductions* by Bouchet [4]. For a graph G and a vertex v of G , let $G * v$ be the graph, obtained by *local complementation* at v , that is, by replacing the subgraph induced by the neighbors of v with its complement graph. We say that G is *locally equivalent* to H if H can be obtained from G by applying a sequence of local complementations. A graph H is a *vertex-minor* of G if H can be obtained from G by applying a sequence of vertex deletions and local complementations. A simple fact is that if H is a vertex-minor of G , then the rank-width of H is at most that of G . For an edge uv of G , *pivoting* on uv , denoted by $G \wedge uv$, is the composition of three local complementations, $G \wedge uv = G * u * v * u$. It is an easy exercise to show that $G * u * v * u = G * v * u * v$ if uv is an edge of G . We say that H is a *pivot-minor* of G if H can be obtained from G by applying a sequence of vertex deletions and pivots. Every pivot-minor of G is a vertex-minor of G , but not vice versa.

In this paper, we prove the following theorem.

THEOREM 4.1. *Let k be a constant. If $\{G_1, G_2, G_3, \dots\}$ is an infinite sequence of graphs of rank-width at most k , then there exist $i < j$ such that G_i is isomorphic to a pivot-minor of G_j , and therefore isomorphic to a vertex-minor of G_j .*

This theorem is motivated by the following two theorems. The first one is for graphs of bounded tree-width, proved by Robertson and Seymour [13].

THEOREM 1.1. *Let k be a constant. If $\{G_1, G_2, G_3, \dots\}$ is an infinite sequence of graphs of tree-width at most k , then there exist $i < j$ such that G_i is isomorphic to a minor of G_j .*

The next one, generalizing the previous one, is due to Geelen, Gerards, and Whittle [8].

THEOREM 1.2. *Let k be a constant. Let $\mathbb{F}$ be a finite field. If $\{M_1, M_2, M_3, \dots\}$ is an infinite sequence of $\mathbb{F}$ -representable matroids of branch-width at most k , then there exist $i < j$ such that M_i is isomorphic to a minor of M_j .*

It is straightforward to prove (section 11) that Theorem 1.2 restricted to binary matroids is equivalent to Theorem 4.1 restricted to bipartite graphs. In fact, the main idea of proving Theorem 1.2 remains in our paper, although we have to go through a different technical notion. In the original proof of Theorem 1.2, the authors use “configurations” to represent $\mathbb{F}$ -representable matroids, and then convert the matroid problem into a vector space problem. In our proof, we use the similar approach but a different notion. Bouchet defined *isotropic systems* and developed their minors and their relation to graphs in a series of papers [1, 2, 3]. Informally speaking, an isotropic system can be considered as an equivalence class of graphs by *local equivalence*. Isotropic systems also generalize pairs of a binary matroid and its dual. A detailed definition will be reviewed in section 3.

In sections 2 and 3, we review some notions and results. The overview of the proof is given in section 4. Then in sections 5 till 8, we prove several lemmas, including an extension of Tutte’s linking theorem to isotropic systems, in section 7. Then in section 9 we prove that isotropic systems of bounded branch-width are well-quasi-ordered under the “isotropic system minor” order and in section 10 we prove that the theorem implies the well-quasi-ordering of graphs under the pivot-minor order. In section 11 we explain why the result restricted to bipartite graphs is the same as Theorem 1.2 restricted to binary matroids.

2. Review on rank-width. In this paper, we assume that graphs are simple, undirected, and finite. Let us review the definition of rank-width, introduced by Oum and Seymour [12]. We will first describe the branch-width of connectivity functions and then use this to define the rank-width.

For a finite set V , an integer-valued function c on subsets of V is called a *connectivity function* if $c(X) + c(Y) \geq c(X \cap Y) + c(X \cup Y)$ for all $X, Y \subseteq V$, $c(X) = c(V \setminus X)$ for all $X \subseteq V$, and $c(\emptyset) = 0$. A *subcubic tree* is a tree such that every vertex has exactly one or three incident edges. We call $(T, \mathcal{L})$ a *branch-decomposition* of a connectivity function c on subsets of V if T is a subcubic tree and $\mathcal{L}$ is a bijection from V to the set of all leaves of T . For an edge e of T , connected components of $T \setminus e$ induce a partition (X, Y) of the set of leaves of T . The *width* of an edge e of a branch-decomposition $(T, \mathcal{L})$ is $c(\mathcal{L}^{-1}(X))$. The *width* of $(T, \mathcal{L})$ is the maximum width of all edges of T . The *branch-width* $\text{bw}(c)$ of c is the minimum width of a branch-decomposition of c . (If $|V| \leq 1$, we define that $\text{bw}(c) = c(\emptyset)$.)

For a branch-decomposition $(T, \mathcal{L})$ of c , let e and f be two edges of T . Let E be the set of leaves of T in the component of $T \setminus e$ not containing f , and let F be the set of leaves of T in the component of $T \setminus f$ not containing e . Let P be the shortest path in T containing e and f . We call e and f *linked* if

$$\min_{h \in E(P)} (\text{width of } h \text{ of } (T, \mathcal{L})) = \min_{\mathcal{L}^{-1}(E) \subseteq Z \subseteq V \setminus \mathcal{L}^{-1}(F)} c(Z).$$

We call a branch-decomposition $(T, \mathcal{L})$ *linked* if each pair of edges of T is linked.

For a matrix $M = (m_{ij} : i \in R, j \in C)$ over a field $\mathbb{F}$, if $X \subseteq R$ and $Y \subseteq C$, let $M[X, Y]$ denote the submatrix $(m_{ij} : i \in X, j \in Y)$. For a graph G , let A_G be its adjacency matrix over the binary field $\text{GF}(2)$.

For a graph $G = (V, E)$ and two disjoint subsets $X, Y \subseteq V$, we define $\rho_G^*(X, Y) = \text{rank}(A_G[X, Y])$ where rank is the matrix rank function; and we define the *cut-rank* function ρ_G of G by $\rho_G(X) = \rho_G^*(X, V(G) \setminus X)$ for $X \subseteq V$.

It is well known that the cut-rank function is an instance of a connectivity function (see [12]). A *rank-decomposition* of a graph is a branch-decomposition of its cut-rank function and the *rank-width* of a graph is the branch-width of its cut-rank function.

3. Review on the isotropic system. In this section, the notion of the isotropic system and a few useful theorems will be reviewed. All material is from Bouchet's papers [1, 2, 3]. We change some notations. The author's thesis [10] also contains the proofs of all theorems in this section.

3.1. Definition of the isotropic system. For a vector space W with a bilinear form $\langle \cdot, \cdot \rangle$, a subspace L of W is called *totally isotropic* if and only if $\langle x, y \rangle = 0$ for all $x, y \in L$.

Let $K = \{0, \alpha, \beta, \gamma\}$ be the 2-dimensional vector space over $\text{GF}(2)$. So this means that $\alpha + \beta + \gamma = \alpha + \alpha = \beta + \beta = \gamma + \gamma = 0$. Moreover, let $\langle \cdot, \cdot \rangle$ be the bilinear form on K defined by

$$\langle x, y \rangle = \begin{cases} 1 & \text{if } x \neq y \text{ and } x, y \neq 0, \\ 0 & \text{otherwise.} \end{cases}$$

Let V be a finite set. Let K^V be the set of functions from V to K , and so K^V is a vector space over $\text{GF}(2)$. We attach the following bilinear form to K^V :

$$\text{for } x, y \in K^V, \quad \langle x, y \rangle = \sum_{v \in V} \langle x(v), y(v) \rangle.$$

DEFINITION 3.1 (see Bouchet [1]). *An isotropic system is a pair $S = (V, L)$ of a finite set V and a totally isotropic subspace L of K^V with $\dim(L) = |V|$. V is called the element set of S .*

For $X \subseteq V$, let $p_X : K^V \rightarrow K^X$ be the *canonical projection* such that

$$(p_X(a))(v) = a(v) \quad \text{for all } v \in X.$$

For $a \in K^V$ and $X \subseteq V$, $a[X]$ is the vector in K^V such that

$$a[X](v) = \begin{cases} a(v) & \text{if } v \in X, \\ 0 & \text{if } v \in V \setminus X. \end{cases}$$

Let L be a subspace of K^V and $v \in V$. Let $x \in K \setminus \{0\} = \{\alpha, \beta, \gamma\}$.

- Let $L^\perp$ be the subspace of K^V such that $L^\perp = \{z \in K^V : \langle z, y \rangle = 0 \text{ for all } y \in L\}$.
- Let $L|_x^v$ be the subspace of $K^{V \setminus \{v\}}$ such that $L|_x^v = \{p_{V \setminus \{v\}}(a) : a \in L, a(v) = 0 \text{ or } x\}$.
- Let $L|_{\subseteq X}$, $L|_X$ be the subspaces of K^X such that

$$\begin{aligned} L|_{\subseteq X} &= \{p_X(a) : a \in L, a(v) = 0 \text{ for all } v \notin X\}, \\ L|_X &= \{p_X(a) : a \in L\}. \end{aligned}$$

Two vectors $a, b \in K^V$ are called *supplementary* if $\langle a(v), b(v) \rangle = 1$ for all $v \in V$. We call $a \in K^V$ *complete* if $a(v) \neq 0$ for all $v \in V$. For $X \subseteq V$ and a complete vector a of K^X , $L|_a^X$ is the subspace of $K^{V \setminus X}$ such that

$$L|_a^X = \{p_{V \setminus X}(b) : b \in L, b(v) \in \{a(v), 0\} \text{ for all } v \in X\}.$$

Note that $L|_{x_1}^{v_1} |_{x_2}^{v_2} |_{x_3}^{v_3} \dots |_{x_k}^{v_k} = L|_x^{\{v_1, v_2, \dots, v_k\}}$ where $x \in K^{\{v_1, v_2, \dots, v_k\}}$ such that $x(v_i) = x_i$.

DEFINITION 3.2. Let $S = (V, L)$ be an isotropic system and $v \in V$. For $x \in K \setminus \{0\}$, $S|_x^v = (V \setminus \{v\}, L|_x^v)$ is called an *elementary minor* of S . An isotropic system S' is called a *minor* of S if S' can be obtained from S by applying a sequence of elementary minor operations; in other words, $S' = S|_{x_1}^{v_1} |_{x_2}^{v_2} |_{x_3}^{v_3} \dots |_{x_k}^{v_k}$ for $v_i \in V$ and $x_i \in K \setminus \{0\}$.

Bouchet [1, (8.1)] proved that an elementary minor of an isotropic system is again an isotropic system and therefore a minor of an isotropic system is an isotropic system.

3.2. Fundamental basis and fundamental graphs. The connection between isotropic systems and graphs was also studied by Bouchet [2].

DEFINITION 3.3. We call $x \in K^V$ an *Eulerian vector* of an isotropic system $S = (V, L)$ if $x[P] \notin L$ for every nonempty subset P of V .

PROPOSITION 3.4 (see Bouchet [2, (4.1)]). For every complete vector c of K^V , there is an Eulerian vector a of S , supplementary to c .

PROPOSITION 3.5 (see Bouchet [2, (4.3)]). Let a be an Eulerian vector of an isotropic system $S = (V, L)$. For every $v \in V$, there exists a unique vector $b_v \in L$ such that

- (i) $b_v(v) \neq 0$,
- (ii) $b_v(w) \in \{0, a(w)\}$ for $w \neq v$.

Moreover, the set $\{b_v : v \in V\}$ is a basis of L .

We call $\{b_v : v \in V\}$ the *fundamental basis* of L with respect to a .

It is straightforward to construct an isotropic system from every graph. Let $G = (V, E)$ be a graph and let a, b be a pair of supplementary vectors of K^V . Let

$n_G(v)$ be the set of neighbors of v . Then, we may construct an isotropic system $S = (V, L)$ [2, (3.1)] by letting L be the subspace of K^V spanned by

$$\{a[n_G(v)] + b[\{v\}] : v \in V\}.$$

We call (G, a, b) a *graphic presentation* of S .

It is interesting that the reverse direction also works. Suppose an isotropic system $S = (V, L)$ is given with an Eulerian vector a . Let $\{b_v : v \in V\}$ be the fundamental basis of $S = (V, L)$ with respect to a . Let $G = (V, E)$ be the graph such that $vw \in E$ if and only if $v \neq w$ and $b_v(w) \neq 0$. Since $\langle b_v, b_w \rangle = 0$ implies $b_v(w) \neq 0 \Leftrightarrow b_w(v) \neq 0$, G is undirected. We call G the *fundamental graph* of S with respect to a . In fact, if S has a graphic presentation (G, a, b) , then G is the fundamental graph of S with respect to a .

Bouchet [2, (7.6)] showed that if (G, a, b) is a graphic presentation of an isotropic system $S = (V, L)$ and $v \in V$, then

$$(G * v, a + b[\{v\}], a[n_G(v)] + b)$$

is also a graphic presentation of S . Thus, local complementations preserve the associated isotropic system. If G and H are locally equivalent, associated isotropic systems can be chosen to be same by an appropriate choice of supplementary vectors. We note that if $uv \in E(G)$, then

$$(G \wedge uv, a[V \setminus \{u, v\}] + b[\{u, v\}], b[V \setminus \{u, v\}] + a[\{u, v\}])$$

is a graphic presentation of S . This fact will be used in section 10.

PROPOSITION 3.6 (see [2, (4.5) and (7.1)]). *If G_1 and G_2 are fundamental graphs of an isotropic system S , then G_1 and G_2 are locally equivalent.*

A minor of an isotropic system is closely related to a vertex-minor of its fundamental graph as follows.

PROPOSITION 3.7 (see [2, (9.1)]). *Let $G = (V, E)$ be a graph. Let $v \in v(G)$ and $x \in K \setminus \{0\}$. If (G, a, b) is a graphic presentation of an isotropic system $S = (V, L)$, then the elementary minor $S|_x^v$ has a graphic presentation, that is,*

- (i) $(G \setminus v, p_{V \setminus \{v\}}(a), p_{V \setminus \{v\}}(b))$ if either $x = a(v)$, or $x = b(v)$ and v is an isolated vertex of G ,
- (ii) $(G \wedge vv \setminus v, p_{V \setminus \{v\}}(a'), p_{V \setminus \{v\}}(b'))$ where $a' = a[V \setminus \{v, w\}] + b[\{v, w\}]$ and $b' = b[V \setminus \{v, w\}] + a[\{v, w\}]$ if $x = b(v)$ and v has a neighbor w in G ,
- (iii) $(G * v \setminus v, p_{V \setminus \{v\}}(a), p_{V \setminus \{v\}}(b + a[n_G(v)]))$ otherwise.

COROLLARY 3.8. *Suppose G_1 and G_2 are fundamental graphs of isotropic systems S_1 and S_2 , respectively. If S_1 is a minor of S_2 , then G_1 is a vertex-minor of G_2 .*

Note that the choice of w in Proposition 3.7 does not affect the isotropic system because of the following proposition, proved in [11].

PROPOSITION 3.9. *If $vv_1, vv_2 \in E(G)$ are two distinct edges incident with v , then $G \wedge vv_1 \wedge v_1 v_2 = G \wedge vv_2$, and therefore $G \wedge vv_1 \setminus v$ is locally equivalent to $G \wedge vv_2 \setminus v$.*

3.3. Connectivity. For a subspace L of K^V , let $\lambda(L) = |V| - \dim(L)$.

DEFINITION 3.10. *For an isotropic system $S = (V, L)$, we call $c : V \rightarrow \mathbb{Z}$ the connectivity function of S if $c(X) = \lambda(L|_{\subseteq X}) = |X| - \dim(L|_{\subseteq X})$.*

If L is a totally isotropic subspace of K^V , then $L|_{\subseteq X}$ is also a totally isotropic subspace of K^X . Thus, $\dim(L|_{\subseteq X}) \leq |X|$, and therefore $c(X) \geq 0$.

Bouchet [3] observed that the connectivity function of an isotropic system is equal to the cut-rank function of its fundamental graph.

PROPOSITION 3.11 (see [3, Theorem 6]). *Let a be an Eulerian vector of an isotropic system $S = (V, L)$ and let c be the connectivity function of S . Let G be the fundamental graph of S with respect to a . Then, $c(X) = \rho_G(X)$ for all $X \subseteq V$.*

By Proposition 3.11, the connectivity function of an isotropic system $S = (V, L)$ is indeed a connectivity function, as defined in section 2. A *branch-decomposition* and the *branch-width* of an isotropic system are defined as a branch-decomposition and the branch-width of its connectivity function, respectively. By Proposition 3.11, the branch-width of an isotropic system is equal to the rank-width of its fundamental graph.

4. Overview of the main proof. Our main objective is to prove the following.

THEOREM 4.1. *Let k be a constant. If $\{G_1, G_2, G_3, \dots\}$ is an infinite sequence of graphs of rank-width at most k , then there exist $i < j$ such that G_i is isomorphic to a pivot-minor of G_j , and therefore isomorphic to a vertex-minor of G_j .*

In general, we say that a binary relation $\leq$ on a set X is a *quasi-order* if it is reflexive and transitive. For a quasi-order $\leq$, we say “ $\leq$ is a *well-quasi-ordering*” or “ X is *well-quasi-ordered* by $\leq$ ” if for every infinite sequence $a_1, a_2, \dots$ of elements of X , there exist $i < j$ such that $a_i \leq a_j$. We may reiterate Theorem 4.1 as follows: a set of graphs of bounded rank-width is well-quasi-ordered up to isomorphism by the vertex-minor relation and also by the pivot-minor relation.

Here is a corollary of Theorem 4.1. Note that this corollary has an elementary proof in [11] and is used in [6] to show the existence of the polynomial-time algorithm to decide whether the rank-width is at most k for a fixed k .

COROLLARY 4.2. *For a fixed k , there is a finite list of graphs $G_1, G_2, \dots, G_m$ such that for every graph H , the rank-width of H is at most k if and only if G_i is not isomorphic to a vertex-minor of H for all i .*

Proof. Let $X = \{G_1, G_2, \dots\}$ be a set of graphs satisfying that for every graph H , the rank-width of a graph H is at most k if and only if G_i is not isomorphic to a vertex-minor of H for all i . We choose X minimal by set inclusion. There are no $G_i, G_j \in X$, such that G_i is isomorphic to a vertex-minor of G_j , because if so, then we may remove G_j from X . By assumption, the rank-width of $G \setminus v$ for $v \in V(G)$ is at most k , and therefore the rank-width of G_i is at most $k + 1$. By Theorem 4.1, X is finite. $\square$

We say that an isotropic system $S_1 = (V_1, L_1)$ is *simply isomorphic* to another isotropic system $S_2 = (V_2, L_2)$ if there exists a bijection $\mu : V_1 \rightarrow V_2$ such that $L_1 = \{a \circ \mu : a \in L_2\}$. A bijection μ is called a *simple isomorphism*. It is clear that if S_1 is simply isomorphic to S_2 , then every fundamental graph of S_1 is isomorphic to a graph locally equivalent to a fundamental graph of S_2 .

We say that an isotropic system S_1 is an $\alpha\beta$ -minor of an isotropic system S if there is $a \in K^X$ with $S_1 = S|_a^X$ and $a(v) \in \{\alpha, \beta\}$ for all $v \in X$. Every $\alpha\beta$ -minor of an isotropic system S is a minor of S , but not vice versa. Pivot-minors of graphs are closely related to $\alpha\beta$ -minors of isotropic systems as follows.

LEMMA 10.2. *For $i \in \{1, 2\}$, let S_i be an isotropic system with a graphic presentation (G_i, a_i, b_i) such that*

$$a_i(v), b_i(v) \in \{\alpha, \beta\}$$

for all $v \in V(G_i)$. If S_1 is an $\alpha\beta$ -minor of S_2 , then G_1 is a pivot-minor of G_2 .

Instead of dealing with graphs, we show the following theorem on isotropic systems.

THEOREM 9.1. *Let k be a constant. If $\{S_1, S_2, S_3, \dots\}$ is an infinite sequence of isotropic systems of branch-width at most k , then there exist $i < j$ such that S_i is simply isomorphic to an $\alpha\beta$ -minor of S_j .*

We deduce Theorem 4.1 from Theorem 9.1.

Proof of Theorem 4.1. Let S_i be the isotropic system with the graphic presentation (G_i, a_i, b_i) where $a_i(v) = \alpha$, $b_i(v) = \beta$ for all $v \in V(G_i)$. Each S_i has branch-width at most k , since its branch-width is equal to the rank-width of G_i . By Theorem 9.1, there exist $i < j$ such that S_i is simply isomorphic to an $\alpha\beta$ -minor of S_j , and therefore by Lemma 10.2, G_i is isomorphic to a pivot-minor of G_j . $\square$

The following theorem was shown by Geelen, Gerards, and Whittle [8]. It was the first step to prove well-quasi-ordering of matroids representable over a fixed finite field having bounded branch-width. Its analogous result by Thomas [15] was used to prove well-quasi-ordering of graphs of bounded tree-width in [13].

THEOREM 4.3 (see [8, Theorem 2.1] and [9]). *A connectivity function with branch-width n has a linked branch-decomposition of width n .*

COROLLARY 4.4. *An isotropic system of branch-width n has a linked branch-decomposition of width n . Equivalently, a graph of rank-width n has a linked rank-decomposition of width n .*

We also use Robertson and Seymour's "lemma on trees," proved in [13]. It enabled them to prove that a set of graphs of bounded tree-width is well-quasi-ordered by the graph minor relation. Geelen, Gerards, and Whittle [8] used it to prove that a set of matroids representable over a fixed finite field and having bounded branch-width is well-quasi-ordered by the matroid minor relation. We need a special case of the "lemma on trees," namely for subcubic forests, that was also used in [8].

The following definitions are as in [8]. A *rooted tree* is a finite directed tree where all but one of the vertices have indegree 1. A *rooted forest* is a collection of countably many vertex-disjoint rooted trees. Its vertices with indegree 0 are called *roots* and those with outdegree 0 are called *leaves*. Edges leaving a root are *root edges* and those entering a leaf are *leaf edges*.

An *n -edge labeling* of a graph F is a map from the set of edges of F to the set $\{0, 1, \dots, n\}$. Let λ be an n -edge labeling of a rooted forest F and let e and f be edges in F . We say that e is λ -linked to f if F contains a directed path P starting with e and ending with f such that $\lambda(g) \geq \lambda(e) = \lambda(f)$ for every edge g on P .

A *binary forest* is a rooted orientation of a subcubic forest with a distinction between left and right outgoing edges. More precisely, we call a triple (F, l, r) a *binary forest* if F is a rooted forest where roots have outdegree 1 and l and r are functions defined on nonleaf edges of F such that the head of each nonleaf edge e of F has exactly two outgoing edges, namely $l(e)$ and $r(e)$.

LEMMA 4.5 (see [8, (3.2) Lemma on Subcubic Trees]). *Let (F, l, r) be an infinite binary forest with an n -edge labeling λ . Moreover, let $\leq$ be a quasi-order on the set of edges of F with no infinite strictly descending sequences such that $e \leq f$ whenever f is λ -linked to e . If the set of leaf edges of F is well-quasi-ordered by $\leq$, but the set of root edges of F is not, then F contains an infinite sequence $(e_0, e_1, \dots)$ of nonleaf edges such that*

- (i) $\{e_0, e_1, \dots\}$ is an antichain with respect to $\leq$,
- (ii) $l(e_0) \leq l(e_1) \leq l(e_2) \leq \dots$,
- (iii) $r(e_0) \leq r(e_1) \leq r(e_2) \leq \dots$.

Informally speaking, at the last stage of proving Theorem 9.1, we need an object describing a piece of isotropic systems such that the number of ways to merge two of such objects into one isotropic system is finite up to simple isomorphisms. More precisely, we call a triple $P = (V, L, B)$ a *scrap* if V is a finite set, L is a totally isotropic subspace of K^V , and B is an ordered basis of $L^\perp/L$. An *ordered basis* is a basis with a linear ordering, and therefore B is of the form $\{b_1 + L, b_2 + L, \dots, b_k + L\}$ with $b_i \in L^\perp$. We denote $V(P) = V$. Note that $L^\perp/L$ is a vector space containing vectors of the form $a + L$ with $a \in L^\perp$ and $a + L = b + L$ if and only if $a - b \in L$. Also note that $|B| = \dim(L^\perp/L) = \dim(L^\perp) - \dim(L) = 2(|V| - \dim(L)) = 2\lambda(L)$.

Two scraps $P_1 = (V, L, B)$ and $P_2 = (V', L', B')$ are called *isomorphic* if there exists a bijection $\mu : V \rightarrow V'$ such that $L = \{a \circ \mu : a \in L'\}$ and $b_i + L = (b'_i \circ \mu) + L$ where $B = \{b_1 + L, b_2 + L, \dots, b_k + L\}$ and $B' = \{b'_1 + L', b'_2 + L', \dots, b'_k + L'\}$.

For $x \in K \setminus \{0\}$ and $v \in V$, let $\delta_x^v \in K^V$ such that $\delta_x^v(v) = x$ and $\delta_x^v(w) = 0$ for all $w \neq v$. We often write δ_x^v without referring to V if that is not ambiguous. If $P = (V, L, B)$ is a scrap and $\delta_x^v \notin L^\perp \setminus L$, we define

$$P|_x^v = (V \setminus \{x\}, L|_x^v, \{p_{V \setminus \{v\}}(b_i) + L|_x^v\}_i),$$

where each $b_i \in L^\perp$ is chosen to satisfy that $B = \{b_i + L\}_i$ and $b_i(v) \in \{0, x\}$. We will prove that $P|_x^v$ is a well-defined scrap in Proposition 6.2. Note that $P|_x^v$ is only defined when $\delta_x^v \notin L^\perp \setminus L$.

A scrap P' is called a *minor* of a scrap P if $P' = P|_{x_1}^{v_1} |_{x_2}^{v_2} \dots |_{x_l}^{v_l}$ for some v_i and x_i . Similarly, a scrap P' is called an $\alpha\beta$ -*minor* of a scrap P if $P' = P|_{x_1}^{v_1} |_{x_2}^{v_2} \dots |_{x_l}^{v_l}$ for some v_i and $x_i \in \{\alpha, \beta\}$.

Two scraps $P_1 = (V, L, B)$ and $P_2 = (V', L', B')$ are called *disjoint* if $V \cap V' = \emptyset$. A scrap $P = (V, L, B)$ is called a *sum* of two disjoint scraps $P_1 = (V_1, L_1, B_1)$ and $P_2 = (V_2, L_2, B_2)$ if

$$V = V_1 \cup V_2, \quad L_1 = L|_{\subseteq V_1}, \quad \text{and} \quad L_2 = L|_{\subseteq V_2}.$$

A sum of two disjoint scraps is not uniquely determined; we, however, will define the *connection types* that will determine a sum of two disjoint scraps such that there are only finitely many connection types. Moreover, we will prove the following.

LEMMA 8.5. *Let P_1, P_2, Q_1, Q_2 be scraps. Let P be the sum of P_1 and P_2 and let Q be the sum of Q_1 and Q_2 . If P_i is a minor of Q_i for $i = 1, 2$ and the connection type of P_1 and P_2 is equal to the connection type of Q_1 and Q_2 , then P is a minor of Q .*

Moreover, if P_i is an $\alpha\beta$ -minor of Q_i for $i \in \{1, 2\}$ and the connection type of P_1 and P_2 is equal to the connection type of Q_1 and Q_2 , then P is an $\alpha\beta$ -minor of Q .

Another requirement to apply Lemma 4.5 is that $e \leq f$ whenever f is λ -linked to e . This condition will be satisfied by the following lemma, which is an extension of Tutte's linking theorem. Tutte's linking theorem for matroids was used by Geelen, Gerards, and Whittle [8] and is an extension of Menger's theorem. Robertson and Seymour also used Menger's theorem in [13].

THEOREM 7.2. *Let V be a finite set and let X be a subset of V . Let L be a totally isotropic subspace of K^V . Let k be a constant. Let b be a complete vector of $K^{V \setminus X}$.*

Then $\lambda(L|_{\subseteq Z}) \geq k$ for all $Z \supseteq X$ if and only if there is a complete vector $a \in K^{V \setminus X}$ such that $\lambda(L|_a^{V \setminus X}) \geq k$ and $a(v) \neq b(v)$ for all $v \in V \setminus X$.

The actual proof of Theorem 9.1 is based on a construction of a forest with a certain k -labeling from branch-decompositions of isotropic systems, and applying the lemmas described above. In the subsequent sections, we will prove these lemmas.

5. Lemmas on totally isotropic subspaces. In this section, L is a totally isotropic subspace of K^V , not necessarily $\dim(L) = |V|$. We prove some general results on totally isotropic subspaces.

LEMMA 5.1. *Let L be a totally isotropic subspace of K^V and $v \in V$, $x \in K \setminus \{0\}$. Then,*

$$(L|_x^v)^\perp = L^\perp|_x^v.$$

Proof. Suppose that $y \in L|_x^v$. There exists $\bar{y} \in L^\perp$ such that $\bar{y}(v) \in \{0, x\}$ and $y = p_{V \setminus \{v\}}(\bar{y})$. For every $z \in L|_x^v$, there exists $\bar{z} \in L$ such that $\bar{z}(v) \in \{0, x\}$ and $p_{V \setminus \{v\}}(\bar{z}) = z$. Since $\langle y, z \rangle = \langle \bar{y}, \bar{z} \rangle - \langle \bar{y}(v), \bar{z}(v) \rangle = 0$, we have $y \in (L|_x^v)^\perp$.

Conversely, suppose that $y \notin L|_x^v$. Let $y \oplus x \in K^V$ be such that $p_{V \setminus \{v\}}(y \oplus x) = y$ and $(y \oplus x)(v) = x$. By assumption, $y \oplus x \notin L^\perp$. Therefore, there exists $z \in L$ such that

$$\langle y, p_{V \setminus \{v\}}(z) \rangle + \langle x, z(v) \rangle = \langle y \oplus x, z \rangle = 1.$$

If $\langle x, z(v) \rangle = 0$, then $p_{V \setminus \{v\}}(z) \in L|_x^v$ and $\langle y, p_{V \setminus \{v\}}(z) \rangle = 1$, and therefore $y \notin (L|_x^v)^\perp$. So, we may assume that $\langle x, z(v) \rangle = 1$.

Let $y \oplus 0 \in K^V$ such that $p_{V \setminus \{v\}}(y \oplus 0) = y$ and $(y \oplus 0)(v) = 0$. By assumption, $y \oplus 0 \notin L^\perp$. Therefore, there exists $w \in L$ such that $\langle y, p_{V \setminus \{v\}}(w) \rangle = \langle y \oplus 0, w \rangle = 1$. If $w(v) \in \{0, x\}$, then $p_{V \setminus \{v\}}(w) \in L|_x^v$ and $y \notin (L|_x^v)^\perp$. Hence we may assume that $\langle x, w(v) \rangle = 1$.

Now, we obtain that $\langle x, w(v) + z(v) \rangle = 0$, and so $w(v) + z(v) \in \{0, x\}$. Therefore $p_{V \setminus \{v\}}(w + z) \in L|_x^v$. Furthermore $\langle p_{V \setminus \{v\}}(w + z), y \rangle = 1$. So, $y \notin (L|_x^v)^\perp$. $\square$

LEMMA 5.2. *If L is a totally isotropic subspace of K^V and $X \subseteq V$, then*

$$(L|_{\subseteq X})^\perp = L^\perp|_X.$$

Proof. We use induction on $|V \setminus X|$. If $|X| < |V| - 1$, then we pick $v \notin X$ and deduce that $(L|_{\subseteq V \setminus \{v\}}|_{\subseteq X})^\perp = (L|_{\subseteq V \setminus \{v\}})^\perp|_X = L^\perp|_{V \setminus \{v\}}|_X = L^\perp|_X$. Therefore we may assume that $V \setminus X = \{v\}$.

For $x \in K^X$ and $y \in K$, we let $x \oplus y$ denote the vector in K^V such that $p_X(x \oplus y) = x$ and $(x \oplus y)(v) = y$.

(1) We claim that $L^\perp|_X \subseteq (L|_{\subseteq X})^\perp$.

Suppose that $a \in L^\perp|_X$. Then there exists $b \in K$ such that $a \oplus b \in L^\perp$. For any $c \in L|_{\subseteq X}$, $\langle a \oplus b, c \oplus 0 \rangle = 0$, and therefore $\langle a, c \rangle = 0$. Thus, $a \in (L|_{\subseteq X})^\perp$.

(2) We claim that $(L|_{\subseteq X})^\perp \subseteq L^\perp|_X$.

Suppose that $a \in (L|_{\subseteq X})^\perp$ and $a \notin L^\perp|_X$. We have $a \oplus x \notin L^\perp$ and therefore for every $x \in K$, there exists $a_x \oplus c_x \in L$ such that $\langle a_x, a \rangle + \langle c_x, x \rangle = \langle a_x \oplus c_x, a \oplus x \rangle = 1$. In particular, $\langle a_0, a \rangle = 1$.

If $c_x = 0$, then $a_x \in L|_{\subseteq X}$ and so $\langle a_x, a \rangle = 0$ and $\langle c_x, x \rangle = 0$, contrary to the fact that $\langle a_x, a \rangle + \langle c_x, x \rangle = 1$. Therefore $c_x \neq 0$ for all $x \in K$.

If $c_x = c_y$ for $x \neq y$, then $a_x + a_y \in L|_{\subseteq X}$. Thus, $\langle c_x, x + y \rangle = 1 + \langle c_x, x \rangle + 1 + \langle c_y, y \rangle = \langle a_x + a_y, a \rangle = 0$. Since $c_x \neq 0$ and $x + y \neq 0$, we have $c_x = c_y = x + y$ and $\langle a_x, a \rangle = 1 + \langle x + y, x \rangle = 1 + \langle x, y \rangle$.

If $c_x = c_y = c_z$ for distinct x, y, z , then $x + y = y + z = z + x$. So, $x = y = z$, which is a contradiction.

If $c_x = c_y$, $c_z = c_w$ for distinct x, y, z, w , then $c_x = x + y = z + w = c_z$. So, $x = y = z = w$. This is a contradiction.

Therefore, there is exactly one pair $x, y \in K$ such that $c_x = c_y$. Let $\{z, w\} = K \setminus \{x, y\}$.

Since $c_z \neq c_w$ and $c_z, c_w \in K \setminus \{0, x + y\}$, we have $c_z + c_w = x + y = c_x = c_y$. Therefore, $a_z + a_w + a_x \in L|_{\subseteq X}$ and $\langle a_z + a_w + a_x, a \rangle = 0$. Since $\langle a_z, a \rangle + \langle a_w, a \rangle = \langle c_z, z \rangle + \langle c_w, w \rangle$, we have

$$\langle c_z, z \rangle + \langle c_w, w \rangle = \langle a_z + a_w + a_x, a \rangle + \langle a_x, a \rangle = 1 + \langle x, y \rangle.$$

If $x = 0$, then $c_z + c_w = y$, hence $c_z, c_w \in \{z, w\}$. So, $\langle c_z, z \rangle + \langle c_w, w \rangle = 0$. A contradiction.

So we may assume that $x \neq 0, y \neq 0, z = 0$, and then $x + y = w$ and $\langle c_w, w \rangle = 0$. But, this implies that $c_w = w = x + y = c_x$. A contradiction. $\square$

PROPOSITION 5.3. *Let V be a finite set and let L be a totally isotropic subspace of K^V and $v \in V, x \in K \setminus \{0\}$. Then,*

$$\dim(L|_x^v) = \begin{cases} \dim(L) & \text{if } \delta_x^v \in L^\perp \setminus L, \\ \dim(L) - 1 & \text{otherwise.} \end{cases}$$

In other words,

$$\lambda(L|_x^v) = \begin{cases} \lambda(L) & \text{if } \delta_x^v \notin L^\perp \setminus L, \\ \lambda(L) - 1 & \text{otherwise.} \end{cases}$$

Proof. Let $L' = \{a \in L : a(v) \in \{0, x\}\}$. Then clearly $L' = L$ if $a(v) \in \{0, x\}$ for each $a \in L$, and $\dim(L') = \dim(L) - 1$ otherwise. Also, $\dim(L|_x^v) = \dim(L')$ when $\delta_x^v \notin L'$, and $\dim(L|_x^v) = \dim(L') - 1$ otherwise. Moreover, obviously, “ $a(v) \in \{0, x\}$ for each $a \in L$ ” is equivalent to “ $\delta_x^v \in L^\perp$ ”; and “ $\delta_x^v \notin L'$ ” is equivalent to “ $\delta_x^v \notin L$.” As $L \subseteq L^\perp$, all this implies this proposition. $\square$

COROLLARY 5.4. *Let V be a finite set and let L be a totally isotropic subspace of K^V and $v \in V$. Let $C \subseteq K \setminus \{0\}$, $|C| = 2$. Then, either there is $x \in C$ such that $\lambda(L|_x^v) = \lambda(L)$ or for all $y \in K \setminus \{0\}$,*

$$L|_y^v = L|_{\subseteq V \setminus \{v\}} \quad \text{and} \quad \lambda(L|_y^v) = \lambda(L) - 1.$$

Proof. Let $C = \{a, b\}$. Suppose there is no such $x \in C$. Then δ_a^v, δ_b^v are in $L^\perp \setminus L$. Therefore, $z(v) = 0$ for all $z \in L$. Thus, $L|_y^v = L|_{\subseteq V \setminus \{v\}}$ and $\lambda(L|_y^v) = \lambda(L) - 1$ for all $y \in K \setminus \{0\}$. $\square$

6. Scraps. In this section, we prove that a minor of a scrap is well defined. From section 4, we recall that a *scrap* is a triple $P = (V, L, B)$ of a finite set V , a totally isotropic subspace L of K^V , and an ordered basis B of $L^\perp/L$.

LEMMA 6.1. *Let $P = (V, L, B)$ be a scrap and $v \in V, x \in K \setminus \{0\}$. If $\delta_x^v \notin L^\perp \setminus L$, then there is a sequence $b_1, b_2, \dots, b_m \in L^\perp$ such that $b_i(v) \in \{0, x\}$ and $B = \{b_1 + L, b_2 + L, \dots, b_m + L\}$.*

Proof. Let $B = \{a_1 + L, a_2 + L, \dots, a_m + L\}$ with $a_i \in L^\perp$. If $\delta_x^v \in L$, then $a_i(v) \in \{0, x\}$ for all i . Hence we may assume that $\delta_x^v \notin L$ and so $\delta_x^v \notin L^\perp$. Therefore there is $y \in L$ such that $\langle y, \delta_x^v \rangle = 1$. Thus, $y(v) \notin \{0, x\}$. Let

$$b_i = \begin{cases} a_i & \text{if } a_i(v) \in \{0, x\}, \\ a_i + y & \text{otherwise.} \end{cases}$$

Then, $b_i + L = a_i + L$ and $b_i(v) \in \{0, x\}$. $\square$

PROPOSITION 6.2. *Let $P = (V, L, B)$ be a scrap. If $\delta_x^v \notin L^\perp \setminus L$, then $P|_x^v$ is well defined and is a scrap.*

Proof. Let us first show that it is well defined. Let $b_1, b_2, \dots, b_k \in L^\perp$ be such that $b_i(v) \in \{0, x\}$ and $B = \{b_i + L : i = 1, 2, \dots, k\}$. We claim that the choice of b_i does not change $P|_x^v$. Suppose $b_i - b'_i \in L$ and $b_i(v), b'_i(v) \in \{0, x\}$. Since $b_i - b'_i \in L$ and $(b_i - b'_i)(v) \in \{0, x\}$, we have $p_{V \setminus \{v\}}(b_i - b'_i) \in L|_x^v$. Therefore, $p_{V \setminus \{v\}}(b_i) + L|_x^v = p_{V \setminus \{v\}}(b'_i) + L|_x^v$.

Now, we claim that $P|_x^v$ is a scrap.

First, we show that $L|_x^v$ is a totally isotropic subspace of $K^{V \setminus \{v\}}$. For all $a, b \in L|_x^v$, there are $\bar{a}, \bar{b} \in L$ such that $\bar{a}(v), \bar{b}(v) \in \{0, x\}$, $p_{V \setminus \{v\}}(\bar{a}) = a$, $p_{V \setminus \{v\}}(\bar{b}) = b$, and $\bar{a}, \bar{b} \in L$. Hence $\langle a, b \rangle = \langle \bar{a}, \bar{b} \rangle = 0$.

Next, we show that $\{p_{V \setminus \{v\}}(b_i) + L|_x^v : i = 1, 2, \dots, k\}$ is a basis of $(L|_x^v)^\perp / (L|_x^v)$. Since $b_i(v) \in \{0, x\}$, we have $p_{V \setminus \{v\}}(b_i) \in (L|_x^v)^\perp = (L^\perp)|_x^v$. Suppose that there exists $C \neq \emptyset$ such that

$$\sum_{i \in C} (p_{V \setminus \{v\}}(b_i) + L|_x^v) = 0 + L|_x^v.$$

Since $\sum_{i \in C} p_{V \setminus \{v\}}(b_i) \in L|_x^v$, there exists $z \in L \subseteq L^\perp$ such that $z(v) \in \{0, x\}$ and $p_{V \setminus \{v\}}(z) = \sum_{i \in C} p_{V \setminus \{v\}}(b_i)$. By assumption, $\sum_{i \in C} b_i \notin L$. Since $p_{V \setminus \{v\}}(\sum_{i \in C} b_i - z) = 0$, we have $\sum_{i \in C} b_i - z = \delta_x^v \in L^\perp \setminus L$, a contradiction. Therefore, $\{p_{V \setminus \{v\}}(b_i) + L|_x^v : i = 1, 2, \dots, k\}$ is linearly independent. Moreover, $\dim((L|_x^v)^\perp / (L|_x^v)) = 2(|V| - 1 - \dim(L|_x^v)) = 2(|V| - \dim(L)) = \dim(L^\perp / L)$ because $\delta_x^v \notin L^\perp \setminus L$. $\square$

7. Generalization of Tutte's linking theorem. In this section, we show a generalization of Tutte's linking theorem [16].

LEMMA 7.1. *Let V be a finite set and $v \in V$. Let L be a totally isotropic subspace of K^V . Let $X_1, Y_1 \subseteq V \setminus \{v\}$. Let $x, y \in K \setminus \{0\}$, $x \neq y$. Then,*

$$\dim(L|_{\subseteq X_1 \cap Y_1}) + \dim(L|_{\subseteq X_1 \cup Y_1 \cup \{v\}}) \geq \dim(L|_x^v|_{\subseteq X_1}) + \dim(L|_y^v|_{\subseteq Y_1}).$$

In other words,

$$\lambda(L|_x^v|_{\subseteq X_1}) + \lambda(L|_y^v|_{\subseteq Y_1}) \geq \lambda(L|_{\subseteq X_1 \cap Y_1}) + \lambda(L|_{\subseteq X_1 \cup Y_1 \cup \{v\}}) - 1.$$

Proof. We may assume that $V = X_1 \cup Y_1 \cup \{v\}$ by taking $L' = L|_{\subseteq X \cup Y \cup \{v\}}$.

Let B be a minimum set of vectors in L such that $p_{X_1 \cap Y_1}(B)$ is a basis of $L|_{\subseteq X_1 \cap Y_1}$ and for every $z \in B$, $z(w) = 0$ for all $w \notin X_1 \cap Y_1$.

Let C be a minimum set of vectors in L such that $p_{X_1}(B \cup C)$ is a basis of $L|_x^v|_{\subseteq X_1}$ and for every $z \in C$, $z(w) = 0$ for all $w \notin X_1 \cup \{v\}$ and $z(v) \in \{0, x\}$. We may assume that at most one vector in C has x on v .

Let D be a minimum set of vectors in L such that $p_{Y_1}(B \cup D)$ is a basis of $L|_y^v|_{\subseteq Y_1}$ and for every $z \in D$, $z(w) = 0$ for all $w \notin Y_1 \cup \{v\}$ and $z(v) \in \{0, y\}$. We may assume that at most one vector in D has y on v .

We claim that $B \cup C \cup D$ is linearly independent. Suppose there are $B' \subseteq B$, $C' \subseteq C$, and $D' \subseteq D$ such that

$$\sum_{b \in B'} b + \sum_{c \in C'} c + \sum_{d \in D'} d = 0.$$

No element of C' has x on v , because all vectors in $B' \cup D'$ have 0 or y on v and at most one element of C' has x on v . Since $\sum_{c \in C'} c(w) = 0$ for all $w \in V \setminus (X_1 \cap Y_1)$,

we have $p_{X_1 \cap Y_1}(\sum_{c \in C'} c) \in L|_{\subseteq X_1 \cap Y_1}$. Since $p_{X_1 \cap Y_1}(B)$ is a basis, there is $B'' \subseteq B$ such that $p_{X_1 \cap Y_1}(\sum_{c \in C'} c) = p_{X_1 \cap Y_1}(\sum_{b \in B''} b)$. So,

$$\sum_{c \in C'} c + \sum_{b \in B''} b = 0.$$

This means that $C' = \emptyset$ because $C \cup B$ is a basis. Similarly $D' = \emptyset$ and so $B' = \emptyset$. Hence $B \cup C \cup D$ is linearly independent indeed. So $\dim(L) \geq |B| + |C| + |D| = \dim(L|_{\subseteq X_1}^v) + \dim(L|_{\subseteq Y_1}^v) - \dim(L|_{\subseteq X_1 \cap Y_1})$. $\square$

Now, we translate Tutte's linking theorem into isotropic subspaces.

THEOREM 7.2. *Let V be a finite set and let X be a subset of V . Let L be a totally isotropic subspace of K^V . Let k be a constant. Let b be a complete vector of $K^{V \setminus X}$.*

Then $\lambda(L|_{\subseteq Z}) \geq k$ for all $Z \supseteq X$ if and only if there is a complete vector $a \in K^{V \setminus X}$ such that $\lambda(L|_a^{V \setminus X}) \geq k$ and $a(v) \neq b(v)$ for all $v \in V \setminus X$.

Proof. ($\Leftarrow$) Let Z be a subset of V such that $X \subseteq Z$. Let $a_1 = p_{V \setminus Z}(a)$, $a_2 = p_{Z \setminus X}(a)$. Since $L|_{\subseteq Z} \subseteq L|_{a_1}^{V \setminus Z}$, we have $\lambda(L|_{\subseteq Z}) \geq \lambda(L|_{a_1}^{V \setminus Z})$. So

$$\lambda(L|_{\subseteq Z}) \geq \lambda(L|_{a_1}^{V \setminus Z}) \geq \lambda(L|_{a_1}^{V \setminus Z}|_{a_2}^{Z \setminus X}) = \lambda(L|_a^{V \setminus X}) \geq k.$$

($\Rightarrow$) We use induction on $|V \setminus X|$. Suppose that there is no such complete vector $a \in K^{V \setminus X}$. We may assume that $|V \setminus X| \geq 1$.

Pick $v \in V \setminus X$. Let $K \setminus \{0, b(v)\} = \{x, y\}$. Since there is no complete vector $a' \in K^{V \setminus \{v\} \setminus X}$ such that $\lambda(L|_{a'}^{V \setminus \{v\} \setminus X}) \geq k$, there exists X_1 such that $X \subseteq X_1 \subseteq V \setminus \{v\}$ and $\lambda(L|_{\subseteq X_1}^v) < k$. Similarly, there exists Y_1 such that $X \subseteq Y_1 \subseteq V \setminus \{v\}$ and $\lambda(L|_{\subseteq Y_1}^v) < k$. By Lemma 7.1, either $\lambda(L|_{\subseteq X_1 \cap Y_1}) < k$ or $\lambda(L|_{\subseteq X_1 \cup Y_1 \cup \{v\}}) < k$, a contradiction. $\square$

COROLLARY 7.3. *Let V be a finite set and let X be a subset of V . Let L be a totally isotropic subspace of K^V . Let b be a complete vector of $K^{V \setminus X}$.*

If $\lambda(L|_{\subseteq Z}) \geq \lambda(L|_{\subseteq X})$ for all $Z \supseteq X$, then there is a complete vector $a \in K^{V \setminus X}$ such that $L|_a^{V \setminus X} = L|_{\subseteq X}$ and $a(v) \neq b(v)$ for all $v \in V \setminus X$.

Proof. By Theorem 7.2, there exists a complete vector $a \in K^{V \setminus X}$ such that

$$\lambda(L|_a^{V \setminus X}) = \lambda(L|_{\subseteq X}) \text{ and } a(v) \neq b(v) \text{ for all } v \in V \setminus X.$$

Since $L|_{\subseteq X} \subseteq L|_a^{V \setminus X}$ and $\dim(L|_{\subseteq X}) = \dim(L|_a^{V \setminus X})$, we have $L|_{\subseteq X} = L|_a^{V \setminus X}$. $\square$

COROLLARY 7.4. *Let $P = (V, L, B)$ be a scrap and $X \subseteq V$. If*

$$\lambda(P) = \lambda(L|_{\subseteq X}) = \min_{X \subseteq Z \subseteq V} \lambda(L|_{\subseteq Z}),$$

then there is an ordered set B' such that $Q = (X, L|_{\subseteq X}, B')$ is a scrap and an $\alpha\beta$ -minor of P .

Proof. By applying Corollary 7.3 with $b(v) = \gamma$ for all $v \in V \setminus X$, there is a complete vector $a \in K^{V \setminus X}$ such that $L|_a^{V \setminus X} = L|_{\subseteq X}$ and $a(v) \in \{\alpha, \beta\}$ for all $v \in V \setminus X$. Let $V \setminus X = \{y_1, y_2, \dots, y_m\}$ and $a_i = a(y_i)$. Then, $L|_{\subseteq X} = L|_{a_1}^{y_1}|_{a_2}^{y_2} \dots |_{a_m}^{y_m}$. Let $L_0 = L$ and $L_i = L_{i-1}|_{a_i}^{y_i}$. By Proposition 5.3, $\lambda(L|_{\subseteq X}) = \lambda(L) = \lambda(L_i)$ implies $\delta_{a_{i+1}}^{y_{i+1}} \notin L_i^\perp \setminus L_i$. So, $P|_{a_1}^{y_1}|_{a_2}^{y_2} \dots |_{a_m}^{y_m} = (X, L|_{\subseteq X}, B')$ is well defined and is an $\alpha\beta$ -minor of P . $\square$

8. Sum. A scrap $P = (V, L, B)$ is called a *sum* of two disjoint scraps $P_1 = (V_1, L_1, B_1)$ and $P_2 = (V_2, L_2, B_2)$ if

$$V = V_1 \cup V_2, \quad L_1 = L|_{\subseteq V_1}, \text{ and } L_2 = L|_{\subseteq V_2}.$$

For given two disjoint scraps, there could be many scraps that are sums of those. In this section, we define the *connection type*, which determines a sum uniquely.

Let $[n]$ denote the set $\{1, 2, 3, \dots, n\}$.

DEFINITION 8.1. Let $P = (V, L, B)$ be a sum of two disjoint scraps $P_1 = (V_1, L_1, B_1)$ and $P_2 = (V_2, L_2, B_2)$ where $B = \{b_1 + L, b_2 + L, \dots, b_n + L\}$, $B_1 = \{b_1^1 + L_1, b_2^1 + L_1, \dots, b_m^1 + L_1\}$, and $B_2 = \{b_1^2 + L_2, b_2^2 + L_2, \dots, b_l^2 + L_2\}$. For $x_1 \in K^{V_1}$ and $x_2 \in K^{V_2}$, let $x_1 \oplus x_2$ denote the vector in K^V such that $p_{V_i}(x_1 \oplus x_2) = x_i$ for $i = 1, 2$. Let

$$C_0 = \left\{ (X, Y) : X \subseteq [m], Y \subseteq [l], \left(\sum_{i \in X} b_i^1 \right) \oplus \left(\sum_{j \in Y} b_j^2 \right) \in L \right\},$$

$$C_s = \left\{ (X, Y) : X \subseteq [m], Y \subseteq [l], \left(\sum_{i \in X} b_i^1 \right) \oplus \left(\sum_{j \in Y} b_j^2 \right) - b_s \in L \right\}, \quad s = 1, \dots, n.$$

The sequence $C(P, P_1, P_2) = (C_0, C_1, C_2, \dots, C_n)$ is called the *connection type* of this sum.

It is easy to see that if $\lambda(P), \lambda(P_1), \lambda(P_2) \leq k$, then the number of distinct connection types is bounded by a function of k , because $|B| = 2\lambda(P) \leq 2k$ and $|B_i| = 2\lambda(P_i) \leq 2k$ for $i = 1$ and 2 .

PROPOSITION 8.2. The connection type is well defined.

Proof. It is enough to show that the choice of b_i , b_i^1 , and b_i^2 does not affect C_i . Suppose $b_i + L = d_i + L$, $b_i^1 + L_1 = d_i^1 + L_1$, and $b_i^2 + L_2 = d_i^2 + L_2$. For any (X, Y) such that $X \subseteq [m]$, $Y \subseteq [l]$, we have $\sum_{i \in X} (b_i^1 - d_i^1) \oplus \sum_{j \in Y} (b_j^2 - d_j^2) \in L$ and $b_s - d_s \in L$, and therefore C_0 and C_s are well defined. $\square$

PROPOSITION 8.3. The connection type uniquely determines the sum of two disjoint scraps P_1 and P_2 .

Proof. Suppose not. Let $P = (V, L, B)$, $Q = (V, L', B')$ be two distinct sums of $P_1 = (V_1, L_1, B_1)$ and $P_2 = (V_2, L_2, B_2)$ by the same connection type $(C_0, C_1, \dots, C_n)$. Let $B_1 = \{b_1^1 + L_1, b_2^1 + L_1, \dots, b_m^1 + L_1\}$ and $B_2 = \{b_1^2 + L_2, b_2^2 + L_2, \dots, b_k^2 + L_2\}$.

We claim that $L = L'$. To show this, it is enough to show that $L \subseteq L'$. For any $a \in L$, $p_{V_1}(a) \in (L|_{\subseteq V_1})^\perp$ and $p_{V_2}(a) \in (L|_{\subseteq V_2})^\perp$. Therefore there is (X, Y) such that

$$x_1 = \sum_{i \in X} b_i^1 - p_{V_1}(a) \in L_1 \quad \text{and} \quad x_2 = \sum_{i \in Y} b_i^2 - p_{V_2}(a) \in L_2.$$

Since $x_1 \oplus 0, 0 \oplus x_2 \in L$, we have $x_1 \oplus x_2 \in L$. We deduce that $\sum_{i \in X} b_i^1 \oplus \sum_{i \in Y} b_i^2 = a + (x_1 \oplus x_2) \in L$. Therefore, $(X, Y) \in C_0$ and $a + (x_1 \oplus x_2) \in L'$. Since $x_1 \oplus 0, 0 \oplus x_2 \in L'$, we have $x_1 \oplus x_2 \in L'$, and so $a \in L'$.

Now, we show that $B = B'$. Let $b_j + L$ be the j th element of B with $b_j \in L^\perp$. Let $b'_j + L$ be the j th element of B' with $b'_j \in L^\perp$. Since $p_{V_i}(b_j) \in (L|_{\subseteq V_i})^\perp$, there is (X, Y) such that

$$x_1 = \sum_{i \in X} b_i^1 - p_{V_1}(b_j) \in L_1 \quad \text{and} \quad x_2 = \sum_{i \in Y} b_i^2 - p_{V_2}(b_j) \in L_2.$$

Since $x_1 \oplus 0, 0 \oplus x_2 \in L$, we have $x_1 \oplus x_2 \in L$, and therefore $\sum_{i \in X} b_i^1 \oplus \sum_{i \in Y} b_i^2 - b_j \in L$. Thus, $(X, Y) \in C_s$, and so

$$\sum_{i \in X} b_i^1 \oplus \sum_{i \in Y} b_i^2 - b'_j \in L' = L.$$

Thus, $b_j + L = b'_j + L = b'_j + L'$. $\square$

PROPOSITION 8.4. *Let $P_1 = (V_1, L_1, B_1)$, $P_2 = (V_2, L_2, B_2)$ be two disjoint scraps. Let P be the sum of P_1 and P_2 by connection type $C(P, P_1, P_2)$. If $v \in V_1$ and $\delta_x^v \notin L_1^\perp \setminus L_1$, then $\delta_x^v \notin L^\perp \setminus L$ and $P|_x^v$ is the sum of $P_1|_x^v$ and P_2 by connection type $C(P, P_1, P_2)$.*

Proof. If $\delta_x^v \in L^\perp \setminus L$, then $\delta_x^v \in (L^\perp)|_{V_1} = (L|_{\subseteq V_1})^\perp = L_1^\perp$ and $\delta_x^v \notin L|_{\subseteq V_1}$. This contradicts $\delta_x^v \notin L_1^\perp \setminus L_1$. So, $\delta_x^v \notin L^\perp \setminus L$.

First, we claim that $P|_x^v$ is a sum of $P_1|_x^v$ and P_2 . This is equivalent to

$$L|_x^v|_{\subseteq V_1 \setminus \{v\}} = L|_{\subseteq V_1}|_x^v \quad \text{and} \quad L|_x^v|_{\subseteq V_2} = L|_{\subseteq V_2}.$$

So, as clearly $L|_x^v|_{\subseteq V_1 \setminus \{v\}} = L|_{\subseteq V_1}|_x^v$ and $L|_{\subseteq V_2} \subseteq L|_x^v|_{\subseteq V_2}$, it suffices to show that

$$L|_x^v|_{\subseteq V_2} \subseteq L|_{\subseteq V_2}.$$

Suppose $z \in L|_x^v|_{\subseteq V_2}$. Let $\bar{z} \in K^V$ such that $p_{V_2}(\bar{z}) = z$, $\bar{z}(v) \in \{0, x\}$, and $p_{V_1 \setminus \{v\}}(\bar{z}) = 0$. If $\bar{z}(v) = 0$, then $z \in L|_{\subseteq V_2}$. If $\bar{z}(v) = x$, then $p_{V_1}(z) = \delta_x^v \in L^\perp|_{V_1} = L_1^\perp$, and therefore $\delta_x^v \in L_1$. So, $\delta_x^v \in L$ and $z + \delta_x^v \in L$. Since $(z + \delta_x^v)(v) = 0$, we have $z \in L|_{\subseteq V_2}$. This proves that $P|_x^v$ is a sum of $P_1|_x^v$ and P_2 .

Now, let us show that $C(P, P_1, P_2) = C(P|_x^v, P_1|_x^v, P_2)$. Let $B_1 = \{b_1^1 + L_1, b_2^1 + L_1, \dots, b_m^1 + L_1\}$ and $B_2 = \{b_1^2 + L_2, b_2^2 + L_2, \dots, b_k^2 + L_2\}$. For $s \in K^{V_1}$ and $t \in K^{V_2}$, let $s \oplus t$ denote the vector in K^V such that $p_{V_1}(s \oplus t) = s$ and $p_{V_2}(s \oplus t) = t$. We may assume that $b_i^1(v) \in \{0, x\}$ for all i by Lemma 6.1. Let $b \in L^\perp$ be such that $b(v) \in \{0, x\}$. Let $a(X, Y) = (\sum_{i \in X} b_i^1) \oplus (\sum_{j \in Y} b_j^2) - b$. Suppose we have (X, Y) such that $X \subseteq [m]$, $Y \subseteq [k]$, and $a(X, Y) \in L$. Since $(\sum_{i \in X} b_i^1(v)) - b(v) \in \{0, x\}$, we have

$$p_{V \setminus \{v\}}(a(X, Y)) = \left(\sum_{i \in X} p_{V_1 \setminus \{v\}}(b_i^1) \right) \oplus \left(\sum_{j \in Y} b_j^2 \right) - p_{V \setminus \{v\}}(b) \in L|_x^v.$$

Conversely, let us suppose that there is (X, Y) such that $X \subseteq [m]$, $Y \subseteq [k]$, and $(\sum_{i \in X} p_{V \setminus \{v\}}(b_i^1)) \oplus (\sum_{j \in Y} b_j^2) - p_{V \setminus \{v\}}(b) \in L|_x^v$. Then, either $a(X, Y) \in L$ or $a(X, Y) + \delta_x^v \in L$. If $\delta_x^v \in L$, then $a(X, Y) \in L$. If $\delta_x^v \notin L^\perp$, then $a(X, Y) + \delta_x^v \notin L^\perp$ because $a(X, Y) \in L^\perp$, and therefore $a(X, Y) \in L$. This proves that $C(P, P_1, P_2) = C(P|_x^v, P_1|_x^v, P_2)$. $\square$

LEMMA 8.5. *Let P_1, P_2, Q_1, Q_2 be scraps. Let P be a sum of P_1 and P_2 and let Q be a sum of Q_1 and Q_2 . If P_i is a minor of Q_i for each $i = 1, 2$ and the connection type of P_1 and P_2 is equal to the connection type of Q_1 and Q_2 , then P is a minor of Q .*

Moreover, if P_i is an $\alpha\beta$ -minor of Q_i for each $i \in \{1, 2\}$ and the connection type of P_1 and P_2 is equal to the connection type of Q_1 and Q_2 , then P is an $\alpha\beta$ -minor of Q .

Proof. We use induction on $|V(Q_1) \setminus V(P_1)| + |V(Q_2) \setminus V(P_2)|$. We may assume $|V(Q_1) \setminus V(P_1)| + |V(Q_2) \setminus V(P_2)| > 0$ and $V(Q_1) \neq V(P_1)$ by symmetry. There are $v \in V(Q_1) \setminus V(P_1)$, $x \in K \setminus \{0\}$, $X = V(Q_1) \setminus V(P_1) \setminus \{v\}$, and a complete vector $a \in K^X$ such that $P_1 = Q_1|_x^v|_a^X$. If P_1 is an $\alpha\beta$ -minor of Q_1 , then we may assume $x \in \{\alpha, \beta\}$ and $a(w) \in \{\alpha, \beta\}$ for all $w \in X$.

By Proposition 8.4, $Q|_x^v$ is the sum of $Q_1|_x^v$ and Q_2 with the connection type $C(Q|_x^v, Q_1|_x^v, Q_2) = C(Q, Q_1, Q_2) = C(P, P_1, P_2)$. So, P is a minor of $Q|_x^v$ by induction and therefore P is a minor of Q .

Similarly, if P_1 is an $\alpha\beta$ -minor of Q_1 and P_2 is an $\alpha\beta$ -minor of Q_2 , then by induction P is an $\alpha\beta$ -minor of Q . $\square$

9. Well-quasi-ordering. We are finally ready to prove our main theorem on isotropic systems.

THEOREM 9.1. *Let k be a constant. If $\{S_1, S_2, S_3, \dots\}$ is an infinite sequence of isotropic systems of branch-width at most k , then there exist $i < j$ such that S_i is simply isomorphic to an $\alpha\beta$ -minor of S_j .*

Proof. By Corollary 4.4, there is a linked branch-decomposition $(T_i, \mathcal{L}_i)$ of $S_i = (V_i, L_i)$ of width at most k for each i . In T_i , we pick an edge and attach a root and direct every edge so that each leaf has a directed path from the root. Let F be the forest such that the i th component is T_i .

For each edge e of T_i , let X_e be the set of leaves of T_i having a directed path from e . Let $A_e = \mathcal{L}_i^{-1}(X_e)$. We associate e with a scrap $P_e = (A_e, L_i|_{\subseteq A_e}, B_e)$ and $\lambda(e) = \lambda(L_i|_{\subseteq A_e}) \leq k$ where B_e is chosen to satisfy the following: If f is λ -linked to e , then P_e is an $\alpha\beta$ -minor of P_f . We claim that we can choose B_e satisfying the above property. We prove it by induction on the length of the directed path from a root edge to e . If no other edge is λ -linked to e , let B_e be a basis of $(L_i|_{\subseteq A_e})^\perp / (L_i|_{\subseteq A_e})$ in an arbitrary order. If f , other than e , is λ -linked to e , choose f such that the distance between e and f is minimal. By induction, there exists B_f so that whenever g is λ -linked to f , P_f is an $\alpha\beta$ -minor of P_g . By Corollary 7.4, there is an ordered basis B_e such that P_e is an $\alpha\beta$ -minor of P_f . Suppose that g is λ -linked to e . Then f is on the path from g to e and therefore g is λ -linked to f . Thus, P_f is an $\alpha\beta$ -minor of P_g and therefore P_e is an $\alpha\beta$ -minor of P_g . We conclude that there is B_e satisfying the property.

For $e, f \in E(F)$, let $e \leq f$ denote that a scrap P_e is isomorphic to an $\alpha\beta$ -minor of a scrap P_f . Clearly, $\leq$ has no infinite strictly descending sequences, because there are finitely many scraps of bounded number of elements up to isomorphisms. By construction if f is λ -linked to e , then $e \leq f$.

The leaf edges of F are well-quasi-ordered, because there are only finitely many distinct scraps of one element up to isomorphisms.

Suppose the root edges are not well-quasi-ordered. By Lemma 4.5, F contains an infinite sequence $(e_0, e_1, \dots)$ of nonleaf edges such that

- (i) $\{e_0, e_1, \dots\}$ is an antichain with respect to $\leq$,
- (ii) $l(e_0) \leq l(e_1) \leq \dots$,
- (iii) $r(e_0) \leq r(e_1) \leq \dots$.

Since $\lambda(e_i) \leq k$ for all i , we may assume that $\lambda(e_i)$ is a constant for all i , by taking a subsequence.

Since the number of distinct connection types $C(P_{e_i}, P_{l(e_i)}, P_{r(e_i)})$ is finite, we may assume that the connection types are the same for all i , also by taking a subsequence.

Then, by Lemma 8.5, P_{e_0} is isomorphic to an $\alpha\beta$ -minor of P_{e_1} , that is, $e_0 \leq e_1$. This contradicts that $\{e_0, e_1, \dots\}$ is an antichain with respect to $\leq$.

Therefore, root edges are well-quasi-ordered, and there exist $i < j$ such that a scrap $(V_i, L_i, \emptyset)$ is isomorphic to an $\alpha\beta$ -minor of a scrap $(V_j, L_j, \emptyset)$. Thus, S_i is simply isomorphic to an $\alpha\beta$ -minor of S_j . $\square$

10. Pivot-minor and $\alpha\beta$ -minor. In this section, we shall show a relation between pivot-minors of graphs and $\alpha\beta$ -minors of isotropic systems.

PROPOSITION 10.1. *For $i \in \{1, 2\}$, let S_i be an isotropic system with a graphic presentation (G_i, a_i, b_i) such that $a_i(v), b_i(v) \in \{\alpha, \beta\}$ for all $v \in V(G_i)$.*

If $S_1 = S_2$, then G_1 can be obtained from G_2 by applying a sequence of pivots.

Proof. Let $V = V(G_1) = V(G_2)$ and let $S = S_1 = S_2 = (V, L)$ be an isotropic system. We show Proposition 10.1 by induction on $N(a_1, a_2) = |\{v \in V : a_1(v) \neq a_2(v)\}|$.

If $N(a_1, a_2) = 0$, then $b_1 = b_2$, so $G_1 = G_2$. Hence we may assume that $N(a_1, a_2) \geq 1$. Let $u \in V$ with $a_1(u) \neq a_2(u)$. This implies that $a_1(u) = b_2(u)$ because $a_i(u), b_i(u) \in \{\alpha, \beta\}$. By Proposition 3.5, there exists a vector $\hat{b}_u \in L$ such that $\hat{b}_u(u) = b_2(u) = a_1(u)$ and $\hat{b}_u(w) \in \{0, a_2(w)\}$ for all $w \neq u$. As a_1 is Eulerian and as $\hat{b}_u \in L$, there exists $v \in V$ such that $\hat{b}_u(v) \notin \{0, a_1(v)\}$. Hence $\hat{b}_u(v) = a_2(v)$ and $a_1(v) \neq a_2(v)$.

Since $\hat{b}_u(u) \neq a_2(u)$, this means that $v \neq u$. Moreover, since $\hat{b}_u(v) \neq 0$, the vertices u and v are adjacent in G_2 . Pivoting (G_2, a_2, b_2) on uv yields $(G_2 \wedge uv, a_2[V \setminus \{u, v\}] + b_2[\{u, v\}], b_2[V \setminus \{u, v\}] + a_2[\{u, v\}])$. As $N(a_1, a_2[V \setminus \{u, v\}] + b_2[\{u, v\}]) = N(a_1, a_2) - 2$, it follows by induction that $G_2 \wedge uv$ can be obtained from G_1 by a sequence of pivots, hence so can G_2 . $\square$

LEMMA 10.2. *For $i \in \{1, 2\}$, let S_i be the isotropic system with a graphic presentation (G_i, a_i, b_i) such that $a_i(v), b_i(v) \in \{\alpha, \beta\}$ for all $v \in V(G_i)$. If S_1 is an $\alpha\beta$ -minor of S_2 , then G_1 is a pivot-minor of G_2 .*

Proof. The lemma is a straightforward consequence of Propositions 10.1 and 3.7. $\square$

11. Binary matroids. We would like to show that Theorem 4.1 implies the well-quasi-ordering theorem of Geelen, Gerards, and Whittle [8] for binary matroids. The proof uses the following lemma.

LEMMA 11.1 (Higman's lemma). *Let $\leq$ be a well-quasi-order on X . For finite subsets $A, B \subseteq X$, we write $A \leq B$ if there is an injective mapping $f : A \rightarrow B$ such that $a \leq f(a)$ for all $a \in A$. Then $\leq$ is a well-quasi-ordering on the set of all finite subsets of X .*

(For proof, see Diestel's book [7, Lemma 12.1.3].)

For a binary matroid M with a fixed base B , the *fundamental graph* of M with respect to B is a bipartite graph $\text{Bip}(M, B)$ such that $V(\text{Bip}(M, B)) = E(M)$ and $v \in E(M) \setminus B$ is adjacent to $w \in B$ if and only if w is in the fundamental circuit of v with respect to B . For a bipartite graph $G = (V, E)$ with a bipartition $V = A \cup B$, $\text{Bin}(G, A, B)$ is a binary matroid on V , represented by an $A \times V$ matrix $(I_A \quad A_G[A, B])$, where I_A is an $A \times A$ identity matrix.

LEMMA 11.2. *Let M_1, M_2 be binary matroids and let B_i be a fixed base of M_i . If M_1 is connected and $\text{Bip}(M_1, B_1)$ is a pivot-minor of $\text{Bip}(M_2, B_2)$, then M_1 is a minor of either M_2 or M_2^* .*

Proof. Let $H = \text{Bip}(M_1, B_1)$ and $G = \text{Bip}(M_2, B_2)$. If H is a pivot-minor of a bipartite graph G , then there is a bipartition (A', B') of H such that a binary matroid $M_3 = \text{Bin}(H, A', B')$ is a minor of $M_2 = \text{Bin}(G, B_2, V(G) \setminus B_2)$. Since M_1 is connected, H is connected, and therefore H has a unique bipartition. So, $M_1 = M_3$ if $A = A'$ or $M_1 = M_3^*$ if $A = B'$. $\square$

COROLLARY 11.3. *Let k be a constant. If $\{M_1, M_2, M_3, \dots\}$ is an infinite sequence of binary matroids of branch-width at most k , then there exist $i < j$ such that M_i is isomorphic to a minor of M_j .*

Proof. First, we claim that if M_i is connected for all i , then the statement is true. Let B_i be a fixed base of M_i and $G_i = \text{Bip}(M_i, B_i)$ for all i . The rank-width of G_i is at most $k - 1$, since rank-width of G_i is equal to (branch-width of M_i) - 1, shown in [11]. By Theorem 4.1, there is an infinite subsequence $G_{a_1}, G_{a_2}, G_{a_3}, \dots$ such that G_{a_i} is isomorphic to a pivot-minor of $G_{a_{i+1}}$ for all i . By Lemma 11.2, M_{a_1} is isomorphic to a minor of either M_{a_2} , or $M_{a_2}^*$, and M_{a_2} is isomorphic to a minor of either M_{a_3} or $M_{a_3}^*$. It follows that M_{a_1} is isomorphic to a minor of M_{a_2} , M_{a_2} is

isomorphic to a minor of M_{a_3} , or M_{a_1} is isomorphic to a minor of M_{a_3} . This proves the above claim.

Now, we prove the main statement. We may consider each M_i as a set of disjoint connected matroids and then M_i is isomorphic to a minor of M_j if and only if there is an injective function f from components of M_i to components of M_j such that a is isomorphic to a minor of $f(a)$ for every component a of M_i . By Higman's lemma, there exist $i < j$ such that M_i is isomorphic to a minor of M_j . $\square$

COLORING AN ORTHOGONALITY GRAPH*

C. D. GODSIL[†] AND M. W. NEWMAN[†]

Abstract. We deal with a graph coloring problem that arises in quantum information theory. Alice and Bob are each given a ± 1 -vector of length 2^k and are to respond with k bits. Their responses must be equal if they are given equal inputs, and distinct if they are given orthogonal inputs; however, they are not allowed to communicate any information about their inputs. They can always succeed using quantum entanglement, but their ability to succeed using only classical physics is equivalent to a graph coloring problem. We resolve the graph coloring problem, thus determining that they can succeed without entanglement exactly when $k \leq 3$.

Key words. orthogonality graph, graph coloring, maximum independent sets, ratio bound, quantum telepathy

1. Introduction and background. We are concerned here with a graph coloring problem that arises in quantum information theory. Following this we describe the motivating problem and how it reduces to a question about the chromatic number of a particular type of graph. We close the first section with a review of some results in the literature.

For the reader unfamiliar with graph theory, we give a brief outline of concepts and notation in an appendix.

1.1. Motivating problem. The graph Ω_n has vertex set the set of ± 1 -vectors of length n ; two vertices are adjacent if they are orthogonal. Our main result is that the chromatic number of this graph is equal to n if and only if $n = 2^k$ with $k \leq 3$.

This problem arises in the following scenario, introduced in [3, 2]. Alice and Bob are each given a 01-vector of length 2^k , and they are each to respond with a 01-vector of length k . If their input vectors are equal, then their output vectors must also be equal; if their input vectors differ in exactly 2^{k-1} positions, then their output vectors must be distinct. Also, they are not allowed to communicate any information about their input vectors to each other.

Their cause is hopeless without some shared resource. Of course this resource must not allow them to share information about their inputs. We consider two possibilities, which correspond roughly to classical physics and quantum physics.

If they are allowed to share prior information, then they could agree beforehand on a proper coloring of Ω_{2^k} . They would then each interpret their input as a vertex of Ω_{2^k} and respond with the color of that vertex. Since they are allowed to output only k bits, this works only if $\chi(\Omega_{2^k}) \leq 2^k$.

Now consider that Alice and Bob have some strategy involving some prior shared information, and that their strategy is guaranteed to succeed. Alice and Bob are then given their respective inputs. Now before they actually answer, each writes down a list of the response they would have given to all possible inputs. If they have a

[†]Department of Combinatorics and Optimization, University of Waterloo, Waterloo, ON, N2L 3G1, Canada (cgodsil@uwaterloo.ca, mikenewman@alumni.uwaterloo.ca).

winning strategy, then they are able to do this. Let $a(x)$ be the entry in Alice's list corresponding to x , and likewise $b(x)$ for Bob. Since Alice and Bob's strategy is guaranteed to succeed for any pair of inputs, we have $a(x) = b(x)$ for all x , and $a(x) \neq b(y)$ whenever x and y correspond to adjacent vertices. Their answers are restricted to k bits, so their lists contain at most 2^k distinct entries. Thus they have a proper coloring with at most 2^k colors. (Note that we have not shown that if Alice is given the same input on different occasions, she must respond in the same way. Rather, at each round, her copy of the shared information amounts to a proper coloring.)

In other words, any strategy based on prior shared information is equivalent to coloring Ω_{2^k} with at most 2^k colors.

If, instead of information, they are allowed a shared resource of *quantum entanglement*, then they can always succeed when $n = 2^k$ for all k . This was first observed by Buhrman, Cleve, and Wigderson [3] (see also Brassard, Cleve, and Tapp [2]).

We do not assume any familiarity with quantum entanglement, qubits, and quantum information theory; however, the interested reader will find a good introduction to these areas in [13]. We summarize briefly the quantum algorithm given in [3, 2] (see [12] for a version that does not assume any background in quantum information theory). Alice and Bob share between them an entangled quantum state consisting of k EPR pairs of qubits. The ± 1 -vectors of length 2^k can be interpreted as indexing a particular family of quantum operations. So given their inputs, they each apply the corresponding operation to their qubits and then measure their qubits. They answer the result of their measurements. This turns out to be a winning strategy.

The point of this scenario is then that Alice and Bob can always succeed using quantum physics (i.e., by sharing quantum entanglement), whereas they cannot always succeed using classical physics (i.e., by sharing prior information). So our result quantifies the difference between what can be accomplished using quantum or classical physics for this particular scenario.

1.2. Prior work. In [3] it is also shown that for sufficiently large k , Alice and Bob cannot succeed by sharing only prior information. This follows directly from a deep result of Frankl and Rödl [7], who show that for large enough $n = 4m$ the size of an independent set in Ω_n is at most $(2 - \epsilon)^n$ for some $\epsilon > 0$. It follows that the chromatic number must eventually be greater than n . We note that the motivation of [7] has nothing to do with any quantum scenario; furthermore, their result is stronger than what we state here.

The reader may easily verify that $\chi(\Omega_n) = n$ for $n = 1, 2$ and with a little more effort for $n = 4$ as well (this case follows trivially from the recursive construction of section 6). Unpublished computations by Gordon Royle determined that $\chi(\Omega_8) = 8$ and characterized all of the proper 8-colorings. Galliard, Tapp, and Wolf [9] show that the size of an independent set in Ω_{16} is at most 3912, which implies that its chromatic number is at least 17.

2. Some simple cases. It is not hard to see that Ω_n is edgeless if n is odd.

If n is an odd multiple of two, then the vertices can be divided into the *even* vertices (those with an even number of -1 's) and the odd vertices; every edge joins an even vertex to an odd vertex, and so the graph is bipartite.

If $n = 4m$, then every edge joins an even vertex to an even vertex or an odd vertex to an odd vertex, and it follows that there are two components: one induced by the even vertices and one induced by the odd vertices. In fact, it is not hard to

see that these two components are isomorphic. Furthermore, if a vertex x is adjacent to y , then it is also adjacent to $-y$, and x is not adjacent to $-x$.

Given graphs G and H , the *lexicographic product* $G[H]$ is obtained by first replacing each vertex of G with a copy of H and then adding edges between every pair of vertices that correspond to adjacent vertices in G . (Thus choosing exactly one vertex from each new copy of H gives a set of vertices that induces a copy of G .) We see then that each component of Ω_n can be written as a lexicographic product $Y_n[\overline{K_2}]$ for some graph Y_n .

It follows from the definition that $\chi(G) = \chi(G[\overline{K_t}])$; in particular $\chi(\Omega_n) = \chi(Y_n)$. Furthermore, maximum independent sets in Ω_n are exactly four copies of maximum independent sets in Y_n . It follows that $\alpha(\Omega_n)$ is a multiple of four. More importantly, it will simplify some of our computational work.

3. Bounding independent sets. One of the main tools we use in analyzing Ω_n is the Delsarte–Hoffman bound on independent sets (see [6, section 3.3] or [4, page 115]; alternatively [12] for more recent work).

THEOREM 3.1. *Let X be a d -regular connected graph on v vertices, and τ the least eigenvalue of its adjacency matrix A . Let S be an independent set of size s and let z be the characteristic vector of S . Then*

$$s \leq v \frac{-\tau}{d - \tau}.$$

Furthermore, equality holds if and only if

$$A \left(z - \frac{s}{v} \mathbf{1} \right) = \tau \left(z - \frac{s}{v} \mathbf{1} \right).$$

The graph Ω_n is a graph in the Hamming scheme. We will not go into details here; the interested reader is directed to [10, Chapter 12] for background material on the Hamming scheme and association schemes in general. For our present purposes, the consequence of this is that we know a complete set of eigenvectors for Ω_n . In our case, Ω_n is a Cayley graph for an Abelian group, so we can use character theory to determine a complete set of eigenvectors (see, e.g., [10, section 12.9]). This gives the following result from [11, section 4.3].

LEMMA 3.2. *Let n be a multiple of four. Then the least eigenvalue of Ω_n is*

$$\tau = -\frac{1}{n-1} \binom{n}{\frac{n}{2}}.$$

Furthermore, let W be the matrix with rows indexed by subsets of $[n]$ and columns indexed by 2-subsets and $(n-2)$ -subsets, with entry in row x and column y equal to $(-1)^{|x \cap y|}$. Then the columns of W form a basis for the τ -eigenspace.

Note that here we are thinking of the vertices of Ω_n as being subsets of $[n]$ instead of ± 1 -vectors ($[n]$ denotes $\{1, 2, \dots, n\}$); two subsets are adjacent when they are at Hamming distance $\frac{n}{2}$. In fact, given any subset $y \subseteq [n]$, the vector w_y defined by $(w_y)_x = (-1)^{|x \cap y|}$ is an eigenvector of Ω_n . As there are 2^n choices for y , we obtain 2^n eigenvectors. As these are characters, they are orthogonal, so we have a complete set of eigenvectors.

Let $\widehat{W} = (W \quad \mathbf{1})$. Putting Theorem 3.1 and Lemma 3.2 together, we obtain the following result for our graphs.

COROLLARY 3.3. *The size of an independent set in Ω_n is bounded by*

$$\alpha(\Omega_n) \leq \frac{2^n}{n}.$$

Furthermore, if equality holds, then the characteristic vector of a maximum independent set lies in the column space of $\widehat{W}$.

Note that if Ω_n is n -colorable, then this bound must hold with equality (in fact, the coloring must be a partition into maximum independent sets). In other words, we have shown that $\chi(\Omega_n) > n$ whenever $n = 4m$ is not a power of two. It is noteworthy that the question “When is $\chi(\Omega_n) \leq n$?” becomes trivial when n is not a power of two: the mathematical analysis is simplest for the cases that are physically less interesting. Of more immediate use is the fact that if the bound does not hold with equality, then Ω_n is not n -colorable. One way to show that the bound is not tight is to use the equality condition of Theorem 3.1: it suffices to show that there are no suitable vectors in the τ -eigenspace.

4. Finding maximum independent sets. Since we know all of the eigenspaces of Ω_n , it is not hard to see that Ω_n , the even component of Ω_n , and Y_n all have the same least eigenvalue τ . If we take only those columns of W that correspond to the 2-subsets, and only those rows that correspond to the even vertices, the resulting column space gives the τ -eigenspace of the even component (this amounts to taking only one of the two eigenspaces of the Hamming scheme that give the τ -eigenspace on Ω_n). If we further reduce by taking only one vertex (i.e., row) from each pair $\{x, -x\}$, then we obtain a matrix whose columns form a basis for the τ -eigenspace for Y_n . We will denote this matrix by H . Furthermore, let $\widehat{H} = \begin{pmatrix} H & \mathbf{1} \end{pmatrix}$.

COROLLARY 4.1. *The size of an independent set in Y_n is bounded by*

$$\alpha(Y_n) \leq \frac{2^n}{4n}.$$

Furthermore, if equality holds then the characteristic vector of a maximum independent set lies in the column space of $\widehat{H}$.

Let z be the characteristic vector of an independent set S that meets the bound of Corollary 4.1. Then $z = \widehat{H}y$ for some vector y . Since Y_n is vertex-transitive, we are free to assume that S contains any particular vertex. As S is maximum, this is equivalent to assuming that S is disjoint from the neighborhood of a vertex. Let $\widehat{N}$ be the submatrix of $\widehat{H}$ with rows corresponding to a neighborhood; then we may assume that z takes the value 0 at the corresponding positions, meaning that y is in the kernel of $\widehat{N}$. Thus we are led to the following result.

LEMMA 4.2. *The kernel of $\widehat{N}$ is given by the row space of $\widehat{B} = \begin{pmatrix} B & \mathbf{1} \end{pmatrix}$, where B is the incidence matrix of K_n .*

Proof. A direct computation shows that

$$NB^T = -\mathbf{1}.$$

This means that

$$\widehat{N}\widehat{B}^T = 0.$$

We will show that this is the whole kernel by a rank argument.

We note that

$$BB^T = (n-1)I + J.$$

Thus the eigenvalues of BB^T are $2n - 1$ and $n - 1$, so B has full rank, and $\text{rk}(B) = \text{rk}(BB^T) = n$. As $B\mathbf{1} = (n - 1)\mathbf{1}$, we see that $\text{rk}(\widehat{B}) = n$.

Essentially the same argument determines the rank of $\widehat{N}$ as well. The rows and columns of $N^T N$ are indexed by 2-subsets, and the (a, b) -entry depends only on $|a \cap b|$. Let L and $\bar{L}$ be the incidence matrices of the line graph of K_n and its complement, respectively. It follows that

$$N^T N = c_0 I + c_1 L + c_2 \bar{L},$$

where

$$\begin{aligned} c_0 &= \binom{n}{\frac{n}{2}}, \\ c_1 &= \binom{n}{\frac{n}{2}} - 8 \binom{n-3}{\frac{n}{2}-1}, \\ c_2 &= \binom{n}{\frac{n}{2}} - 16 \binom{n-4}{\frac{n}{2}-1}. \end{aligned}$$

The matrices $I, L, \bar{L}$ are simultaneously diagonalizable with known eigenvectors (more precisely: the line graph of K_n is strongly regular). It follows that the eigenvalues of $N^T N$ are

$$\frac{n}{2(n-1)} \binom{n}{\frac{n}{2}}, \quad \frac{n(n-2)}{(n-1)(n-3)} \binom{n}{\frac{n}{2}}, \quad 0,$$

with respective multiplicities 1, $\binom{n}{2} - n$, and $n - 1$. As $N\mathbf{1} = \frac{n}{2}\mathbf{1}$, we see that $\text{rk}(\widehat{N}) = \text{rk}(N)$, and so $\dim(\ker(\widehat{N})) = \text{rk}(\widehat{B})$. The result follows. $\square$

We note that the rank arguments in the above proof amount to observing that BB^T and $N^T N$ both lie in the Bose–Mesner algebras of known association schemes.

Let C be the reduced column echelon form of the matrix $\widehat{H}\widehat{N}$ (C is in reduced column echelon form means that C^T is in reduced row echelon form). Then it follows that there are vectors x, x' such that

$$z = \widehat{H}y = \widehat{H}\widehat{B}^T x = Cx'.$$

Furthermore, since z is a 01-vector so is x' . Since H and B^T have full column rank, it follows that the rank of C is n . Thus it suffices to check all 2^n possibilities for x' in order to determine if there exist any independent sets that meet the bound. We have carried out this computation for $n = 8, 16$: for $n = 8$, we find that there are eight independent sets of the required size containing a given vertex; for $n = 16$, there are none.

On its own this computation is not particularly satisfying: we have not contradicted Royle's result mentioned above, and we have established a weaker bound on $\alpha(\Omega_{16})$ than the one given in [9]. However, it will turn out that our computations for $n = 8, 16$ suffice to determine all values of n for which Ω_n is n -colorable. For this purpose, we will rederive the bound of Theorem 3.1 for Ω_n twice more.

5. Coloring Ω_n . It is well-known that for any vertex-transitive graph X on v vertices, $\alpha(X)\omega(X) \leq v$. This is the *clique-coclique bound*. It also holds for any graph that is a union of classes in an association scheme. Ω_n falls into both of these categories, but it is also a normal Cayley graph, for which we can extend this result.

In particular, we will show that for a normal Cayley graph X , if $\alpha(X)\omega(X) = |V(X)|$, then $\chi(X) = \omega(X)$. We will need some preliminary results first.

Recall that the *connection set* of a Cayley graph for a group G is the subset D of G such that $a \sim b$ whenever $ba^{-1} \in D$. If S is a subset of G , then we write

$$S^{-1} = \{g^{-1} : g \in S\}, \\ Sa = \{ga : g \in S\}.$$

LEMMA 5.1. *Let X be a Cayley graph for a group G with connection set $D \subseteq G$. Let S be an independent set of X . If a and b are adjacent, then $S^{-1}a \cap S^{-1}b = \emptyset$.*

Proof. Assume $g^{-1}a = h^{-1}b$ for some $g, h \in S$. Then $hg^{-1} = ba^{-1}$. But $h \sim g$ so $hg^{-1} \notin D$, while $b \sim a$ so $ba^{-1} \in D$. $\square$

COROLLARY 5.2. *If X is a Cayley graph, then $\alpha(X)\omega(X) \leq |V(X)|$.*

Proof. Let S be an independent set and C a clique. Then by the previous result the sets

$$S^{-1}c, c \in C$$

are all disjoint. $\square$

We note parenthetically that this can be extended to a proof for all vertex-transitive graphs. It is an old result of Sabidussi [14] that if X is a vertex-transitive graph, there is an integer m such that the lexicographic product $X[\overline{K_m}]$ is a Cayley graph. Since

$$\alpha(X[\overline{K_m}]) = m\alpha(X), \quad \omega(X[\overline{K_m}]) = \omega(X), \quad |V(X[\overline{K_m}])| = m|V(X)|,$$

the result follows for all vertex transitive graphs.

Recall that a Cayley graph is *normal* if its connection set is closed under conjugation. Our purpose in approaching the clique-coclique bound through Cayley graphs is the following extension from [11].

COROLLARY 5.3. *If X is a normal Cayley graph and $\alpha(X)\omega(X) = v$, then $\chi(X) = \omega(X)$.*

Proof. Let S be a maximum independent set and C be a maximum clique. Again, the sets

$$S^{-1}c, c \in C$$

are disjoint, and so they partition the vertex set. Since X is normal, they are also independent sets and hence form a coloring. $\square$

For our purposes, Corollary 5.3 rederives the bound of Theorem 3.1 for Ω_n , but with a different equality condition. Notice that any clique in Ω_n is a set of pairwise orthogonal vectors; hence it is linearly independent and has size at most n . Furthermore, an n -clique would correspond to a Hadamard matrix, which certainly exists if $n = 2^k$. It follows that we can use Corollary 5.3 to rederive the bound of Theorem 3.1, but with a different equality condition.

COROLLARY 5.4. *Let n be a power of two.*

The size of an independent set in Ω_n is bounded as

$$\alpha(\Omega_n) \leq \frac{2^n}{n}.$$

Furthermore, if equality holds, then $\chi(\Omega_n) = n$.

So $\chi(\Omega_n) = n$ if and only if $\alpha(\Omega_n) = \frac{2^n}{n}$. Our determination of $\alpha(\Omega_8)$ above is now upgraded to a proof that $\chi(\Omega_8) = 8$.

We see that $\chi(\Omega_n) = n$ only if n is a power of two; this is because $\alpha(\Omega_n)$ must be an integer. Furthermore, if $\chi(\Omega_n) = n$, then each color class is an independent set that meets the bound of Theorem 3.1.

6. A recursive construction. The graph Ω_n is an induced subgraph of Ω_{2n} : take exactly those vertices of Ω_{2n} whose last n entries are the same as the first n entries. In fact, we can say much more than this.

For vertices x, r of Ω_n , let $x^{(r)}$ be the vertex of Ω_{2n} obtained by concatenating x with the entrywise product of x and r (recall that vertices are ± 1 -vectors). Let $\Omega_n^{(r)}$ be the subgraph induced by the vertices

$$\{x^{(r)} : x \in V(\Omega_n)\}.$$

Then we see that $\Omega_n^{(r)}$ is isomorphic to Ω_n , for any r . The vertex set of Ω_{2n} can be partitioned as

$$\{V(\Omega_n^r) : r \in V(\Omega_n)\}.$$

Furthermore, every vertex of $\Omega_n^{(r)}$ is adjacent to every vertex of $\Omega_n^{(-r)}$.

The *join* of two graphs X_1 and X_2 is $X_1 + X_2 = \overline{X_1} \cup \overline{X_2}$. (Informally, we first take the disjoint union of the two graphs, and then add edges between each vertex in X_1 and each vertex in X_2 .) We have established the following result.

LEMMA 6.1. *The vertex set of Ω_{2n} can be partitioned into 2^{n-1} copies of $\Omega_n + \Omega_n$.*

Note that any independent set in the join of two graphs must lie entirely within one or the other. This gives us a bound on the size of an independent set in Ω_{2n} : it is at most 2^{n-1} times the size of a maximum independent set in Ω_n . We can use this to again rederive the bound of Theorem 3.1, with yet another equality condition.

COROLLARY 6.2. *Let $n = 2^k$ where $k > 1$.*

The size of an independent set in Ω_n is bounded as

$$\alpha(\Omega_n) \leq \frac{2^n}{n}.$$

Furthermore, if equality holds then it also holds for $n = 2^{k-1}$.

We can in fact apply the recursive construction when n is not a power of two. If $n = m2^k$, where m is odd, then we find that

$$(6.1) \quad \alpha(\Omega_n) \leq \frac{2^n}{2^k}.$$

When $k > 1$ the bound of Corollary 3.3 is better than (6.1) by a factor of m . When $k = 1$, the bound of (6.1) is half the number of vertices, and is tight since Ω_n is then bipartite. But for $k = 1$ the least eigenvalue of Ω_n is no longer given by Lemma 3.2, and applying Theorem 3.1 in this case again gives half the number of vertices.

In other words, this recursion does not ever give a tighter bound than Theorem 3.1; rather, it is useful because of the equality condition of Corollary 6.2.

We mention another point of view on this recursion.

For $n = 2^k$, let the graphs Ψ_n be defined by setting $\Psi_1 := \Omega_1 = \overline{K_2}$, and recursively defining Ψ_{2n} to be the disjoint union of 2^{n-1} copies of $\Psi_n + \Psi_n$. Then Ψ_n

is a spanning subgraph of Ω_n , and so the method of Corollary 6.2 gives a bound on independent sets in Ψ_n as well. It follows that

$$\alpha(\Psi_n) = \frac{2^n}{n},$$

$$\chi(\Psi_n) = n.$$

Furthermore we see that $\Psi_n = \Omega_n$ for $n = 1, 2, 4$, by simply observing that their degrees are the same. This is an easy way to see that $\chi(\Omega_4) = 4$.

There are of course other edges in Ω_n for general n . In fact, Ψ_n is not only spanning, it is asymptotically sparse, in the following sense.

LEMMA 6.3.

$$\lim_{k \rightarrow \infty} \frac{|E(\Psi_{2^k})|}{|E(\Omega_{2^k})|} = 0.$$

In other words, for $n = 2^k$, Theorem 3.1 effectively only “sees” the edges of Ψ_n . This is expected, since one consequence of the Frankl–Rödl result is that for large enough n , the bound of Corollary 3.3 is exponentially too big.

7. Main result. Recall that although we can easily define Ω_n for any positive integer n , it is the cases where $n = 2^k$ that are most of interest. In exactly these cases, we have three different ways of proving the same bound on independent sets: using the Delsarte–Hoffman bound, using the maximum cliques, and a recursive construction. Furthermore, each approach gives different information in the case where the bound is tight.

We now find that our main result follows directly.

THEOREM 7.1. $\chi(\Omega_n) = n$ if and only if $n = 2^k$ with $k \leq 3$.

Proof. It follows from Corollary 3.3 and the comments after it that $\chi(\Omega_n) \neq n$ if n is not a power of two. Furthermore, if $\chi(\Omega_n) = n$, then the bound of Corollary 3.3 holds with equality, and Corollary 5.4 tells us that it is sufficient that this bound holds with equality. Our computations of section 4 deal with the cases $n = 2^k$ for $k = 3, 4$. We then invoke Corollary 6.2 to conclude that $\chi(\Omega_{2^k}) > 2^k$ for all $k > 4$. $\square$

8. Further bounds. Galliard [8] has a construction of an independent set inspired by the methods of Ahlswede and Khachatrian [1]. We state it in terms of the graph Y_n . It is convenient to regard the vertices as being subsets of $[n]$.

Let $n = 2^k$ and $c = \frac{n}{4} - 1$. Then the following collection is an independent set in Y_n :

$$\mathcal{F}_n = \{F \subseteq [n] : |F| = 2i, i \leq 2c; |F \cap [c]| \geq |F \setminus [c]|\}.$$

It is not hard to see that $\mathcal{F}$ is not properly contained in any larger independent set.

It turns out that for $k \leq 3$ this set meets the bound of Corollary 3.3, and hence this construction is maximum. Up to automorphisms of Ω_n , this is unique (this follows both from Gordon Royle’s computations and from our work in section 4). Galliard conjectured that $\mathcal{F}_n$ is maximum for all $n = 2^k$.

A recent computation of de Klerk and Pasechnik [5], using a technique of Schrijver [15] gives that $\alpha(Y_{16}) \leq 576$, which is exactly the size of $\mathcal{F}_{16}$. The reader is referred to [5] for details and further results. We do not know the value of $\alpha(\Omega_{4m})$ for $m > 4$.

There is another way to look at the collection $\mathcal{F}$. If we replace each element F of $\mathcal{F}_n$ with its symmetric difference with $[c]$ we obtain the collection of all odd subsets of $[n]$ of size at most c . More generally, if we assume only that $n = 4m$, we have the following construction:

$$\mathcal{S}_n = \{F \subseteq [n] : |F| \not\equiv m \pmod{2}; |F| < m\}.$$

We conjecture that these are in fact maximum in general. If this is true, it would imply our statement of the Frankl–Rödl result, namely that

$$\alpha(\Omega_{4m}) \leq (2 - c)^{4m}$$

for some $c > 0$, for large enough m .

Appendix. Graph theory notation.

A *graph* is a pair (V, E) where the elements of V are called *vertices* and E is a set of pairs of distinct vertices, called *edges*. If $\{x, y\} \in E$, we say that x and y are adjacent, and we write $x \sim y$. We often write the edge $\{x, y\}$ as xy . A *path* is a sequence of vertices with consecutive vertices adjacent; a graph is *connected* if there is a path between any two distinct vertices.

A *subgraph* of (V, E) is a pair (V', E') with $V' \subseteq V$, $E' \subseteq E$, where $xy \in E'$ implies $x, y \in V'$. It is *induced* if whenever $x, y \in V'$ and $xy \in E$, then $xy \in E'$ as well. The complement of a graph $X = (V, E)$ is the graph $\bar{X}$ which has the same vertex set as X , and where vertices are adjacent in $\bar{X}$ if and only if they are not adjacent in X .

An *independent set* is a set of vertices no two of which are adjacent. By a *maximum independent set*, we will always mean one of maximum size in the graph. A *clique* is a set of vertices where every two (distinct) vertices are adjacent; a clique with m vertices is denoted by K_m . (An independent set is sometimes called a *coclique*.) The size of a largest independent set in a graph X is denoted by $\alpha(X)$, and the size of the largest clique is denoted by $\omega(X)$.

A proper (vertex) coloring of a graph is a function c from the vertex set to a finite set of “colors” (the positive integers will do) such that whenever $x \sim y$, $c(x) \neq c(y)$. The preimage of a color (sometimes called a *color class*) is an independent set; thus a coloring is a partition of the vertex set into independent sets. A *t-coloring* is a coloring using t colors. The *chromatic number* of a graph X is the least positive integer t such that the graph has a t -coloring; it is denoted by $\chi(X)$.

The adjacency matrix of a graph is the (square) matrix with rows and columns indexed by the vertices, whose (i, j) -entry is equal to one or zero according to whether i and j are adjacent or not. The *eigenvalues of a graph* are the eigenvalues of its adjacency matrix.

FINDING A MAXIMUM INDEPENDENT SET IN A SPARSE RANDOM GRAPH*

URIEL FEIGE[†] AND ERAN OFEK[‡]

Abstract. We consider the problem of finding a maximum independent set in a random graph. The random graph G , which contains n vertices, is modeled as follows. Every edge is included independently with probability $\frac{d}{n}$, where d is some sufficiently large constant. Thereafter, for some constant α , a subset I of αn vertices is chosen at random, and all edges within this subset are removed. In this model, the planted independent set I is a good approximation for the maximum independent set I_{max} , but both $I \setminus I_{max}$ and $I_{max} \setminus I$ are likely to be nonempty. We present a polynomial time algorithm that with high probability (over the random choice of random graph G and without being given the planted independent set I) finds the maximum independent set in G when $\alpha \geq \sqrt{c_0/d}$, where c_0 is some sufficiently large constant independent of d .

1. Introduction. Let $G = (V, E)$ be a graph. An independent set I is a subset of vertices which contains no edges. The problem of finding a maximum size independent set in a graph is a fundamental problem in computer science, and it was among the first problems shown to be NP-hard [17]. Moreover, Håstad shows [14] that for any $\epsilon > 0$ there is no $n^{1-\epsilon}$ approximation algorithm for the maximum independent set problem unless $\text{NP} = \text{ZPP}$. The best approximation ratio currently known for a maximum independent set [6] is $O(n(\log \log n)^2/(\log n)^3)$.

In light of the above-mentioned negative results, we may try to design a heuristic that performs well on typical instances. Karp [16] proposed trying to find a maximum independent set in a random graph. However, even this problem appears to be beyond the capabilities of current algorithms. For example, let $G_{n,1/2}$ denote the random graph on n vertices obtained by choosing randomly and independently each possible edge with probability $1/2$. The size of the maximum independent set in a random $G_{n,1/2}$ graph is almost surely $2(1 + o(1)) \log_2 n$. A simple greedy algorithm almost surely finds an independent set of size $\log_2 n$ [13]. However, there is no known polynomial time algorithm that almost surely finds an independent set of size $(1 + \epsilon) \log_2 n$ (for any $\epsilon > 0$).

To further simplify the problem, Jerrum [15] and Kučera [18] proposed a *planted model* $G_{n,1/2,k}$ in which a random graph $G_{n,1/2}$ is chosen and then a clique of size k is randomly placed in the graph. (A clique in a graph G is an independent set in the edge complement of G , and hence all algorithmic results that apply to one of the problems apply to the other.) Alon, Krivelevich, and Sudakov [2] gave an algorithm based on spectral techniques that almost surely finds the planted clique for $k = \Omega(\sqrt{n})$. More

generally, one may extend the range of parameters of the above model by planting an independent set in $G_{n,p}$, where p need not be equal to $1/2$ and may also depend on n . The $G_{n,p,\alpha}$ model is as follows: n vertices are partitioned at random into two sets of vertices, I of size αn and C of size $(1 - \alpha)n$. No edges are placed within the set I , thus making it an independent set. Every other possible edge (with at least one end point not in I) is added independently at random with probability p . The goal of the algorithm given the input G (but without being given the partition into I and C) is to find a maximum independent set. Intuitively, as α becomes smaller, the size of the planted independent is closer to the probable size of the maximum independent set in $G_{n,p}$, and the problem becomes harder.

We consider values of p as small as d/n , where d is a large enough constant. A difficulty that arises in this sparse regime (i.e., when d is constant) is that the planted independent set I is not likely to be a maximum independent set. Moreover, with high probability I is not contained in a maximum independent set of G . For example, there are expected to be $e^{-d}n$ vertices in C of degree one. It is very likely that two (or more) such vertices $v, w \in C$ will have the same neighbor and that it will be some vertex $u \in I$. This implies that every maximum independent set will contain v and w and not u , and thus I contains vertices that are not contained in the maximum independent set. See Figure 1.

FIG. 1. The vertex $u \in I$ is not contained in any maximum independent set because no other edges touch v, w .

A similar argument shows that there are expected to be $e^{-\Omega(d)}n$ isolated edges. This implies that there will be an exponential number of maximum independent sets.

1.1. Our result. Our main result is summarized in the following theorem.

THEOREM 1.1. *There is a polynomial time algorithm that almost surely finds the maximum independent set of a graph G selected at random from the distribution $G_{n,\frac{d}{n},\alpha}$, when $d > d_0$ and $\alpha \geq \sqrt{c_0/d}$ (d_0, c_0 are some universal constants). The parameter d can also be an increasing function of n .*

The bulk of the paper is devoted to proving the above theorem. To simplify the presentation of the proof, it will be convenient to assume upper bounds on d and on α , namely, $d < n^{1/40}$ and $\alpha < 1/3$. These upper bounds do not limit the generality of our results, because when d or α exceeds these upper bounds the proof becomes simpler (see later discussions in the paper).

1.2. Related work. For $p = 1/2$, $\alpha = \Omega(1/\sqrt{n})$, Alon, Krivelevich, and Sudakov [2] gave an efficient spectral algorithm which almost surely finds the planted

independent set. For the above-mentioned parameters the planted independent set is likely to be the unique maximum independent set.

A few papers deal with *semirandom* models which extend the planted model by enabling a mixture of random and adversarial decisions. Feige and Kilian [7] considered the following model: a random $G_{n,p,\alpha}$ graph is chosen, and then an adversary may add arbitrarily many edges between I and C and make arbitrary changes (adding or removing edges) inside C . For any constant $\alpha > 0$ they give a heuristic that almost surely outputs a list of independent sets containing the planted independent set, whenever $p > (1 + \epsilon) \ln n / \alpha n$ (for any $\epsilon > 0$). The planted independent set may not be the only independent set of size αn since the adversary has full control over the edges inside C . Possibly, this makes the task of finding the planted independent set harder. In [8] Feige and Krauthgamer considered a less adversarial semirandom model in which an adversary is allowed to add edges to a random $G_{n, \frac{1}{2}, \frac{1}{\sqrt{n}}}$ graph. Their algorithm almost surely extracts the planted independent set and certifies its optimality. Coja-Oghlan [4] considered similar semirandom variants of random $G_{n,p,\sqrt{c/pn}}$ graphs, with $\ln(n)^2/n < p < 0.99$ (and c a sufficiently large constant). He shows among other things that in most such graphs a maximum independent set can be found in polynomial time.

By extracting from the above discussion the known previous results on planted independent set models (and ignoring issues such as handling semirandom instances), we see that the same trade-off between d and α as claimed in the current paper (namely, $\alpha \geq \sqrt{c_0/d}$) was previously established for the case $d = n/2$ (first in [2] and then again in [8]) and then extended all the way down to $d = \ln^2 n$ in [4]. The condition $\alpha \geq \sqrt{c_0/d}$ is needed mainly to ensure that the effect of planting the independent set I shows up in the spectrum of the adjacency matrix of the graph. For the previous range of parameters, the planted independent set is likely to be the maximum independent set in the graph. In this paper we address the case that d is a (sufficiently large) constant, which introduces difficulties not present in earlier work, mainly due to the fact that the planted independent set is not likely to be the maximum independent set.

Heuristics for optimization problems different from the max independent set will be discussed in the following section.

1.2.1. Technique and outline of the algorithm. Our algorithm builds on ideas from the algorithm of Alon and Kahale [1], which was used for recovering a planted 3-coloring in a random graph. The algorithm that we propose has four phases and is sketched below. This overall structure is similar to the structure of the algorithm of [1], but phases 3 and 4 include ingredients that are different from those of [1]. These differences are discussed towards the end of this section.

1. Get a coarse approximation I', C' of I, C with $|C \Delta C'| + |I \Delta I'| < \frac{1}{60}|I|$. This phase is based on spectral techniques.
2. Reduce the error in the approximation by using an iterative procedure based on the number of neighbors that each vertex has in I' . The error term $|C \Delta C'| + |I \Delta I'|$ is reduced to at most n/d^{18} .
3. Commit to placing certain vertices of I' in the final independent set. This is done by moving vertices from I' and C' to *OUT* (a new set) and committing to placing the remaining part of I' in the final independent set. The choice of vertices to move to *OUT* depends on their degree into I' . When this process ends, I' is an independent set, every vertex of C' has at least 4 edges

to I' , and no vertex of I' has edges to OUT . By using the fact that sparse random graphs (almost surely) have no small dense sets, it will be shown that $I' \subseteq I_{max}$ and also that OUT is rather small.

4. Extend the independent set I' optimally by using the vertices of OUT . This is done by finding a maximum independent set among the vertices of OUT and adding it to I' . The structure of OUT will be simple enough so that a maximum independent set can be efficiently found. The proof is based to a large extent on the fact that OUT is small. If vertices of OUT were chosen independently at random from the input graph G , then it would have been easy to show that all connected components in OUT are very small (say, of size $O(\log n)$), and then a maximum independent set in OUT can be found in time polynomial in n (even by an exhaustive search). However, OUT is a result of a deterministic process applied to G , which makes the analysis of its structure considerably more difficult.

The technique of [1] was implemented successfully on various problems in the planted model: planted hypergraph coloring, planted 3-SAT, planted 4-NAE, and min-bisection (by Chen and Frieze [3], Flaxman [11], Goerdts and Lanka [12], and Coja-Oghlan [5], respectively).

Perhaps the work closest in nature to the work in the current paper is that of Coja-Oghlan [5] on finding a bisection in a sparse random graph. Both in our work and in that of [5], one is dealing with an optimization problem, and the density of the input graph is such that the planted solution is not an optimal solution. The algorithm for bisection in [5] is based on spectral techniques and has the advantage that it provides a certificate showing that the solution that it finds is indeed optimal. We do not address the issue of certification in this paper. In [5] the random instance is generated as follows. The vertices of the graph are partitioned into two classes of equal size randomly. Then the edges are inserted: edges inside the two classes with probability p' and edges crossing the partition with probability p independently. Intuitively, as $p' - p$ becomes smaller, the problem becomes harder.

Denote by $d_1 = np'/2$ and $d_2 = np/2$ the expected degree of a vertex into its own class and into the other class, respectively. The algorithm in [5] is proven to succeed (almost surely) whenever $d_1 - d_2 \geq \sqrt{c_0 d_1 \log d_1}$. In our independent set model the problem becomes harder as αd becomes smaller. If we denote by $\tilde{d}_1 = d$ and $\tilde{d}_2 = (1 - \alpha)d$ the expected degrees of a vertex in C and I , respectively, then our algorithm (almost surely) succeeds whenever $\tilde{d}_1 - \tilde{d}_2 = \alpha \tilde{d}_1 \geq \sqrt{c_0 \tilde{d}_1}$. We remark that a significant source for complications in our algorithm and its analysis comes from a tightening of the parameters, saving a $\sqrt{\log \tilde{d}}$ factor in the size of α . A preliminary version of this work (see [10]) presents a simpler algorithm but requires $\alpha \tilde{d}_1 \geq \sqrt{c_0 \tilde{d}_1 \log \tilde{d}_1}$.

An important difference between planted models for an independent set and those for other problems such as 3-coloring and min-bisection is that in our case the planted classes I, C are not symmetric. The lack of symmetry between I and C makes some of the ideas used for the more symmetric problems insufficient. In the approach of [1], a vertex is removed from its current color class and placed in OUT if its degree into some other current color class is very different from what one would typically expect to see between the two color classes. This procedure is shown to “clean” every color class C from all vertices that should have been from a different color class but were wrongly assigned to class C in phase 2 of the algorithm. (The argument proving

this goes as follows. Every vertex remaining in the wrong color class by the end of phase 3 must have many neighbors that are wrongly assigned themselves. Thus the set of wrongly assigned vertices induces a small subgraph with a large edge density. But G itself does not have any such subgraphs, and hence by the end of phase 3 it must be the case that all wrongly assigned vertices were moved into OUT .) It turns out that this approach works well when classes are of similar nature (such as color classes or two sides of a bisection) but does not seem to suffice in our case, where I' is supposed to be an independent set whereas C' is not. Specifically, the set I' might still contain wrongly assigned vertices and might not be a subset of a maximum independent set in the graph. Under these circumstances, phase 4 will not result in a maximum independent set. Our solution to this problem involves the following aspects, not present in previous work. In phase 3 we remove from I' every vertex that has even one edge connecting it to OUT . This adds more vertices to OUT and makes the connected components in OUT larger. We do not attempt to analyze the maximum size of connected components in OUT , which is a key ingredient in previous approaches. Instead, we analyze the 2-core of OUT and show that the 2-core has no large components. Then, in phase 4, we use dynamic programming to find a maximum independent set in OUT and use the special structure of OUT to show that the algorithm runs in polynomial time.

1.3. Notation. Let $G = (V, E)$, and let $U \subset V$. The subgraph of G induced by the vertices of U is denoted by $G[U]$. When the set of edges used is clear from the context, we will use $\deg(v)_U$ to denote the degree of a vertex v into a set $U \subset V$. To specify exactly the set of edges used, we use $\deg^E(v)_U$, which is the degree of a vertex v into a set U induced by the set of edges E . We use $\Gamma(U)$ to denote the vertex neighborhood of $U \subset V$ (excluding U). The parameter d (specifying the expected degree in the random graph G) is assumed to be sufficiently large, and some of the inequalities that we shall derive implicitly use this assumption, without stating it explicitly. The term *with high probability* (w.h.p.) is used to denote a sequence of probabilities that tends to 1 as n tends to infinity.

2. The algorithm. The first step of the algorithm is tailored to deal with the case that α is small. When α is large (in fact, $\alpha > \sqrt{100 \log d/d}$ suffices), the combination of steps 1 and 2 can be replaced by a simpler step based on partitioning the vertices according to their degrees (see section 3.2 for details). Hence we shall assume here that $\alpha \leq 1/3$, and this will somewhat simplify the presentation of the algorithm and its analysis. Furthermore, we assume for simplicity that the values of the parameters α, d are given as inputs to the algorithm. This assumption can be avoided by enumerating all possible values of α, d (actually we need only a good approximation of α, d).

Figure 2 depicts the situation after step 3 of the algorithm is done. At that point, I_3 is an independent set, there are no edges between I_3 and OUT_3 , and every vertex $v \in C_3$ has at least four neighbors in I_3 .

3. Correctness. Let I_{max} be a maximum independent set of G . We establish two theorems. Theorem 3.1 guarantees the correctness of the algorithm, and Theorem 3.2 guarantees its efficient running time. Here we present these two theorems, and their proofs are deferred to later sections.

THEOREM 3.1. *W.h.p. there exists some maximum independent set I_{max} such that $I_3 \subseteq I_{max}$, $C_3 \cap I_{max} = \emptyset$.*

ALGORITHM *FindIS*(V, E).

1. Let A' be the adjacency matrix of the graph induced by removing from G all vertices of degree $> 5d$. Compute the eigenvector of the most negative eigenvalue of A' , denoted by $v_{n'}$. Sort the vertices of V' in order of the value of the corresponding entry in $v_{n'}$, breaking ties arbitrarily. Let I_1 be either the first αn vertices in this sorted order or the last αn vertices. (To choose between the above two options, find a maximal matching in each of the two possible induced graphs $G(I_1)$, and pick the option for which the maximal matching found is smaller.) Set $C_1 = V \setminus I_1$.
2. Set $C_2^0 = C_1, I_2^0 = I_1$. Iterate $j = 1, 2, \dots, \log n$:
for every vertex v : if $\deg(v)_{I_2^{j-1}} < \alpha d/2$, then $v \in I_2^j$; otherwise, $v \in C_2^j$.
3. (a) Set $I_3 = I_2^{\log n}$, $C_3 = C_2^{\log n}$, $OUT_3 = \emptyset$.
(b) For every edge (u, v) such that both u, v are in I_3 , move u, v to OUT_3 .
(c) A vertex $v \in C_3$ is *removable* if $\deg(v)_{I_3} < 4$.
Iteratively: find a removable vertex v , and move it from C_3 to OUT_3 . If v has neighbors in I_3 , move these neighbors from I_3 to OUT_3 .
4. Find a maximum independent set in $G[OUT_3]$ (this will be shown to be doable in polynomial time; see Corollary 3.2). Output the union of this independent set and I_3 .

FIG. 2. *FindIS* step 3 outcome.

DEFINITION 3.1. The 2-core of a graph G is the maximal subgraph in which the minimal degree is 2.

It is easy to see that the 2-core is unique and can be found by iteratively removing vertices whose degree < 2 .

THEOREM 3.2. *W.h.p. the largest connected component in the 2-core of $G[OUT_3]$ has cardinality of at most $2 \log n$.*

Let G be any graph. Those vertices of G that do not belong to the 2-core form trees. Each such tree is either disconnected from the 2-core or it is connected by exactly one edge to the 2-core. To find a maximum independent set of $G[OUT_3]$ we need to find a maximum independent set in each connected component of $G[OUT_3]$ separately. For each connected component D_i of $G[OUT_3]$ we find the maximum independent set as follows: let C_i be the intersection of D_i with the 2-core of $G[OUT_3]$. We enumerate all possible independent sets in C_i (there are at most $2^{|C_i|} \leq 2^{2 \log n}$

possibilities), and each one of them can be optimally extended to an independent set of D_i by solving (separately) a maximum independent set problem on each of the trees connected to C_i . For some trees we may have to exclude the tree vertex which is connected to D_i if it is connected to a vertex of the independent set that we try to extend. On each tree the problem can be solved by dynamic programming.

COROLLARY 3.2. *A maximum independent set in $G[OUT_3]$ can be found in polynomial time.*

3.1. Dense sets, degree deviations, and other properties. In proving the correctness of the algorithm, we will use structural properties of the random graph G . In particular, such a random graph most likely has no small dense sets (small sets of vertices that induce many edges). This fact will be used on several occasions to derive a proof by contradiction. Namely, certain undesirable outcomes of the algorithm cannot occur, as otherwise they will lead to a discovery of a small dense set in G . Most of the following lemmas are standard, and those proofs not given in this section will be given in section 4.

LEMMA 3.3. *Let G be a random $G_{n,p,\alpha}$ ($p = \frac{d}{n}$, $d < n^{1/40}$) random graph. W.h.p. the following hold:*

1. *There is no set $U \subset V$ of cardinality smaller than $2n/d^5$ such that the number of edges induced by U is more than $\frac{4}{3}|U|$.*
2. *There is no set $U \subset V$ of size $< \alpha n/40$ containing $\alpha d|U|/14$ edges (and this happens with probability of at least $> 1 - o(n^{-\sqrt{d}})$).*
3. *There is no $C' \subseteq C$ such that $n/2d^5 \leq |C'| \leq \frac{2n \log d}{d}$ and $|\Gamma(C') \cap I| \leq |C'|$.*

COROLLARY 3.4. *Let G be a graph which has the property from Lemma 3.3, part 1. Let A, B be any two disjoint sets of vertices each of size smaller than n/d^5 . If every vertex of B has at least 2 edges going into A , then $|A| \geq |B|/2$.*

Proof. Assume for the sake of contradiction that $|A| = \delta|B|$ for some $0 < \delta < 1/2$. The number of internal edges of $A \cup B$ is at least $2|B| > \frac{4}{3}(1 + \delta)|B| = \frac{4}{3}|A \cup B|$. The last inequality contradicts part 1 of Lemma 3.3. $\square$

The following lemma bounds the number of vertices whose degree largely deviates from its expectation.

LEMMA 3.5. *Let $d < n^{1/40}$. With probability $> 1 - e^{-n^{0.1}}$ the following hold:*

1. *There are at most n/d^{21} vertices in C whose degree into I is $< 0.9\alpha d$.*
2. *There are at most $3e^{-d}dn$ edges that contain a vertex with degree at least $3d$.*

LEMMA 3.6. *W.h.p. the size of a maximum independent set in $G[C]$ is $< \frac{2n \log d}{d}$.*

Proof. The probability for an independent set of size k is at most

$$(1) \quad \binom{n}{k} \left(1 - \frac{d}{n}\right)^{k(k-1)/2} \leq \left(\frac{ne}{k}\right)^k e^{-\frac{dk(k-1)}{2n}} = e^{k(\log(\frac{n}{k}) + 1 - \frac{d(k-1)}{2n})}.$$

By setting $k = \frac{2n \log d}{d}$ the above term becomes

$$(2) \quad e^{k(\log d - \log \log d - \log 2 + 1)} e^{-k(\log d - o(1))} = e^{-k(\log \log d + \log 2 - 1 - o(1))} = o(1). \quad \square$$

The following lemma differs from previous lemmas in this section in the sense that it does not refer to a “static” property that the input graph G is likely to have but rather to the likely outcome of step 1 of the algorithm $FindIS(G)$. It also differs from other lemmas in this section in the sense that its proof is considerably more complicated.

LEMMA 3.7. *Let $\sqrt{\frac{c_0}{d}} \leq \alpha \leq 1/3$, $d < n^{1/40}$. W.h.p. $|I_1 \triangle I| < |I|/60$.*

DEFINITION 3.8. *An instance G (taken from $G_{n,d/n,\alpha}$) is good if it has all of the properties listed in Lemmas 3.3, 3.5, 3.6, and 3.7.*

3.2. Proof of Theorem 3.1. In the proof of Theorem 3.1 we will assume that $d < n^{1/40}$. When d is very large (e.g., $d = n/2$), some of the lemmas that we use, such as Lemma 3.3, are not true. However, when d is very large, these lemmas are also not needed. When $d > n^{1/40}$, the planted independent set is almost surely the unique maximum independent set and can be found by using algorithms described in earlier work [2, 4].

When $\alpha \geq 1/3$, step 1 of the algorithm can be replaced by the following simpler step: put in I_1 all of the vertices of degrees $< (1 - \alpha/2)d$ and the rest of the vertices in C_1 . A simple argument (similar to the proof of Lemma 3.5) shows that in this case w.h.p. $|I \triangle I_1| < |I|/60$ (see [10] for more details). Hence when analyzing step 1 of the algorithm (proving that w.h.p. $|I \triangle I_1| < |I|/60$), we will without loss of generality limit the range of α to $\alpha < 1/3$.

We will show that if G is good, then steps 1–3 of the algorithm give a very good approximation of I, C .

3.2.1. An aid in the analysis. For the sake of the analysis, we introduce Definition 3.9. This definition identifies certain key sets of vertices in the graph (V_2 and V_3). Definition 3.9 involves an algorithm that has complete knowledge of the planted independent set I . To avoid the possibility of confusion, let us stress here that this algorithm is not part of the algorithm *FindIS*, and, moreover, the sets V_2 and V_3 are neither given to nor computed by the algorithm *FindIS*.

DEFINITION 3.9. *Given a graph $G = (V, E)$ with an independent set I (and a corresponding vertex cover $C = V \setminus I$), the P-core of G is a subset of V which is extracted by using the following steps:*

- CR0:** *Initialization:* $V_2 = I \cup \{v \in C \mid \deg(v)_I \geq 0.9\alpha d\}$.
 Iteratively: (i) If there is $v \in I \cap V_2$ with $\deg(v)_{V \setminus V_2} > \alpha d/4$,
 remove v from V_2 .
 (ii) If there is $v \in C \cap V_2$ with $\deg(v)_{I \cap V_2} < 0.8\alpha d$,
 remove v from V_2 .
- CR1:** *Initialization:* $V_3 = V_2$,
 remove from V_3 all of the vertices of $V_3 \cap I$ that have
 edges to $V \setminus V_3$.
 Iteratively: Find a vertex $v \in V_3 \cap C$ with $\deg(v)_{V_3 \cap I} < 4$, and
 remove v and its neighbors in I from V_3 .

The P-core of G is defined to be V_3 . We use $\overline{P\text{-core}}$ to denote $V \setminus P\text{-core}$.

The sets V_2 and V_3 have certain structural properties, as defined in Definition 3.9. We shall also need the fact that if G is a good graph (in the sense of Definition 3.8), then almost all vertices of G are in V_2 and in V_3 .

LEMMA 3.10. *For a good graph G , the following hold:*

1. $|V \setminus V_2| < n/d^{20}$ (where $V_2 = \text{CR0}(G)$).
2. $|\overline{P\text{-core}}| < n/d^{18}$.

Proof. Since G is good, after setting $V_2 = I \cup \{v \in C \mid \deg(v)_I \geq 0.9\alpha d\}$ (and before the iterations of CR0) it holds that $|V \setminus V_2| < n/d^{21}$ (see Lemma 3.5, part 1). In the iteration process, every vertex that we remove from V_2 contributes at least $0.1\alpha d$ edges to $V \setminus V_2$. If the iteration steps are repeated too many times, $V \setminus V_2$ will become dense. Assume by contradiction that at some point the set $V \setminus V_2$ doubled its size (when we compare it to the size before the first iteration). At this point it contains at least $\frac{1}{2}|V \setminus V_2|0.1\alpha d$ edges, and its size is at most $2n/d^{21}$, which contradicts the definition of good G (see Lemma 3.3, part 2). This proves item 1 of the lemma.

We now prove item 2 of the lemma. Initially, $V_3 = V_2$; at this point, $|V \setminus V_3| \leq$

n/d^{20} (using part 1 of this lemma). We then remove from V_3 all of the vertices of I that have edges to $V \setminus V_3$. By doing so, we lose at most $3dn/d^{20} + 3de^{-d}n$ vertices (see the definition of good G in Lemma 3.5, part 2; for a random G this happens with probability $> 1 - e^{-n^{0.1}}$). At this point (just before the iteration steps) $|V \setminus V_3| \leq 4n/d^{19}$. We now begin the iteration process. In every iteration we remove a vertex u of $V_3 \cap C$ whose degree into $V_3 \cap I$ became < 4 (we also remove its neighbors from $V_3 \cap I$). Note that after the initialization of CR1 the degree of u into $V_3 \cap I$ was $\geq 0.8\alpha d$. It follows that after removing u and its neighbors from $V_3 \cap I$ there are at least $0.8\alpha d$ additional edges in $V \setminus V_3$. If the iteration step is repeated too many times, the set $V \setminus V_3$ will become too dense. Assume by contradiction that at some point (for the first time during the iterations) $|V \setminus V_3|$ doubled its size when compared to the size of $V_3 \setminus V$ before the first iteration. At this point the number of edges inside $V \setminus V_3$ is at least $\frac{1}{2}|V \setminus V_3| \cdot \frac{1}{4} \cdot 0.8\alpha d$. Moreover, the size of $V \setminus V_3$ at this point is $\leq 8n/d^{19} + 3 < n/d^5$. This cannot happen in a good G (see Lemma 3.3, part 2; for a random G this happens with probability $o(n^{-\sqrt{d}})$). We conclude that $|V \setminus V_3| < n/d^{18}$. $\square$

Remark. The reader can verify by inspection that those properties of good graphs that are used in the proof of Lemma 3.10 hold with probability at least $1 - o(n^{-\sqrt{d}})$ (for a random graph taken from $G_{n,d/n,\alpha}$). Hence $\Pr[\overline{\text{P-core}} < n/d^{18}] > 1 - o(n^{-\sqrt{d}})$.

3.2.2. Analysis of step 1. Lemma 3.7 states that the spectral phase of the algorithm (step 1) is likely to give a good approximation of the planted independent set. The proof of Lemma 3.7 follows from known principles, but it is rather involved. It is given in section 4.2.

3.2.3. Analysis of step 2. In this section, we assume that G is good (as in Definition 3.8). The approximation I_1, C_1 serves as a bootstrap for the “error reduction” done at step 2. In Lemma 3.11 we show that step 2 significantly reduces the error term, i.e., $|I_2 \triangle I| < n/d^{20} < |I|/d^{19}$.

The idea of the proof is as follows. Recall that in Lemma 3.10 we showed that the set $V_2 = \text{CR0}(G)$ from Definition 3.9 is of size $> (1 - 1/d^{20})n$. Here we will use the assumption that G is good to show that every iteration of step 2 of *FindIS* reduces the number of errors (with respect to I, C) in V_2 by a factor of 2. It then follows that, after step 2 is done, all of the vertices of V_2 are assigned correctly.

LEMMA 3.11 (error reduction). *Let G be a good graph, $V_2 = \text{CR0}(G)$, and $I_2 = I_2^{\log n}$ from step 2 of *FindIS*(G). Then $V_2 \cap (I \triangle I_2) = \emptyset$ and $|I_2 \triangle I| \leq n/d^{20}$.*

Proof. When step CR0 ends, every vertex of $C \cap V_2$ has at least $0.8\alpha d$ edges to $I \cap V_2$, and every vertex of $I \cap V_2$ has at most $\alpha d/4$ edges to $V \setminus V_2$.

For each iteration i of step 2 of *FindIS*(G), define the respective “error” E_i to be the set of those vertices of V_2 that are assigned incorrectly, namely, $E_i = V_2 \cap (I_2^i \triangle I)$. We will show that each iteration of step 2 of *FindIS*(G) reduces the error by a factor of at least 2. This is based on the fact (to be shown shortly) that every vertex of E_i has at least $\alpha d/4$ edges to E_{i-1} . Based on this fact, we show that an event $|E_i| \geq |E_{i-1}|/2$ would lead to a contradiction. Fix E'_i to be any subset of E_i whose size is $|E_{i-1}|/2$ (if $|E_{i-1}|$ is odd, we take a subset of size $\lceil |E_{i-1}|/2 \rceil$, and essentially the same argument goes through). The set $E'_i \cup E_{i-1}$ is of cardinality $\leq \frac{3}{2}|E_{i-1}|$, and it contains at least $\frac{\alpha d}{4}|E_{i-1}|/2$ edges. This contradicts the definition of good G as $|E_{i-1}| \leq |E_0| \leq \alpha n/60$ (see Lemma 3.3, part 2, and note that $|E'_i \cup E_{i-1}| \leq \frac{3}{2}|E_{i-1}| \leq \alpha n/40$).

We now show that each vertex of E_i has at least $\alpha d/4$ edges to E_{i-1} .

Case 1. $v \in E_{i-1} \cap E_i$ (either $v \in I \cap C_2^{i-1}$ or $v \in C \cap I_2^{i-1}$): If $v \in I \cap C_2^{i-1}$ (and $v \in E_i$), then in round $i-1$ it has at least $\alpha d/2$ neighbors in I_2^{i-1} , and these

neighbors are in $C \cap I_2^{i-1}$ since $v \in I$. At least $\alpha d/4$ of these neighbors are in V_2 since v has at most $\alpha d/4$ edges to $V \setminus V_2$ (because $v \in I \cap V_2$). Thus v has $> \alpha d/4$ neighbors in E_{i-1} . If $v \in C \cap I_2^{i-1}$ (and $v \in E_i$), then in round $i-1$ it has at most $\alpha d/2$ neighbors in I_2^{i-1} . Since $v \in V_2 \cap C$, it has $0.8\alpha d$ neighbors in $I \cap V_2$, and thus at least $0.3\alpha d$ of them are in $I \cap C_2^{i-1} \subseteq E_{i-1}$.

Case 2. $v \in E_i \setminus E_{i-1}$: If $v \in E_i \setminus E_{i-1} \cap I$, then v was moved from I_2^{i-1} to C_2^i , and therefore it has at least $\alpha d/2$ neighbors in $I_2^{i-1} \cap C$. Among them, at least $\alpha d/4$ belong to V_2 because v has at most $\alpha d/4$ edges to $V \setminus V_2$. If $v \in E_i \setminus E_{i-1} \cap C$, then v was moved from C_2^{i-1} to I_2^i , and therefore it has at most $\alpha d/2$ neighbors in I_2^{i-1} . Since $v \in V_2 \cap C$, it has at least $0.8\alpha d$ neighbors in $I \cap V_2$, among which at least $0.3\alpha d$ are in $I \cap C_2^{i-1} \subseteq E_{i-1}$.

It follows that when step 2 is done all of the vertices of V_2 are correctly assigned by the algorithm. It then follows that $|I_2 \triangle I| \leq |V \setminus V_2| \leq n/d^{20}$, where the last inequality follows from Lemma 3.10, part 1. $\square$

3.2.4. Analysis of step 3. So far we have shown that at most n/d^{20} vertices of I_2, C_2 are wrongly assigned (with respect to I, C). The goal of step 3 is to “clean” I_2, C_2 yielding I_3, C_3 that can be extended into an optimal solution. Before showing that $I_3 \subseteq I_{max}$ (for some maximum independent set I_{max}), we show that the process of “cleaning” in step 3 does not move too many vertices to OUT_3 . This will be used later for proving that $I_3 \subseteq I_{max}$. For the following lemma, recall the notion of $\bar{P}$ -core from Definition 3.9.

LEMMA 3.12. *Let G be a good graph, and let OUT_3 be the outcome of step 3 of $FindIS(G)$. Then $OUT_3 \subseteq \bar{P}$ -core, and $OUT_3 < n/d^{18}$.*

Proof. As $\overline{OUT}_3 = I_3 \cup C_3$ (where I_3, C_3 are from step 3 of $FindIS(G)$) it is enough to show that $V_3 \subseteq I_3 \cup C_3$. Immediately after step 3(a) it holds that $I_3 \cup C_3 = V$ and thus $V_3 \subseteq I_3 \cup C_3$. We will show that this is kept during steps 3(b) and 3(c). Initially (at CR1) $V_3 = V_2$. Removing from V_3 all of the vertices of $V_3 \cap I$ that have edges to $V \setminus V_3$ ensures that there are no edges between vertices of $V_3 \cap I$ and vertices which were assigned incorrectly (all of the vertices of $V_3 \subseteq V_2$ are correctly assigned after step 2 of the algorithm; see Lemma 3.11). Thus, step 3(b) of the algorithm does not touch any vertex of V_3 because it removes only edges that contain at least one wrongly assigned end point. Finally, the iteration process of CR1 ensures that every vertex of $V_3 \cap C$ has at least 4 edges to vertices in $V_3 \cap I$. Since V_3 is a subset of $I_3 \cup C_3$ at the beginning of step 3(c) and there are no wrongly assigned vertices in V_3 , during step 3(c) there will never be a vertex of $V_3 \cap C$ that has fewer than 4 edges to vertices of $V_3 \cap I$. We conclude that $V_3 \subseteq I_3 \cup C_3$ at the end of step 3.

By combining with Lemma 3.10, part 2, we deduce that w.h.p. $OUT_3 < n/d^{18}$. $\square$

As $|I_3 \triangle I| < |I_2 \triangle I| + |OUT_3|$, by using Lemmas 3.11 and 3.12 we deduce the following.

COROLLARY 3.13. *For a good G , it holds that $|I_3 \triangle I| < 2n/d^{18}$.*

It turns out that I_3, C_3 is also a good approximation of I_{max}, C_{max} (I_{max} is any maximum independent set, and $C_{max} = V \setminus I_{max}$).

LEMMA 3.14. *For a good G it holds that $|I_3 \triangle I_{max}| < n/d^5$.*

Proof.

$$|I_{max} \triangle I_3| \leq |I_{max} \triangle I| + |I \triangle I_3|.$$

By Corollary 3.13, $|I_3 \triangle I| < n/d^{18}$. It remains to bound $|I_{max} \triangle I|$:

$$|I_{max} \triangle I| = |I_{max} \setminus I| + |I \setminus I_{max}| \leq 2|I_{max} \setminus I| = 2|I_{max} \cap C|.$$

$I_{max} = (I_{max} \cap I) \cup (I_{max} \cap C)$. One can always replace $I_{max} \cap C$ with $\Gamma(I_{max} \cap C) \cap I$ to get an independent set $(I_{max} \cap I) \uplus (\Gamma(I_{max} \cap C) \cap I)$. The size of a maximum independent set of C is $< \frac{2n \log d}{d}$ (as G is good; see Lemma 3.6). This upper bounds $|I_{max} \cap C|$. From Lemma 3.3, part 3, if $|I_{max} \cap C| > n/(2d^5)$, then $|\Gamma(I_{max} \cap C) \cap I| > |I_{max} \cap C|$, which contradicts the maximality of I_{max} . $\square$

At this point (for a good G) we know that I_3, C_3 have the following two properties:

- (i) the error term $|(I_3 \cap C_{max}) \cup (I_{max} \cap C_3)| \leq |I_{max} \Delta I_3| < n/d^5$;
- (ii) I_3 is an independent set, and every vertex of C_3 has at least 4 neighbors in I_3 .

The above two properties and the fact that G is good imply that $I_3 \subseteq I_{max}$. This is proven in the following lemma.

LEMMA 3.15 (extension lemma). *Let I_m be any independent set of G (the reader may think of I_m as I_{max}), and let $C_m \triangleq V \setminus I_m$. Let I', C', OUT' be an arbitrary partition of V for which I' is an independent set. If the following hold:*

1. $|(I' \cap C_m) \cup (I_m \cap C')| < n/d^5$;
2. every vertex of C' has at least 4 neighbors in I' (none of the vertices of I' have edges to OUT');
3. the graph G has no small dense subsets as described in Lemma 3.3, part 1,

then there exists an independent set I_{new} (and $C_{new} \triangleq V \setminus I_{new}$) such that $I' \subseteq I_{new}$, $C' \subseteq C_{new}$, and $|I_{new}| \geq |I_m|$.

Proof. If we could show that on average a vertex of $U = (I' \cap C_m) \cup (I_m \cap C')$ contributes at least $4/3$ internal edges to U , then U would form a small dense set that contradicts Lemma 3.3. This would imply that $U = (I' \cap C_m) \cup (I_m \cap C')$ is the empty set, and we could take $I_{new} = I_m$ in the proof of Lemma 3.15. The proof below extends this approach to cases where we cannot take $I_{new} = I_m$.

Every vertex $v \in C'$ has at least 4 edges into vertices of I' . Since I_m is an independent set, it follows that every vertex of $I_m \cap C'$ has at least 4 edges into $I' \cap C_m$. To complete the argument we would like to show that every vertex of $I' \cap C_m$ has at least 2 edges into $I_m \cap C'$. However, some vertices $v \in I' \cap C_m$ might have less than two neighbors in $I_m \cap C'$ (see Figure 3). In this case, we will modify I_m to get an independent set I_{new} (and $C_{new} \triangleq V \setminus I_{new}$) at least as large as I_m , for which every vertex of $I' \cap C_{new}$ has 2 neighbors in $I_{new} \cap C'$. This is done iteratively; after each iteration we set $I_m = I_{new}$, $C_m = C_{new}$. Consider a vertex $v \in (I' \cap C_m)$ with $\deg(v)_{I_m \cap C'} < 2$:

FIG. 3. A vertex $v \in (I' \cap C_m)$ which has strictly less than 2 edges into $I_m \cap C'$.

- If v has no neighbors in $I_m \cap C'$, then define $I_{new} = I_m \cup \{v\}$. I_{new} is an independent set because v (being in I') has no neighbors in I' or in OUT' .

- If v has only one edge into $w \in (I_m \cap C')$, then define $I_{new} = (I_m \setminus \{w\}) \cup \{v\}$. I_{new} is an independent set because v (being in I') has no neighbors in I' or in OUT' . The only neighbor of v in $I_m \cap C'$ is w .

The three properties are maintained also with respect to I_{new}, C_{new} (replacing I_m, C_m): properties 2, 3 are independent of the sets I_m, C_m , and property 1 is maintained since after each iteration it holds that $|(I' \cap C_{new}) \cup (I_{new} \cap C')| < |(I' \cap C_m) \cup (I_m \cap C')|$.

When the process ends, let U denote $(I' \cap C_m) \cup (I_m \cap C')$. Each vertex of $I' \cap C_m$ has at least 2 edges into $I_m \cap C'$, and thus $|I_m \cap C'| \geq \frac{1}{2}|I' \cap C_m|$ (see Corollary 3.4). Each vertex of $I_m \cap C'$ has 4 edges into $I' \cap C_m$, so the number of edges in U is at least $4|I_m \cap C'| \geq 4|U|/3$ and also $|U| < n/d^5$, which implies that U is empty (by Lemma 3.3, part 1). $\square$

Proof of Theorem 3.1. Assume that G is good (w.h.p. this is the case; see section 3.1). By Lemma 3.14, $|I_3 \triangle I_{max}| < n/d^5$. By using Lemma 3.15 (instantiating I_m and I' from Lemma 3.15 to be I_{max} and I_3 , respectively), we derive that I_3 is contained in some maximum independent set. $\square$

It remains to show that the 2-core of OUT_3 has no large connected components.

3.3. Proof of Theorem 3.2. Having established that, for a good G , OUT_3 is small (Lemma 3.12), we would now like to establish that its structure is simple enough to allow one to find a maximum independent set of $G[OUT_3]$ in polynomial time. Establishing such a structure would have been easy if the vertices of OUT_3 were chosen independently at random, because a small random subgraph of a random graph G is likely to decompose into connected components no larger than $O(\log n)$. However, OUT_3 is extracted from G by using some deterministic algorithm and hence might have a more complicated structure. For this reason, we shall now consider the 2-core of $G[OUT_3]$ and bound the size of its connected components. Note that for good G it holds that $OUT_3 \subseteq \overline{\text{P-core}}$ (Lemma 3.12), and thus for such G it is enough to handle $\overline{\text{P-core}}$. This simplifies the proof because the definition of $\overline{\text{P-core}}$ (namely, the procedure that generates it in Definition 3.9) is simpler than that of OUT_3 .

To prove that the 2-core of $G[\overline{\text{P-core}}]$ has no large connected component, we shall introduce a notion of a *balanced* connected component. A set of vertices $U \subset V$ will be called *balanced* if it contains at least $|U|/3$ vertices from C . The following lemma shows the relevance of the notion of being balanced to our context.

PROPOSITION 3.3. *For good G , every connected component of the 2-core of $G[\overline{\text{P-core}}]$ is balanced.*

Proof. Let A_i be such a connected component. Every vertex of A_i has degree of at least 2 in the 2-core (of $G[\overline{\text{P-core}}]$). Since A_i is a connected component of the 2-core, it follows that every vertex of A_i has degree of at least 2 inside A_i . $|A_i| \leq |\overline{\text{P-core}}| < \frac{n}{d^5}$. If $\frac{|A_i \cap I|}{|A_i|}$ is more than $\frac{2}{3}$, then the number of internal edges in A_i is $> 2 \cdot \frac{2}{3}|A_i| > \frac{4}{3}|A_i|$, which contradicts Lemma 3.3, part 1. $\square$

The following lemma shows that a connected component is balanced only if it contains a sufficiently large balanced tree.

LEMMA 3.16. *Let G be a connected graph whose vertices are partitioned into two sets: C and I . Let $\frac{1}{k}$ be a lower bound on the fraction of C vertices, where k is an integer. For any $1 \leq t \leq |V(G)|/2$ there exists a tree whose size is in $[t, 2t-1]$ and at least $\frac{1}{k}$ fraction of its vertices belong to C .*

Proof. We use the following well-known fact: any tree T contains a *center* vertex v such that each subtree hanging on v contains strictly less than half of the vertices of T .

Let T be an arbitrary spanning tree of G . Observe that at least a fraction of $\frac{1}{k}$

of its vertices belongs to C . We show that any such tree T has a subtree T' of size $|T|/2 < |T'| < |T|$ with at least a fraction of $\frac{1}{k}$ of its vertices in C . Repeating this argument until the first time that $|T'| < 2t$ proves the lemma.

Let v be the center of T , and let $T_1, \dots, T_k$ be the subtrees hanging on v . Let T_j be the subtree with the smallest fraction of C vertices, and take T' to be the tree that remains by removing T_j from T . By properties of the center vertex, $|T|/2 < |T'| < |T|$, as desired. Moreover, if the fraction of C vertices in T_j is $\frac{1}{k}$ or less, then clearly the fraction of C vertices in T' is at least $\frac{1}{k}$. If the fraction of C vertices in T_j is strictly more than $\frac{1}{k}$, then this holds also for all other subtrees of T . By the integrality of k , this implies that the fraction of C vertices in T' is at least $\frac{1}{k}$ (because then $k|C \cap T'| > |T'| - 1$ implies $k|C \cap T'| \geq |T'|$). $\square$

To proceed with our discussion, we introduce the following definition.

DEFINITION 3.17. *We say that G is extension friendly if $G[\overline{P\text{-core}}]$ has no balanced trees of size in $[\log n, 2 \log n]$.*

In Lemma 3.18 to follow, we will see that G is likely to be extension friendly. This is a key component in the proof of Theorem 3.2.

Proof of Theorem 3.2. W.h.p. it holds that G is both good and extension friendly (see section 3.1 and Lemma 3.18). Since G is good, Proposition 3.3 implies that every connected component of the 2-core of $G[\text{P-core}]$ is balanced. Furthermore, any balanced connected component of size at least $2 \log n$ (in vertices) must contain a balanced tree of size in $[\log n, 2 \log n - 1]$ (see Lemma 3.16). Since G is extension friendly, the 2-core of $G[\text{P-core}]$ does not contain a balanced tree with size $[\log n, 2 \log n]$. By combining these three facts we derive that the 2-core of $G[\text{P-core}]$ has no connected components of size $> 2 \log n$. Note that since G is good it holds that $\text{OUT}_3 \subseteq \overline{\text{P-core}}$, and thus also the 2-core of $G[\text{OUT}_3]$ has no connected components of size more than $2 \log n$. $\square$

We will now show that G is likely to be extension friendly.

LEMMA 3.18. *Assume that G is taken from $G_{n,d/n,\alpha}$. W.h.p. $G[\overline{P\text{-core}}]$ has no balanced tree of size in $[\log n, 2 \log n]$.*

Proof. As we have seen in Lemma 3.12, $|\overline{\text{P-core}}|$ is likely to be very small, smaller than n/d^{18} . If we were to pick at random such a small subgraph of G , then it would have been very sparse (average degree at most d^{-17}), making it highly unlikely to contain any connected component of size $\log n$ or more and hence also no tree (let alone a balanced tree) of size $\log n$ or more. The difficulty in proving Lemma 3.18 is that $\overline{\text{P-core}}$ is not a random set of vertices in G . To overcome this difficulty, we look more closely at the random processes by which G is generated and decouple the random decisions that govern which set of vertices comprise $\overline{\text{P-core}}$ from the random decisions that govern which edges are present in $G[\overline{\text{P-core}}]$. To achieve this decoupling, we shall modify the notion of a P -core and slightly enlarge $\overline{\text{P-core}}$.

We now proceed with the detailed proof. We start with the empty graph (a set V of n vertices and no edges) and build the random graph G as we go.

Step 1. Choose an arbitrary partition of the vertex set V into I and C , with $|I| = \alpha n$.

Step 2. Choose a value t for the size of the balanced tree T . As $\log n \leq t \leq 2 \log n$, there are $\log n + 1$ possible ways of choosing t .

For a tree T , let $I(T)$ denote those vertices of T that are in I , and let $C(T)$ denote those vertices of T that are in C .

Step 3. Choose $t_1 = |I(T)|$, the number of vertices of T in I . Observe that $t_1 \leq 2t/3$ because the tree is balanced. Let $t_2 = |C(T)| = t - t_1 \geq t/3$. There are at

most $2t/3 + 1 \leq 2 \log n$ ways of choosing t_1 .

Step 4. Choose $I(T)$, the vertices of I that will be in the tree T . There are $\binom{\alpha n}{t_1}$ ways of doing this.

Step 5. In this step we start constructing the edge set E of the random graph G . For every pair of vertices $u \in C$ and $v \in I \setminus I(T)$ we include the edge (u, v) in E with probability $p = d/n$. For other pairs of vertices, we do not yet decide whether to include an edge or not. We call the graph obtained after this stage G' .

Step 6. At this step we construct a P' -core which is a modified version of the P -core. Its construction follows the construction of a P -core, except for two differences: it is constructed based on G' rather than on G , and the vertices of $I(T)$ are forced not to be part of the P' -core. A detailed description of the procedure for constructing the P' -core will be presented in Definition 3.20. The key properties of the P' -core that we shall need are summarized in the following lemma.

LEMMA 3.19. *For the construction of P' -core as described in Definition 3.20, the following hold:*

1. *Regardless of the choice of $I(T)$ and regardless of which other edges are added to G' so as to create the final graph G , P' -core is always contained in P -core (where P -core is constructed with respect to G in Definition 3.9).*
2. *The bad event of $|\overline{P'-core}| > n/d^{18}$ occurs with probability at most $n^{-\sqrt{d}}$ (here probability is taken over choice of edges in G'). Hence the complementary good event $|\overline{P-core}| \leq n/d^{18}$ happens almost surely.*

We now assume Lemma 3.19, deferring its proof to later, and continue with the proof of Lemma 3.18.

Step 7. Choose the vertices in $C(T)$. If the good event in Lemma 3.19 occurs, then there are at most $\binom{n/d^{18}}{t_2}$ ways of doing this. If the bad event occurs, then there are $\binom{n}{t_2}$ ways of doing this.

Step 8. Having chosen all vertices of T , we need to choose those pairs of vertices that form the tree edges. We call it the interconnection pattern $E(T)$. There are at most t^{t-2} ways of doing this (which is the number of labeled trees on t vertices). The number may actually be much smaller than t^{t-2} , because there cannot be any edges between vertices in the set $I(T)$.

Step 9. Only now do we complete the construction of the random graph G . For every pair of vertices $u, v \in C$, the edge (u, v) is included in E with probability p . Likewise, for every pair of vertices $u \in C$ and $v \in I(T)$, the edge (u, v) is included in E with probability p . Now we compute the probability that all edges of $E(T)$ are in. This probability depends only on Step 9 and is exactly p^{t-1} , regardless of the outcome of Steps 1–8 above.

We can now upper bound the expected number of balanced trees T in $G[\overline{P-core}]$ with t vertices and $\log n \leq t \leq 2 \log n$. Let us fix a value for t and a value for $t_1 = |I(T)|$. By Steps 2 and 3 there are at most $2(\log n)^2$ ways of doing so. By Step 4, there are $\binom{\alpha n}{t_1}$ ways of choosing $I(T)$. By item 1 in Lemma 3.19 it suffices to upper bound the number of balanced trees in $G[\overline{P'-core}]$, as this will also be an upper bound on the number of balanced trees in $G[\overline{P-core}]$. By Step 7, the expected number of ways of choosing the vertices of $C(T)$ in $\overline{P'-core}$ is at most $\binom{n/d^{18}}{t_2} + n^{-\sqrt{d}} \binom{n}{t_2}$. By Step 8, the number of interconnection patterns to consider is at most t^{t-2} . Finally, by Step 9, the probability that all edges of the interconnection pattern are in G is $(d/n)^{t-1}$. Multiplying out all of the terms, the expected number of balanced trees is

at most

$$2(\log n)^2 \binom{\alpha n}{t_1} \left(\binom{n/d^{18}}{t_2} + n^{-\sqrt{d}} \binom{n}{t_2} \right) t^{t-2} \left(\frac{d}{n} \right)^{t-1}.$$

The above expression is much smaller than 1. To see this, observe that for sufficiently large d and $t_2 \leq 2 \log n$ the term $n^{-\sqrt{d}} \binom{n}{t_2}$ is negligible compared to $\binom{n/d^{18}}{t_2}$. Observe also that $\frac{t^t}{t_1^{t_1} t_2^{t_2}} \leq 2^t$ because $t_1 + t_2 = t$. By using these observations, the above expression can be upper bounded by essentially

$$\frac{(2e)^t (\log n)^2 \alpha^{t_1} d^{t-1} n}{d^{18t_2}}.$$

By observing further that $t_1 \leq t$, $t_2 \geq t/3$, $\alpha < 1$, and using the fact the d is sufficiently large and hence larger than $2e$, this last expression is upper bounded by $n(\log n)^2/d^{4t}$. Using the fact that $t \geq \log n$ now implies that the expected number of balanced trees is at most $1/n^2$, and hence with probability at least $1 - 1/n^2$ there is no balanced tree of size between $\log n$ and $2 \log n$ in $G[\text{P-core}]$. $\square$

We present here the detailed definition for the P' -core.

DEFINITION 3.20. *Given a graph G' with the vertex set partitioned into I and C as in Step 1 of the proof of Lemma 3.18, a set $I(T) \subset I$ as in Step 4 of the proof of Lemma 3.18, and an edge set as in Step 5 of the proof of Lemma 3.18, the P' -core of G' is a subset of V which is extracted by using the following steps:*

- CR0':** *Initialization:* $V'_2 = (I \setminus I(T)) \cup \{v \in C \mid \deg(v)_{I \setminus I(T)} \geq 0.9\alpha d\}$.
 Iteratively: (i) If there is $v \in I \cap V'_2$ with $\deg(v)_{V \setminus V'_2} > \alpha d/4$,
 remove v from V'_2 .
 (ii) If there is $v \in C \cap V'_2$ with $\deg(v)_{I \cap V'_2} < 0.8\alpha d$,
 remove v from V'_2 .
- CR1':** *Initialization:* $V'_3 = V'_2$,
 remove from V'_3 all of the vertices of $V'_3 \cap I$ that have
 edges to $V \setminus V'_3$.
 Iteratively: Find a vertex $v \in V'_3 \cap C$ with $\deg(v)_{V'_3 \cap I} < 4$, and
 remove v and its neighbors in I from V'_3 .

The P' -core of G is V'_3 .

We now prove Lemma 3.19.

Proof of Lemma 3.19, part 1. The notion of a P-core is defined in Definition 3.9. The notion of a P' -core is defined in Definition 3.20. Both definitions are similar in many respects and differ only in the following details:

1. $V'_2 \cap I$ is initialized to be smaller than $V_2 \cap I$, because all vertices of $I(T)$ are excluded from it. This is in agreement with our goal of showing that P' -core is contained in P-core.
2. $V'_2 \cap C$ is initialized to be smaller than $V_2 \cap C$, because vertices in C have fewer edges into $I \setminus I(T)$ than they have into I and hence less opportunity of achieving a degree of $0.9\alpha d$. Again, this is in agreement with our goal of showing that P' -core is contained in P-core.
3. The notion of P-core refers to the graph G , whereas the notion of P' -core refers to the graph G' . This difference is irrelevant. The two graphs completely agree on all edges between C and $I \setminus I(T)$. The procedure for constructing P' -core looks only at those edges and no other edges. It would produce exactly the same P' -core even if it is run on the graph G instead of G' .

Having understood the differences between the constructions of P-core and P'-core, it is easy to verify by inspection that every vertex that is removed from P-core will be removed from P'-core as well, and hence P'-core is contained in P-core, as desired. $\square$

Proof of Lemma 3.19, part 2. The proof is similar to the proof of Lemma 3.10 (see also the remark after Lemma 3.10). The difference is that in the initialization of CR0' we remove the vertices of $I(T)$ and ignore the edges of C connected to these vertices. The fact that $|I(T)| < 2 \log n$ together with the fact that the number of vertices of C affected by the removal of $I(T)$ is bounded by the sum of degrees in $I(T)$ (this number is small because the probability of G having a vertex of degree above $d^2 \log n$ is $O(n^{-d})$) imply that the total number of vertices removed by the initializations of CR0' and CR0 differ by $O(d^2 \log n)^2 = o(n/d^{20})$. The rest of the proof of Lemma 3.10 applies without change. $\square$

4. Proofs of the technical lemmas.

4.1. Expansion properties and degrees deviation.

Proof of Lemma 3.3. Let $c > 1$ and $k \geq 3$ (k is an integer) satisfy the following three inequalities:

- (i) $c < d$,
- (ii) $k < n/e$,
- (iii) $\left(\frac{d}{c}\right)^c \left(\frac{ke}{n}\right)^{c-1} e^2 < 1/2$.

The probability that there is a set U of cardinality at most k with $c|U|$ internal edges is at most

$$\begin{aligned}
 \sum_{i=3}^k \binom{n}{i} \binom{\binom{i}{2}}{\lceil ic \rceil} \left(\frac{d}{n}\right)^{\lceil ic \rceil} &\leq \sum_{i=3}^k \left(\frac{ne}{i}\right)^i \left(\frac{i^2 e}{2ic}\right)^{\lceil ic \rceil} \left(\frac{d}{n}\right)^{\lceil ic \rceil} \\
 (3) \quad &\leq \sum_{i=3}^k \left(\frac{d}{c}\right)^{\lceil ic \rceil} \left(\frac{ie}{n}\right)^{\lceil ic \rceil - i} e^{2i} \stackrel{(i), (ii)}{\leq} \sum_{i=3}^k \left(\frac{d}{c}\right)^{ic+1} \left(\frac{ie}{n}\right)^{ic-i} e^{2i} \\
 &= \frac{d}{c} \sum_{i=3}^k \left[\left(\frac{d}{c}\right)^c \left(\frac{ie}{n}\right)^{c-1} e^2 \right]^i \stackrel{(iii)}{\leq} \frac{2d}{c} \left(\left(\frac{d}{c}\right)^c \left(\frac{3e}{n}\right)^{c-1} e^2 \right)^3.
 \end{aligned}$$

Proof of part 1. Set $c := 4/3$, $k := 2n/d^5$. For $d > d_0$ conditions (i)–(iii) hold. The last term in (3) is at most $\frac{6e^7 d^5}{n}$.

Proof of part 2. Set $c := \alpha d/14$, $k := \alpha n/40$. For $d > d_0$ conditions (i)–(iii) hold. The last term in (3) is

$$\frac{2d}{c} \left(\left(\frac{d}{c}\right)^c \left(\frac{3e}{n}\right)^{c-1} e^2 \right)^3 \leq \frac{(3ed)^{3c+3}}{n^{3c-3}} = o(n^{-\sqrt{d}}),$$

where in the last inequality we used $d < n^{1/40}$ and $c = \alpha d/20 \geq c_0 \sqrt{d}/20 \gg \sqrt{d}$ (for large enough c_0).

Proof of part 3. We first show that w.h.p. there is no set $U \subset V$ of size $< \frac{10n \log d}{d}$ containing $50(\log d)|U|$ edges. Set $c := 50 \log d$ and $k := \frac{10n \log d}{d}$. For $d > d_0$ conditions (i)–(iii) hold, and the last term in (3) is $o(1)$. It thus follows that w.h.p. there is no set U of cardinality $\leq \frac{10n \log d}{d}$ that contains at least $50 \log d |U|$ edges.

By contradiction, assume that there is a bad set C' for which $|\Gamma(C') \cap I| \leq |C'|$ and $n/2d^5 \leq |C'| \leq \frac{2n \log d}{d}$. By Lemma 3.5, part 1, at least $|C'| - n/d^{20} > \frac{9}{10}|C'|$ vertices of C' have at least $\frac{\alpha d}{2}$ edges to I . It follows that $C' \cup (\Gamma(C') \cap I)$ has at least

$\frac{\alpha d}{5}|C' \cup (\Gamma(C') \cap I)| > \sqrt{d}|C' \cup (\Gamma(C') \cap I)|$ internal edges and its cardinality is at most $2|C'| < \frac{4n \log d}{d} < \frac{10n \log d}{d}$. By the first part of the proof w.h.p. such a dense set does not exist. $\square$

We now prove Lemma 3.5.

Proof of part 1. The degrees into I are independent random variables. Set $\delta = 1/d^{21}$. For a fixed set of size δn the expected sum of degrees is $\mu = \delta n \alpha d$. A bad set has only $0.9\delta n \alpha d$ edges to I . The probability for a bad set of size δn is bounded by

$$\begin{aligned} \binom{n}{\delta n} e^{-\frac{1}{2}(0.1)^2 \mu} &\leq e^{-\delta n (\alpha d / 200 - \log(e/\delta))} \leq e^{-\delta n (\sqrt{c_0 d} / 200 - 21 \log d - 1)} \\ &\leq e^{-\delta n} < e^{-n/d^{21}} < e^{-n^{0.4}}. \end{aligned}$$

In the last inequality we used $d < n^{1/40}$. $\square$

Proof of part 2. The proof of this lemma is very similar to the proof of (26), and details are omitted. $\square$

4.2. Spectral approximation (proof of Lemma 3.7). Recall that eigenvectors of the adjacency matrix of the graph G are of dimension n , equal to the number of vertices of G . Every coordinate of an eigenvector can be naturally associated with a vertex in the graph.

Let V' be the set of vertices of G with degree $< 5d$, and set $n' \triangleq |V'|$. Note that n' is also the dimension of A' —the adjacency matrix of $G[V']$. Let $I' = V' \cap I$ and $C' = V' \cap C$, and set $\alpha' \triangleq \frac{|I'|}{|V'|}$.

Denote by $\bar{A}'$ the $n' \times n'$ matrix such that $\bar{A}'_{i,j} = 0$ for any $\{i, j\} \subset I'$ and $\bar{A}'_{i,j} = p = d/n$ for the other entries. We will use the fact that $\bar{A}'$ (which is the “expectation” of A' if we ignore the diagonal) is almost surely a good spectral approximation of A' (i.e., the spectral norm of $A' - \bar{A}'$ is small). The rank of $\bar{A}'$ is 2, and it has two nonzero eigenvalues. Each of the two nonzero eigenvectors which we denote by $\bar{v}_1, \bar{v}_{n'}$ is constant on I' and constant on C' (this follows from symmetry). Given that each one of $\bar{v}_1, \bar{v}_{n'}$ has only two values, we need to find $\bar{\beta}, \bar{\lambda}$ which satisfy

$$\begin{array}{c} \overbrace{\begin{array}{|ccc|ccc|} \hline 0 & . & . & 0 & p & . & p & p \\ . & . & & & & & & \\ . & & . & & & & & \\ 0 & . & . & 0 & & & & \\ \hline p & & & & p & & & \\ . & & & & & . & & \\ p & & & & & & p & \\ p & & & & & & & p \\ \hline \end{array}}^{I'} \end{array} \begin{bmatrix} 1 \\ . \\ . \\ . \\ 1 \\ \bar{\beta} \\ . \\ . \\ \bar{\beta} \end{bmatrix} = \begin{bmatrix} (1 - \alpha')n'p\bar{\beta} \\ . \\ . \\ . \\ \alpha'n'p + \bar{\beta}(1 - \alpha')n'p \\ . \\ . \\ . \end{bmatrix} = \bar{\lambda} \begin{bmatrix} 1 \\ . \\ . \\ . \\ 1 \\ \bar{\beta} \\ . \\ . \\ \bar{\beta} \end{bmatrix},$$

or equivalently,

$$(4) \quad (1 - \alpha')n'\bar{\beta}p = \bar{\lambda},$$

$$(5) \quad \alpha'n'p + \bar{\beta}(1 - \alpha')n'p = \bar{\lambda}\bar{\beta},$$

and a simple calculation gives a quadratic equation in $\bar{\beta}$ whose solutions are

$$(6) \quad \bar{\beta}_{1,2} = \frac{1}{2} \left(1 \pm \sqrt{1 + \frac{4\alpha'}{1-\alpha'}} \right).$$

By substituting $\bar{\beta}$ at (4) we derive

$$(7) \quad \begin{aligned} \bar{\lambda}_1 &= (1 - \alpha')n' \bar{\beta}_1 p, \\ \bar{\lambda}_{n'} &= (1 - \alpha')n' \bar{\beta}_2 p, \\ \bar{v}_1 &= (\underbrace{1, 1, \dots, 1}_{\alpha' n'}, \underbrace{\bar{\beta}_1, \bar{\beta}_1, \dots, \bar{\beta}_1}_{(1-\alpha')n'}), \\ \bar{v}_{n'} &= (\underbrace{1, 1, \dots, 1}_{\alpha' n'}, \underbrace{\bar{\beta}_2, \bar{\beta}_2, \bar{\beta}_2, \dots, \bar{\beta}_2}_{(1-\alpha')n'}). \end{aligned}$$

Define $\beta_{1,2} := \frac{1}{2}(1 \pm \sqrt{1 + \frac{4\alpha}{1-\alpha}})$.

LEMMA 4.1. (i) For every $x \geq 0$ it holds that $|1 - \sqrt{1+x}| \leq \frac{x}{2}$.

(ii) For $0 \leq x \leq 3$ it holds that $1 - \sqrt{1+x} \leq -\frac{x}{3}$.

Proof of part (i). Note that $1 - \sqrt{1+x} \leq 0$ for $x \geq 0$, and thus it is enough to show that $1 - \sqrt{1+x} \geq -\frac{x}{2}$:

$$-\frac{x}{2} \leq 1 - \sqrt{1+x} \iff \sqrt{1+x} \leq 1 + \frac{x}{2} \iff 1+x \leq 1+x + \frac{x^2}{4}. \quad \square$$

Proof of part (ii).

$$1 - \sqrt{1+x} \leq -\frac{x}{3} \iff 1 + \frac{x}{3} \leq \sqrt{1+x}$$

$$\iff 1 + \frac{2}{3}x + \frac{x^2}{9} \leq 1+x \iff \frac{x^2}{9} \leq \frac{x}{3} \iff \frac{x}{3} \leq 1. \quad \square$$

In the reminder of this section we will use the following facts:

$$(8) \quad \forall x \perp \bar{v}_1, \bar{v}_{n'} \text{ it holds that } \sum_{i \in C'} x_i = 0, \quad \sum_{i \in I'} x_i = 0,$$

$$(9) \quad \alpha' = (1 \pm e^{-\Omega(d)})\alpha, \quad n' \geq (1 - e^{-\Omega(d)})n,$$

$$(10) \quad \sqrt{\frac{c_0}{d}} \leq \alpha \leq 1/3, \quad d < n^{1/40},$$

$$(11) \quad \|\bar{v}_{n'}\|_2^2 \geq \alpha' n' \geq (1 - e^{-\Omega(d)})\alpha n, \quad \|\bar{v}_1\|_2^2 \geq n' \geq (1 - e^{-\Omega(d)})n,$$

$$(12) \quad \beta_2 = (1 \pm e^{-\Omega(d)})\bar{\beta}_2, \quad \beta_1 = (1 \pm e^{-\Omega(d)})\bar{\beta}_1,$$

$$(13) \quad |\bar{\beta}_2| \leq \frac{\alpha'}{1-\alpha'} \text{ (see the definition of } \bar{\beta}_2 \text{ at (6) and Lemma 4.1, part (i))},$$

$$(14) \quad |\bar{\beta}_2 \sqrt{1-\alpha'}| \leq 1, \quad |\beta_2 \sqrt{1-\alpha}| \leq 1.$$

Proof: $\beta_2 \leq 0$, and thus it is enough to show that $\beta_2 \sqrt{1-\alpha} \geq -1$:

$$\beta_2 \sqrt{1-\alpha} = \frac{1}{2}(\sqrt{1-\alpha} - \sqrt{1-\alpha+4\alpha}) \geq -1$$

$$\iff 2 + \sqrt{1-\alpha} \geq \sqrt{1+3\alpha} \iff 4 + 4\sqrt{1-\alpha} + 1 - \alpha \geq 1 + 3\alpha$$

$$\iff 4 + 4\sqrt{1-\alpha} \geq 4\alpha,$$

$$(15) \quad (1 - \alpha')\bar{\beta}_2 \leq -0.66\sqrt{\frac{c_0}{d}}.$$

$$\begin{aligned} \text{Proof: } (1 - \alpha)\beta_2 &= (1 - \alpha)\frac{1}{2}\left(1 - \sqrt{1 + \frac{4\alpha}{1 - \alpha}}\right) \\ &\stackrel{(10)}{\leq} \frac{1}{3}\left(1 - \sqrt{1 + \frac{4\alpha}{1 - \alpha}}\right) \stackrel{(4.1) \text{ part (ii), (10)}}{\leq} -\frac{1}{3}\frac{4\alpha}{3(1 - \alpha)} \stackrel{(10)}{\leq} -\frac{2}{3}\sqrt{\frac{c_0}{d}}. \end{aligned}$$

(15) follows from the last inequality and (9) and (12).

Additional notation. We will use $v_1, v_2, \dots, v_{n'}$ to denote the unit eigenvectors of A' corresponding to the eigenvalues $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{n'}$. The vector of all ones is denoted by $\bar{1}$.

LEMMA 4.2. *Let $\bar{v}_{n'}$ be the eigenvector corresponding to the most negative eigenvalue of A' (as defined at (7)). Let $v_{n'}$ be the eigenvector corresponding to the most negative eigenvalue of A' normalized such that $\|v_{n'}\| = \|\bar{v}_{n'}\|$ and also $\langle v_{n'}, \bar{v}_{n'} \rangle \geq 0$. W.h.p. it holds that $\|\bar{v}_{n'} - v_{n'}\|^2 < \frac{1}{800}\|\bar{v}_{n'}\|^2$.*

We first prove Lemma 3.7 and only then give the proof of Lemma 4.2.

Proof of Lemma 3.7. The vector $\bar{v}_{n'}$ equals

$$\underbrace{(1, 1, \dots, 1)}_{\alpha'n'} \underbrace{(\bar{\beta}_2, \bar{\beta}_2, \dots, \bar{\beta}_2)}_{(1-\alpha')n'}$$

($\bar{\beta}_2$ is defined at (6)). In this proof we will assume that the eigenvector $v_{n'}$ used in step 1 of *FindIS* is normalized so that $\|v_{n'}\| = \|\bar{v}_{n'}\|$ and also that $\langle v_{n'}, \bar{v}_{n'} \rangle \geq 0$. We may use this assumption since the outcome of step 1 does not change if we multiply $v_{n'}$ (used by step 1 of the algorithm) by any nonzero constant.

Denote by L the $\alpha'n'$ indices of $v_{n'}$ which correspond to the largest values in $v_{n'}$. Similarly, denote by $\bar{L}$ the $\alpha'n'$ indices of $\bar{v}_{n'}$ which correspond to the largest values in $\bar{v}_{n'}$ (hence $\bar{L} = I'$). For every vertex $i' \in L \cap C$ we match a unique vertex $i \in \bar{L} \setminus L$. Note that $v_{n'}(i') \geq v_{n'}(i)$, $\bar{v}_{n'}(i) - \bar{v}_{n'}(i') = 1 - \bar{\beta}_2$. Summing the last two inequalities gives

$$(16) \quad (\bar{v}_{n'}(i) - v_{n'}(i)) + (v_{n'}(i') - \bar{v}_{n'}(i')) \geq 1 - \bar{\beta}_2 \geq 1$$

and thus

$$(17) \quad (\bar{v}_{n'}(i) - v_{n'}(i))^2 + (v_{n'}(i') - \bar{v}_{n'}(i'))^2 \geq \frac{1}{2}.$$

By Lemma 4.2 w.h.p. it holds that $\|\bar{v}_{n'} - v_{n'}\|^2 \leq \frac{1}{800}\|\bar{v}_{n'}\|^2$. It thus follows that

$$(18) \quad \frac{1}{2}|L \setminus \bar{L}| \leq \frac{1}{800}\|\bar{v}_{n'}\|^2.$$

Option 1. By setting I_1 to contain the indices of the largest αn entries in $v_{n'}$ we get

$$\begin{aligned} |I_1 \setminus I| &\leq |L \setminus \bar{L}| + |\alpha n - \alpha'n'| \leq \frac{1}{400}\|\bar{v}_{n'}\|^2 + |\alpha n - \alpha'n'| \\ (19) \quad &\stackrel{(9)}{\leq} \frac{\alpha'n' + \bar{\beta}_2^2(1 - \alpha')n'}{400} + e^{-\Omega(d)}n \stackrel{(13)}{\leq} \frac{\alpha'n\left(1 + \frac{\alpha'}{1 - \alpha'}\right)}{400} + e^{-\Omega(d)}n \\ &\stackrel{(10)}{\leq} \frac{1.5\alpha'n'}{400} + e^{-\Omega(d)}n \stackrel{(9)}{\leq} \frac{\alpha n}{200}. \end{aligned}$$

In this case the maximum matching in $G[I_1]$ contains at most $2|C' \cap I_1| \leq \frac{\alpha n}{100}$ vertices.

Remark. Note that since $|I| = |I_1|$, (19) implies that $|I \setminus I_1| \leq \frac{\alpha n}{200}$, or in other words: the intersection of I with the indices of the $(1-\alpha)n$ smallest vertices is bounded by $\frac{\alpha n}{200}$.

Option 2. By setting I_1 to contain the indices of the smallest αn entries in $v_{n'}$, we get $|I_1 \cap I| \leq \frac{\alpha n}{200}$. (Observe that $\alpha < 1/3$ and $n' \simeq n$ imply that the largest αn entries are disjoint from the smallest αn entries, and then use the last remark.) The maximum independent set in $G[C]$ is bounded by $\frac{2 \log dn}{d}$ (Lemma 3.6). It follows that the maximum independent set in $G[I_1]$ contains at most $\frac{\alpha n}{200} + \frac{2 \log dn}{d}$ vertices. Since the complement of a maximal matching is an independent set, it follows that every maximal matching in $G[I_1]$ has at least $\frac{199\alpha n}{200} - \frac{2 \log dn}{d}$ vertices.

Since step 1 of the algorithm takes the option with the smallest maximum matching (between 1 and 2), it chooses Option 1. It then follows that

$$(20) \quad |I_1 \triangle I| = 2|I_1 \setminus I| \leq \frac{\alpha n}{100}. \quad \square$$

Proof of Lemma 4.2. For simplicity, we normalize the vectors so that $\|v_{n'}\| = \|\bar{v}_{n'}\| = 1$. We need to prove that $\|\bar{v}_{n'} - v_{n'}\|^2 < \frac{1}{800}$.

Since the vectors $v_1, v_2, \dots, v_{n'}$ are orthogonal, the vector $\bar{v}_{n'}$ can be written as $\sum_{i=1}^{n'} c_i v_i$ such that $\sum_{i=1}^{n'} c_i^2 = 1$. We will use the following properties:

- (i) $\|(A' - \bar{\lambda}_{n'} I) \bar{v}_{n'}\| \leq 2\sqrt{d}$ (see Lemma 4.3, part (ii));
- (ii) all of the eigenvalues of A' except $\lambda_1, \lambda_{n'}$ are bounded by $2c\sqrt{d}$ in absolute value (Lemma 4.4), where c is some absolute constant independent of α and d ;
- (iii) $\bar{\lambda}_{n'} \leq -0.65\sqrt{c_0 d}$:

$$\text{by (7) second line } \bar{\lambda}_{n'} = (1 - \alpha')n' \bar{\beta}_2 p$$

$$\stackrel{(15)}{\leq} -0.66\sqrt{\frac{c_0}{d}} n' p \stackrel{(9)}{\leq} -0.65\sqrt{c_0 d};$$

(iv) $\lambda_1 \geq 0$ (because the trace of A' is 0);

(v) $c_{n'} = \langle v_{n'}, \bar{v}_{n'} \rangle \geq 0$:

$$(21) \quad \begin{aligned} 4d &\stackrel{(i)}{\geq} \|(A' - \bar{\lambda}_{n'} I) \bar{v}_{n'}\|^2 = \left\| (A' - \bar{\lambda}_{n'} I) \left(\sum_{i=1}^{n'} c_i v_i \right) \right\|^2 \\ &= \sum_{i=1}^{n'} (c_i)^2 (\lambda_i - \bar{\lambda}_{n'})^2 \geq \sum_{i=1}^{n'-1} (c_i)^2 (\lambda_i - \bar{\lambda}_{n'})^2. \end{aligned}$$

Facts (iii) and (iv) imply that $\lambda_1 - \bar{\lambda}_{n'} \geq 0.65\sqrt{c_0 d}$. Fact (ii) states that $|\lambda_i| \leq 2c\sqrt{d}$ ($1 < i < n'$) for some constant c independent of α, d . Thus by setting $c_0 > (4c)^2$ we have $\lambda_i - \bar{\lambda}_{n'} > 0.65\sqrt{c_0 d} - 2c\sqrt{d} > \sqrt{c_0 d}/5$. By combining the last inequality with (21) we derive

$$(22) \quad \sum_{i=1}^{n'-1} c_i^2 \leq \frac{4}{c_0/25} < \frac{100}{c_0}.$$

By using

$$(23) \quad \|\bar{v}_{n'} - v_{n'}\|^2 = \sum_{i=1}^{n'-1} c_i^2 + (1 - c_{n'})^2, \quad \sum_{i=1}^{n'} c_i^2 = 1, \quad c_{n'} \geq 0,$$

we derive that for large enough c_0 it holds that $\|\bar{v}_{n'} - v_{n'}\|^2 < \frac{1}{800}$ as needed. $\square$

LEMMA 4.3. *Let $\bar{v}_1$ and $\bar{v}_{n'}$ be the first and last eigenvectors, respectively, of the matrix $\bar{A}'$ with corresponding eigenvalues $\bar{\lambda}_1$ and $\bar{\lambda}_{n'}$. The following inequalities hold w.h.p.:*

- (i) $\|(A' - \bar{\lambda}_1 I)\bar{v}_1\| \leq 2\sqrt{d}\|\bar{v}_1\|$,
- (ii) $\|(A' - \bar{\lambda}_{n'} I)\bar{v}_{n'}\| \leq 2\sqrt{d}\|\bar{v}_{n'}\|$,
- (iii) for all $x \perp \bar{v}_1, \bar{v}_{n'}$ $\|A'x\| \leq c\sqrt{d}\|x\|$ (where $c \geq 2$ is a universal constant independent of d, α).

Proof of Lemma 4.3, part (ii). By (11), $\|\bar{v}_{n'}\| \geq \sqrt{\alpha n}(1 - e^{-\Omega(d)})$. We will prove that $\|(A' - \bar{\lambda}_{n'} I)\bar{v}_{n'}\| < 2\sqrt{d}\|\bar{v}_{n'}\|$. We use (see (7))

$$\bar{\lambda}_{n'} = (1 - \alpha')\beta_2 n' p = (1 - \alpha)\beta d \pm e^{-\Omega(d)}, \quad \bar{v}_{n'} = \underbrace{(1, 1, \dots, 1)}_{\alpha' n'} \underbrace{(\bar{\beta}_2, \bar{\beta}_2, \dots)}_{(1 - \alpha') n'},$$

$$\begin{aligned} \|(A' - \bar{\lambda}_{n'} I)\bar{v}_{n'}\| &= \left\| (A' - \bar{\lambda}_{n'} I) \begin{bmatrix} 1 \\ \cdot \\ \cdot \\ \bar{\beta}_2 \\ \cdot \\ \cdot \end{bmatrix} \right\| = \left\| \begin{bmatrix} \bar{\beta}_2 \deg(v)_{C'} - \bar{\lambda}_{n'} \\ \cdot \\ \cdot \\ \deg(v)_{I'} + \bar{\beta}_2 \deg(v)_{C'} - \bar{\lambda}_{n'} \bar{\beta}_2 \\ \cdot \\ \cdot \end{bmatrix} \right\| \\ &\stackrel{\beta_2 = \bar{\beta}_2(1 \pm e^{-\Omega(d)})}{\leq} \left\| \begin{bmatrix} \beta_2(\deg(v)_{C'} - (1 - \alpha)d) \\ \cdot \\ \cdot \\ \deg(v)_{I'} + \beta_2 \deg(v)_{C'} - (1 - \alpha)\beta_2^2 d \\ \cdot \\ \cdot \end{bmatrix} \right\| + \underbrace{\left\| \begin{bmatrix} e^{-\Omega(d)} \\ \cdot \\ \cdot \\ e^{-\Omega(d)} \\ \cdot \\ \cdot \end{bmatrix} \right\|}_{\leq e^{-\Omega(d)}\sqrt{n}}. \end{aligned}$$

It remains to upper bound the norm of the left vector, and we do that by upper bounding its squared norm with $2.3d\|\bar{v}_{n'}\|^2$. We will estimate the random variable:

$$(24) \quad \beta_2^2 \sum_{v \in I'} (\deg(v)_{C'} - (1 - \alpha)d)^2 + \sum_{v \in C'} (\deg(v)_{I'} + \beta_2 \deg(v)_{C'} - (1 - \alpha)\beta_2^2 d)^2.$$

Note that the difference between the sum in (24) and

$$(25) \quad \underbrace{\beta_2^2 \sum_{v \in I} (\deg(v)_C - (1 - \alpha)d)^2}_{S_1} + \underbrace{\sum_{v \in C} (\deg(v)_I + \beta_2 \deg(v)_C - (1 - \alpha)\beta_2^2 d)^2}_{S_2}$$

can be classified into two types:

- (i) vertices of $V \setminus V'$ that add summands to (25) which do not exist in (24);
- (ii) vertices of $V \cap V'$ for which the degrees $\deg(v)_C, \deg(v)_{C'}$ or $\deg(v)_I, \deg(v)_{I'}$ are different.

It is more convenient to upper bound (25) rather than (24). The differences of type (i) can only make (25) bigger than (24). The difference induced by type (ii) is $O(e^{-\Omega(d)}nd^3)$, and the explanation is as follows. For any fixed vertex v of degree $< 5d$ in G , its summand in S_1 (or in S_2) is bounded by $O(d^3)$ (because $\beta_2 < 5\sqrt{d}$). The number of vertices in V' which have an edge to a vertex in $V \setminus V'$ is bounded by $e^{-\Omega(d)}n$ (since w.h.p. the total number of edges that touch $|V \setminus V'|$ is at most $e^{-\Omega(d)}n$).

We will now prove the following inequalities:

$$(26) \quad S_1 \leq 1.1\alpha n(1-\alpha)d, \quad S_2 \leq 1.1(1-\alpha)n(\alpha d + \beta_2^2(1-\alpha)).$$

We start with S_2 . The graph G is taken from $G_{n,p,\alpha}$. We denote by $e(G)$ the number of edges in G . Let L be the set of all edges which do not have both end points in I . Denote that $l := |L| = \binom{n}{2} - \binom{\alpha n}{2}$. The expectation of $e(G)$ is $\mu := pl$ (where $\mu \geq 0.4dn$ since $\alpha \leq \frac{1}{3}$). By Chernoff's inequality it holds that

$$(27) \quad \Pr_{G_{n,p,\alpha}} [e(G) \in (1 \pm n^{-0.1})\mu] \geq 1 - o(1)$$

(we used here $\mu \geq 0.4dn$). Denote by $G_{n,m,\alpha}$ the uniform distribution over all graphs with m edges such that none of the edges is inside I . For a graph G taken from $G_{n,p,\alpha}$, given that $e(G) = m$, the graph G has the distribution of $G_{n,m,\alpha}$. Thus, it is sufficient to show that for any $m \in (1 \pm n^{-0.1})\mu$ it holds that

$$(28) \quad \Pr_{G_{n,m,\alpha}} [S_2 > 1.1(1-\alpha)n(\alpha d + \beta_2^2(1-\alpha))] = o(1).$$

Fix some $m \in (1 \pm n^{-0.1})\mu$. Technically, it is more convenient to prove a concentration result in a product measure. Denote by $C_{n,m,\alpha}$ the distribution induced by taking a uniformly random m -tuple from L^m . Let G be taken from $C_{n,m,\alpha}$. Note that G is actually a multigraph. Given that G is simple (i.e., no parallel edges), G is distributed as $G_{n,m,\alpha}$. Note that

$$(29) \quad \Pr_{C_{n,m,\alpha}} [G \text{ is simple}] \geq \left(1 - \frac{m}{l}\right)^m \stackrel{(i)}{\geq} e^{-\frac{2m^2}{l}} \geq e^{-(1+o(1))\frac{1}{2}p^2l} \\ \stackrel{l \leq 0.5n^2}{\geq} e^{-0.2d^2} \stackrel{d < n^{1/40}}{\geq} e^{-0.2n^{0.05}}$$

(in inequality (i) we used $1 - x \geq e^{-2x}$, which holds for $x \in [0, 0.5]$).

We will now prove that

$$(30) \quad \Pr_{C_{n,m,\alpha}} [S_2 > 1.1(1-\alpha)n(\alpha d + \beta_2^2(1-\alpha))] \leq 2e^{-n^{0.1}}.$$

We first calculate the expectation of S_2 . Fix a vertex $v \in C$. Denote that $X := \deg(v)_I + \beta_2 \deg(v)_C - (1-\alpha)\beta_2^2 d$.

$$\begin{aligned} \mathbb{E}[X] &= m \frac{\alpha n + \beta_2((1-\alpha)n-1)}{l} - (1-\alpha)\beta_2^2 d \\ &\stackrel{(9)}{=} (1 \pm n^{-0.1}) p \left[(1 \pm e^{-\Omega(d)})(\alpha' n' + \bar{\beta}_2(1-\alpha')n') \right] - (1 \pm e^{-\Omega(d)})(1-\alpha')d\bar{\beta}_2^2 \\ (31) \quad &\stackrel{(14)}{=} (\alpha' n' p + \bar{\beta}_2(1-\alpha')n' p - \underbrace{(1-\alpha')n'\bar{\beta}_2 p \bar{\beta}_2}_{\bar{\lambda}_{n'}}) \pm 4(n^{-0.1} + e^{-\Omega(d)})d \pm e^{-\Omega(d)}d \\ (32) \quad &\stackrel{(5)}{=} \pm 5d(n^{-0.1} + e^{-\Omega(d)}) \stackrel{d < n^{1/40}}{=} \pm(o(1) + e^{-\Omega(d)}). \end{aligned}$$

By using (10) a straightforward calculation (see Lemma 4.5 for details) shows that for any $v \in C$ it holds that

$$(33) \quad \text{VAR}[X] = (1 + o(1))(\alpha d + \beta_2^2(1 - \alpha)d).$$

Thus for large enough d

$$(34) \quad \mathbb{E}[X^2] = \text{VAR}[X] + (\mathbb{E}[X])^2 = (1 \pm 0.01)(\alpha d + \beta_2^2(1 - \alpha)d).$$

By summing over all C we derive

$$(35) \quad \mathbb{E}[S_2] = (1 \pm 0.01)(1 - \alpha)n(\alpha d + \beta_2^2(1 - \alpha)d).$$

We will now show that w.h.p. S_2 is tightly concentrated around its expectation. Recall that G is taken from $C_{n,m,\alpha}$ for some fixed $m \in (1 \pm n^{-0.1})\mu$. By Chernoff's inequality it holds that

$$(36) \quad \Pr[\text{all vertices degrees in } G \text{ are bounded by } dn^{0.1}] \geq 1 - e^{-n^{0.1}}$$

(the expected degree of a vertex in C is $\frac{n}{l}m = \frac{n}{l}(1 \pm n^{-0.1})pl = d(1 \pm n^{-0.1})$). Thus, with probability of at least $1 - e^{-n^{0.1}}$ every summand of S_2 is bounded by $3d^2n^{0.2}$ (we use here $|\beta_2| \leq 1$, (14)). Consider the function

$$(37) \quad f(v) := \min \{ (\deg(v)_I + \beta_2 \deg(v)_C - (1 - \alpha)\beta_2^2 d)^2, 3d^2n^{0.2} \}.$$

Let $f(G) := \sum_{v \in C} f(v)$. Adding/removing a single edge from G changes $f(G)$ by at most $6d^2n^{0.2}$ since all of the summands of $f(G)$ have values in $[0, 3d^2n^{0.2}]$. Since G is taken from $C_{n,m,\alpha}$, which is a product measure (L^m), we can use Azuma's inequality

$$(38) \quad \Pr[f(G) - \mathbb{E}[f(G)] > \lambda] < 2e^{-\lambda^2/2m(6d^2n^{0.2})^2}.$$

Since for any G it holds that $f(G) \leq S_2$ we derive

$$(39) \quad \Pr[f(G) - \mathbb{E}[S_2] > \lambda] < 2e^{-\lambda^2/2m(2d^4n^{0.2})^2},$$

and by setting $\lambda = 0.01\mathbb{E}[S_2]$ and using $m \in (1 \pm n^{-0.1})\mu$, $\mu = pl \leq dn$, and $\mathbb{E}[S_2] \geq \frac{n}{4}$ we derive

$$(40) \quad \Pr[f(G) \leq 1.01\mathbb{E}[S_2]] \geq 1 - 2e^{-\Omega(n^2/dnd^4n^{0.4})} \stackrel{d < n^{1/40}}{\geq} 1 - 2e^{-\Omega(n^{0.475})}.$$

Note that if all of the degrees in G are bounded by $dn^{0.1}$, then $f(G) = S_2$. Inequalities (36) and (40) imply that

$$(41) \quad \Pr_{C_{n,m,\alpha}} [S_2 > 1.01\mathbb{E}[S_2]] \leq 2e^{-n^{0.1}}.$$

By combining (29) with (41) we derive

$$(42) \quad \Pr_{C_{n,m,\alpha}} [S_2 \geq 1.01\mathbb{E}[S_2] \mid G \text{ is simple}] \leq \frac{2e^{-n^{0.1}}}{\Pr[G \text{ is simple}]} \leq \frac{2e^{-n^{0.1}}}{e^{-0.2n^{0.05}}} = o(1),$$

which together with (35) proves (28) and thus also the second part of (26). The proof of the first part of (26) is similar, so we omit the details. By having (26) proved we derive

$$(43) \quad \beta_2^2 S_1 + S_2 \stackrel{(26)}{\leq} \beta_2^2 1.1\alpha n(1-\alpha)d + 1.1(1-\alpha)n(\alpha d + \beta_2^2(1-\alpha))$$

$$(44) \quad \stackrel{(14)}{\leq} 1.1\alpha dn + 1.1(1-\alpha)n(\alpha d + \beta_2^2(1-\alpha)d)$$

$$(45) \quad \leq 2.2\alpha dn + 1.1(1-\alpha)n\beta_2^2 d \leq 2.2d(\alpha n + (1-\alpha)n\beta_2^2)$$

$$(46) \quad \leq 2.2d(1 + e^{-\Omega(d)})(\alpha' n' + (1-\alpha')n'\beta_2^2) \leq 2.3d\|\bar{v}_{n'}\|_2^2. \quad \square$$

Proof of Lemma 4.3, part (i). By (11), $\|\bar{v}_1\| \geq \sqrt{n}(1 - e^{-\Omega(d)})$. We will prove that $\|(A' - \bar{\lambda}_1 I)\bar{v}_1\| < 2\sqrt{d}\|\bar{v}_1\|$. We use (from (7))

$$\bar{\lambda}_1 = (1 - \alpha')\bar{\beta}_1 n' p = (1 - \alpha)\beta_1 d \pm e^{-\Omega(d)}, \quad \bar{v}_1 = (\underbrace{1, 1, \dots, 1}_{\alpha' n'}, \underbrace{\bar{\beta}_1, \bar{\beta}_1, \dots}_{(1-\alpha')n'}),$$

$$\begin{aligned} \|(A' - \bar{\lambda}_1 I)\bar{v}_1\| &= \left\| (A' - \bar{\lambda}_1 I) \begin{bmatrix} 1 \\ \vdots \\ \bar{\beta}_1 \\ \vdots \end{bmatrix} \right\| = \left\| \begin{bmatrix} \bar{\beta}_1 \deg(v)_{C'} - \bar{\lambda}_1 \\ \vdots \\ \deg(v)_{I'} + \bar{\beta}_1 \deg(v)_{C'} - \bar{\lambda}_1 \bar{\beta}_1 \\ \vdots \end{bmatrix} \right\| \\ &\stackrel{\beta_1 = \bar{\beta}_1(1 \pm e^{-\Omega(d)})}{\leq} \left\| \begin{bmatrix} \beta_1 (\deg(v)_{C'} - (1-\alpha)d) \\ \vdots \\ \deg(v)_{I'} + \beta_1 \deg(v)_{C'} - (1-\alpha)\beta_1^2 d \\ \vdots \end{bmatrix} \right\| + \underbrace{\left\| \begin{bmatrix} e^{-\Omega(d)} \\ \vdots \\ e^{-\Omega(d)} \\ \vdots \end{bmatrix} \right\|}_{\leq e^{-\Omega(d)}\sqrt{n}}. \end{aligned}$$

It remains to upper bound the norm of the left vector, and we do that by upper bounding its squared norm with $2.3d\|\bar{v}_1\|_2^2$. The squared norm of the left vector is

$$(47) \quad \beta_1^2 \sum_{v \in I'} (\deg(v)_{C'} - (1-\alpha)d)^2 + \sum_{v \in C'} (\deg(v)_{I'} + \beta_1 \deg(v)_{C'} - (1-\alpha)\beta_1^2 d)^2.$$

An argument similar to the one used in the proof of part (ii) shows that w.h.p. the last term is bounded by $2.3\|\bar{v}_1\|^2$. $\square$

Proof of Lemma 4.3, part (iii). If $x \perp \bar{v}_1$, $x \perp \bar{v}_{n'}$, then $\sum_{i \in I'} x_i = 0$, $\sum_{i \in C'} x_i = 0$ (by (8)). Thus, for such x the following holds:

$$x^t A' x = x^t \left(A' + \overbrace{\begin{bmatrix} p & \cdot & \cdot & p & 0 & \cdot & 0 & 0 \\ \cdot & \cdot & & & & & & \\ \cdot & & \cdot & & & & & \\ p & \cdot & \cdot & p & & & & \\ 0 & & & & 0 & & & \\ \cdot & & & & & \cdot & & \\ 0 & & & & & & 0 & \\ 0 & & & & & & & 0 \end{bmatrix}}^{I'} \right) x = x^t B' x,$$

where B' is derived from A by removing vertices of degree $> 5d$ and adding the value $p = \frac{d}{n}$ in entries of the submatrix which corresponds to $I' \subset I$. This matrix B' is very similar to the matrices analyzed in [9]. The difference is that in [9] the whole matrix is random, whereas, in our case, a small (about $\alpha n \times \alpha n$) portion of the matrix is deterministically fixed to be p (the expectation). One would expect that having this fixed portion in the matrix would make the eigenvalue structure more similar to that of the all p matrix (a similarity that we wish to establish here). Indeed, a simple modification of the arguments in [9] (in sections 2.2.3, 2.2.4, 3.2, and 3.3) yields that w.h.p. for any $x \perp \bar{1}$ it holds that $x^t B' x \leq c\sqrt{d}$, where c is a universal constant independent of d and α (without loss of generality, we may further assume that $c \geq 2$). We omit the proof from the current manuscript and refer the reader to [9]. $\square$

LEMMA 4.4. *Let $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{n'}$ be the eigenvalues of A' . If conditions (i), (ii), and (iii) from Lemma 4.3 hold, then for $i = 2, 3, \dots, n' - 1$ it holds that $|\lambda_i| \leq 2c\sqrt{d}$ ($c \geq 2$ is the universal constant from Lemma 4.3).*

Proof. It is enough to prove that $\lambda_2 \leq 2c\sqrt{d}$ and $\lambda_{n'-1} \geq -2c\sqrt{d}$. We first show $\lambda_{n'-1} \geq -2c\sqrt{d}$. It is well known that

$$\lambda_{n'-1} = \max_{\substack{H \text{ subspace of} \\ \text{dimension } n-1}} \min_{\substack{x \neq 0, \\ x \in H}} \frac{x^t A' x}{x^t x}.$$

Let us fix H to be the subspace perpendicular to $\bar{v}_{n'}$. Consider any vector $x \perp \bar{v}_{n'}$. The vector x can be written as $x = f + s$, where f is a multiple of $\bar{v}_1$ and $s \perp \bar{v}_1, \bar{v}_{n'}$.

$$\begin{aligned} x^t A' x &= (f + s)^t A' (f + s) = f^t A' f + s^t A' s + 2s^t A' f \\ &\geq \bar{\lambda}_1 \|f\|^2 - c\sqrt{d} \|s\|^2 + 2s^t (A' - \bar{\lambda}_1 I) f \\ &\geq -c\sqrt{d} \|s\|^2 - 2(1.2\sqrt{d} \|s\| \|f\|) \geq -2c\sqrt{d} \|x\|^2. \end{aligned}$$

In the first equality we used the symmetry of A' , in the first inequality we used Lemma 4.3(iii) for the second term and $s \perp f$ for the third term, in the following inequality we used $\bar{\lambda}_1 \geq 0$ and Lemma 4.3(i), and in the last inequality we used $c > 1.2$, $2\|s\| \|f\| \leq \|s\|^2 + \|f\|^2 = \|x\|^2$. A similar argument using

$$\lambda_2 = \min_{\substack{H \text{ subspace of} \\ \text{dimension } n-1}} \max_{\substack{x \in H \\ x \neq 0}} \frac{x^t A' x}{x^t x}$$

gives $\lambda_2 \leq 2c\sqrt{d}$. $\square$

LEMMA 4.5. *Fix $l = \binom{n}{2} - \binom{\alpha n}{2}$, and let G be taken from $C_{n,m,\alpha}$, where $m \in (1 \pm n^{-0.1})pl$. Fix any $v \in C$, and define $X := \deg(v)_I + \beta_2 \deg(v)_C - (1 - \alpha)\beta_2^2 d$. It holds that $\text{VAR}[X] = (1 + o(1))(\alpha d + \beta_2^2(1 - \alpha)d)$.*

Proof. The random variable X can be written as the sum of m independent random variables $X_1, \dots, X_m$, where $X_i := \deg(v)_I + \beta \deg(v)_C - (1 - \alpha)\beta^2 d$ when G is composed of only one random edge from L . It holds that $\text{VAR}[X] = m\text{VAR}[X_1]$. We will now calculate

$$(48) \quad \text{VAR}[X_1] = \text{VAR}[\deg(v)_I] + \beta_2^2 \text{VAR}[\deg(v)_C] + 2\beta_2 \text{COV}(\deg(v)_I, \deg(v)_C).$$

Since $\deg(v)_I$ and $\deg(v)_C$ are in fact indicators, we will denote them, respectively,

by z_1 and z_2 , where $\Pr[z_1] = p_1$ and $\Pr[z_2] = p_2$.

$$(49) \quad \text{VAR}[\deg(v)_I] = p_1(1 - p_1) = \frac{\alpha n}{l} \left(1 - \frac{\alpha n}{l}\right) \stackrel{(10)}{=} (1 \pm o(1)) \frac{\alpha n}{l},$$

$$(50) \quad \begin{aligned} \text{VAR}[\deg(v)_C] &= p_2(1 - p_2) \\ &= \frac{(1 - \alpha)n - 1}{l} \left(1 - \frac{(1 - \alpha)n - 1}{l}\right) \stackrel{(10)}{=} (1 \pm o(1)) \frac{(1 - \alpha)n}{l}, \end{aligned}$$

$$\beta_2 \text{COV}[\deg(v)_I, \deg(v)_C] = \beta_2(\Pr[z_1 \wedge z_2] - p_1 p_2) = \beta_2(0 - p_1 p_2)$$

$$(51) \quad = -\beta_2(1 \pm o(1)) \frac{\alpha(1 - \alpha)n^2}{l^2} \stackrel{(10)}{=} o(1).$$

It thus follows that

$$(52) \quad \text{VAR}[X] = (1 \pm o(1)) \frac{mn}{l} (\alpha + \beta_2^2(1 - \alpha)) = (1 \pm o(1)) d (\alpha + \beta_2^2(1 - \alpha)). \quad \square$$

A CENSUS OF SMALL LATIN HYPERCUBES*

BRENDAN D. MCKAY[†] AND IAN M. WANLESS[‡]

Abstract. We count all latin cubes of order $n \leq 6$ and latin hypercubes of order $n \leq 5$ and dimension $d \leq 5$. We classify these (hyper)cubes into isotopy classes and paratopy classes (main classes). For the same values of n and d we classify all d -ary quasigroups of order n into isomorphism classes and also count them according to the number of identity elements they possess (meaning we have counted the d -ary loops). We also give an exact formula for the number of (isomorphism classes of) d -ary quasigroups of order 3 for every d . Then we give a number of constructions for d -ary quasigroups with a specific number of identity elements. In the process, we prove that no 3-ary loop of order n can have exactly $n - 1$ identity elements (but no such result holds in dimensions other than 3). Finally, we give some new examples of latin cuboids which cannot be extended to latin cubes.

Key words. Latin cube, Latin hypercube, Latin cuboid n -ary quasigroup, n -ary loop, identity elements, Jacobsthal sequence, total loop, MDS code

1. Basic definitions. Let $[n]$ denote the set $\{1, 2, \dots, n\}$ and let $[n]^d$ denote the cartesian product $[n] \times [n] \times \dots \times [n]$ of d copies of $[n]$. By a *hypercube of order n and dimension d* we mean a d -dimensional array of n^d cells where the cells are indexed by $[n]^d$ and each cell contains an element of $[n]$ (which we will call a *symbol*). Suppose that H is such a hypercube and c is any cell of H . A *line through c* is the set of n cells of H whose coordinates match those of c except possibly in the k th coordinate (there is one line for each choice of k). A *hyperplane through c* is the set of n^{d-1} cells of H whose k th coordinate matches that of c (there is one hyperplane for each choice of k). Any hyperplane in a d -dimensional hypercube can be considered to be a $(d-1)$ -dimensional hypercube, simply by dropping the common coordinate. We use vector notation such as $\vec{v}$ for an element of $[n]^d$. In a hypercube H we denote the symbol in the cell with coordinates $\vec{v} = (v_1, v_2, \dots, v_d)$ by $H(\vec{v})$ or $H(v_1, v_2, \dots, v_d)$.

We say that a hypercube H is *latin* if the n cells in any line of H contain each of the symbols in $[n]$ exactly once. We define $\mathcal{H}_n^d$ to be the set of latin hypercubes of order n and dimension d . Given a hypercube $L \in \mathcal{H}_n^d$ and a cell $\vec{v} = (v_1, v_2, \dots, v_d) \in [n]^d$, we can define d permutations of $[n]$ corresponding to the lines through $\vec{v}$. Namely, for each $j \in [d]$ we define $\rho_j(\vec{v}, L)$ to be the permutation

$$k \mapsto L(i_1, \dots, i_{j-1}, k, i_{j+1}, \dots, i_d) \quad \text{for } k \in [n].$$

If $\rho_j((1, 1, \dots, 1), L)$ is the identity permutation for each $j \in [d]$, then we say that L is *reduced*. We define $\mathcal{R}_n^d \subseteq \mathcal{H}_n^d$ to be the set of reduced latin hypercubes of order n and dimension d .

For some purposes it is easier to think of each hypercube $H \in \mathcal{H}_n^d$ as, instead, a set $T_H \subseteq [n]^{d+1}$ where for each $\vec{v} = (v_1, v_2, \dots, v_d) \in [n]^d$ there is a $(d+1)$ -tuple $\langle v_1, v_2, \dots, v_d, H(\vec{v}) \rangle$ in T_H . (We adopt the convention of writing the tuples of a

[‡]School of Mathematical Sciences, Monash University, Clayton, Vic 3800, Australia (ian.wanless@sci.monash.edu.au).

hypercube inside angle brackets $\langle \cdot \rangle$.) The latin property of the hypercube is equivalent to saying that no two of its tuples differ in exactly one coordinate.

Some of the interest in latin hypercubes stems from coding theory, given that a hypercube $L \in \mathcal{H}_n^d$ is equivalent to a maximum distance separable (MDS) code over an alphabet of size n , with length $d + 1$ and minimum distance 2. See Laywine and Mullen [16] for a good introduction to this area.

Another source of interest in latin hypercubes is in nonassociative algebra. A d -ary quasigroup of order n is a function $Q : [n]^d \rightarrow [n]$ such that $Q(\vec{u}) \neq Q(\vec{v})$ whenever $\vec{u}$ and $\vec{v}$ differ in exactly one coordinate. Such a quasigroup is clearly equivalent to a latin hypercube $L \in \mathcal{H}_n^d$, where $L(\vec{v}) = Q(\vec{v})$. Moreover L is reduced if and only if 1 is an identity element in the corresponding quasigroup Q . (An *identity element* of Q is an $x \in Q$ such that

$$Q(y, x, x, \dots, x) = Q(x, y, x, \dots, x) = \dots = Q(x, x, \dots, x, y) = y$$

for all $y \in Q$.) A quasigroup possessing an identity element is called a *loop*. One of the aims of this paper is to count d -ary quasigroups and d -ary loops of order n (up to isomorphism) for small d and n . We do this using the theory in section 2 and the algorithm in section 3. For $d > 2$ it transpires that identity elements in d -ary loops need not be unique. Hence, in section 5 we examine constructions for loops with various numbers of identity elements.

A third source of applications for latin hypercubes is in the design of statistical experiments. In this field the phrases “latin cube” and “latin hypercube” are used for a broader class of objects than we are allowing in our definition. See [6] or [24] in this regard. The statistical definition of latin hypercube seems unnatural in other contexts since it does not have the property that each hyperplane is necessarily a latin hypercube of one lower dimension. The confusion arising from these different definitions is unfortunate, but we choose to follow, for example, [4] and [15] in our use of “latin hypercube” and many papers (e.g., [8, 9, 14, 17, 22]) in our use of “latin cube”. The alternative terminology “permutation (hyper)cube” was advocated in [6] and used in [1, 3, 7, 11]. This terminology is better reserved for the higher dimensional analogues of permutation matrices (that is, multidimensional arrays with all entries 0 or 1 such that each line contains a unique 1). Interestingly, $(d+1)$ -dimensional permutation hypercubes of order n are combinatorial objects essentially equivalent to d -dimensional latin hypercubes of order n (both objects described in our preferred terminology). This simple observation was made by Gupta [9], who used the phrase “permutation cube” in our preferred sense.

In the cases $d = 1, 2, 3$ a latin hypercube of dimension d is a permutation, a latin square and a latin cube, respectively. Much of the theory of latin hypercubes is yet to be developed although some analogues of results for latin squares have been investigated for latin cubes and occasionally for hypercubes in general. Completion and embedding results have been obtained by Cruse [4], Kochol [14], and Lindner [17]. Fu [8] considered the range of values possible for the number of common entries shared by distinct latin cubes. (In other terminology, this equates to studying the possible sizes of trades in latin cubes.) A number of authors have considered sets of k mutually orthogonal latin hypercubes. Here again several different definitions are possible; see [6] and [16] for further information and references. The notions of intercalates, transversals, and prolongation were generalized by Heinrich [11] from latin squares to higher dimensions. The same generalization of transversals was used in [15] but a different generalization of transversals was given by Beljavskaja and Murathudjaev

[3]. Finally, strongly diagonal latin squares (also called Knut Vik designs) and totally symmetric latin squares were generalized to higher dimensions by Alavi, Lick, and Liu [1] and Bailey, Preece, and Zemroch [2], respectively.

The usual notions of isotopism, paratopism, and isomorphism generalize naturally from latin squares to higher dimension. Let S_n be the symmetric group on $[n]$ and let S_n^c denote the direct product of c copies of S_n . Then the natural action of S_n^{d+1} on $[n]^{d+1}$ induces an action on $\mathcal{H}_n^d$ (where, as discussed above, we associate each $H \in \mathcal{H}_n^d$ with a subset $T_H \subseteq [n]^{d+1}$). This action is called *isotopism* (or *isotopy*) and its orbits are called *isotopy classes*. Define Δ_n^{d+1} to be the diagonal subgroup of S_n^{d+1} , that is, $\Delta_n^{d+1} = \{(g, g, \dots, g) \in S_n^{d+1}\}$. An important special case of isotopism is the action of Δ_n^{d+1} on $\mathcal{H}_n^d$. This action is called *isomorphism* and its orbits are called *isomorphism classes*. If the hypercube is regarded as the table of values of a d -ary quasigroup on $[n]$, then isomorphisms of the hypercube correspond to standard isomorphisms of the quasigroup.

A further group action on a hypercube is provided by permutation of the elements of tuples. In this action, a permutation $\tau \in S_{d+1}$ maps the tuple $\langle v_1, v_2, \dots, v_{d+1} \rangle$ onto the tuple $\langle v_1, v_2, \dots, v_{d+1} \rangle^\tau = \langle w_1, w_2, \dots, w_{d+1} \rangle$, where $w_{i\tau} = v_i$ for $1 \leq i \leq d+1$. Here, and elsewhere, we use the superscript notation for the image of an object under a function; thus i^τ means $\tau(i)$, and L^τ is the image of L obtained by applying τ to each of its tuples. Such images are the *conjugates* (also called *parastrophes*) of L .

An arbitrary combination of a conjugacy and an isotopism is called a *paratopism* (or *paratopy*). The set of all paratopisms corresponds to the wreath product $S_n \wr S_{d+1}$ in its natural action on $[n]^{d+1}$. The orbits of its action on the set of all hypercubes are called *paratopy classes*, *main classes* or *species*.

The stabilizers of a latin hypercube L under isotopism, paratopism, and isomorphism are known respectively as the autotopism group, autoparatopism group, and automorphism group of L . We use, respectively, $\text{Is}(L)$, $\text{Par}(L)$, and $\text{Aut}(L)$ to denote these groups. For example, $\text{Aut}(L) = \{\sigma \in \Delta_n^{d+1} \mid L^\sigma = L\}$.

One of the main objectives of this paper is enumeration of latin hypercubes and associated structures (such as d -ary quasigroups). The enumeration of latin squares has a lengthy and well-known history for which we refer to the recent survey given in [18]. Considerably less work has been done for higher dimensions.

To count latin hypercubes it suffices to count reduced latin hypercubes and then apply the formula

$$(1) \quad |\mathcal{H}_n^d| = n! (n-1)!^{d-1} |\mathcal{R}_n^d|.$$

One of the first works was by Gupta [9], who enumerated latin cubes by hand and obtained the incorrect value $|\mathcal{R}_4^3| = 58$. The correct value $|\mathcal{R}_4^3| = 64$ was subsequently obtained by Mullen and Weber [22] and much later by Jia and Qin [13], with both pairs of researchers attempting to count and classify latin cubes of orders 1 up to 5.

Mullen and Weber [22] reported the numbers of reduced latin cubes of orders 1 up to 5 to be 1, 1, 1, 64, 40246 and the numbers of isomorphism classes to be 1, 1, 1, 19, 1860. They did not establish the number of isotopism classes for order 5 but found the number for orders 1 to 4, respectively, to be 1, 1, 1, 12. Zinoviev and Zinoviev [28] found that there are five paratopy classes of latin cubes of order 4. Our computations confirm the above numbers.

Apparently unaware of Mullen and Weber's work two decades earlier, Jia and Qin [13] attempted similar computations. They reported the same numbers of reduced latin cubes but gave the numbers of isotopism classes to be 1, 1, 1, 15, 479. These last two values are incorrect.

A patent application by Ito [12] included values of $|\mathcal{R}_4^d|$ for $d \leq 5$ that agree with our computations (see Table 1) and also with the values found by Potapov and Krotov [23]. Potapov and Krotov also proved that

$$3^{d+1}2^{2^d+1} \leq |\mathcal{H}_4^d| \leq (3^{d+1} + 1)2^{2^d+1}$$

for $d \geq 5$.

2. Counting equivalence classes. The numbers of isotopy and paratopy classes of latin hypercubes are related to the total number of latin hypercubes via the sizes of the autotopism and autoparatopism groups. The exact relationship is specified in the following lemma, whose proof is elementary.

LEMMA 1. *For any $L \in \mathcal{H}_n^d$, the paratopy class of L contains*

- (a) $\frac{(d+1)!}{|\text{Par}(L)|/|\text{Is}(L)|}$ isotopy classes,
- (b) $\frac{(d+1)!n!n^{d-1}}{|\text{Par}(L)|}$ reduced latin hypercubes, and
- (c) $\frac{(d+1)!(n!)^{d+1}}{|\text{Par}(L)|}$ latin hypercubes.

In the case of isomorphism classes, the natural setting is that of quasigroups and loops. The procedure for counting isomorphism classes of ordinary quasigroups given in [18, Theorem 4] applies equally well to the d -ary case, and the same proof applies with obvious adaptations, so we state our first theorem without proof.

Let $\mathcal{I}_n^d$ be a set containing one hypercube from each isotopy class of $\mathcal{H}_n^d$, and let $\mathcal{M}_n^d$ be a set containing one hypercube from each paratopy class of $\mathcal{H}_n^d$.

Define the *cycle structure* of a permutation γ to be the sequence $(n_1, n_2, \dots)$, where n_i is the number of cycles of length i in γ . If $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_{d+1})$ is a $(d+1)$ -tuple of permutations, define $\psi(\sigma)$ as follows:

- (i) If $\sigma_1, \sigma_2, \dots, \sigma_{d+1}$ have the same cycle structure, $(n_1, n_2, \dots)$, then $\psi(\sigma) = \prod_i n_i! i^{n_i}$.
- (ii) Otherwise, $\psi(\sigma) = 0$.

THEOREM 2. *The number of isomorphism classes of d -ary quasigroups of order n is*

$$\sum_{L \in \mathcal{I}_n^d} \frac{1}{|\text{Is}(L)|} \sum_{\sigma \in \text{Is}(L)} \psi(\sigma)^d = \sum_{L \in \mathcal{M}_n^d} \frac{(d+1)!}{|\text{Par}(L)|} \sum_{\sigma \in \text{Is}(L)} \psi(\sigma)^d.$$

As pointed out by a referee, some of these results are true in a more general setting. For some set X , let $\mathcal{F}_n^d(X)$ be the class of all functions from $[n]^{d+1}$ to X . A latin hypercube is such a function for $X = \{0, 1\}$, namely, the characteristic function of the set of $(d+1)$ -tuples it comprises. Isotopy, paratopy, and isomorphism are defined for $\mathcal{F}_n^d(X)$ by permutations of the domain $[n]^{d+1}$ in the same way as for latin hypercubes. We then have, with essentially the same proofs, that Lemma 1(a) and (c) and Theorem 2 are true for any subclass of $\mathcal{F}_n^d(X)$ which is closed under paratopy.

While counting d -ary quasigroups required no new theory, it turns out that counting d -ary loops is less straightforward. The “obvious” extension of [18, Theorem 5] to the d -ary case does not work, primarily due to the possibility that loops have more than one identity element (see section 5 for examples). Therefore, we need to develop a more complicated approach.

We say that two cells $\vec{u}$ and $\vec{v}$ of $L \in \mathcal{H}_n^d$ are *line-equivalent* if $\rho_j(\vec{u}, L) = \rho_j(\vec{v}, L)$ for all $j \in [d]$. If x, y are both identity elements of a d -ary loop, then $(x, x, \dots, x)$ is line equivalent to $(y, y, \dots, y)$.

For $1 \leq i \leq d+1$, define $L^{[i]}$ to be the conjugate of L obtained by exchanging the i th and $(d+1)$ th elements of tuples. This includes the case $L^{[d+1]} = L$. Also, for $h, s \in S_n^{d+1}$ we write $h^s = s^{-1}hs$.

THEOREM 3. *For $L \in \mathcal{H}_n^d$, choose $C(L)$ to be a set of cells that includes exactly one cell from each line-equivalence class of cells of L . For each cell $\vec{v}$, define*

$$N(\vec{v}, L) = |\{h \in \text{Is}(L) \mid h^{(\rho_1, \rho_2, \dots, \rho_d, 1)} \in \Delta_n^{d+1}\}|,$$

where $\rho_j = \rho_j(\vec{v}, L)$ for each j , and 1 is the identity of S_n .

Then the number of isomorphism classes of d -ary loops of order n is

$$(2) \quad \sum_{L \in \mathcal{I}_n^d} \frac{1}{|\text{Is}(L)|} \sum_{\vec{v} \in C(L)} N(\vec{v}; L) = \sum_{L \in \mathcal{M}_n^d} \frac{d!}{|\text{Par}(L)|} \sum_{t=1}^{d+1} \sum_{\vec{v} \in C(L^{[t]})} N(\vec{v}; L^{[t]}).$$

Proof. Let $\mathcal{L}_n^d$ consist of all the loops in $\mathcal{H}_n^d$. Note that we do not require any particular elements to be the identity elements. The number we seek is the number of equivalence classes of $\mathcal{L}_n^d$ under Δ_n^{d+1} . By the Burnside–Frobenius lemma, this is equal to the average number of loops fixed by an element of Δ_n^{d+1} . Our task is therefore to find the number of pairs (M, g) for $M \in \mathcal{L}_n^d$ and $g \in \Delta_n^{d+1}$, such that $M^g = M$.

We start by seeking the number of such pairs where M is in the isotopy class of some fixed $L \in \mathcal{H}_n^d$. This isotopy class consists of all L^σ for $\sigma \in S_n^{d+1}$, with the caveat that each hypercube appears for exactly $|\text{Is}(L)|$ values of σ . Leaving that factor for later, we need to find the number of pairs (σ, g) for $\sigma \in S_n^{d+1}$ and $g \in \Delta_n^{d+1}$, such that L^σ is a loop and $L^{\sigma g} = L^\sigma$. The last condition is equivalent to $\sigma g \sigma^{-1} \in \text{Is}(L)$.

Writing h for $\sigma g \sigma^{-1}$, our problem reduces to counting all pairs (σ, h) for $\sigma \in S_n^{d+1}$ and $h \in \text{Is}(L)$ such that

- (a) L^σ is a loop and
- (b) $h^\sigma \in \Delta_n^{d+1}$.

We proceed by parameterizing those σ satisfying (a). This is analogous to reducing a latin square, except that we do not require an identity element in the first position, and, indeed, we must remember that there can be more than one identity element.

- Choose a cell $\vec{v}$ and a permutation $\delta \in S_n$.
- Permute rows, columns, etc., so that the lines through cell $\vec{v}$ are all the identity permutation.
- Apply $\delta \in S_n$ to each of the $d+1$ components.

The resulting loop has $L(\vec{v})^\delta$ as an identity element. Symbolically, we have

$$(3) \quad \sigma = \sigma(\vec{v}, \delta) = (\rho_1(\vec{v}, L)\delta, \rho_2(\vec{v}, L)\delta, \dots, \rho_d(\vec{v}, L)\delta, \delta).$$

It is easy to see that every σ satisfying (a) has this form. However, this parameterisation has redundancies: $\sigma(\vec{u}, \delta') = \sigma(\vec{v}, \delta)$ if and only if $\vec{u}$ is line-equivalent to $\vec{v}$ and $\delta' = \delta$.

Finally, for each $\sigma = \sigma(\vec{v}, \delta)$, we need to know how many $h \in \text{Is}(L)$ satisfy (b). This does not depend on δ since $h^{\sigma(\vec{v}, \delta)} \in \Delta_n^{d+1} \Leftrightarrow h^{\sigma(\vec{v}, 1)} \in \Delta_n^{d+1}$.

TABLE 1

Number of reduced latin hypercubes, isotopy classes of latin hypercubes, paratopy classes of Latin hypercubes, and isomorphism classes of quasigroups for small orders n and dimensions d .

d	n	reduced	isotopy classes	paratopy classes	quasigroups

6	3	1	1	1	85

We can now derive the first expression in (2). For each $L \in \mathcal{I}_n^d$, the number of pairs (σ, h) satisfying (a) and (b) can be found by testing, for one $\vec{v}$ from each line-equivalence class of cell, whether $\sigma(\vec{v}, 1)$ satisfies (b). For each of those that pass the test, we have $n!$ choices of δ . Then we divide by $|\text{Is}(L)|$ to account for the number of times each hypercube appears as L^σ and by $|\Delta_n^{d+1}| = n!$ as required by the Burnside–Frobenius lemma.

The summand of the outside summation in the first half of (2) is not invariant under conjugacy, so converting to a sum over paratopy classes is not just a matter of applying some factors. However, the summand is invariant under conjugacies that leave the $(d+1)$ th position fixed. Therefore, we get all the information we need from the conjugates $L^{[1]}, L^{[2]}, \dots, L^{[d+1]}$. Each of these represents $d! |\text{Is}(L)| / |\text{Par}(L)|$ isotopy classes, so the second half of (2) is obtained. $\square$

In Table 1 we give the results of our enumeration of latin hypercubes, classified according to various notions of equivalence. A more detailed count of hypercubes, classified according to group sizes, is presented in the appendix. A representative of each of the paratopy classes covered by Table 1 can be found in [21]. In Table 2 we give the results of our enumeration of loops (up to isomorphism) according to the number of identity elements they have. In section 5 we consider further the question of how many identity elements a loop can have. To save space, we have omitted a number of known values for $d = 2$ and $n \in \{9, 10, 11\}$; see [18, 20].

3. Construction method. To reduce the probability of error, all the computations were carried out independently by the two authors using slightly different algorithms. We now describe the first algorithm used.

Let $L \in \mathcal{H}_n^d$. For $1 \leq k \leq n$, the k th hyperplane of L is $L^{(k)} \in \mathcal{H}_n^{d-1}$ defined by $L^{(k)}(i_1, \dots, i_{d-1}) = L(i_1, \dots, i_{d-1}, k)$ for all $i_1, \dots, i_{d-1}$.

TABLE 2
Counts of loops according to their number of identity elements.

d	n	Number of identity elements						Total
		1	2	3	4	5	6	
2	2	1						1

5	5	2122915806	805040	280	0	70		2123721196
6	2	1	0					1
6	3	1	0	0				1

Next we define an ordering on latin hypercubes. The hypercube L can be specified by listing the symbols in each of the n^d cells in a particular order:

$$\begin{aligned} \Sigma(L) = [& L(1, 1, 1, \dots, 1), L(2, 1, 1, \dots, 1), \dots, L(n, 1, 1, \dots, 1), \\ & L(1, 2, 1, \dots, 1), L(2, 2, 1, \dots, 1), \dots, L(n, 2, 1, \dots, 1), \\ & L(1, 3, 1, \dots, 1), \dots, \\ & L(1, n, 1, \dots, 1), L(2, n, 1, \dots, 1), \dots, L(n, n, 1, \dots, 1), \\ & L(1, 1, 2, \dots, 1), \dots, \\ & L(1, n, n, \dots, n), L(2, n, n, \dots, n), \dots, L(n, n, n, \dots, n)]. \end{aligned}$$

The order of the cells (earlier indices varying faster) is important for what follows. We call L *isotopy-minimal* if $\Sigma(L) \leq \Sigma(L')$ for every L' in the isotopy class of L . Similarly, L is *paratopy-minimal* if $\Sigma(L) \leq \Sigma(L')$ for every L' in the paratopy class of L . In each case, the comparison $\leq$ is lexicographic order. The following properties follow easily from the definitions.

LEMMA 4. *Let L be a latin hypercube. Then the following hold.*

- (i) *There is exactly one isotopy-minimal hypercube in each isotopy class and exactly one paratopy-minimal hypercube in each paratopy class.*
- (ii) *If L is paratopy-minimal, then L is isotopy-minimal.*
- (iii) *If L is isotopy-minimal, then L is reduced.*
- (iv) *If L is paratopy-minimal in $\mathcal{H}_n^d$, then $L^{(1)}$ is paratopy-minimal in $\mathcal{H}_n^{d-1}$.*

The aim of the computation was to find all paratopy-minimal hypercubes $L \in \mathcal{H}_n^d$. As permitted by Lemma 4(iv), we took the paratopy-minimal hypercubes in $\mathcal{H}_n^{d-1}$ as $L^{(1)}$. Then we extended $L^{(1)}$ to L in all possible ways such that L was reduced. Finally, we rejected L if it was not paratopy-minimal.

To check that L is paratopy-minimal, we verified that $\Sigma(L) \leq \Sigma(L^\gamma)$ for each of the $n^{d-1}(d+1)!n!$ paratopisms γ that take L to a reduced hypercube. These paratopisms have the form $\gamma = \gamma(\vec{v}, \delta, L) = \sigma(\vec{v}, \delta)\tau$, where τ is one of the $(d+1)!$ conjugacies, and $\sigma(\vec{v}, \delta)$ is defined as in (3) with $\delta \in S_n$ such that $L(\vec{v})^\delta = 1$. In this case, the redundancy issue noted just after (3) does not occur: all these $n^{d-1}(d+1)!n!$ paratopisms are different. To see this, note that the condition $L(\vec{v})^\delta = 1$ implies that $\sigma(\vec{v}, \delta)$ maps position $\vec{v}$ onto position $(1, 1, \dots, 1)$. If $\gamma = \gamma(\vec{v}, \delta, L)$ was found such that $\Sigma(L^\gamma) < \Sigma(L)$, thereby rejecting L as not paratopy-minimal, the next candidate hypercube L' was first tested with $\gamma(\vec{v}, \delta, L')$. This often rejected L' as well, giving a useful speedup.

If the minimality test for L was passed, we had also found the autopatopism group: $\text{Par}(L)$ consists of those γ for which $\Sigma(L^\gamma) = \Sigma(L)$.

The second algorithm used to count $|\mathcal{H}_n^d|$ was similar to the first in that it generated a catalogue of paratopy class representatives by extending all paratopy class representatives from $\mathcal{H}_n^{d-1}$ in all ways that produced a reduced hypercube. However, the isomorphism testing was different. The reduced hypercubes were canonically labelled using nauty [19] in much the same way as latin squares were treated in [18]. Any hypercube was rejected if its canonical labelling was identical to that of a previously constructed hypercube. The autopatopism group of each hypercube was calculated by nauty while finding the canonical labelling.

It is clear that both these generation methods are quite crude, but the use of more sophisticated techniques, such as applying a minimality test after each hyperplane is added, would not help very much with these small values of n and d . In particular, we do not think they would improve the efficiency enough to make hypercubes with higher order and/or dimension enumerable with present computing power.

4. Number of quasigroups of order 3. In this section we count the d -ary quasigroups of order $n = 3$, for arbitrary d . Before developing that result we need to introduce a notion of linearity.

We say that $H \in \mathcal{H}_n^d$ is *linear* if there exist $s \in [n]$ and $c_i \in [n]$ for $i \in [d]$, such that

$$(4) \quad H(x_1, x_2, \dots, x_d) \equiv s + \sum_{i=1}^d c_i x_i \pmod{n}$$

for each $(x_1, x_2, \dots, x_d) \in [n]^d$. We say that a quasigroup/loop is *linear* if its corresponding hypercube is linear. For (4) to define a latin hypercube it is necessary and sufficient that each c_i should be relatively prime to n . Let ϕ denote Euler's phi function. It follows that there are exactly $n(\phi(n))^d$ linear hypercubes in $\mathcal{H}_n^d$, since we have n choices for s and $\phi(n)$ choices for each c_i .

For $n \leq 3$ and arbitrary d it is easy to prove by induction on d that every hypercube in $\mathcal{H}_n^d$ is linear. This conclusion also follows from the values of $|\mathcal{H}_n^d|$ as given, for example, by Finizio and Lewis [7] or Laywine and Mullen [16, p. 224].

In our next theorem we will use the fact that each of the $2^d 3$ hypercubes in $\mathcal{H}_3^d$ is linear to count the d -ary quasigroups of order 3. Our result is phrased in terms of the Jacobsthal sequence, which is defined by $a_n = \frac{1}{3}(2^n + (-1)^{n+1})$, or alternatively by the recurrence

$$(5) \quad a_n = a_{n-1} + 2a_{n-2} \quad \text{with} \quad a_1 = a_2 = 1.$$

This is sequence A001045 in Sloane's On-Line Encyclopedia of Integer Sequences [25],

which lists many combinatorial objects counted by the sequence. Here we extend that list.

THEOREM 5. *Let $\mathcal{Q}_{3,g}^d$ be the set of d -ary quasigroups of order 3 with an automorphism group of order g . Then $|\mathcal{Q}_{3,2}^d| = a_{d+1}$, $|\mathcal{Q}_{3,3}^d| = |\mathcal{Q}_{3,6}^d| = a_d$, and $|\mathcal{Q}_{3,g}^d| = 0$ for $g \notin \{2, 3, 6\}$. Hence $|\mathcal{Q}_3^d| = a_{d+2}$.*

Proof. First note that the result for $|\mathcal{Q}_3^d|$ follows from the other results and (5), since $|\mathcal{Q}_3^d| = \sum_g |\mathcal{Q}_{3,g}^d|$.

Let $\mathcal{H}_{3,g}^d$ be the set of d -dimensional hypercubes of order n for which the corresponding quasigroup is in $\mathcal{Q}_{3,g}^d$. Clearly, $|\mathcal{Q}_{3,g}^d| = |\mathcal{H}_{3,g}^d| g/3!$.

Consider the diagonal cells of an arbitrary $H \in \mathcal{H}_3^d$. Specifically, for $i \in \{1, 2, 3\}$ define u_i by $\langle i, i, i, \dots, i, u_i \rangle \in H$. Since H must be linear, we find that $u_2 - u_1 \equiv u_3 - u_2 \equiv u_1 - u_3 \pmod{3}$.

We now argue that $u_k = k$ if and only if H possesses an automorphism τ fixing k and swapping the other two elements of $\{1, 2, 3\}$.

Certainly if H has such an automorphism, then it must map $\langle k, k, \dots, k, u_k \rangle$ to $\langle k, k, \dots, k, \tau(u_k) \rangle$, from which we infer that $u_k = k$, the only fixed point of τ .

So assume that $u_k = k$ and define $\tau : [3] \rightarrow [3]$ by $\tau(x) \equiv -k - x \pmod{3}$. Note that τ fixes k and swaps the elements of $[3] \setminus \{k\}$. Since H is linear we can assume the existence of s, c_i satisfying (4). Given that $u_k = k$, this implies that $k = s + k \sum c_i$. Now if we apply the isomorphism τ to a general element $\langle x_1, x_2, \dots, x_d, s + \sum c_i x_i \rangle$ of H , it maps that element to

$$\left\langle -k - x_1, -k - x_2, \dots, -k - x_d, -k - s - \sum c_i x_i \right\rangle,$$

where all coordinates should be calculated mod 3. However, this is an element of H since

$$s + \sum c_i (-k - x_i) = s - k \sum c_i - \sum c_i x_i = s + (s - k) - \sum c_i x_i \equiv -k - s - \sum c_i x_i$$

mod 3. We conclude that τ is indeed an automorphism, as we contended.

At this point we separate into three cases. Define $\alpha \in [3]$ by $\alpha \equiv u_2 - u_1 \equiv u_3 - u_2 \equiv u_1 - u_3 \pmod{3}$.

Case 1. $\alpha \neq 1$.

By the definition of α there exists a unique $k \in \{1, 2, 3\}$ such that $u_k = k$. This means $\text{Aut}(H)$ contains a unique transposition and hence $|\text{Aut}(H)| = 2$.

Case 2. $\alpha = 1$ and there exists $k \in \{1, 2, 3\}$ such that $u_k = k$.

Since $\alpha = 1$ we know $u_k = k$ for all $k \in \{1, 2, 3\}$. This means $\text{Aut}(H)$ contains three transpositions and hence $|\text{Aut}(H)| = 6$.

Case 3. $\alpha = 1$ and there does not exist $k \in \{1, 2, 3\}$ such that $u_k = k$.

In this case $\text{Aut}(H)$ contains no transpositions. However, by applying the permutation $\pi : u_k \rightarrow k$ to the symbols of H we obtain a hypercube H' to which Case 2 applies. That means that π is an automorphism of H' , and hence also of H . We deduce that $|\text{Aut}(H)| = 3$.

Moreover, there must be exactly twice as many hypercubes in Case 3 as there are in Case 2. Any example from Case 2 can be turned into an example from Case 3 by applying either (123) or (321) to its symbols. Exactly one of these permutations will map an example from Case 3 to one from Case 2. It follows that $|\mathcal{H}_{3,3}^d| = 2|\mathcal{H}_{3,6}^d|$ and thus $|\mathcal{Q}_{3,3}^d| = |\mathcal{Q}_{3,6}^d|$.

We now consider how a $(d-1)$ -dimensional hypercube H can be embedded as the first hyperplane of a d -dimensional hypercube H' . Since our hypercubes are linear there is only one choice to make, namely, whether $c_d = 1$ or $c_d = 2$. If H is in Case 2 or 3, then for either choice H' must fall into Case 1. On the other hand, if H is in Case 1, then there is exactly one choice of c_d so that H' is also in Case 1. Compiling this information we get

$$\begin{aligned} |\mathcal{H}_{3,2}^d| &= 2|\mathcal{H}_{3,3}^{d-1} \cup \mathcal{H}_{3,6}^{d-1}| + |\mathcal{H}_{3,2}^{d-1}|, \\ |\mathcal{H}_{3,3}^d \cup \mathcal{H}_{3,6}^d| &= |\mathcal{H}_{3,2}^{d-1}| \end{aligned}$$

and hence

$$\begin{aligned} |\mathcal{Q}_{3,2}^d| &= 2|\mathcal{Q}_{3,3}^{d-1}| + |\mathcal{Q}_{3,2}^{d-1}|, \\ |\mathcal{Q}_{3,3}^d| &= |\mathcal{Q}_{3,2}^{d-1}|. \end{aligned}$$

The theorem now follows from (5) by induction on d . $\square$

5. Number of identity elements. It is well known that a binary quasigroup can have at most one identity element but that d -ary quasigroups for $d > 2$ can have multiple identity elements. In this section we investigate constructions which produce quasigroups with a specific number of identity elements.

It is beyond the scope of this paper to provide a complete answer to the question of for which n , d , and i there exists a quasigroup in $\mathcal{Q}_n^d$ with exactly i identity elements. We set the more modest goal of, at a minimum, constructing at least one quasigroup in all cases for which Table 2 claims existence. Our methods and results represent a step toward an eventual solution of the more general question. We begin with some notation that will be used throughout this section.

Suppose $A \in \mathcal{Q}_n^\alpha$ and $B \in \mathcal{Q}_n^\beta$. We define a new quasigroup in $\mathcal{Q}_n^{\alpha+\beta-1}$, which we call the *composition* of A and B and write as $A \vdash B$, by

$$(A \vdash B)(x_1, \dots, x_{\alpha+\beta-1}) = A(B(x_1, \dots, x_\beta), x_{\beta+1}, \dots, x_{\alpha+\beta-1}).$$

Also, for any quasigroup A and positive integer c we define A^c inductively by $A^1 = A$ and $A^c = A^{c-1} \vdash A$ for $c > 1$. In particular, if $\mathbb{Z}_n$ denotes the quasigroup in $\mathcal{Q}_n^2$ defined by $\mathbb{Z}_n(x, y) \equiv x + y \pmod{n}$, then $(\mathbb{Z}_n)^c$ is the quasigroup in $\mathcal{Q}_n^{c+1}$ which is evaluated simply by adding coordinates modulo n .

The next lemma makes some observations about the number of identity elements in compositions. The (entirely elementary) proof will be omitted. In part 3, the meaning of *total loop* is a loop in which every element is an identity element.

LEMMA 6.

1. $(\mathbb{Z}_n)^c \in \mathcal{Q}_n^{c+1}$ has $\gcd(n, c)$ identity elements.
2. If x is an identity element in both A and B , then x is an identity element in $A \vdash B$. The converse is false, as can easily be seen by considering observation 1.
3. Suppose A is a total loop. Then x is an identity element in $A \vdash B$ if and only if x is an identity element in B .

The following result proves, among other things, existence of total loops in many cases.

THEOREM 7. Suppose that n, d, i are positive integers satisfying

1. $n \notin \{3, 7\}$,
2. $d \geq 3$ and d is odd,
3. $i \equiv n \pmod{2}$ or $i = 2$.

Then there exists a loop in $\mathcal{Q}_n^d$ with exactly i identity elements.

Proof. For any odd $d > 1$ and any $n \notin \{3, 7\}$ Teirlinck [26] showed the existence in $\mathcal{Q}_n^d$ of a 2-idempotent quasigroup, namely, a quasigroup in which each subset of cardinality 1 or 2 is a subquasigroup. It is easy to see that every 2-idempotent quasigroup is a total loop, proving the case $i = n$.

Suppose $i \equiv n \pmod{2}$. In a 2-idempotent quasigroup, we can replace each of the subquasigroups on the pairs $\{i+1, i+2\}$, $\{i+3, i+4\}, \dots, \{n-1, n\}$ by the other possible subquasigroup on the same two elements. Doing so results in a new quasigroup in which none of $i+1, \dots, n$ is an identity element. However, no tuple containing any element less than $i+1$ has been altered, so the elements $1, \dots, i$ are all still identity elements.

It remains to show the $i = 2$ case. Again we start with a 2-idempotent quasigroup. Suppose after replacing the subquasigroup on the elements $\{1, 2\}$ by the other possible subquasigroup on those elements, we arrive at a quasigroup Q . Now define Q' by

$$Q'(\vec{x}) = \begin{cases} 1 & \text{if } Q(\vec{x}) = 2, \\ 2 & \text{if } Q(\vec{x}) = 1, \\ Q(\vec{x}) & \text{otherwise.} \end{cases}$$

Then Q' will be a quasigroup in which 1 and 2 are identity elements. However, if $x \notin \{1, 2\}$, then $Q'(1, x, x, \dots, x) = 2$ so x is not an identity element. $\square$

Teirlinck left open the case of existence when $n = 7$, but it is easy to check by computer that no total loop (and hence no 2-idempotent quasigroup) exists in $\mathcal{Q}_7^3$. Despite this, we will show that a total loop exists in $\mathcal{Q}_7^d$ for all sufficiently large d . Also, total loops (unlike 2-idempotent quasigroups) can exist in even dimensions. Consider $S \in \mathcal{Q}_7^3$ given by

$$\begin{aligned} S = & [5671234.6237415.7364152.1743526.2415763.3152647.4526371. \\ & 6237415.2345671.3471526.7514263.4652137.1726354.5163742. \\ & 7364152.3471526.6712345.4125637.1536274.5243761.2657413. \\ & 1743526.7514263.4125637.3456712.5267341.2631475.6372154. \\ & 2415763.4652137.1536274.5267341.7123456.6374512.3741625. \\ & 3152647.1726354.5243761.2631475.6374512.4567123.7415236. \\ & 4526371.5163742.2657413.6372154.3741625.7415236.1234567]. \end{aligned}$$

It is easy to check that $(\mathbb{Z}_7)^3 \vdash S$ is a total loop in $\mathcal{Q}_7^6$. By composing this total loop with itself we can then produce total loops in $\mathcal{Q}_7^{6+5k}$ for any integer $k \geq 0$.

THEOREM 8. For each odd $n > 3$ there exists a D such that $\mathcal{Q}_n^d$ contains a total loop for all $d \geq D$.

Proof. We first show that for $n = 7$ we can choose $D = 25$. For arbitrary positive integers k, c we have shown above the existence of a total loop $T \in \mathcal{Q}_7^{5k+1}$ and also noted in Lemma 6 that $(\mathbb{Z}_7)^{7c}$ is a total loop in $\mathcal{Q}_7^{7c+1}$. Forming $T \vdash (\mathbb{Z}_7)^{7c}$ then produces a total loop in $\mathcal{Q}_7^{7c+5k+1}$. Every integer exceeding 24 can be written in the form $7c + 5k + 1$ for nonnegative integers c, k . (See, for example, Theorem 3.15.1 in [27].)

The argument for odd $n \notin \{3, 7\}$ is similar, but we use a total loop $T \in \mathcal{Q}_n^{2k+1}$ instead (whose existence is guaranteed by Theorem 7). Using $T \vdash (\mathbb{Z}_n)^{nc}$ gives a total loop in $\mathcal{Q}_n^{nc+2k+1}$. Since n is odd, every integer exceeding $n-1$ can be written in the form $nc+2k+1$ for nonnegative integers c, k . Thus we may take $D = n$. $\square$

Next we consider quasigroups in which there is (only) one element which is *not* an identity element. It seems plausible, given the data from Table 2, that the following is the only general restriction on how many identity elements there can be in a ternary quasigroup.

LEMMA 9. *A 3-ary quasigroup of order n cannot have exactly $n-1$ identity elements.*

Proof. Let Q be a 3-ary quasigroup of order n on the symbols $[n]$ in which every $x \in [n] \setminus \{u\}$ is an identity element. Take an arbitrary $v \in [n] \setminus \{u\}$. Then there exists $x \in [n]$ such that $\langle v, x, u, v \rangle \in Q$. If $x \neq u$ this contradicts the fact that $\langle v, x, x, v \rangle \in Q$ since x is an identity element. We conclude that $\langle v, u, u, v \rangle \in Q$, and a similar argument shows that $\langle u, v, u, v \rangle \in Q$ and $\langle u, u, v, v \rangle \in Q$. Finally, there is some $x \in [n]$ such that $\langle x, u, u, u \rangle \in Q$. If $x \neq u$ this contradicts $\langle x, u, u, x \rangle \in Q$, so we must have $\langle u, u, u, u \rangle \in Q$. We have shown that u is an identity element, so if Q has at least $n-1$ identity elements then it must have n identity elements. $\square$

The data in Table 2 are consistent with a generalization of Lemma 9 to some higher dimensions. However, no such generalization is possible.

LEMMA 10. *For every $d > 3$ there exists an n and a $Q \in \mathcal{Q}_n^d$ such that Q has exactly $n-1$ identity elements.*

Proof. We first show that 5-ary quasigroups can have exactly $n-1$ identity elements. Let

$$\begin{aligned} E = & [78123456.85274163.12385674.27816345.34567812.41638527.56741238.63452781. \\ & 85274163.56781234.27416385.78123456.41638527.12345678.63852741.34567812. \\ & 12385674.27416385.34567812.81634527.56741238.63852741.78123456.45278163. \\ & 27816345.38527416.81634527.12345678.63452781.74163852.45278163.56781234. \\ & 34567812.41638527.56741238.63452781.78123456.85274163.12385674.27816345. \\ & 41638527.72143658.63852741.34567812.85274163.56781234.27416385.18325476. \\ & 56741238.63852741.78123456.45278163.12385674.27416385.34567812.81634527. \\ & 63452781.14365872.45278163.56781234.27816345.38527416.81634527.72143658] \end{aligned}$$

Now $Q \in \mathcal{Q}_8^5$ defined by $Q = (\mathbb{Z}_8)^2 \vdash E$ has exactly seven identity elements (the element 8 is not an identity element, since $Q(1, 8, 8, 8, 8) = 7$). By Theorem 7, there is a total loop $T \in \mathcal{Q}_8^{2k+1}$ for all $k \geq 1$. Then by Lemma 6, $T \vdash Q$ is a loop in $\mathcal{Q}_8^{2k+5}$ with exactly seven identity elements. Thus we have the required example whenever the dimension is odd.

For any even d , $(\mathbb{Z}_2)^{d-1}$ provides a (rather trivial) example. By Lemma 6, it is a d -ary quasigroup of order 2 with one identity element. $\square$

Our next result shows among other things that the $n=2$ examples used to prove Lemma 10 are the only linear examples of order n quasigroups with $n-1$ identity elements.

LEMMA 11. *The number of identity elements in a linear d -ary loop of order n divides n .*

Proof. Suppose L is a linear d -ary loop of order n , defined by (4). Since L is a loop it possesses at least one identity element, say, ι . Then $\langle y, \iota, \iota, \dots, \iota, y \rangle \in L$ for all $y \in [n]$ which implies that

$$(6) \quad s + \iota \sum_{i=2}^d c_i + c_1 y \equiv y \pmod{n}.$$

As (6) must hold for all y we conclude that $c_1 = 1$. A similar argument shows that $c_j = 1$ for all $j \in [d]$. Hence (6) reduces to $s + (d-1)\iota \equiv 0 \pmod{n}$. This recurrence either has no solution for ι (impossible since we know L has an identity element), or its number of solutions is a divisor of n . It is obvious that each solution will yield a (different) identity element. $\square$

Having considered loops with a high number of identity elements, we turn briefly to the other end of the spectrum. It is a trivial matter for any $n \geq 3$ and $d \geq 2$ to create a linear quasigroup with no identity elements. For example, take $c_i = -1$ for all i in (4), and consider the proof of Lemma 11 above. Building quasigroups with a unique identity element is also easy.

THEOREM 12. *For all $n \geq 4$ and $d \geq 2$ there exists a loop in $\mathcal{Q}_n^d$ with a unique identity element.*

Proof. The result for $d = 2$ is well known. For $d = 3$ and odd n we can use $(\mathbb{Z}_n)^2$, by Lemma 6.

Suppose n is even and $n > 2$. Let $Z'_n = \mathbb{Z}_n^{(\tau, \tau, \tau)}$ be the binary quasigroup isomorphic to $\mathbb{Z}_n$ by applying the transposition $\tau = (1 \frac{n}{2})$ uniformly to the triples. Now consider $Q = \mathbb{Z}_n \vdash Z'_n$. The element n is an identity element of $\mathbb{Z}_n$, Z'_n and hence also of Q , by Lemma 6. For $x \notin \{\frac{n}{2}, n\}$, we have $Q(x, n, x) \equiv Z'_n(x, n) + x \equiv 2x \not\equiv n \pmod{n}$, so x is not an identity element. Moreover, $\frac{n}{2}$ is not an identity element either, since $Q(\frac{n}{2}, \frac{n}{2}, n) = Z'(\frac{n}{2}, \frac{n}{2}) = 2 \neq n$.

We have thus shown the theorem for $d \leq 3$. From these base cases the theorem now follows for $d > 3$ and $n \neq 7$ by composition with a total loop whose existence is guaranteed by Theorem 7. For $n = 7$, we use the base cases $(\mathbb{Z}_7)^c$ for $c \in [6]$, each of which has a unique identity element, by Lemma 6. By composing these with the total loops from $\mathcal{Q}_7^{5k+1}$, we generate all the required examples for $n = 7$. $\square$

We now describe examples of quasigroups with each of the possible number of identity elements shown in Table 2.

If $n \leq 3$, then part 1 of Lemma 6 provides the examples we need. So we can assume henceforth that $n \in \{4, 5, 6\}$. In particular this means there exists a total loop in $\mathcal{Q}_n^3$, by Theorem 7, and a loop with a unique identity element in $\mathcal{Q}_n^d$ for all $d \geq 2$, by Theorem 12. This provides the required examples for $d = 4$, except that we need a quasigroup in $\mathcal{Q}_5^4$ with two identity elements. Let

$$\begin{aligned} Q_a &= [12345.23451.34512.45123.51234], \\ Q_b &= [12345.25413.34251.41532.53124], \\ Q_c &= [12345.25413.34521.43152.51234]. \end{aligned}$$

Then the quasigroup $Q(x_1, x_2, x_3, x_4) = Q_c(Q_a(x_1, x_2), Q_b(x_3, x_4))$, has two identity elements, as required.

By composition with a total loop we will obtain all required examples for $d = 5$ as soon as we find the examples for $d = 3$. Moreover, most of the examples needed for $d = 3$ can be found by applying Theorems 7 and 12. Only one case remains, namely,

we need an example in Q_6^3 with three identity elements. In fact, we give examples of all possible numbers of identity elements in Q_6^3 . Let

$$\begin{aligned} Q_0 &= [124653.213546.431265.652134.546312.365421], \\ Q_1 &= [123456.214365.632514.351642.465231.546123], \\ Q_2 &= [123456.214365.635214.356142.542631.461523], \\ Q_3 &= [123456.214365.632541.351624.546132.465213], \\ Q_4 &= [123456.214365.632514.351642.546231.465123], \\ Q_6 &= [123456.214365.632541.351624.546213.465132]. \end{aligned}$$

For each $i \in \{0, 1, 2, 3, 4, 6\}$, the quasigroup $Q_i \vdash Q_0$ has exactly i identity elements.

6. Incompletable latin cuboids. A natural method of building latin hypercubes is to add hyperplanes one at a time, as we did in section 3. We call the intermediate objects thereby created *latin hypercuboids*. In the three-dimensional case, Kochol [14] used the name “latin parallelepipeds.”

There is celebrated result due to Marshall Hall [10] that every latin rectangle is completable to a latin square. However, the equivalent statement is not true in higher dimensions. Kochol [14] proved that for any k and n satisfying $\frac{1}{2}n < k \leq n - 2$ there is an $n \times n \times k$ latin cuboid which cannot be completed to an $n \times n \times n$ latin cube. Although he did not say so, it is simple to use such examples to create noncompletable $n \times n \times \cdots \times n \times k$ latin hypercuboids in higher dimensions.

It is an open question how “thin” a noncompletable latin hypercuboid can be. In acknowledging that his theorem is not best possible, Kochol [14] alluded to an example of a noncompletable $5 \times 5 \times 2$ latin cuboid, although it seems this example might never have been published. Below we give examples of noncompletable $5 \times 5 \times 2$, $6 \times 6 \times 2$, $7 \times 7 \times 3$, and $8 \times 8 \times 4$ latin cuboids. In the latter two cases it remains open whether there are thinner examples. The $5 \times 5 \times 2$ cuboid cannot be extended even to three layers, while the other examples can be extended to $n \times n \times (n-2)$ latin cuboids, but no further.

$$\begin{aligned} &[12345.21453.34521.45132.53214. \\ &21453.13542.52134.34215.45321], \end{aligned}$$

$$\begin{aligned} &[123456.214365.345612.436521.561234.652143. \\ &214365.125643.456231.362154.643512.531426], \end{aligned}$$

$$\begin{aligned} &[1632745.6173452.2356174.5264317.3417526.7541263.4725631. \\ &2147653.7456231.3715462.6523174.4362715.1634527.5271346. \\ &3715426.1624573.6243751.4176235.2531647.5467312.7352164], \end{aligned}$$

These examples show that Kochol’s theorem is not best possible for $n \in \{5, 6, 7, 8\}$ and hence leave wide open the question of what the best result might be in general. Cutler and Öhman [5] showed for all $a \leq m$ that every $(2mk) \times (2mk) \times a$ latin cuboid can be extended by one layer provided k is sufficiently large.

Appendix. In Tables 3, 4, and 5 we present the number of paratopy classes of latin hypercubes L with each combination of the parameters $d, n, I, P/I$, where d is the dimension, n is the order, $I = |\text{Is}(L)|$, and $P = |\text{Par}(L)|$. Lemma 1 explains how to compute the numbers of hypercubes, reduced hypercubes, and isotopy classes of hypercubes.

A representative of each of these paratopy classes can be found in [21].

THE NINE MORSE GENERIC TETRAHEDRA*

D. SIERSMA[†] AND M. VAN MANEN[‡]

Abstract. There are two types of shapes for a generic triangle—acute and obtuse. These shapes are also distinguished by the (topological) Morse theory of the minimal distance function to the vertices. We can use the same method for a tetrahedron, and we show in this paper that there exist nine generic shapes. These can be described by a Morse poset or by a Gabriel graph. We also report on some computer experiments and compare our classification to another criterion used in computational geometry.

Key words. Morse theory, polyhedra, Voronoi diagram, tetrahedral shape

1. Introduction. Take N points $P_1, \dots, P_N$ in $\mathbb{R}^n$ and consider the function $d : \mathbb{R}^n \rightarrow \mathbb{R}$ defined by

$$d(X) = \min_{j=1, \dots, N} d(X, P_j).$$

We study the evolution of the sets $d_\epsilon = \{X \mid d(X) \leq \epsilon\}$ as ϵ increases. In particular, we are interested in the Euler characteristic χ of d_ϵ . In case ϵ is very small, d_ϵ consists of N small solid spheres. Thus $\chi = N$. If ϵ is very big, then d_ϵ is contractible, and hence $\chi = 1$.

For a generic set of points, d is a topological Morse function. In that case, as ϵ grows, d passes through a number of nondegenerate critical values. When d passes a critical value of index i , an i -cell gets attached.

The number of critical points of index i is s_i . From Morse theory we know that

$$\sum (-1)^i s_i = 1.$$

As an example, take a triangle with an obtuse angle in the plane. This is a special case of the above problem with $n = 2$ and $N = 3$. Assume further that the two legs that encompass the obtuse angle have different lengths. In that case, $s_0 = 3$, $s_1 = 2$, and $s_2 = 0$. For an acute triangle where the edges have different lengths, we obtain $s_0 = 3$, $s_1 = 3$, and $s_2 = 1$. In this sense, there are two different generic triangles.

Returning to the n -dimensional case, each critical point of index i corresponds to a subset of size $i + 1$ of $\{P_1, \dots, P_N\}$, but not every subset of size $i + 1$ corresponds to a critical point of index i . (With the obtuse triangle, the 2-face of the triangle, that is, the triangle itself, does not correspond to a local maximum of the function d .) Thus to the N -point set $P_1, \dots, P_N$ we can associate a set of subsets that correspond to critical points of d . By extension we will call these subsets and the geometric simplices that they span critical as well. This set of subsets is partially ordered by inclusion, and thus it is a poset. We will call it the *Morse poset*.

Question. In $\mathbb{R}^n$, for generic sets of N points, how many different Morse posets are there, up to combinatorial equivalence?

When $N = n + 1$ we thus ask how many “different” generic simplices there are. This is a natural first problem to consider.

In the plane the answer is two; see [Sie99, section 2]. For obtuse triangles, the Morse poset is

$$\{\{P_1\}, \{P_2\}, \{P_3\}, \{P_1, P_3\}, \{P_2, P_3\}\},$$

and for acute triangles, we get the Morse poset

$$\{\{P_1\}, \{P_2\}, \{P_3\}, \{P_1, P_2\}, \{P_1, P_3\}, \{P_2, P_3\}, \{P_1, P_2, P_3\}\}.$$

The main theorem of this article says that in $\mathbb{R}^3$, there are nine different generic tetrahedra (3-simplices).

In the first section, we recall the relevant Morse theory. Then we establish some notation and state what Voronoi diagrams and Gabriel graphs are. Next, we state and prove the main theorem. We also report on numerical experiments concerning volume data of the different compartments of the configuration space where the Morse poset is of a certain type. Finally, we compare our classification to the classification by shape types in [Ede01]. The Morse theoretic approach relates to alpha shapes as defined by Edelsbrunner [EM94].

2. Genericity conditions. We focus here on four points in $\mathbb{R}^3$, but most of the notation and definitions have straightforward extensions to the (n, N) general case.

We write P_{ij} for the middle of the interval P_iP_j , P_{ijk} for the center of the circumscribed circle of the triangle $P_iP_jP_k$, and P_{1234} for the center of the circumscribed sphere of the tetrahedron. For the tetrahedron itself, that is, the convex hull of $\{P_1, P_2, P_3, P_4\}$, we will use the notation $\mathbb{T}$.

We impose the following condition.

GENERICITY CONDITION 2.1. *We require the set of points P_1, P_2, P_3, P_4 to be in general position, so that the convex hull of P_1, P_2, P_3, P_4 is 3-dimensional. Moreover, the points P_{ijk} do not lie on one of the edges of the triangle $P_iP_jP_k$, and also P_{1234} does not lie on one of the planes of the triangles $P_iP_jP_k$.*

Genericity Condition 2.1 means that the function d is not too badly behaved. To express more carefully what that means we recall the definition of a topological Morse function; see [Mor59]. Let $P \in \mathbb{R}^n$, and let f be a continuous real-valued function on $\mathbb{R}^n$.

DEFINITION 2.2. *The function f is topologically regular at $P \in \mathbb{R}^n$ if there is some neighborhood U of P and a homeomorphism $\phi: U \rightarrow U$ such that the composition $f \circ \phi$ is a nonconstant affine function on U . The function f has a critical point at $P \in \mathbb{R}^n$ if f is not topologically regular at P . In that case, P is called a nondegenerate critical point of index i if there is a neighborhood U of P and a homeomorphism $\phi: U \rightarrow U$ such that*

$$f \circ \phi = f(P) - \sum_{j=1}^i x_j^2 + \sum_{j=i+1}^n x_j^2.$$

A topological Morse function is a continuous function that has only regular and nondegenerate critical points.

For topological Morse functions the two crucial statements that hold in the differentiable case—the regular interval theorem and the attachment of cells (see Chapter 5

in [Mil63])—are true as well, as Morse proves in [Mor73]. So, if we show that d is topologically regular, we can apply those theorems, just as was done in [Sie99].

We will need the following notation.

Let

$$\text{Terr}(P_i) = \{X \in \mathbb{R}^3 \mid d(X, P_i) \leq d(X, P_k) \text{ for all } k\}$$

and $V_i = \text{Terr}(P_i)$, $V_{ij} = V_i \cap V_j$ (i different from j), $V_{ijk} = V_i \cap V_j \cap V_k$ (i, j, k different from one another), and $V_{1234} = V_1 \cap V_2 \cap V_3 \cap V_4$.

PROPOSITION 2.3. *The function d is a topological Morse function if Genericity Condition 2.1 is fulfilled. In that case, d is topologically regular in all points of $\mathbb{R}^3$, except in P_1, P_2, P_3, P_4 , where d has a minimum, and (perhaps) in the points P_{ij} , P_{ijk} , and P_{1234} . Moreover, d has*

- a minimum exactly in the points P_1, P_2, P_3, P_4 ,
- a 1-saddle (saddle point of index 1) in P_{ij} iff $P_{ij} = V_{ij} \cap P_i P_j$,
- a 2-saddle (saddle point of index 2) in P_{ijk} iff $P_{ijk} = V_{ijk} \cap P_i P_j P_k$, and
- a maximum in P_{1234} iff $P_{1234} = V_{1234} \cap \mathbb{T}$ (equivalently, $P_{1234} \in \mathbb{T}$).

Proof. If $x = P_i$, then because the points lie in general position all P_j with $i \neq j$ lie at some positive distance from x , so d has a minimum there. If $x \in \text{Terr}(P_i)$ but $x \neq P_i$, then x is obviously topologically regular.

The function d restricted to the interior V_{ij} has a minimum if P_{ij} lies in that interior. This can happen only when $P_{ij} \neq P_{ijk}$, which is ensured by Genericity Condition 2.1.

In the directions, orthogonal to V_{ij} , d decreases, so we see that d has a critical point of index 1 at P_{ij} .

The function d restricted to the interior of V_{ijk} has a minimum at P_{ijk} if P_{ijk} lies in that interior. This can be the case only when $P_{ijk} \neq P_{1234}$. In the directions orthogonal to V_{ijk} , d decreases, so d has a critical point of index 2 at P_{ijk} .

Finally, if $P_{1234} \in \mathbb{T}$, d obviously has a local maximum there. $\square$

Remark 2.4. This statement is well known. One can find it in several places; see, for instance, [Ede04].

Remark 2.5. In the 2-dimensional case the distance function d is always a topological Morse function, whether the points are in general position or not. For a proof, see [Sie99]. It would be interesting to know whether the distance function would always be a topological Morse function in higher dimensions also, irrespective of general position considerations.

The conditions of Proposition 2.3 tell us exactly the positions of the critical points. As explained in the introduction, a critical point determines a subset of the points P_1, P_2, P_3, P_4 , which we call *critical subset*. The *Morse poset* is the set of critical subsets, partially ordered by inclusion. Two sets of points in $\mathbb{R}^3$ are called *combinatorially equivalent* if there exists a bijection between points that sends the critical subsets onto each other. We want to give a classification with respect to this equivalence relation.

Throughout this paper we deal with four points, generic in the sense of Genericity Condition 2.1 and contained in $\mathbb{R}^3$. However, it seems relevant to point out that our problem can be formulated in a more general setting. In the next few definitions we will deal with a point set $\{P_1, \dots, P_N\}$ in $\mathbb{R}^n$ without making any genericity assumptions.

DEFINITIONS 2.6. *A subset $\{P_i\}_{i \in I}$ belongs to the Delaunay triangulation if there are points $X \in \mathbb{R}^n$ with $d(X, P_i) = d(X, P_j)$ for all pairs $\{i, j\} \subset I$ and $d(X, P_i) < d(X, P_j)$ for all pairs $\{i, j\}$ with $i \in I$ and $j \notin I$. The Voronoi cell of such a subset $\{P_i\}_{i \in I}$ consists of the points $X \in \mathbb{R}^n$ that make the subset part of the Delaunay*

triangulation. The Delaunay cell of such a subset $\{P_i\}_{i \in I}$ is simply the convex hull of $\{P_i\}_{i \in I}$.

In particular, all subsets of cardinality 1 are part of the Delaunay triangulation. For each $1 \leq i \leq N$ we denote the closure of the Voronoi cell of P_i by $\text{Terr}(P_i)$, because such a Voronoi cell is best thought of as a territory with capital P_i .

The union of all $< n$ dimensional Voronoi cells is usually called the Voronoi diagram. In fact, the closure of any $(n - 1)$ -dimensional Voronoi cell is always the intersection of exactly two sets $\text{Terr}(P_i)$ and $\text{Terr}(P_j)$. Thus, dual to the Voronoi diagram we have the 1-skeleton

$$\{P_i P_j \mid \dim(\text{Terr}(P_i) \cap \text{Terr}(P_j)) = n - 1\}.$$

The Gabriel graph (see [BKOS97], where it is defined in $\mathbb{R}^2$) is a subset of this skeleton: it consists of those edges $P_i P_j$ such that the circumball with poles P_i and P_j does not contain any of the other points in the point set $\{P_1, \dots, P_N\}$. The Gabriel complex (see [AGJ00]) is the subcomplex of the Delaunay triangulation, generated by those $(n - 1)$ -dimensional Delaunay cells whose smallest circumball does not contain any of the other points.

Remark 2.7. General position is defined in this more general case as follows. We require that for each subset $\{P_i\}_{i \in I}$ in the Delaunay triangulation the possibly empty intersection of the Delaunay cell and the Voronoi cell is contained in both the relative interior of the Delaunay and the relative interior of the Voronoi cell. For more details, see [Ede01] and [EM94].

QUESTION 2.8. What is the relation between the Morse poset and the Gabriel graph and complex? The edge between P_i and P_j is part of the Gabriel graph iff the point P_{ij} is a saddle point (index 1) of d . These are exactly the critical subsets of size 2 of the Morse poset. In the 3-dimensional case a face between P_i , P_j , and P_k is part of the Gabriel complex iff the point P_{ijk} is a saddle point (index 2) of d . These are precisely the critical subsets of size 3 of the Morse poset. But the Gabriel complex also contains by definition the boundaries of those 2-simplices, while for the Morse poset this is not automatically the case. So the Morse poset is not a simplicial complex and can differ from the Gabriel complex. See examples of tetrahedrons of type $(4, 5, 3, 1)$ in the next section.

The Morse poset contains the information from both the Gabriel graph and the Gabriel complex. Two Morse posets can be combinatorially equivalent only if the underlying Gabriel graph and Gabriel complex are the same.

3. The main classification. From Proposition 2.3 we know the maximal number of critical points of each type. Moreover, the Euler characteristic is $+1$: $s_0 - s_1 + s_2 - s_3 = 1$. This gives a priori the following 9 possibilities:

s_0	s_1	s_2	s_3
4	6	4	1
4	5	3	1
4	4	2	1
4	3	1	1
4	2	0	1
4	6	3	0
4	5	2	0
4	4	1	0
4	3	0	0

But not all possibilities will occur. Since we start with four vertices and the result should be a connected space, we need at least three saddle points of index 1. This rules out the possibility $(4, 2, 0, 1)$.

FIG. 1. List of possible Gabriel graphs. The vertices are the minima of the distance function. Each vertex of the tetrahedron $\mathbb{T}$ is a minimum of d . There are no other minima. The edges of the graph are the index 1 critical points of the distance function. Not each midpoint of an edge of $\mathbb{T}$ is an index 1 critical point of the distance function d . The graph $(4410)O$ can be laid out so as to form the letter “O.” The names of the other graphs are chosen similarly.

We list in Figure 1 the (a priori) possible Gabriel graphs for the above cases; they are the connected graphs with four vertices. Just as the cases $(4, 2, 0, 1)$ cannot occur, we will prove in this section by deriving a contradiction that the cases $(4, 4, 2, 1)P$, $(4, 3, 1, 1)T$, and $(4, 3, 1, 1)L$ do not occur. We will prove our main theorem.

THEOREM 3.1. *Up to combinatorial equivalence of their Morse posets there are nine generic tetrahedra. They are uniquely described by the nine Gabriel graphs $(4, 6, 4, 1)$, $(4, 6, 3, 0)$, $(4, 5, 3, 1)$, $(4, 5, 2, 0)$, $(4, 4, 2, 1)O$, $(4, 4, 1, 0)O$, $(4, 4, 1, 0)P$, $(4, 3, 0, 0)L$, and $(4, 3, 0, 0)T$, drawn in Figure 1.*

Proof. We have to exclude $(4, 3, 1, 1)T$, $(4, 3, 1, 1)L$, and $(4, 4, 2, 1)P$ from the list. In these cases M is critical. We first pay attention to the following.

3.1. Saddle points of index 1. We consider the plane E through $P_1P_2P_3$ (and set it as the “ground plane” in the picture). The half space containing P_4 is called “above,” and the other is called “below.”

We are going to consider the condition that the point $Y = P_{i4}$ is critical. We first make no assumptions about the triangle $P_1P_2P_3$ except that it does not have a right angle. We consider the point $X = P_4$ as a variable and denote its projection on the E -plane by X' . Let $Y = P_{14}$ and its projection be Y' . From the condition

that $Y = P_{14}$ is critical we get

$$d(P_1, Y) = d(P_4, Y) < \min \{d(P_2, Y), d(P_3, Y)\}.$$

The inequality is strict because of Genericity Condition 2.1.

For the projection, this means that in terms of Voronoi diagrams in E ,

$$Y' \in \text{Interior}(\text{Terr}(P_1)).$$

In terms of the projection X' , this means

$$X' \in \text{Interior}(2\text{Terr}(P_1)),$$

where by $2\text{Terr}(P_1)$ we mean scalar multiplication of $\text{Terr}(P_1)$ by a factor 2 from the point P_1 .

We can do the same for P_{24} and P_{34} . We get three subsets $2\text{Terr}(P_1)$, $2\text{Terr}(P_2)$, and $2\text{Terr}(P_3)$, which cover the plane E . They divide the plane into regions, where one, two, or three of the points P_{14} , P_{24} , or P_{34} are critical.

Inside the plane E , the border of $\text{Terr}(P_i)$ consists of two half lines that meet in P_{123} . The scalar multiplication by 2 maps P_{123} to P_i^* , the antipodal point of P_i on the circle through P_1 , P_2 , and P_3 .

Next, look at the case of an acute triangle drawn in Figure 2.

FIG. 2. The plane E when the triangle is acute.

The regions where only one P_{i4} is critical are all outside the disc D , which is bounded by the circumscribed circle of triangle $P_1P_2P_3$.

The picture for the obtuse case is in Figure 3.

Let P_2 be the vertex with the obtuse angle. We see that the region where only P_{24} is critical is outside D but that the regions where P_{14} or P_{34} is the only critical point can have some intersections with D .

3.2. The center M of the circumscribed sphere. We assume again that $P_1P_2P_3$ lies in the plane E . We know that $M = P_{1234}$ belongs to the axis of the triangle $P_1P_2P_3$, so its projection is $M' = P_{123}$. Fix M for the moment, and consider

FIG. 3. The plane E when the triangle is obtuse. Indicated are the territories $2\text{Terr}(P_i)$, $i = 1, \dots, 3$, and their intersections.

$X = P_4$ as a variable. Possible positions of $X = P_4$ are on the sphere with center M and radius $r = d(P_1, M) = d(P_2, M) = d(P_3, M)$. Denote by $P_1^*P_2^*P_3^*$ the mirror image of $P_1P_2P_3$ after central reflection through P_{123} .

In the cases we wish to exclude, M is critical. In other words, the distance function has a local maximum in M , and M lies inside the tetrahedron. The point X must lie in the double cone with apex M and base the triangle $P_1P_2P_3$, but also on the sphere (M, r) . Consider the plane E'' , which is the image of E by central reflection through M . E'' is parallel to E . The cone intersects the plane in a triangle, whose orthogonal projection onto the plane E is the triangle $P_1^*P_2^*P_3^*$. X belongs to a part of the cap of the sphere, which lies “above” E'' (seen from M). It follows that X projects to a point X' which lies inside the disc D . This is true for any position of M . For the acute case this is all we need to conclude that it is not possible that M and only one P_{i4} are critical. In the obtuse case we have to use additional arguments to get to this same conclusion. Let P_2 be the obtuse angle. Recall that M is critical iff it belongs to the interior of the tetrahedron $P_1P_2P_3X$. Equivalently, X' lies in the interior of the reflected triangle, that is, in $P_1^*P_2^*P_3^*$. This triangle is contained in the sector $P_1^*M'P_3^*$, which implies that M is critical only if X' lies in the interior of this sector (the one which does not contain P_2). We combine the conditions for M to be critical and one single P_{i4} is critical. From the geometric observations above it follows that the combination of M being critical and a single P_{i4} being critical cannot occur together.

Next choose the appropriate labels for the vertices of the tetrahedron: In cases $(4, 3, 1, 1)T$ and $(4, 3, 1, 1)L$ the ground plane should contain two adjacent critical edges, and in case $(4, 4, 2, 1)P$ it should contain the triangle with the three critical edges. This observation rules out the graphs $(4, 3, 1, 1)T$, $(4, 3, 1, 1)L$, and $(4, 4, 2, 1)P$.

3.3. Positions of index 2 saddles. We are left with nine possibilities of Gabriel graphs. The Gabriel graphs do not give a complete picture of the combinatorics of the Morse points. The Gabriel graph, together with the information on whether M is a critical point or not, tells us only the number of saddles of index 2, but not the position.

LEMMA 3.2. *Generic tetrahedra with isomorphic Gabriel graphs have combinatorially equivalent Morse posets.*

Proof. We need to prove that in all cases there are unique positions for the 2-saddles.

(4, 6, 4, 1): Unique positions (no choices).

(4, 5, 3, 1): There are two triangles, where all three midpoints are critical. Both triangles must be acute. Take one of them in the “ground plane” and assume it to be $P_1P_2P_3$. Since P_{1234} is critical, P_{1234} lies on the same side as P_4 . It follows that V_{123} must intersect the ground plane in the point P_{123} , so that point is critical. The same reasoning applies to the second triangle; this fixes the position of two 2-saddles. The two positions left for the third saddle are combinatorially equivalent.

(4, 4, 1, 0) O : All positions equivalent.

(4, 4, 2, 1): Suppose P_{12} is not critical. Now P_3 or P_4 must be contained in the ball $B = B(P_{12}, r_{12})$, where $r_{12} = d(P_1, P_{12})$. If P_{123} is critical, then triangle $P_1P_2P_3$ must be acute; this means that P_3 is outside the ball B . If P_{124} is critical, then triangle $P_1P_2P_4$ must be acute; this means that P_4 is outside the ball B . It follows that the situation where two 2-saddles are separated by a noncritical edge cannot occur. This fixes the places of the 2-saddles up to permutation.

(4, 6, 3, 0): All positions equivalent.

(4, 5, 2, 0): Choose a triangle, say, $P_1P_2P_3$, where all three edges are critical. If P_{123} is not critical, then it follows that P_{1234} lies below the ground plane E . We look again at the projection P'_4 . First P'_4 must lie inside D . But since two of the P_{i4} (say, P_{14} and P_{24}) must be critical, we know that P'_4 also must lie in the region described in section 3.1. The intersection is a subset of D , which is contained in the region D^* bounded by the arc $P_1P_3^*P_2$ and by the edges $P_2P_3^*$ and $P_3^*P_1$. There are still other conditions to meet:

- P_4 must lie outside the ball $B(P_{12}, r_{12})$, since P_{12} is critical.
- P_4 must lie inside the ball $B(P_{123}, r_{123})$, where $r_{123} = d(P_1, P_{123})$.

This is not simultaneously possible if P'_4 lies in D^* . It follows that there is only one possibility: the 2-saddles are the centers of two triangles with all edges critical.

(4, 4, 1, 0) P : Let $P_1P_2P_3$ be the triangle with all three midpoints of the edges critical. This triangle is acute; take its plane as ground plane. If P_{1234} is above the ground plane, then P_{123} is critical. Assume now that P_{1234} is below the ground plane. It follows that P'_4 lies inside the disc D . But the fact that only P_{14} is critical means that P'_4 is outside. This is a contradiction, so only P_{123} can be critical.

(4, 3, 0, 0) T : All places equivalent.

(4, 3, 0, 0) L : All places equivalent. $\square$

3.4. Existence and statistics. We carried out some statistical experiments to see how the different types of tetrahedra are distributed among different 4-tuples of points. That all the cases do occur follows from the computer experiments described below. As a consequence all nine generic tetrahedrons are realized and the proof of Theorem 3.1 is complete. $\square$

Four points in $\mathbb{R}^3$ do not form a bounded space, and thus there lives no uniform probability distribution on it. As the Morse poset is invariant under translations, scaling, and rotations, without loss of generality we can assume that all four points lie on S^2 . By translation and scaling, this can always be achieved. We consider the configuration space of different points in S^2 . The nongeneric tetrahedra form a hypersurface (of measure zero) in this space—the discriminant hypersurface.

The uniform distribution on $[0, 1]^2$ leads (as Archimedes already used) to a uniform distribution on the 2-sphere by the map $\gamma : [0, 1]^2 \rightarrow S^2 \subset \mathbb{R}^3$ given by

$$\gamma(a_1, a_2) = (\sin(\arccos(2a_1 - 1)) \sin(2\pi a_2), \sin(\arccos(2a_1 - 1)) \cos(2\pi a_2), 2a_1 - 1).$$

We take two random numbers in $[0, 1]$ and map them to S^2 using γ .

For our experiment we used the Gnu Scientific Library; see [Gal06]. This library has an implementation of the apparently very reliable MT19937 random number generator. Two random numbers in $[0, 1]$ were mapped to S^2 using γ . We took samples of 10^8 tetrahedra. Here is one:

1	(4, 3, 0, 0) L	17,807,919
2	(4, 3, 0, 0) T	898,689
3	(4, 4, 1, 0) O	26,224,574
4	(4, 4, 1, 0) P	16,421,773
5	(4, 5, 2, 0)	24,350,101
6	(4, 6, 3, 0)	1,797,721
7	(4, 4, 2, 1)	3,266,345
8	(4, 5, 3, 1)	2,697,783
9	(4, 6, 4, 1)	6,535,095

Other samples gave approximately the same numbers, with a maximum difference of 3000.

For three random points on the circle, it is a simple exercise to see that chances are 3 out of 4 that one gets an obtuse triangle. These results indicate that for four random points on the unit sphere the chances are 7 out of 8 that the center of the unit sphere is a local maximum for the distance function. Indeed, the last three entries of the above table add up to 12,499,223. Doubtlessly, a more general statement can be proven here.

4. Notes and remarks.

4.1. Discrete Morse functions. A natural question is the existence of a discrete Morse function (in the sense of Forman) [For02] on the tetrahedron, which realizes the same effect as the minimal distance function. The question is discussed extensively in [vMS05]. It turns out that the corresponding discrete function contains more information than the Morse poset. It also includes, e.g., information about the critical values. Taking into account the critical values, one can make a much finer classification, which distinguishes, e.g., in the (4, 6, 4, 1) case, between an almost regular tetrahedron and one with a small acute base triangle and a top vertex far away. Another related concept is the alpha shape as discussed in, e.g., [EM94], which has applications in molecular shape analysis.

4.2. Higher dimensional results. We have not been able to prove a classification theorem in $\mathbb{R}^n$. However, upon request the authors will send interested readers a computer program that calculates the list in higher dimensions by just trying a lot of random point sets.

Except for the results in [Sie99] on four points in the plane we have no results on the number of Morse posets for N points when $N > n + 1$.

4.3. Edelsbrunner ratio.

DEFINITION 4.1. *The Edelsbrunner ratio ρ is the radius R of the circumsphere of $\mathbb{T}$ divided by the minimal edge length $\min_{i \neq j} d(P_i, P_j)$.*

The ratio is used by Edelsbrunner (see [Ede01, section 6.2]) to classify tetrahedra into “shape types.” This article has the same objective, so it is worthwhile to compare his criterion to ours.

For each of the nine generic types of tetrahedra the ratio ρ is bounded from below by the values in the table below. The infimum corresponds to the quadruple of points in the third column. These quadruples are not generic tetrahedra, except for the case $(4, 6, 4, 1)$, which corresponds to the global minimum of ρ .

Type	Ratio ρ	Infimum
$(4, 3, 0, 0) L$	$\frac{1}{2}\sqrt{3}$	$(0,0,0), (1,0,0), (1,1,0), (1,1,1)$
$(4, 3, 0, 0) T$	$\frac{1}{2}\sqrt{3}$	$(1,0,0), (0,1,0), (0,0,1), (0,0,0)$
$(4, 4, 1, 0) P$	$\sqrt{\frac{7}{12}}$	$(\frac{1}{2}\sqrt{3}, -\frac{1}{2}, 0), (-\frac{1}{2}\sqrt{3}, -\frac{1}{2}), (0,1,0), (0,1,\sqrt{3})$
$(4, 4, 1, 0) O$	$\frac{1}{2}\sqrt{2}$	$(0,0,0), (1,0,0), (1,1,0), (0,1,0)$
$(4, 5, 2, 0)$	$\frac{1}{2}\sqrt{2}$	$(0,0,0), (1,0,0), (1,1,0), (0,1,0)$
$(4, 6, 3, 0)$	$\frac{1}{2}\sqrt{2}$	$(\cos \alpha_j, \sin \alpha_j, 0) \ j = 1, \dots, 3, (0,0,1)$
$(4, 4, 2, 1)$	$\frac{1}{2}\sqrt{2}$	$(1,0,0), (0,1,0), (0,-1,0), (\cos \alpha, 0, \sin \alpha)$
$(4, 5, 3, 1)$	$\frac{1}{2}\sqrt{2}$	$(1,0,0), (0,1,0), (0,-1,0), (0,0,1)$
$(4, 6, 4, 1)$	$\frac{1}{4}\sqrt{6}$	$(0,1,0), (\frac{1}{2}\sqrt{3}, -\frac{1}{2}, 0), (-\frac{1}{2}\sqrt{3}, -\frac{1}{2}, 0), (0,0,\sqrt{2})$

For the case $(4, 6, 3, 0)$ the triangle $P_1P_2P_3$ is acute. For the case $(4, 4, 2, 1)$ the angle α should satisfy $-\frac{\pi}{2} \leq \alpha \leq 0$.

Hence, small values of ρ can be attained by all the types listed in Theorem 3.1. One can see from this that the two classifications are incomparable and conclude that they define different features.

WALKERS ON THE CYCLE AND THE GRID*

J. DÍAZ[†], X. PÉREZ[†], M. J. SERNA[†], AND N. C. WORMALD[‡]

Abstract. We present a model of the establishment and maintenance of communication between mobile agents. We assume that the agents move through a fixed environment modeled by a motion graph and are able to communicate if they are within distance at most d of each other. As the agents move randomly, we analyze the evolution in time of the connectivity between a set of w agents, asymptotically for a large number N of vertices, when w also grows large. The particular topologies of the environment we study here are the cycle and the toroidal grid.

Key words. mobile agents, ad hoc network, connectivity, distance graph

1. Introduction. Consider a setting in which a large number of mobile agents can perform concurrent basic movements: either ahead/behind/left/right, determining a grid pattern, or left/right, describing a line. Each agent can communicate directly with any other agents which are within a given distance d . This enables communications with agents at a further distance using several intermediate agents. At each step in time there is an ad hoc network defined by the dynamic graph whose vertex set consists of the agents, with an edge between any two agents iff they are within distance d of each other.

Various aspects of such networks (connectivity, transport capacity, protocols, etc.) have been studied in the static case, i.e., the case in which the agents are randomly placed but fixed (see, for example, [XK06, H06] and references therein). Also, there has been quite a bit of experimental study dealing with the dynamic situation, i.e., the situation in which the agents are mobile: connections in the network are created and destroyed as the agents move further apart or closer together; see, for example, [AGE02, JBAS03, RMM01]. The paper [GHSZ] also deals with the problem of maintaining connectivity of mobile agents communicating by radio frequency, but from a perspective orthogonal to the one in the present paper. It describes a *kinetic data structure* to maintain the connected components of the union of unit-radius disks moving in the plane.

To the best of our knowledge, ours is the first work in which the dynamic features of such a network are studied theoretically. Moreover, we obtain much sharper results on the static properties than previously obtained for this type of network. In the static case, our results bear a strong resemblance to analogous results for similar problems of random points in continuous spaces (see Holst [H80] and Penrose [P97], [P99]). The

study of the behavior of multiple, simultaneous random walks has its own merits and could have further applications in computer science.

We propose what we call the *walkers model*, defined as follows. A connected graph $G = (V, E)$ with $|V| = N$ is given, as well as a number w of *walkers* (agents). Also given is a “distance” d . A set W of walkers, with $|W| = w$, is placed randomly and independently on the vertices of G (a vertex may contain more than one walker). Each walker has a range d for communication; that is, two walkers w_1 and w_2 can communicate in one hop if the distance, in G , between the position of the walkers is at most d . Two walkers can communicate if they can reach each other by a sequence of such hops. In addition, each walker takes an independent standard random walk on G , i.e., moves at each time step to a neighboring vertex, each neighbor chosen with equal probability.

The interesting features of the walkers model are encapsulated by the *random graph of walkers*, $\mathcal{W}(G, w, d)$. This random graph is generated using a random assignment $f : W \rightarrow V$ of walkers into the vertices of G . The vertices of $\mathcal{W}(G, w, d)$ are the vertices in G that receive at least one walker, two vertices in $\mathcal{W}(G, w, d)$ being joined by an edge iff they are at distance at most d in G . We are interested in the probability of $\mathcal{W}(G, w, d)$ being connected, or in the number of components and their sizes, with certain mild asymptotic restrictions on w and d .

Our primary goal with the walkers model is to characterize the dynamics of the connectivity of the communication network as represented by the random graph process $(\mathcal{W}_t(G, w, d))_{t \geq 0}$. Here $\mathcal{W}_t(G, w, d)$ denotes the graph of walkers at time $t = 0, 1, \dots$, and, at each time step, each walker simultaneously moves one step to a randomly selected neighbor vertex in G . In order to study this model, we first examine $\mathcal{W}(G, w, d)$, which we call the *static* model. This is a snapshot of the process at one point in time: we are interested in the distribution of the number of components, as well as some other information which helps to answer the dynamic questions. In particular, we are interested in studying the birth and death of components and the sudden connection and disconnection of $\mathcal{W}_t(G, w, d)$. We generally abbreviate $\mathcal{W}(G, w, d)$ to $\mathcal{W}(G)$ when w and d are understood and, similarly, $\mathcal{W}_t(G, w, d)$ to $\mathcal{W}_t(G)$.

We consider a sequence of graphs G with increasing numbers of vertices N for N tending to infinity. The parameters w and d are functions of N . We restrict our attention to the case $w \rightarrow \infty$ in order to avoid considering small-case effects. Of course we take $d \geq 1$. We make further restrictions on w and d in order to rule out noninteresting cases, such as values of the parameters in which the network is a.a.s. disconnected or a.a.s. connected. (Throughout this paper, a.a.s. will abbreviate “asymptotically almost surely,” which denotes “with probability tending to 1 as $N \rightarrow \infty$.”) We study the walkers model for two particular sequences of graphs G : the cycle C_N of length N and the $n \times n$ toroidal grid T_N of size $N = n^2$. (In the case of the grid, we use the ℓ^p distance for any $1 \leq p \leq \infty$.) The two cases have an essential difference that prevents a unified treatment: for the interesting values of w and d , disconnectedness of the graph of walkers for the cycle is basically caused by the presence of at least two large “gaps” between the walkers around the cycle, whereas for the grid, it is caused by the presence of one or more isolated walkers.

We now give a description of some of our main results. Throughout this paper, ϱ denotes w/N , which is the expected number of walkers at a vertex.

1.1. The cycle. First we consider the cycle C_N on N vertices. We will show that if $d = \Omega(N)$, then $\mathcal{W}(C_N)$ is a.a.s. connected, so all results here refer to $d = o(N)$.

To study connectedness in this case, we introduce the concept of a *hole*. There is a *hole* between two vertices u and v if u and v each contain at least one walker, but no vertex in the clockwise path from u to v contains a walker. We say that such a hole *follows* u or that u is the *start vertex* of the hole. The number of internal vertices in a hole is its *exact size*. A k -*hole* is a hole whose exact size is at least k .

Let H be the random variable counting the number of d -holes in the walkers model for C_N . Notice that at least two d -holes are needed to disconnect the walkers on C_N . To be precise,

$$(1) \quad \mathcal{W}(C_N) \text{ is connected iff } H \leq 1.$$

We define a new parameter $\mu = N(1 - e^{-\varrho})e^{-d\varrho}$, which plays a key role in characterizing the connectedness of $\mathcal{W}(C_N)$. It is straightforward to check that

$$\mu \sim \begin{cases} we^{-d\varrho} & \text{if } \varrho \rightarrow 0, \\ N(1 - e^{-\varrho})e^{-d\varrho} & \text{if } \varrho \rightarrow c, \\ Ne^{-d\varrho} & \text{if } \varrho \rightarrow \infty. \end{cases}$$

Here, and throughout the paper, asymptotics refer to $N \rightarrow \infty$ unless otherwise stated.

Regarding the behavior of H , and connectedness, we have the following.

THEOREM 1.1. *The expected number of holes satisfies $\mathbf{E}[H] \sim N(1 - e^{-\varrho})(1 - d/N)^w$. Furthermore,*

- (i) *if $\mu \rightarrow 0$, then $\mathcal{W}(C_N)$ is connected a.a.s.,*
- (ii) *if $\mu \rightarrow \infty$, then $\mathcal{W}(C_N)$ is disconnected a.a.s., and*
- (iii) *if $\mu = \Theta(1)$, then H is asymptotically Poisson with mean μ .*

The following corollary gives the asymptotic probability that $\mathcal{W}(C_N)$ is connected. It follows immediately from the theorem in view of (1).

COROLLARY 1.2. $\mathbf{P}(\mathcal{W}(C_N) \text{ is connected}) = e^{-\mu}(1 + \mu) + o(1)$.

We now turn to dynamic properties of the random graph of walkers on the cycle. One of our main end results concerns the expected time that the graph of walkers remains disconnected after a point in time at which it becomes disconnected. Define a *disconnected period* to be a maximal sequence of consecutive time steps for which the graph of walkers $\mathcal{W}_t(C_N)$ is disconnected. We define for $t > 0$

$$LD_t = \begin{cases} \max\{k \in \mathbb{N} \mid \mathcal{W}_t(C_N), \dots, \mathcal{W}_{t+k-1}(C_N) \text{ disconnected}\} & \text{if } \mathcal{W}_{t-1}(C_N) \\ & \text{is connected,} \\ 0 & \text{otherwise.} \end{cases}$$

This is the random variable counting the length of the disconnected period starting at time step t provided that it really starts then. Formally we define the *average length* of a disconnected period starting at time t to be

$$LD_{\text{av}} := \mathbf{E}[LD_t \mid LD_t > 0].$$

By symmetry, this is independent of t and so is a function of N , d , and w . The next result finds its size.

THEOREM 1.3. *For the walkers model on the cycle C_N , the average length of a disconnected period of $(\mathcal{W}_t(C_N))_{t \geq 0}$ satisfies*

$$LD_{\text{av}} \sim \begin{cases} 2 \frac{e^\mu - 1 - \mu}{\mu^2} \varrho^{-1} & \text{if } \varrho \rightarrow 0, \\ \frac{e^\mu - 1 - \mu}{1 + \mu - (1 + \mu + \lambda + \lambda^2)e^{-\lambda}} & \text{if } \varrho \rightarrow c, \\ \frac{e^\mu}{1 + \mu} & \text{if } \varrho \rightarrow \infty, \end{cases}$$

where $\lambda = (1 - \frac{3e^{-e} - e^{-\frac{3}{2}e}}{1 + e^{-\frac{1}{2}e}})\mu$. Here $0 < \lambda < \mu$ for $\varrho \rightarrow c$.

To convey a feeling of the complexity of the question of how long a network remains disconnected once it becomes so, we introduce the following *train paradox*. A visitor to Barcelona goes every morning to Catalunya station, where there are two metro lines meeting (red and green), though at different levels. He wishes to measure the average length of a train. Since there is plenty to see in Barcelona, each morning he chooses either the red line or the green line at random. He waits for the first train to leave on that line and records its length. He finds after many days that the average length recorded is 9 cars. But he notices that, restricted to the days that the train is already at the platform when he arrives, the average length is only 8 cars.

Could it be that the shorter trains wait longer for him? No, because the trains in Barcelona stop at stations for equal times. Moreover, on any given line they arrive regularly at equally spaced intervals, so the well-known bus paradox does not directly apply.

Which is a better measure—the length of the first train to arrive or the length of trains arriving at a prescribed time? The former, yielding the answer 9, might seem more natural at first. However, the explanation for the differing answers reveals the other to be meaningful, and perhaps even more so. The data above, in both versions of the paradox, arise if the red line has trains of average length 12 arriving every 10 minutes, and the green line has trains of average length 6 arriving at 5 minute intervals. In an extended time period, recording all the lengths of trains on all lines will yield 8 as the average.

Returning to the walkers model, as we shall see in section 3, when N is even there are many different configurations of walkers that cannot arise from a given initial configuration. As a Markov chain, the process is not ergodic; each configuration belongs to a class of mutually reachable configurations. The different classes of states correspond to different metro lines in the train paradox. The quantity LD_{av} in Theorem 1.3 is roughly equivalent to our traveler's measurement of the length of trains restricted to those days that a train is just arriving. However, the train paradox shows that this is not the only reasonable measure of average length. Moreover, the situation is even more complicated, as the train paradox would be if the intertrain time periods were variable on a given line. The average length of the first train to arrive would then be affected by any dependence between the length of a train and the time before the previous train. We wish to study the analogue of the average length of trains on a given metro line—the average length of a period of disconnection given the initial state. If N is divisible by 2 and the initial configuration is conditioned upon, the walkers process is “locked in” to a future in which the (conditional) average length of connected periods may be different from LD_{av} . However, we show that for almost all initial configurations this average is essentially asymptotically equal to LD_{av} . For $T \in \mathbb{Z}^+$, we define the *average disconnection time* of the graph of walkers in $[1, T]$ to be

$$LD_T = \frac{\sum_{t=1}^T LD_t}{|\{t \in \{1, \dots, T\} : LD_t > 0\}|}.$$

We show that LD_T converges in probability as $T \rightarrow \infty$ to a random variable which may depend on the class of the initial state but nothing else. (Actually, the value is in general different for different classes.) The notation $f \sim g$ a.a.s. used in the following theorem denotes that for all $\epsilon > 0$, a.a.s. $|f/g - 1| < \epsilon$ (see, for example, [W04]).

THEOREM 1.4. *For the walkers model on C_N , LD_T converges in probability as*

$T \rightarrow \infty$ (with N fixed) toward a random variable LD , uniquely determined almost everywhere. Furthermore, (as $N \rightarrow \infty$) we have $LD \sim LD_{\text{av}}$ a.a.s.

Intuitively, LD is the average length of the disconnected periods appearing in all the trajectories of the random process starting from the initial state.

In section 3.2 we give analogous results for maximal connected periods of $\mathcal{W}(C_N)$ (see Theorems 3.10 and 3.11).

During our examination of the cycle, we derive an incidental result (Corollary 3.7) on the expected time required before a certain infinite set of random walkers sprinkled on the nonnegative integers meets another such set sprinkled on the negative integers.

1.2. The grid. We turn now to the toroidal grid T_N with $N = n^2$ vertices, for which our results apply with any normed ℓ^p distance, for $1 \leq p \leq \infty$. We will show that if $d = \Omega(n)$, then $\mathcal{W}(T_N)$ is a.a.s. connected, so all results here refer to $d = o(n)$. We define h to be the number of grid points within distance d of any fixed point in T_N . This depends on the particular metric chosen, but in all cases it is easy to see that $h = \Theta(d^2)$.

We call a component of $\mathcal{W}(T_N)$ *simple* if it is formed by only one isolated vertex. Let X be the number of simple components. To examine the connectedness of $\mathcal{W}(T_N)$, we need to redefine the μ used for the cycle. For the following grid results, $\mu = N(1 - e^{-\varrho})e^{-h\varrho}$. Hence

$$\mu \sim \begin{cases} we^{-h\varrho} & \text{if } \varrho \rightarrow 0, \\ N(1 - e^{-\varrho})e^{-h\varrho} & \text{if } \varrho \rightarrow c, \\ Ne^{-h\varrho} & \text{if } \varrho \rightarrow \infty. \end{cases}$$

THEOREM 1.5.

- (i) For $\mu \rightarrow \infty$, $\mathcal{W}(T_N)$ is disconnected a.a.s.
- (ii) For $\mu = \Theta(1)$, a.a.s. all but one component of $\mathcal{W}(T_N)$ are simple, and the number X of simple components is asymptotically Poisson with expected value μ .
- (iii) For $\mu \rightarrow 0$, $\mathcal{W}(T_N)$ is connected a.a.s.

The theorem immediately gives the following.

COROLLARY 1.6. $\mathbf{P}(\mathcal{W}(T_N) \text{ is connected}) = e^{-\mu} + o(1)$.

For dynamic considerations, we also need a function $b = \Theta(d)$ which is related to the boundary of a ball of radius d in the grid. Like h , this function also depends on the metric. It is defined in section 4.2.

We define LD_{av} and LD_T for disconnected periods as for the cycle case above.

THEOREM 1.7. For the walkers model on the grid T_N with $d > 1$,

$$LD_{\text{av}} \sim \begin{cases} \frac{e^\mu - 1}{\mu b \varrho} & \text{if } d\varrho \rightarrow 0, \\ \frac{e^\mu - 1}{1 - e^{-\lambda}} & \text{if } d\varrho \rightarrow c, \\ e^\mu & \text{if } d\varrho \rightarrow \infty, \end{cases}$$

where $\lambda = (1 - e^{-b\varrho})\mu$. Here $0 < \lambda < \mu$ for $d\varrho \rightarrow c$. Furthermore, LD_T converges in probability for T growing large (N fixed) toward a random variable LD , uniquely determined almost everywhere, where $LD \sim LD_{\text{av}}$ a.a.s.

The case $d = 1$ is excluded for this result because of a technical complication that will be explained in the proofs, though our basic approach could be modified to deal with this case also. We also obtain exactly the same result as in Theorem 1.7 for connected periods as opposed to disconnected periods.

The remainder of the paper gives proofs of these theorems as well as stating and proving related ones. In section 2 we give basic definitions and technical lemmas to be used throughout the paper. In section 3 we deal with the cycle C_N , and in section 4 the toroidal grid T_N . One of the main differences between this case and the cycle is the need for a geometric lemma that may be of independent interest (Lemma 4.3). This bounds from below the number of nonoccupied vertices at distance at most d from the boundary of any connected component in $\mathcal{W}(T_N)$, as a function of a measure of the length of the boundary. The last section contains some discussion and related problems.

2. General definitions and basic results. We begin with some definitions and results which are common for all G . We call a component *simple* if it is formed by only one isolated vertex. Recall that $\varrho = w/N$ is the expected number of walkers at a vertex. For any $v \in V$, define h_v to be the number of vertices in G at distance at most d from v , and define $h = \min_{v \in V} h_v$. We say that a vertex or set of vertices is *empty of walkers* (*e.o.w.*), or simply *empty*, if it contains no walkers, and *occupied* otherwise. Note that there must be h empty vertices in G within distance d of a simple component.

By considering the coupon collector's problem, we observe that if $w = N \log N + \omega(N)$, then $\mathcal{W}(G, w, d)$ is trivially a.s. connected due to every vertex being occupied. Moreover, for the graphs G which we consider in this paper, if $h \in \Omega(N/\sqrt{w})$, then $\mathcal{W}(G, w, d)$ is a.s. connected as well. This last claim will be seen in Observations 3.1 and 4.1. Thus, we consider throughout the paper $w < N \log N + O(N)$ and $h = o(N/\sqrt{w})$. In fact, our proofs will just assume h to be $o(N)$. Note that, for the cycle, $h = 2d$.

We will need to compute the probability of certain configurations of walkers at two consecutive time steps t and $t+1$ in order to record the event that walkers jump to the appropriate place at that step. There is a convenient way to formulate this in terms of occupancy of directed edges. Let us regard G as a directed graph by considering each edge as a symmetric pair of directed edges. For any directed edge e going from vertex u to v , we say that a walker is on e between time steps t and $t+1$ if the walker is on u at time step t and jumps onto v within one step. Note that in this way we can encode dynamic transitions in terms of static configurations of walkers.

There is an alternative formulation in terms of cells. Each vertex is divided into as many cells as its degree, and each cell is associated with one of the directed edges stemming from the vertex. Then, the transition of the system between two consecutive time steps can be described by the placement of the walkers in the cells (see Figure 1). We use this representation particularly in our figures for the sake of simplicity and visual clarity.

Assign *size* 1 to all vertices in G . For a given directed edge stemming from a vertex v with degree δ_v , its *size* will be $1/\delta_v$. Given a set A of vertices or directed edges, we define the *size* of A to be the sum of the sizes of its elements.

The following technical lemma is used in most of our proofs to compute the probability of having a certain configuration of walkers (in terms of vertex or directed edge occupancy) at a given time step. The lemma applies to any graph G . Its proof, using an inclusion-exclusion argument, is fairly straightforward and so is omitted. (See [DPSW06] for details.)

LEMMA 2.1. *Let $A_0, \dots, A_m$ be pairwise disjoint sets of vertices (or directed edges) in G , with sizes $S_0, \dots, S_m$, respectively. Let $N = |V(G)|$. If $\sum_{i=0}^m S_i = o(N)$,*

FIG. 1. The walker jumps to a neighbor according to which cell it is placed on.

then

$$\mathbf{P} \left(A_0 \text{ e.o.w.} \wedge \bigwedge_{i=1}^m (A_i \text{ not e.o.w.}) \right) \sim \left(1 - \frac{S_0}{N} \right)^w \prod_{i=1}^m (1 - e^{-S_i \varrho}).$$

To cover large sizes S , not necessarily $o(N)$, we need the following variation.

LEMMA 2.2. *Let A be a set of vertices in G of size S , and $v_1, \dots, v_m$ vertices not in A , with $m \geq 1$. Assume $N - S \rightarrow \infty$. The probability that no vertex in A is occupied and $v_1, \dots, v_m$ are all occupied is at most $p_0 p^{m-1} \alpha^w (1 + o(1))$, where $p_0 = 1 - e^{-\varrho/\alpha}$, $\alpha = 1 - S/N$, and $p = \min(1, \varrho/\alpha)$. Here the asymptotics are uniform over all m .*

Proof. The probability of the event $\mathcal{E}$ that all walkers avoid A is α^w . The probability that v_1 is occupied conditional upon $\mathcal{E}$ is $1 - (1 - (N - S)^{-1})^w$, which is asymptotic to p_0 . The lemma follows for $\varrho > \alpha$, i.e., $w > N - S$. Otherwise, conditional upon $\mathcal{E}$ and the event that $v_1, \dots, v_i$ are occupied, the probability that the next is occupied is clearly decreasing with i and is thus at most $w/(N - S) = \varrho/\alpha$. The lemma follows. $\square$

3. The cycle. Here $G = C_N$, the cycle with N vertices.

OBSERVATION 3.1. *Cover C_N with $\lceil \frac{N}{\lceil d/2 \rceil} \rceil$ paths of $\lceil d/2 \rceil$ vertices. If $d = \Omega(N/\sqrt{w})$, then the probability that some path is e.o.w. is at most*

$$\left\lceil \frac{N}{\lceil d/2 \rceil} \right\rceil \left(1 - \frac{\lceil d/2 \rceil}{N} \right)^w \leq O(\sqrt{w}) e^{-\Omega(\sqrt{w})} \rightarrow 0.$$

Thus, a.a.s. each of these paths is occupied (by at least one walker), and $\mathcal{W}(G, w, d)$ is connected.

In view of this observation, we assume for the rest of the section that $d = o(N)$. If $d = \Omega(N)$, then $\mathcal{W}(G, w, d)$ is a.a.s. connected.

Recall the definition of a hole from section 1 and that H is the random variable counting the number of d -holes. For this section, μ is defined as for Theorem 1.1.

3.1. Static properties. Here, we study the connectedness of the graph of walkers $\mathcal{W}(G, w, d)$ in the static situation by analyzing the behavior of H . In view of (1), if $\mathbf{E}[H] \rightarrow 0$, then $\mathcal{W}(G, w, d)$ is a.a.s. connected. Theorem 1.1 gives the asymptotic distribution of H .

Proof of Theorem 1.1. For any vertex v in C_N , let H_v be an indicator random variable such that $H_v = 1$ iff there is a d -hole following vertex v . Then,

$$(2) \quad H = \sum_{v \in V} H_v \quad \text{and} \quad \mathbf{E}[H] = \sum_{v \in V} \mathbf{P}(H_v = 1).$$

We shall compute the k th factorial moment:

$$(3) \quad \mathbf{E}[H]_k = \sum_{v_1 \neq \dots \neq v_k \in V} \mathbf{P}(H_{v_1} = 1 \wedge \dots \wedge H_{v_k} = 1).$$

Let $\mathcal{S}$ denote the set of tuples such that each v_i and v_j , $i \neq j$, have distance at least $d + 1$ around the cycle. For $(v_1, \dots, v_k) \notin \mathcal{S}$, the probability in (3) is 0 since one of the v_i “lies in” the hole following some v_j , and yet v_i must be occupied. For $(v_1, \dots, v_k) \in \mathcal{S}$, the probability in (3) is easily computed by applying Lemma 2.1:

$$\mathbf{P}(H_{v_1} = 1 \wedge \dots \wedge H_{v_k} = 1) \sim \left(1 - \frac{kd}{N}\right)^w (1 - e^{-\varrho})^k.$$

Since $d = o(N)$, we have $|\mathcal{S}| \sim N^k$, and thus from (3)

$$(4) \quad \mathbf{E}[H]_k \sim \left[N (1 - e^{-\varrho}) e^{-d\varrho + O(\frac{d^2 w}{N^2})} \right]^k.$$

In particular,

$$(5) \quad \begin{aligned} \mathbf{E}[H] &\sim N (1 - e^{-\varrho}) \left(1 - \frac{d}{N}\right)^w \\ &\sim N (1 - e^{-\varrho}) e^{-d\varrho + O(\frac{d^2 w}{N^2})}. \end{aligned}$$

In the case $\mu \rightarrow 0$, we have also $\mathbf{E}[H] \rightarrow 0$ since $(1 - d/N)^w \leq e^{-d\varrho}$. Then $\mathbf{P}(H = 0) \rightarrow 1$, and $\mathcal{W}(G, w, d)$ is connected a.a.s.. In the case that μ is bounded away from 0, taking logarithms,

$$(6) \quad d\varrho = \log N (1 - e^{-\varrho}) - \log \mu.$$

Considering separately the cases when $\varrho \rightarrow 0$ and when $\varrho \rightarrow c, \infty$, we get from (6) that $\frac{d^2 w}{N^2} = o(1)$, so we can ignore the term $O(\frac{d^2 w}{N^2})$ in the expression (4) and obtain

$$(7) \quad \mathbf{E}[H]_k \sim [N (1 - e^{-\varrho}) e^{-d\varrho}]^k = \mu^k.$$

Moreover, if μ is bounded, then it follows, from (7) and (for instance) from Theorem 1.23 in [Bol02], that H is asymptotically Poisson. For $\mu \rightarrow \infty$, we have that $\mathbf{E}[H]_2 \sim \mu^2$, and so it follows from Chebyshev’s inequality that a.a.s. $H > \mu/2$ (and $\mathcal{W}(G, w, d)$ is disconnected). $\square$

3.2. Dynamic properties. Assume that from an initial random placement f of the walkers, at each step, every walker moves from its current position to one of its neighbors, with probability $1/2$ of going either way. This is a standard random walk on the cycle for each walker. To study the connectivity properties of the dynamic graph of walkers we need to introduce some notation.

A *configuration* or *state* is an arrangement of the w walkers on the vertices of C_N . Consider the graph of configurations, where the vertices are the N^w different configurations. Each configuration can be represented by a vector $\mathbf{a} = (a_1, \dots, a_w) \in (\mathbb{Z}_N)^w$, where a_i indicates the label of the vertex being occupied by walker i . Given a configuration $\mathbf{a}$, there exists an edge between $\mathbf{a}$ and all configurations $(a_1 \pm 1, \dots, a_w \pm 1)$. Thus, any configuration has 2^w neighbors, and the relationship of being neighbors is symmetric. The dynamic process can be viewed as a random walk on the graph of configurations, in particular, a Markov chain $\mathcal{M}(N, w, d)$. We denote by $\mathcal{M}_t$ the state of the process at time step t .

For N even, given any two configurations $\mathbf{a}$ and $\mathbf{b}$, we say that they have the *same parity* if for all i and j , $a_i - a_j \equiv b_i - b_j \pmod{2}$. There are 2^{w-1} different parities. Note that the initial parity stays invariant during the dynamic process. The following lemma is straightforward, and the proof is left to the reader.

LEMMA 3.2. *Let $\mathbf{a}$ and $\mathbf{b}$ be any two configurations, and let $h_{\mathbf{a}, \mathbf{b}}$ denote the hitting time from $\mathbf{a}$ to $\mathbf{b}$. If N is odd, then $\mathbf{b}$ is reachable from $\mathbf{a}$ and $h_{\mathbf{a}, \mathbf{b}}$ is finite for any $\mathbf{a}$ and $\mathbf{b}$. If N is even, then $\mathbf{b}$ is reachable from $\mathbf{a}$ provided that $\mathbf{a}$ and $\mathbf{b}$ have the same parity, and in this case $h_{\mathbf{a}, \mathbf{b}}$ is finite.*

Then, if N is odd, $\mathcal{M}(N, w, d)$ consists of a single closed class of states, so it is irreducible and positive recurrent. It is trivial to verify aperiodicity, and hence we have that the chain is ergodic. However, if N is even, there are 2^{w-1} closed classes of states, where each class consists of all configurations with the same parity. We denote by $\mathcal{A}$ the set of classes. Let $A \in \mathcal{A}$ be any class of states, and let $\mathbf{a} \in A$ be a configuration. For this particular configuration, we can partition the set of walkers $W = W_1 \cup W_2$ so that the ones in W_1 lie in odd positions of the cycle and the ones in W_2 lie in even positions. Let A_1 be the set of all states which lead to this same partition, and A_2 the set of those which lead to the complementary one. Clearly, $A = A_1 \cup A_2$. Those states in A_1 are only reachable by an even number of steps from $\mathbf{a}$, and those in A_2 by an odd number of steps. Hence, if we restrict the Markov chain to any class of states, it is irreducible and positive recurrent but 2-periodic and hence not ergodic.

OBSERVATION 3.3. *Note that for any fixed t , the distribution of $\mathcal{W}_t(C_N)$ is just that of $\mathcal{W}(C_N)$ in the static case. That is, the initial uniform distribution stays invariant, even though when N is even the chain is not ergodic and there is no limit distribution. Hence, by Theorem 1.1, if $\mu \rightarrow 0$ or ∞ , then for any fixed t , $\mathcal{W}_t(C_N)$ is a.a.s. connected or a.a.s. disconnected, respectively.*

In view of this observation, we assume that $\mu = \Theta(1)$ for the remainder of the section, since we wish to study only the nontrivial dynamic situations. One thing this implies, in view of the definition of μ , is that

$$(8) \quad d\varrho \rightarrow \infty.$$

We define $H(t)$ to be the random variable that counts the number of d -holes at time step t . Then from section 3.1, $H(t)$ is asymptotically Poisson with expectation $\mu = \Theta(1)$.

For the dynamic properties of $\mathcal{W}_t(C_N)$, we are interested in the probability that

a new d -hole appears at a given time step. Moreover, we require knowledge of this probability conditional upon the number of d -holes already existing.

If there is a d -hole from u to v at time step t and all walkers at u and v move in the same direction on the next step, a new d -hole may appear following one of the neighbors of u (provided no new walkers move in to destroy this). These two d -holes, though different, are related, and the presence of the first makes the second more likely to occur. Similarly, the exact size of a d -hole following u may change in one step, making it technically a different d -hole but, again, related. In all these cases, the start vertex of the d -hole “moves” by at most 1; a d -hole at time step $t+1$ which does not follow u or a neighbor of u is not related to a d -hole following u at time step t . We need some definitions to make this loose description rigorous. Define a *d -hole line* to be a maximal sequence of pairs $(h_1, t_1), \dots, (h_l, t_l)$, where h_i is a d -hole existing at time step t_i for $1 \leq i \leq l$, and such that $t_i = t_{i-1} + 1$ and the start vertex of h_i is adjacent to, or equal to, the start vertex of h_{i-1} for $2 \leq i \leq l$. Fix two consecutive time steps t and $t+1$. If $t_1 = t+1$, we say that the line is *born* between t and $t+1$; if $t_l = t$, the line *dies* between t and $t+1$; and if $t = t_i$, $i \in \{1, \dots, l-1\}$, we say that the line *survives* during the interval $[t, t+1]$. Note that the time-reversal of the process has a d -hole line born at vertex u between $t+1$ and t iff the d -hole line dies at u between t and $t+1$.

We define random variables $S(t)$, $B(t)$, and $D(t)$ to be the number of d -hole lines surviving, being born, and dying between t and $t+1$. We have $D(t) + S(t) = H(t)$ and $B(t) + S(t) = H(t+1)$.

The proof of the following result is similar to that of Theorem 1.1 but rather more complicated, so we give only an abbreviated proof here. A full proof may be found in [DPSW06] or [P07]. Here “asymptotically independent Poisson” means that the joint distribution tends to that of independent Poisson variables.

PROPOSITION 3.4. *For any fixed t , the random variables $S(t)$, $B(t)$, and $D(t)$ are asymptotically independent Poisson, with the expectations*

$$\mathbf{E}[S(t)] \sim \begin{cases} \mu & \text{if } \varrho \rightarrow 0, \\ \mu - \lambda & \text{if } \varrho \rightarrow c, \\ 3\mu e^{-\varrho} & \text{if } \varrho \rightarrow \infty, \end{cases} \quad \text{and} \quad \mathbf{E}[B(t)] = \mathbf{E}[D(t)] \sim \begin{cases} \frac{1}{2}\mu\varrho & \text{if } \varrho \rightarrow 0, \\ \lambda & \text{if } \varrho \rightarrow c, \\ \mu & \text{if } \varrho \rightarrow \infty, \end{cases}$$

where λ is defined in Theorem 1.3.

Proof. We will estimate factorial moments of the appropriate variables. In C_N , let right denote “clockwise” and left “counterclockwise.” Moreover, for a vertex $v \in V$ and $i \geq 0$, let $v+i$ (respectively, $v-i$) denote the vertex i positions to the right (respectively, left) from v . All probabilities and events in this proof will involve two consecutive time steps t and $t+1$. We can describe these events from a static point of view, as explained in section 2.

We consider births in detail. There are four ways that a d -hole line can be born at v between time steps t and $t+1$ according to the following descriptions, as shown in Figure 2:

- b1. At time step t , there is a hole between $v+1$ and $v+d$ of exact size $d-2$. Then all walkers at v and $v+1$ move left and all walkers at $v+d$ and $v+d+1$ move right.
- b2. At time step t , there is a hole between $v+1$ and $v+d+1$ of exact size $d-1$. Then all walkers at v and $v+1$ move left and all walkers at $v+d+1$ and $v+d+2$ move right.

- b3. At time step t there is a hole between $v + 1$ and $v + d + 1$ of exact size $d - 1$, and $v + d + 2$ is occupied. Then all walkers at v and $v + 1$ move left, all walkers at $v + d + 1$ move right, and at least one walker at $v + d + 2$ moves left.
- b4. At time step t there is a hole between v and $v + d$ of exact size $d - 1$, and $v - 1$ is occupied. Then all walkers at v move left, all walkers at $v + d$ and $v + d + 1$ move right, and at least one walker at $v - 1$ moves right.

FIG. 2. Birth of a d -hole line at vertex v .

The expected number of d -hole lines born at a given time is N times the sum of the probabilities of these four events. Applying Lemma 2.1, together with the fact that $(1 - d/N)^w \sim e^{-d\varrho}$ (Theorem 1.1), we get (writing the four terms separately)

$$\begin{aligned} \frac{1}{N} \mathbf{E}[B(t)] &\sim \left(1 - e^{-\varrho/2}\right)^2 e^{-d\varrho} + \left(1 - e^{-\varrho/2}\right)^2 e^{-(d+1)\varrho} \\ &\quad + \left(1 - e^{-\varrho/2}\right)^3 e^{-(d+1/2)\varrho} + \left(1 - e^{-\varrho/2}\right)^3 e^{-(d+1/2)\varrho}. \end{aligned}$$

This leads to the expression for $\mathbf{E}[B(t)]$ stated in the theorem. The other expected values are obtained in a similar way (with three types of survival event and four types of death event). Computing the joint factorial moments of random variables counting births, deaths, and survivals gives the claim about Poisson distribution, similar to the proof of Theorem 1.1. We omit the remaining details. $\square$

As $H(t) = S(t) + D(t)$ and $H(t+1) = S(t) + B(t)$, the following is immediate.

COROLLARY 3.5. $H(t)$ and $B(t)$ are asymptotically independent, and so are $D(t)$ and $H(t+1)$.

It is natural to define the *lifespan* of a d -hole line as the number of time steps for which the line is alive. For any vertex v and time step t , the random variable $L_{v,t}$ is the lifespan of the d -hole line born at vertex v between time steps t and $t+1$. If no such birth takes place, $L_{v,t}$ is defined to be 0. Note that the random variables $L_{v,t}$ are identically distributed for all v and t .

In view of (8), it is easy to see that a state can be reached in which there are no holes. One way to do this is to force the walkers to move to positions in which they are almost equally spaced around the cycle. Then, by Lemma 3.2, for any initial state, the process will reach some such state within finite expected time. Thus the

expected lifespan of any given d -hole line, given the configuration of walkers at its birth, is bounded (and the bound is simply a function of N , d , and w).

Considering the train paradox discussed in section 1, we define the *average lifespan* of d -hole lines to be the expected time that a d -hole line will survive once born. Formally,

$$L_{\text{av}} := \mathbf{E}[L_{v,t} \mid L_{v,t} > 0].$$

By symmetry, this is independent of v and t and so is a function of N , d , and w . The next result finds its size.

THEOREM 3.6. *The average lifespan of d -hole lines satisfies*

$$L_{\text{av}} = \frac{\mathbf{E}[H(0)]}{\mathbf{E}[B(0)]} \sim \begin{cases} 2\rho^{-1} & \text{if } \rho \rightarrow 0, \\ \frac{\mu}{\lambda} & \text{if } \rho \rightarrow c, \\ 1 & \text{if } \rho \rightarrow \infty, \end{cases}$$

where λ is defined as in Theorem 1.3.

Proof. For any vertex v and time step t , we have

$$\begin{aligned} N\mathbf{E}[L_{v,t}] - \mathbf{E}[H(0)] &= \sum_{v \in V} \mathbf{E}[L_{v,t}] - \mathbf{E}[H(0)] \\ &= \frac{1}{T} \left(\sum_{v \in V} \sum_{t=0}^{T-1} \mathbf{E}[L_{v,t}] - \sum_{t=0}^{T-1} \mathbf{E}[H(t)] \right) \quad \text{for any } T \in \mathbb{Z}^+ \\ &= \frac{1}{T} \mathbf{E} \left[\sum_{v \in V} \sum_{t=0}^{T-1} L_{v,t} - \sum_{t=0}^{T-1} H(t) \right] \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \mathbf{E} \left[\sum_{v \in V} \sum_{t=0}^{T-1} L_{v,t} - \sum_{t=0}^{T-1} H(t) \right] \\ &= 0, \end{aligned}$$

since $H(t)$ is uniformly bounded (the bound depending on N) and so is the expected lifespan of any line. Thus, the portions of lifespans omitted in $\sum_{t=0}^{T-1} H(t)$ are bounded in expectation.

Now the rest follows easily:

$$\begin{aligned} \mathbf{E}[L_{v,t} \mid L_{v,t} > 0] &= \frac{\mathbf{E}[L_{v,t}]}{\mathbf{P}(L_{v,t} > 0)} \\ &= \frac{\mathbf{E}[H(0)]}{N\mathbf{P}(L_{v,t} > 0)} \\ &= \frac{\mathbf{E}[H(0)]}{\sum_v \mathbf{P}(L_{v,t} > 0)} \\ &= \frac{\mathbf{E}[H(0)]}{\mathbf{E}[B(0)]}. \end{aligned}$$

The final formula for this expression comes immediately from Proposition 3.4, noting that $H(t) = S(t) + D(t) \sim S(t)$ for $\rho \rightarrow 0$ and $D(t)$ dominates for $\rho \rightarrow \infty$. $\square$

The previous theorem has the following consequence of a rather different nature. Although this is entirely incidental to our main goals, it seems interesting enough to

mention. It is not clear how to establish this result without reference to our result on the cycle.

COROLLARY 3.7. *For constant $0 < p < 1$, randomly place walkers on the integers, each independently with probability p , but with probability 1 for integers 0 and 1. Let them all take the usual independent random walks. Then the expected time $g(p)$ before one of the initially nonpositive walkers meets or passes one of the initially positive walkers satisfies $g(p) \sim 2/p$ as $p \rightarrow 0$.*

Proof. We call the model introduced in the statement of the theorem the p -model. For fixed p , let $m = \lceil p^{-1} \rceil$. For fixed $i > 0$, consider the intervals $I_{-i} = [-im, -(i-1)m - 1]$ and $I_i = [(i-1)m + 1, im]$. Let H_i denote the event that in the first $i^2 m^2$ steps, some walker initially in I_i meets some walker initially in I_{-i} . Then $\mathbf{P}(H_i) > c > 0$ for some constant c independent of i (and p). This is because the probability that at least one site in I_i is initially occupied is at least $1 - (1-p)^m$, which is bounded below, and because after $i^2 m^2$ steps a walker's position is binomially distributed, subject to parity and relative to its starting point, with variance $i^2 m^2$, not forgetting that the walkers move independently.

Call a walker *positive* if it is initially positive and *negative* otherwise. For fixed M , the events $H_1, H_2, \dots, H_M$ are mutually independent, so the probability that none of them occurs is at most $(1-c)^M$. Thus the probability that none of the negative walkers meets or passes one of the positive walkers in the first $M i^2 m^2$ steps is at most $(1-c)^M$, i.e., exponentially small in M . It follows that $g(p)$ is finite and that a.s. the number of steps before the first positive walker passes the first negative walker is bounded in probability.

Still for fixed p , define a sequence of integers $d = d(N)$ satisfying $d = p^{-1} \log N + O(1)$, where the $O(1)$ term ensures that such an integer sequence can be found. Define $\tilde{g}(p)$ analogously to $g(p)$ but restricted to the walkers initially occupying the set $\mathbb{Z}(d) = \{k : |k| \leq d\}$. By the observation at the end of the previous paragraph, $\tilde{g}(p) \sim g(p)$.

Next consider our standard model of w walkers on a cycle of length $N + d$, where $w = \lfloor pN \rfloor$. Let $g_1(p)$ denote the expected lifespan of a d -hole line conditional upon it being born of size d . This is clearly independent of the time and place of birth, but let us fix the birth at a vertex v between time steps t and $t+1$. All possible configurations that are feasible at time steps t and $t+1$ and such that this birth occurs are equally likely. At time step t there is a walker at v and one at $v + d + 1 \pmod{N}$, with none in between. For any such configuration of walkers at time step $t+1$, we can map the part of the configuration near v (to its “left”) and near $v + d + 1$ (to its “right”) onto the integers, taking $[v-d, v]$ onto the integers $[-d, 0]$ and $[v+d+1, v+2d]$ onto $[1, d]$. Let V_d denote the set of sites mapped in this way to $\mathbb{Z}(d)$, and let f denote the mapping.

For the rest of the proof we omit some technical details. For any particular configuration in V_d , the probability that it arises is close to the probability of its image under f occurring in the p -model. In fact, it tends toward the same probability as $N \rightarrow \infty$. Similarly, the probability that two walkers occupy the same position within $\mathbb{Z}(d)$ or V_d will tend to 0 as $N \rightarrow \infty$ (in both cases). Hence $g_1(p) \rightarrow g(p)$ as $N \rightarrow \infty$.

Now let $g_2(p)$ denote the expected lifespan of a d -hole line conditional upon it being born of size $d+1$. The same argument as above gives $g_2(p) \rightarrow g(p)$ as $N \rightarrow \infty$.

It follows that for the walkers on the cycle with these parameters, $L_{\text{av}} \rightarrow g(p)$ as $N \rightarrow \infty$. Letting $p \rightarrow 0$ slowly and applying Theorem 3.6 now gives the theorem. $\square$

It is also interesting to ask how the average lifespan relates to the initial config-

uration of the walkers (see the train paradox in section 1). As noted earlier, if N is odd, then $\mathcal{M}(N, w, d)$ is ergodic and parity is immaterial. However, if N is even and the initial configuration is conditioned upon, the (conditional) average lifespan of d -hole lines may be different from L_{av} . Define $T \in \mathbb{Z}^+$,

$$L_T = \frac{\sum_{t=0}^{T-1} \sum_{v \in V} L_{v,t}}{|\{(v, t) : L_{v,t} > 0\}|},$$

where the denominator runs over all pairs $(v, t) \in V \times \{0, \dots, T-1\}$. If the denominator is zero (or the numerator is infinite, which happens with probability 0), the value is immaterial and may be defined as 0. Note that L_T is a function of a given trajectory of the process.

We next aim for an analogue of Theorem 1.4. Define

$$L = \frac{\mathbf{E}[H(0)|\Lambda]}{\mathbf{E}[B(0)|\Lambda]},$$

where Λ is the random variable which is the closed class in which the initial state $\mathcal{M}_0$ lies.

THEOREM 3.8. *For the walkers model on C_N , L_T converges in probability as $T \rightarrow \infty$ (with N fixed) toward a random variable L . Furthermore, (as $N \rightarrow \infty$) we have $L \sim L_{\text{av}}$ a.a.s.*

Proof. The proof proceeds by a renewal theory type of argument, showing a sharp concentration of the number of times that the associated Markov chain revisits a given state over a given long time period.

Let us define the truncated average lifespan of d -hole lines in $[0, T-1]$ to be

$$\overline{L}_T = \frac{\sum_{t=0}^{T-1} H(t)}{H(0) + \sum_{t=0}^{T-2} B(t)}$$

(defined by convention to be 0 if the denominator is 0). As we prove below, this is an approximation of L_T .

We first deal with the case that N is even. To prove the result we need to take into account the class of states containing the initial state, since different starting configurations of walkers may lead to different expected numbers of holes and births.

Let Λ be the random variable accounting for the closed class of states where the initial state $\mathcal{M}_0$ lies. Let A be any closed class of states. We condition on the event $(\Lambda = A)$, which we call A with some abuse of notation. By Lemma 3.2, the hitting time between any two states is finite.

We consider the Doob martingale $\Sigma_0, \dots, \Sigma_T$ defined by

$$\Sigma_i = \mathbf{E} \left[\sum_{t=0}^{T-1} H(t) \middle| A, \mathcal{M}_0, \dots, \mathcal{M}_{i-1} \right], \quad i = 0, \dots, T.$$

We have $\Sigma_0 = T\mathbf{E}[H(0)|A]$ and $\Sigma_T = \sum_{t=1}^T H(t)$. (We recall that this last expression is regarded in the probability space induced by restricting to the event A .)

From the fact that the expected hitting time between any two states is finite, we deduce that the differences $|\Sigma_{i+1} - \Sigma_i|$ are bounded above by a constant independent of T . Hence as an immediate consequence of Azuma's inequality we get that, conditional upon the event A ,

$$(9) \quad \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{t=0}^{T-1} H(t) = \mathbf{E}[H(0)|A] \quad \text{in probability}$$

and by a similar argument

$$(10) \quad \lim_{T \rightarrow \infty} \frac{1}{T} \left(H(0) + \sum_{t=0}^{T-2} B(t) \right) = \mathbf{E}[B(0)|A] \quad \text{in probability.}$$

Then, by taking the ratio of (9) and (10), we get that

$$(11) \quad \lim_{T \rightarrow \infty} \overline{L_T} = L \quad \text{in probability.}$$

The case that N is odd is easier. There is just one closed class of states, and $\mathcal{M}(N, w, d)$ is ergodic. By the martingale argument as above, we get (noting Theorem 3.6)

$$(12) \quad \lim_{T \rightarrow \infty} \overline{L_T} = \frac{\mathbf{E}[H(0)]}{\mathbf{E}[B(0)]} = L_{\text{av}} \quad \text{in probability.}$$

Moreover, we obtain

$$(13) \quad \lim_{T \rightarrow \infty} L_T - \overline{L_T} = 0 \quad \text{in probability}$$

since $H(t)$ and $B(t)$ are uniformly bounded (the bound depending on N) and so is the expected lifespan of any line. Thus the portions of lifespans omitted in $\overline{L_T}$ are bounded in expectation, which is insignificant since the denominator grows linearly with T , as shown in (10).

In order to finish the proof, it suffices to show that as $N \rightarrow \infty$

$$L \sim L_{\text{av}} \quad \text{a.a.s.}$$

We note that the quantity $\mathbf{E}[H(0)|A]/\mathbf{E}[B(0)|A]$ may vary depending on the particular closed class of states A . Let us study this in more detail. Let $\mathbf{a} \in A$ be a configuration. As in section 3.2, let us partition the set of walkers W into W_1 and W_2 according to the parity of their positions in the cycle. Let us define the *imbalance* of the configuration as $\Delta(\mathbf{a}) = |w_1 - w_2|$, where $w_i = |W_i|$. It makes sense to define $\Delta(A) = \Delta(\mathbf{a})$ since it does not depend on the choice of $\mathbf{a}$.

We can compute the expectations of S , B , and D conditional upon $(\mathcal{M}_0 \in A)$ by proceeding the same way as in Proposition 3.4. The only difference is that w_1 walkers must go to $\frac{N}{2}$ of the vertices (say, those with odd position) and w_2 must go to the other $\frac{N}{2}$. We omit the details here since they are fairly tedious and completely analogous to the previous computations. We note that these expectations do not depend on the particular partition (W_1, W_2) but only on the imbalance $\Delta(A)$. In all cases we get

$$(14) \quad \frac{\mathbf{E}[H(0)|A]}{\mathbf{E}[B(0)|A]} = \Theta \left(\frac{\mathbf{E}[H(0)]}{\mathbf{E}[B(0)]} \right).$$

In fact, for $\frac{\Delta(A)}{N} = O(1)$ we have $\mathbf{E}[H(0)|A] = \Theta(\mathbf{E}[H(0)])$ and $\mathbf{E}[B(0)|A] = \Theta(\mathbf{E}[B(0)])$. For $\frac{\Delta(A)}{N} \rightarrow \infty$, these two statements are no longer true, but the extra factors in the numerator and denominator of (14) cancel out to within a factor of $\Theta(1)$.

However, not all imbalances are equally likely. In fact, for any $\epsilon > 0$, we have

$$(15) \quad \mathbf{P} \left(\Delta(\mathcal{M}_0) \geq w^{\frac{1+\epsilon}{2}} \right) = \mathbf{P} \left(\left| w_1(\mathcal{M}_0) - \frac{w}{2} \right| \geq \frac{1}{2} w^{\frac{1+\epsilon}{2}} \right) \leq \frac{w}{w^{1+\epsilon}} = o(1).$$

Moreover, for a (typical) class A such that $\Delta(A) < w^{\frac{1+\epsilon}{2}}$ and by the method explained above, we get

$$(16) \quad \frac{\mathbf{E}[H(0)|A]}{\mathbf{E}[B(0)|A]} \sim \frac{\mathbf{E}[H(0)]}{\mathbf{E}[B(0)]}.$$

From this last fact, together with (14) and (15), the theorem follows. $\square$

We turn now to connectivity issues, for which we use (1). The next lemma gives us the probability that there is one component at time step t but at least two at time step $t+1$.

LEMMA 3.9. *The probability that $\mathcal{W}_t(C_N)$ is connected and that $\mathcal{W}_{t+1}(C_N)$ is disconnected is given by*

$$\mathbf{P}\left(H(t+1) \geq 2 \wedge H(t) < 2\right) \sim \begin{cases} \frac{1}{2}\mu^2 e^{-\mu} \varrho & \text{if } \varrho \rightarrow 0, \\ e^{-\mu} (1 + \mu - (1 + \mu + \lambda + \lambda^2)e^{-\lambda}) & \text{if } \varrho \rightarrow c, \\ (1 + \mu)e^{-\mu}(1 - (1 + \mu)e^{-\mu}) & \text{if } \varrho \rightarrow \infty, \end{cases}$$

where λ is defined as in Theorem 1.3.

Proof. We can split the probability on the left-hand side according to the events $H(t) = 0$ and $H(t) = 1$. Noting that

$$\mathbf{P}\left(H(t+1) \geq 2 \wedge H(t) = 0\right) = \mathbf{P}\left(H(t) = 0 \wedge B(t) \geq 2\right),$$

and

$$\begin{aligned} \mathbf{P}\left(H(t+1) \geq 2 \wedge H(t) = 1\right) &= \mathbf{P}\left(S(t) + B(t) \geq 2 \wedge S(t) + D(t) = 1\right) \\ &= \mathbf{P}\left(S(t) = 1 \wedge B(t) \geq 1 \wedge D(t) = 0\right) + \mathbf{P}\left(S(t) = 0 \wedge B(t) \geq 2 \wedge D(t) = 1\right), \end{aligned}$$

the result follows from Proposition 3.4 and Corollary 3.5 provided $\varrho \not\rightarrow 0$. If $\varrho \rightarrow 0$, we need, for instance, to estimate the vanishingly small quantity $\mathbf{P}(S(t) = 1 \wedge B(t) \geq 1 \wedge D(t) = 0)$ asymptotically, but the moment calculations, as for the proof of Proposition 3.4, suffice for this, and we omit the routine details. $\square$

Recall the definition of a disconnected period from section 1. By Lemma 3.2, from a disconnected state the graph will always reach some connected one (for example, one in which all walkers occupy one of two adjacent sites) within finite expected time. Thus the expected length of any disconnected period is bounded (this bound depending on N).

Proof of Theorem 1.3. Arguing as in the proof of Theorem 3.6, and obtaining the asymptotic expressions for the numerator and the denominator from Theorem 1.1 and Lemma 3.9, we obtain

$$(17) \quad LD_{\text{av}} = \frac{\mathbf{P}(H(1) \geq 2)}{\mathbf{P}(H(0) < 2 \wedge H(1) \geq 2)} \sim \begin{cases} 2 \frac{e^\mu - 1 - \mu}{\mu^2} \varrho^{-1} & \text{if } \varrho \rightarrow 0, \\ \frac{e^\mu - 1 - \mu}{1 + \mu - (1 + \mu + \lambda + \lambda^2)e^{-\lambda}} & \text{if } \varrho \rightarrow c, \\ \frac{e^\mu}{1 + \mu} & \text{if } \varrho \rightarrow \infty. \end{cases} \quad \square$$

Proof of Theorem 1.4. Let the random variable $\Phi(t) = 1_{[H(t) \geq 2]}$ be the indicator of the event that $\mathcal{W}_t(C_N)$ is disconnected, and let $\Psi(t) = 1_{[H(t-1) < 2 \wedge H(t) \geq 2]}$ be the indicator of the event that a disconnected period starts at time step t .

We define the truncated average disconnection time of the graph of walkers in $[1, T]$ as

$$\overline{LD_T} = \frac{\sum_{t=1}^T \Phi(t)}{\sum_{t=1}^T \Psi(t)}.$$

Proceeding as in the proof of Theorem 3.8, we get that $\overline{LD_T}$ converges in probability for large T toward a random variable LD such that $LD \sim LD_{\text{av}}$. $\square$

From the definitions in section 1 relating to disconnected periods, by changing disconnected to connected, we define *connected periods* LC_t , LC_{av} , and LC_T . Using

$$LC_{\text{av}} = \frac{\mathbf{P}(H(1) < 2)}{\mathbf{P}(H(0) \geq 2 \wedge H(1) < 2)}$$

and an analogue of Lemma 3.9, we obtain the following.

THEOREM 3.10. *The average length of a connected period satisfies*

$$LC_{\text{av}} \sim \begin{cases} 2^{\frac{1+\mu}{\mu^2}} \varrho^{-1} & \text{if } \varrho \rightarrow 0, \\ \frac{1+\mu}{1+\mu-(1+\mu+\lambda+\lambda^2)e^{-\lambda}} & \text{if } \varrho \rightarrow c, \\ \frac{e^\mu}{e^\mu-(1+\mu)} & \text{if } \varrho \rightarrow \infty, \end{cases}$$

where λ is defined as in Theorem 1.3.

The result for connection times analogous to Theorem 1.4 is the following. The proof is almost identical and so is omitted.

THEOREM 3.11. *LC_T converges in probability as $T \rightarrow \infty$ (N fixed) toward a random variable LC , where $LC \sim LC_{\text{av}}$ a.a.s.*

4. The grid. In this section, we study the walkers model for $G = T_N$, the toroidal grid with $N = n^2$ vertices. We can refer to vertices by using coordinates in $\mathbb{Z}_n \times \mathbb{Z}_n$. For the grid we encounter significant new obstacles as compared to the cycle; see, for instance, the Geometric Lemma below.

For any $p \in [1, \infty]$ and any two vertices u and v in T_N , we define the distance $\text{dist}_{\ell^p}(u, v)$ as the minimal ℓ^p distance between any two points u' and v' in the square grid such that the coordinates of u' are congruent to those of u taken modulo n , and similarly for v and v' . Let us fix any such metric for our study of the connectedness of $\mathcal{W}(G, w, d)$ and write $\text{dist}(u, v)$ for short. We use dist to refer to this measure of distance, distinguishing it from Euclidean distance. Note that

$$(18) \quad \frac{1}{2} \cdot \text{dist}_{\ell^1}(u, v) \leq \text{dist}(u, v) \leq \text{dist}_{\ell^1}(u, v).$$

The number of vertices at distance at most d from any given vertex is $h = \Theta(d^2)$. The exact expression of h depends on the choice of the metric. Some examples are found in Table 1.

OBSERVATION 4.1. *Assume that $d < 2n$ (otherwise, the graph of walkers is always complete). For each $i, j < 4n/d$, let v_{ij} denote the vertex in T_N with coordinates $(\lfloor id/4 \rfloor, \lfloor jd/4 \rfloor)$. Let S_{ij} denote the set of grid points closer to v_{ij} than any of the other $v_{i'j'}$. Then there are $\Theta(N/d^2)$ disjoint sets S_{ij} each containing $\Theta(d^2)$ points. The probability that at least one of these S_{ij} is empty of walkers is at most*

$$\Theta(N/d^2)(1 - \Theta(d^2/N))^w = O(\sqrt{w})e^{-\Omega(\sqrt{w})},$$

TABLE 1
Number of vertices at distance at most d from a given vertex.

Metric	h
ℓ^1	$h = 2d(d+1)$
ℓ^2	$h \sim \pi d^2$ if $d \rightarrow \infty$
ℓ^∞	$h = 4d(d+1)$

which goes to 0 if $d^2 = \Omega(N/\sqrt{w})$. Thus, a.a.s. each of these pieces is occupied by at least one walker, and $\mathcal{W}(G, w, d)$ is connected.

In view of the observation, we assume for the rest of the section that $h = o(N)$, i.e., $d = o(n)$. If $d = \Omega(n)$, then $\mathcal{W}(G, w, d)$ is a.a.s. connected.

We wish to study the connection and disconnection of $\mathcal{W}(G, w, d)$ in a similar way to the cycle. For the grid, the notion of hole does not help, and we deal directly with components. Recall from the introduction that a simple component is one with just one vertex. These play a major role, and we shall prove that, for the interesting values of the parameters, a.a.s. there exist only simple components aside from one giant one.

Let $\mathcal{C}$ be any given component. The *edges* of $\mathcal{C}$ are the straight edges joining occupied vertices in $\mathcal{C}$ of distance at most d . The associated *forbidden region* $A_{\mathcal{C}}$ is the set of vertices not in $\mathcal{C}$ but at distance at most d from some vertex in $\mathcal{C}$ (i.e., those vertices which must be free of walkers for $\mathcal{C}$ to exist as a component). The *exterior* $\mathcal{E}_{\mathcal{C}}$ of $\mathcal{C}$ is the set containing all those vertices not in $\mathcal{C} \cup A_{\mathcal{C}}$. We partition $\mathcal{E}_{\mathcal{C}}$ into *external regions* as follows: two vertices belong to the same external region when they can be joined by a continuous arc not intersecting any edge of $\mathcal{C}$. Figure 3 shows a component with different external regions.

FIG. 3. Component (black), empty area (gray), external regions A, B, and C (white).

Recall that, in the terminology of planar maps, the *bounding cycle* of a face is a walk around the boundary of the face. Given an external region $\mathcal{E}_{\mathcal{C}}^i$, let $\mathcal{C}'$ be any connected subgraph of $\mathcal{C}$ that has no edges crossing and such that no vertices of $\mathcal{C}$ are contained in the face F of $\mathcal{C}'$ which contains $\mathcal{E}_{\mathcal{C}}^i$. Such subgraphs always exist: for instance, take the spanning tree of $\mathcal{C}$ whose length (sum of lengths

of edges) in terms of dist has been minimized and, subject to this, has the shortest Euclidean length. We refer to the bounding cycle of this face F as a *boundary walk* β in $\mathcal{C}$ with respect to $\mathcal{E}_C^i$. Such a walk is *maximal* if the face F does not properly contain a face of some other subgraph of $\mathcal{C}$ of the same type. In Figure 4, $\{1, 5, 3, 7, 9, 11, 13, 15, 13, 12, 14, 12, 10, 8, 6, 2, 4, 1\}$ is a nonmaximal boundary walk, and $\{1, 5, 3, 7, 9, 11, 13, 14, 12, 10, 8, 6, 2, 4, 1\}$ is a maximal one. A maximal walk always exists, because any nonmaximal walk can be diverted around any face that prevents it from being maximal.

FIG. 4. The boundary walk.

We call a (directed) closed walk in $\mathcal{C}$ *regular* if, for each edge entering a vertex v , the next edge in the walk is the next edge in the clockwise direction around v .

For $i < n$, let us call a v -band of width i to any subset of T_N defined by $\{a, \dots, a + i - 1\} \times \mathbb{Z}_n$. Similarly, we define an h -band of height j . Define a *rectangle* of width i and height j to be the intersection of a v -band of width i and an h -band of height j . We can compare vertices in a rectangle according to their coordinates and use statements such as v_1 is more left than v_2 or v_3 is an uppermost vertex in the rectangle.

We say that a component $\mathcal{C}$ with at least 2 vertices is a *rectangular component* (*r-component*) if all of its vertices and edges and its forbidden region are contained in a rectangle as defined above. In particular, this implies that $\mathcal{C}$ contains no nonseparating cycle of the torus. Otherwise, $\mathcal{C}$ is an *nr-component*. For a given r -component $\mathcal{C}$, we define its *origin* as the leftmost of the lowermost vertices of $\mathcal{C}$. The *outside region* of an r -component is the only external region of the component having vertices outside any containing rectangle. We say that an nr -component is *type 1* if it is not the subgraph of some graph of walkers containing more than one nr -component and *type 2* otherwise. Note that this property is simply determined by the subgraph of the toroidal grid remaining when the component and the vertices of distance at most d from it are deleted. By definition, $\mathcal{W}(G, w, d)$ has at most one nr -component of type 1.

Let X , Y , and Z be the number of simple components, r -components, and nr -components, respectively, and note that $Z = Z_1 + Z_2$, where Z_i is the number of nr -components of type i . Then $\mathbf{E}[Z] = \mathbf{P}(Z_1 = 1) + \mathbf{E}[Z_2]$.

4.1. Static properties. In this section, we study the connectedness of $\mathcal{W}(G, w, d)$ in the static situation for the case $G = T_N$; in particular, we analyze the behavior of X , Y , and Z . For section 4, the value of μ is as defined for Theorem 1.5, rather than the value for the cycle.

PROPOSITION 4.2. *The expected number of simple components of $\mathcal{W}(G, w, d)$ for $G = T_N$ satisfies $\mathbf{E}[X] \sim N(1 - e^{-\mu})(1 - \frac{h}{N})^w$. Furthermore,*

- (i) *if $\mu \rightarrow 0$, then $\mathbf{E}[X] \rightarrow 0$ and there are no simple components a.s.,*

- (ii) if $\mu \rightarrow \infty$, then there exist simple components a.a.s. (and $\mathcal{W}(G, w, d)$ is disconnected), and
- (iii) if $\mu = \Theta(1)$, then X is asymptotically Poisson with mean μ .

Proof. We repeat the proof of Theorem 1.1 in the present context. To compute $\mathbf{E}[X]_k$, we focus on the set $\mathcal{S} = \{(v_1, \dots, v_k) | \text{dist}(v_i, v_j) > 2d \text{ if } i \neq j\}$, with size $|\mathcal{S}| \sim N^k$. Applying Lemma 2.1, we obtain

$$(19) \quad \mathbf{E}[X]_k \sim \left[N (1 - e^{-\ell}) e^{-h\ell + O(\frac{h^2 w}{N^2})} \right]^k.$$

Comparing with (4), the rest of the proof is as for Theorem 1.1. $\square$

From part (ii) of the proposition, if $h\varrho = O(1)$, then $\mu \rightarrow \infty$ and $\mathcal{W}(G, w, d)$ is disconnected a.a.s. In view of this, we may restrict our attention to the condition $h\varrho \rightarrow \infty$ in the study of r -components and nr -components.

Given a boundary walk $\beta = (v_1, \dots, v_k)$, we define $\text{length}(\beta) = \sum_{1 \leq i < k} \text{dist}(v_i, v_{i+1})$ as the sum of the distances (using the chosen metric) between consecutive vertices in β . We shall write $\text{length}_{\ell^p}(\beta)$ when we want specify that we are measuring distances in ℓ^p . Similarly, we define $\text{length}_v(\beta)$ (the vertical length) as the sum of the differences between y coordinates of consecutive vertices along the cycle and $\text{length}_h(\beta)$ (the horizontal length) using x coordinates in the same way.

The next lemma relates the size of the forbidden region outside a boundary cycle of a component to the length of the cycle and will play a key role in proving the main results.

LEMMA 4.3 (Geometric Lemma). *Let $\mathcal{C}$ be a component in T_N with β one of its maximal boundary walks and $l = \text{length}(\beta)$ its length. Assume that $\mathcal{C}$ has at least two occupied sites. Then the size of the forbidden region A_β outside β is bounded below by $|A_\beta| \geq dl/J$ for some sufficiently large constant J . Moreover, if $\mathcal{C}$ is rectangular, and β is a maximal boundary walk with respect to the outside region, we have $|A_\beta| \geq h + dl/J$.*

Proof. The main idea in this proof is to consider intervals in the grid “sticking outward” from the boundary walk and show that at least some small proportion of these intervals is on average free of walkers.

For convenience we take $J = 10^{10}$, though probably without large modifications the proof method will yield the result for $J = 1000$. (We do not attempt to optimize the constant J , since probably the theorem holds for J close to 2 when d is large, while for $d = 1$ in all but the case $p = 1$ we need $J \geq 4$. Some experiments suggest that $J = 4$ suffices even in this case.) Observe that in the 3×3 subgrid centered on the endpoint of an edge of β , there must be at least one vertex in the forbidden region outside β ; otherwise the boundary walk can be rerouted to contradict its maximality. Each point of the forbidden region can be counted in this way at most 8 times. Thus the forbidden region has size at least $l/(8d)$. This implies the first statement in the lemma provided that $8d^2 \leq 10^{10}$.

Throughout this proof, all distances referred to are measured using dist . For the second statement in the lemma, we begin with the fact that for a rectangular component, there are “caps” of empty region of size at least $h/2 - d$ on the top and bottom of the component, being the set of grid points within distance d , but above the leftmost point of $\mathcal{C}$ of the greatest vertical coordinate (or below the leftmost point of the least vertical coordinate). Without loss of generality, we assume that the component has vertical height greater than 1 (otherwise, we may interchange “vertical” and “horizontal”). Then there are also intervals of empty region of length

d projecting outward from the left- and rightmost vertices of the top level of $\mathcal{C}$. These caps and intervals account for an empty region of size h but use up some of the forbidden region counted in relation to ends of edges of β in the argument above. The number of endvertices of edges of β that are involved in the region of size h described is at most $4d + 2$, and there is still at least one endvertex of an edge of β not involved (the rightmost one in the bottom row of $\mathcal{C}$, say—we cannot claim two vertices here because it might be the same as the leftmost one), which means the above argument is valid if the bound on the size of the forbidden region is reduced by a factor of $4d + 3$. That is, the size of the forbidden region is at least $h + l/8d(4d + 3)$. So the second statement in the lemma holds provided that $8d^2(4d + 3) \leq 10^{10}$. Hence we may now assume that $d > 400$.

Choose $k = \lceil \frac{d}{100} \rceil$. Then $k \leq (d + 99)/100 \leq (d/100)(1 + 99/d) < d/80$. Assume without loss of generality that for the boundary walk β we have $\text{length}_v(\beta) \geq \text{length}(\beta)/2$. We place intervals of length k (note that all the ℓ_p metrics measure these intervals the same) horizontally along all grid lines from a maximal boundary cycle toward the outside. Those starting from a vertex of β point toward the outside according to the previous edge of β . (We assume β is oriented in some direction.) We delete any intervals that touch the boundary cycle in two or more places. Then each remaining interval will touch k vertices of the forbidden region outside β , and each such vertex will be touched by at most two different intervals. (Two intervals coming from opposite directions may touch the same vertex.)

We need to bound the number of intervals which were deleted. Call an edge of $\mathcal{C}$ *short* if the distance between its endpoints is less than $d/4$ and *long* otherwise. Suppose that an interval (that is to be deleted) touches a short edge at a point E and a point F on another edge of β , with the part between E and F in the exterior of β . Suppose that F has distance at most $d - d/4 - k$ from both endvertices of its edge. Then by the triangle inequality each endvertex (say, P and Q) of that edge is of distance at most d from each endvertex (R and T) of E 's edge. Thus the quadrilateral $PQRT$ (or triangle, if two points coincide) has diameter at most d , and thus the walk β can be changed to make a smaller face “outside” (meaning the side which was minimized). This can clearly be done also if other parts of β enter this quadrilateral, contradicting the maximality of β . Thus, F has distance at least $d - d/4 - k > 2d/3$ from one of the endvertices of its edge. So F 's edge is long, or, if F lies on more than one edge, they are all long.

We call a *middle* interval any interval originating from a long edge from point at least $1/8$ of the length of the edge from each end. Suppose that such a middle interval originating at a point E (called a *middle point*), on edge e of β , is deleted. Then it hits some other edge f at a point F of horizontal distance at most k from E . If f has an endvertex of distance less than $d/8 - k \geq d/8 - d/80 \geq d/9$ from F , we get a contradiction as above. Since e is long, its endvertices have distance at least $d/32$ from E . Since e and f are straight, either point on e of distance $rd/32$ from E , for any $r > 0$, has horizontal distance at most $(r + 1)k$ from f or the extension of f . (Furthermore, note for later that any two points on e and f at the same vertical coordinate have distance at most $32k$ apart.) It follows that the endvertices P and R of e and f above the line EF have distance less than d apart, as do the ends Q and T below (or on) the line EF . If either $P = R$ or $Q = T$, we now obtain a contradiction as before by rerouting β . A similar contradiction arises if either PT or QR has length at most d . So, picturing e and f with the line EF as making a near-perfect but very thin “H,” the distances along the H from P to T and from Q to R are both greater

than d . Thus the sum of the lengths of e and f is at least $2d - 2k$ (since the edge EF is included twice in these distances), and so each of e and f has length at least $d - 2k$, and the lengths of the arms of e and f above EF differ by at most k (as for the arms below EF). It follows that both PR and QT have length at most $34k$ (recalling the observation above about horizontal distance), which is at most $d/2$. Without loss of generality, PR is not an edge of β . This again contradicts the choice of β , either by shortening it at PR or, if another edge of β crosses PR , by joining P or R to an end of such an edge. We conclude that no middle intervals are deleted. Moreover, this shows that the point F in the previous paragraph cannot be a middle point. So every interval starting at a short edge that is deleted first hits a nonmiddle point of a long edge. Such a point can be hit by only one interval from a short edge unless it is a vertex of β , in which case it can be hit by two intervals. Thus if i_1 is the number of intervals starting at short edges that are deleted, j_1 is the number of long edges of β , and j_2 is the number of nonmiddle intervals originating at nonends of long intervals,

$$i_1 \leq 4j_1 + j_2.$$

Moreover, since no middle intervals are deleted, the number i_2 of intervals originating on long edges that are deleted similarly satisfies

$$i_2 \leq 4j_1 + j_2.$$

If j_3 is the total number of intervals before any deletions occur, we clearly have

$$j_2 \leq j_3/4$$

and also since long edges have length at least $d/4$,

$$(20) \quad j_3 \geq \text{length}_v(\beta) \geq \text{length}(\beta)/2 \geq j_1 d/8.$$

Combining these gives

$$i_1 + i_2 \leq 8j_1 + 2j_2 \leq j_3 \left(\frac{64}{d} + \frac{1}{2} \right) \leq 3j_3/4,$$

which shows that at least $j_3/4$ of all the intervals are not deleted. These intervals each cover $k \geq d/100$ vertices of the forbidden region, at most two covering any one such vertex, so the first part of the lemma follows for $d > 400$, using (20).

For the second claim of the lemma when $d > 400$, we may again add the caps of size $h - 2d$ but also two extra intervals of length d at the sides: assuming that β is oriented in the clockwise direction, the intervals of length k projecting from the leftmost vertex in the bottom level of $\mathcal{C}$, and from the rightmost vertex in the top level, are not used. It is here that extra intervals of the empty region of length d may be found. $\square$

The next lemma will be used to show that nr-components of type 2 are rare.

LEMMA 4.4. *Let $\mathcal{C}$ be an nr-component of type 2. Then $\mathcal{C}$ has a maximal boundary walk β with $\text{length}(\beta) \geq n - o(n)$.*

Proof. Let us divide T_N into $\lfloor \frac{n}{d+1} \rfloor$ v-bands $c_1, \dots, c_{\lfloor \frac{n}{d+1} \rfloor}$ of width $\geq d + 1$, and similarly into $\lfloor \frac{n}{d+1} \rfloor$ h-bands $r_1, \dots, r_{\lfloor \frac{n}{d+1} \rfloor}$ of width $\geq d + 1$.

Let $\mathcal{C}$ be an nr-component. Since $\mathcal{C}$ is connected, the v-bands (or h-bands) not containing vertices of $\mathcal{C}$ must be consecutive. If there were at least 2 consecutive v-bands and at least 2 consecutive h-bands without vertices of $\mathcal{C}$, then $\mathcal{C}$ would be

rectangular since $\mathcal{C}$ and $A_{\mathcal{C}}$ would be embeddable in the complements of the v-bands and h-bands. Hence, at most one v-band and some consecutive h-bands (or at most one h-band and some consecutive columns) may be without vertices of $\mathcal{C}$.

We assume now that $\mathcal{C}$ coexists with another nr-component $\mathcal{C}'$.

Case 1. Let us suppose first that $\mathcal{C}$ has no vertices in more than one v-band or h-band (v-band without loss of generality). Let c_1, c_2 be two consecutive v-bands not containing vertices of $\mathcal{C}$. Hence all h-bands, excepting at most one, contain vertices in $\mathcal{C}$. For each such h-band r_i , choose a vertex v_i in $\mathcal{C} \cap r_i$. We can also find some vertex w_i in $(c_1 \cup c_2) \cap r_i$ such that w_i is at distance $\geq d+1$ from any vertex in $\mathcal{C}$. By this construction, all w_i belong to the same external region of the component. Let β be any maximal boundary walk of $\mathcal{C}$ with respect to this external region. Then, the straight line joining v_i and w_i must intersect an edge of β , part of the edge contained in r_i . Hence, β crosses all h-bands except at most 3 and $\text{length}(\beta) \geq n - 4d - 3$.

Case 2. On the other hand, let us suppose that $\mathcal{C}$ has vertices in all v-bands and h-bands except for at most one of each. Without loss of generality, the other component, $\mathcal{C}'$, has vertices in all v-bands except for at most one. Thus, there are at least $\lfloor \frac{n}{d+1} \rfloor - 2$ v-bands with some vertices of both components. For each such v-band c_i , let us take vertices $v_i \in \mathcal{C} \cap c_i$, $w_i \in \mathcal{C}' \cap c_i$ and join them by a straight line. Notice that all the w_i belong to the same external region of $\mathcal{C}$, and let β be any maximal boundary walk with respect to this region. Then the line joining v_i and w_i must intersect an edge of β , part of the edge contained in c_i . Hence, β crosses all v-bands except at most 4 and $\text{length}(\beta) \geq n - 5d - 4$.

In any case, $\mathcal{C}$ has a maximal boundary walk β with $\text{length}(\beta) \geq n - o(n)$. $\square$

The next technical result shows that simple components are predominant a.a.s. in T_N . The proof uses the Geometric Lemma.

LEMMA 4.5. *If $h_Q \rightarrow \infty$, then $\mathbf{E}[Y] = o(\mathbf{E}[X])$ and $\mathbf{E}[Z_2] = o(\mathbf{E}[X])$.*

Proof. Let us first bound the expected number $\mathbf{E}[Y]$ of rectangular components with more than one vertex. The amount of area that is e.o.w., as guaranteed by the Geometric Lemma, is large enough to make such components rare.

Notice from (18) that the ℓ^1 -length of the edges of any boundary walk of a component are integers between 1 and $2d$.

Let $\mathcal{B}$ be the set of walks in T_N which are (for some configuration of the walkers) a maximal boundary walk of some r-component with respect to its outside region. For each $\beta \in \mathcal{B}$, choose a rooted spanning tree $T(\beta)$ of the graph induced by the edges of β . Note that given any such tree T of m vertices, we may recover β by joining certain pairs of vertices (with no edges crossing). The edges added are just diagonals added to a face of degree $2m - 2$. For each vertex $v \in V$, natural $m \geq 2$, and tuple $\mathbf{l} = (l_1, \dots, l_{m-1})$ of naturals $1 \leq l_i \leq 2d$, let $\mathcal{B}_{v,m,\mathbf{l}}$ be the set of all $\beta \in \mathcal{B}$ such that $T(\beta)$ has m vertices, is rooted at v , and has edges of ℓ^1 -lengths $l_1, \dots, l_{m-1}$. The number of such trees is at most $\prod_{j=1}^{m-1} 16l_j$, where a factor 4^m comes from the number of rooted plane trees, and each factor $4l_j$ is the number of vertices of ℓ^1 distance l_j from a given vertex. Therefore,

$$(21) \quad |\mathcal{B}_{v,m,\mathbf{l}}| \leq \prod_{j=1}^{m-1} Cl_j,$$

where C is constant, and also clearly

$$(22) \quad \mathbf{E}[Y] \leq \sum_{\substack{v \in V \\ m \geq 2 \\ 1 \leq l_1, \dots, l_{m-1} \leq 2d}} \sum_{\beta \in \mathcal{B}_{v,m,l_1,\dots,l_{m-1}}} \mathbf{P}(Y_\beta = 1),$$

where Y_β indicates the event of having some r -component with β one of its maximal boundary walks with respect to its outside region.

By Lemma 4.3, the size $|A_\beta|$ of the forbidden region outside β is an integer bounded below by $h + dl/J$, where $l = \text{length}(\beta)$. For technical purposes we consider a subset of A_β of size $h + \lceil dl/(2J+1) \rceil$, representing a region free of walkers. By Lemma 2.2, and noting that $\alpha > 1/2$ and hence $p < 2\varrho$, we obtain an upper bound for the probability of this emptiness occurring and the m vertices in β being occupied. Since this is necessary for the event Y_β to occur, we have

$$(23) \quad \begin{aligned} \mathbf{P}(Y_\beta = 1) &= O(1 - e^{-\varrho/\alpha})(2\varrho)^{m-1} \left(1 - \frac{S}{N}\right)^w \\ &= O(1 - e^{-\varrho})(2\varrho)^{m-1} \left(1 - \frac{h}{N}\right)^w e^{-\lceil dl/(2J+1) \rceil \varrho} \end{aligned}$$

since $\alpha \leq 1$. Furthermore, let $l' = l_1 + \dots + l_{m-1}$. Then since the spanning tree has length no more than the length of β , $\text{length}_{\ell^1}(\beta) > l'$. By (18), we have $l \geq l'/2$, and hence we get

$$(24) \quad \mathbf{P}(Y_\beta = 1) = O(1 - e^{-\varrho})(2\varrho)^{m-1} \left(1 - \frac{h}{N}\right)^w e^{-dl'\varrho/J'},$$

where $J' = 2(2J+1)$.

From (22), (21), and (24), we get

$$\mathbf{E}[Y] = O(1) \sum_{\substack{m \geq 2 \\ 1 \leq l_1, \dots, l_{m-1} \leq 2d}} N \left(\prod_{j=1}^{m-1} Cl_j \right) (1 - e^{-\varrho}) (2\varrho)^{m-1} \left(1 - \frac{h}{N}\right)^w e^{-dl'\varrho/J'}.$$

Therefore, using Proposition 4.2 for the asymptotic value of $\mathbf{E}[X]$,

$$(25) \quad \begin{aligned} \mathbf{E}[Y]/\mathbf{E}[X] &= O(1) \sum_{\substack{m \geq 2 \\ 1 \leq l_1, \dots, l_{m-1} \leq 2d}} \left(\prod_{j=1}^{m-1} Cl_j \right) (2\varrho)^{m-1} e^{-dl'\varrho/J'} \\ &= O(1) \sum_{m \geq 2} \left(\frac{C'}{d} \sum_{k=1}^{2d} kd\varrho e^{-kd\varrho/J'} \right)^{m-1}. \end{aligned}$$

In the case where $d\varrho \rightarrow \infty$, we have $\varrho e^{-c'd\varrho} = o(\max(1, \varrho)) = o(1)$ and hence $\mathbf{E}[Y] = o(\mathbf{E}[X])$. In the case where $d\varrho = O(1)$, we use $\sum_{k \geq 1} kc^{-\epsilon kd\varrho} = O((d\varrho)^{-2})$.

In the case where $d\varrho = O(1)$, we use $\sum_{k \geq 1} kc^{-kd\varrho} = O((d\varrho)^{-2})$ for $c < 1$, and (25) gives

$$\mathbf{E}[Y]/\mathbf{E}[X] = O(1) \sum_{m \geq 2} \left(\frac{C''}{d^2\varrho} \right)^{m-1} = o(1) \quad \text{as } d^2\varrho \rightarrow \infty.$$

To prove $\mathbf{E}[Z_2] = o(\mathbf{E}[X])$, from Lemma 4.4, each component counted by Z_2 has some maximal boundary walk β with $\text{length}(\beta) \geq n - o(n)$. If we apply Lemma 4.3 to this β , we have $|A_\beta| \geq ld/J$, where $l = \text{length}(\beta)$. Using $d = o(n)$ (since $h = o(N)$), we have $|A_\beta| \geq h + ld/2J$ for large N , and we then proceed similarly as for Y . $\square$

Proof of Theorem 1.5. From Proposition 4.2, if $\mu \rightarrow \infty$, then $\mathcal{W}(G, w, d)$ is disconnected a.a.s. In the other two cases, $\mu = O(1)$ and we must have $h\varrho \rightarrow \infty$. In this case we can apply Lemma 4.5 and get

$$\mathbf{P}(Y > 0) \leq \mathbf{E}[Y] = o(\mathbf{E}[X]) = o(1), \quad \mathbf{P}(Z_2 > 0) \leq \mathbf{E}[Z_2] = o(\mathbf{E}[X]) = o(1).$$

Thus, a.a.s. we have only simple components and at most one nr-component of type 1. The rest of the theorem follows from the asymptotic distribution of X given in Proposition 4.2. $\square$

4.2. Dynamic properties. According to the model, from an initial random placement f of the walkers, at each step, every walker moves from its current position to one of its neighbors, with a probability of $1/4$ of going either way. This is a standard random walk on the grid for each walker. We wish to study the connectivity properties of $\mathcal{W}_t(T_N)$. The analysis of the dynamic case is quite similar to that of the cycle, so we state the major results and point to the differing details in the proofs.

We define *states* (or *configurations*) and the graph of configurations in an analogous way to the cycle (see section 3.2). In this case, there are $N^w = n^{2w}$ different configurations of walkers, each one represented by a vector $\mathbf{a} = (a_1, \dots, a_w) \in (\mathbb{Z}_n \times \mathbb{Z}_n)^w$, where $a_i = (a_{i,x}, a_{i,y})$ indicates the label of the vertex being occupied by walker i . Given a configuration $\mathbf{a} = (a_1, \dots, a_w)$, there exists an edge between $\mathbf{a}$ and all configurations $\mathbf{b} = (b_1, \dots, b_w)$, such that $\text{dist}(a_i, b_i) = 1$. Thus, any configuration has 4^w neighbors, and the relationship of being neighbors is symmetric. As in the case of the cycle, the dynamic process can be seen as a random walk on the graph of configurations and thus as a Markov chain $\mathcal{M}(N, w, d)$.

For N even, given any two configurations $\mathbf{a}$ and $\mathbf{b}$, we say that they have the *same parity* if, for all i and j , $(a_{i,x} - a_{j,x}) + (a_{i,y} - a_{j,y}) \equiv (b_{i,x} - b_{j,x}) + (b_{i,y} - b_{j,y}) \pmod{2}$. With this definition of parity, Lemma 3.2 and its consequences also apply to the grid. Then, if N is odd, $\mathcal{M}(N, w, d)$ is ergodic, and if N is even, there are 2^{w-1} closed classes of states, where each class consists of all configurations with the same parity. The Markov chain restricted to any of these classes of states is irreducible and positive recurrent, but also 2-periodic, so we do not have ergodicity.

OBSERVATION 4.6. *Using the same argument as in Observation 3.3, for any fixed t , we can consider $\mathcal{W}_t(T_N)$ as a static $\mathcal{W}(T_N)$.*

In view of this observation and Theorem 1.5, we assume $\mu = \Theta(1)$ for the remainder of the section. This covers the nontrivial dynamic situations where $\mathcal{W}(G, w, d)$ is neither a.a.s. disconnected nor a.a.s. connected. Furthermore, in this case we need only to focus on the study of simple components. We also assume for the present subsection that $d \geq 2$. The case $d = 1$ is excluded for technical reasons.

We define $X = X(t)$ to be the random variable that counts the number of simple components at time step t . Given our assumptions about μ , for t in any fixed bounded time interval, $X(t)$ is asymptotically Poisson with expectation $\mu = \Theta(1)$, as studied in Proposition 4.2.

In analogy with d -hole lines in section 3.2, we define a *simple component line* to be a maximal sequence of pairs $(v_1, t_1), \dots, (v_l, t_l)$, where v_i is a simple component existing at time step t_i for $1 \leq i \leq l$, and such that $t_i = t_{i-1} + 1$ and the vertex v_i is adjacent to v_{i-1} , for $2 \leq i \leq l$. Birth, death, and survival of lines and the random

variables $B(t)$, $D(t)$, and $S(t)$ are defined analogously to the cycle case. For the case that $d = 1$, the concept of simple component lines is not quite adequate to describe what is going on unless $\varrho \rightarrow 0$, since otherwise it is reasonably likely that a vertex is occupied by several walkers that in one step jump to several different neighbors and create several component lines simultaneously. For this reason we exclude $d = 1$ at this point, though it is very easy to obtain most of the results claimed if $\varrho \rightarrow 0$. Presumably a suitable analysis of the simultaneous creation or destruction of several simple component lines gives results even for $\varrho \not\rightarrow 0$, but we have not done this.

We need one more definition referred to in section 1. Let v and v' be any two adjacent vertices in the grid. Let b be the number of directed edges whose origin is a vertex at distance strictly greater than d from v and whose destination is at distance at most d from v' . Note that this quantity b does not depend on the particular v and v' but just on parameter d . We have that $b = \Theta(d)$, but the exact expression of this b depends on the particular chosen metrics. Some examples are found in Table 2.

TABLE 2
Parameter b .

Metrics	b
ℓ^1	$b = 2d + 1/2$
ℓ^p ($p < \infty$)	$b \sim (1/\sqrt[p]{2} + 3/2) d$, if $d \rightarrow \infty$
ℓ^∞	$b = 3d + 1$

We next have a result analogous to Proposition 3.4.

PROPOSITION 4.7. *Let $d > 1$. For t in any fixed bounded time interval, the random variables $S(t)$, $B(t)$, and $D(t)$ are asymptotically independent Poisson, with the expectations*

$$\mathbf{E}[S(t)] \sim \begin{cases} \mu & \text{if } d\varrho \rightarrow 0, \\ \mu - \lambda & \text{if } d\varrho \rightarrow c, \\ 4 \frac{1-e^{-\varrho/4}}{1-e^{-\varrho}} e^{-(b+3/4)\varrho} \mu & \text{if } d\varrho \rightarrow \infty, \end{cases}$$

$$\mathbf{E}[B(t)] = \mathbf{E}[D(t)] \sim \begin{cases} b\varrho\mu & \text{if } d\varrho \rightarrow 0, \\ \lambda & \text{if } d\varrho \rightarrow c, \\ \mu & \text{if } d\varrho \rightarrow \infty, \end{cases}$$

where $\lambda = (1 - e^{-b\varrho}) \mu$ as in Theorem 1.7.

Proof. For a vertex $v \in V$ with coordinates (x, y) , let v_N, v_S, v_E, v_W denote the vertices with coordinates $(x, y + 1), (x, y - 1), (x + 1, y), (x - 1, y)$. The proof is so similar to that of Proposition 3.4 that we discuss in detail only the ways that a simple component line can be born at v between time steps t and $t + 1$. We classify these events in 4 main classes, as shown in Figure 5.

- b1. At time step t , just one vertex of v_N, v_S, v_E, v_W is occupied and belongs to some bigger component. Then, all walkers there jump to v and stop communicating with other walkers.
- b2. At time step t , just two vertices of v_N, v_S, v_E, v_W are occupied. Then, all walkers there jump to v and do not communicate with other walkers.
- b3. At time step t , just three vertices of v_N, v_S, v_E, v_W are occupied. Then, all walkers there jump to v and do not communicate with other walkers.

FIG. 5. Birth of a simple component line at vertex v .

b4. At time step t , vertices v_N, v_S, v_E, v_W are occupied. Then, all walkers there jump to v and do not communicate with other walkers.

The first three classes have several subtypes (four for b1, six for b2, and four for b3) which correspond to choosing a subset of the four possible compass directions.

The rest of the proof follows that of Proposition 3.4. (See [DPSW06] for the full details.) $\square$

From Proposition 4.7, we can easily derive important consequences analogous to those of the cycle, always under the assumption stated after Observation 4.6. The first one gives us the probability that $\mathcal{W}_t(T_N)$ is connected but $\mathcal{W}_{t+1}(T_N)$ is disconnected. Note that this is a.s. equivalent to having no simple components at time step t and just one at $t+1$. The proof is immediate by the same argument as for Lemma 3.9.

LEMMA 4.8. *Let $d > 1$. The probability that $\mathcal{W}_t(T_N)$ is connected and that $\mathcal{W}_{t+1}(T_N)$ is disconnected is given by*

$$\mathbf{P}(X(t+1) \geq 1 \wedge X(t) = 0) \sim \begin{cases} \mu e^{-\mu} b \varrho & \text{if } d\varrho \rightarrow 0, \\ e^{-\mu}(1 - e^{-\lambda}) & \text{if } d\varrho \rightarrow c, \\ e^{-\mu}(1 - e^{-\mu}) & \text{if } d\varrho \rightarrow \infty, \end{cases}$$

where λ is defined as in Theorem 1.7.

In a similar way to the cycle case, we define the *lifespan* of a simple component line as the number of time steps for which the line is alive. For any vertex v and time t , the random variable $L_{v,t}$ counts the lifespan of the simple component line born at

vertex v between time steps t and $t + 1$. If this birth does not take place, $L_{v,t}$ is defined to be 0.

We finish by considering lifespans and connected periods. Define L_{av} (the average lifespan of simple component lines), L_T , and L as in section 3.2 but in terms of the new definition of $L_{v,t}$. Similarly, define LC_{av} to be the average length of the period from time t for which the graph of walkers on the grid is connected. We state the following theorem without proof because it is not difficult to adapt the argument used for Theorems 1.3, 1.4, 3.6, and 3.8. The proof is entirely straightforward in the case that L_{av} is bounded (i.e., $d\rho \not\rightarrow 0$). If L_{av} is unbounded, then there are two modifications to the argument. First, one needs to do the moment calculations more carefully (this is analogous to the situation at the end of the proof of Proposition 3.4; there is less independence when d is large, so this takes a bit of care). Second, for connectivity issues the observation that a complex component exists at any one time with probability tending to 0 does not show that we can ignore them, since the lifespan is no longer bounded. However, we may easily adapt the analysis to consider the creation or destruction of components (not just simple ones) in any given step to obtain the required result. We omit these details; they can be found in [P07].

THEOREM 4.9. *For the walkers model on T_N with $d > 1$,*

$$L_{\text{av}} \sim \begin{cases} \frac{1}{b\rho} & \text{if } d\rho \rightarrow 0, \\ \frac{\mu}{\lambda} & \text{if } d\rho \rightarrow c, \\ 1 & \text{if } d\rho \rightarrow \infty, \end{cases} \quad \text{and} \quad LC_{\text{av}} \sim \begin{cases} \frac{1}{\mu b\rho} & \text{if } d\rho \rightarrow 0, \\ \frac{1}{1-e^{-\lambda}} & \text{if } d\rho \rightarrow c, \\ \frac{1}{1-e^{-\mu}} & \text{if } d\rho \rightarrow \infty, \end{cases}$$

where λ is defined as in Theorem 1.7. Furthermore, L_T (LC_T) converges in probability for T growing large (N fixed) toward a random variable L (LC , respectively), uniquely determined almost everywhere, where $L \sim L_{\text{av}}$ and $LC \sim LC_{\text{av}}$ a.a.s.

The proof of Theorem 1.7 is a simple adjustment of the proof of Theorem 4.9 (as in the cycle case).

5. Conclusions and open problems. In this work we have characterized connectivity issues of a very large set of moving agents which move through a prescribed real or virtual graph. We believe it is the first time that these kinds of characterizations have been obtained, and it could open an interesting line of research. We gave characterizations for the cycle and the grid. The results obtained for the grid could easily be extended to the grid with diagonals. Also, an approach similar to ours should work with the k -dimensional toroidal grid, but a suitable substitute for the Geometric Lemma needs to be found.

Our results are based on results for the static problem, and the most difficult was to show that, for the crucial values of w and d , there is a.a.s. just one big component apart from simple ones. There is a corresponding argument in Penrose [P97], [P99] for the related problem in which w walkers are placed at random in a unit box in continuous Euclidean space (or the toroidal counterpart), and walkers of distance at most r can communicate directly. Our setting has one more parameter, but it is clear that the behavior for our problem should be similar to the continuous one with $r = d/n$, where our toroidal grid is $n \times n$. However, proving this equivalence would not be entirely straightforward in the case that d is small (constant or near-constant), since then the discrete ball of radius d is not well approximated by the continuous one.

In our model we use a fixed number w of walkers. One could alternatively place walkers randomly so that each vertex is occupied independently with probability p .

For example, they could be Poisson-distributed at each vertex (as suggested by an anonymous referee) with parameter λ such that $1 - e^{-\lambda} = p$. In the static case this alternative would bear the same relation to our model as the relation between the random graph models $G(n, m)$ and $G(n, p)$, and as for that case, one would expect similar properties when p is approximately w/N (or, more precisely, $1 - e^{-w/N}$, to capture the case that w is close to or greater than N). This would simplify some of our analysis (e.g., the proof of Lemma 2.1). However, it would be difficult to deduce all the results for our model in such a way. For one thing, some of the properties we study are not convex in the required sense (see [JLR00]). There are also other obstacles to using models with independent occupancy probabilities. For instance, if $w(s_0/N)^2 \neq o(1)$, then $(1 - (S_0/N))^w$, as in Lemma 2.1, is not asymptotic to $e^{-S_0 e}$.

Further planned work is the extension of the results to random geometric graphs, which will provide a model for omnidirectional radio communication in the setting described in [GHSZ]. Another interesting extension is the hypercube, as the number of neighbors of a vertex is then not constant. A further project is to study the connectivity of walkers when the underlying topology has obstacles which can interfere with communication.

COMBINATORIAL PROPERTIES OF A ROOTED GRAPH POLYNOMIAL*

DAVID EISENSTAT[†], GARY GORDON[‡], AND AMANDA REDLICH[§]

Abstract. For a rooted graph G , let $EV(G; p)$ be the expected number of vertices reachable from the root when each edge has an independent probability p of operating successfully. We examine combinatorial properties of this polynomial, proving that G is k -edge connected if and only if $EV'(G; 1) = \dots = EV^{(k-1)}(G; 1) = 0$. We find bounds on the first and second derivatives of $EV(G; p)$; applications yield characterizations of rooted paths and cycles in terms of the polynomial. We prove reconstruction results for rooted trees and a negative result concerning reconstruction of more complicated rooted graphs. We also prove that the norm of the largest root of $EV(G; p)$ in $\mathbb{Q}[i]$ gives a sharp lower bound on the number of vertices of G .

Key words. expected rank, probabilistic graph

1. Introduction. Graph polynomials have a long history, dating to Birkhoff's use of the chromatic polynomial in an (unsuccessful) attempt to prove the four color theorem [7]. Two other polynomials, the reliability polynomial [12] and the 2-variable Tutte polynomial [8], also encode combinatorial data about the graph (the Tutte polynomial specializes to both the chromatic and reliability polynomials). While the original motivation for the study of these invariants is still important, much of the current interest in the Tutte polynomial is not related to any of its applications. See [9, 14] for some recent combinatorial applications.

It is in this spirit that we continue the study of the expected value polynomial $EV(G; p)$ applied to a rooted graph G , i.e., a graph with a distinguished vertex. The polynomial was introduced in [1] and [2], extended to antimatroids in [18], and applied to rooted graphs in [5, 19]. A closely related polynomial, called *pair connected reliability* by Amin, Siegrist, and Slater in [3, 4] and Siegrist in [21, 22] and *network resilience* by Colbourn in [13], is motivated by the reliability polynomial. A similar polynomial has also been defined for (nonrooted) graphs [6, 23].

In this paper, we concentrate on combinatorial properties of the rooted graph and their connection to the polynomial. In the sequel paper [15], we turn to applications, including practical questions about optimal location for the root for a given graph, randomness, and estimation.

Section 2 is concerned with bounds on the first and second derivatives of $EV(G; p)$. Applications of these bounds to the edge connectivity of the graph and graph reconstruction are given. The main result is Theorem 2.7.

THEOREM 2.7. *If G is a rooted graph, then G is k -edge connected if and only if $EV'(G; 1) = \dots = EV^{(k-1)}(G; 1) = 0$.*

Section 3 examines the behavior of $EV(G; p)$ under standard graph-theoretic constructions. We give limits on the possibility of reconstructing G from $EV(G; p)$. When G is a rooted cycle or a rooted path, reconstruction is possible; in almost all other cases, it is not possible.

THEOREM 3.4.

- (1) $EV(G; p) = p + \cdots + p^n$ if and only if G is isomorphic to the rooted path P_{n-1} .
- (2) $EV(G; p) = 2p + \cdots + 2p^{n-1} + (n-1)p^n$ if and only if G is isomorphic to the rooted cycle C_n .

Conversely, Theorem 3.1 shows that *any* rooted graph is a subgraph of another rooted graph with a linear expected value polynomial. In a slightly different direction, Theorem 3.9 shows that rooted trees can be reconstructed from a *family* of expected rank polynomials.

In section 4 we give connections between the maximum norm of the zeros of $EV(G; p)$ in $\mathbb{C}$ and the number of vertices of G . This section is motivated by the study of the roots of the chromatic polynomial, which has connections to statistical physics [10, 20]. Our main result is Theorem 4.3.

THEOREM 4.3. *Let G be a connected rooted graph with $n > 1$ vertices. Suppose that the polynomial $EV(G; r) = 0$ for some $r \in \mathbb{Q}[i]$. Then $|r - 1| \leq n - 1$.*

While many of the proofs given here are straightforward (especially those concerning derivatives of the 1-variable polynomial), we believe the results are of sufficient interest to warrant further study. These results show that the polynomial encodes meaningful information about the rooted graph, but we also place bounds on how successful such an approach can be (Theorem 3.1).

2. Derivatives and edge connectivity. Let G be a connected rooted graph with edge set E , where each edge has the same independent probability p of being operational. We give two equivalent formulations of the expected rank polynomial, both of which will be important throughout this work. For a nonroot vertex v , let $Pr(v)$ denote the probability that v remains connected to the root. The following result appears explicitly in [5] and implicitly in [13] and [3, 4].

DEFINITION 2.1 (Proposition 2.7 of [5]). *Let G be a rooted graph, and let V be all the nonroot vertices of G . Then*

$$EV(G; p) = \sum_{v \in V} Pr(v).$$

We will also need the following deletion-contraction expansion for the polynomial.

PROPOSITION 2.2 (deletion-contraction: Proposition 2.3 of [5]). *Let G be a rooted graph, and let e ($\neq$ loop) be an edge adjacent to the root. Then*

$$EV(G; p) = (1 - p) \cdot EV(G - e; p) + p \cdot EV(G/e; p) + p.$$

We will use the deletion-contraction formula of Proposition 2.2 repeatedly in this section. Throughout this section, we will assume an edge e incident to the root is not a loop (loops have no effect on the polynomial).

Example 2.3. We consider the expected rank polynomial $EV(K_n; p)$ for the rooted complete graph. This example is important since any random graph can be thought of as a subgraph of K_n . Obtaining closed form expressions for $EV(K_n; p)$ is difficult; see [4] for one approach. When applying deletion-contraction to K_n , multiple edges arise, and this gives rise to a recursive formula for $EV(K_n; p)$. (Replacing e by k

FIG. 1. Graphs of $EV(K_n; p)/(n-1)$ for $n = 2, \dots, 10$.

multiple edges can be thought of as increasing the probability that e succeeds from p to $1 - q^k$, where $q = 1 - p$.) If G' is obtained from the rooted graph G by replacing every edge of G by k parallel edges, then $EV(G') = EV(G; 1 - q^k)$. The proof of the next proposition follows from this observation.

PROPOSITION 2.4. *Let $q = 1 - p$. Then*

$$EV(K_n; p) = \sum_{k=1}^{n-1} \binom{n-1}{k} p^k q^{n-1-k} (EV(K_{n-k}; 1 - q^k) + k).$$

For fixed $p > 0$, we have $EV(K_n; p)/(n-1) \rightarrow 1$ as $n \rightarrow \infty$. This follows from a famous result of Erdős and Rényi [17]. If $p \gg \log n/n$, then the probability that G is connected approaches 1 as $n \rightarrow \infty$. Graphs of $EV(K_n; p)/(n-1)$ for $2 \leq n \leq 10$ appear in Figure 1.

We now turn our attention to the derivative $EV'(G; p)$, which is closely related to the connectivity of the rooted graph G . We begin by deriving sharp bounds on the size of $EV'(G; p)$ and $EV''(G; p)$.

We omit the straightforward proof of the lemma.

LEMMA 2.5. *Let G be a rooted graph with an edge e incident to the root. Then for all $p \in [0, 1]$, $1 + EV(G/e; p) \geq EV(G - e; p)$, with equality possible only when $p = 1$.*

It is easy to see that $EV'(G; p) \geq 0$ for all $0 \leq p \leq 1$: increasing p increases the expected number of vertices reachable from the root, so $EV(G; p)$ is an increasing function. We now give sharp upper and lower bounds on $EV'(G; p)$ and an upper bound on the second derivative $|EV''(G; p)|$.

PROPOSITION 2.6. *Let G be a rooted graph with n edges. Then for all $p \in [0, 1]$, the following hold:*

- (1) $EV'(G; p) \geq 0$. This inequality is strict if G has an edge incident to the root and $p < 1$.
- (2) $EV'(G; p) \leq n(n+1)/2$.
- (3) $|EV''(G; p)| \leq (n-1)n(n+1)/3$.

Proof. We prove (2)—the proofs of (1) and (3) are similar. We proceed by induction on n , and the base case $n = 0$ is trivial. When $n > 0$, we differentiate the formula 2.2:

$$\begin{aligned} EV'(G; p) &= (1 + EV(G/e; p)) - EV(G - e; p) \\ &\quad + pEV'(G/e; p) + (1 - p)EV'(G - e; p). \end{aligned}$$

If G has no edge e incident to the root, then $EV'(G; p) = 0$. Otherwise, we examine each term in this formula.

First, note that $1 + EV(G/e; p) \leq n$ since $EV(G/e; 1) = n - 1$ and $EV(G; p)$ is an increasing function. Also, $EV(G - e; p) \geq 0$ is clear. Finally,

$$pEV'(G/e; p) + (1 - p)EV'(G - e; p) \leq (n - 1)n/2$$

by induction. Putting the pieces together gives $EV'(G; p) \leq n(n + 1)/2$. $\square$

Notes.

1. The lower bound in Proposition 2.6(1) is sharp for all 2-edge connected graphs at $p = 1$. For the rooted cycle C_n ,

$$EV'(C_n; p) = \sum_{k=1}^{n-1} 2kp^{k-1} - n(n-1)p^{n-1},$$

so $EV'(C_n; 1) = 0$.

2. The upper bound in Proposition 2.6(2) is also sharp for rooted paths with n edges. If P_{n+1} denotes the rooted path on n edges with the root located at a leaf, then

$$EV(P_{n+1}; p) = \sum_{k=1}^n p^k,$$

so $EV'(P_{n+1}; 1) = \sum_{k=1}^n k = n(n + 1)/2$. The converse is also true when $p = 1$: If $EV'(G; 1) = n(n + 1)/2$, then G is a rooted path (Lemma 3.3(1)).

3. Note that it is not possible to bound $EV'(G; p)$ in terms of the number of vertices: if G is a graph with two vertices joined by k edges, then $EV(G; p) = 1 - (1 - p)^k$, so $EV'(G; 0) = k$.
4. The bounds of Proposition 2.6(3) are sharp for paths (upper bound) and cycles (lower bound) with n edges (P_{n+1} and C_n), again at $p = 1$. We will also prove a converse for the lower bound: If $EV''(G; 1) = -(n - 1)n(n + 1)/3$, then G is the rooted cycle C_n (Lemma 3.3(2)).

It is possible to derive bounds for even higher derivatives in this fashion, but these bounds will not be sharp, in general, with the exception of the lower bound for the third derivative. Further, the expected value polynomials of paths and cycles do not have maximal and minimal derivatives of all orders at $p = 1$.

Note that the second derivative of the deletion-contraction formula in Proposition 2.2 simplifies when $p = 1$:

$$EV''(G; 1) = 2EV'(G/e; 1) - 2EV'(G - e; 1) + EV''(G/e; 1).$$

This allows us to rewrite the upper bound in Proposition 2.6(3) in terms of the number of vertices of G , since G/e has one fewer vertex than G .

Recall that G is k -edge connected if removing fewer than k edges from G cannot disconnect G . The next result shows that k -edge connectivity is determined by $EV(G; p)$.

THEOREM 2.7. *If G is a rooted graph, then G is k -edge connected if and only if $EV'(G; 1) = \dots = EV^{(k-1)}(G; 1) = 0$.*

Proof. From Definition 2.1, we have

$$EV(G; p) = \sum_{v \in V} Pr(v),$$

where $Pr(v)$ is the probability that v is connected to the root. Fix v and let $S_1, \dots, S_n$ be the minimal subsets of E that, when removed, disconnect v from the root. Let $F(S)$ be the probability that all edges in S fail. Then we can compute $Pr(v)$ in terms of $F(S)$ via inclusion-exclusion:

$$Pr(v) = 1 - F(S_1) - \dots - F(S_n) + F(S_1 \cup S_2) + \dots \pm F(S_1 \cup \dots \cup S_n).$$

Now $F(S_i) = (1-p)^{|S_i|}$, so $Pr(v) = 1 + \sum_{j=1}^m a_j(1-p)^j$. Clearly, if k is the size of the smallest S_i , then $a_1 = \dots = a_{k-1} = 0$ and $a_k \neq 0$ (in fact, we must have $a_k < 0$). Finally, summing over all vertices gives the result. $\square$

As a quick check, note that $EV'(T; 1) > 0$ for any tree having $n > 0$ edges, so Theorem 2.7 shows that any tree is 1-edge connected. For the cycle C_n , we have $EV'(C_n; 1) = 0$ (see the remarks immediately following Proposition 2.6), but $EV''(C_n; 1) = -(n-1)n(n+1)/3$, so the theorem gives a verification that cycles are 2-edge connected.

When G is not rooted, Proposition 2.2 of [6] shows that $EV'(G; 1) = 0$ if and only if G is connected, where $EV(G; p)$ is defined using the matroid (cycle) rank function. In this case, the value of $|EV'(G; 1)|$ is just the number of isthmuses of G . Thus, Theorem 2.7 is a rooted generalization of this result.

3. Reconstructing graphs and an embedding theorem. $EV(G; p)$ is defined via connectivity; thus, it is not surprising that graph reconstruction is not possible using this invariant. The next theorem, one of the main results of this section, is a negative reconstruction result.

THEOREM 3.1. *Let G be a rooted graph. Then there is a rooted graph G' such that G is an induced subgraph of G' and $EV(G') = kp$ for some positive integer k .*

Proof. Let $EV(G; p) = a_1p + a_2p^2 + \dots + a_np^n$, where $a_i \in \mathbb{Z}$ and $a_n \neq 0$. We first show how to find a graph H_1 with the property that $EV(G \oplus H_1; p)$ has degree less than n . We then iterate this procedure, eventually producing a graph $G' = G \oplus H_1 \oplus \dots \oplus H_{n-1}$ so that $EV(G'; p)$ is a linear polynomial.

Case 1. $a_n < 0$. Let H_1 be the direct sum of a_n copies of the path P_{n+1} , the path with n edges, with each path rooted at a vertex of degree 1. Since $EV(P_{n+1}; p) = \sum_{k=1}^n p^k$, we find that the degree of $EV(G \oplus H_1)$ is at most $n-1$.

Case 2. $a_n > 0$. First attach k n -cycles to the root of G , where $k(n-1) > a_n$, and call the new graph G_1 . Now $EV(G_1; p) = b_np^n + \dots$ has degree n , and $b_n = a_n - k(n-1) < 0$, by construction. Now proceed as in Case 1.

Now iterate this procedure to produce rooted graphs $H_2, H_3, \dots$ so that the degree of $EV(G \oplus H_1 \oplus \dots \oplus H_k)$ is at most $n-k$. This process will terminate when $k = n-1$. $\square$

Example 3.2. We apply (a variation of) the procedure described in the proof of Theorem 3.1 to the rooted cycle C_3 . First, note that $EV(C_3; p) = 2p + 2p^2 - 2p^3$. We attach a tree H_1 with $EV(H_1; p) = p + p^2 + 2p^3$, as in Figure 2. This gives $EV(C_3 \oplus H_1; p) = 3p + 3p^2$.

Now let $H_2 = C_2 \oplus C_2 \oplus C_2$, so $EV(H_2; p) = 6p - 3p^2$. Thus $EV(G'; p) = 9p$, where $G' = C_3 \oplus H_1 \oplus H_2$.

For example, if we let A_k denote the rooted graph formed by k parallel edges, then $EV(C_2 \oplus C_2 \oplus C_2 \oplus C_2; p) = EV(A_3 \oplus A_3 \oplus C_3; p) = 8p - 4p^2$.

Given Theorem 3.1, it is quite easy to construct nonisomorphic graphs with the same expected value polynomial. However, for certain classes of graphs, G can be uniquely reconstructed from $EV(G; p)$. We now show how rooted cycles are completely

FIG. 2. $EV(S_9; p) = EV(G'; p) = 9p$.

determined (within the class of all rooted graphs) by these polynomials. Recall that P_{n+1} denotes the rooted path with n edges.

LEMMA 3.3. *Let G be a rooted graph with n edges.*

- (1) $EV'(G; 1) = (n+1)n/2$ if and only if G is isomorphic to P_{n+1} .
- (2) $EV''(G; 1) = -(n+1)n(n-1)/3$ if and only if G is isomorphic to C_n .

Proof. We prove (1) and leave the similar proof of (2) to the reader. From the remarks following the proof of Proposition 2.6(2), $EV'(P_{n+1}; 1) = n(n+1)/2$.

For the converse, we use induction. If G has one edge, then there is nothing to prove. Now suppose $n > 1$ and $EV'(G; 1) = (n+1)n/2$. If G has no edges incident to the root, then $EV'(G; 1) = 0$, so we may assume that e is incident to the root. Then, as in the proof of Proposition 2.6(2), we have $EV'(G; 1) = 1 + EV(G/e; 1) - EV(G - e; 1) + EV'(G/e; 1)$.

Now $EV(G/e; 1) \leq n-1$ (since $G - e$ has $n-1$ edges) and $EV(G - e; 1) \geq 0$. Thus,

$$EV'(G/e; 1) = EV'(G; 1) - EV(G/e; 1) + EV(G - e; 1) - 1,$$

which gives $EV'(G/e; 1) \geq (n+1)n/2 - (n-1) - 1 = n(n-1)/2$. By Proposition 2.6(2), we have $EV'(G/e; 1) = n(n-1)/2$, which forces each of the inequalities given above to be equalities. Thus, $EV(G - e; 1) = 0$, so e is the only edge incident to the root of G , and $EV(G/e; 1) = n-1$, so G/e is connected. Furthermore, since $EV'(G/e; 1) = n(n-1)/2$, we have that G/e is isomorphic to the path P_n , by induction.

Now we have a rooted graph G with exactly one edge e incident to the root such that G/e is the path P_n . This forces G to be the path P_{n+1} . $\square$

An immediate consequence of Lemma 3.3 is the following.

THEOREM 3.4.

- (1) $EV(G; p) = p + \cdots + p^n$ if and only if G is isomorphic to the rooted path P_{n-1} .
- (2) $EV(G; p) = 2p + \cdots + 2p^{n-1} + (n-1)p^n$ if and only if G is isomorphic to the rooted cycle C_n .

Obviously, for any positive integer k , it is possible to produce k nonisomorphic rooted trees, all sharing the same expected value polynomial. On the other hand,

it is possible to uniquely reconstruct a rooted tree from a *sequence* of expected rank polynomials. We begin with a definition.

DEFINITION 3.5. *Let G be a rooted graph. Then the expected rank k polynomial is defined by*

$$EV_k(G; p) = \sum_{A \subseteq E: r(A)=k} p^{|A|} (1-p)^{|E|-|A|},$$

where $r(A)$ is the number of vertices in the component of A containing the root (not including the root).

Thus, $EV_k(G; p)$ is the probability that exactly k vertices are connected to the root. The proof of the next proposition is immediate.

PROPOSITION 3.6. *Let G be a rooted graph with $n+1$ vertices. Then*

- (1) $\sum_{k=1}^n EV_k(G; p) = 1$, and
- (2) $EV(G; p) = \sum_{k=1}^n k \cdot EV_k(G; p)$.

To keep track of this sequence of expected rank k polynomials, it is convenient to introduce a 2-variable generating function.

DEFINITION 3.7. *Let T be a rooted tree, and let $X(T)$ be a tree with a single edge e adjacent to the root such that $X(T)/e = T$. Then define $F(T; p, q)$ recursively as follows:*

$$F(\bullet) = 1,$$

$$F(X(T)) = q + pF(T),$$

$$F(T_1 \oplus T_2) = F(T_1)F(T_2).$$

The connection between the generating function $F(T; p, q)$ and the sequence of rank k expected rank polynomials $EV_k(T; p)$ is made explicit in the next proposition.

PROPOSITION 3.8. *$F(T; p, q)$ is uniquely recoverable from the sequence of polynomials $EV_0, \dots, EV_n$, where EV_k is the probability that exactly k vertices are connected to the root.*

Proof. Let $EV_k(p) = p^k g_k(p)$. Then set $q = 1 - p$, so $p = 1 - q$, and it is easy to show that $F(T) = \sum_k p^k g_k(1 - q)$. Thus, we can recover $F(T)$ from the sequence of polynomials, and this operation is easily invertible. $\square$

We now prove that rooted trees can be uniquely reconstructed from their sequence of rank k expected rank polynomials $\{EV_0, \dots, EV_n\}$.

THEOREM 3.9. *Let T be a rooted tree. Then $F(T(p, q))$ uniquely determines T up to isomorphism.*

Proof. It suffices to show that for all T , $F(X(T))$ is irreducible over $\mathbf{Z}[p, q]$. The result then follows by induction: if $F(T; p, q)$ factors, we reconstruct the rooted trees corresponding to the factors inductively. If $F(T; p, q)$ is irreducible, we will have $T = X(T')$ for some rooted tree T' , and $F(T'; p, q) = p^{-1}(F(T; p, q) - q)$, so we can reconstruct T' (and hence, T) inductively again.

Now write $F(T) = q + pG(p, q)$ for some polynomial $G(p, q)$, and suppose that $F(X(T)) = AB$. Then $F(X(T)) = (1 + pA')(q + pB')$ for some 2-variable polynomials A' and B' . If $q \mid B'$, then $q \mid (q + pB')$, so $q \mid F(X(T))$, which cannot be the case since $F(X(T))$ has exactly one pure p term, p^n , corresponding to all n edges operating successfully.

Hence q does not divide B' , and we let cp^α with $c \neq 0$ be the pure p term in B' of lowest degree. Then $F(X(T))$ contains a term cp^α that cannot be canceled by $p^2 A' B'$. As a result, $A' = 0$, and the factorization is trivial. $\square$

The sequence $\{EV_0, \dots, EV_n\}$ is equivalent to the (greedoid) Tutte polynomial of a rooted tree, which encodes information about the number of rooted subtrees of size k with exactly l leaves. More information about rooted tree reconstruction from this version of the Tutte polynomial can be found in [2, 11]. (Unrooted tree reconstruction is not possible in general—see [16].)

4. Zeros of the polynomial. Proposition 3.1 of [19] shows that the largest rational root of $EV(G; p)$ is a lower bound on the number of vertices (including the root). We generalize this result now, extending the bound to the absolute value of the largest rational root.

PROPOSITION 4.1. *Let G be a connected rooted graph with $n > 1$ vertices. Suppose the polynomial $EV(G; r) = 0$ for some $r \in \mathbb{Q}$. Then $|r - 1| \leq n - 1$.*

Proof. Let $f(p) = EV(G; p + 1)$. Then we can write

$$f(p) = (a - bp)g(p),$$

where $a/b = r - 1$ and $g \in \mathbb{Z}[p]$. $f(0) = a \cdot g(0) = n - 1$, so $a \mid (n - 1)$; and since $|a/b| \leq |a|$, $|r - 1| \leq n - 1$. $\square$

We can extend this result further, to the case where the root $r \in \mathbb{Q}[i]$.

PROPOSITION 4.2. *Let G be a connected rooted graph with $n > 1$ vertices. Suppose the polynomial $EV(G; r) = 0$ for some $r \in \mathbb{Q}[i] - \mathbb{Q}$. Then $|r - 1|^2 \leq n - 1$.*

Proof. Again, let $f(p) = EV(G; p + 1)$, and write $(a + bi)/c = r - 1$ for integers a, b , and c . Then

$$f(p) = (a^2 + b^2 - 2a(cp) + (cp)^2)g(p),$$

where $g(p) \in \mathbb{Z}[p]$. Since $n - 1 = f(0) = (a^2 + b^2)g(0)$ and $a^2 + b^2 \mid n - 1$, we have $(a^2 + b^2) = |c(r - 1)|^2 \geq |r - 1|^2$, so $|r - 1|^2 \leq (n - 1)$. $\square$

Putting Propositions 4.1 and 4.2 together gives the following.

THEOREM 4.3. *Let G be a connected rooted graph with $n > 1$ vertices. Suppose that the polynomial $EV(G; r) = 0$ for some $r \in \mathbb{Q}[i]$. Then $|r - 1| \leq n - 1$.*

All of these bounds are sharp. For the rational roots of Proposition 4.1, let G_1 be a graph with one vertex connected to the root by two edges and k vertices connected by one edge. Then $EV(G_1; p) = (k + 2)p - p^2$, which has a root at $p = k + 2$. For the lower bound, if we let G_2 be a tree with polynomial $kp + p^2$, then $EV(G_2; p)$ has a root at $p = -k$.

For the imaginary rational roots of Proposition 4.2, let $a^2 + b^2 = c^2$ be a Pythagorean triple, and let T be a tree with polynomial $((a - 1)^2 + b^2)p + 2(a - 1)p^2 + p^3$. Then $EV(T; p)$ has roots at $p = 1 - a \pm bi$, and T has $((a - 1) + 1)^2 + b^2 + 1 = c^2 + 1$ vertices and $|1 - a \pm bi - 1| = c$.

The next result is applicable to any polynomial $f(p)$ with positive integer coefficients and $f(0) = 0$.

PROPOSITION 4.4. *Let T be a tree with $n > 1$ vertices. Suppose the polynomial $EV(T; z) = 0$ for some $z \in \mathbb{C}$. Then $|z| \leq n - 2$.*

Proof. $EV(T; p) = n_1p + n_2p^2 + \dots + n_kp^k$ for positive integers n_j . Let $C = n_1 + \dots + n_{k-1}$. Then $C \leq n - 2$, since $n_1 + \dots + n_k = n - 1$.

When $C = 0$, $EV(T; p) = n_kp^k$, which has zeros only at $p = 0$. Otherwise, we can assume that $C \geq 1$. Suppose to the contrary that $|z| > C$. Then

$$|-n_kz^k| > C|z^{k-1}| > n_1|z| + \dots + n_{k-1}|z^{k-1}| > |n_1z + \dots + n_{k-1}z^{k-1}|,$$

and z is clearly not a zero. $\square$

When T is a tree, Proposition 4.4 allows us to drop the restriction that $r \in \mathbb{Q}[i]$.

COROLLARY 4.5. *Let T be a tree with $n > 1$ vertices. Suppose the polynomial $EV(T; p)$ has a zero at $p = z \in \mathbb{C}$. Then $|z - 1| \leq n - 1$.*

Unfortunately, this bound does not extend to all graphs and all complex zeros. For example, let $G = K_4 \oplus T$, where T is a tree such that $EV(T; p) = p + p^2 + p^3 + p^4 + p^5 + 5p^6$. Then $EV(G; p) = 4p + 7p^2 + p^3 - 20p^4 + 22p^5 - p^6$, which has a zero near $p = 21$. G , however, has only 14 vertices and 16 edges.

Similar constructions work with larger complete graphs, where we attach the smallest tree that will make the leading coefficient of $EV(G; p)$ equal to -1 .

It would be interesting to determine what other restrictions exist on zeros of the polynomial. This is similar to much of the current research on the chromatic polynomial of a graph [10, 20].

Acknowledgments. We thank Jennifer Feder and Greg Francos for useful discussions and the anonymous referee for several suggestions.

TESTING TRIANGLE-FREENESS IN GENERAL GRAPHS*

NOGA ALON[†], TALİ KAUFMAN[‡], MICHAEL KRIVELEVICH[§], AND DANA RON[¶]

Abstract. In this paper we consider the problem of testing whether a graph is triangle-free and, more generally, whether it is H -free, for a fixed subgraph H . The algorithm should accept graphs that are triangle-free and reject graphs that are far from being triangle-free in the sense that a constant fraction of the edges should be removed in order to obtain a triangle-free graph. The algorithm is allowed a small probability of error. This problem has been studied quite extensively in the past, but the focus was on dense graphs, that is, when $d = \Theta(n)$, where d is the average degree in the graph and n is the number of vertices. Here we study the complexity of the problem in general graphs, that is, for varying d . In this model a testing algorithm is allowed to ask neighbor queries (i.e., “What is the i th neighbor of vertex v ?”), vertex-pair queries (i.e., “Is there an edge between vertices v and u ?”), and degree queries (i.e., “What is the degree of vertex v ?”). Our main finding is a lower bound of $\Omega(n^{1/3})$ on the necessary number of queries that holds for every $d < n^{1-\nu(n)}$, where $\nu(n) = o(1)$. Since when $d = \Theta(n)$ the number of queries sufficient for testing has been known to be independent of n , we observe an abrupt, *threshold-like* behavior of the complexity of testing around n . This lower bound holds for testing H -freeness of every nonbipartite subgraph H . Additionally, we provide sublinear upper bounds for testing triangle-freeness that are at most quadratic in the stated lower bounds, and we describe a transformation from certain one-sided error lower bounds for testing subgraph-freeness to two-sided error lower bounds. Finally, in the course of our analysis we show that dense random Cayley graphs behave like quasi-random graphs in the sense that relatively large subsets of vertices have the “correct” edge density. The result for subsets of this size cannot be obtained from the known spectral techniques that only supply such estimates for much larger subsets.

Key words. property testing, triangle-freeness, subgraph-freeness, randomized algorithms, approximation algorithms, Cayley graphs

1. Introduction. *Property testing* is the study of the following type of computational tasks: Let P be some predetermined property, where we shall be interested in properties of a combinatorial nature. The task is to distinguish quickly and reliably between input objects possessing property P and input objects that are “far”

from having P , where distance is measured in some appropriately defined quantitative sense. In order to fulfill this task, the testing algorithm is given *query access* to a description of the input object O , adhering to some pre-agreed upon format; the algorithm's complexity is measured by the number of queries it asks before reaching a reliable decision. A testing algorithm is expected to query a sublinear portion of the input; hence, randomness plays an essential role in developing property testing algorithms. Property testing was defined by Rubinfeld and Sudan [18], who focused on testing algebraic properties. Goldreich, Goldwasser, and Ron [9] initiated the study of combinatorial property testing and in particular considered testing properties of graphs. Since then, the field has progressed enormously, with many papers devoted to it, where one of the main focuses is on testing graph properties. The interested reader is invited to consult the surveys [8, 17] for more details.

In this work we consider the problem of testing subgraph-freeness, and in particular triangle-freeness, in general graphs. Let n denote the number of vertices in the graph, let d denote the average degree, and let $d_{\max}$ denote the maximum degree. Given a distance parameter $\epsilon > 0$, we would like to design an algorithm that distinguishes with high probability between the case that the graph contains no triangles and the case in which more than $\epsilon \cdot dn$ edges should be removed so that no triangles remain. To this end we allow the algorithm query access to the graph. In particular, for any vertex of its choice, the algorithm may ask for the degree of the vertex, it may ask to get the i th neighbor of the vertex for every $i \leq n$ (if the vertex has less than i neighbors, then a null answer is returned), and it may ask whether there is an edge between any two vertices.¹

Subgraph-freeness, and more specifically, triangle-freeness, is one of the most basic problems studied in property testing. The interest in this problem is both due to the fact that triangle-freeness is a fundamental and simple graph property and due to the relation between triangle-freeness and the study of dense sets of integers with no three-term arithmetic progression.

Dense graphs. Most of the focus in previous works was on testing triangle-freeness in dense graphs, that is, when $d = \Theta(n)$. For this class of graphs the most appropriate input graph representation is the graph adjacency matrix, and a testing algorithm is allowed to query whether (u, v) is an edge of an input graph G , where $u, v \in V(G)$ (the so-called *vertex-pair* queries). The authors of [2] showed that it is possible to test triangle-freeness in dense graphs using a number of queries that are *independent* of n and have a tower-type behavior in $1/\epsilon$. Alon [1] proved that a superpolynomial dependence on $1/\epsilon$ is necessary for testing the subgraph-freeness of all nonbipartite subgraphs. When the fixed subgraph is bipartite, then $O(1/\epsilon)$ queries suffice [1]. It is also observed in [1] (and much earlier, though implicitly, in [19]) that the problem of testing triangle-freeness is intimately related to the famous (and very hard) problem of the existence of dense sets of integers without a three-term arithmetic progression. Alon's lower bound, which was proved for one-sided error algorithms, was extended in [6] to two-sided error algorithms. Other related results include [5].

Bounded-degree graphs. At the other extreme, an input graph is assumed to have its maximum degree bounded by an absolute constant $d_{\max} = O(1)$. In such a case, the input graph is usually represented by an array of incidence lists of all of its vertices

¹Clearly, a degree query to a vertex v can be implemented by performing at most $\log n$ queries concerning the neighbors of v . Therefore, an algorithm can do without degree queries and incur at most a logarithmic factor overhead. For simplicity of the presentation, we allow the algorithm to perform these queries.

(of length at most $d_{\max}$ each); accordingly, a testing algorithm queries the i th neighbor of a vertex v , where $1 \leq i \leq d_{\max}$ (the so-called *neighbor* queries). As was observed in [10], in this case $O(1/\epsilon)$ queries suffice for testing triangle-freeness. More generally, $O(d^\tau/\epsilon)$ queries suffice for testing H -freeness in graphs with maximum degree $O(d)$, where τ is the diameter of H .

General graphs. In this work we study the complexity of testing triangle-freeness of graphs that lie between the two extremes. Namely, we would like to understand the dependence of the query complexity on the average degree d , and we do not want to necessarily assume that $d_{\max} = O(d)$. In the latter aspect we follow the work [15] on testing the diameter of sparse, but unbounded-degree, graphs, and in both aspects we follow the work [14] on testing bipartiteness of general graphs. In particular, as in [14] we allow queries of both types—vertex-pair queries and neighbor queries—as well as degree queries (i.e., the algorithm may query the degree of any vertex). Note that the fact that the graph has varying degrees makes the task of testing triangle-freeness significantly harder. Consider, for example, sparse graphs, that is, graphs with average degree $d = O(1)$. As we mentioned before, when $d_{\max} = O(1)$, $O(1/\epsilon)$ queries suffice for testing triangle-freeness. However, our work shows that when $d_{\max} = \Theta(n)$ and $d = O(1)$, the number of queries required for testing triangle-freeness is $\Omega(\sqrt{n})$.

Our contributions. The main contributions of this paper, on a qualitative level, are as follows:

- We discover a threshold-type behavior in testing triangle-freeness: whenever $d = O(n^{1-\nu(n)})$, where $\nu(n)$ is a function that satisfies $\nu(n) = o(1)$, the number of queries necessary to test triangle-freeness is $\Omega(n^{1/3})$, while, as discussed above, for $d = \Theta(n)$ the query complexity is a function of ϵ only. This is in sharp contrast to the results of [14], where a smooth behavior of the complexity of testing bipartiteness as a function of d was described.
- We provide a transformation from lower bounds for testing triangle-freeness using one-sided error algorithms to those for two-sided error algorithms; though the suggested transformation is stated and proved for triangles and carries some technical restrictions, it is general enough to capture a variety of lower bounds of this sort.
- We give quantitative lower and upper bounds for testing triangle-freeness in general graphs.
- We show that the edge distribution in random Cayley graphs is close to that of truly random graphs of the same edge density. This is proven by direct combinatorial and probabilistic arguments, without relying on the eigenvalue machinery, which is incapable of proving such results for subsets that are too small. Although we need this result for property testing purposes, we feel it is of enough independent interest to be stated here.

1.1. A lower bound and a sharp threshold. Our main result is the following theorem.

THEOREM 1. *There is a lower bound of $\Omega(n^{1/3})$ for testing triangle-freeness in general graphs. The lower bound holds for algorithms that are allowed two-sided error, and for every d that is upper bounded by $O(n^{1-\nu(n)})$, where $\nu(n) = \frac{\log \log \log n + 4}{\log \log n}$. For some values of d the lower bound reaches $\Omega(n^{1/2})$.*

Theorem 1 is actually the union of three lower bounds (whose one-sided error versions are stated in Lemmas 1, 2, and 6), which are applied to different values of d .

FIG. 1. A schematic illustration of our lower and upper bounds. The x -axis represents the average degree d , and the y -axis represents the bounds. For the sake of simplicity we ignore logarithmic factors in the bounds. Notice that the lower bound lies entirely above the horizontal line at height $n^{1/3}$, and the upper bound lies entirely below the horizontal line at height $n^{6/7}$.

The exact expression for the lower bound is

$$(1) \quad \Omega\left(\max\left\{\sqrt{n/d}, \min\{d, n/d\}, \min\left\{\sqrt{d}, n^{2/3}/d^{1/3}\right\} \cdot n^{-o(1)}\right\}\right).$$

For a schematic illustration see Figure 1.

Recall that when $d = \Theta(n)$ then testing can be performed using a number of queries that is independent of n [2]. Thus we observe a sharp transition between our lower bound of $\Omega(n^{1/3})$ that holds until $d = n^{1-\nu(n)}$ (recall that $\nu(n) = o(1)$) and the query complexity at $d = \Theta(n)$, which does not depend on n . The abrupt change of testing complexity around linear density can be partially explained by the fact that the celebrated regularity lemma of Szemerédi (whose relevance to testing triangle-freeness has been first indicated in [19] and was made explicit in [2]) starts yielding meaningful results for graphs whose number of edges is almost quadratic in the number of vertices. The exact behavior of the complexity of testing triangle-freeness when $n^{1-\nu(n)} \leq d \leq n$ remains open.

Remark. Using techniques that were previously applied in [1] it is possible to extend Theorem 1 to testing subgraph-freeness for other nonbipartite subgraphs and to show that for any fixed nonbipartite graph H there is a constant $a = a(H) > 0$ such that an algorithm for testing H -freeness in graphs on n vertices with average degree $d \leq n^{1-o(1)}$ has to ask at least n^a queries. This lower bound holds for two-sided error algorithms, using both vertex-pair and neighbor queries. We wish to note that the difference between the complexity of testing subgraph-freeness of bipartite and nonbipartite subgraphs is caused by the difference in the behavior of their Turán numbers—they are subquadratic for the former and quadratic for the latter. A more detailed discussion can be found in [1]. The technical details of the aforementioned general statement concerning testing H -freeness and its proof are quite cumbersome,

while the threshold-type behavior of the query complexity as a function of average degree d is observed already for the case when H is a triangle. Therefore, we prefer to concentrate on the basic case of testing triangle-freeness.

1.2. Upper bounds. We show that for every graph density, there exists an algorithm for testing triangle-freeness whose query complexity is sublinear in n . Furthermore, the upper bound is always at most quadratic in the corresponding lower bound (up to a factor of $\log n$).

THEOREM 2. *There is an upper bound of $\tilde{O}(n^{6/7})$ for testing triangle-freeness in general graphs for every value of d . The upper bound can go down to $\tilde{O}(n^{1/2})$ for some values of d . In all cases, up to logarithmic factors, the upper bound is at most quadratic in the lower bound that holds for that density. If $d_{\max} = O(d)$, then the upper bound is $O(n^{4/5})$ for all values of d .*

The exact expression for our upper bound is $\tilde{O}(\min\{\sqrt{nd}/\epsilon^{3/2}, (n^{4/3}/d^{2/3})/\epsilon^2\})$, where, in the case that $d_{\max} = O(d)$, the first term is replaced by d/ϵ . For a schematic illustration, see Figure 1.

1.2.1. Tight results. There are two cases in which our lower and upper bounds essentially match. The first case is graphs in which $d_{\max} = O(d)$ and $d \leq \sqrt{n}$. For this case the complexity is $\Theta(d)$ (for constant ϵ). The second case is general sparse graphs, that is, graphs for which $d = \Theta(1)$. For these graphs the complexity is $\tilde{\Theta}(\sqrt{n})$.

1.3. Our techniques.

Behrend graphs and Cayley graphs. In the proof of our third lower bound (Lemma 6), we build on graphs that are known as Behrend graphs, which were previously used in the context of testing triangle-freeness in [1]. Here we prove that random Behrend graphs have a certain property that we can exploit in order to obtain our lower bound. Behrend graphs are variants of the well-studied Cayley graphs, and our proof concerning properties of random Behrend graphs extends to Cayley graphs.

Specifically, we show that for dense random Cayley graphs the edge density in relatively large induced subgraphs is close to the edge density of the whole graph. It was previously shown [4] that random Cayley graphs are expanders and hence have the property that the density of every induced subgraph on sufficiently many vertices is very close to the density of the graph. However, the known techniques for proving this property are based on estimating the second eigenvalue of the graph's adjacency matrix and do not supply any informative bounds for sets of vertices that are much smaller than the number of vertices divided by the square root of the degree. Our results for Cayley graphs apply for Cayley graphs over both Abelian and non-Abelian groups, while Behrend graphs were considered only in an Abelian setting. Our techniques are somewhat reminiscent of those of [3, 11].

A reduction from one-sided error lower bounds to two-sided error lower bounds. We obtain our two main lower bounds by first establishing lower bounds that hold for one-sided error algorithms. We then prove a transformation from one-sided error lower bounds to two-sided error lower bounds that holds under certain assumptions and apply it to obtain our two-sided error lower bounds. This transformation may be of use in future lower bound proofs for subgraph freeness. We note that in [6] a transformation was given in the case of dense graphs, but it is not applicable in general.

1.4. Subsequent work. In [12] and [16] our lower bound and upper bound, respectively, were improved somewhat for particular ranges of d . Specifically, Guggemann [12] slightly modifies one of our constructions and obtains a lower bound of

$\Omega(\min\{(nd)^{1/3}, n/d\})$, instead of our lower bound of $\Omega(\min\{d, n/d\})$. Given our additional lower bound of $\Omega(\sqrt{n/d})$, this improves on our result for d that ranges between $\Omega(n^{1/5})$ and $O(n^{1/2})$.

In terms of upper bounds, Rast [16] describes an algorithm that combines ideas from our algorithms in a nontrivial manner and obtains an algorithm whose query complexity (in terms of its dependence on n and d) is $O(\max\{(nd)^{4/9}, n^{2/3}/d^{1/3}\})$. This improves on our result for d that ranges between $\Omega(n^{2/5})$ and $O(n^{4/5})$.

1.5. Paper organization. After giving some preliminary definitions in section 2, we proceed to lower bounds in sections 3, 4, and 5. In particular, section 5 describes Behrend graphs and proves a result on the edge density of random Behrend graphs, whose more general version (applicable to random Cayley graphs of Abelian groups) is discussed in section 8. Section 6 describes a reduction from lower bounds for two-sided testers to those for one-sided testers. Section 7 contains upper bounds for testing triangle-freeness.

2. Preliminaries. Let $G = (V, E)$ be an undirected graph with n vertices labeled $1, \dots, n$, and let d denote the average degree in G , where we assume that $d = \Omega(1)$.² For each vertex $v \in V$ let $\deg(v)$ denote the degree of vertex v . The edges incident to v (and their endpoints, the neighbors of v) are labeled from 1 to $\deg(v)$. Note that each edge has two, possibly different, labels, one with respect to each of its endpoints. For a graph G and a subset of vertices $U \subseteq V$, we refer to the edges in the subgraph of G that is induced by U as the edges *spanned* by U in G .

A graph G is said to be *triangle-free* if for every three vertices u, v, w in G , at least one of the three vertex-pairs (u, v) , (v, w) , or (w, u) is not an edge in G . A graph G is ϵ -far from (being) *triangle-free* if it is necessary to remove more than ϵdn edges from G in order to obtain a triangle-free graph. We note that since the number of edges in the graph is $(dn)/2$, the standard definition of ϵ -far would be that more than $(\epsilon dn)/2$ edges should be removed so that the graph becomes triangle-free. In order to simplify the presentation we slightly modify the definition.

A testing algorithm for triangle-freeness is required to accept with probability at least $2/3$ every graph that is triangle-free and to reject with probability at least $2/3$ every graph that is ϵ -far from being triangle-free, where ϵ is a given distance parameter. If the algorithm always accepts triangle-free graphs, then it has *one-sided error*; otherwise, it has *two-sided error*. In order to perform this task the testing algorithm is allowed the following types of queries:

- *Degree* queries: For any vertex u of its choice, the algorithm can obtain $\deg(u)$.
- *Neighbor* queries: For any vertex u and index $1 \leq i \leq \deg(u)$, the algorithm may obtain the i th neighbor of vertex u .
- *Vertex-pair* queries: For any pair of vertices (u, v) , the algorithm can query whether there is an edge between u and v in G .

3. A lower bound of $\Omega(\sqrt{n/d})$. In this section we establish our first and simplest lower bound.

LEMMA 1. *Every algorithm for testing triangle-freeness must perform $\Omega(\sqrt{n/d})$ queries. This lower bound holds for two-sided error algorithms as well.*

²Our results can be extended to the case that $d = o(1)$ (that is, very sparse graphs). However, for the sake of simplicity, and since we believe that the very sparse case is of less interest, we assume that $d = \Omega(1)$.

Proof. In order to prove a two-sided error lower bound of $\Omega(q)$ queries for testing triangle-freeness, it suffices to describe two families of graphs for which the following two conditions hold: (1) The graphs in the first family are all triangle-free, while the graphs in the second family are all $\Theta(1)$ -far from being triangle-free. (2) Any algorithm that distinguishes with constant probability between a graph selected uniformly in one family, and a graph selected uniformly in the second family, must perform $\Omega(q)$ queries.

In particular, consider the following two families of graphs over n vertices and with average degree d . Each family is determined by a single graph and consists of all possible $n!$ labelings of the vertices of the graph. Hence it suffices to describe the two graphs (one per family). In one graph there is a complete bipartite graph between two sets of vertices, each of size $\sqrt{nd}/2$. In the other graph there is a clique of size $\sqrt{nd}$. (We ignore rounding issues here.) In addition, in both graphs the remaining vertices are isolated. The first graph is clearly triangle-free, and it is not hard to verify that the second graph is $\Theta(1)$ -far from being triangle-free. However, in order to distinguish between the two graphs (or more precisely, in order to distinguish between graphs that are selected uniformly from each of the two families), the algorithm must obtain a vertex in the complete bipartite subgraph/clique. To this end the algorithm must perform $\Omega(n/\sqrt{nd}) = \Omega(\sqrt{n/d})$ queries. $\square$

4. A lower bound of $\Omega(\min\{d, n/d\})$. Our next lower bound improves on the lower bound in section 3 when $d > n^{1/3}$.

LEMMA 2. *Every one-sided error algorithm for testing triangle-freeness must perform $\Omega(\min\{d, n/d\})$ queries. This lower bound holds even when $d_{\max} = O(d)$.*

The lower bound in Lemma 2 is extended to two-sided error algorithms in section 6.

We prove Lemma 2 by describing a distribution on graphs such that the following hold: On one hand almost all of the support of the distribution is on graphs that are far from triangle-free. On the other hand, every algorithm that uses neighbor and/or vertex-pair queries must perform $\Omega(\min\{d, n/d\})$ queries before it views a triangle (with sufficiently high constant probability). Since we currently focus on testing algorithms that have one-sided error, this implies a lower bound on the query complexity of such algorithms.

We start by considering the case that $d = c \cdot \sqrt{n}$ for a particular constant $c < 1$. We later discuss how to deal with the case that $d > c \cdot \sqrt{n}$ and with the case that $d < c \cdot \sqrt{n}$.

4.1. Definition of the lower-bound distribution. The graphs we consider below are d -regular for $d = \Theta(\sqrt{n})$ but may have multiple edges. At the end of this section we discuss how to remove the multiple edges. Let D_Δ be a distribution over graphs with n vertices and degree $d = \frac{2}{3}\sqrt{n/3}$ that is defined as follows. A graph is generated by first partitioning the vertices into equal-size subsets of size $n' = n/3$ denoted V_1, V_2, V_3 . Next, between each pair of subsets, $d' = d/2 = \sqrt{n'}/3$ random perfect matchings are selected. In all that follows we assume that n' is sufficiently large ($n' > 100$ suffices).

LEMMA 3. *With probability $1 - o(1)$, a graph chosen uniformly according to the distribution D_Δ is $\Omega(1)$ -far from being triangle-free.*

Proof. We shall show that with high probability over the choice of a graph according to D_Δ , there are at least $\gamma \cdot nd$ edge-disjoint triangles in the graph for some constant γ .

Let the vertices in each set V_ℓ , $\ell \in \{1, 2, 3\}$, be denoted $v_{\ell,1}, \dots, v_{\ell,n'}$. For each pair of vertices $v_{\ell,i} \in V_\ell$, $v_{\ell',j} \in V_{\ell'}$, where $\ell \neq \ell'$, let $\alpha_{i,j}^{\ell,\ell'}$ be a 0/1 random variable that is 1 if there is an edge between $v_{\ell,i}$ and $v_{\ell',j}$ and is 0 otherwise. Then

$$(2) \quad \Pr \left[\alpha_{i,j}^{\ell,\ell'} = 1 \right] = 1 - \left(1 - \frac{1}{n'} \right)^{d'},$$

and so

$$(3) \quad \Pr \left[\alpha_{i,j}^{\ell,\ell'} = 1 \right] \leq \frac{d'}{n'}$$

and

$$(4) \quad \Pr \left[\alpha_{i,j}^{\ell,\ell'} = 1 \right] \geq \frac{d'}{n'} - \binom{d'}{2} \cdot \frac{1}{(n')^2} \geq \frac{d'}{n'} - \frac{1}{18n'} = \frac{d'}{n'} \cdot \left(1 - \frac{1}{18d'} \right).$$

Next consider any choice of three vertices $v_{1,i} \in V_1$, $v_{2,j} \in V_2$, and $v_{3,k} \in V_3$. Let $\Delta_{i,j,k}$ denote the 0/1 random variable that is 1 if and only if there is a triangle between the three vertices. Since the choice of the matchings between V_1 and V_2 is independent of the choice of the matchings between V_2 and V_3 and the choice of the matching between V_1 and V_3 ,

$$(5) \quad \Pr[\Delta_{i,j,k} = 1] \leq \left(\frac{d'}{n'} \right)^3$$

and

$$(6) \quad \Pr[\Delta_{i,j,k} = 1] \geq \left(\frac{d' - 1/18}{n'} \right)^3 = \left(\frac{d'}{n'} \right)^3 \cdot \left(1 - \frac{1}{18d'} \right)^3.$$

Let $\beta_{i,j,k}$ denote a 0/1 random variable that is 1 if and only if there is a triangle *different from* $(v_{1,i}, v_{2,j}, v_{3,k})$ that includes one of the edges $(v_{1,i}, v_{2,j})$ or $(v_{1,i}, v_{3,k})$ or $(v_{2,j}, v_{3,k})$. That is, there is a triangle of the form $(v_{1,i'}, v_{2,j}, v_{3,k})$, where $i' \neq i$, or $(v_{1,i}, v_{2,j'}, v_{3,k})$, where $j' \neq j$, or $(v_{1,i}, v_{2,j}, v_{3,k'})$, where $k' \neq k$. Since the probability of having an edge $(v_{\ell,r}, v_{\ell',s})$ conditioned on having the edge $(v_{\ell,r}, v_{\ell',s'})$ for any choice of $s' \neq s$ is at most $1 - (1 - \frac{1}{n'})^{d'-1}$,

$$\begin{aligned} \Pr[\Delta_{i,j,k} = 1 \ \& \ \beta_{i,j,k} = 1] &= \Pr[\Delta_{i,j,k} = 1] \cdot \Pr[\beta_{i,j,k} = 1 \mid \Delta_{i,j,k} = 1] \\ &\leq \left(\frac{d'}{n'} \right)^3 \cdot 3 \cdot (n' - 1) \cdot \left(\frac{d' - 1}{n'} \right)^2 \\ (7) \quad &\leq \left(\frac{d'}{n'} \right)^3 \cdot \frac{3(d' - 1)^2}{n'}. \end{aligned}$$

It follows that

$$\begin{aligned} \Pr[\Delta_{i,j,k} = 1 \ \& \ \beta_{i,j,k} = 0] &= \Pr[\Delta_{i,j,k} = 1] - \Pr[\Delta_{i,j,k} = 1 \ \& \ \beta_{i,j,k} = 1] \\ &\geq \left(\frac{d' - 1/18}{n'} \right)^3 - \left(\frac{d'}{n'} \right)^3 \cdot \frac{3(d' - 1)^2}{n'} \end{aligned}$$

$$\begin{aligned}
&= \left(\frac{d'}{n'}\right)^3 \cdot \left(\left(1 - \frac{1}{18d'}\right)^3 - 3 \cdot \left(1 - \frac{1}{d'}\right)^2 \cdot \frac{(d')^2}{n'} \right) \\
&\geq \frac{1}{2} \cdot \left(\frac{d'}{n'}\right)^3 \\
(8) \quad &= \frac{1}{54} \cdot (n')^{-3/2},
\end{aligned}$$

where we have used our assumption that n' and $d' = \sqrt{n'}/3$ are sufficiently large. Hence, the expected number of triples $(v_{1,i}, v_{2,j}, v_{3,k})$ that constitute a triangle that does not share an edge with any other triangle is at least

$$(9) \quad (n')^3 \cdot \frac{1}{54} \cdot (n')^{-3/2} = \frac{1}{54} \cdot (n')^{3/2}$$

$$(10) \quad = \frac{1}{54} \cdot n \cdot d.$$

Next, we shall use Chebyshev's inequality to show that with high probability, the number of such triples is not much smaller than this expected value.

For each triple $v_{1,i}, v_{2,j}, v_{3,k}$ let $\eta_{i,j,k}$ be the 0/1 random variable that is 1 if and only if $(v_{1,i}, v_{2,j}, v_{3,k})$ constitute a triangle, and there is no other triangle that shares any of its edges. Using our previous notation we have that

$$(11) \quad \Pr[\eta_{i,j,k} = 1] = \Pr[\Delta_{i,j,k} = 1 \ \& \ \beta_{i,j,k} = 0],$$

which implies (using (9)) that

$$(12) \quad \left(\text{Exp} \left[\sum_{i,j,k} \eta_{i,j,k} \right] \right)^2 \geq (n')^3 / c$$

for some constant $c > 1$. By Chebyshev's inequality,

$$\begin{aligned}
(13) \quad \Pr \left[\sum_{i,j,k} \eta_{i,j,k} < \frac{1}{2} \text{Exp} \left[\sum_{i,j,k} \eta_{i,j,k} \right] \right] &\leq \frac{4 \text{Var} \left[\sum_{i,j,k} \eta_{i,j,k} \right]}{\left(\text{Exp} \left[\sum_{i,j,k} \eta_{i,j,k} \right] \right)^2} \\
&< \frac{c' \text{Var} \left[\sum_{i,j,k} \eta_{i,j,k} \right]}{(n')^3}
\end{aligned}$$

for a constant $c' > 1$. We would like to bound the variance of $\sum_{i,j,k} \eta_{i,j,k}$:

$$(14) \quad \text{Var} \left[\sum_{i,j,k} \eta_{i,j,k} \right] = \text{Exp} \left[\left(\sum_{i,j,k} \eta_{i,j,k} \right)^2 \right] - \left(\text{Exp} \left[\sum_{i,j,k} \eta_{i,j,k} \right] \right)^2.$$

Now,

$$\text{Exp} \left[\left(\sum_{i,j,k} \eta_{i,j,k} \right)^2 \right] = \sum_{i,j,k} \sum_{i',j',k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}]$$

$$\begin{aligned}
&= \sum_{i \neq i'} \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] \\
&\quad + 3 \cdot \sum_i \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i,j',k'}] \\
&\quad + 3 \cdot \sum_{i,j} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i,j,k'}] \\
&\quad + \sum_{i,j,k} \text{Exp}[\eta_{i,j,k}^2],
\end{aligned}
\tag{15}$$

while

$$\begin{aligned}
&\left(\text{Exp} \left[\sum_{i,j,k} \eta_{i,j,k} \right] \right)^2 = \sum_{i,j,k} \sum_{i',j',k'} \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}] \\
&> \sum_{i \neq i'} \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}].
\end{aligned}
\tag{16}$$

Therefore,

$$\begin{aligned}
\text{Var} \left[\sum_{i,j,k} \eta_{i,j,k} \right] &\leq \sum_{i \neq i'} \sum_{j \neq j'} \sum_{k \neq k'} \left(\text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] - \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}] \right) \\
&\quad + 3 \cdot \sum_i \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i,j',k'}] \\
&\quad + 3 \cdot \sum_{i,j} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i,j,k'}] \\
&\quad + \sum_{i,j,k} \text{Exp}[\eta_{i,j,k}^2].
\end{aligned}
\tag{17}$$

First, observe that, by definition of $\eta_{i,j,k}$ for every i, j and $k \neq k'$, since if both $(v_{1,i}, v_{2,j}, v_{3,k})$ and $(v_{1,i}, v_{2,j}, v_{3,k'})$ are triangles then they share an edge, we get that

$$\eta_{i,j,k} \cdot \eta_{i,j,k'} = 0.
\tag{18}$$

Next, observe that since $\Pr[\eta_{i,j,k} = 1] \leq \Pr[\Delta_{i,j,k} = 1]$, where by (5) $\Pr[\Delta_{i,j,k} = 1] \leq (d'/n')^3$,

$$\sum_{i,j,k} \text{Exp}[\eta_{i,j,k}^2] = \sum_{i,j,k} \text{Exp}[\eta_{i,j,k}] \leq (n')^3 \cdot \left(\frac{d'}{n'} \right)^3 = (d')^3.
\tag{19}$$

We turn to the sum over triangles that share a (single) vertex. Conditioned on there being a triangle $(v_{1,i}, v_{2,j}, v_{3,k})$, i.e., $\Delta_{i,j,k} = 1$, the probability of having the edge $(v_{1,i}, v_{2,j'})$ for $j' \neq j$, i.e., $\eta_{i,j}^{1,2} = 1$ (and similarly the edge $(v_{1,i}, v_{3,k'})$ for $k' \neq k$),

is upper bounded³ by $1 - (1 - \frac{1}{n'})^{d'-1} < \frac{d'}{n'}$. The probability of having the edge $(v_{2,j'}, v_{3,k'})$ (conditioned on the existence of the triangle $(v_{1,i}, v_{2,j}, v_{3,k})$) is upper bounded by $1 - (1 - \frac{1}{n-1})^{d'}$, which is at most $\frac{2d'}{n'}$ for $n' \geq 2$. Therefore,

$$\begin{aligned} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] &\leq \text{Exp}[\Delta_{i,j,k} \cdot \Delta_{i',j',k'}] \\ &= \Pr[\Delta_{i,j,k} = 1] \cdot \Pr[\Delta_{i',j',k'} = 1 \mid \Delta_{i,j,k} = 1] \\ (20) \quad &\leq 2 \left(\frac{d'}{n'} \right)^6, \end{aligned}$$

and so

$$(21) \quad \sum_i \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] \leq (n')^5 \cdot \frac{2(d')^6}{(n')^6} = \frac{2(d')^6}{n'}.$$

To complete the proof we bound the difference between $\text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}]$ and $\text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}]$ (for $i \neq i'$, $j \neq j'$, and $k \neq k'$). By definition,

$$\begin{aligned} &\text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] - \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}] \\ (22) \quad &= \Pr[\eta_{i,j,k} = 1] \cdot (\Pr[\eta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1] - \Pr[\eta_{i',j',k'} = 1]). \end{aligned}$$

Since the proof of the following claim is a bit technical, we give it in the appendix.

CLAIM 4.

$$(23) \quad \Pr[\eta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1] = \left(1 + O\left(\frac{1}{d'}\right) \right) \cdot \Pr[\eta_{i',j',k'} = 1].$$

Since $\Pr[\eta_{i,j,k} = 1] = \Pr[\eta_{i',j',k'} = 1] \leq (\frac{d'}{n'})^3$, Claim 4 implies that

$$(24) \quad \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] - \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}] = O\left(\frac{(d')^5}{(n')^6}\right).$$

Hence,

$$\begin{aligned} \sum_{i \neq i'} \sum_{j \neq j'} \sum_{k \neq k'} \text{Exp}[\eta_{i,j,k} \cdot \eta_{i',j',k'}] - \text{Exp}[\eta_{i,j,k}] \cdot \text{Exp}[\eta_{i',j',k'}] &= O\left((n')^6 \cdot \frac{(d')^5}{(n')^6}\right) \\ (25) \quad &= O((d')^5). \end{aligned}$$

By combining (13) with (17)–(25), we get that

$$(26) \quad \Pr\left[\sum_{i,j,k} \eta_{i,j,k} < \frac{1}{2} \text{Exp}\left[\sum_{i,j,k} \eta_{i,j,k}\right]\right] = \frac{O((d')^5) + O((d')^3)}{(n')^3} = O\left(\frac{1}{d'}\right).$$

Because we have shown (see (10)) that $\text{Exp}[\sum_{i,j,k} \eta_{i,j,k}] = \Omega(nd)$, the lemma follows. $\square$

³The reason this is an upper bound and equality does not necessarily hold is that the triangle $(v_{1,i}, v_{2,j}, v_{3,k})$ may have parallel edges. That is, the event $\Delta_{i,j,k} = 1$ is a union of events in which each edge of the triangle may appear with different multiplicity.

The case $d > \frac{2}{3\sqrt{3}}\sqrt{n}$. The distribution in this case is the same as described at the start of this section: the graph vertices are partitioned into three equal parts V_1 , V_2 , and V_3 , and between every pair V_i and V_j we put $d/2$ random perfect matchings. We would like to show that with high probability the resulting graph contains at least $\frac{1}{c} \cdot nd$ edge-disjoint triangles in the graph for some constant c . To this end we think of the matchings as being selected in $k = \frac{3\sqrt{3}}{2} \cdot \frac{d}{\sqrt{n}}$ rounds, where in each round $d' = \frac{1}{3\sqrt{3}} \cdot \sqrt{n}$ matchings are selected between every pair $V_i, V_j, i \neq j$. For each round we can apply Lemma 3 and get that with high probability we have at least $\frac{1}{c} \cdot n \cdot d'$ edge-disjoint triangles. Observe that the triangles created in the different rounds are edge-disjoint. When $k = o(d')$ (i.e., $d = o(n)$), we can apply a union bound and get that with probability at least $1 - O(k/d') = 1 - o(1)$ we obtain $\frac{1}{c} \cdot n \cdot d$ edge-disjoint triangles. For larger k we can use the fact that the different rounds are independent. Therefore, with probability $1 - \exp(-k) = 1 - o(1)$ in at least $1/2$ of the rounds there are $\frac{1}{c} \cdot n \cdot d'$ edge-disjoint triangles, implying that there are at least $\frac{1}{2c} \cdot n \cdot d$ edge-disjoint triangles.

The case $d < \frac{2}{3\sqrt{3}}\sqrt{n}$. In this case we first partition the vertices into k parts $V^1, \dots, V^k$, where $|V^i| = \frac{27}{4}d^2$. We then apply the construction described at the start of this section to each V^i . In this case, too, for small k we can apply a union bound on the different V^i 's, and once k is sufficiently large we can use the fact that the different subgraphs are constructed independently. In either case we get that with high probability, for at least a half of the V^i 's there are $\Omega(|V^i| \cdot d)$ edge disjoint triangles within the subgraph induced by V^i .

4.2. The lower bound. Let A be any one-sided error algorithm for testing triangle-freeness, where A is allowed to perform both neighbor queries and vertex-pair queries. If A views a triangle in the tested graph, then clearly it can reject the graph. However, since A is a one-sided error algorithm, if it terminates before viewing a triangle, then it must accept. Suppose we run A on a graph chosen according to D_Δ , with some (sufficiently small) constant ϵ . Since we have shown that with high probability such a graph is ϵ -far from being triangle-free, the probability that A terminates before viewing a triangle must be small. Hence it remains to prove the following lemma.

LEMMA 5. *Any algorithm whose goal is to detect, with high constant probability, a triangle in a graph selected according to D_Δ must ask $\Omega(\min\{d, n/d\})$ queries.*

We note that the proof actually establishes the stronger statement: $\Omega(\min\{d, n/d\})$ queries are required to detect a cycle of any length.

Proof. We first present the argument for $d \geq \frac{2}{3\sqrt{3}}\sqrt{n}$ and later discuss the modifications required for $d < \frac{2}{3\sqrt{3}}\sqrt{n}$.

It will be convenient to view graphs in the support of D_Δ as being represented by “matchings over tables.” Namely, there are six tables: $T_{1,2}, T_{1,3}, T_{2,1}, T_{2,3}, T_{3,1}, T_{3,2}$, two for each set of vertices $V_b, b \in \{1, 2, 3\}$. Each table $T_{b,b'}$ is of size $(n/3) \times (d/2)$: there is a row for each vertex v in V_b , and each entry in v 's row corresponds to one of the $d/2$ edges that are incident to v and to vertices in $V_{b'}$. An edge between $u \in V_b$ and $v \in V_{b'}$ is represented by a pair of entries $(T_{b,b'}[u][i], T_{b',b}[v][j])$. Hence the $d/2$ perfect matchings between V_b and $V_{b'}$ correspond to a single perfect matching between the entries of the two tables $T_{b,b'}$ and $T_{b',b}$.

Let ALG be an algorithm that performs $Q = Q(n, d)$ queries and whose goal is to detect a triangle with probability at least $9/10$. The probability is taken over the choice of the graph G in the support of D_Δ and the coin flips of the algo-

rithm. Namely, ALG is a (possibly probabilistic) mapping from *query-answer histories* $\langle (q_1, a_1), \dots, (q_t, a_t) \rangle$ to q_{t+1} for every $t < Q$. A vertex-pair query is of the form $q_t = (u, v)$, where $u \in V_b$ and $v \in V_{b'}$ for some $b \neq b'$, $b, b' \in \{1, 2, 3\}$. The answer is either $a_t = (1, i, j)$, which denotes that there is an edge between u and v and it corresponds to the pair of entries $(T_{b,b'}[u][i], T_{b',b}[v][j])$, or $a_t = 0$, which denotes that there is no edge between u and v . A neighbor query is of the form $q_t = (u, b', i)$, where $u \in V_b$, $b' \neq b$. The answer is of the form $a_t = (v, j)$, where $v \in V_{b'}$, denoting that there is an edge between u and v and it corresponds to the pair of entries $(T_{b,b'}[u][i], T_{b',b}[v][j])$. We note that the mapping from query-answer histories to queries needs to be defined only on histories that are consistent with some graph in the support of D_Δ .

In what follows we define a process that answers the queries of the algorithm while generating a graph according to D_Δ . At any time t , the queries of the algorithm and the answers it is provided with determine the *knowledge graph* $G^t = (V^t, E^t, \bar{E}^t)$, where V^t are the vertices, E^t are the edges, and $\bar{E}^t$ are the nonedges. Namely, V^t consists of all vertices that appeared in queries of the algorithm or in answers to neighbor queries. Similarly E^t consists of all pairs u, v such that either (u, v) was a vertex-pair query that was answered positively or v was an answer to a neighbor query involving u , and $\bar{E}^t$ consists of all pairs u, v such that either (u, v) was a vertex-pair query that was answered negatively. For every edge $(u, v) \in E^t$ the knowledge graph will include the indices of the entries in the tables by which u and v are connected (that is, (i, j) such that $T_{b,b'}[u][i]$ is matched to $T_{b',b}[v][j]$).

Vertex-pair queries. Given a vertex-pair query $q_t = (u, v)$, where $u \in V_b$ and $v \in V_{b'}$, the process computes the probability, conditioned on the current knowledge graph, that (u, v) is an edge. Namely, it considers all graphs in the support of D_Δ that are consistent with G^{t-1} and answers positively with probability that is proportional to the number of these graphs in which there is an edge between u and v . Let $U_{t-1,b,b'}$ denote the number of unmatched entries in $T_{b,b'}$ at time t (before the t th query). Note that this number equals the number of unmatched entries in $T_{b',b}$ at the same time.

The conditional probability that there is an edge between u and v is upper bounded by

$$(27) \quad \frac{(d/2) \cdot (d/2)}{U_{t-1,b,b'} - |\bar{E}^{t-1}| \cdot (d/2) - (d/2)}.$$

To verify this consider an iterative process in which the (at most $d/2$) unmatched entries in u 's row in $T_{b,b'}$ are matched one by one to unmatched entries in $T_{b',b}$. After $0 \leq i < d/2$ steps, the probability of selecting any of the (at most $d/2$) unmatched entries in v 's row in $T_{b',b}$ is the current number of unmatched entries in v 's row, divided by $U_{t-1,b,b'} - i - |\bar{E}^{t-1}| \cdot (d/2)$. The term $U_{t-1,b,b'} - i$ is the number of unmatched entries after i steps, and the term $|\bar{E}^{t-1}| \cdot (d/2)$ is the maximum number of unmatched entries that cannot be matched to entries in u 's row because they correspond to vertices w such that $(u, w) \in \bar{E}^{t-1}$.

Since $U_{t-1,b,b'} \geq (n/3) \cdot (d/2) - (t-1)$, $|\bar{E}^{t-1}| \leq t-1$, and $t-1 < Q = o(n/d)$, the probability is $O(d/n)$. It follows that the probability that the algorithm gets a positive answer for *any* of the at most $Q = o(n/d)$ vertex-pair queries is $o(1)$. But if the algorithm always gets negative answers for its vertex-pair queries, it clearly cannot close a triangle with such a query.

Neighbor queries. Given a neighbor query (u, b', i) , where $u \in V_b$, the process gives an answer (v, j) , where $v \in V_{b'}$ according to the conditional probability that the entries $T_{b,b'}[u, i]$ and $T_{b',b}[v, j]$ are matched (where again, the conditioning is on the current knowledge graph G^{t-1}). Here we would like to upper bound the probability that v already belongs to the knowledge graph. Observe that the knowledge graph G^{t-1} contains at most $2t$ vertices and at most t edges and nonedges. Hence the conditional probability that $T_{b,b'}[u, i]$ is matched to $T_{b',b}[v, j]$ for some $v \in V_{b'}^{t-1} = V^{t-1} \cap V_{b'}$ and $j \in \{1, \dots, d/2\}$ is upper bounded by the following expression: $(d/2) \times (2t)$ (the maximum number of unmatched entries $T_{b',b}[v, j]$ for $v \in V_{b'}^{t-1}$) divided by the total number of unmatched entries in $T_{b',b}$ that do not belong to rows of vertices $u \in V_{b'}$ such that $(u, v) \in \bar{E}^{t-1}$, minus $d/2$ (where the argument is very similar to the one given for vertex-pair queries). By our assumption on Q (where $t-1 < Q$), the numerator in the above expression is $o(\min\{n, d^2\})$, and the denominator is at least $(n/3) \cdot (d/2) - (t-1) \cdot (d/2) - (d/2) = \Omega(n \cdot d)$. Hence, the probability that such an event occurs at a given particular time t is $o(\min\{(1/d), (d/n)\})$, and the probability that it occurs at any $t \leq Q$ is $o(1)$. But if the algorithm never gets a vertex in the knowledge graph as an answer to a neighbor query, it clearly cannot close a triangle, or any cycle, with such a query.

Finally, we address the case that $d < \frac{2}{3\sqrt{3}}\sqrt{n}$. Recall that in this case we first partition the vertices into k parts $V^1, \dots, V^k$, where $|V^i| = n' = \frac{27}{4}d^2$. We then apply the construction to each V^i . By the argument described above, here we can get a lower bound of the form $\Omega(\min\{d, n'/d\}) = \Omega(d)$. But for the current setting of d we also have that $\min\{d, n/d\} = d$, and so the lower bound holds in this case as well. $\square$ (Lemmas 5 and 2)

A remark about multiple edges. The lower bound proof stated above is valid for graphs that may contain multiple edges. In the distribution D_Δ the probability of a multiple edge between a pair of vertices is $O(\frac{d^2}{n^2})$. Thus, graphs created according to this distribution contain multiple edges with probability close to 1. However, with probability $1 - o(1)$, there are $O(d^2)$ multiple edges in the graphs created according to this distribution. We have shown in Lemma 3 that graphs created according to the distribution D_Δ are $\Omega(1)$ -far from being triangle-free with probability $1 - o(1)$. Hence we can deduce that by removing multiple edges from a graph G constructed according to the distribution D_Δ , the resulting graph is $\Omega(1)$ -far from being triangle-free with probability $1 - o(1)$. In addition, an algorithm ALG that interacts with the process detects a multiple edge with probability $o(1)$ due to the following reason: ALG does not detect any edges by vertex-pair queries with probability $1 - o(1)$. The probability of detecting a multiple edge in a neighbor query is at most the probability that such a query is answered by a vertex in the knowledge graph. This probability was shown in Lemma 3 to be $o(1)$. Thus, at the end of the interaction with ALG, the process can delete all the multiple edges from the resulting graph so that the resulting graph contains no multiple edges. The graph remains $\Omega(1)$ -far from being triangle-free after the deletion, and its average degree is $d - o(1)$. As a conclusion we get that our lower bound is valid also for graphs with no multiple edges.

5. An improved lower bound for high degrees. In this section we establish the following lemma, which improves on our previous lower bound of $\min\{d, n/d\}$ when the degree of the graph is at least $n^{2/3+o(1)}$.

LEMMA 6. *Every one-sided error testing algorithm for triangle-freeness must perform $\Omega(\min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)})$ queries, where $\nu(n) = \frac{\log \log \log n + 4}{\log \log n}$. This lower*

bound holds even for d -regular graphs.

In order to prove the lemma, here too we define a distribution over graphs that are far from being triangle-free. We then prove a lower bound on the number of queries that are required in order to detect a triangle with probability bounded away from zero in a graph that is generated according to the distribution. As we shall see, it will actually be convenient to consider graphs over $3n$ vertices and degree $2d$.

5.1. A variant of Behrend graphs. Our lower-bound distribution builds on graphs that are variants of what are known as *Behrend graphs* [7, 19, 20]. These graphs are defined by sets of integers that include no three-term arithmetic progression. Namely, these are sets $X \subset \{1, \dots, n\}$ such that for every three elements $x_1, x_2, x_3 \in X$, if $x_2 - x_1 = x_3 - x_2$ (i.e., $x_1 + x_3 = 2x_2$), then necessarily $x_1 = x_2 = x_3$. Below we describe a construction of such sets that are large (relative to n) and later explain how such sets determine Behrend graphs. Our construction of X uses ideas similar to those used in known constructions [7, 20] and gives a slightly weaker result. However, our alternative construction is somewhat simpler, and the size of the resulting set suffices for our purposes.

LEMMA 7. *For every sufficiently large n there exists a set $X \subset \{1, \dots, n\}$, $|X| \geq n^{1 - \frac{\log \log \log n + 4}{\log \log n}}$, such that X contains no three-term arithmetic progression.*

Proof. For simplicity we do not explicitly write floors (or ceilings). Let $b = \log n$ and $k = \log n / \log b - 2$. Since $\log n / \log b = \log n / \log \log n$, we have that $k < b/2$ for every $n \geq 8$. We arbitrarily select a subset of k different numbers $\{x_1, \dots, x_k\} \subset \{0, \dots, b/2 - 1\}$ and define $X = \{\sum_{i=1}^k x_{\pi(i)} b^i : \pi \text{ is a permutation of } \{1, \dots, k\}\}$. By the definition of X we have that $|X| = k!$. By using $z! > (z/e)^z$, we get that

$$(28) \quad |X| = k! \geq \left(\frac{\log \log n}{\log n} \right)^2 \cdot \left(\frac{\log n}{\log \log n} \right)! > n^{1 - \frac{\log \log \log n + 4}{\log \log n}}.$$

Consider any three elements $u, v, w \in X$ such that $u + v = 2w$. By definition of X , these elements are of the form $u = \sum_{i=1}^k x_{\pi_u(i)} b^i$, $v = \sum_{i=1}^k x_{\pi_v(i)} b^i$, and $w = \sum_{i=1}^k x_{\pi_w(i)} b^i \in X$, where π_u, π_v, π_w are permutations over $\{1, \dots, k\}$. Since $x_i < b/2$ for every $1 \leq i \leq k$, it must be the case that, for each i ,

$$(29) \quad x_{\pi_u(i)} + x_{\pi_v(i)} = 2x_{\pi_w(i)}.$$

This implies that, for every i ,

$$(30) \quad x_{\pi_u(i)}^2 + x_{\pi_v(i)}^2 \geq 2x_{\pi_w(i)}^2,$$

where the inequality in (30) is strict unless $x_{\pi_u(i)} = x_{\pi_v(i)} = x_{\pi_w(i)}$. If we sum over all i 's and there is at least one index i for which the inequality in (30) is strict, we get that

$$(31) \quad \sum_{i=1}^k x_{\pi_u(i)}^2 + \sum_{i=1}^k x_{\pi_v(i)}^2 > \sum_{i=1}^k 2x_{\pi_w(i)}^2,$$

which is a contradiction since we took permutations of the same numbers. Thus, we get that $u = v = w$. $\square$

Remark. In fact, the set constructed above is also three-term arithmetic progression free when all calculations are performed modulo n . We will use this observation below.

Behrend graphs. Given a set $X \subset \{1, \dots, n\}$ with no three-term arithmetic progression, we define the Behrend graph BG_X as follows. It has $3n$ vertices that are partitioned into three equal parts: V_1 , V_2 , and V_3 . For each $i \in \{1, 2, 3\}$ we associate with each vertex in V_i a different integer in $\{0, \dots, n-1\}$. The edges of the graph are defined as follows:

- The edges between V_1 and V_2 : For every $x \in X$ and $j \in \{0, \dots, n-1\}$ there is an edge between $j \in V_1$ and $(j+x) \bmod n \in V_2$.
- The edges between V_2 and V_3 : For every $x \in X$ and $j \in \{0, \dots, n-1\}$ there is an edge between $(j+x) \bmod n \in V_2$ and $(j+2x) \bmod n \in V_3$.
- The edges between V_1 and V_3 : For every $x \in X$ and $j \in \{0, \dots, n-1\}$ there is an edge between $j \in V_1$ and $(j+2x) \bmod n \in V_3$.

We shall say that an edge between $j \in V_1$ and $j' \in V_2$ or between $j \in V_2$ and $j' \in V_3$ is *labeled* by x if $j' = (j+x) \bmod n$, and we shall say that an edge between $j \in V_1$ and $j' \in V_3$ is *labeled* by x if $j' = (j+2x) \bmod n$.

The graph BG_X is $2|X|$ -regular and it contains $3|X|n$ edges. For every $j \in \{0, \dots, n-1\}$ and $x \in X$, the graph contains a triangle $(j, (j+x) \bmod n, (j+2x) \bmod n)$, where $j \in V_1$, $(j+x) \bmod n \in V_2$, and $(j+2x) \bmod n \in V_3$. There are $n \cdot |X|$ such edge-disjoint triangles, and every edge is part of one such triangle. Moreover, there are no other triangles in the graph. To verify this consider any three vertices j_1, j_2, j_3 , where $j_i \in V_i$ and such that there is a triangle between the three vertices. By definition of the graph, $j_2 = (j_1 + x_1) \bmod n$ for some $x_1 \in X$. $j_3 = (j_2 + x_2) \bmod n$ for some $x_2 \in X$. $j_3 = (j_1 + 2x_3) \bmod n$ for some $x_3 \in X$. Therefore, $(j_1 + x_1 + x_2) \bmod n = (j_1 + 2x_3) \bmod n$. That is, we get that $(x_1 + x_2) \bmod n = (2x_3) \bmod n$. Note that by the definition of X , for every $x \in X$, $x < n/2$, and so $x_1 + x_2 = 2x_3$. Since X contains no three-term arithmetic progression, the last implies that $x_1 = x_2 = x_3$, meaning that the triangle (j_1, j_2, j_3) is of the form $(j, (j+x) \bmod n, (j+2x) \bmod n)$.

5.2. The edge density of large sets in random Behrend graphs. In this subsection we prove the following lemma, which is central to the proof of Lemma 6. We shall use the following notation: For a subset $Y \subseteq X$ and a subset of vertices C in BG_Y , we let $e_Y(C)$ denote the number of edges spanned by C in BG_Y .

LEMMA 8. Let $0 < \beta < \frac{1}{2}$ and $0 < \alpha \leq 1$ be such that $\alpha - 2\beta > \frac{1}{\log \log n}$, and let $X \subset \{1, \dots, n\}$, $|X| \geq n^\beta$. Consider the random Behrend graph BG_Y obtained by choosing a random subset $Y \subseteq X$, $|Y| = d = \frac{|X|}{n^\beta}$. With high probability over the choice of Y , for every subset C of vertices in BG_Y , where $|C| = n^\alpha$, we have $e_Y(C) \leq \frac{90}{\alpha - 2\beta} \frac{n^{2\alpha}}{n^\beta}$ edges.

The lemma states that for sufficiently large subsets C (i.e., for $|C| = n^\alpha$, where $\alpha - 2\beta$ is a constant), the number of edges $e_Y(C)$ is not much larger than its expected value. Note that the smaller we choose β (i.e., the larger we choose Y), the smaller α can be. Thus, the lemma can be applied to sets of relatively small size.

Before proving the lemma we introduce some notation and prove two claims. For a subset $W \subseteq V_1 \cup V_2$, $|W| = s$, let $W_1 = W \cap V_1$, $W_2 = W \cap V_2$, and consider the subgraph of BG_X induced by W . Let

$$(32) \quad \begin{aligned} \Delta(W) = \{ & (j_2 - j_1) \bmod n : j_1 \in W_1, j_2 \in W_2, \\ & \text{and } (j_2 - j_1) \bmod n \in X \} \end{aligned}$$

denote the set of *differences* in W . That is, it is the set of labels of the edges between W_1 and W_2 in BG_X . Obviously, $|\Delta(W)| \leq |W|^2 = s^2$. For every difference $x \in \Delta(W)$, we define the *multiplicity* of x in W as the number of edges in BG_X between vertices in W_1 and vertices in W_2 that are labeled by x .

Let $k = \frac{5}{\alpha-2\beta}$. For β and α that satisfy the condition of the lemma ($\alpha - 2\beta > \frac{1}{\log \log n}$) we have that $k \leq 5 \log \log n$. We shall say that W is *good* if no difference in $\Delta(W)$ has multiplicity higher than k in W .

CLAIM 9. *With high probability over the choice of $Y \subseteq X$, for every good W such that $|W| = s \geq n^\beta \log n$, we have that $e_Y(W) \leq \frac{2ks^2}{n^\beta}$.*

Proof. Consider a fixed choice of a good W such that $|W| = s = n^\beta \log n$. By definition, $|\Delta(W)| \leq |W|^2 = s^2$. Since W is good, for every $x \in \Delta(W)$, if $x \in Y$, then the number of edges labeled by x in the subgraph of BG_X induced by W is at most k .

Since $Y \subseteq X$, $|Y| = d = \frac{|X|}{n^\beta}$ is a random subset selected uniformly from a set of size $|X|$, the expected size of $\Delta(W) \cap Y$ is $|\Delta(W)| \cdot n^{-\beta} \leq s^2 \cdot n^{-\beta}$. Using known bounds of the tail of the hypergeometric distribution (see, e.g., [13, p. 29]), the probability that $|\Delta(W) \cap Y| > 2 \cdot s^2 \cdot n^{-\beta}$ is upper bounded by $\exp(-\frac{cs^2}{n^{-\beta}})$ for some constant c . The claim follows by taking a union bound over all choices of W of size s . $\square$

We also need the following claim.

CLAIM 10. *Let C be a subset of $V_1 \cup V_2$ such that $|C| = n^\alpha$. Suppose we uniformly and independently select $W \subset C$, $|W| = n^\beta \log n$. Then the probability that W is not good is at most $\frac{1}{n^\beta}$.*

Proof. Note that by the definition of Behrend graphs, the edges between vertices in C that are labeled by a specific difference form a matching. When we choose a random subset $W \subset C$, the probability that there exists a single difference of C (i.e., an element of $\Delta(C)$) that has multiplicity at least $k+1$ in W is bounded by

$$(33) \quad |C|^2 |C|^{k+1} \binom{|C| - (2k+2)}{|W| - (2k+2)} \left(\frac{|C|}{|W|} \right)^{-1}.$$

To verify this expression, note first that there are at most $|C|^2$ possibilities from which to choose a difference from $\Delta(C)$. Since the edges of a specific difference form a matching of size at most $|C|$ over the edges of C , there are at most $|C|^{k+1}$ possibilities from which to choose the $k+1$ edges of this difference. The $k+1$ edges of the difference determine $2k+2$ of the vertices of W . Thus there are $\binom{|C| - (2k+2)}{|W| - (2k+2)}$ possibilities from which to choose the remaining vertices of W . Now,

$$(34) \quad \frac{|C|^2 |C|^{k+1} \binom{|C| - (2k+2)}{|W| - (2k+2)}}{\binom{|C|}{|W|}} \leq |C|^2 \cdot |C|^{k+1} \cdot \left(\frac{|W|}{|C|} \right)^{2k+2} \\ \leq n^{2\alpha} \left(\frac{\log^2 n}{n^{\alpha-2\beta}} \right)^{\frac{5}{\alpha-2\beta}} \leq \frac{1}{n^2}.$$

The last expression is upper bounded by $\frac{1}{n^\beta}$, as required. $\square$

Proof of Lemma 8. Consider a set C of vertices of BG_Y such that $|C| = n^\alpha$. Let $C_i = C \cap V_i$ for $1 \leq i \leq 3$. We will show that almost surely the number of edges between C_1 and C_2 is at most $\frac{30}{\alpha-2\beta} \frac{n^{2\alpha}}{n^\beta}$. The argument for the number of edges between C_2 and C_3 and between C_1 and C_3 is analogous, and hence the lemma

follows. We shall prove the claim for every C_1, C_2 such that $|C_1 \cup C_2| = n^\alpha$. Clearly this implies that it holds for every C_1, C_2 such that $|C_1 \cup C_2| \leq n^\alpha$.

By Claim 9, with high probability over the choice of Y , the following holds. For every good W , $W \subset C$, such that $|W| = s \geq n^\beta \log n$, the number of edges spanned by W in BG_Y is at most $2ks^2n^{-\beta}$. Assume from now on that the selected Y has this property. We shall use Claim 10 to derive an upper bound on the number of edges in BG_Y that are spanned by the vertices of C .

By our assumption on Y , if W is good and $|W| = s \geq n^\beta \log n$, then $e_Y(W) \leq 2ks^2n^{-\beta}$. Clearly, $e_Y(W) \leq s^2$. If we uniformly at random select $W \subset C$ such that $|W| = s$, then

$$\text{Exp}[e_Y(W)] \geq \frac{1}{2} \cdot e_Y(C) \cdot \frac{s^2}{n^{2\alpha}}.$$

We stress that the expectation is taken only over the choice of W and not over the choice of Y . Now,

$$\begin{aligned} & \text{Exp}[e_Y(W)] \\ &= \text{Exp}[e_Y(W) \mid W \text{ is good}] \cdot \Pr[W \text{ is good}] \\ & \quad + \text{Exp}[e_Y(W) \mid W \text{ is not good}] \cdot \Pr[W \text{ is not good}] \\ &\leq 2ks^2 \cdot n^{-\beta} + s^2 \cdot n^{-\beta} \\ (35) \quad &= (2k+1)s^2 \cdot n^{-\beta}. \end{aligned}$$

It follows that

$$(36) \quad e_Y(C) \leq (2k+1) \cdot 2|C|^2 \cdot n^{-\beta} \leq 5k|C|^2 \cdot n^{-\beta}.$$

Since $k = \frac{5}{\alpha-2\beta}$, the lemma follows. $\square$

As a corollary of Lemma 8 we get the following.

COROLLARY 11. *Let $0 < \beta < \frac{1}{2}$ and $X \subset \{1, \dots, n\}$, where $|X| \geq n^{1-\nu(n)}$ for $\nu(n) = \frac{\log \log \log n + 4}{\log \log n}$. Consider the random Behrend graph BG_Y obtained by choosing a random subset $Y \subseteq X$, $|Y| = d = \frac{|X|}{n^\beta}$. With high probability over the choice of Y , for every subset C of vertices in BG_Y such that $|C| \leq \min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)}$, the following bound applies: $|C| \cdot e_Y(C) \leq n^{1-\nu(n)}$.*

Proof. Note that $d = n^{1-\nu(n)-\beta}$, and so we need to bound the number of edges in sets C such that

$$(37) \quad |C| \leq \min \left\{ n^{\frac{1-\nu(n)-\beta}{2}}, n^{\frac{1+\nu(n)+\beta}{3}} \right\} \cdot n^{-\nu(n)} \leq n^{2/5-\nu(n)},$$

where $n^{2/5-\nu(n)}$ is obtained for $\beta = 1/5 - \nu(n)$.

Consider first the case that $\beta \leq \frac{1}{5} - \nu(n)$. In this case we need to bound the number of edges in sets C such that $|C| \leq \frac{n^{2/3-\nu(n)}}{d^{1/3}} = n^{\frac{1-2\nu(n)+\beta}{3}}$.

Let $\alpha = \frac{1-2\nu(n)+\beta}{3}$ and observe that $\alpha - 2\beta \geq \nu(n) > \frac{1}{\log \log n}$. Hence we can apply Lemma 8 and get that with high probability over the choice of Y , for every subset C such that $|C| = n^\alpha$, we have that $e_Y(C) \leq \frac{90}{\alpha-2\beta} \cdot \frac{n^{2\alpha}}{n^\beta}$. Clearly this upper bound also holds for every subset C such that $|C| \leq n^\alpha$. Hence,

$$(38) \quad |C| \cdot e_Y(C) \leq \frac{90}{\alpha-2\beta} \cdot \frac{n^{3\alpha}}{n^\beta} \leq \frac{90}{\nu(n)} \cdot n^{1-2\nu(n)} \leq n^{1-\nu(n)}.$$

Consider now the case that $\beta > \frac{1}{5} - \nu(n)$. Note that we need to bound the number of edges in sets C such that $|C| \leq n^{2/5 - \nu(n)}$. We have shown that the bound applies for the case that $\beta = \frac{1}{5} - \nu(n)$, and $|C| = n^{2/5 - \nu(n)}$. Hence, for $\beta > \frac{1}{5} - \nu(n)$, the sets C for which $|C| \leq n^{2/5 - \nu(n)}$ contain fewer edges, and therefore the previous bound applies. $\square$

5.3. The lower-bound distribution $BG(n, d)$. Let $X \subset [n]$ be a set with no three-term arithmetic progression, as constructed in subsection 5.1, such that $|X| = n^{1 - \nu(n)}$ (where $\nu(n) = \frac{\log \log \log n + 4}{\log \log n}$). Consider the Behrend graph, denoted BG_X , whose set of generators is X . Recall that BG_X , which is a graph over $3n$ vertices, contains $|X| \cdot n$ edge-disjoint triangles: every edge belongs to exactly one triangle, and every triangle corresponds to some $x \in X$.

For each subset $Y \subset X$ such that $|Y| = d$, we consider the subgraph of BG_X that contains all its vertices but only the edges labeled by differences $y \in Y$. This (sub)graph contains $n \cdot |Y| = nd$ edge-disjoint triangles and is hence ϵ -far from being triangle-free for any $0 < \epsilon < 1/3$. Next we apply a permutation π on the names of the vertices. More precisely, π consists of 3 permutations, $\pi^{(b)}$, $b \in \{1, 2, 3\}$, each over $\{0, \dots, n-1\}$. If we denote each vertex v in BG_X by a pair (b, i) , where $b \in \{1, 2, 3\}$ is the index of the subset that the vertex belongs to and $i \in \{0, \dots, n-1\}$, then $\pi(v) = \pi(b, i) = (b, \pi^{(b)}(i))$. We denote the resulting graph by $BG_{Y, \pi}$.

A graph is generated according to the distribution $BG(n, d)$ by uniformly selecting Y and π and outputting the resulting graph $BG_{Y, \pi}$. We also assume that the edges incident to a vertex v are ordered randomly in the incidence list of v . For the sake of simplicity, we do not include these random labelings in the notation.

5.4. Online generation of graphs according to $BG(n, d)$. In order to prove Lemma 6 we would like to show that any algorithm that is given query access to a graph generated according to $BG(n, d)$ must perform $\Omega(\min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)})$ queries in order to detect a triangle with sufficiently high constant probability. We wish to stress that the algorithm can be much more powerful/sophisticated potentially than just an algorithm that samples a random set of the input and looking for a triangle inside.

For the sake of our analysis, it will be convenient to define an online process, denoted P , that answers the algorithm's queries while generating a graph according to $BG(n, d)$. The process P will actually provide the algorithm with more information than required by neighbor and vertex-pair queries. Namely, whenever the algorithm asks a query involving a vertex $v \in \{(1, 0), \dots, (3, n-1)\}$ (in either type of query), the process will provide it with $\pi^{-1}(v)$. This will also be the case when the process answers a neighbor query (u, i) with a vertex v . Thus the algorithm is provided with the "identity" in BG_X of the vertices it has observed and can also derive the labels $y \in Y$ of the edges it has observed.

Clearly, a lower bound on the number of queries of an algorithm that is provided with the additional information described above constitutes a lower bound on an algorithm that is not provided with this additional information. It will actually be convenient to consider the following three types of queries:

1. Vertex queries: For any choice of a vertex $v \in \{(1, 0), \dots, (3, n-1)\}$ the algorithm is provided with $\pi^{-1}(v)$.
2. Random neighbor queries: For any vertex v the algorithm has already observed, it may ask for a new random neighbor u of v (together with $\pi^{-1}(u)$). The algorithm can indicate the subset to which the neighbor belongs.

3. Difference queries: For any $x \in X$ the algorithm can ask whether $x \in Y$.

Vertex queries are denoted $(VQ, (b, i))$, neighbor queries are denoted $(NQ, (b, i), b')$, and difference queries are denoted (DQ, x) , where $b \neq b' \in \{1, 2, 3\}$, $i \in \{0, \dots, n-1\}$, and $x \in X$.

Note that a vertex-pair query can be performed by asking at most two vertex queries and one difference query, and a neighbor query can be performed by asking a vertex query and a random neighbor query (recall that the edges adjacent to a vertex are labeled randomly in $BG_{Y,\pi}$). It follows that any lower bound on algorithms that perform these types of queries implies a lower bound that is at most a factor of 3 smaller on algorithms that perform vertex-pair and neighbor queries.

Let ALG be an algorithm that performs $Q = Q(n, d)$ queries of the above three types and whose goal is to detect a triangle with probability at least $9/10$. The probability is taken over the choice of the graph $BG_{Y,\pi}$ and the coin flips of the algorithm. Namely, ALG is a (possibly probabilistic) mapping from *query-answer histories* $\langle (q_1, t_1), \dots, (q_t, a_t) \rangle$ to q_{t+1} for every $t < Q$. The mapping needs to be defined only on histories that are consistent with some graph $BG_{Y,\pi}$.

As described above, a vertex query $q_t = (VQ, v_t)$ for $v_t \in \{(1, 0), \dots, (3, n-1)\}$ that has not yet been observed is answered by $\pi^{-1}(v_t)$. A random neighbor query $q_t = (NQ, v_t, b')$ for $v_t = (b, i)$ that has been observed is answered by a new random neighbor $U_t = (b', j)$ of v_t together with $\pi^{-1}(U_t)$. A difference query $q_t = (DQ, x)$ for $x \in X$ is answered by “1” (yes) or “0” (no), indicating whether $x \in Y$ or not.

Any query-answer history of length t can be used to define the *knowledge base* $K_t = (V_t, Y_t, \bar{Y}_t, \pi_t)$, where $V_t \subset \{(1, 0), \dots, (3, n-1)\}$, $Y_t, \bar{Y}_t \subset X$, and $\pi_t : V_t \rightarrow \{(1, 0), \dots, (3, n-1)\}$ (where π_t is one-to-one). Specifically, V_t consists of all vertices (b, j) such that $(b, j) = \pi^{-1}(v)$ for some v that appeared either in one of the first t queries of ALG or in one of the first t answers. The set Y_t consists of all $x \in X$ such that for some $t' \leq t$ there was either a query $q_{t'} = (DQ, x)$ that was answered by “1” or a query $q_{t'} = (NQ, v_{t'}, b')$ that was answered with $U_{t'}$, where the edge between $\pi^{-1}(v_{t'})$ and $\pi^{-1}(U_{t'})$ is labeled by x . The set $\bar{Y}_t$ consists of all $x \in X$ such that for some $t' \leq t$ there was a query $q_{t'} = (DQ, x)$ that was answered by “0.” Finally, for every $(b, j) \in V_t$, $\pi_t(b, j) = v$, where v is such that $\pi^{-1}(v) = (b, j)$.

Observe that V_t together with Y_t determine a subgraph of BG_X : the vertices of the subgraph are the vertices of V_t , and the edges are all pairs (u, v) , $u, v \in V_t$, such that there is an edge between u and v in BG_X and this edge is labeled by some $x \in Y_t$. For each $b \in \{1, 2, 3\}$ we let $V_{t,b} = \{(b, j) : (b, j) \in V_t\}$.

5.4.1. Definition of the process P . Let $R = R(n, d)$ denote the set of all graphs $BG_{Y,\pi}$ in the support of $BG(n, d)$. For $b \in \{1, 2, 3\}$ and $i, j \in \{0, \dots, n-1\}$ let $R_{b,i,j} \subset R$ denote the subset of graphs $BG_{Y,\pi} \in R$ such that $\pi(b, j) = (b, i)$. For $x \in X$ let $R_x \subset R$ denote the subset of graphs $BG_{Y,\pi} \in R$ such that $x \in Y$, and let $R_{\neg x} \subset R$ denote the subset of graphs $BG_{Y,\pi} \in R$ such that $x \notin Y$.

The process P answers ALG’s queries as follows, where we assume without loss of generality that ALG does not ask any query q_t whose answer can be deduced from the knowledge base K_{t-1} . In particular, for every vertex query $q_t = (VQ, v)$ we have that $v \notin V_{t-1}$, and for every difference query $q_t = (DQ, x)$ we have that $x \notin Y_{t-1} \cup \bar{Y}_{t-1}$. The process P initializes $R_0 = R$, and in general, for any $t \geq 0$, we have that R_t consists of all graphs in R that are consistent with the first t queries.

- To answer a vertex query $q_t = (VQ, v)$, where $v = (b, i)$, the process uniformly selects $(b, j) \in \{(b, 0), \dots, (b, n-1)\} \setminus V_{t-1,b}$ and sets $R_t = R_{b,i,j} \cap R_{t-1}$. Note that (b, j) is selected with probability $\frac{|R_{b,i,j} \cap R_{t-1}|}{|R_{t-1}|} = \frac{|R_t|}{|R_{t-1}|}$.

- Given a difference query (DQ, x) , with probability $\frac{d-|Y_{t-1}|}{|X|-|Y_{t-1}|-|\bar{Y}_{t-1}|}$ the process answers “1” and with probability $1 - \frac{d-|Y_{t-1}|}{|X|-|Y_{t-1}|-|\bar{Y}_{t-1}|} = \frac{|X|-d-|\bar{Y}_{t-1}|}{|X|-|Y_{t-1}|-|\bar{Y}_{t-1}|}$ it answers “0.” In the former case it sets $R_t = R_x \cap R_{t-1}$ and in the latter case it sets $R_t = R_{\neg x} \cap R_{t-1}$. Note that here the answer is “1” with probability $\frac{|R_x \cap R_{t-1}|}{|R_{t-1}|} = \frac{|R_t|}{|R_{t-1}|}$ and is “0” with probability $1 - \frac{|R_x \cap R_{t-1}|}{|R_{t-1}|} = \frac{|R_{\neg x} \cap R_{t-1}|}{|R_{t-1}|} = \frac{|R_t|}{|R_{t-1}|}$.
- To answer a random neighbor query $q_t = (NQ, v, b')$, the process performs two steps. First it selects $x \in X$ in the following manner. With probability $\frac{|Y_{t-1}|}{d}$ it selects x uniformly from Y_{t-1} , and with probability $1 - \frac{|Y_{t-1}|}{d}$ it selects x uniformly from $X \setminus (Y_{t-1} \cup \bar{Y}_{t-1})$. In either case the choice of x (together with b') determines the value of $j \in \{0, \dots, n-1\}$ such that there is an edge labeled x in BG_X between $\pi^{-1}(v)$ and (b', j) . If $(b', j) \in V_{t-1}$, then $u = \pi_t(b', j) = \pi(b', j)$ is known and $R_t = R_x \cap R_{t-1}$. Otherwise, $u = (b', i)$ is selected uniformly in $\{(b', 0), \dots, (b', n-1)\} \setminus V_{t-1, b'}$ and $R_t = R_x \cap R_{b', i, j} \cap R_{t-1}$.

Once P completes answering the Q queries of ALG it uniformly selects a graph in R_Q . The next lemma is easily derived from the definition of the process.

LEMMA 12. *For every algorithm ALG , the process P , when interacting with ALG , uniformly generates graphs in $BG(n, d)$*

Proof. Consider a specific graph G in $R_0 = BG(n, d)$. The probability that G is generated by P is

$$\begin{aligned}
 & \Pr[G \in R_1] \cdot \Pr[G \in R_2 | G \in R_1] \cdots \Pr[G \in R_Q | G \in R_{Q-1}] \cdot \frac{1}{|R_Q|} \\
 (39) \quad &= \frac{|R_1|}{|R_0|} \cdot \frac{|R_2|}{|R_1|} \cdots \frac{|R_Q|}{|R_{Q-1}|} \cdot \frac{1}{|R_Q|} = \frac{1}{|R_0|},
 \end{aligned}$$

and the lemma follows. $\square$

5.5. Proof of Lemma 6. Consider any algorithm ALG that interacts with the process P . We shall show that if ALG asks $Q = o(\min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)})$ queries, then the probability that it reveals a triangle is $o(1)$. By Corollary 11, with high probability over the choice of Y , $|Y| = d$, for every subset U of vertices such that $|U| = o(\min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)})$, we have $|U| \cdot e(U) = o(n^{1-\nu(n)})$, where $e(U)$ denotes the number of edges induced by the vertices of U . In what follows we assume that the graph generated by P in fact has this property, where we take into account the probability of $o(1)$ that this is not the case. Let E_t be the set of edges between vertices in V_t that are known to the algorithm after the first t queries. That is, E_t consists of all edges in BG_X whose labels are in Y_t and are between vertices in V_t . Therefore, for every $t = o(\min\{\sqrt{d}, \frac{n^{2/3}}{d^{1/3}}\} \cdot n^{-\nu(n)})$ we have that $t|E_t| = o(n^{1-\nu(n)})$.

Recall that every edge $(i, j) \in E_t$ participates in exactly one triangle. There are two ways by which ALG can close a triangle in its t th query. If the query is either a vertex query or a random neighbor query, the algorithm must receive as an answer one of the $|E_{t-1}|$ vertices that close triangles with (the known) edges between vertices in V_{t-1} . If the query is a difference query (DQ, x) (where $x \notin Y_{t-1} \cup \bar{Y}_{t-1}$), then there must be three vertices $(1, i), (2, j), (3, k) \in V_{t-1}$ that form a triangle in BG_X whose edges are labeled by x and the answer to the query is “1” (i.e., $x \in Y$). For the sake of simplicity we assume that whenever the algorithm obtains a vertex that

closes a triangle in BG_X , then it is also told whether this triangle is in $BG_{Y,\pi}$ or not (i.e., it gets a difference query “for free”). We now turn to bounding the probability of each of the above events by which a triangle is closed.

We first observe that since $|V_t| \leq t = o(n)$, whenever ALG asks a vertex query (VQ, v) , where $v = (b, i)$, the answer, (b, j) , is uniformly distributed in a subset of size $\Theta(n)$. Since $|Y_t| + |\bar{Y}_t| \leq t$, whenever ALG asks a random neighbor query $q_t = (NQ, v, b')$, with probability at least $1 - \frac{t}{d}$ we have that $(b', j) = \pi^{-1}(u)$ is uniformly distributed in a subset of size $|X| - t$. Since $|X| = \Omega(n^{1-\nu(n)})$ and $t = o(\sqrt{d}) = o(\sqrt{|X|})$, with probability $1 - o(1)$, for every neighbor query performed, the answer to the neighbor query is uniformly distributed in a subset of size $\Omega(n^{1-\nu(n)})$. Let us assume from this point on that this is in fact the case (where we take into account the $o(1)$ probability that this is not the case).

Given the above, the probability that ALG closes a triangle in the t th query when one of the edges of the triangle is already in E_t is $\frac{|E_t|}{\Omega(n^{1-\nu(n)})}$. It remains to bound the probability that ALG closes a triangle by obtaining a vertex (b, j) that closes a triangle in the subgraph of BG_X that is induced by V_{t-1} , and that the difference $x \notin Y_{t-1} \cup \bar{Y}_{t-1}$ corresponding to the triangle is determined to be in Y . Since the number of edges in the subgraph of BG_X that is induced by V_{t-1} is upper bounded by t^2 , the probability of the above event is at most

$$(40) \quad \frac{t^2}{\Omega(n^{1-\nu(n)})} \cdot \frac{d-t}{\Omega(n^{1-\nu(n)})} = \frac{t^2(d-t)}{\Omega(n^{2(1-\nu(n))})}.$$

Since $t = o(\min\{\sqrt{d}, n^{2/3}/d^{1/3}\} \cdot n^{-\nu(n)})$, we know that $t|E_t| = o(n^{1-\nu(n)})$ and $t^3 \cdot (d-t) = o(n^{2(1-\nu(n))})$. Hence, the probability that one of the above events occurs for any $t \leq Q$ is $o(1)$, as required. $\square$

6. From 1-sided error to 2-sided error. In this section we establish that under certain conditions, a one-sided error lower bound for triangle-freeness can be transformed into a two-sided error lower bound. Since these conditions hold for our one-sided error lower bounds, we obtain two-sided error lower bounds.

THEOREM 3. *Let D_Δ be a distribution over graphs with n vertices and average degree d , and let $q(n, d)$ be a function of these parameters. Assume that the following hold:*

- *With probability $1 - o(1)$ a graph selected according to D_Δ is ϵ -far from being triangle-free for some constant ϵ .*
- *One of the following two conditions holds:*
 1. *In all graphs in the support of D_Δ , the triangles are edge-disjoint, and for any algorithm A , the probability that A reveals a triangle in a graph selected according to D_Δ using $o(q(n, d))$ queries is less than $2/3$.*
 2. *For any algorithm A , the probability that A reveals a cycle (of any length) in a graph selected according to D_Δ using $o(q(n, d))$ queries is less than $2/3$.*

Then any two-sided error algorithm for testing triangle-freeness that has success probability at least $5/6$ must perform $\Omega(q(n/2, d))$ queries.

Since the distributions that are defined for our one-sided error lower bounds, which are stated in Lemmas 2 and 6, are as required by Theorem 3, we get the following corollary.

COROLLARY 13. *Any algorithm for testing triangle-freeness must perform*

$$\Omega\left(\max\left\{\min\{d, n/d\}, \min\left\{\sqrt{d}, n^{2/3}/d^{1/3}\right\} \cdot n^{-\nu(n)}\right\}\right)$$

queries. This lower bound holds even if the algorithm is allowed two-sided error and $d_{\max} = O(d)$.

6.1. Proof of Theorem 3: Condition 1. Given the distribution D_Δ we define two distributions over graphs that have $n' = 2n$ vertices and average degree d . One distribution, denoted D'_Δ , generates graphs that are ϵ -far from being triangle-free, and the other distribution, denoted $D_{\bar{\Delta}}$, generates graphs that are triangle-free. Assume, contrary to what is claimed in the theorem, that there exists a two-sided error algorithm A' for testing triangle freeness that performs $o(q(n'/2, d))$ queries and has success probability at least $5/6$. Then, in particular, using $o(q(n'/2, d)) = o(q(n/d))$ queries, A' should be able to distinguish with sufficiently high probability between graphs generated by D'_Δ and graphs generated by $D_{\bar{\Delta}}$. We shall show that we can then use A' to obtain an algorithm A that performs $o(q(n, d))$ queries and with probability at least $2/3$ reveals a triangle in a random graph generated according to D_Δ .

Defining the two distributions. In both distributions, a graph G' over $n' = 2n$ vertices is generated by first selecting a graph G from D_Δ . Every vertex v in G is replaced by two vertices, v_0 and v_1 . Every edge (u, v) in G is replaced by two edges—either the two edges (u_0, v_0) and (u_1, v_1) (so that they are “in parallel”) or the two edges (u_0, v_1) and (u_1, v_0) (so that they are “crossing”). If v is the j th neighbor of u and u is the ℓ th neighbor of v , then in both cases we maintain the ordering on neighbors. Namely, in the case of parallel edges we have that v_0 is the j th neighbor of u_0 and v_1 is the j th neighbor of u_1 , and u_0 is the ℓ th neighbor of v_0 and u_1 is the ℓ th neighbor of v_1 (an analogous correspondence holds for crossing edges). The difference between the distributions is in the choice (distribution on the choice) between the above two options.

Recall that the triangles in G are edge-disjoint. Hence, for each triangle in G , the edges between the corresponding vertices in G' can be determined independently from the edges that belong to other triangles. Consider a particular triangle (u, v, w) in G . There are $2^3 = 8$ ways to select the edges between the vertices $u_0, u_1, v_0, v_1, w_0, w_1$ (depending on whether we select parallel or crossing edges). In 4 of these ways we get 2 edge-disjoint triangles (e.g., (u_0, v_0, w_0) and (u_1, v_1, w_1)), and in 4 of these ways we get a single cycle of length 6 (e.g., $(u_0, v_0, w_0, u_1, v_1, w_1)$). The graph generated by D'_Δ simply selects one of the former 4 ways uniformly, and the graph generated by $D_{\bar{\Delta}}$ selects one of the latter 4 ways uniformly. For an illustration see Figure 2.

The basic but important observation is that for both distributions the following holds: If we consider any edge that belongs to a particular triangle in G , then the probability that the corresponding pair of edges in G' are parallel is equal to the probability that they are crossing. Moreover, this remains true if we condition it on any other (single) edge in the triangle being transformed to either parallel or crossing edges. Independence breaks down only when we consider all 3 edges in a triangle. We shall refer to this observation as the *independence observation*.

Using a two-sided error algorithm to find triangles. Let A' be a two-sided error algorithm for testing triangle freeness that performs $o(q(n'/2, d))$ queries when testing graphs over $n' = 2n$ vertices and has success probability at least $5/6$. We next show how to use it in order to detect triangles in a graph G over n vertices that is generated randomly according to D_Δ . The idea is that by performing queries to G and flipping some coins, we shall actually be emulating the execution of A' on graphs generated by either D'_Δ or $D_{\bar{\Delta}}$. Since A' is supposed to test graphs over $n' = 2n$ vertices, we denote the vertices in the queries it performs by $\{v_{1,0}, v_{1,1}, \dots, v_{n,0}, v_{n,1}\}$.

Let G be a graph generated according to D_Δ . Algorithm A (whose goal is to

FIG. 2. On the top is a triangle (u, v, w) . On the bottom left is a transformation of this triangle into two disjoint triangles, and on the bottom right is a transformation into a cycle of length 6. In particular, on the left all pairs of edges are parallel, and on the right two are parallel and one is crossing.

detect a triangle in G) runs A' as a subroutine and answers its queries by performing queries to G and transforming the answers to the queries in an appropriate manner described below. In this process A maintains a *knowledge graph*, denoted $\hat{G}$, which contains all the edges it has observed in G as well as the “nonedges” (i.e., pairs (u, v) that do not have an edge between them). In addition, A records all the answers it has already given to A' .

Whenever A' performs a degree query for a vertex $v_{i,b}$ ($b \in \{0, 1\}$), algorithm A queries the degree of v_i and returns it as an answer. Whenever A' performs a vertex-pair query $(v_{i,b}, v_{j,b'})$ ($b, b' \in \{0, 1\}$), if (u, v) is an edge or a nonedge in the knowledge graph $\hat{G}$, then the answer to A' is determined. If this is not the case, then A performs the vertex-pair query (v_i, v_j) . If the answer is that there is no edge between the two vertices, then the answer given to A' is “no” as well. If the answer is that there is an edge, then there are two cases. If this edge closes a triangle with two other edges in $\hat{G}$, then A terminates successfully. Otherwise, with probability $1/2$ A answers that there is an edge between $v_{i,b}$ and $v_{j,b'}$ and with probability $1/2$ it answers that there is no such edge. In both cases the existence of the edge in G is recorded in the knowledge graph $\hat{G}$. In addition, in the former case A' is provided with the information concerning which neighbor is $v_{j,b'}$ of $v_{i,b}$.

Whenever A' performs a neighbor query $(v_{i,b}, \ell)$ (that does not correspond to an edge already in $\hat{G}$), algorithm A performs the neighbor query (v_i, ℓ) . Let the answer be (v_j, t) . Namely, there is an edge between v_i and v_j , where v_j is the ℓ th neighbor of v_i , and v_i is the t th neighbor of v_j . Here, too, if a triangle in G is detected, then A terminates successfully. Otherwise, it answers the query of A' in an analogous manner to the way a vertex-pair query is answered. If A' terminates before A has found a triangle, then A terminates unsuccessfully.

Completing the proof. Since A always terminates when or before it finds a triangle, by the independence observation, the distribution on the answers it gives to the queries of A' is exactly the same as the one we would get if the queries of A' were

answered by a graph that is selected either according to D'_Δ or according to $D_{\bar{\Delta}}$. We claim that this implies that the probability that A' terminates before A finds a triangle (thus causing A to terminate unsuccessfully) is less than $1/3$. Here the probability is taken over the choice of G , the coin flips of A , and the possible coin flips of A' .

Assume, contrary to the claim, that the probability that A' terminates before A finds a triangle is at least $1/3$. Consider the distribution over graphs that results from selecting with probability $1/2$ a graph G' according to D'_Δ , and with probability $1/2$ a graph G' according to $D_{\bar{\Delta}}$. By our counterassumption, the probability that A' terminates before it sees three edges of the form (v_{i,b_1}, v_{j,b_2}) , (v_{j,b_3}, v_{k,b_4}) , and (v_{k,b_5}, v_{i,b_6}) (where $b_1, \dots, b_6 \in \{0, 1\}$) is greater than $1/3$. In such a case, by the independence observation, the distribution on the answers to the queries of A' (and hence on its queries conditioned on these answers) is the same if the graph G' is selected according to D'_Δ or according to $D_{\bar{\Delta}}$. Therefore, the probability that A' terminates with an incorrect output is greater than $1/6 - o(1) > 1/9$, where the term $o(1)$ is due to the probability that G is not ϵ -far from triangle-free. But this contradicts our assumption on A' .

Since the number of queries performed by A before it terminates is upper bounded by the number of queries performed by A' , the theorem follows. $\square$

6.2. Proof of Theorem 3: Condition 2. Similarly to the proof of Theorem 3 under condition 1, given the distribution D_Δ we define two distributions over graphs that have $n' = 2n$ vertices and average degree d . One distribution, denoted D'_Δ , generates graphs that are $\Omega(1)$ -far from being triangle-free, and the other distribution, denoted $D_{\bar{\Delta}}$, generates graphs that are triangle-free. In fact, the graphs in the support of $D_{\bar{\Delta}}$ are all bipartite. We then show how it is possible to use an algorithm A' that can distinguish with high probability between graphs generated according to D'_Δ and graphs generated according to $D_{\bar{\Delta}}$ in order to obtain an algorithm A that with high probability reveals a cycle in a random graph generated according to D_Δ .

Defining the two distributions. In both distributions, a graph G' over $n' = 2n$ vertices is generated by first selecting a graph G from D_Δ . Here, too, each edge $(u, v) \in E(G)$ is replaced by two edges in G' : either the “parallel” edges (u_0, v_0) and (u_1, v_1) or the “crossing” edges (u_0, v_1) and (u_1, v_0) . The difference between the distributions is in the choice (distribution on the choice) between the above two options.

In the distribution D'_Δ , the decision whether an edge is transformed into parallel edges or into crossing edges is done independently, and with equal probability. Namely, for each function $\sigma : E(G) \rightarrow \{p, c\}$, there is a graph G_σ in the support of D'_Δ . For every edge $(u, v) \in E(G)$, if $\sigma(u, v) = p$, then in G_σ we have the parallel edges (u_0, v_0) and (u_1, v_1) , and if $\sigma(u, v) = c$, then in G_σ we have the crossing edges (u_0, v_1) and (u_1, v_0) . The function σ is selected uniformly at random.

On the other hand, each graph in the support of $D_{\bar{\Delta}}$ is determined by a function $\pi : V(G) \rightarrow \{\ell, r\}$. Here ℓ stands for “left” and r for “right” so that π defines a two-way partition of the vertices: If $\pi(v) = \ell$, then v_0 is put on the “left” side, and if $\pi(v) = r$, then v_0 is put on the “right” side. In either case, v_1 is put on the opposite side. The decision between parallel and crossing edges is done so that the resulting graph is bipartite. Specifically, for every edge $(u, v) \in E(G)$, if $\pi(u) = \pi(v)$, then in G_π we have the crossing edges (u_0, v_1) and (u_1, v_0) , and if $\pi(u) \neq \pi(v)$, then we have the parallel edges (u_0, v_0) and (u_1, v_1) . The function π is selected uniformly at random. We note that different choices of π may result in the same graph, but this is inconsequential to our argument.

Properties of the distributions. By definition of $D_{\bar{\Delta}}$, every graph in the support of $D_{\bar{\Delta}}$ is bipartite and hence is necessarily triangle-free. On the other hand, we claim that if the graph G (that is selected according to D_{Δ}) is ϵ -far from being triangle-free, then with probability $1 - \exp(-\Omega(\epsilon dn))$ over the choice of σ , the graph G_{σ} (in the support of D'_{Δ}) is at least $\epsilon/4$ -far from being triangle-free. To verify this claim observe that since G is ϵ -far from being triangle-free, it contains at least ϵdn edge-disjoint triangles. For each such triangle, the probability that it is transformed into two triangles in G_{σ} is $1/2$. By a multiplicative Chernoff bound, the probability that less than $(\epsilon dn)/4$ of the disjoint triangles in G are transformed into a pair of disjoint triangles is $\exp(-\Omega(\epsilon dn))$. That is, with probability $1 - \exp(-\Omega(\epsilon dn))$ there are $(\epsilon dn)/2$ disjoint triangles in the resulting graph, and since the graph contains $2n$ vertices, it is $(\epsilon/4)$ -far from being triangle-free. Since the probability that G is ϵ -far from triangle free for some constant ϵ is $1 - o(1)$, we get that with probability $1 - o(1)$, a graph generated according to D'_{Δ} is at least $\Omega(1)$ -far from being triangle-free.

Completing the proof. Most parts of the argument are almost identical to those in the proof of Theorem 3 subject to Condition 1, where the only difference is that “detecting a triangle” is replaced by “detecting a cycle.” The only essential difference is that the independence observation concerning the distribution on parallel/crossing edges conditioned on a triangle not being detected needs to be modified. Specifically, consider any fixed choice of edges in G that do not contain a cycle. We shall show that under both distributions, all mappings of these edges to parallel/crossing pairs of edges in G' have equal probability. This implies that if we fix any choice of parallel/crossing pairs of edges in G' , where the corresponding edges in G do not contain a cycle, and we consider a new edge that does not close a cycle with these edges, then under both distributions it has equal conditional probability to be mapped to a parallel/crossing pair of edges in G' .

Let $F = \{(u_1, v_1), \dots, (u_t, v_t)\}$ be any subset of edges in G that do not contain a cycle. For a graph G' either in the support of $D_{\bar{\Delta}}$ or in the support of D'_{Δ} , let $\sigma_{G'}(u_i, v_i) = p$ if the edge (u_i, v_i) is transformed into parallel edges in G' , and let $\sigma_{G'}(u_i, v_i) = c$ if it is transformed into crossing edges. By definition of the distributions, if G' is in the support of D'_{Δ} , so that $G' = G_{\sigma}$ for $\sigma : E(G) \rightarrow \{p, c\}$, then $\sigma_{G'}(u_i, v_i) = \sigma$, and if G' is in the support of $D_{\bar{\Delta}}$, so that $G' = G_{\pi}$ for $\pi : V(G) \rightarrow \{\ell, r\}$, then $\sigma_{G'}(u_i, v_i) = c$ when $\pi(u_i) = \pi(v_i)$, and $\sigma_{G'}(u_i, v_i) = p$ otherwise.

Consider the distribution over $\sigma_{G'}(u_1, v_1), \dots, \sigma_{G'}(u_t, v_t)$ when G' is chosen according to each of the two distributions. Then we claim that the distribution is uniform over $\{p, c\}^t$. This is clearly the case when G' is selected according to D'_{Δ} (as G' is determined by selecting $\sigma : E(G) \rightarrow \{p, c\}$ uniformly at random). It remains to verify that this is also true when $G' = G_{\pi}$, and $\pi : V(G) \rightarrow \{\ell, r\}$ is selected uniformly at random. Consider any vector $h \in \{p, c\}^t$ (where $h_i = p$ means that (u_i, v_i) is transformed into a parallel edge, and $h_i = c$ means that it is transformed into a crossing edge). Since F does not contain a cycle, it consists of a forest of trees, $T_1, \dots, T_s$. The total number of vertices in these trees is $t + s$. For each tree T_j , if the value of $\pi(v)$ is determined for some arbitrary vertex v in the tree, then the setting of h enforces a unique value $\pi(u)$ for every $u \in T_j$. In other words, the number of settings of π that induce a particular h is 2^s . Since the total number of settings of π is 2^{s+t} we get

$$(41) \quad \forall h \in \{p, c\}^t, \quad \Pr_{\pi} [\sigma_{G_{\pi}}(u_1, v_1), \dots, \sigma_{G_{\pi}}(u_t, v_t) = h] = \frac{2^s}{2^{t+s}} = \frac{1}{2^t},$$

and so the (modified) independence observation is established. The proof is completed analogously to the way it was completed under Condition 1 (using the modified independence observation and replacing detection of triangles with detection of cycles). $\square$

7. Upper bounds.

7.1. An upper bound of $\tilde{O}(\sqrt{nd}/\epsilon^{3/2})$ for general graphs. In this subsection we prove the next lemma.

LEMMA 14. *It is possible to test triangle-freeness by performing $\tilde{O}(\sqrt{nd}/\epsilon^{3/2})$ queries. If $d_{\max} = O(d)$, then $O(d/\epsilon)$ queries suffice.*

Proof. Let G be a graph with average degree d over n vertices that is ϵ -far from being triangle-free. By definition, G must contain at least ϵdn edges that belong to triangles. If $d_{\max} = O(d)$, then by uniformly selecting $\Theta(1/\epsilon)$ vertices and for each uniformly selecting an incident edge, with high probability we obtain an edge that belongs to a triangle. Conditioned on this event, if we now perform all $O(d)$ neighbor queries to the endpoints of each selected edge, we reveal a triangle.

If the maximum degree of the graph differs significantly from its average degree, then the above argument cannot be applied: First, the suggested edge selection process might not select with sufficiently high probability an edge that belongs to a triangle because the algorithm uniformly selects vertices rather than edges. Second, even if we obtain such an edge, its endpoints might have a very high degree. To address these issues, we first introduce some notation.

We say that a vertex has *high degree* if its degree is more than $c\sqrt{nd}$ (where we set c momentarily). We shall say that an edge is *covered* by these high degree vertices if *both* its endpoints have high degree. By definition, the high-degree vertices can cover at most $((1/c)\sqrt{nd})^2 = (1/c^2)nd$ edges. Hence, among the edges that belong to triangles, there are at least $(\epsilon - (1/c^2))nd$ edges that have at least one endpoint with degree at most $c\sqrt{nd}$. If we set $c = \sqrt{2/\epsilon}$, then we have at least $(\epsilon/2)nd$ such edges.

In order to obtain one of these edges, we would like to sample edges uniformly in G . In fact, it suffices to sample edges “almost uniformly” as defined in [14]. In [14] an algorithm is described that uses $\tilde{O}(\sqrt{n/\delta})$ queries to a graph G and for which the following holds: For all but at most $\delta/4$ -fraction of the edges of G the probability that the edge is selected is at least $\frac{1}{32nd}$. We refer to this algorithm as “Edge-Select.” By definition of the algorithm, if we set $\delta = \epsilon$, we get that there are at least $(\epsilon/4)nd$ edges that can be returned by “Edge-Select” such that these edges belong to triangles and have at least one endpoint with degree at most $\sqrt{2/\epsilon}\sqrt{nd}$. It follows that at a cost of $\tilde{O}(\sqrt{n}/\epsilon^{3/2})$ queries we obtain such an edge with a high constant probability. Thus the algorithm for detecting a triangle runs “Edge-Select” $\Theta(1/\epsilon)$ times. For each selected edge, if it has one endpoint with degree less than $\sqrt{2/\epsilon} \cdot \sqrt{nd}$, then it asks all neighbor queries for that vertex, and for each of them it asks all pair queries with the other endpoint. (If both endpoints have high degree, then the algorithm does nothing.) $\square$

7.2. An improved upper bound for relatively dense general graphs.

When the graph is relatively dense we can get the following improvement.

LEMMA 15. *It is possible to test triangle-freeness by performing $O(\max\{\frac{n^{4/3}}{\epsilon^{2/3}d^{2/3}}, \frac{d_{\max}^2}{\epsilon^2 d^2}\})$ queries.*

As a corollary we get the following.

COROLLARY 16. *It is possible to test triangle-freeness of graphs with average degree $d = \Omega(\sqrt{n})$ by performing $O(\frac{n^{4/3}}{d^{2/3}\epsilon^2})$ queries.*

Proof of Lemma 15. Let G be a graph over n vertices with average degree d and maximum degree $d_{\max}$ that is ϵ -far from being triangle-free. We shall show that if we take a uniform sample of $\Theta(\max\{\frac{n^{2/3}}{\epsilon^{1/3}d^{1/3}}, \frac{d_{\max}}{\epsilon d}\})$ vertices of G and ask vertex-pair queries between all pairs in the sample, then a triangle is detected with probability at least $2/3$.

Since G is ϵ -far from being triangle-free, it must contain at least ϵdn triples of vertices that form a triangle. This lower bound on the number of triangles implies that the expected number of triangles in a set of s uniformly selected vertices is at least $s^3 \cdot \frac{\epsilon dn}{n^3}$. It follows that for $s \geq n^{2/3}/(\epsilon d)^{1/3}$ the expected number of triangles spanned by the sample is at least 1. This unfortunately does not imply in general that a uniform sample of $s = \Omega(n^{2/3}/(\epsilon d)^{1/3})$ vertices spans a triangle with probability at least $2/3$. Rather, the size of the sample should depend on the ratio between $d_{\max}$ and d .

Let $s = c \cdot \max(\frac{n^{2/3}}{(\epsilon d)^{1/3}}, \frac{d_{\max}}{\epsilon d})$, where $c > 0$ is a sufficiently large constant. Since G is ϵ -far from being triangle-free, G must contain a family T of $(\epsilon dn)/3$ pairwise edge-disjoint triangles. Fix such a family, and for every $v \in V(G)$, let $d_T(v)$ be the number of triangles in T containing v ; obviously, $d_T(v) \leq d(v)/2 \leq d_{\max}/2$. We sample a set S of s vertices of G uniformly at random. Let X be the random variable counting the number of triangles of T spanned by S . Due to the Chebyshev inequality, it is enough to prove that $\text{Exp}[X]$ is at least a large constant, and the ratio $\text{Var}[X]/\text{Exp}^2[X]$ is at most a small enough constant. We will estimate both quantities.

Observe that each triangle of T falls into S with probability $(1 + o(1))s^3/n^3$. It follows that

$$(42) \quad \text{Exp}[X] = (1 + o(1)) \frac{s^3}{n^3} |T| = \Theta\left(\frac{\epsilon ds^3}{n^2}\right).$$

Thus, taking c large enough, we get that $\text{Exp}[X]$ is large enough, too. Also,

$$(43) \quad \begin{aligned} \text{Var}[X] &\leq \sum_{\substack{t, t' \in T \\ t \cap t' \neq \emptyset}} \Pr[t, t' \subset S] \\ &= \sum_{v \in V(G)} \binom{d_T(v)}{2} \frac{(1 + o(1))s^5}{n^5} \end{aligned}$$

(the latter estimate is due to the fact that, since T is pairwise edge-disjoint, for any $t, t' \in T$ with $t \cap t' \neq \emptyset$, the union $t \cup t'$ contains exactly five vertices). Recall that $d_T(v) \leq d_{\max}$. Due to convexity, we get

$$(44) \quad \text{Var}[X] = O\left(\frac{\epsilon dn}{d_{\max}} \cdot d_{\max}^2\right) \frac{s^5}{n^5}.$$

Using the assumption $s = \Omega(\frac{d_{\max}}{\epsilon d})$, we derive that $\text{Var}[X]/\text{Exp}^2[X]$ is small enough, as required. $\square$

8. Bounds on the edge density of random Cayley graphs with large sets of generators. In this section we consider random Cayley graphs. Behrend graphs are essentially variants of Cayley graphs. Using methods that were introduced

in subsection 5.2, we get bounds on the edge density of random Cayley graphs with large sets of generators. We start with a definition of Cayley graphs. For simplicity we consider only Cayley graphs over Abelian groups, but all arguments apply to the non-Abelian case as well.

Let H be a finite Abelian group. A set $X \subseteq H$ is *symmetric* if $X = -X$, where $-X = \{-x : x \in X\}$. The *Cayley graph* over H with respect to a symmetric set X , denoted CG_X , has H as its vertex set and distinct vertices $a, b \in H$ are connected by an edge if and only if $a - b$ (hence also $b - a$) is in X . We shall say in such a case that the edge *corresponds* to $x = a - b$. All operations involving vertices are performed in H . A *difference* of a set $T \subseteq H$ is an element $a - b$ such that $a, b \in T$. We let $\Delta(T)$ denote the set $\{a - b : a, b \in T\}$ of differences of T . By definition $\Delta(T)$ contains at most $|T|(|T| - 1)$ nonzero elements. The *multiplicity* in T of a difference $x \in \Delta(T)$ is $|\{(a, b) : a, b \in T \text{ and } a - b = x\}|$. Clearly, the differences that correspond to edges that are incident to a specific vertex are all distinct. It follows that the multiplicity in T of any specific difference in $\Delta(T)$ is at most $|T|$. Moreover, if we consider the complete graph over H , then the edges that correspond to a specific difference form a set of cycles that cover H .

In what follows we show that for dense random Cayley graphs the edge density in relatively large induced subgraphs is close to the edge density of the whole graph. It was previously shown [4] that random Cayley graphs are expanders and hence have the property that the density of every induced subgraph on sufficiently many vertices is very close to the density of the graph. However, the known techniques for proving this property are based on estimating the second eigenvalue of the graph's adjacency matrix and do not supply any informative bounds for sets of vertices that are much smaller than the number of vertices divided by the square root of the degree.

We shall use the following notation: For $X, C \subseteq H$, we let $e_X(C)$ denote the number of edges in the subgraph of CG_X that is induced by C .

THEOREM 4. *Let $0 < \beta < \frac{1}{2}$ and $0 < \alpha \leq 1$ satisfy $\alpha - 2\beta > \frac{1}{\log \log n}$, and let H be an Abelian group where $|H| = n$. Let $X \subset H$, $X = -X$, be determined as follows: Every pair $x, -x$ is chosen independently with probability $p(n) = \frac{1}{n^\beta}$ to be in X . With high probability over the choice of X , for every subset C of n^α vertices in CG_X , we have that $e_X(C) \leq \frac{90}{\alpha - 2\beta} \frac{n^{2\alpha}}{n^\beta}$.*

Similarly to Lemma 8, Theorem 4 shows that for sufficiently large subsets C (i.e., for $|C| = n^\alpha$, where $\alpha - 2\beta$ is a constant), the number of edges spanned by C in CG_X is close to its expected value. Here, too, the smaller we choose β (i.e., the larger we choose X), the smaller α can be. That is, the theorem can be applied to sets with smaller size. The proof of Theorem 4 is similar to the proof of Lemma 8. The difference lies in the proof of Claim 18, which is analogous to Claim 9. Here, too, we let $k = \frac{5}{\alpha - 2\beta}$ and note that for β and α as required in the theorem, $k \leq 5 \log \log n$. We shall say that W is *good* if no difference in $\Delta(W)$ has multiplicity higher than k in W . Theorem 4 follows from the next two claims using the same arguments that were applied in showing that Lemma 8 follows from Claims 9 and 10.

CLAIM 17. *With high probability over the choice of X , for every good W such that $|W| = s \geq n^\beta \log n$, we have that $e_X(W) \leq \frac{2ks^2}{n^\beta}$.*

Proof. Consider a fixed choice of a good W such that $|W| = s = n^\beta \log n$. By definition, $|\Delta(W)| \leq |W|^2 = s^2$. Since W is good, for every $x \in \Delta(W)$, if $x \in X$, then the number of edges labeled by x in the subgraph of CG_X induced by W is at most k . Since each $x \in \Delta(W)$ is chosen to be in X independently with probability $n^{-\beta}$, the expected size of $\Delta(W) \cap X$ is $|\Delta(W)| \cdot n^{-\beta} \leq s^2 \cdot n^{-\beta}$. By a multiplicative

Chernoff bound, the probability that $|\Delta(W)| \cap X > 2 \cdot s^2 \cdot n^{-\beta}$ is upper bounded by $\exp(-s^2 \cdot n^{-\beta})$. The claim follows by taking a union bound over all choices of W of size s . $\square$

CLAIM 18. *Let $C \subset H$ satisfy $|C| = n^\alpha$. Suppose we uniformly and independently select $W \subset C$, $|W| = n^\beta \log n$. Then the probability that W is not good is at most $\frac{1}{n^\beta}$.*

Proof. Consider any fixed difference $x \in \Delta(C)$, where there are at most $|C|^2$ such differences. Recall that there are at most $|C|$ edges in the subgraph of CG_H induced by C that correspond to x . We denote this set of edges by $E_x(C)$. Since $E_x(H)$ is a union of disjoint cycles, $E_x(C)$ is a union of disjoint cycles and paths. Therefore, every choice of $k+1$ edges in $E_x(C)$ is a union of r_1 (sub)paths and r_2 cycles where $1 \leq r_1 \leq k+1$ and $r_2 \leq (k+1-r_1)/3$ (the second inequality follows from the fact that the length of a cycle is at least 3). Note that when $r_1 = k+1$, then the $k+1$ edges constitute a matching, as was the case in the proof of Claim 10. In this case the number of vertices incident to them is $2(k+1)$.

More generally, the number of incident vertices is $k+1+r_1$. For each pair (r_1, r_2) , the number of choices of $k+1$ edges that constitute r_1 paths and r_2 cycles is at most $|C|^{r_1}(k+1)^{r_1} \cdot |C|^{r_2}$. Namely, to determine each of the r_1 paths, we select a starting vertex (out of $|C|$ vertices) and a length (between 1 and $k+1$). To determine each of the r_2 cycles, we select a vertex (that belongs to the cycle). Once the edges are selected, the number of choices of the remaining $|W| - (k+1+r_1)$ vertices in W is $\binom{|C|-(k+1+r_1)}{|W|-(k+1+r_1)}$. Therefore, for each fixed choice of r_1 and r_2 , the probability that W spans $k+1$ edges in $E_x(C)$ that constitute r_1 paths and r_2 cycles is at most

$$\begin{aligned}
 & \frac{|C|^{r_1}(k+1)^{r_1} |C|^{r_2} \binom{|C|-(k+1+r_1)}{|W|-(k+1+r_1)}}{\binom{|C|}{|W|}} \leq |C|^{r_1}(k+1)^{r_1} |C|^{r_2} \cdot \left(\frac{|W|}{|C|} \right)^{k+1+r_1} \\
 & = (k+1)^{r_1} \cdot \frac{|W|^{k+1+r_1}}{|C|^{k+1+r_2}} \\
 (45) \quad & < (k+1)^{r_1} \frac{|W|^{k+1+r_1}}{|C|^{(2/3)(k+1)+(1/3)r_1}}.
 \end{aligned}$$

The expression in (45) is maximized when the ratio between $|W|$ and $|C|$ is maximized (i.e., β is maximized with respect to α) and r_1 is maximized (i.e., $r_1 = k+1$). In this case we get an upper bound of $(k+1)^{k+1}(\log n)^{2(k+1)}n^{(2\beta-\alpha)(k+1)}$. Substituting $k = \frac{5}{\alpha-2\beta}$, where $k \leq 5 \log \log n$, summing over all r_1, r_2 , and taking a union bound over the at most $|C|^2 = n^{2\alpha} \leq n^2$ choices of $x \in \Delta(C)$, the claim follows. $\square$

It is worth noting that the technique here can be applied with other parameters as well. In particular, it can be shown, for example, that with high probability, in random Cayley graphs over groups of size n in which the number of generators is $(1+o(1))\frac{n}{2}$, every set X of at least some $\text{poly} \log(n)$ vertices spans $(1+o(1))\frac{1}{2}\binom{|X|}{2}$ edges. This is related to the results in [3] and [11].

Appendix. Proof of Claim 4. Recall that this claim is part of the proof of Lemma 3. Specifically, it is part of the probabilistic analysis of the number of disjoint triangles obtained when drawing a graph according to the distribution D_Δ , which is defined as follows. A graph is generated by first partitioning the vertices into equal-size subsets of size $n' = n/3$, denoted V_1, V_2, V_3 , where the vertices in each V_ℓ , $\ell \in \{1, 2, 3\}$ are denoted $\{v_{\ell,1}, \dots, v_{\ell,n'}\}$. Next, between each pair of subsets, $d' = d/2 = \sqrt{n}/3$

random perfect matchings are selected. Recall that $\eta_{i,j,k}$ is a 0/1 random variable that equals 1 if and only if the graph contains the triangle $(v_{1,i}, v_{2,j}, v_{3,k})$ and there is no other triangle that shares an edge with this triangle. The claim is that, for $i' \neq i, j' \neq j, k' \neq k$,

$$(46) \quad \Pr[\eta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1] = \left(1 + O\left(\frac{1}{d'}\right)\right) \cdot \Pr[\eta_{i',j',k'} = 1].$$

To prove the claim we break both $\Pr[\eta_{i',j',k'} = 1]$ and $\Pr[\eta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1]$ into a product of (conditional) probabilities and bound the ratio between each corresponding pair of probabilities. Recall that $\alpha_{i,j}^{\ell,\ell'}$ is a 0/1 random variable that indicates the existence of the edge $(v_{\ell,i}, v_{\ell',j})$, $\Delta_{i,j,k}$ is a 0/1 random variable that indicates the existence of the triangle $(v_{1,i}, v_{2,j}, v_{3,k})$, and $\beta_{i,j,k}$ is a 0/1 random variable that indicates whether there is a triangle different from $(v_{1,i}, v_{2,j}, v_{3,k})$ that contains one of the three edges $(v_{1,i}, v_{2,j})$, $(v_{1,i}, v_{3,k})$, $(v_{2,j}, v_{3,k})$. By definition,

$$(47) \quad \Pr[\eta_{i',j',k'} = 1] = \Pr[\Delta_{i',j',k'} = 1] \cdot \Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1]$$

and

$$(48) \quad \Pr[\eta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1] = \Pr[\Delta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1] \cdot \Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \eta_{i,j,k} = 1].$$

We first bound the ratio between $\Pr[\Delta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1]$ and $\Pr[\Delta_{i',j',k'} = 1]$, and then between $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \eta_{i,j,k} = 1]$ and $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1]$.

Before doing so we make a few observations (some of which were already used in the proof of Lemma 3). For illustrations of these observations, see Figure 3. Consider an event of the form $\alpha_{r,s}^{\ell,\ell'} = 1$. We know that $\Pr[\alpha_{r,s}^{\ell,\ell'} = 1] = 1 - \left(1 - \frac{1}{n'}\right)^{d'}$. How is the probability of this event influenced by the existence or nonexistence of other edges? Consider first conditioning on the event that $\alpha_{r',s'}^{\ell,\ell'} = 1$ for $r' \neq r$ and $s' \neq s$. This means that for at least one of the d' matchings between V_ℓ and $V_{\ell'}$, the vertex s' cannot be matched to r (and similarly, r' cannot be matched to s). In other words, in each of these matchings where the vertex s' cannot be matched to r , the probability that r is matched to s is $\frac{1}{n'-1}$ rather than $\frac{1}{n'}$. Therefore, for $r' \neq r, s' \neq s$,

$$(49) \quad \begin{aligned} \Pr\left[\alpha_{r,s}^{\ell,\ell'} = 1 \mid \alpha_{r',s'}^{\ell,\ell'} = 1\right] &\leq 1 - \left(1 - \frac{1}{n'-1}\right)^{d'} \\ &\leq \frac{d'}{n'-1} = \frac{d'}{n'} \cdot \frac{n'}{n'-1}. \end{aligned}$$

That is, the probability that $\alpha_{r,s}^{\ell,\ell'} = 1$ slightly increases when conditioning on $\alpha_{r',s'}^{\ell,\ell'} = 1$. Next, consider conditioning on there *not* being an edge between r' and s for $r' \neq r$, that is, $\alpha_{r',s}^{\ell,\ell'} = 0$. We claim that the probability that $\alpha_{r,s}^{\ell,\ell'} = 1$ increases as well in this case. This is true because $\alpha_{r',s}^{\ell,\ell'} = 0$ means that in each of the d' matchings, r' is matched to some vertex $s' \neq s$, so that the conditional probability that r is matched to s in every matching is $\frac{1}{n'-1}$. Therefore, for $r' \neq r$,

FIG. 3. An illustration of how the existence and nonexistence of edges influences the probability of obtaining another edge. On the top is an illustration of the case in which there is an edge between $v_{\ell,r}$ and $v_{\ell',s}$, and the event we are interested in is the existence of an edge between $v_{\ell,r'}$ and $v_{\ell',s'}$, where $r' \neq r$ and $s' \neq s$. In this illustration the label of the edge between $v_{\ell,r}$ and $v_{\ell',s}$ (the number of the matching among the d' matchings) is c , which implies that, in this matching, $v_{\ell,r}$ cannot be matched to $v_{\ell',s'}$, which increases the probability that $v_{\ell,r'}$ is matched to $v_{\ell',s'}$ in this matching. On the bottom is an illustration of the case that there is no edge between $v_{\ell,r}$ and $v_{\ell',s'}$. This means that in all d' matchings, $v_{\ell,r}$ is matched to other vertices in $V_{\ell'}$, which increases the probability, in every matching, that $v_{\ell,r'}$ is matched to $v_{\ell',s'}$.

$$\begin{aligned}
 \Pr \left[\alpha_{r,s}^{\ell,\ell'} = 1 \mid \alpha_{r',s}^{\ell,\ell'} = 0 \right] &= 1 - \left(1 - \frac{1}{n' - 1} \right)^{d'} \\
 (50) \qquad \qquad \qquad &\leq \frac{d'}{n' - 1} = \frac{d'}{n'} \cdot \frac{n'}{n' - 1}.
 \end{aligned}$$

Finally, we observe that for any $s' \neq s$

$$(51) \qquad \Pr \left[\alpha_{r,s}^{\ell,\ell'} = 1 \mid \alpha_{r',s}^{\ell,\ell'} = 0 \ \& \ \alpha_{r',s'}^{\ell,\ell'} = 1 \right] = \Pr \left[\alpha_{r,s}^{\ell,\ell'} = 1 \mid \alpha_{r',s}^{\ell,\ell'} = 0 \right].$$

This is true since the event $\alpha_{r',s}^{\ell,\ell'} = 0$ implies that $\alpha_{r',s'}^{\ell,\ell'} = 1$ for some $s' \neq s$, and the identity of s' is irrelevant when computing the probability that $\alpha_{r,s}^{\ell,\ell'} = 1$.

Given the above discussion, how does the conditioning on $\eta_{i,j,k} = 1$ (i.e., $\Delta_{i,j,k} = 1$ and $\beta_{i,j,k} = 0$) influence the probability of the event $\Delta_{i',j',k'} = 1$? Consider the event $\alpha_{i',j'}^{1,2} = 1$ (the other two events, $\alpha_{i',k'}^{1,3}$ and $\alpha_{j',k'}^{2,3}$, are analyzed similarly). Since $\Delta_{i,j,k} = 1$, we have that $\alpha_{i,j}^{1,2} = 1$. Since $\beta_{i,j,k} = 0$ we know that for every $j'' \neq j$ either $\alpha_{i,j''}^{1,2} = 0$ or $\alpha_{j'',k}^{2,3} = 0$. In particular, setting $j'' = j'$, we have that either $\alpha_{i,j'}^{1,2} = 0$ or $\alpha_{j',k}^{2,3} = 0$. Recall that we have argued above that conditioning on $\alpha_{i,j'}^{1,2} = 0$ can only increase the probability that $\alpha_{i',j'}^{1,2} = 1$ (assuming $i' \neq i$). Therefore,

$$(52) \qquad \Pr \left[\alpha_{i',j'}^{1,2} = 1 \mid \eta_{i,j,k} = 1 \right] \leq \Pr \left[\alpha_{i',j'}^{1,2} = 1 \mid \alpha_{i,j}^{1,2} = 1 \ \& \ \alpha_{i,j'}^{1,2} = 0 \right]$$

$$(53) \qquad \qquad \qquad \leq \Pr \left[\alpha_{i',j'}^{1,2} = 1 \mid \alpha_{i,j'}^{1,2} = 0 \right]$$

$$(54) \quad \leq \frac{d'}{n'} \cdot \frac{n'}{n' - 1}$$

$$(55) \quad \leq \frac{d'}{n'} \cdot \left(1 + \frac{2}{n'}\right).$$

In (53) we applied (51), in (54) we applied (50), and in (55) we used the assumption that $n' \geq 2$. The same upper bound holds for $\alpha_{j,k}^{2,3}$ and $\alpha_{i,k}^{1,3}$. Using the lower bound on $\Pr[\Delta_{i',j',k'} = 1]$ given in (6), we get

$$(56) \quad \frac{\Pr[\Delta_{i',j',k'} = 1 \mid \eta_{i,j,k} = 1]}{\Pr[\Delta_{i',j',k'} = 1]} \leq \frac{\left(1 + \frac{2}{n'}\right)^3}{\left(1 - \frac{1}{18d'}\right)^3} \leq 1 + O\left(\frac{1}{d'}\right).$$

It remains to upper bound the ratio between $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \eta_{i,j,k} = 1]$ and $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1]$. We start by observing that since the constraints imposed by the conditioning on $\beta_{i,j,k} = 0$ can only increase the probability of *having* a triangle that shares an edge with $(v_{1,i'}, v_{2,j'}, v_{3,k'})$,

$$(57) \quad \begin{aligned} & \Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \eta_{i,j,k} = 1] \\ & \leq \Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \Delta_{i,j,k} = 1]. \end{aligned}$$

Next, in order to upper bound the ratio between $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \Delta_{i,j,k} = 1]$ and $\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1]$, we lower bound the ratio between $\Pr[\beta_{i',j',k'} = 1 \mid \Delta_{i',j',k'} = 1 \ \& \ \Delta_{i,j,k} = 1]$ and $\Pr[\beta_{i',j',k'} = 1 \mid \Delta_{i',j',k'} = 1]$. This suffices since $\Pr[\beta_{i',j',k'} = 1 \mid \Delta_{i',j',k'} = 1] < 1/2$, and for every $y \leq 1/2$, if we have that $x \geq (1 - \alpha)y$ for some $\alpha < 1$, then $(1 - x) \geq (1 + \alpha)(1 - y)$.

The event $\beta_{i',j',k'} = 1$ is a union of events of the form $\Delta_{i',j',k''} = 1$ for $k'' \neq k'$ (the other two types of events, $\Delta_{i',j'',k'} = 1$ and $\Delta_{i'',j',k'} = 1$, are analyzed analogously). The key observation is that for every $k'' \notin \{k', k\}$, the conditioning on the event $\Delta_{i,j,k} = 1$ (in addition to the conditioning on the event $\Delta_{i',j',k'} = 1$) can only increase the probability that $\Delta_{i',j',k''} = 1$ (since for at least one of the matchings i' cannot be matched to k). Therefore, the only case in which the conditioning on $\Delta_{i,j,k} = 1$ decreases the probability that $\Delta_{i',j',k''} = 1$ is for $k'' = k$. However, the weight of the event $\Delta_{i',j',k} = 1$ (and, similarly, $\Delta_{i,j',k'} = 1$ and $\Delta_{i',j,k'}$) relative to $\beta_{i',j',k'} = 1$ is $O(1/n')$, and so

$$(58) \quad \begin{aligned} & \Pr[\beta_{i',j',k'} = 1 \mid \Delta_{i',j',k'} = 1 \ \& \ \Delta_{i,j,k} = 1] \\ & \geq \left(1 - O\left(\frac{1}{n'}\right)\right) \cdot \Pr[\beta_{i',j',k'} = 1 \mid \Delta_{i',j',k'} = 1], \end{aligned}$$

from which it follows that

$$(59) \quad \frac{\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1 \ \& \ \Delta_{i,j,k} = 1]}{\Pr[\beta_{i',j',k'} = 0 \mid \Delta_{i',j',k'} = 1]} \leq 1 + O\left(\frac{1}{n'}\right).$$

The claim follows by combining (47), (48), (56), (57), and (59).

Acknowledgments. The authors wish to thank Angelika Steger for bringing theses [12] and [16] to their attention. The authors would also like to thank the anonymous reviewer of this paper for helpful comments.

A NOTE ON REED'S CONJECTURE*

LANDON RABERN†

Abstract. In [*J. Graph Theory*, 27 (1998), pp. 177–212], Reed conjectures that every graph satisfies $\chi \leq \lceil \frac{\omega + \Delta + 1}{2} \rceil$. We prove that this holds for graphs with disconnected complement. Combining this fact with a result of Molloy proves the conjecture for graphs satisfying $\chi > \lceil \frac{n}{2} \rceil$. Generalizing this we prove that the conjecture holds for graphs satisfying $\chi > \frac{n+3-\alpha}{2}$. It follows that the conjecture holds for graphs satisfying $\Delta \geq n + 2 - (\alpha + \sqrt{n+5-\alpha})$. In the final section, we show that if G is an even order counterexample to Reed's conjecture, then $\bar{G}$ has a 1-factor.

Key words. graph coloring, Reed's conjecture, chromatic number

AMS subject classification. 05C15

DOI. 10.1137/060659193

1. Introduction. Reed's conjecture states that every graph satisfies

$$(1) \quad \chi \leq \left\lceil \frac{\omega + \Delta + 1}{2} \right\rceil.$$

The weaker statement that every graph satisfies

$$(2) \quad \chi \leq \frac{\omega + n}{2}$$

follows easily by observing that in any optimal coloring the set of vertices in singleton color classes induces a clique.

We prove the following intermediate result.

KEY LEMMA. $\chi \leq \frac{\omega + \frac{n+\Delta+1}{2}}{2}$.

Using this result it is easy to prove Reed's conjecture for graphs with disconnected complement. Combining this fact with a result of Molloy tells us that Reed's conjecture holds for graphs satisfying $\chi > \lceil \frac{n}{2} \rceil$. Building on this result, we show that the conjecture holds for graphs satisfying $\chi > \frac{n+3-\alpha}{2}$. With a bit more work we determine that the conjecture holds for graphs satisfying $\Delta \geq n + 2 - (\alpha + \sqrt{n+5-\alpha})$.

Further analysis allows us to prove some related results.

In all that follows, *graph* will mean a finite simple graph with nonempty vertex set. Let $\mathbb{G}$ be the collection of all graphs. Let $R_t \subseteq \mathbb{G}$ be the graphs satisfying $\chi \leq \frac{1}{2}(\omega + \Delta + 1) + t$.

DEFINITION 1. Given graphs A and B , their join $A + B$ is the graph with vertex set $V(A) \cup V(B)$ and edge set $E(A) \cup E(B) \cup \{ab \mid a \in V(A), b \in V(B)\}$. Also, if X and Y are collections of graphs, we let $X + Y = \{A + B \mid A \in X, B \in Y\}$.

First, we present a few basic facts about joins.

LEMMA 1.1. Let A and B be graphs. Then

- (a) $|A + B| = |A| + |B|$,
- (b) $\omega(A + B) = \omega(A) + \omega(B)$,
- (c) $\chi(A + B) = \chi(A) + \chi(B)$,
- (d) $\Delta(A + B) = \max\{\Delta(A) + |B|, |A| + \Delta(B)\}$.

Proof. These all follow immediately from the definitions. $\square$

2. Reed's conjecture for joins of graphs.

PROPOSITION 2.1. *Let A and B be graphs. Then $A + B \in R_0$.*

Proof. Applying the Key Lemma to A and B and adding the inequalities yields

$$\chi(A) + \chi(B) \leq \frac{1}{2} \left(\omega(A) + \omega(B) + \frac{\Delta(A) + |B| + |A| + \Delta(B) + 2}{2} \right).$$

Using Lemma 1.1(b), (c), and (d), this becomes

$$\chi(A + B) \leq \frac{1}{2} \left(\omega(A + B) + \frac{2\Delta(A + B) + 2}{2} \right) = \frac{1}{2} (\omega(A + B) + \Delta(A + B) + 1).$$

Hence $A + B \in R_0$. $\square$

LEMMA 2.2. $\mathbb{G} + R_t \subseteq R_t$ for all $t \in \mathbb{R}$.

Proof. Fix $t \in \mathbb{R}$. Let $G \in \mathbb{G}$ and $H \in R_t$. Applying (2) to G gives

$$\chi(G) \leq \frac{1}{2} (\omega(G) + |G|).$$

Also, since $H \in R_t$,

$$\chi(H) \leq \frac{1}{2} (\omega(H) + \Delta(H) + 1) + t.$$

Adding these inequalities and applying Lemma 2(b) and (c) gives

$$\chi(G + H) \leq \frac{1}{2} (\omega(G + H) + |G| + \Delta(H) + 1) + t.$$

Now Lemma 1.1(d) gives $|G| + \Delta(H) \leq \Delta(G + H)$ and the result follows. $\square$

Remark. We will use Lemma 2.2 in our proof of the Key Lemma; we note that we did not use the Key Lemma in its proof. It should also be noted that Lemma 2.2 just says that R_t is an ideal in the Abelian semigroup $(\mathbb{G}, +)$.

3. Proof of the Key Lemma. Combining Lemma 2.2 with the following two results of Molloy (see [2]) allows us to prove Reed's conjecture for graphs satisfying $\alpha = 2$. We note that these lemmas were proved by Gallai decades before Molloy rediscovered them (see [1]).

LEMMA 3.1. *Let G be a graph with $\chi(G) > \lceil \frac{|G|}{2} \rceil$. Then there exists $X \subseteq V(G)$ such that $\overline{G - X}$ is disconnected and $\chi(G - X) = \chi(G)$.*

As a corollary we get the following.

LEMMA 3.2. *If G is a vertex critical graph with $\chi(G) > \lceil \frac{|G|}{2} \rceil$, then $\overline{G}$ is disconnected.*

PROPOSITION 3.3. *If G is a graph with $\alpha(G) \leq 2$, then $G \in R_{\frac{1}{2}}$.*

Proof. Assume this is not the case and let G be a counterexample with the minimum number of vertices, say $|G| = n$. Since $\alpha(G) \leq 2$, we see that $V(G) \setminus N(v) \cup \{v\}$ induces a clique for each $v \in V(G)$. Hence $\omega(G) \geq n - \delta(G) - 1$ which gives

$$\Delta(G) + \omega(G) + 1 \geq n.$$

So, since $G \notin R_{\frac{1}{2}}$, we have $\chi(G) > \lceil \frac{n}{2} \rceil$.

Now, using minimality of G , we see that G is vertex critical. Thus $\overline{G}$ is disconnected by Lemma 3.2. Hence we have $m \geq 2$ and (nonempty) graphs $C_1, \dots, C_m$ such

that $G = C_1 + \cdots + C_m$. But, for $1 \leq i \leq m$, minimality of G gives $C_i \in R_{\frac{1}{2}}$ since $\alpha(C_i) \leq \alpha(G) \leq 2$ and $|C_i| < n$. Hence $G = C_1 + \cdots + C_m \in R_{\frac{1}{2}}$ by Lemma 2.2. This contradiction completes the proof. $\square$

To prove our Key Lemma, we will also need the following result from [3].

THEOREM 3.4. *Let $I_1, \dots, I_m$ be disjoint independent sets in a graph G . Then*

$$(3) \quad \chi(G) \leq \frac{1}{2} \left(\omega(G) + |G| - \sum_{j=1}^m |I_j| + 2m - 1 \right).$$

Remark. If we increase the bound in this theorem by $\frac{1}{2}$ we get a corollary of (2).

To apply Theorem 3.4 and Proposition 3.3 we need a definition.

DEFINITION 2. *Let G be a graph and r a positive integer. A collection of disjoint independent sets in G , each with at least r vertices, will be called an r -greedy partial coloring of G . A vertex of G is said to be missed by a partial coloring just in case it appears in none of the independent sets.*

We use the following consequence of Theorem 3.4.

COROLLARY 3.5. *Let G be a graph which is not complete and let C be an r -greedy partial coloring of G . Then*

$$\chi(G) \leq \frac{1}{2}(\omega(G) + |G| - (r-2)|C| - 1).$$

Combining Corollary 3.5 for $r = 3$ with the following lemma yields the Key Lemma.

LEMMA 3.6. *Let G be a graph, and of all 3-greedy partial colorings of G , let C be one that misses the minimum number of vertices. Then*

$$\chi(G) \leq \frac{1}{2}(\omega(G) + \Delta(G) + 1) + \frac{|C|+1}{2}.$$

Proof. The first case to consider is when C misses zero vertices. In this case, C is a proper coloring of G , and hence $\chi(G) \leq |C|$. Thus

$$\chi(G) \leq \frac{1}{2}(\chi(G) + |C|) \leq \frac{1}{2}(\Delta(G) + 1 + |C|) \leq \frac{1}{2}(\omega(G) + \Delta(G) + 1) + \frac{|C|+1}{2}.$$

Otherwise, C misses at least one vertex, and by the minimality condition placed on C , each vertex missed by C must be adjacent to at least one vertex in each element of C . Hence $\Delta(G - \cup C) \leq \Delta(G) - |C|$. In addition, $\alpha(G - \cup C) \leq 2$. Thus applying Proposition 3.3 to $G - \cup C$ yields

$$\begin{aligned} \chi(G) &\leq |C| + \chi(G - \cup C) \\ &\leq |C| + \frac{1}{2}(\omega(G - \cup C) + \Delta(G - \cup C) + 1) + \frac{1}{2} \\ &\leq |C| + \frac{1}{2}(\omega(G) + \Delta(G) - |C| + 1) + \frac{1}{2} \\ &= \frac{1}{2}(\omega(G) + \Delta(G) + 1) + \frac{|C|+1}{2}. \quad \square \end{aligned}$$

4. Further details. Proposition 2.1 allows us to prove Reed's conjecture for graphs satisfying $\chi > \lceil \frac{n}{2} \rceil$.

COROLLARY 4.1. *If G is a graph with $\chi(G) > \lceil \frac{|G|}{2} \rceil$, then $G \in R_0$.*

Proof. Let G be a graph with $\chi(G) > \lceil \frac{|G|}{2} \rceil$. Then, by Lemma 3.1, we have $X \subseteq V(G)$ such that $\overline{G-X}$ is disconnected and $\chi(G-X) = \chi(G)$. Since $\overline{G-X}$

is disconnected, there exist graphs A and B such that $G - X = A + B$. Hence, by Proposition 2.1,

$$\chi(G) = \chi(G - X) \leq \frac{1}{2}(\omega(G - X) + \Delta(G - X) + 1) \leq \frac{1}{2}(\omega(G) + \Delta(G) + 1),$$

whence $G \in R_0$. $\square$

We can generalize the above corollary by passing from R_0 to $R_{\frac{1}{2}}$.

COROLLARY 4.2. *If G is a graph with $\chi(G) > \frac{|G|+3-\alpha(G)}{2}$, then $G \in R_{\frac{1}{2}}$.*

Proof. Let G be a graph with $\chi(G) > \frac{|G|+3-\alpha(G)}{2}$ and I an independent set in G with $\alpha(G)$ vertices. Put $H = G \setminus I$. Then

$$\begin{aligned} \chi(H) &\geq \chi(G) - 1 \\ &> \frac{|G| + 3 - \alpha(G)}{2} - 1 \\ &= \frac{|G| + 1 - \alpha(G)}{2} \\ &= \frac{|H| + 1}{2}. \end{aligned}$$

Hence, by Corollary 4.1, we have

$$\chi(H) \leq \frac{\omega(H) + \Delta(H) + 1}{2}.$$

But I is a maximal independent set, and hence each vertex of H is adjacent to at least one vertex in I . In particular, $\Delta(H) \leq \Delta(G) - 1$, whence

$$\chi(G) \leq \chi(H) + 1 \leq \frac{\omega(H) + \Delta(G) - 1 + 1}{2} + 1 \leq \frac{\omega(G) + \Delta(G) + 1}{2} + \frac{1}{2}.$$

The theorem follows. $\square$

Remark. After noting that the conditions on the graph order in both Corollaries 4.1 and 4.2 are sufficient to force the existence of a doubly critical edge in a minimum counterexample to Reed's conjecture, it is natural to ask if similar results can be proved under the weaker condition that the graph contains a doubly critical edge. This is indeed the case, as is shown in [4] and [5]. The former paper generalizes the method of proof using singleton color classes that was sketched in the introduction as justification of (2). It is proved that a graph with more than $\frac{n}{2}$ singleton color classes satisfies Reed's conjecture. The latter paper proves Reed's conjecture for claw-free graphs containing a doubly critical edge and shows that general graphs containing a doubly critical edge satisfy $\chi \leq \frac{1}{3}\omega + \frac{2}{3}(\Delta + 1)$.

COROLLARY 4.3. *Let G be a graph and $t \geq \frac{1}{2}$. If $G \notin R_t$, then $\Delta(G) + 1 \leq |G| - 2t - \omega(G) - \alpha(G) + 2$.*

Proof. This is an immediate consequence of the previous corollary. $\square$

LEMMA 4.4. *Let G be a graph with $\alpha(G) \leq 2$. Then $\omega(G)^2 + \omega(G) \geq |G|$.*

Proof. Let K be a maximal clique in G . Then each vertex of $G - K$ is nonadjacent to at least one vertex in K , and hence some vertex $v \in K$ is nonadjacent to at least $\frac{|G-K|}{|K|}$ vertices. Since $\alpha(G) \leq 2$, the vertices nonadjacent to v form a clique, whence $\omega(G) \geq \frac{|G-K|}{|K|} = \frac{|G|-\omega(G)}{\omega(G)}$, which yields

$$\omega(G)^2 + \omega(G) \geq |G|. \quad \square$$

PROPOSITION 4.5. *If G is a graph with $\Delta(G) \geq |G| + 2 - (\alpha(G) + \sqrt{|G| + 5 - \alpha(G)})$, then $G \in R_{\frac{1}{2}}$.*

Proof. We prove the contrapositive. Let G be a graph with n vertices, maximal degree Δ , clique number ω , and independence number α such that $G \notin R_{\frac{1}{2}}$. Let I be a maximal independent set in G . Let S be a maximal collection of disjoint 3-vertex independent sets of $G - I$. Since $\alpha(G - (\cup S) \cup I) \leq 2$, we may apply Lemma 4.4 to get $\omega^2 + \omega \geq |G - (\cup S) \cup I| = n - \alpha - 3|S|$. Hence

$$(4) \quad |S| \geq \frac{n - \alpha - (\omega^2 + \omega)}{3}.$$

Now, combining the fact that $G \notin R_{\frac{1}{2}}$ with Corollary 3.5, we have $n - \alpha - |S| + 1 > \Delta + 2$. Putting this together with (4), we have

$$n - \alpha - \Delta - 1 > |S| \geq \frac{n - \alpha - (\omega^2 + \omega)}{3},$$

which implies that

$$(5) \quad \Delta < \frac{2n + \omega^2 + \omega - 2\alpha - 3}{3}.$$

By Corollary 4.3, $\omega \leq n - \Delta - \alpha$. Plugging this into (5) and doing a little algebra, we find that $\Delta < n - \alpha + 2 - \sqrt{n - \alpha + 5}$. This completes the proof of the contrapositive. $\square$

COROLLARY 4.6. *If G is a graph with $\Delta(G) \geq |G| - (1 + \sqrt{|G| + 2})$, then $G \in R_{\frac{1}{2}}$.*

Proof. Let G be a graph with $\Delta(G) \geq |G| - (1 + \sqrt{|G| + 2})$. If $\alpha(G) \leq 2$, then $G \in R_{\frac{1}{2}}$ by Proposition 3.3. Otherwise, $\alpha(G) \geq 3$ and $G \in R_{\frac{1}{2}}$ by Proposition 4.5. $\square$

5. Graphs without perfect matchings in their complements. The bound on Δ in Corollary 4.3 works only for $t \geq \frac{1}{2}$. In this section we need bounds on Δ that work for $t = 0$ as well. Using a single independent set of maximal order in Theorem 3.4, we deduce the following.

COROLLARY 5.1. *Let G be a graph. Then*

$$\chi(G) \leq \frac{1}{2}(\omega(G) + |G| - \alpha(G) + 1).$$

COROLLARY 5.2. *Let G be a graph and $t \in \frac{1}{2}\mathbb{Z}$. If $G \notin R_t$, then $\Delta(G) + 1 \leq |G| - 2t - \alpha(G)$.*

Proof. Assume $G \notin R_t$. Applying Corollary 5.1 gives

$$\frac{1}{2}(\omega(G) + \Delta(G) + 1) + t < \chi(G) \leq \frac{1}{2}(\omega(G) + |G| - \alpha(G) + 1).$$

The corollary follows. $\square$

COROLLARY 5.3. *Let G be a graph and $t \geq 0$. If $G \notin R_t$, then $\Delta(G) + 1 \leq |G| - 2t - \omega(G)$.*

Proof. This is an immediate consequence of Corollary 4.1. $\square$

Note that for $t \geq \frac{1}{2}$ in Corollary 5.2, we must have $\alpha(G) \geq 3$ by Proposition 3.3, so the lemma gives $\Delta(G) + 1 \leq |G| - 2t - 3$.

LEMMA 5.4. *If $k \geq 2$ and $G_1, \dots, G_k$ are graphs with $\Delta(G_i) + 1 \leq |G_i| - 3$ for each i , then*

$$G_1 + \dots + G_k \in R_{2-k}.$$

Proof. Assume this is not the case and let $G_1, \dots, G_k$ constitute a counterexample with the smallest k . Then, by Proposition 2.1, $k > 2$. Set $D = G_1 + \dots + G_{k-1}$. Note that $D \in R_{2-(k-1)} = R_{3-k}$ by the minimality of k . Let $t \in \frac{1}{2}\mathbb{Z}$ be minimal such that $G_k \in R_t$. Since $G_k \notin R_{t-\frac{1}{2}}$, using Corollary 5.2 for $t \geq 1$ and the fact that $\Delta(G_k) + 1 \leq |G_k| - 3$ for $t \leq \frac{1}{2}$, we find that $\Delta(G_k) + 1 \leq |G_k| - 2t - 2$. We have

$$\begin{aligned} \chi(D + G_k) &= \chi(D) + \chi(G_k) \\ &\leq \frac{1}{2}(\omega(D) + \omega(G_k) + \Delta(D) + \Delta(G_k) + 2) + 3 - k + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + \Delta(G_k) + 2) + 3 - k + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + |G_k| + 1 + \Delta(G_k) - |G_k| + 1) + 3 - k + t \\ &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(\Delta(G_k) - |G_k| + 1) + 3 - k + t \\ &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(-2t - 3 + 1) + 3 - k + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + 2 - k. \end{aligned}$$

Hence $G_1 + \dots + G_k \in R_{2-k}$, contradicting our assumption. $\square$

The hypotheses of this lemma can be weakened, but we do not use the following stronger lemma in what follows.

LEMMA 5.5. *If $k \geq 2$ and $G_1, \dots, G_k$ are graphs, which are not 5-cycles, with $\Delta(G_i) + 1 \leq |G_i| - 2$ for each i , then*

$$G_1 + \dots + G_k \in R_{2-k}.$$

Proof. This is similar to the proof of Lemma 5.4. Graphs with $\Delta(G_i) + 1 \leq |G_i| - 3$ matter only if $G_i \in R_{\frac{1}{2}} \setminus R_0$. Corollary 5.3 shows that such graphs have $\omega(G_i) \leq 2$ and Corollary 5.2 shows they have $\alpha(G) \leq 2$. Thus they have order less than 6 and we see that the only one that breaks the lemma is C_5 . $\square$

DEFINITION 3. *The matching number of a graph G , denoted $\nu(G)$, is the number of edges in a maximum matching of G .*

PROPOSITION 5.6. *Let G be a graph. If $\nu(\overline{G}) < \lfloor \frac{|G|}{2} \rfloor$, then $G \in R_0$.*

Proof. Assume $\nu(\overline{G}) < \lfloor \frac{|G|}{2} \rfloor$. Then, by Tutte's theorem, we have $X \subseteq V(G)$ such that $\overline{G} - X$ has at least m odd components, where $m \geq |X| + 2$ if $|G|$ is even and $m \geq |X| + 3$ if $|G|$ is odd. Hence we have graphs $G_1, \dots, G_m$ such that $G - X = G_1 + \dots + G_m$. Note that by picking one vertex from each component we induce a clique. Hence $\omega(G) \geq m$. To get a contradiction, assume $G \notin R_0$. First, assume there is some G_i for which $\Delta(G_i) + 1 \geq |G_i| - 2$; then

$$\begin{aligned} \Delta(G) + 1 &\geq \Delta(G - X) + 1 \geq |G_1| + \dots + |G_{i-1}| + \Delta(G_i) + |G_{i+1}| + \dots + |G_m| + 1 \\ &\geq |G| - |X| - 2. \end{aligned}$$

Since $G \notin R_0$,

$$\chi(G) > \frac{1}{2}(\omega(G) + \Delta(G) + 1) \geq \frac{1}{2}(m + (|G| - |X| - 2)) \geq \left\lceil \frac{|G|}{2} \right\rceil.$$

Hence $G \in R_0$ by Corollary 4.1! Thus we may assume $\Delta(G_i) + 1 \leq |G_i| - 3$ for each i . Now Lemma 5.4 yields $G - X \in R_{-|X|}$, whence $G \in R_0$. This contradiction completes the proof. $\square$

COROLLARY 5.7. *Let G be an even order graph. If $G \notin R_0$, then $\overline{G}$ has a 1-factor.*

DEFINITION 4. A graph is called *matching covered* if every edge participates in a perfect matching.

COROLLARY 5.8. Let G be an even order graph with $G \notin R_1$. Then $\overline{G}$ is matching covered.

Lemma 5.4 can be generalized.

LEMMA 5.9. Let $m \in \mathbb{N}$. Let $k \geq 2$ and $G_1, \dots, G_k$ be graphs such that $|G_i| < r(m, m) \Rightarrow G_i \in R_{\frac{1}{2}}$. If $\Delta(G_i) + 1 \leq |G_i| - m$ for each i , then

$$G_1 + \dots + G_k \in R_{(m-1)(1-\frac{k}{2})}.$$

Proof. Assume this is not the case and let $G_1, \dots, G_k$ constitute a counterexample with the smallest k . Then, by Proposition 2.1, $k > 2$. Set $D = G_1 + \dots + G_{k-1}$. Note that $D \in R_{(m-1)(1-\frac{k-1}{2})}$ by the minimality of k . Let $t \in \frac{1}{2}\mathbb{Z}$ be minimal such that $G_k \in R_t$. We would like to have $\Delta(G_k) + 1 \leq |G_k| - 2t - (m-1)$. If $t \leq \frac{1}{2}$, then we are all good since $\Delta(G_k) + 1 \leq |G_k| - m$. So, to get a contradiction, assume $t \geq 1$ and $\Delta(G_k) + 1 > |G_k| - 2t - (m-1)$. Then, by Corollary 5.3, $\omega(G_k) \leq (m-1)$. Also, by Corollary 5.2, $\alpha(G_k) \leq (m-1)$. Hence $|G_k| < r(m, m)$, contradicting the fact that $G_k \notin R_{\frac{1}{2}}$. Hence we do indeed have $\Delta(G_k) + 1 \leq |G_k| - 2t - (m-1)$.

We have

$$\begin{aligned} \chi(D + G_k) &= \chi(D) + \chi(G_k) \\ &\leq \frac{1}{2}(\omega(D) + \omega(G_k) + \Delta(D) + \Delta(G_k) + 2) + (m-1)(1 - \frac{k-1}{2}) + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + \Delta(G_k) + 2) + (m-1)(1 - \frac{k-1}{2}) + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + |G_k| + 1 + \Delta(G_k) - |G_k| + 1) \\ &\quad + (m-1)(1 - \frac{k-1}{2}) + t \\ &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(\Delta(G_k) - |G_k| + 1) \\ &\quad + (m-1)(1 - \frac{k-1}{2}) + t \\ &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(-2t - 4 + 1) \\ &\quad + (m-1)(1 - \frac{k-1}{2}) + t \\ &= \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + (m-1)(1 - \frac{k}{2}). \end{aligned}$$

Hence $G_1 + \dots + G_k \in R_{(m-1)(1-\frac{k}{2})}$, contradicting our assumption. $\square$

We can do a bit better than Lemma 5.9 in the following special case.

LEMMA 5.10. If $k \geq 2$ and $G_1, \dots, G_k$ are noncomplete graphs, then

$$G_1 + \dots + G_k \in R_{1-\frac{k}{2}}.$$

Proof. Assume this is not the case and let $G_1, \dots, G_k$ constitute a counterexample with the smallest k . Then, by Proposition 2.1, $k > 2$. Set $D = G_1 + \dots + G_{k-1}$. Note that $D \in R_{1-\frac{(k-1)}{2}}$ by the minimality of k . Let $t \in \frac{1}{2}\mathbb{Z}$ be minimal such that $G_k \in R_t$. Since $G_k \notin R_{t-\frac{1}{2}}$, if $t \geq \frac{1}{2}$, then, by Corollary 5.3, $\Delta(G_k) + 1 \leq |G_k| - 2t - 1$. If $t \leq 0$ and $\Delta(G_k) + 1 > |G_k| - 2t - 1$, then $t = 0$ and $\Delta(G_k) + 1 = |G_k|$; however, Corollary 5.1 shows that the only such graphs are complete graphs, which we have excluded,

whence $\Delta(G_k) + 1 \leq |G_k| - 2t - 1$. We have

$$\begin{aligned}
 \chi(D + G_k) &= \chi(D) + \chi(G_k) \\
 &\leq \frac{1}{2}(\omega(D) + \omega(G_k) + \Delta(D) + \Delta(G_k) + 2) + 1 - \frac{(k-1)}{2} + t \\
 &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + \Delta(G_k) + 2) + 1 - \frac{(k-1)}{2} + t \\
 &= \frac{1}{2}(\omega(D + G_k) + \Delta(D) + |G_k| + 1 + \Delta(G_k) - |G_k| + 1) + 1 - \frac{(k-1)}{2} + t \\
 &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(\Delta(G_k) - |G_k| + 1) + 1 - \frac{(k-1)}{2} + t \\
 &\leq \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + \frac{1}{2}(-2t - 2 + 1) + 1 - \frac{(k-1)}{2} + t \\
 &= \frac{1}{2}(\omega(D + G_k) + \Delta(D + G_k) + 1) + 1 - \frac{k}{2}.
 \end{aligned}$$

Hence $G_1 + \cdots + G_k \in R_{1-\frac{k}{2}}$, contradicting our assumption. $\square$

Combining Reed's conjecture with Lemma 5.9 proves the following conjecture.

CONJECTURE 5.11. *Let $m \in \mathbb{N}$. If $k \geq 2$ and $G_1, \dots, G_k$ are graphs with $\Delta(G_i) + 1 \leq |G_i| - m$ for each i , then*

$$G_1 + \cdots + G_k \in R_{(m-1)(1-\frac{k}{2})}.$$

Acknowledgments. The referee's comments helped to greatly improve this paper's layout and readability. Thanks to Michael Molloy for pointing out that Lemmas 3.1 and 3.2 had already been proven by Gallai long before he rediscovered them.

THE MINIMUM NUMBER OF DISTINCT AREAS OF TRIANGLES DETERMINED BY A SET OF n POINTS IN THE PLANE*

ROM PINCHASI†

Abstract. We prove a conjecture of Erdős, Purdy, and Straus on the number of distinct areas of triangles determined by a set of n points in the plane. We show that if P is a set of n points in the plane, not all on one line, then P determines at least $\lfloor \frac{n-1}{2} \rfloor$ triangles with pairwise distinct areas. Moreover, one can find such $\lfloor \frac{n-1}{2} \rfloor$ triangles all sharing a common edge.

Key words. triangles, distinct areas, Euler's formula

AMS subject classification. 52C10

DOI. 10.1137/07068299X

1. Introduction. Let P be a set of n points in the plane. We consider all the triangles whose vertices are any three noncollinear points of P . We regard these triangles as triangles determined by the set P . Denote by $g(P)$ the number of distinct areas of triangles determined by P . Clearly, $g(P)$ can be as large as $\binom{n}{3}$ if P is in a general enough position. We are interested in the minimum possible value of $g(P)$. Denote by $g(n)$ the minimum possible value of $g(P)$ over all noncollinear sets P of n points in the plane.

The function $g(n)$ was first investigated by Erdős and Purdy [EP77]. They showed that there exist positive absolute constants c_1, c_2 such that for every n we have

$$c_1 n^{3/4} \leq g(n) \leq c_2 n.$$

It is easy to observe an $\lfloor \frac{n-1}{2} \rfloor$ upper bound for $g(n)$ by taking P to be a set of equally spaced $\lfloor \frac{n}{2} \rfloor$ points on a line ℓ together with $\lceil \frac{n}{2} \rceil$ equally spaced points on a line ℓ' parallel to ℓ (see [BP79] and [S78]).

Erdős, Purdy, and Straus conjectured the following.

CONJECTURE 1.1. *For every n , $g(n) \geq \lfloor \frac{n-1}{2} \rfloor$.*

The problem of bounding the function $g(n)$ from below is listed, for instance, in the problem collection by Croft, Falconer, and Guy [CFG91] as well as in the problem collection by Brass, Moser, and Pach [BMP05].

A linear lower bound for $g(n)$ was obtained by Burton and Purdy in 1979 [BP79]. They showed $g(n) \geq 0.32n$ by relating this problem to another problem on the minimum number of distinct directions determined by a noncollinear point set of size n . A complete solution of the latter problem was found only a little later in 1982 by Ungar [U82]. Combining the result in [U82] with the technique of [BP79], one obtains the lower bound $g(n) \geq (\sqrt{2} - 1)n - \mathcal{O}(1)$.

Recently, Dumitrescu and Tóth [DT] improved the lower bound and showed $g(n) \geq \frac{17}{38}n - \mathcal{O}(1) \approx 0.4473n$.

In this paper we prove Conjecture 1.1.

THEOREM 1.2. *The number of distinct areas of triangles determined by a noncollinear point set of size n is at least $\lfloor \frac{n-1}{2} \rfloor$.*

†Israel Institute of Technology, Technion, Haifa, Israel (room@math.technion.ac.il).

We note that all the previously mentioned results, as well as the result in Theorem 1.2, are in fact a little stronger. The lower bounds refer even to triangles that have distinct areas but that all share a common edge.

2. The proof. We show the existence of a line γ determined by at least two points of the set P such that there are at least $\lfloor \frac{n-1}{2} \rfloor$ distinct positive distances of points of P from γ . This will clearly prove the theorem.

It will be more convenient for us to consider the dual problem in the plane. That is, we perform a standard duality transform which takes a point (a, b) to the line $y + ax + b = 0$ in the plane, and it takes a nonvertical line $y + a'x + b' = 0$ to the point (a', b') .

It is easy to observe that if a point p lies on a line L , then the dual of p is a line containing the point which is the dual of L . It is also easy to see that two points with the same x -coordinate in the dual plane represent the dual of two parallel lines in the primal plane. Finally, observe that if a line $y + a'x + b' = 0$ lies above a point (a, b) (that is, if $b + a'a + b' < 0$), then the point (a', b') , dual to the line, lies below the line $y + ax + b = 0$, which is the dual of (a, b) .

Therefore, we rotate the set P , if necessary, so that no two points of P have the same x -coordinate, and then the dual of P is a collection $\mathcal{M}$ of n lines, no two of which are parallel and not all passing through the same point (for otherwise the points of P are all collinear). Consider now an intersection point q of two or more lines in $\mathcal{M}$. q is the dual of a line γ containing two or more points of P . Draw a vertical line r through q and let $x_1, \dots, x_k$ be all the intersection points of r with lines in $\mathcal{M}$, which lie above q on r . For each $i = 1, \dots, k$ let ℓ_i be a line in $\mathcal{M}$ passing through x_i . Assume that for every $1 \leq i \leq k$, ℓ_i is the dual of the point $p_i \in P$. Then the points $p_1, \dots, p_k$ lie strictly below γ , because the lines $\ell_1, \dots, \ell_k$ lie strictly above q . Moreover, for every $1 \leq i < j \leq k$, the line through p_i and p_j cannot be parallel to γ , because ℓ_i and ℓ_j do not meet on r . It follows that the distances from $p_1, \dots, p_k$ to γ are distinct. A similar scenario holds if we consider the intersection points of r with lines in $\mathcal{M}$, which are all strictly below q on r .

Theorem 1.2 therefore follows from the following theorem.

THEOREM 2.1. *Let $\mathcal{A}$ be an arrangement of n blue nonvertical lines in the plane such that no two of the lines are parallel, and not all the lines pass through the same point. Draw vertical red lines such that each red line passes through an intersection point of (at least) two blue lines, and every intersection point of two (or more) blue lines lies on a red line. Then there is an intersection point p of at least two blue lines, and a red line ℓ through p such that either there are at least $\lfloor \frac{n-1}{2} \rfloor$ different intersection points of ℓ with blue lines such that all are above p on ℓ , or there are at least $\lfloor \frac{n-1}{2} \rfloor$ different intersection points of ℓ with blue lines, all which lie below p on ℓ .*

Proof. Let $\mathcal{L}$ denote the collection of red lines, and let $m = |\mathcal{L}|$.

For every line $\ell \in \mathcal{L}$ let $b(\ell)$ denote the intersection point of (at least) two blue lines on ℓ with the least y -coordinate. Similarly, let $t(\ell)$ denote the intersection point of (at least) two blue lines on ℓ with the largest y -coordinate (it is possible that $b(\ell) = t(\ell)$). Denote by $S(\ell)$ the set of all intersection points of ℓ with blue lines that are either strictly below $b(\ell)$ or strictly above $t(\ell)$. Denote by $Q(\ell)$ the set of all intersection points of ℓ with a single blue line that are strictly above $b(\ell)$ and strictly below $t(\ell)$. Finally, denote by $R(\ell)$ the set of all intersection points of (at least) two blue lines on ℓ .

Observe that there are at least $S(\ell)/2 + Q(\ell) + R(\ell) - 1$ intersection points on ℓ that are either all above $b(\ell)$ or all below $t(\ell)$.

Let $S = \cup_{\ell \in \mathcal{L}} S(\ell)$, $Q = \cup_{\ell \in \mathcal{L}} Q(\ell)$, and $R = \cup_{\ell \in \mathcal{L}} R(\ell)$.

Let p and q be two intersection points in $R(\ell)$ for some red line ℓ . We say that p and q are adjacent if there is no point $s \in R(\ell)$ on the open line segment between p and q (on ℓ). Since there are exactly m lines and each includes at least one point from R , we deduce that there are exactly $|R| - m$ pairs of adjacent intersection points from R . Let p and q be a pair of adjacent intersection points on a red line ℓ . We say that the pair (p, q) is *nice* if there is no blue line separating p from q . Consequently, if p and q are adjacent but (p, q) is not a nice pair, then there must be a point in Q on the open line segment of ℓ between p and q . Therefore, the number of nice pairs of adjacent intersection points is at least $|R| - m - |Q|$.

Consider now the arrangement $\mathcal{A}$ of the blue lines only. We denote, as usual, by f_k the number of faces in the arrangement with precisely k edges. It is important to note that we consider the arrangement $\mathcal{A}$ on the *projective* plane, and so we identify the two ends at infinity for each of the blue lines. For $k \geq 2$ denote by t_k the number of intersection points through which there are precisely k blue lines. Observe that since not all the blue lines pass through the same point, there is no face with two edges in $\mathcal{A}$. Recall (see for example [F04, p. 73]) that from Euler's formula it follows that

$$(1) \quad 3 + \sum_{k \geq 2} (k-3)t_k + \sum_{k \geq 3} (k-3)f_k = 0.$$

One crucial observation is that if (p, q) is a nice pair, then p and q are vertices of the same face in $\mathcal{A}$. Moreover, the line segment between p and q is a diagonal of that face. For a face F with k edges the maximum possible number of diagonals in the vertical direction is $\lfloor \frac{k-2}{2} \rfloor$. Observe that this number is always less than or equal to $k-3$, as long as $k \geq 3$, which is true in our case. It follows that the maximum number of nice pairs (p, q) is at most $\sum_{k \geq 3} (k-3)f_k$. This, together with the lower bound on the number of nice pairs, gives

$$(2) \quad |R| - m - |Q| \leq \sum_{k \geq 3} (k-3)f_k.$$

Observe also that by definition,

$$(3) \quad |R| = \sum_{k \geq 2} t_k.$$

Equation (2), together with (3), gives

$$(4) \quad |Q| \geq \sum_{k \geq 2} t_k - m - \sum_{k \geq 3} (k-3)f_k.$$

We are now ready to complete the proof. Since every red line crosses each of the n blue lines we conclude that $|S| + |Q| = mn - \sum_{k \geq 2} kt_k$.

Therefore,

$$\begin{aligned} \frac{|S|}{2} + |Q| + |R| &= \frac{|S| + |Q|}{2} + \frac{|Q|}{2} + |R| \\ &\geq \frac{1}{2} \left(mn - \sum_{k \geq 2} kt_k + \sum_{k \geq 2} t_k - m - \sum_{k \geq 3} (k-3)f_k \right) + \sum_{k \geq 2} t_k \\ &= \frac{1}{2} \left(m(n-1) - \left(\sum_{k \geq 2} (k-3)t_k + \sum_{k \geq 3} (k-3)f_k \right) \right) = \frac{m(n-1) + 3}{2}. \end{aligned}$$

Since there are precisely m red lines, it follows by averaging that there exists a red line ℓ such that

$$\frac{|S(\ell)|}{2} + |Q(\ell)| + |R(\ell)| \geq \frac{n-1}{2} + \frac{3}{2m}.$$

It follows that either there are at least $\lceil \frac{n-1}{2} + \frac{3}{m} - 1 \rceil = \lfloor \frac{n-1}{2} \rfloor$ intersection points of ℓ with blue lines, all of which lie below $t(\ell)$, or there are at least this many intersection points of blue lines with ℓ , all of which lie above $b(\ell)$. $\square$

ON THE COMPLEXITY OF ORDERED COLORINGS*

ARVIND GUPTA[†], JAN VAN DEN HEUVEL[‡], JÁN MAŇUCH[†], LADISLAV STACHO[§],
AND XIAOHONG ZHAO[†]

Abstract. We introduce two variants of proper colorings with imposed partial ordering on the set of colors. One variant shows very close connections to some fundamental problems in graph theory, e.g., directed graph homomorphism and list colorings. We study the border between tractability and intractability for both variants.

Key words. graph coloring, ordered coloring, directed graph homomorphism, complexity, NP-completeness, polynomial algorithm

AMS subject classifications. 05C15, 68Q25, 05C85

DOI. 10.1137/060676222

1. Introduction. We introduce two variants of proper colorings with imposed partial ordering on the set of colors. Vertices of all considered graphs G are labeled with integers from 1 to $|V(G)|$, and we will use the normal order of the integers. In particular, the vertices form a completely ordered set. The set of colors forms a partially ordered set. The following ordered colorings are proper colorings satisfying additional requirements.

In the first coloring problem, we require that every vertex colored A is smaller than every vertex colored B for every two colors A, B for which A is smaller than B in the partial order. We will show that this problem is in P if the set of colors contains at most two incomparable colors by reduction to 2-SAT; otherwise, it is intractable.

In the second coloring problem, we require that for every edge whose end vertices are colored by A and B that the vertex with color A is smaller than the vertex with color B , for every two colors A, B for which A is smaller than B in the partial order. Note that a vertex colored A can be greater than a vertex colored B , provided they are not adjacent. We show that this problem is NP-complete if the partial ordering on colors contains at least two incomparable pairs. Otherwise, the problem is in P.

2. Basic definitions. Most of our terminology and notation will be standard and can be found in any textbook on graph theory such as [2], and on computational complexity such as [4].

Throughout this paper a graph $G = (V, E)$ is finite, simple, and loopless. We will always use n for the number of vertices and assume that the vertices of the input

graph G are integers from 1 to n (in other words, we set $V = [1, n]$). With this assumption we can consider the vertex set as a linearly ordered set $(V, \leq)$.

The set of available colors is denoted by Col . A *coloring* of a graph G is a function $\varphi : V \rightarrow Col$ so that for every edge $uv \in E$ we have $\varphi(u) \neq \varphi(v)$. We additionally assume that $\preceq$ is an antisymmetric, reflexive, and transitive relation on Col ; i.e., $\mathcal{C} = (Col, \preceq)$ is a partially ordered set. We sometimes call $(Col, \preceq)$ the *color-poset*. We will study the complexity of two coloring problems in which we will color vertices of the input graph G with colors in Col satisfying further requirements. We will refer to a coloring that satisfies these requirements as a *feasible coloring*.

Let $C \in Col$, where the set V_C of vertices in G colored by C will be called a *color class*.

If $(P, \preceq)$ is a poset, then an *antichain* is a set $S \subseteq P$ so that no two elements from S are comparable (i.e., for all $x, y \in S$ we have $x \not\preceq y$ and $y \not\preceq x$).

Given $X, Y \subseteq V$, an edge with one end-vertex in X and the other in Y is called an X, Y -edge. Let $E(X, Y)$ be the set of all X, Y -edges.

3. Coloring with ordered color classes. In this section we study the complexity of the following decision problem.

PROBLEM 3.1. *Fix a color-poset $(Col, \preceq)$. Given a graph $G = (V, E)$ with $V = [1, n]$, determine whether G can be colored with Col such that for any two colors A, B with $A \preceq B$ and for any two vertices $u \in V_A$ and $v \in V_B$ we have $u \leq v$.*

If a coloring as in Problem 3.1 exists, then we say that the graph G can be *feasibly colored with $(Col, \preceq)$* .

Note that if $\preceq$ is the empty relation on Col , then Problem 3.1 is the well-known graph coloring problem.

THEOREM 3.1. *If the poset $(Col, \preceq)$ does not contain an antichain of size 3, then Problem 3.1 can be solved in polynomial time. Otherwise, the problem is NP-complete.*

The proof that Problem 3.1 is in P if the longest antichain in $(Col, \preceq)$ has length at most 2 is quite technical. For this reason we first give the proof for a specific small poset with all of the details. The proof of the general case will be done with less detail after that. The fairly straightforward proof that the problem is NP-complete if $(Col, \preceq)$ contains an antichain of length 3 will be the final proof in this section.

LEMMA 3.2. *Let $Col = \{A, B, C\}$ and suppose that the only relation between the colors is $A \preceq B$. Problem 3.1 can be solved in polynomial time for this poset $(\{A, B, C\}, \preceq)$.*

Proof. Suppose a graph G can be feasibly colored with $(\{A, B, C\}, \preceq)$. It then follows that there exists a vertex $v \in V$ such that vertices in the set $V_{AC} = [1, v-1]$ are colored A or C , and vertices in the set $V_{BC} = [v, n]$ are colored B or C . Therefore, the subgraphs G_{AC} and G_{BC} of G , induced by V_{AC} and V_{BC} , respectively, are bipartite. Suppose G_{AC} has k components and G_{BC} has ℓ components. Let $\{(X_i, \overline{X}_i)\}_{i=1}^k$ be the set of bipartitions of connected components $\{\mathcal{X}_i\}_{i=1}^k$ of G_{AC} , and let $\{(Y_j, \overline{Y}_j)\}_{j=1}^\ell$ be the set of bipartitions of connected components $\{\mathcal{Y}_j\}_{j=1}^\ell$ of G_{BC} .

Every bipartite component $\mathcal{X}_i$ (respectively, $\mathcal{Y}_j$) has exactly two 2-colorings. Thus, we can associate each $\mathcal{X}_i$ with a Boolean variable x_i as follows: If the bipartition X_i of $\mathcal{X}_i$ is colored C , then $x_i = 0$; otherwise, $x_i = 1$. Similarly, we associate each $\mathcal{Y}_j$ with a Boolean variable y_j : If the bipartition Y_j of $\mathcal{Y}_j$ is colored C , then $y_j = 0$; otherwise, $y_j = 1$.

Every (V_{AC}, V_{BC}) -edge of G imposes a constraint on a feasible coloring of G . This constraint can be equivalently expressed in terms of the Boolean variables as follows:

- For every (X_i, Y_j) -edge of G , the clause $x_i \vee y_j$ should be satisfied.
- For every $(X_i, \overline{Y_j})$ -edge of G , the clause $x_i \vee \overline{y_j}$ should be satisfied.
- For every $(\overline{X_i}, Y_j)$ -edge of G , the clause $\overline{x_i} \vee y_j$ should be satisfied.
- For every $(\overline{X_i}, \overline{Y_j})$ -edge of G , the clause $\overline{x_i} \vee \overline{y_j}$ should be satisfied.

Let f_v be the conjunction of the above 2-literal disjunctions for all (V_{AC}, V_{BC}) -edges of G ; see Figure 3.1 for an example.

FIG. 3.1. An example of the transformation of a graph G into a 2-CNF formula.

Obviously, there exists a feasible coloring of G if and only if the formula f_v is satisfiable. An assignment of Boolean values to variables in f_v can be translated into a coloring of G in linear time. Hence, to find a coloring for G feasible with $(\{A, B, C\}, \preceq)$, we can use the following algorithm:

- For each $v \in V$, check if the subgraphs induced on $[1, v-1]$ and on $[v, n]$ are bipartite. If so, construct the formula f_v and use a 2-SAT solver to check the satisfiability of the formula. The graph G has a feasible coloring if and only if for at least one $v \in V$ the subgraphs induced on $[1, v-1]$ and on $[v, n]$ are bipartite and the formula f_v is satisfiable.

In [3], a 2-SAT solver working in linear time in the size of the formula is described. Note that each f_v has $O(n)$ variables and $O(n^2)$ clauses. Since there are n choices for v , Problem 3.1 can be solved in $O(n^3)$ steps. $\square$

We next give the general proofs of the two parts of Theorem 3.1.

THEOREM 3.1 A. *If the poset $(Col, \preceq)$ does not contain an antichain of size 3, then Problem 3.1 can be solved in polynomial time.*

Proof. If $\mathcal{P} = (P, \preceq)$ is a poset and $u \in P$, then by $(P - u, \preceq)$ we denote the poset with the same ordering $\preceq$ on the set $P \setminus \{u\}$. For a poset $\mathcal{P}$ with $|P| = p$ elements that does not contain an antichain of size 3, we will construct a collection $\Lambda_{\mathcal{P}}$ of p -tuples $\bar{\lambda} = (\lambda_1, \dots, \lambda_p)$, where each λ_i is a set of one or two elements from P . The concatenation of two tuples $\bar{\lambda} = (\lambda_1, \dots, \lambda_k)$ and $\bar{\mu} = (\mu_1, \dots, \mu_\ell)$ is $\bar{\lambda} * \bar{\mu} = (\lambda_1, \dots, \lambda_k, \mu_1, \dots, \mu_\ell)$.

The construction of $\Lambda_{\mathcal{P}}$ is recursive, as follows:

- If P has one element, say $P = \{a\}$, then $\Lambda_{\mathcal{P}} = \{\{a\}\}$.
- If $|P| \geq 2$ and P has a maximum element a , then $\Lambda_{\mathcal{P}} = \{\bar{\lambda} * (\{a\}) \mid \bar{\lambda} \in \Lambda_{\mathcal{P}-a}\}$.
- If $|P| \geq 2$ and P has no maximum element, then, since the longest antichain has length 2, there are two maximal elements a, b (so $a \not\preceq b$ and $b \not\preceq a$, while $p \preceq a$ or $p \preceq b$ for all $p \in P$). In that case we set $\Lambda_{\mathcal{P}} = \{\bar{\lambda} * (\{a, b\}) \mid \bar{\lambda} \in \Lambda_{\mathcal{P}-a}\} \cup \{\bar{\lambda} * (\{a, b\}) \mid \bar{\lambda} \in \Lambda_{\mathcal{P}-b}\}$.

Note that the number of tuples in $\Lambda_{\mathcal{P}}$ is finite.

Now we go back to a color poset $\mathcal{C} = (Col, \preceq)$ with no antichain longer than 3. Set $c = |Col|$. Consider a graph $G = (V, E)$ with $V = [1, n]$. Suppose G can be feasibly

colored with $\mathcal{C}$. With any such coloring we can associate a c -tuple $\bar{\lambda} = (\lambda_1, \dots, \lambda_c) \in \Lambda_{\mathcal{C}}$ and a $(c+1)$ -tuple of integers $(v_1, v_2, \dots, v_{c+1})$ so that the following hold:

1. We have $1 = v_1 \leq v_2 \leq \dots \leq v_c \leq v_{c+1} = n+1$.
2. For all $i = 1, \dots, c$, the subgraph of G induced by $[v_i, v_{i+1} - 1]$ is an independent set or a bipartite graph.
3. For all $i = 1, \dots, c$, the colors appearing on the vertices $[v_i, v_{i+1} - 1]$ are exactly the colors in λ_i .

The existence of these tuples follows directly from the fact that each antichain in $\mathcal{C}$ has length 1 or 2, and hence we cannot “mix” three or more colors from Col when coloring the graph.

Given a $(c+1)$ -tuple of integers $(v_1, v_2, \dots, v_{c+1})$, it is easy to check if this tuple satisfies conditions 1 and 2 above. If it does, then we can choose a c -tuple $\bar{\lambda} = (\lambda_1, \dots, \lambda_c) \in \Lambda_{\mathcal{C}}$ and use the same technique as applied in the proof of Lemma 3.2 to transform the problem of the existence of a feasible coloring of G in accordance with condition 3 into the existence of a solution of a certain 2-SAT problem. Hence, the question if there exists a coloring of G in accordance with two chosen tuples satisfying conditions 1–3 can be done in time polynomial in n .

The number of $(c+1)$ -tuples $(v_1, v_2, \dots, v_{c+1})$ with $1 = v_1 \leq v_2 \leq \dots \leq v_c \leq v_{c+1} = n+1$ is $O(n^c)$. And the number of tuples in $\Lambda_{\mathcal{C}}$ is $O(2^c)$. Therefore, to check if a graph G on n ordered vertices $[1, n]$ can be feasibly colored with $\mathcal{C}$, we need to consider at most $O(n^c)$ 2-SAT problems. Using estimates for the numbers of variables and clauses in each of the 2-SAT problems similar to those in the proof of Lemma 3.2, we can conclude that Problem 3.1 can be solved in polynomial time. $\square$

THEOREM 3.1 B. *If the poset $(Col, \preceq)$ contains an antichain of size 3 or more, then Problem 3.1 is NP-complete.*

Proof. Let $\mathcal{C} = (Col, \preceq)$ be a poset containing an antichain of size 3 or more. It is obvious that Problem 3.1 is in NP. To prove the problem is NP-complete we give a reduction from the proper K -coloring problem, which is well known to be NP-complete for any fixed $K \geq 3$.

Let $S \subseteq Col$ be an antichain in $\mathcal{C}$ with $|S| \geq 3$, chosen such that S is *maximal*; i.e., for all $C \in Col \setminus S$ we have that either $C \preceq A$ for some $A \in S$, or $A' \preceq C$ for some $A' \in S$, but not both (since S is an antichain). Let $Col_D \subseteq Col$ be the set of colors $C \in Col \setminus S$ such that $C \preceq A$ for some $A \in S$, and define $Col_U \subseteq Col$ similarly for colors in $Col \setminus S$ which are larger than some color in S . Set $K = |S|$, $n_D = |Col_D|$, and $n_U = |Col_U|$.

Given a graph $G' = (V', E')$ on n' vertices, we construct a graph G with ordered vertex set $[1, n]$, where $n = n_D + n' + n_U$, so that G' has a K -coloring if and only if G can be feasibly colored with $\mathcal{C}$. Let the vertices of G be $[1, n_D] \cup [n_D + 1, n_D + n'] \cup [n_D + n' + 1, n_D + n' + n_U]$. Add edges so that the graph on $[n_D + 1, n_D + n']$ is isomorphic to G' , and vertices in $[1, n_D] \cup [n_D + n' + 1, n_D + n' + n_U]$ are universal (joined to all other vertices).

Suppose G' has a K -coloring. Then we can color G in accordance with $\mathcal{C}$ as follows:

- Give each vertex in $[1, n_D]$ its own color from Col_D , using some linear extension of the order imposed by $\mathcal{C}$ on Col_D .
- Color the vertices in $[n_D + 1, n_D + n']$ with colors from S , according to the K -coloring possible on G' .
- Give each vertex in $[n_D + n' + 1, n_D + n' + n_U]$ its own color from Col_U , using some linear extension of the order imposed by $\mathcal{C}$ on Col_U .

It is easy to check that this coloring of G is feasible with $\mathcal{C}$, where the crucial observation is that S is an antichain in $\mathcal{C}$, and hence every proper coloring with colors from S is always in accordance with the poset order.

Next suppose that G has a feasible coloring with $\mathcal{C}$. Such a coloring must have the following properties:

- Each vertex in $[1, n_D]$ has a distinct color from Col_D , and this color is smaller than any color appearing on $[n_D + 1, n_D + n'] \cup [n_D + n' + 1, n_D + n' + n_U]$.
- Each vertex in $[n_D + n' + 1, n_D + n' + n_U]$ has a distinct color from Col_U , and this color is larger than any color appearing on $[1, n_D] \cup [n_D + 1, n_D + n']$.

From this it follows that the vertices in $[n_D + 1, n_D + n']$ are colored with colors from S . Since S is an antichain, the only requirement to color those vertices with S is that it must be a proper coloring. Such a proper coloring immediately gives a K -coloring of G' . $\square$

4. Coloring with ordered edges. In this section we study the complexity of the following decision problem.

PROBLEM 4.1. *Fix a color-poset $(Col, \preceq)$. Given a graph $G = (V, E)$ with $V = [1, n]$, determine whether G can be colored with Col such that for any two colors A, B with $A \preceq B$ and for any edge $(u, v) \in E$ with $u \in V_A$ and $v \in V_B$ we have $u \leq v$.*

We will transform this problem into a directed graph homomorphism problem. In this section, by (u, v) we mean a directed edge (arc) from u to v . We will use E to denote the set of directed edges of a directed graph (digraph) as well.

The semicomplete digraphs depicted in Figure 4.1 play a crucial role in our characterization.

FIG. 4.1. The crucial semicomplete digraphs in the dichotomy characterization of Problem 4.1. F'_k is obtained by taking the transitive closure of F_k .

DEFINITION 4.1. *Let H be a fixed digraph. An H -coloring of a digraph G is a homomorphism from G to H (a mapping φ from $V(G)$ to $V(H)$ such that if $(x, y) \in E(G)$, then $(\varphi(x), \varphi(y)) \in E(H)$). The acyclic H -coloring problem asks whether for a given acyclic digraph G there is an H -coloring of G .*

DEFINITION 4.2. A semicomplete digraph is a digraph H which contains a spanning tournament; i.e., between any two vertices there is either one arc or both opposite arcs. We say that a semicomplete digraph is quasi-acyclic if after removal of all pairs of oppositely directed arcs we obtain a transitive acyclic subdigraph of H .

An alternative definition of a quasi-acyclic semicomplete digraph is as a semicomplete digraph in which every directed cycle contains at least two arcs that come from pairs of opposite arcs. It is easy to see that there is a one-to-one correspondence between posets and quasi-acyclic semicomplete digraphs. Given a color-poset $\mathcal{C} = (Col, \preceq)$, to obtain the corresponding digraph take $V = Col$. And for every two colors A and B , $A \neq B$, if $A \prec B$ add an arc (A, B) , if $B \prec A$ add an arc (B, A) , and, otherwise, add a pair of opposite arcs (A, B) and (B, A) . The resulting semicomplete digraph is quasi-acyclic and will be denoted $H_{\mathcal{C}}$.

Similarly, a graph G with ordered vertex set $[1, n]$ can be considered as a digraph G' if we replace all edges $uv \in E(G)$ with $u < v$ by arcs (u, v) .

Without a proof we note that, with this notation, we have that G has a coloring by $\mathcal{C}$ feasible for Problem 4.1 if and only if there is an $H_{\mathcal{C}}$ -coloring of G' .

THEOREM 4.3. Let H be a quasi-acyclic semicomplete digraph. The acyclic H -coloring problem can be solved in polynomial time if H contains at most one directed 2-cycle (a pair of oppositely directed arcs). Otherwise, the problem is NP-complete.

This is exactly the same dichotomy as for the general H -coloring problem where H is any semicomplete digraph; cf. [1]. In particular, the first part of the theorem follows from the polynomiality of this problem. But for convenience we give a short proof below as well (Lemma 4.4).

The second part of the theorem follows from Lemmas 4.5–4.10 that make up most of the remainder of this section. In those lemmas we first prove the NP-completeness of the acyclic H -coloring problem for three crucial quasi-acyclic semicomplete digraphs and then for any quasi-acyclic semicomplete digraph containing any of those three as an induced subdigraph.

LEMMA 4.4. Let H be a quasi-acyclic semicomplete digraph. The acyclic H -coloring problem can be solved in polynomial time if H contains at most one directed 2-cycle.

Proof. The problem is trivial if $|V(H)| = 1$. If $|V(H)| = 2$ and there is a 2-cycle in H , then an acyclic digraph G has a homomorphism from G to H if and only if the underlying graph of G (obtained by ignoring the directions on the arcs) is bipartite. Similarly, if $|V(H)| = 2$ and there is no 2-cycle in H , then an acyclic digraph G has a homomorphism from G to H if and only if we can partition $V(G)$ into $G_D \cup G_U$ such that every arc in G has its tail in G_D and its head in G_U .

So assume $|V(H)| \geq 3$. Since H has an acyclic spanning tournament, there are both a universal sink and a universal source in H , i.e., there is a vertex $u \in V(H)$ so that for all $v \in V(H)$, $v \neq u$, we have $(v, u) \in E(H)$; and there is a vertex $u' \in V(H)$ so that for all $v \in V(H)$, $v \neq u'$, we have $(u', v) \in E(H)$. Since H has at most one 2-cycle $\{(p, q), (q, p)\}$ and after removing that 2-cycle we obtain a transitive acyclic subdigraph of H , it is easy to check that we can choose at least one of u, u' different from both p and q . Suppose that the universal sink u in H is different from p and q . Let G be an acyclic digraph, and let G_i be the set of sinks in G . Then there is a homomorphism from G to H if and only if there is a homomorphism from $G - G_i$ to $H - u$. Indeed, homomorphisms from $G - G_i$ to $H - u$ are easily extendable to homomorphisms from G to H . The converse follows since in any homomorphism from G to H , the neighbors of vertices in G_i are not mapped to u , and hence we can

remap the vertices in G_i to u if necessary.

A similar observation holds if the universal source in H is different from p and q . We use induction on $|V(H)|$ to get a straightforward polynomial algorithm to check if there is a homomorphism from H to G . $\square$

The following lemma follows immediately from the NP-completeness of the ordinary 3-coloring problem.

LEMMA 4.5. *Let H_0 be the quasi-acyclic semicomplete digraph depicted in Figure 4.1. The acyclic H_0 -coloring problem is NP-complete.*

LEMMA 4.6. *Let H_1 be the quasi-acyclic semicomplete digraph depicted in Figure 4.1. The acyclic H_1 -coloring problem is NP-complete.*

Proof. The problem is obviously in NP. We will show that given a Boolean formula $f(x_1, x_2, \dots, x_m)$ in conjunctive normal form (CNF), we can construct an acyclic digraph $\tilde{G}(f)$ which has an H_1 -coloring φ if and only if f is satisfiable. For every Boolean variable a of f (respectively, every auxiliary variable encoding the Boolean value of a subformula of f), we will construct the gadget $G_a = (V_a, E_a)$ defined as follows: $V_a = \{v_a^1, \dots, v_a^6\}$ and $E_a = \{(v_a^2, v_a^1), (v_a^3, v_a^1), (v_a^3, v_a^2), (v_a^4, v_a^2), (v_a^5, v_a^3), (v_a^5, v_a^4), (v_a^6, v_a^1), (v_a^6, v_a^4), (v_a^6, v_a^5)\}$; see Figure 4.2.

FIG. 4.2. The two possible homomorphisms (coloring patterns) from G_a to H_1 : On the left-hand side $Pat(G_a) = P^0$; On the right-hand side $Pat(G_a) = P^1$.

Each gadget G_a is acyclic and has only two H_1 -colorings, called *color patterns*; see Figure 4.2. Let the color pattern P^0 of G_a with $\varphi(v_a^1) = \varphi(v_a^4) = A$, $\varphi(v_a^3) = \varphi(v_a^6) = B$, and $\varphi(v_a^2) = \varphi(v_a^5) = C$ represent the fact that the value of the Boolean variable a is 0. Similarly, let the color pattern P^1 of G_a with $\varphi(v_a^1) = \varphi(v_a^5) = A$, $\varphi(v_a^2) = \varphi(v_a^6) = B$, and $\varphi(v_a^3) = \varphi(v_a^4) = C$ represent the fact that $a = 1$.

Now let us give an overview of the main ideas in the construction of $\tilde{G}(f)$. First, we construct a gadget G_{x_i} for every variable x_i occurring in the formula f . Second, for every disjunctive subformula d_i of $f = d_1 \wedge d_2 \wedge \dots \wedge d_k$, we construct an acyclic digraph $G(d_i)$ containing a gadget G_{d_i} and using the gadgets $G_{x_1}, \dots, G_{x_m}$ such that for every H_1 -coloring of $G(d_i)$, $Pat(G_{d_i}) = P^1$ if and only if color patterns of $G_{x_1}, \dots, G_{x_m}$ correspond to a true assignment for d_i . Finally, we extend each $G(d_i)$ to a digraph $\tilde{G}(d_i)$ such that the gadget G_{d_i} will have the color pattern P^1 in every H_1 -coloring of $\tilde{G}(d_i)$. Since the gadgets $G_{x_1}, \dots, G_{x_m}$ are common for every $\tilde{G}(d_i)$, it will follow that there is an H_1 -coloring of $\tilde{G}(f) = \bigcup_{i=1}^k \tilde{G}(d_i)$ if and only if there is a true assignment for f , i.e., if f is satisfiable.

In the following we describe a recursive construction of the digraph $G(d)$, where $d = d_i$. If d has no $\vee$'s, then either $d = x_j$ or $d = \overline{x_j}$, for some $j = 1, \dots, m$. As

FIG. 4.3. On the left: $G(d)$ for the Boolean formula $d = x_j$; on the right: $G(d)$ for the Boolean formula $d = \bar{x}_j$.

described earlier, add a gadget G_d to $G(d)$. To complete the construction add the arc $(v_d^3, v_{x_j}^2)$ if $d = x_j$, and the arc $(v_d^2, v_{x_j}^2)$ if $d = \bar{x}_j$; see Figure 4.3. First, suppose $d = x_j$. If the color pattern of G_{x_j} is P^0 , then because of the arc $(v_d^3, v_{x_j}^2)$, the only possible color pattern for G_d is P^0 , and similarly if the color pattern of G_{x_j} is P^1 , then the only possible color pattern for G_d is P^1 . Since every true assignment of d has $x_j = 1$ and the remaining variables can have arbitrary values, for every H_1 -coloring of $G(d)$, $\text{Pat}(G_d) = P^1$ if and only if color patterns of $G_{x_1}, \dots, G_{x_m}$ correspond to such a true assignment. If $d = \bar{x}_j$, then the argument is similar.

Assume now that d contains an $\vee$. Then there are disjunctive subformulas d' and d'' in f such that $d = d' \vee d''$. We recursively construct digraphs $G(d')$ and $G(d'')$ (in polytime). Construct $G(d)$ as follows. Take a union of $G(d')$ and $G(d'')$ and add a new variable gadget G_d and a disjunction gadget consisting of three new vertices w_d^1, w_d^2, w_d^3 and the arcs $(w_d^2, w_d^1), (w_d^3, w_d^2)$. Furthermore, add the arcs $(w_d^1, v_d^2), (w_d^1, v_d^5), (w_d^3, v_d^2), (w_d^3, v_d^5)$, and (v_d^4, w_d^2) connecting the disjunction gadget with the variable gadgets; see Figure 4.4.

It is easy to check that in every H_1 -coloring of $G(d')$ (respectively, $G(d'')$), the gadget $G_{d'}$ in $G(d')$ (respectively, $G_{d''}$ in $G(d'')$) has the color pattern P^1 if and only if the color patterns of gadgets $G_{x_1}, \dots, G_{x_m}$ represent a true assignment for d' (respectively, d''). Otherwise it has the color pattern P^0 . Since the color patterns of gadgets $G_{x_1}, \dots, G_{x_m}$ represent a true assignment for d if and only if they represent a true assignment for d' or d'' , it is enough to show that in any H_1 -coloring of $G(d)$, $\text{Pat}(G_d) = P^1$ if and only if $\text{Pat}(G_{d'}) = P^1$ or $\text{Pat}(G_{d''}) = P^1$.

Consider an H_1 -coloring of $G(d)$. If $\text{Pat}(G_{d'}) = \text{Pat}(G_{d''}) = P^1$, then $\varphi(w_d^1) = \varphi(w_d^3) = C$ and $\varphi(w_d^2) = A$ or B ; hence $\text{Pat}(G_d) = P^1$. (Note that this is true even if $\varphi(w_d^2) = B$; the vertex v_d^4 cannot be colored A because of the arc (v_d^4, w_d^2) .) If $\text{Pat}(G_{d'}) = P^1$ and $\text{Pat}(G_{d''}) = P^0$, then $\varphi(w_d^1) = C$, and since (w_d^3, w_d^2) is an arc, $\varphi(w_d^2) = A$ and $\varphi(w_d^3) = B$. Hence, $\text{Pat}(G_d) = P^1$. The case $\text{Pat}(G_{d'}) = P^0$ and $\text{Pat}(G_{d''}) = P^1$ is analogous to the previous one. If $\text{Pat}(G_{d'}) = \text{Pat}(G_{d''}) = P^0$, then $\varphi(w_d^1)$ and $\varphi(w_d^3)$ is either A or B . Since $G(d)$ contains the arcs (w_d^2, w_d^1) and (w_d^3, w_d^2) , we must have $\varphi(w_d^2) = C$; hence $\text{Pat}(G_d) = P^0$. This verifies the construction of the digraph $G(d)$.

Finally, we extend each $G(d)$ to a digraph $\tilde{G}(d)$ such that the gadget G_d will have the color pattern P^1 in every H_1 -coloring of $\tilde{G}(d)$. Then, for every H_1 -coloring of $\tilde{G}(d)$, the color patterns of $G_{x_1}, \dots, G_{x_m}$ must represent a true assignment for d .

FIG. 4.4. The construction of $G(d)$ for the Boolean formula $d = d' \vee d''$ using the union of the digraphs $G(d')$ and $G(d'')$. In the example above we assume that d' contains both x_1 and $\bar{x}_1$, which is indicated by two arcs entering the gadget G_{x_1} . Similarly, the arcs entering the gadget G_{x_2} indicate that the variable x_2 (or its complement) occurs in both d' and d'' . Finally, no arc entering the gadget G_{x_m} indicates that neither d' nor d'' contain x_m or $\bar{x}_m$.

FIG. 4.5. The construction of $\tilde{G}(d)$.

It follows that $\tilde{G}(f)$ has an H_1 -coloring if and only if f is satisfiable.

Let Z be the digraph with $V(Z) = \{z^1, \dots, z^5\}$, and $E(Z) = \{(z^2, z^1), (z^3, z^2), (z^4, z^3), (z^5, z^4), (z^1, z^5)\}$. Since z^3 has two incoming (outgoing) arcs from vertices connected by an arc, it cannot be colored B (respectively, A). Hence, z^3 must be colored C . Consequently, $\varphi(z^1) = \varphi(z^4) = A$ and $\varphi(z^2) = \varphi(z^5) = B$. Now, we are ready to construct $\tilde{G}(d)$. Take the union of $G(d)$ and Z and add an arc (v_d^2, z^3) ; see Figure 4.5. Obviously, in any H_1 -coloring of $\tilde{G}(d)$, $\text{Pat}(G_d) = P^1$.

Finally, let us deduce that the digraph $\tilde{G}(f)$ is acyclic. First, by induction, we show that for every subformula d used in the construction, $G(d)$ is acyclic. This is certainly true for every $d = x_j$ or $d = \bar{x}_j$. Now, consider the formula $d = d' \vee d''$; see Figure 4.4. By induction, $G(d')$ and $G(d'')$ are acyclic and since all arcs incident with the common part of $G(d')$ and $G(d'')$ (the input variable gadgets) end in the common part, the union $G(d') \cup G(d'')$ is acyclic as well. The digraph $G(d)$ contains this union and two new gadgets, and all arcs connecting these two parts start in the new gadgets and end in the union. Hence, $G(d)$ is also acyclic. Thus, for every d_i in f , $G(d_i)$ and, obviously, also $\tilde{G}(d_i)$ are acyclic. By the same argument as earlier their union $\tilde{G}(f)$

FIG. 4.6. The digraph Z .

is also acyclic. $\square$

LEMMA 4.7. Let F_0 be the quasi-acyclic semicomplete digraph depicted in Figure 4.1. The acyclic F_0 -coloring problem is NP-complete.

Proof. The problem is obviously in NP. The proof of NP-hardness follows the lines of the proof of Lemma 4.6. We will again show that given a Boolean formula $f(x_1, x_2, \dots, x_m)$ in CNF, we can construct an acyclic digraph $\tilde{G}(f)$ which has a F_0 -coloring if and only if f is satisfiable.

The main differences with the proof of Lemma 4.6 is that the new variable gadgets will share a four-vertex subdigraph Z with $V(Z) = \{z^1, \dots, z^4\}$ and $E(Z) = \{(z_i, z_j) \mid i > j\}$; see Figure 4.6. Note that the digraph Z has a unique F_0 -coloring up to swapping A and B , or C and D . Without loss of generality, it is enough to consider only those F_0 -colorings φ of $\tilde{G}(f)$ which have $\varphi(z^1) = A$, $\varphi(z^2) = B$, $\varphi(z^3) = C$, and $\varphi(z^4) = D$. This assumption will reduce the number of color patterns of variable gadgets to two.

For every Boolean variable a of f (input or auxiliary), we will construct the following acyclic gadget $G_a = (V_a, E_a)$ with $V_a = \{v_a^1, \dots, v_a^6\}$ and $E_a = \{(v_a^2, v_a^1), (v_a^3, v_a^2), (v_a^4, v_a^3), (v_a^5, v_a^4), (v_a^6, v_a^5), (v_a^6, v_a^3), (v_a^6, v_a^5)\}$. As proposed above, we complete the construction of the gadget by connecting it to the common digraph Z by arcs (v_a^3, z^1) , (v_a^4, z^1) , (v_a^5, z^1) , (v_a^6, z^1) , (v_a^2, z^2) , (z^3, v_a^3) , and (z^3, v_a^4) ; see Figure 4.7. The figure shows two coloring patterns of G_a : P^0 with $\varphi(v_a^1) = \varphi(v_a^3) = B$, $\varphi(v_a^2) = A$, $\varphi(v_a^4) = \varphi(v_a^6) = D$, and $\varphi(v_a^5) = C$, which will represent the fact that $a = 0$; and P^1 with

FIG. 4.7. Two coloring patterns of the gadget G_a : $\text{Pat}(G_a) = P^0$ (on the left) and $\text{Pat}(G_a) = P^1$ (on the right). The squares labeled with A , B , and C represent vertices z^1 , z^2 , and z^3 of the digraph Z common to all gadgets, respectively. For simplicity, we omitted the fourth vertex of Z and the arcs inside Z .

$\varphi(v_a^1) = A$, $\varphi(v_a^2) = \varphi(v_a^6) = C$, $\varphi(v_a^3) = \varphi(v_a^5) = D$, and $\varphi(v_a^4) = B$ corresponding with $a = 1$.

For each disjunctive subformula $d = d_i$ of $f = d_1 \wedge \dots \wedge d_k$, the construction of $\tilde{G}(d)$ is analogous to the construction in the proof of Lemma 4.6. Therefore, we describe only the main ingredients of the construction: the base step $d = x_j$ or $d = \bar{x}_j$,

the inductive step $d = d' \vee d''$, and forcing the color pattern of G_d to P^1 . In the base step, add the arc $(v_{x_j}^6, v_d^5)$, if $d = x_j$; or the arc $(v_{x_j}^6, v_d^6)$, if $d = \overline{x_j}$, joining the input variable gadget G_{x_j} to the variable gadget G_d ; see Figure 4.8.

FIG. 4.8. On the left: $G(d)$ for the Boolean formula $d = x_j$; on the right: $G(d)$ for the Boolean formula $d = \overline{x_j}$.

One can easily check that $G(d)$ is acyclic and has the required property.

In the inductive step, construct $G(d)$ as follows. Take the union of $G_{d'}$ and $G_{d''}$ and add one new gadget G_d and three new vertices w_d^1, w_d^2, w_d^3 . Furthermore, add the arcs $(v_{d'}^2, w_d^1)$, $(v_{d'}^5, w_d^2)$, $(v_{d'}^5, v_d^4)$, $(w_d^3, v_{d''}^5)$, $(v_{d''}^5, v_d^4)$, (w_d^2, w_d^1) , (w_d^2, v_d^1) , and (w_d^3, w_d^2) ; see Figure 4.9.

FIG. 4.9. The construction of $G(d)$ for the Boolean formula $d = d' \vee d''$ using the union of the digraphs $G(d')$ and $G(d'')$.

We show that in any feasible coloring of $G(d)$, $\text{Pat}(G_d) = P^1$ if and only if $\text{Pat}(G_{d'}) = P^1$ or $\text{Pat}(G_{d''}) = P^1$. Notice that the arcs $(v_{d'}^2, w_d^1)$ and $(v_{d'}^5, v_d^4)$ guarantee that if one of the gadgets $G_{d'}$ or $G_{d''}$ has the color pattern P^1 , then gadget G_d must have the color pattern P^1 . Now, it is enough to show that there is a feasible coloring for the three w -vertices in each of these three cases. Indeed, we can color the w -vertices as follows: if $\text{Pat}(G_{d'}) = P^1$ and $\text{Pat}(G_{d''}) = P^0$, $\varphi(w^1) = A$, $\varphi(w^2) = B$, $\varphi(w^3) = D$;

if $\text{Pat}(G_{d'}) = P^0$ and $\text{Pat}(G_{d''}) = P^1$, $\varphi(w^1) = B$, $\varphi(w^2) = D$, $\varphi(w^3) = C$; and if $\text{Pat}(G_{d'}) = P^1$ and $\text{Pat}(G_{d''}) = P^1$, $\varphi(w^1) = A$, $\varphi(w^2) = B$, $\varphi(w^3) = C$. It remains to consider the case when $\text{Pat}(G_{d'}) = P^0$ and $\text{Pat}(G_{d''}) = P^0$. We have $\varphi(v_{d'}^2) = A$ and $\varphi(v_{d'}^5) = \varphi(v_{d''}^5) = C$. The arc $(v_{d'}^2, w_d^1)$ forces $\varphi(w_d^1) = B$, and the arc $(w_d^3, v_{d''}^5)$ forces $\varphi(w_d^3) = D$. Furthermore, the arcs $(v_{d'}^2, w_d^1)$, $(w_d^3, v_{d''}^5)$, and $(v_{d''}^5, w_d^2)$ force $\varphi(w_d^2) = A$ because of the arc (w_d^2, v_d^1) , $\varphi(v_d^1) = B$. Hence, $\text{Pat}(G_d) = P^0$. This verifies the construction of the digraph $G(d)$.

Finally, to extend $G(d)$ to $\tilde{G}(d)$ forcing G_d to the color pattern P^1 , add the arc (v_d^1, z^2) . Let us observe that the digraph $\tilde{G}(f)$ is acyclic. Note that if a digraph contains a sink (only incoming arcs) or a source (only outgoing arcs), then it can be removed from the digraph without affecting its acyclicity. Therefore, it is enough to show that the digraph $\tilde{G}(f)'$ obtained from $\tilde{G}(f)$ by removing the vertices of Z and the vertices w_d^1 and w_d^3 , for every subformula d used in the construction, is acyclic, which can be easily seen using a similar argument as in the proof of Lemma 4.6. $\square$

LEMMA 4.8. *Let $k \geq 1$, and let F_k be the quasi-acyclic semicomplete digraph obtained by forming the transitive closure of the digraph F'_k depicted in Figure 4.1. The acyclic F_k -coloring is NP-complete.*

Proof. The reduction from SAT is similar to the reduction described in the proof of Lemma 4.7. In fact, all of the gadgets and connections among them require just slight modifications. The digraph Z in the proof of Lemma 4.7 can be viewed as the transitive closure of the directed path (z^4, z^3, z^2, z^1) . In this proof the digraph Z will be the transitive closure of the path $(z^4, z^3, q^k, \dots, q^1, z^2, z^1)$. Again, Z has a unique F^k -coloring up to swapping A and B , or C and D . In any coloring, $\varphi(q^i) = E_i$ and, without loss of generality, let $\varphi(z^1) = A$, $\varphi(z^2) = B$, $\varphi(z^3) = C$, and $\varphi(z^4) = D$.

There are $k + 4$ colors available to color a variable gadget G_a depicted in Figure 4.7, which would result in many different color patterns for the gadget. In order to restrict the number of color patterns of G_a to two, we replace the arcs connecting the vertices of the variable gadget with vertices of the digraph Z with the following ten arcs: (q^1, v_a^1) , (v_a^2, z^2) , (q^2, v_a^2) , (v_a^3, q^{k-1}) , (z^3, v_a^3) , (v_a^4, z^1) , (q^2, v_a^4) , (v_a^5, q^{k-1}) , (z^4, v_a^5) , and (v_a^6, q^k) , and replace the arcs (v_a^3, v_a^2) and (v_a^5, v_a^4) by two directed paths with $k - 1$ internal nodes (with all arcs on each path having the same direction as the original arc); see Figure 4.10(a).

In the case $k = 1$, there are no vertices q^2 and q^{k-1} . Instead of the arcs (q^2, v_a^2) , (q^2, v_a^4) , (v_a^3, q^{k-1}) , and (v_a^5, q^{k-1}) , we add arcs (v_a^3, z^1) , (v_a^5, z^1) , (v_a^3, z^2) , (v_a^5, z^2) , (z^3, v_a^2) , (z^3, v_a^4) , (z^4, v_a^2) , and (z^4, v_a^4) . Note also that in this case the vertices q^1 and q^k are the same (the squares labeled E_1 and E_k in Figure 4.10(a)), and that the directed paths $(v_a^3, \dots, v_a^2)$ and $(v_a^5, \dots, v_a^4)$ contain only one arc each, as in the original variable gadget depicted in Figure 4.7.

It is easy to see that the arcs connecting vertices of Z to vertices of the gadget force exactly two color choices for each vertex v_a^i : A or B for v_a^1 ; A or E_1 for v_a^2 ; E_k or D for v_a^3 ; B or E_1 for v_a^4 ; E_k or C for v_a^5 ; and C or D for v_a^6 . Now, assume that $\varphi(v_a^1) = A$. Then $\varphi(v_a^2) = E_1$. Since the path $(v_a^3, \dots, v_a^2)$ contains $k - 1$ internal nodes, $\varphi(v_a^3) \neq E_k$; i.e., $\varphi(v_a^3) = D$. Then $\varphi(v_a^4) = C$ and $\varphi(v_a^5) = E_k$. Similarly, v_a^4 cannot be colored with E_1 ; i.e., $\varphi(v_a^4) = B$. Note also that $\varphi(v_a^4) = B$ implies that $\varphi(v_a^1) = A$. This defines the color pattern P^1 of the variable gadget G_a . The only other possible color pattern is the complementary one. One can easily check that this complementary color pattern P^0 is valid as well; see Figure 4.10(b).

In the inductive construction of $\tilde{G}_d$, there are no differences in the base step in the case $d = \overline{x_j}$ (see the right-hand side picture in Figure 4.8). In the case $d = x_j$,

FIG. 4.10. (a) A variable gadget used in the proof that F_k -coloring is NP-complete for $k > 1$. The squares labeled with $A, B, C, D, E_1, E_2, E_{k-1}$, and E_k represent vertices $z^1, z^2, z^3, z^4, q^1, q^2, q^{k-1}$, and q^k of the common digraph Z , respectively. The arrows with circles connecting v_a^3 with v_a^2 and v_a^5 with v_a^4 depict directed paths $(v_a^3, \dots, v_a^2)$ and $(v_a^5, \dots, v_a^4)$ with $k-1$ internal nodes.

(b) Two color patterns of the variable gadget: $\text{Pat}(G_a) = P^0$ (on the left) and $\text{Pat}(G_a) = P^1$ (on the right).

we add an arc $(v_{x_j}^6, v_d^3)$; see Figure 4.11. It is easy to see that both gadgets must be in the same state.

In the inductive step $d = d' \vee d''$, we construct $G(d)$ as follows. Take the union of $G_{d'}$ and $G_{d''}$ and add one new gadget G_d and one new vertex w_d . Furthermore, add the arcs $(v_{d'}^6, v_d^5), (v_{d''}^6, v_d^5), (w_d, v_d^1), (w_d, v_{d'}^1)$ and a directed path from $v_{d''}^3$ to w_d with $k-1$ internal nodes; see Figure 4.11. If $\text{Pat}(G_{d'}) = P^1$ (respectively, $\text{Pat}(G_{d''}) = P^1$), then the arc $(v_{d'}^6, v_d^5)$ (respectively, $(v_{d''}^6, v_d^5)$) forces $\text{Pat}(G_d) = P^1$. On the other hand, if $\text{Pat}(G_{d'}) = P^0$, then $\varphi(w_d)$ cannot be B ; and if $\text{Pat}(G_{d''}) = P^0$, then $\varphi(v_{d''}^3) = E_k$. Hence, $\varphi(w_d)$ is either A or B . Thus, if both $\text{Pat}(G_{d'}) = \text{Pat}(G_{d''}) = P^0$, then $\varphi(w_d) = A$. Hence, $\varphi(v_d^1) = B$; i.e., $\text{Pat}(G_d) = P^0$. Note that only $\varphi(w_d) = A$ forces $\text{Pat}(G_d) = P^0$ and that w_d is not forced to have color A if either $\text{Pat}(G_{d'})$ or $\text{Pat}(G_{d''})$ is P^1 . Thus, we can see that $\text{Pat}(G_d) = P^1$ if and only if $\text{Pat}(G_{d'}) = P^1$ or $\text{Pat}(G_{d''}) = P^1$. The rest of the proof is analogous to the proof of Lemma 4.7. $\square$

The following lemma gives a simple characterization when a digraph contains at least two directed 2-cycles.

LEMMA 4.9. *A quasi-acyclic semicomplete digraph H contains at least two directed 2-cycles if and only if it contains either H_0, H_1 , or F_0 (see Figure 4.1) as an induced subdigraph.*

FIG. 4.11. On the left: $G(d)$ for the Boolean formula $d = x_j$. On the right: $G(d)$ for the Boolean formula $d = d' \vee d''$. The path connecting $v_{d'}^3$ with v_d^5 contains $k - 1$ internal nodes.

Proof. Sufficiency is trivial. For necessity, suppose that H does not contain H_0 . Now, if there are two 2-cycles in H which share a vertex, then the three vertices on these two 2-cycles induce H_1 . Otherwise, take any two 2-cycles. Since they are vertex-disjoint, the four vertices on them induce F_0 . $\square$

Therefore, to prove the NP-completeness part of Theorem 3.1, it is enough to show the following lemma.

LEMMA 4.10. Suppose H is a quasi-acyclic semicomplete digraph. If H contains either H_0 , H_1 , or F_0 (see Figure 4.1) as an induced subdigraph, then the acyclic H -coloring problem is NP-complete.

Proof. We will distinguish three cases.

Case 1. We first prove that when H contains H_0 as an induced subdigraph, the acyclic H -coloring problem is NP-complete by reduction from the proper 3-coloring problem. In particular, given a graph G , we will construct an acyclic digraph K which has an H -coloring if and only if G is 3-colorable.

Let A , B , and C be the vertices of H_0 . Find a directed Hamilton path P in H on which vertices A , B , and C are consecutive (by using a topological sort on the poset corresponding to H). Let P_ℓ (respectively, P_u) denote the subpath of P containing all vertices preceding (respectively, following) the three vertices A , B , and C on P . Note that P has the property that its transitive closure is H -colorable. This will be used later in the proof.

We construct an acyclic digraph K as follows. Start with subpaths P_ℓ and P_u and vertices in $V(G)$. Add an arc from the last vertex of P_ℓ to every vertex in $V(G)$ and from every vertex in $V(G)$ to the first vertex of P_u ; see Figure 4.12.

FIG. 4.12. First step in the construction of the acyclic digraph $\vec{K}$.

Next, take the transitive closure of this digraph. Observe that the resulting

digraph has many H -colorings in which vertices on P_ℓ and P_u are mapped to corresponding vertices in H , and vertices in $V(G)$ are arbitrarily mapped to vertices A , B , and C . Consider any acyclic orientation of G and add every arc of this orientation to the constructed digraph joining corresponding vertices in $V(G)$. The resulting acyclic digraph is K .

First, suppose that G is 3-colorable with colors A , B , and C . For an H -coloring of K choose the H -coloring from the previous paragraph that agrees on vertices in $V(G)$ with the 3-coloring.

Second, suppose that K has an H -coloring. Since $V_P = V(P_\ell) \cup V(P_u)$ induces a transitive tournament in K , any such H -coloring must use all but three vertices of H . Since every vertex of $V(G)$ is incident (is a tail or a head of an arc) with every vertex in V_P , in any H -coloring of K the vertices in $V(G)$ are mapped to the remaining three vertices of H ; i.e., G is 3-colorable.

Case 2. Next, we prove that when H contains H_1 but not H_0 as an induced subdigraph, the H -coloring problem is NP-complete by reduction from the acyclic H_1 -coloring problem (see Lemma 4.6). Let G be an acyclic digraph for which we want to decide whether it is H_1 -colorable. We will construct an acyclic digraph K which is H -colorable if and only if G is H_1 -colorable. The construction of K is exactly as in the previous case with the only difference that G already fixes an acyclic orientation used in the construction. However, it is not obvious that there exists a directed Hamilton path in H with three consecutive vertices B , C , and A inducing H_1 .

Consider the poset $(V(H), \preceq)$ corresponding to H . We say that a triple $[B, A, C]$ of different vertices in H is *nice* if $B \preceq A$ and the pairs A, C and B, C are both incomparable. Obviously, there is a nice triple since H_1 is an induced subdigraph of H . Take a directed Hamilton path P in H on which there is a nice triple $[B, A, C]$ such that the distance between B and A along P is the smallest possible. We will show that the distance between B and A along P is one. Suppose by contradiction that $E \neq B$ is the immediate predecessor of A on P . Note that for any two X, Y such that X precedes Y on P , H contains the arc (X, Y) . (This follows since H is semicomplete.) Hence, if H contains both arcs (A, E) and (E, A) (a double arc (A, E)), then by exchanging A and E we obtain another directed Hamilton path in H with smaller distance of A and B , a contradiction. Thus, we may assume that H contains the arc (E, A) but not (A, E) , i.e., $E \prec A$. Moreover, either $E \prec C$ or they are incomparable, since otherwise $C \prec A$.

Suppose that $B \prec E$. It follows that C and E are incomparable; hence the triple $[B, E, C]$ is nice and the distance between B and E is smaller along P . Hence, B and E must be incomparable. Let F be an immediate successor of B on P . By a similar argument as above, it follows that $B \prec F$, and A and F are incomparable. Therefore, $E \neq F$ and they are incomparable. Now, $[B, F, E]$ is a nice triple with distance one between B and F on P , a contradiction.

We say that a nice triple $[B, A, C]$ on a directed Hamilton path is *very nice* if the distance between B and A along P is one. By the above argument, there is a directed Hamilton path with a very nice triple. Take such a path P and a very nice triple $[B, A, C]$ such that the sum of the distances between B and C and between A and C on P is the smallest possible. We will show that this sum of distances is three. Without loss of generality, suppose that C follows A on P . Suppose by contradiction that $E \neq C$ is the immediate successor of A on P . If E is incomparable with both A and B , then $[B, A, E]$ is a very nice triple with a smaller sum of distances. It follows that C and E must be incomparable (otherwise, by transitivity, at least one of A, C

or B, C would be comparable). If A and E are incomparable as well, then A, C, E induce H_0 in H , a contradiction. Hence, $[A, E, C]$ is a very nice triple with a smaller sum of distances on P , a contradiction.

Obviously, if G is H_1 -colorable, then we can use this coloring to construct an H -coloring of K as above. Conversely, suppose now that K has an H -coloring. As before, it follows that $V(G)$ is mapped to some three vertices of H . Since H_0 is not an induced subdigraph of H , the three vertices induce a subdigraph of H_1 . Therefore, G is H_1 -colorable.

Case 3. Finally, we prove that when H contains F_0 but neither H_0 nor H_1 as an induced subdigraph, the H -coloring problem is NP-complete by reduction from one of the following problems: the acyclic F_0 -coloring problem (Lemma 4.7) or the acyclic F_k -coloring problem for some $k \geq 1$ (Lemma 4.8).

Take a directed Hamilton path P in H . Since H_0 and H_1 are not induced subdigraphs of H , it is easy to see that we can make sure that any two incomparable vertices in the corresponding poset $(V(H), \preceq)$ are consecutive on P . Since F_0 is an induced subdigraph of H there are at least two incomparable pairs. Take two such pairs D, C and B, A which are in this order on P and are closest to each other. Similarly, it is easy to see that for any vertex E in between C and B on P , $D \prec E$, $C \prec E$, $E \prec B$, and $E \prec A$. Therefore, vertices of the subpath P_m of P from D to A induce F_k , where k is the number of vertices between C and D .

We will show that the H -coloring problem is NP-complete by reduction from the acyclic F_k -coloring problem. Let P_ℓ (respectively, P_u) denote the subpath of P containing all vertices preceding D (respectively, following A) on P . Given G , construct the acyclic digraph K similarly as in the previous cases. Obviously, if G is F_k -colorable, then we can use this coloring to construct an H -coloring of K as in the previous cases. Conversely, suppose now that K has an H -coloring. We will show that vertices of $V(G)$ in K are colored with colors on P_m in H . By contradiction, suppose $x \in V(G)$ is colored by Y not on P_m . Without loss of generality, let $Y \in P_\ell$. Since for every vertex z on P_ℓ there is an arc (z, x) in K , the color of z must be either incomparable with Y or a predecessor of Y on P . Since there is at most one incomparable vertex with Y and it must lie on P_ℓ of H , we conclude that the color of z is on P_ℓ in H and different from Y . Since each vertex on P_ℓ of K must have a different color, there are not enough colors for them, a contradiction. Therefore, G is F_k -colorable. $\square$

Acknowledgment. We would like to thank the anonymous referees for their careful reading and extremely helpful comments.

HEREDITARY DOMINATION IN GRAPHS: CHARACTERIZATION WITH FORBIDDEN INDUCED SUBGRAPHS*

ZSOLT TUZA†

Abstract. The leaf graph of a connected graph is obtained by joining a new vertex of degree one to each noncutting vertex. We prove that if a connected graph G is not dominated by any of its induced paths, then G is dominated by a connected induced subgraph whose leaf graph, too, is an induced subgraph of G . It follows that, for every nonempty class $\mathcal{D}$ of connected graphs, all of the minimal graphs not dominated by any induced subgraph isomorphic to some $D \in \mathcal{D}$ are cycles (of well-determined lengths) and leaf graphs of some graphs $H \notin \mathcal{D}$. In particular, if $\mathcal{D}$ is closed under the operation of taking connected induced subgraphs, then the hereditarily $\mathcal{D}$ -dominated graphs are characterized by the following family of forbidden induced subgraphs: leaf graphs of the connected graphs that are not in $\mathcal{D}$, but all of their connected induced subgraphs are in $\mathcal{D}$, and the cycle C_{t+2} , where t is the length of the shortest path not in $\mathcal{D}$ (if $\mathcal{D}$ does not contain all paths). This solves a problem that was open since the 1980s. A solution for the case of induced-hereditary classes $\mathcal{D}$ has been found simultaneously by Bacsó by applying a different method.

Key words. dominating set, forbidden induced subgraph, induced-hereditary property, leaf graph, structural domination

1. Introduction. Let $G = (V, E)$ be a *finite* simple graph. A vertex subset $X \subseteq V$ is called a *dominating set* of G if every $v \in V \setminus X$ is adjacent to some $x \in X$. A *dominating (induced) subgraph* is a(n) (induced) subgraph whose vertex set is dominating in G . We shall use the notation $G' \sqsubseteq G$ to express that G' is an *induced* subgraph of G (allowing $G' = G$). Further definitions and notation will be introduced in section 1.1.

The goal of this short note is to give a complete solution to the long-standing problem of characterizing the *structure* of dominating subgraphs in terms of forbidden induced subgraphs. More precisely, a necessary and sufficient condition will be described for the graphs in which every connected induced subgraph admits a dominating induced subgraph of a given type.

The first paper relating the structure of dominating subgraphs with that of the graphs themselves appears to be [7], where it was proved that every connected graph without induced $2K_2$ (two disjoint edges) has a dominating set that induces a complete subgraph or a P_3 (path of length two). Inspired by this result, a systematic study of this phenomenon with respect to hereditary domination was started in [2]. From this perspective, the characterization of “trivially perfect” graphs in the early paper [9] from 1962 can be viewed as the very first member of a long sequence of theorems of this kind, even if it deals just with a single dominating vertex.

Although several powerful related methods have been developed in earlier papers (the star-cutset lemma [2], the induced path lemma [3], the cut-point lemma, and the sequential construction of nondominating subgraphs [5]), the current proof is

self-contained and unexpectedly short. The heart of the present method is the leaf subgraph theorem. This structural result on connected graphs not dominated by any induced paths is proved in section 2. The complete solution for the graph-class equation $\text{Dom}(\mathcal{D}) = \text{Forb}(\mathcal{F})$ is derived from it in section 3. In the same section, a lemma of independent interest is presented, too, namely, that the operation of creating so-called leaf graphs preserves the “induced subgraph” relation between connected graphs. In the last section we illustrate the method with two applications.

Bacsó [1] has found a different proof of the main theorem simultaneously and also obtained for nonhereditary $\mathcal{D}$ that all 2-connected minimal forbidden subgraphs are cycles. We note here, without entering into details, that, on the other hand, the “king theorem” of [1] can be derived shortly from our leaf subgraph theorem. We refer to the longer paper [1] for a survey on the literature of structural domination.

It should be noted that the situation for *infinite* graphs is different. Some results in that direction have been obtained jointly by Bacsó, Jung, and the author.

1.1. Leaf graphs and the main theorem. Let $\mathcal{D}$ and $\mathcal{F}$ be given (finite or infinite) classes of graphs; it will be assumed throughout that $\mathcal{D} \neq \emptyset$ and all $D \in \mathcal{D}$ are *connected*. We denote by $\text{Forb}(\mathcal{F})$ the class of graphs containing no induced subgraphs isomorphic to any $F \in \mathcal{F}$.

A graph G is said to be *hereditarily $\mathcal{D}$ -dominated* if every *connected* $G' \subseteq G$ has a dominating $D \subseteq G'$, with $D \in \mathcal{D}$. The class of all such G will be denoted by $\text{Dom}(\mathcal{D})$.

Given a graph H with at least two vertices, the *leaf graph* of H —denoted by $F(H)$ —is obtained by attaching a leaf (i.e., joining a “pendant” vertex of degree one) to each of its *noncutting* vertices. This notion was introduced in [5]. In the next section we shall prove the following notion.

LEAF SUBGRAPH THEOREM. *If a connected graph G is not dominated by any induced paths, then it has a connected dominating induced subgraph H that can be extended to its leaf graph $F(H)$ as an induced subgraph of G .*

From this result, the complete solution of the graph-class equation $\text{Dom}(\mathcal{D}) = \text{Forb}(\mathcal{F})$ will be derived in section 3. We say that a graph H is *minimal not in $\mathcal{D}$* if H is connected, $H \notin \mathcal{D}$, and every *connected* proper induced subgraph of H is in $\mathcal{D}$. As usual, let P_n and C_n denote the path and cycle, respectively, on n vertices. The characterization for *hereditary* classes $\mathcal{D}$ is as follows.

MAIN THEOREM. *If $\mathcal{D} \neq \emptyset$ is a class of connected graphs, closed under connected induced subgraphs, then the minimal forbidden induced subgraphs for $\text{Dom}(\mathcal{D})$ are the following:*

- (i) *the leaf graphs $F(H)$ for the graphs H minimal not in $\mathcal{D}$ and*
- (ii) *the cycle C_{t+2} if $P_t \notin \mathcal{D}$ but $P_{t-1} \in \mathcal{D}$.*

In particular, if $\mathcal{D}$ contains all paths, then (ii) is void and there do not exist any 2-connected minimal forbidden induced subgraphs. On the other hand, if $\mathcal{D}$ does not contain all paths, then the value of t above is uniquely determined, since $\mathcal{D}$ is assumed to be a hereditary class.

One direction of the *main theorem*—namely, that the graphs listed in (i) and (ii) are minimal forbidden ones—is easy to see, and therefore the message of the result is that no others exist. For the non-2-connected ones, (i) was already proved in the cut-point lemma of [5]; but the present proof for both (i) and (ii) is entirely self-contained.

In the proofs, the following standard notion will be applied. Given a subgraph H of a graph G and a vertex v of H , a *private neighbor* of v is a vertex $x \in V(G) \setminus V(H)$ whose *unique* neighbor in H is v .

2. Proof of the leaf subgraph theorem. Let H be a connected graph, and suppose that it has $k + 1$ noncutting vertices $v_0, v_1, \dots, v_k$; $k = k(H)$. The case of $k(H) = 1$ characterizes the paths with at least one edge (and $k = 0$ would mean a single vertex, but we do not need to consider it). If H is not a path—that is, if $k(H) \geq 2$ —we assign a value $m(H)$ to H as follows.

First, introduce a positive integer ℓ_i for $0 \leq i \leq k$ as follows. If v_i is not a leaf of H , let $\ell_i = 1$; and if v_i has degree one, let $\ell_i - 1$ be equal to the distance of v_i from the nearest vertex of degree greater than two (i.e., $\ell_i > 1$ in the latter case). This ℓ_i is well-defined because H is supposed to be connected and not a path. We assume that the noncutting vertices are indexed in an order satisfying $\ell_0 \geq \ell_1 \geq \dots \geq \ell_k$. Let

$$m(H) = \sum_{i=0}^k \ell_i \cdot 2^i.$$

We prove next that the following property is valid:

- (1) For each $0 \leq i \leq k$, either $k(H - v_i) < k(H)$ (where $H - v_i$ possibly is a path, for which no m -value is assigned) or $k(H - v_i) = k(H)$ and $m(H - v_i) \leq m(H) - 2^i$.

Indeed, if a cut-vertex x of H becomes noncutting in $H - v_i$, then v_i is an isolated vertex in $H - x$, and thus the ℓ -value for x in $H - v_i$ is precisely $\ell_i - 1$; there can be at most one such x for each v_i , implying that $k(H - v_i) \leq k(H)$. If $\ell_{i+1} < \ell_i$ in H , then x keeps the position of v_i in the noncutting vertex order and yields $m(H - v_i) = m(H) - 2^i$. But otherwise, to make the ℓ -sequence of $H - v_i$ nonincreasing, it is necessary to place x somewhere after ℓ_{i+1} , and then $m(H)$ decreases with a higher power of two.

Now, among all connected dominating induced subgraphs of G , we choose H^* with the smallest k -value and, under this condition, with the smallest m -value, too. We are going to prove that suitable vertices x_i ($i = 0, 1, \dots, k$) can be sequentially selected in G , such that each x_i is a private neighbor of v_i and those x_i are mutually nonadjacent; i.e., the subgraph induced by $V(H^*) \cup \{x_i \mid 0 \leq i \leq k\}$ is isomorphic to $F(H^*)$.

Let i be arbitrary in the range $0 \leq i \leq k$, and suppose that x_j has been selected for all $0 \leq j < i$. In order to find x_i , consider the subgraph H_i of G induced by

$$(V(H^*) \cup \{x_j \mid 0 \leq j < i\}) \setminus \{v_i\}.$$

This H_i is connected (since v_i is noncutting in H^*) and $k(H_i) = k(H^* - v_i)$; moreover, the ℓ -value of each x_j ($j < i$) in H_i is precisely $\ell_j + 1$, where ℓ_j is meant for v_j in H^* . Hence, $m(H_i \cup \{v_i\}) = m(H^*) + 2^i - 1$ holds, because $x_0, \dots, x_{i-1}, v_i, \dots, v_k$ keep the nonincreasing order of ℓ -values. Thus, by (1) for $H = H^*$, either $k(H_i) < k(H^*)$ or $k(H_i) = k(H^*)$ and $m(H_i) < m(H^*)$ is obtained. We conclude, by the choice of H^* , that this H_i cannot be dominating in G , so that the next private neighbor x_i for v_i can be selected.

3. Solution of $\text{Dom}(\mathcal{D}) = \text{Forb}(\mathcal{F})$. Before proving the *main theorem*, we present a useful auxiliary result.

INDUCED LEAF SUBGRAPH LEMMA. *If $H' \subseteq H$ and H' is connected, then $F(H') \subseteq F(H)$. Moreover, if $F(H) \subseteq G$ and $H' \subseteq H$, then also $F(H') \subseteq G$.*

Proof. Let $v_1, \dots, v_s$ be the noncutting vertices of H' . If v_i (for any $1 \leq i \leq s$) is a noncutting vertex of H as well, then it has a private neighbor x_i in $F(H) - H$; and if v_i is a cut-vertex of H , then it has a neighbor x_i in some component of $H - v_i$ that

contains no vertices of H' . This proves that $F(H') \subseteq F(H)$. From here, the second assertion follows by the transitivity of " $\subseteq$." $\square$

Proof of the main theorem. Let a connected graph G and a class $\mathcal{D} \neq \emptyset$ of connected graphs be given, with $\mathcal{D}$ closed under connected induced subgraphs. It suffices to prove that G contains either a dominating induced subgraph in $\mathcal{D}$ or an induced subgraph of type (i) or (ii). Choose either a *shortest* dominating path $P_t \subseteq G$, if there exists one, or a dominating $H \subseteq G$ with the properties described in the *leaf subgraph theorem*. The former, P_t , either is in $\mathcal{D}$ —that surely holds in the particular case of $t = 1$ —or yields $P_{t+2} \subseteq G$ or $C_{t+2} \subseteq G$, since both endpoints of the dominating P_t have private neighbors in G (by the minimality of t). The latter, H , either is in $\mathcal{D}$ or contains a connected $H' \subseteq H$ minimal not in $\mathcal{D}$. On applying the *induced leaf subgraph lemma*, we then obtain $F(H') \subseteq G$. Concerning C_{t+2} , the side condition (ii) is needed because if $P_t, P_{t-1} \notin \mathcal{D}$, then $P_{t+1} \notin \mathcal{D}$ by the assumptions on $\mathcal{D}$, and so P_{t+1} has no dominating subgraph in $\mathcal{D}$; hence, C_{t+2} is not *minimal* non- $\mathcal{D}$ -dominated. $\square$

3.1. Unrestricted $\mathcal{D}$. If $K_1 \notin \mathcal{D}$, then no graph (having at least one vertex) can be *hereditarily* $\mathcal{D}$ -dominated. To avoid this trivial negative case, let $K_1 \in \mathcal{D}$. It is still assumed that all $D \in \mathcal{D}$ are *connected*. Then, the following facts are easy to see:

- A cycle C_{t+2} is not $\mathcal{D}$ -dominated if and only if $P_t, P_{t+1}, C_{t+2} \notin \mathcal{D}$.
- The leaf graph $F(H)$ of a connected graph H is not $\mathcal{D}$ -dominated if and only if there doesn't exist any $D \in \mathcal{D}$ such that $H \subseteq D \subseteq F(H)$.

The second case includes the non- $\mathcal{D}$ -dominated *paths*, too, since $P_{t+2} = F(P_t)$ for all $t \geq 2$.

If a graph G is not (hereditarily) $\mathcal{D}$ -dominated and $G \subseteq G'$, then G' is not hereditarily $\mathcal{D}$ -dominated either. Thus, in characterizing $\text{Dom}(\mathcal{D}) = \text{Forb}(\mathcal{F})$, also for arbitrary $\mathcal{D}$, the class $\mathcal{F}$ is determined by its members *minimal under induced inclusion*. Hence, along the lines of the proof of the *main theorem*, the following solution is obtained.

CHARACTERIZATION THEOREM. *Let $\mathcal{D}$ be a family of graphs, where all $D \in \mathcal{D}$ are connected. Then the minimal forbidden subgraphs for $\text{Dom}(\mathcal{D})$ are those of the cycles and leaf graphs described above that are minimal under the partial order " $\subseteq$."*

To obtain $\mathcal{F}$ for a given $\mathcal{D}$, the following procedure can be designed:

1. Construct $\mathcal{F}^*$ by considering all connected $H \notin \mathcal{D}$ and selecting
 - (a) $L(H)$, if there exist no $D \in \mathcal{D}$ such that $H \subseteq D \subseteq L(H)$, and also
 - (b) C_{t+2} , if H is the path P_t , and $P_t, P_{t+1}, C_{t+2} \notin \mathcal{D}$.
2. Determine $\mathcal{F} = \{\text{minimal members of } \mathcal{F}^* \text{ under } \subseteq\}$.

It is important to note that, in the case of nonhereditary $\mathcal{D}$, first the leaf graphs of the connected graphs $H \notin \mathcal{D}$ and the non- $\mathcal{D}$ -dominated cycles should be selected, and only after that should the minimal ones among them be kept; the opposite order (selecting the minimal graphs $H \notin \mathcal{D}$ and then taking their leaf graphs and cycles) may yield a different—and hence incorrect—output.

4. Applications. Here we present two applications of the method. The first one is an alternative derivation of a result proved in [4] on dominating subgraphs of bounded diameter (what is a nonhereditary property). The second one illustrates with a theorem of [8] on triangle-free graphs how domination in a restricted graph class can be handled.

The proofs apply the steps and notation of the procedure described after the *characterization theorem* of the previous section without further reference to it.

Dominating with bounded diameter. Let $k \geq 0$ be an integer and $\mathcal{D} = \mathcal{D}_k$ the family of graphs of diameter at most k . This $\mathcal{D}$ is not an induced-hereditary class, because, e.g., every wheel graph belongs to it for all k , but removing the central vertex from a wheel yields a cycle, which has a dominating subgraph of diameter at most k only if its length does not exceed $2k + 1$.

The graphs $H \notin \mathcal{D}$ are precisely those containing at least two vertices at distance $k + 1$ apart, which necessarily yields P_{k+2} as an induced subgraph. Thus, $F \in \mathcal{F}^*$ holds if and only if $F = C_t$ for some $t \geq k + 4$ or F is a leaf graph and $P_{k+4} \subseteq F$. Since $P_{k+4} \subseteq C_t$ for all $t > k + 4$, the only candidates to be minimal members of $\mathcal{F}^*$ are P_{k+4} and C_{k+4} . Taking into account that $\text{diam}(C_{k+4}) \leq k$ if and only if $k \geq 3$, we obtain the following:

$$\mathcal{F} = \{P_{k+4}, C_{k+4}\} \text{ if } k \leq 2 \text{ and } \mathcal{F} = \{P_{k+4}\} \text{ if } k \geq 3.$$

Dominating triangle-free graphs with complete bipartite subgraphs.

Let $\mathcal{D}$ be the family of complete bipartite graphs, excluding edgeless graphs with more than one vertex but including K_1 . The following theorem was proved in [8]:

*A triangle-free graph G is hereditarily $\mathcal{D}$ -dominated if and only if
 $P_6 \not\subseteq G$ and $C_6 \not\subseteq G$.*

To derive this from our results, we first observe that P_4 is a graph minimal not in $\mathcal{D}$. Hence, $P_6, C_6 \in \mathcal{F}^*$, and, moreover, the *induced leaf subgraph lemma* yields that $P_6 \subseteq L(H)$ for all H with $P_4 \subseteq H$. On the other hand, if a connected graph H' has more than one vertex and $P_4 \not\subseteq H'$, then $V(H')$ can be partitioned into two nonempty subsets A and B that are completely joined [6]. Since our attention is restricted now to triangle-free graphs, both A and B must be independent sets, so that $H' \in \mathcal{D}$ holds and such an H' cannot generate any further members of $\mathcal{F}^*$. Consequently, $\mathcal{F} = \{P_6, C_6\}$.

MATROID PARITY AND JUMP SYSTEMS: A SOLUTION TO A CONJECTURE OF RECSKI*

JÁCINT SZABÓ†

Abstract. In 1981 András Recski conjectured that, if given a number $q \in \mathbb{N}$, a linearly represented matroid M , a partition $S_1 \dot{\cup} \dots \dot{\cup} S_n$ of a subset of its ground set S into classes of size k , and a prescription $A \subseteq \{0, 1, \dots, k\}$ without two consecutive gaps, then one can find in polynomial time an independent set F of M of size q such that $|F \cap S_i| \in A$ for all $1 \leq i \leq n$, if one exists. In this paper we prove this conjecture. The proof is based on Lovász' result on the polynomial solvability of the matroid parity problem for linearly represented matroids and on an important technique about jump systems, proved by Sebő. We give an application to rigidity theory and another one to the unique solvability of linear networks containing memoryless multiports.

Key words. matroid parity, jump systems, rigidity

1. Introduction. Matroid parity is a problem of high importance in combinatorial optimization. It is a common generalization of the matching problem of graphs and the matroid intersection problem. If M is a matroid on ground set S , and some (not necessarily disjoint) pairs are designated in S , then we call a set of k pairs a *matching* in M , if their union has rank $2k$ (that is, maximum possible). Given a matroid together with some designated pairs, the matroid parity problem is to find a maximum matching in it. Jensen and Korte [5] and Lovász [8] have shown that, in general, the matroid parity problem is of exponential complexity under the independence oracle framework. However, as a groundbreaking result, Lovász [7] gave a polynomial algorithm for finding a maximum matching in a matroid which is linearly represented over $\mathbb{Q}$. The diversity and the importance of solvable special cases of the matroid parity problem make it a vivid and intriguing field of research. For more references and background, see [10, 16].

DEFINITION 1.1. We denote by $\mathbb{N}$ the set of nonnegative integers. If $H \subseteq \mathbb{N}$, then $i \in \mathbb{N} - H$ is called a *gap* of H if $\min H < i < \max H$.

In [14] Recski studied the following slight generalization of the matroid parity problem. For $k \in \mathbb{N}$ and $A \subseteq \{0, \dots, k\}$ we define the problem $P(A)$ as follows. Given a number $q \in \mathbb{N}$, a matroid $M = (S, r)$, and a partition $\pi = S_1 \dot{\cup} \dots \dot{\cup} S_n$ of a subset of S into classes of size k , decide whether M has an independent set F of size q such that $|F \cap S_i| \in A$ for all $1 \leq i \leq n$. This problem was motivated by engineering applications; see [12, 13]. It is easy to see that, if π is a partition into pairs and $A = \{0, 2\}$, we get back the matroid parity problem. Recski [14] proved that, under the independence oracle model, $P(A)$ is polynomial if A is an interval and is of exponential complexity otherwise. He also proved that, if we are given a representation of M over $\mathbb{Q}$, then $P(A)$ is NP-complete if A has two consecutive gaps, and for the prescriptions A without two consecutive gaps he conjectured $P(A)$ to be

polynomial [14]. In this paper we verify a slight extension of this conjecture, Theorem 1.3 below.

DEFINITION 1.2. Let S be a finite set, $S = \dot{\bigcup}_{t \in T} S_t$ be a partition, and $H(t) \subseteq \mathbb{N}$ be prescriptions for all $t \in T$. We say that a set $F \subseteq S$ is H -conformal if $|F \cap S_t| \in H(t)$ for all $t \in T$.

THEOREM 1.3. The following problem is solvable in polynomial time. Given $q \in \mathbb{N}$, a matroid $M = (S, r)$ represented over $\mathbb{Q}$, a partition $S = \dot{\bigcup}_{t \in T} S_t$, and for all $t \in T$ a prescription $H(t) \subseteq \mathbb{N}$ without two consecutive gaps, find an H -conformal independent set F of M of size q , if one exists.

Just like in the linear matroid parity algorithm of Lovász [7], the field $\mathbb{Q}$ can be replaced by any fields where algebraic operations can be performed in constant time.

We show two applications. First we prove a result on a three-dimensional pinning problem of bar-and-joint frameworks. Then we show that Theorem 1.3 yields a polynomially verifiable sufficient condition to the unique solvability of linear networks with memoryless multiports, a question raised by Recski and Takács [13].

2. Proof of the conjecture.

DEFINITION 2.1. For $F \subseteq T$ we denote by $\chi_F \in \{0, 1\}^T$ the characteristic vector of F . For $x, y \in \mathbb{Z}^T$ we say that x' is a step from x to y , if either $x' = x + \chi_t$ and $x(t) < y(t)$ or $x' = x - \chi_t$ and $x(t) > y(t)$ for some $t \in T$. We call $J \subseteq \mathbb{Z}^T$ a jump system if, for all $x, y \in J$ and step x' from x to y , either $x' \in J$ or some step from x' to y is contained in J .

Let $J \subseteq \mathbb{Z}^S$ be a jump system and $\varphi : S \rightarrow T$ a function. For $x \in \mathbb{Z}^S$ let $\varphi x \in \mathbb{Z}^T$ be the vector, with components $\varphi x(t) = \sum \{x(s) : \varphi(s) = t\}$ for $t \in T$. Finally, let $\varphi(J) = \{\varphi x : x \in J\}$, the homomorphic image of J .

Jump systems were introduced by Bouchet and Cunningham [1], who justified their importance by claiming that the following sets are jump systems:

- the set of degree sequences of all subgraphs of an undirected graph $G = (V, E)$, denoted by $J_G \subseteq \mathbb{N}^V$,
- the set of characteristic vectors of bases of a matroid $M = (S, r)$, denoted by $J_M \subseteq \mathbb{N}^S$.

The notion of the homomorphic image was introduced by Cunningham [3], who proved that the homomorphic image of a jump system is a jump system again.

DEFINITION 2.2. Let T be a finite set, $J \subseteq \mathbb{Z}^T$ be a jump system, and $H(t) \subseteq \mathbb{N}$ be a prescription for every $t \in T$. For $x \in \mathbb{Z}^T$ and $t \in T$ define

$$\delta_H^x(t) = \min\{|x(t) - i| : i \in H(t)\},$$

and let $\delta_H^x = \sum \{\delta_H^x(t) : t \in T\}$. Finally, $\delta_H = \min\{\delta_H^x : x \in J\}$. A vector $x \in J$ minimizing δ_H^x is called H -optimal in J .

A set $H \subseteq \mathbb{N}$ of the form $\{l, l+2, \dots, u-2, u\}$ is called a parity interval.

The membership problem of jump systems is to determine δ_H for a jump system J under the assumption that no $H(t)$ contains two consecutive gaps. An involved formula to the membership problem was worked out by Lovász [9]. We do not need this deep result here, only a simpler but very important tool, Lemma 2.4, which was developed by Sebő. This lemma appeared in Cornuéjols [2], where it was originally used in the construction of the first polynomial algorithm to the so-called *degree prescribed subgraph problem*, that is, the problem of determining δ_H for a jump system J_G , if $G = (V, E)$ is an undirected graph. Building on this lemma, it was possible to reduce the improvement of δ_H^x to the much easier problem of determining $\delta_{H'}$, where $H'(v)$ is a parity interval for all $v \in V$. This is exactly what we shall do but now for a jump system $\varphi(J_M)$, with M a matroid.

DEFINITION 2.3 (Sebő [2]). Let $J \subseteq \mathbb{Z}^T$ be a jump system and $H(t) \subseteq \mathbb{Z}$ for $t \in T$ be prescriptions without two consecutive gaps, and let $x \in J$. Define $I(t) \subseteq \mathbb{Z}$ to be the maximal interval such that $x(t) \in I(t)$ and the elements of

$$H^x(t) := I(t) \cap H(t)$$

have the same parity. (Observe that either $I(t)$ is unbounded from above or $\max I(t)$ and $\max I(t) + 1$ belong to $H(t)$. Similarly from below.) Now we define at most $2|T| + 1$ collections of prescriptions:

- H^x .
- ${}^w H^x$ for $w \in T$ with $I(w)$ bounded from above: ${}^w H^x(t) = H^x(t)$ for $t \neq w$ and ${}^w H^x(w) = \{\max I(w) + 1\}$.
- ${}_w H^x$ for $w \in T$ with $I(w)$ bounded from below: ${}_w H^x(t) = H^x(t)$ for $t \neq w$ and ${}_w H^x(w) = \{\min I(w) - 1\}$.

LEMMA 2.4 (Sebő [2]). Let $J \subseteq \mathbb{Z}^T$ be a jump system and $H(t) \subseteq \mathbb{Z}$ for $t \in T$ be prescriptions without two consecutive gaps. Let $x \in J$ be a vector which is not H -optimal in J . Then there exists an $x_0 \in J$ such that $\delta_{H_0}^{x_0} < \delta_H^x$ for either $H_0 = H^x$, or $H_0 = {}^w H^x$, or $H_0 = {}_w H^x$ for some $w \in T$.

Proof. Let $x^* \in J$ with $\delta_H^{x^*} < \delta_H^x$. Choose x' minimizing $\sum \{|x'(t) - x^*(t)| : t \in T\}$ among all vectors $x' \in J$ for which $\delta_H^{x'} \leq \delta_H^x$ and $x'(t) \in I(t)$ for all $t \in T$. If $\delta_H^{x'} < \delta_H^x$, then we are done with $x_0 = x'$ and $H_0 = H^x$. Otherwise there exists a coordinate $z \in T$ with $\delta_H^{x'}(z) > \delta_H^{x^*}(z)$. Assume that $x'(z) > x^*(z)$ (one can argue analogously if $x'(z) < x^*(z)$). Let $x'' = x' - \chi_z$ be a step from x' to x^* . It is easy to see that $\delta_H^{x''} < \delta_H^{x'}$ and $x''(t) \in I(t)$ for all $t \in T$. Thus $x'' \in J$ is impossible by the choice of x' . So we assume that there exists a step $x''' = x'' + \chi_w \in J$ from x'' to x^* (the case $x''' = x'' - \chi_w$ can be treated analogously). Clearly, $\delta_H^{x'''} \leq \delta_H^{x''} + 1 \leq \delta_H^{x'}$; hence by the choice of x' we get $x'''(w) \notin I(w)$. This can happen only if $x''(w) \in H(w)$ and $x''(w) + 1 = x'''(w) \in H(w)$, and thus $\delta_H^{x'''} = \delta_H^{x''} < \delta_H^x$. This means that we are done with $x_0 = x'''$ and $H_0 = {}^w H^x$. $\square$

Proof of Theorem 1.3. Denote $r(M)$ simply by r , and let $l_t = \min H(t)$ and $u_t = \max H(t)$ for $t \in T$. We can clearly assume that $q \leq r$ and that $u_t \leq |S_t|$ for all $t \in T$. We already mentioned that the set of characteristic vectors of bases of a matroid is a jump system. As the q -truncation of M is a matroid, we have that

$$J' = \{\chi_F : F \subseteq S \text{ is independent in } M \text{ of size } q\} \subseteq \{0, 1\}^S$$

is a jump system. We define a function $\varphi : S \rightarrow T$, which maps $s \in S_t$ to $t \in T$ for all $s \in S$, and define $J = \varphi(J') \subseteq \mathbb{N}^T$. J is a jump system, and our goal is to decide whether $\delta_H = 0$ holds in J . Choose a vector $x \in J$. By Lemma 2.4 it is enough to construct a polynomial algorithm which finds an H_0 -optimal vector in J , where H_0 runs over the prescription sets listed in Definition 2.3. Fix such a prescription set H_0 , and recall that $H_0(t)$ is a parity interval for all $t \in T$.

Next we construct a representation over $\mathbb{Q}$ of an auxiliary linear matroid $\hat{M}$; see Figure 1. First, for all $t \in T$ add a set C_t of u_t coloops to M , and then add a set C of $r - q$ coloops to M . The representation of this new linear matroid $\hat{M}$ is trivial to construct, its rank is $\hat{r} = r + \sum u_t + r - q$, and its ground set $\hat{S}$ has size $|S| + \sum u_t + r - q$. We designate some pairs in $\hat{M}$ as follows: For all $t \in T$ take all $|C_t||S_t|$ pairs between C_t and S_t , together with $(u_t - l_t)/2$ disjoint pairs inside C_t , and then take all pairs between C and S .

Using the matroid parity algorithm of Lovász [7] we can find a maximum matching of $\hat{M}$ in polynomial time. Let us denote the size of this matching by ν and the union

FIG. 1. The auxiliary represented matroid $\hat{M}$.

of pairs in it by $K \subseteq \hat{S}$. Recall that K is independent in $\hat{M}$ and $|K| = 2\nu$. Denote by $K' \subseteq K$ the union of those pairs which are disjoint from C , and let $F' = K' \cap S$. Note that F' is independent in M . For a set $F \subseteq S$ we denote $\varphi\chi_F \in \mathbb{N}^T$ by $v(F)$. We will be done if we prove that if $F_0 \subseteq S$ is an independent set of M of size q , minimizing $|F_0 \Delta F'|$ (that is, if $|F_0 \Delta F'| = ||F'| - q|$), then $v(F_0)$ is H_0 -optimal in J .

First, it is not hard to see that

$$\delta_{H_0}^{v(F')}(t) \leq |C_t \setminus K| = u_t - |C_t \cap K| \quad \text{for all } t \in T.$$

Trivially, $r \geq |S \cap K|$ and $r - q \geq |C \cap K|$. Clearly,

$$q - |F'| \leq r - |S \cap K| \quad \text{and} \quad |F'| \leq r - |C \cap K|,$$

and thus

$$||F'| - q| \leq (r - |S \cap K|) + (r - q - |C \cap K|).$$

Summarizing,

$$\begin{aligned} \delta_{H_0}^{v(F_0)} &\leq \delta_{H_0}^{v(F')} + |F_0 \Delta F'| = \sum_{t \in T} \delta_{H_0}^{v(F')}(t) + ||F'| - q| \\ &\leq \sum_{t \in T} u_t - \sum_{t \in T} |C_t \cap K| + 2r - q - |(S \cup C) \cap K| = \hat{r} - |K|. \end{aligned}$$

On the other hand, if F is an independent set of M of size q such that $v(F)$ is H_0 -optimal in J , then it is straightforward to construct a matching of $\hat{M}$ with the union of size $\hat{r} - \delta_{H_0}^{v(F)}$. Thus $\delta_{H_0} = \hat{r} - |K|$, and $v(F_0)$ is indeed H_0 -optimal in J . $\square$

3. Applications to rigidity and to unique solvability of linear networks.

For a thorough background on rigidity we refer to Jackson and Jordán [4]. If $G = (V, E)$ is a graph and $p : V \rightarrow \mathbb{R}^d$ is an embedding into the Euclidean d -space, then (G, p) is said to be a *framework*. We think of the edges of G as rigid bars with flexible joints at the vertices. An *infinitesimal motion* means an assignment of velocity $x(v) \in \mathbb{R}^d$ to each vertex $v \in V$ such that the bar lengths are preserved, that is, $(p(u) - p(v)) \perp (x(u) - x(v))$ for all $uv \in E$. Given a subspace $U_v \leq \mathbb{R}^d$ for all $v \in V$ we say that (G, p) is *fixed* by the collection $(U_v : v \in V)$ if 0 is the only

infinitesimal motion under the constraint $x(v) \in U_v$ for all $v \in V$. We say that $Z \subseteq V$ is a *pinning set* if (G, p) is fixed by the collection

$$U_v = \begin{cases} \{0\} & \text{if } v \in Z, \\ \mathbb{R}^d & \text{if } v \notin Z. \end{cases}$$

We recollect the notion of the *rigidity matrix* $A \in \mathbb{R}^{E \times dV}$ of the framework (G, p) , where $dV = \{(v, i) : v \in V, 1 \leq i \leq d\}$: For each edge $uv \in E$, in the row indexed by uv , the entries in the d columns of u and v contain the d coordinates of $p(v) - p(u)$ and $p(u) - p(v)$, respectively, and the other entries are 0. The rigidity matrix has the important and well-known property that the infinitesimal motions of (G, p) are exactly the vectors $x \in \mathbb{R}^{dV}$ with $Ax = 0$. Let $Z \subseteq V$, and let A_Z be the submatrix of A we get when deleting the $d|Z|$ columns indexed by Z . Observe that $Z \subseteq V$ is a pinning set if and only if $x = 0$ is the only solution of $A_Z x = 0$. This is tantamount to saying that the columns of A_Z are linearly independent or, in other words, that they form an independent set in the column matroid M_A of A . Thus in dimension $d = 2$, the problem of finding a minimum pinning set leads to the parity problem of a linearly represented matroid, which can be solved by the algorithm of Lovász [7]. A combinatorial formula to this problem was subsequently given by Lovász in [6]. For $d = 3$, finding a minimum pinning set is NP-complete by Mansfield [11].

However, with the following modification we get a tractable problem for $d = 3$. Take a partition of V into two subsets V_1 and V_2 , and define $H(v) = \{0, i, 3\}$ for $v \in V_i$. $H(v)$ has no two consecutive gaps for all $v \in V$, so Theorem 1.3 implies that we can find in polynomial time the maximum q for which there exists an H -conformal independent set of M_A of size q . If $J \subseteq 3V$ is such an independent set and $U_v \leq \mathbb{R}^3$ is the subspace spanned by $\{e_i : (v, i) \in 3V \setminus J\}$ ($e_i \in \mathbb{R}^3$ is the i th unit vector), then by the above considerations (G, p) is fixed by $(U_v : v \in V)$. We obtain the following.

THEOREM 3.1. *The following problem is polynomial time solvable. Given a three-dimensional framework (G, p) and a partition $V = V_1 \dot{\cup} V_2$, find a collection $(U_v \leq \mathbb{R}^3 : v \in V)$ minimizing $\sum_{v \in V} \dim U_v$ such that (G, p) is fixed by $(U_v : v \in V)$ and*

- for $v \in V_1$ $U_v = \{0\}$, $U_v = \mathbb{R}^3$, or U_v is a coordinate line,
- for $v \in V_2$ $U_v = \{0\}$, $U_v = \mathbb{R}^3$, or U_v is a coordinate plane.

More generally, assign to every vertex $v \in V$ a set of vectors $\{a_i^v \in \mathbb{R}^d : i \in S_v\}$, where the S_v 's are disjoint finite sets and $S = \bigcup_{v \in V} S_v$. Then define a matrix $A \in \mathbb{R}^{E \times S}$ as follows. For all $uv = e \in E$ and $i \in S_v$ let

$$A_{e,i} = (p(u) - p(v))^T a_i^v,$$

and let the other entries be 0. We point out that if a_i^v is the i th unit vector for all $v \in V$ and $1 \leq i \leq d$, then A is simply the rigidity matrix. Again, if $y \in \mathbb{R}^S$, with $Ay = 0$, then $x \in \mathbb{R}^{dV}$, with $x(v) = \sum \{a_i^v y_i : i \in S_v\}$ is an infinitesimal motion of (G, p) . Thus given a framework (G, p) , and for each $v \in V$ a set of vectors $\{a_i^v \in \mathbb{R}^d : i \in S_v\}$ and prescription $H(v) \subseteq \mathbb{N}$ without two consecutive gaps, we can find in polynomial time a collection $(U_v \leq \mathbb{R}^d : v \in V)$ minimizing $\sum_{v \in V} \dim U_v$ with the following properties:

- (G, p) is fixed by $(U_v : v \in V)$,
- U_v is generated by some vectors a_i^v for $v \in V$,
- $\dim U_v \in H(v)$ for $v \in V$.

Another application of Theorem 1.3 is that we can check in polynomial time a weaker version of a sufficient condition obtained by Recski and Takács [12, 13] to the

unique solvability of linear networks with memoryless multiports. It is well known how to assign a *network graph* $G = (V, F)$ to an electric network containing voltage and current sources and linear memoryless multiports (e.g., resistors and gyrators) in such a way that V corresponds to the wires, disjoint n -tuples of F correspond to the n terminal-pairs of the n -ports, while the remaining edges of F correspond to the voltage and current sources (for a survey on electric networks, see Recski [15]). Recski and Takács [12, 13] introduced the notion of *potentially singular* multiports, which are the only possible devices in the network which can contribute to singularities. If D is a potentially singular n -port and $F_D \subseteq F$ is the set of n corresponding edges in G , then they introduce a collection of k_D partitions of F_D : $\pi_D^j = \{L^j, C^j, N_1^j, \dots, N_{l_j}^j\}$ for $1 \leq j \leq k_D$. They extend the well-known notion of a normal tree as follows.

DEFINITION 3.2 (see [13]). *A normal tree of the network graph $G = (V, F)$ is a spanning tree T of G satisfying the following conditions:*

1. T contains all edges corresponding to voltage sources.
2. T contains no edges corresponding to current sources.
3. If D is a potentially singular n -port, then for all $1 \leq j \leq k_D$ at least one of the following statements is met:
 - (a) $E(T) \cap L^j \neq \emptyset$,
 - (b) $C^j \not\subseteq E(T)$,
 - (c) $|E(T) \cap N_i^j| \neq 1$ for at least one index i with $1 \leq i \leq l_j$.

They proved the following.

THEOREM 3.3 (Recski and Takács [13]). *If the network graph has a normal tree, then the network has a unique solution.*

We show how to decide the existence of a normal tree *under the assumption that* $k_D = 1$ *for all potentially singular multiports* D . First recall that the edge sets of the spanning trees of a graph form the bases of the cycle matroid M_G of $G = (V, F)$. We define a hypergraph $H = (W, \mathcal{E})$, with $F \subseteq W$, and a collection of prescriptions $(H(e) \subseteq \mathbb{N} : e \in \mathcal{E})$ as follows. For every voltage source (resp., current source) and corresponding edge $f \in F$ add a hyperedge $e = \{f\}$ to $\mathcal{E}$ with prescription $H(e) = \{1\}$ (resp., $H(e) = \{0\}$). Then do the following for each potentially singular n -port D with partition $\pi_D = \{L, C, N_1, \dots, N_l\}$ of F_D . First add a set $X = \{x_D, y_D\}$ consisting of two coloops to M_G , and let $\tilde{L} = L \cup \{x_D\}$. In addition, add the following hyperedges to $\mathcal{E}$ with prescriptions as indicated:

1. the classes of $\pi_D - L + \tilde{L}$, with $H(\tilde{L}) = \{1, 2, \dots, |\tilde{L}|\}$, $H(C) = \{0, 1, \dots, |C| - 1\}$, and $H(N_i) = \{0, 2, 3, \dots, |N_i|\}$ for $1 \leq i \leq l$,
2. $U := \bigcup_{1 \leq i \leq l} N_i$, with $\{0, 1, \dots, l - 1\}$,
3. X with $\{0, 2\}$,
4. and $Y := F_D \cup \{y_D\}$ with $\{0, 1, 2\}$.

Denote the resulting matroid, which is just M_G plus some coloops, by M . Finally, construct a matroid M' from M as follows: For every element f of M which is incident to the hyperedges $e_1, \dots, e_d \in \mathcal{E}$ for $d = \deg_H(f)$, replace f by a parallel class $\{f^{e_1}, \dots, f^{e_d}\}$. For $e \in \mathcal{E}$ let $e' = \{f^e : f \in e\}$. In this way $\mathcal{E}' := \{e' : e \in \mathcal{E}\}$ is a partition of the new ground set W' .

CLAIM 3.4. *If B' is an H -conformal base of M' , and B is the corresponding base of M then $B \cap F$ is the edge set of a normal tree in G .*

Proof. If $f \in F$ corresponds to a voltage source (resp., current source) then, as $|B \cap \{f\}| \in H(\{f\})$, we have $f \in B$ (resp., $f \notin B$). Now let D be a potentially singular n -port.

- (a) If $B \cap L = \emptyset$, then necessarily $B' \cap \tilde{L}' = \{x_D^{\tilde{L}}\}$; thus $B' \cap X' = \emptyset$ and so $y_D^Y \in B' \cap Y'$.

- (b) If $C \subseteq B$, then $B' \cap Y'$ contains an element s^Y , with $s \in C$.
- (c) If $|B \cap N_i| = 1$ for all $1 \leq i \leq l$, then $B' \cap N'_i = \emptyset$. As $|B' \cap U'| \leq l - 1$ we can conclude that $B' \cap Y'$ contains an element s^Y , with $s \in U$.

Thus if all of (a), (b), and (c) are violated in Definition 3.2, condition 3, then $|B' \cap Y'| \geq 3$, which is impossible by the hyperedge defined in 4. $\square$

Using similar arguments, from a normal tree of G it is not hard to construct an H -conformal base of M' . As a representation of M' over $\mathbb{Q}$ is trivial to construct using the well-known representation of M_G , we can decide in polynomial time whether M' has an H -conformal base, and we are done.

Acknowledgments. I would like to thank Tibor Jordán, for his suggestions and for calling my attention to the application in rigidity, and András Recski for helpful discussions.

CYCLES INTERSECTING EDGE-CUTS OF PRESCRIBED SIZES*

TOMÁŠ KAISER[†] AND RISTE ŠKREKOVSKI[‡]

Abstract. We prove that every cubic bridgeless graph G contains a 2-factor which intersects all (minimal) edge-cuts of size 3 or 4. This generalizes an earlier result of the authors, namely that such a 2-factor exists provided that G is planar. As a further extension, we show that every graph contains a cycle (a union of edge-disjoint circuits) that intersects all edge-cuts of size 3 or 4. Motivated by this result, we introduce the concept of a coverable set of integers and discuss a number of questions, some of which are related to classical problems of graph theory such as Tutte's 4-flow conjecture and the Dominating Cycle Conjecture.

Key words. graph, edge-cut, coverable set, dominating cycle

AMS subject classification. 05C38

DOI. 10.1137/070683635

1. Introduction. We study the existence of cycles intersecting all edge-cuts of prescribed sizes in a graph. Throughout this paper, a *cycle* in a graph G is a subgraph all of whose vertex degrees are even, and an *edge-cut* (in short, a *cut*) is an inclusionwise minimal set of edges whose removal increases the number of components of G . Our graphs are undirected and contain no loops, but they may contain parallel edges.

Our starting point is the main result of [8].

THEOREM 1.1. *For any planar graph G , there exists a (not necessarily proper) 2-coloring of $V(G)$ such that there is no monochromatic circuit of length 3 or 4.*

In an equivalent dual form, Theorem 1.1 states that every bridgeless planar cubic graph has a 2-factor intersecting all cuts of size 3 or 4. (A graph is *bridgeless* if it is connected and has no bridges.) In the present paper, we extend the latter result to all bridgeless cubic graphs. Furthermore, we lift the regularity assumption, proving the following.

THEOREM 1.2. *Every graph G has a cycle intersecting all cuts of size 3 or 4.*

We note the following direct consequence of this result.

COROLLARY 1.3. *Every 3-edge-connected graph contains a cycle C such that the graph G/C (obtained by contracting each component of C to a vertex) is 5-edge-connected.*

Motivated by Theorem 1.2, we introduce a concept which plays a central role in this paper. Let $\mathbb{N}$ be the set of positive integers and $A \subseteq \mathbb{N}$. We say that a cycle C in a graph G is *A-covering* if it intersects all cuts T with $|T| \in A$. If $\mathcal{Q}$ is a class of graphs, then A is *coverable in $\mathcal{Q}$* if every graph from $\mathcal{Q}$ contains an A -covering cycle. A set that is coverable in the class of all graphs is just said to be *coverable*.

Thus, an equivalent version of Theorem 1.2 is that the set $\{3, 4\}$ is coverable. Which other sets are coverable? $\mathbb{N}$ itself is not; clearly, a connected graph has an $\mathbb{N}$ -covering cycle if and only if it has a spanning Eulerian subgraph (spanning connected cycle), which is not the case, for instance, for the graph $K_{2,3}$ (or for any graph with a bridge). In fact, $K_{2,3}$ shows that even the set $\{2\}$ is not coverable.

For a less trivial example of a noncoverable set, consider $A = \{3, 5\}$ and the Petersen graph P_{10} . For any vertex v of P_{10} , the edges incident with v constitute a cut as P_{10} is 3-edge-connected. Since $3 \in A$, any A -covering cycle is a 2-factor. Every 2-factor F of P_{10} is formed by two circuits of length 5. The complement of F is a cut of size 5 that is not intersected by F . It follows that P_{10} has no A -covering cycle.

On the other hand, it may well be that the presence of P_{10} in a graph G (as a minor) is the only obstruction to the existence of a $\{3, 5\}$ -covering cycle in G . Recall that a graph H is a *minor* of a graph G if H can be obtained from a subgraph of G by a sequence of edge contractions. The graph G is *Petersen-minor-free* (or *P_{10} -free*) if P_{10} is not a minor of G . Petersen-minor-free graphs are the subject of the famous *4-flow conjecture* of Tutte [15]. Since we will not need to go into the details of integer flows (which can be found in [16]), let us state Tutte's conjecture in a form that does not refer to 4-flows.

CONJECTURE 1.4. *The edges of any P_{10} -free bridgeless graph can be covered by two cycles.*

Observe that if $E(G)$ is covered by two cycles C_1 and C_2 , then C_1 is $(2\mathbb{N} + 1)$ -covering, where $2\mathbb{N} + 1 = \{3, 5, 7, \dots\}$. Indeed, any odd cut not intersected by C_1 cannot be covered by C_2 , for the intersection of a cycle and a cut has even size. Conversely, it is not difficult to prove that if G has a $(2\mathbb{N} + 1)$ -covering cycle, then $E(G)$ can be covered by two cycles. Thus, Conjecture 1.4 can equivalently be stated in terms of coverability.

CONJECTURE 1.5. *The set $2\mathbb{N} + 1 = \{3, 5, 7, \dots\}$ is coverable in the class of P_{10} -free graphs.*

Observe that Conjecture 1.5 is not restricted to bridgeless graphs. The reason is that any set $A \subseteq \mathbb{N}$ with $1 \notin A$ is coverable in the class of bridgeless graphs if and only if it is coverable in the class of all graphs.

Conjecture 1.4 is well known to be true for planar graphs. Indeed, this special case is equivalent to the Four Color Theorem (see, e.g., [16]). It follows that $2\mathbb{N} + 1$ is coverable in the class of planar graphs.

To conclude this section, we point out a relation to another long-standing conjecture. A *dominating cycle* in G is a circuit C such that each edge of G is incident with a vertex of C . (Note that in our terminology, “dominating circuit” would be a more appropriate term.) The *Dominating Cycle Conjecture* has several equivalent forms [3, 10, 13]; we state the one due to Fleischner and Jackson [4] (see section 2 for a definition of cyclically k -connected graphs).

CONJECTURE 1.6. *Every cyclically 4-edge-connected cubic graph has a dominating cycle.*

By Tutte's theorem [14], Conjecture 1.6 is true for planar graphs. Note that if G is a cyclically 4-edge-connected cubic graph, then a circuit is a dominating cycle in G if and only if it is $(\mathbb{N} + 3)$ -covering, where $\mathbb{N} + 3 = \{4, 5, 6, \dots\}$. Thus, the following is a generalization of the Dominating Cycle Conjecture.

CONJECTURE 1.7. *The set $\mathbb{N} + 3$ is coverable.*

A result of Thomassen [12, Theorem 4.1] implies that $\mathbb{N} + 3$ is coverable in the class of planar graphs. Further questions related to coverable sets are asked in section 6.

2. Notation and definitions. Let us review a few definitions. As mentioned above, all the graphs we consider are loopless multigraphs. The vertex set and the edge set of a graph G are denoted by $V(G)$ and $E(G)$, respectively. If $E = E(G)$, we write $E(v)$ for the set of edges incident with the vertex v . For a subset $X \subseteq V(G)$, let $G[X]$ denote the subgraph of G induced by the vertices of X . If V_1, V_2 are vertex-disjoint subsets of $V(G)$, let $[V_1, V_2]$ denote the set of edges of G with one endvertex in V_1 and the other endvertex in V_2 . Recall that a *cut* in a connected graph G is a subset $C \subseteq E(G)$ such that $G - C$ is disconnected and C is minimal with this property. Note that $G - C$ has two components, say, G_1 and G_2 , and that $C = [V(G_1), V(G_2)]$. If any of the graphs G_i consists of a single vertex, then C is a *trivial* cut; otherwise C is called *nontrivial*. Similarly, if any of the graphs G_i is a tree, then C is an *acyclic* cut; otherwise C is *cyclic*.

We write $G_1(C)$ ($G_2(C)$, respectively) for the graph obtained from G by contracting all of G_2 (G_1 , respectively) to a new vertex and removing any loops which arise. Note that in both graphs thus constructed, C corresponds to a trivial cut.

Let v be a vertex of degree 2 in a graph. *Suppressing* v consists in removing v along with the incident edges, and joining the former neighbors of v by an edge if they are distinct. Note that if v is incident with two parallel edges, then suppressing v is the same as removing it. To *contract* an edge means to identify its endvertices and remove all the resulting loops. By definition, the contraction of a subgraph is the contraction of all of its edges.

A graph G is *cyclically k -edge-connected* if it contains no cyclic cut of size at most $k - 1$. A cycle H is *spanning* in G if each vertex of G is incident with an edge of H .

We refer to edge cuts of size k as *k -cuts*. Similarly, a set of size n is referred to as an *n -set*. A set of even size is an *even set*. The terms *n -subset* and *even subset* are defined in an analogous way.

3. Interlaced cuts. Before proving Theorem 1.2 (in sections 4 and 5), we need to obtain some information on the possible configurations of cuts of size 3 and 4. Throughout this section, G is a connected graph and $C_1 = [X_1, X_2]$ and $C_2 = [Y_1, Y_2]$ are two cuts in G . For $i, j \in \{1, 2\}$, set $A_{ij} = X_i \cap Y_j$. (See Figure 1 for an illustration.) The sets A_{ij} are called the *regions* corresponding to C_1 and C_2 . We say that C_1 *interlaces* C_2 if each of $G[X_1]$ and $G[X_2]$ contains an edge of C_2 . In this section, we study the interlacement relation for small cuts in connected graphs.

PROPOSITION 3.1. *With the above definitions,*

$$C_1 \cap C_2 = [A_{11}, A_{22}] \cup [A_{12}, A_{21}].$$

Proof. An edge of C_1 joins a vertex of X_1 to a vertex of X_2 , and an edge of C_2 joins a vertex of Y_1 to a vertex of Y_2 . Thus, if $e \in C_1 \cap C_2$, then either e has one endvertex in $X_1 \cap Y_1 = A_{11}$ and the other one in $X_2 \cap Y_2 = A_{22}$, or else e has one endvertex in $X_1 \cap Y_2 = A_{12}$ and the other one in $X_2 \cap Y_1 = A_{21}$. $\square$

By the following proposition, C_1 interlaces C_2 if and only if C_2 interlaces C_1 . If these equivalent conditions hold, then we say that C_1 and C_2 are *interlaced* or that they form an *interlacing pair*.

PROPOSITION 3.2. *The following three claims are equivalent (under our assumption that G is connected):*

- (a) C_1 interlaces C_2 ,
- (b) C_2 interlaces C_1 ,
- (a) (c) all the sets A_{ij} ($i, j \in \{1, 2\}$) are nonempty.

FIG. 1. The regions A_{ij} corresponding to cuts $C_1 = [X_1, X_2]$ and $C_2 = [Y_1, Y_2]$.

FIG. 2. A 2-cut C_1 (vertical edges) interlaced with a cut C_2 of size 3 or 4 (horizontal edges).

Proof. By symmetry, it is enough to prove that (a) $\Rightarrow$ (c) $\Rightarrow$ (b).

We first show that (a) $\Rightarrow$ (c). Since C_1 interlaces C_2 , there exists an edge of C_2 with both endvertices in X_1 . Notice that one of these two endvertices is in $X_1 \cap Y_1$ and the other one is in $X_1 \cap Y_2$. Thus, $A_{11} \neq \emptyset$ and $A_{12} \neq \emptyset$. Similarly, one can show that $A_{21} \neq \emptyset$ and $A_{22} \neq \emptyset$.

It remains to show that (c) $\Rightarrow$ (b). The graph G has an edge e_1 with one endvertex in A_{11} and the other one in A_{21} . Otherwise, since G is connected, the assumptions $A_{11} \neq \emptyset$ and $A_{21} \neq \emptyset$ imply that the set $C^* = [A_{11}, V(G) \setminus A_{11}]$ is nonempty and that it is a proper subset of C_2 . Thus, C^* contradicts the minimality of C_2 . Since $e_1 \in [A_{11}, A_{21}]$ belongs to Y_1 , it follows that $e_1 \in C_1$ and $e_1 \in G[Y_1]$. Similarly, one can show that C_1 has an edge e_2 in $G[Y_2]$. Thus, C_2 interlaces C_1 . $\square$

From the above two propositions, we easily obtain the following:

PROPOSITION 3.3. *Suppose that the cuts C_1 and C_2 are interlaced. Then there exist edges $e_1, e_2 \in C_1 \setminus C_2$ and $f_1, f_2 \in C_2 \setminus C_1$ such that for each $i \in \{1, 2\}$, it holds that $e_i \in [A_{1i}, A_{2i}]$ and $f_i \in [A_{i1}, A_{i2}]$.*

PROPOSITION 3.4. *Let C_1 and C_2 be interlaced cuts in a graph G . If $|C_1| = 2$, then $C_1 \cap C_2 = \emptyset$.*

Proof. Apply Propositions 3.1 and 3.3. $\square$

Observe that by Propositions 3.1–3.3, all the possible mutual positions of the cuts C_1, C_2 from Proposition 3.4, where $|C_2| \in \{3, 4\}$, are as shown in Figure 2.

PROPOSITION 3.5. *If G is a 3-edge-connected graph, then it has no interlacing pair of 3-cuts.*

Proof. Suppose that C_1 and C_2 are two such cuts. Propositions 3.1–3.3 imply that one of the sets $A_{11}, A_{12}, A_{21}, A_{22}$ is connected to the rest of G by at most 2 edges. This contradicts the 3-edge-connectedness of G . $\square$

Propositions 3.1 and 3.3 imply the following:

PROPOSITION 3.6. *Suppose that G is a 3-edge-connected graph, C_1 is a 3-cut, C_2 is a 4-cut, and the cuts C_1 and C_2 are interlaced. Then $C_1 \cap C_2 = \emptyset$.*

The structure of G with respect to the cuts C_1, C_2 from Proposition 3.6 is necessarily the one shown in Figure 3.

FIG. 3. A 3-cut C_1 interlaced with a 4-cut C_2 .

PROPOSITION 3.7. *Suppose that G is a 3-edge-connected graph without nontrivial 3-cuts, C_1 and C_2 are interlaced 4-cuts, and C_1 is cyclic. Then the following hold:*

- (a) $C_1 \cap C_2 = \emptyset$;
- (b) if C_2 is acyclic, then one component of $G - C_2$ consists of a single edge;
- (c) if C_2 is cyclic, then each component of $G - C_1 - C_2$ is incident with exactly two edges of C_1 and two edges of C_2 .

Proof. (a) Suppose that $C_1 \cap C_2 \neq \emptyset$. If the set $[A_{11}, A_{22}]$ contains at least two edges, then Proposition 3.3 implies that each of the sets A_{12}, A_{21} is connected to the rest of G by at most 2 edges; this contradicts the edge-connectivity assumption on G . Thus, $[A_{11}, A_{22}]$ and (by a symmetric argument) $[A_{12}, A_{21}]$ contain at most one edge each.

Suppose now that the set $[A_{12}, A_{21}]$ is empty. Then $[A_{11}, A_{22}]$ contains precisely one edge. Using the assumption that all 3-cuts are trivial, one can easily show that either one of the sets A_{ij} ($i, j \in \{1, 2\}$) is connected to the rest of the graph by at most 2 edges, or for some $i, j \in \{1, 2\}$, the subgraphs $G[X_i]$ and $G[Y_j]$ are isomorphic to K_2 . The former possibility contradicts the edge-connectivity assumption on G , while the latter one contradicts the assumption that C_1 or C_2 is cyclic.

By the above, each of the sets $[A_{11}, A_{22}]$ and $[A_{12}, A_{21}]$ contains precisely one edge. Proposition 3.3 implies that each A_{ij} is connected to the rest of the graph by exactly 3 edges. Since G contains no nontrivial 3-cuts, it follows that each A_{ij} consists of a single vertex, and so G is isomorphic to K_4 . Hence, both of the cuts C_1 and C_2 are acyclic, a contradiction.

(b) Given an acyclic 4-cut C_2 , let K be a component of $G - C_2$ that contains no cycle. Thus, K is a tree, and since K contains an edge of C_1 (because C_1 and C_2 are interlaced), we have $|V(K)| \geq 2$. It follows that K has at least two leaves. Since G is 3-edge-connected, each leaf of K is incident with at least two edges of C_2 . This implies that K has exactly two leaves, and hence is a path. Any internal vertex of the path would also have to be incident with an edge of C_2 , which is impossible. We conclude that K consists of a single edge.

(c) Assume that both C_1 and C_2 are cyclic and let K be a component of $G - C_1 - C_2$. Also let L denote the component of $G - C_2$ containing K . By symmetry, all we need is to show that K is incident with at least two edges of C_1 . Suppose the contrary. Then either K or the other component K' of $G - C_1 - C_2$ contained in L is incident with at most 3 edges of $C_1 \cup C_2$. Our assumption that G is 3-edge-connected implies that, in fact, both K and K' are incident with exactly two edges of C_2 and one edge of C_1 . Since G has no nontrivial 3-cuts, both K and K' consist of a single vertex. We conclude that L consists of a single edge, which contradicts the assumption that $G - C_2$ is cyclic. $\square$

The structure of G with respect to the cuts C_1, C_2 from Proposition 3.7 is as depicted in Figure 4.

FIG. 4. Two interlaced 4-cuts from Proposition 3.7.

PROPOSITION 3.8. If C_1 and C_2 are distinct noninterlaced cuts with $C_1 \cap C_2 \neq \emptyset$, then precisely one of the sets $A_{11}, A_{12}, A_{21}, A_{22}$ is empty.

Proof. Note that by Proposition 3.2, at least one of the sets A_{ij} is empty. Since the cuts are distinct, no more than one of these sets can be empty. $\square$

The structure of two distinct noninterlaced cuts with nonempty intersection is shown in Figure 5. Note that between any two of the 3 parts, there must be at least one edge.

FIG. 5. Noninterlaced cuts C_1 and C_2 with common edges.

4. Graphs with small degrees. By a well-known theorem of Petersen, every bridgeless cubic graph G has a 2-factor. In this section, we prove a result which implies that in fact, G has a 2-factor which is a $\{3, 4\}$ -covering cycle. To this end, we shall make use of the following extension of Petersen's theorem, due to Schönberger [11].

THEOREM 4.1. Let G be a cubic bridgeless multigraph and $e, f \in E(G)$. Then G has a 2-factor containing both e and f .

Let v be a vertex of degree 4 in a graph $G = (V, E)$. Let $Y \subset E(v)$ be a 2-set and let $X \subseteq E(v)$ be a nonempty even set. Note that if $|X| \neq 2$, then $X = E(v)$. We say

that X crosses Y if $X \cap Y \neq \emptyset$ and $Y \neq X$. Thus, $E(v)$ crosses each of its 2-subsets. For example, if $E(v) = \{a, b, c, d\}$ and $Y = \{a, b\}$, then the even sets which cross Y are $\{a, c\}$, $\{a, d\}$, $\{b, c\}$, $\{b, d\}$, and $\{a, b, c, d\}$.

Let $w \in V(G)$. We say that a subgraph $H \subseteq G$ extends a set $X \subseteq E(w)$ if $E(H) \cap E(w) = X$. For brevity, we call a cycle *good* if it is $\{3, 4\}$ -covering.

For a partition E_1, E_2 of $E(w)$, let $G(w, E_1, E_2)$ denote the graph constructed from G by splitting w into two new adjacent vertices w_1 and w_2 so that $E(w_1) = E_1 \cup \{w_1 w_2\}$ and $E(w_2) = E_2 \cup \{w_1 w_2\}$. Notice that G can be obtained from $G(w, E_1, E_2)$ by contracting the edge $w_1 w_2$. Furthermore, any cut in G is a cut in $G(w, E_1, E_2)$. Thus, a good cycle in $G(w, E_1, E_2)$ gives rise to a good cycle in G .

If C is a cut in a graph G , then we identify C with the corresponding edge-sets in $G_1(C)$ and $G_2(C)$. We say that a subgraph F_1 of $G_1(C)$ and a subgraph F_2 of $G_2(C)$ agree on C if they contain precisely the same edges of C (with respect to this identification). For such a pair of subgraphs, $F_1 \cup F_2$ denotes the subgraph of G consisting of all edges corresponding to those in F_1 or in F_2 .

LEMMA 4.2. *Suppose that C is a minimum size cut in a bridgeless graph G and $|C| \leq 3$. If each graph $G_i(C)$ ($i = 1, 2$) has a good cycle F_i such that F_1 and F_2 agree on C , then $F_1 \cup F_2$ is a good cycle of G .*

Proof. We need to verify that $F_1 \cup F_2$ intersects each cut of size 3 or 4 in G . Let D be such a cut. Let A_{ij} ($i, j \in \{1, 2\}$) be the regions corresponding to the cuts $C_1 = C$ and $C_2 = D$ in G as defined at the beginning of section 3. If C and D are not interlaced, then D corresponds to a cut D' of the same size in some $G_i(C)$ (in $G_1(C)$, say). Since F_1 is a good cycle, it intersects D' , which implies that $F_1 \cup F_2$ intersects D .

We can thus assume that C and D are interlaced. By Propositions 3.4–3.6, the structure of G with respect to C and D is shown in Figure 2 or 3. Observe that in each of the possible cases, there is a region (say, A_{11}) incident with a single edge of C and 2 or 3 edges of D . Let R be the set of edges of $G_1(C)$ with exactly one endvertex in A_{11} . Since R is a cut of size 3 or 4 in $G_1(C)$, it is intersected by F_1 . As $|R \cap C| = 1$, F_1 must use at least one edge of D . It follows that $F_1 \cup F_2$ intersects D . $\square$

The following theorem deals with $\{3, 4\}$ -covering cycles in graphs with maximum degree at most 4, the focus being on cubic graphs where any such cycle is a 2-factor.

THEOREM 4.3. *Let G be a 2-connected graph and let v be a vertex of G . Assume that v is of degree at most 4 and all the other vertices of G are of degree at most 3.*

- (a) *If v is of degree at most 3, then each 2-set $Y \subset E(v)$ can be extended to a good cycle of G .*
- (b) *If v is of degree 4, then there exists a 2-set $X \subset E(v)$ such that every even set $Y \subseteq E(v)$ which crosses X can be extended to a good cycle of G .*

Before proving Theorem 4.3, let us consider an example. Let v be a vertex of degree 4 and write $E(v) = \{a, b, c, d\}$ and $Y = \{a, b\}$. Part (b) of the theorem claims that each of the sets $\{a, c\}$, $\{a, d\}$, $\{b, c\}$, $\{b, d\}$, and $\{a, b, c, d\}$ can be extended to a $\{3, 4\}$ -covering cycle of G .

Proof of Theorem 4.3. Suppose that the theorem is false and G is a counterexample with the minimum number of vertices. Since G is 2-connected, $|V(G)| > 2$ and G has no vertices of degree 1. In a series of claims, we show that G is cyclically 5-edge-connected.

Whenever we consider a cut $C = [X_1, X_2]$ and the graphs $G_1(C)$ and $G_2(C)$, we write v_1 for the vertex of $G_2(C)$ obtained by contracting X_1 . Similarly, we let v_2 denote the vertex of $G_1(C)$ obtained by contracting X_2 .

CLAIM 1. *The graph G contains no vertex of degree 2.*

If $w \neq v$ is a vertex of degree 2, then use the induction hypothesis to find a good cycle in the graph obtained by suppressing w and note that this yields a suitable good cycle in G . We may thus assume that the only vertex of degree 2 is v . Let z be a neighbor of v . Since G is 2-connected, v and z are joined by a single edge. Consider the graph G' obtained by suppressing v and let e be the newly created edge. The degree of z in G' is 3. Let $Y \subset E(G')$ be a set consisting of e and one other edge incident with z . Use the induction hypothesis to find a good cycle of G' extending Y . This yields a suitable good cycle of G .

CLAIM 2. *The degree of v is 4.*

Assume that v has degree 3. Let $Y = \{a_1, a_2\} \subset E(v)$ be the given 2-set, and let b be the edge in $E(v) \setminus Y$. Let w be the endvertex of a_1 distinct from v . If the edges a_1, a_2 are parallel, then since G is bridgeless, $|V(G)| > 2$, and the degree of w is 3, there is a unique edge $c \in E(w) \setminus Y$. This implies that $\{b, c\}$ is a 2-cut. Let G' be the graph obtained from $G \setminus \{v, w\}$ by adding an edge e' joining the endvertex $v' \neq v$ of b to the endvertex $w' \neq w$ of c . The edge e' is not a loop, as otherwise G would contain a bridge incident with v' .

Note that the degree of v' in G' is 3. Let Y' be the set of edges incident with v' distinct from e' . By the induction hypothesis (in which v' plays the role of v), G' has a good cycle F' that extends Y' and, therefore, does not contain e' . Since any cut of size 3 or 4 in G corresponds to a cut of size 3 or 4 in G' (although not necessarily a cut of the same size), it follows that adding the edges a_1 and a_2 to F' , we obtain a good cycle of G extending Y .

It remains to consider the case that a_1 and a_2 are not parallel. Let G'' be the graph obtained by contracting a_1 . Clearly, we may assume that b is not parallel to a_1 , so the contraction does not create a loop. Note that G'' contains a unique vertex v'' of degree 4. Write E'' for the set of edges incident with v'' . By the induction hypothesis (applied to v''), find a 2-set $X'' \subset E''$ with the property stated in the theorem. Since a subset of E'' crosses X'' if and only if it crosses its complement in E'' , we may assume that $a_2 \in X''$. Observe that there are exactly two 2-subsets of E'' containing a_2 and crossing X'' . It follows that at least one of them—call it Y'' —is different from $\{a_2, b\}$. By the assumption, Y'' can be extended to a good cycle F'' of G'' . The corresponding edges in G , together with a_1 , comprise a good cycle of G .

CLAIM 3. *The graph G is 3-edge-connected and cyclically 4-edge-connected.*

Assume the claim false. Since G is bridgeless, there is a cut C that is either a 2-cut or a cyclic 3-cut. Consider the graphs $G_1(C)$ and $G_2(C)$. We may assume that $v \in V(G_1(C))$. Let E_1 be the set of edges of $G_1(C)$ incident with v . By the minimality of G , there is a 2-set $X \subset E_1$ such that any even set $Y \subset E_1$ crossing X can be extended to a good cycle of $G_1(C)$. We assert that X , as a subset of $E(G)$, has the property stated in the theorem.

Indeed, let $Y \subset E(v) \subset E(G)$ be an even set crossing X . In $G_1(C)$, Y can be extended to a good cycle F_1 . Let Y_2 be the set of edges of $F_1 \subset G_1(C)$ containing the vertex v_2 of $G_1(C)$. (Recall that this is the vertex representing a contracted component of $G - C$.) The size of Y_2 is either 0 or 2.

If $|Y_2| = 2$, we can use the minimality of G to extend Y_2 to a good cycle F_2 of $G_2(C)$. The cycles F_1 and F_2 agree on C . By Lemma 4.2, $F_1 \cup F_2$ is a good cycle of G .

In the remaining case, Y_2 is empty (and, necessarily, $|C| = 2$). Let z be a neighbor of v_1 in $G_2(C)$. By Claim 1, the degree of z in $G_2(C)$ is at least 3. Let Y'_2 be a set of

two edges incident with z but not with v_2 . (Note that v_2 is not incident with a pair of parallel edges by the 2-connectedness of G .) If we extend Y'_2 to a good cycle F_2 in $G_2(C)$, then F_1 and F_2 may be combined as above to a good cycle in G .

CLAIM 4. *Every cyclic 4-cut is interlaced with some other cyclic 4-cut.*

Suppose that the claim is false. We may thus assume that a cyclic 4-cut $C = \{a, b, c, d\}$ is not interlaced with any other cyclic 4-cut. It follows that every cyclic 4-cut corresponds to a 4-cut in either $G_1(C)$ or $G_2(C)$. Clearly, a trivial cut in G corresponds to a cut of the same size in G_1 or G_2 . Since, by Claim 3, G has no nontrivial 3-cuts, we conclude the following:

(*) *Each 3-cut in G corresponds to a 3-cut in $G_1(C)$ or $G_2(C)$, and each cyclic 4-cut in G corresponds to a 4-cut in $G_1(C)$ or $G_2(C)$.*

Note that $G_1(C)$ and $G_2(C)$ are bridgeless and v_2 and v_1 are vertices of degree 4.

We may assume that $v \in V(G_1)$. Let $E_i = E(G_i)$ ($i = 1, 2$). By the minimality of G , there is a 2-set $X_2 \subset E_2(v_1)$ such that any even subset of $E_2(v_1)$ crossing X_2 can be extended to a good cycle of G_2 .

Let $G_1^* = G_1(v_2, X_2, C \setminus X_2)$ be the result of the splitting operation defined at the beginning of this section. Thus, v_2 is split into two adjacent vertices. Let us write v_2^1 for the vertex incident with the edges in X_2 and v_2^2 for the other vertex. Furthermore, we let E_1^* denote the set $E(G_1^*)$. Note that G_1^* has fewer vertices than G . By the minimality of G , G_1^* contains a 2-set $X_1 \subset E_1^*(v)$ such that any even set $Y_1 \subset E_1^*(v)$ crossing X_1 can be extended to a good cycle of G_1 . We claim that $X = X_1$ satisfies the analogous condition for G in place of G_1 . Let $Y \subset E(v)$ be an even set. Extend the corresponding set of edges of G_1^* to a good cycle F_1^* of G_1^* . This determines a good cycle F_1 of G_1 . Consider the set Y_2 of edges of $E_2(v_1)$ corresponding to the edges in $F_1 \cap C$.

Due to the way we split v_2 , the even set Y_2 crosses X_2 , for otherwise F_1^* would not pass through either v_2^1 or v_2^2 . By the choice of X_2 , Y_2 can be extended to a good cycle F_2 of G_2 . The good cycles F_1 and F_2 agree on C . By (*), the cycle $F_1 \cup F_2$ intersects all 3-cuts and cyclic 4-cuts of G .

We claim that if C' is an acyclic 4-cut, then it is also intersected by $F_1 \cup F_2$. This is clear if C' is not interlaced with C . In the opposite case, Proposition 3.7 (b) implies there is a 3-cut C'' in G such that C' intersects C'' in two edges. Since $F_1 \cup F_2$ intersects C'' , it must also intersect C' . We conclude that $F_1 \cup F_2$ is a good cycle of G .

CLAIM 5. *The graph G is cyclically 5-edge-connected.*

Assume, to the contrary, that G contains a cyclic 4-cut C . By Claim 4, C is interlaced with a cyclic 4-cut C' . By Proposition 3.7 (c), each component of $G - C_1 - C_2$ is incident with exactly two edges from C_1 and two edges from C_2 ; moreover, these edges clearly form a 4-cut in G (see Figure 4 (b)). We may thus define $\mathcal{E} = (E_0, E_1, \dots, E_{k-1})$ to be an inclusion-maximal collection of pairwise disjoint 2-subsets of $E(G)$ with the following properties:

- (1) $C = E_r \cup E_s$ and $C' = E_{r'} \cup E_{s'}$ for some $r, s, r', s' \in \{0, 1, \dots, k-1\}$,
- (2) $E_i \cup E_j$ is a 4-cut for all distinct $i, j \in \{0, 1, \dots, k-1\}$.

Notice that $k \geq 4$ (since r, s, r' , and s' are all distinct). Let E^* be the union of all the sets E_i . We may assume that $E_0, E_1, \dots, E_{k-1}$ are enumerated in such a way that for each $j \in \{0, 1, \dots, k-1\}$, the graph $G - (E_j \cup E_{j+1})$ has a component A_j containing no edge from E^* (the indices being taken modulo k throughout this proof). Clearly, the structure of G with respect to the sets E_i is “cyclic” as shown in Figure 6.

FIG. 6. The structure of G with respect to the sets E_i .FIG. 7. The cut C^* in the proof of Claim 5 (shown in bold lines).

We now prove that for each j , $E_j \cup E_{j+1}$ is an acyclic 4-cut. Assume the opposite. By Claim 4, $E_j \cup E_{j+1}$ is interlaced with a cyclic 4-cut C^* . Let B be a component of $G - (E_j \cup E_{j+1}) - C^*$ contained in A_j . Proposition 3.7 (c) implies that B is incident with two edges (e_1 and e'_1) of $E_j \cup E_{j+1}$ and two edges (c and c') of C^* . If $E_j = \{e_1, e'_1\}$, then $\{c, c'\} \cup E_j$ and $\{c, c'\} \cup E_{j+1}$ are 4-cuts and, more generally, the collection $(\{c, c'\}, E_0, \dots, E_{k-1})$ satisfies (1) and (2) above. This leads to a contradiction with the maximality of k . Since a symmetric argument applies if $E_{j+1} = \{e_1, e'_1\}$, we conclude that $e_1 \in E_j$ and $e'_1 \in E_{j+1}$. Let e_2 be the edge of E_j distinct from e_1 , and let e'_2 be the edge of E_{j+1} distinct from e'_1 . The situation is illustrated in Figure 7.

Since e_1 and e_2 are in different components of $G - C^*$, their endvertices in A_{j-1} must be in different components of $A_{j-1} - C^*$. Thus, A_{j-1} contains an edge d of C^* .

FIG. 8. The prism $C_7 \square K_2$ with a contracted edge.

By a similar argument, A_{j+1} contains an edge d' of C^* . Since $|C^*| = 4$, each of A_{j-1} and A_{j+1} contain exactly one edge of C^* , and each A_i with $i \notin \{j-1, j, j+1\}$ is disjoint from C^* . Note that there is at least one such set A_i , since we observed above that $k \geq 4$.

Each component of $A_{j-1} - d$ is incident with an edge of E_{j-1} , for otherwise $\{e_1, d\}$ or $\{e_2, d\}$ would be a 2-cut in G . But A_{j-2} contains no edge of C^* , and hence all of $A_{j-1} - d$ is contained in a single component of $G - C^*$. By the same token, this component also contains $A_{j+1} - d'$. It follows that C^* does not separate G , which is a contradiction. We have shown that each $E_j \cup E_{j+1}$ is an acyclic 4-cut as claimed.

This implies that each A_j is either a single vertex or a copy of K_2 . If A_j is a single vertex, then this vertex is v and it is adjacent to each of the four vertices of $A_{j-1} \cup A_j$. In the other case, each of the two vertices $\{a_j, a'_j\}$ of A_j is adjacent to a vertex from A_{j-1} and a vertex from A_{j+1} . Finally, a_j and a'_j have no common neighbor except possibly for v . Thus, we have completely determined the structure of G . It can be described as follows. Let B_k be the k -prism (the Cartesian product of a cycle C_k with K_2). There are two copies of C_k in B_k ; let $a_0, \dots, a_{k-1}$ be the vertices of one copy and $b_0, \dots, b_{k-1}$ be the vertices of the other copy, with a_i adjacent to b_i in B_k for each i . By the above, G is (up to isomorphism) the graph obtained from B_k by contracting the edge $a_0 b_0$ (see Figure 8).

Let us determine which even subsets of $E(v)$ can be extended to a good cycle. Let $Y \subseteq E(v)$ be an even subset. First, if $Y = E(v)$, then the cycle consisting of all the edges $a_i a_{i+1}$ and $b_i b_{i+1}$ (indices modulo k) is good and extends Y . A good cycle extending $\{va_1, vb_1\}$ is $va_1 a_2 \dots a_{k-1} b_{k-1} b_{k-2} \dots b_1 v$, while a good cycle extending $\{va_{k-1}, vb_{k-1}\}$ is obtained in a symmetric manner. The remaining cases depend on the parity of k .

Assume that k is odd and $Y = \{va_1, va_{k-1}\}$. A good cycle extending Y is $va_1 b_1 b_2 a_2 \dots b_{k-1} a_{k-1} v$. The case $Y = \{vb_1, vb_{k-1}\}$ is symmetric. Thus, if we define $X = \{va_1, vb_{k-1}\}$, then any even subset of $E(v)$ crossing X can be extended to a good cycle.

If k is even, then $Y = \{va_1, vb_{k-1}\}$ extends to the good cycle $va_1 b_1 b_2 a_2 \dots a_{k-1} b_{k-1} v$, and the case $Y = \{vb_1, va_{k-1}\}$ is symmetric again. We put $X = \{vb_1, vb_{k-1}\}$ and observe that, as above, every even subset of $E(v)$ that crosses X extends to a good cycle. This contradiction with the assumption that G is a counterexample establishes Claim 5.

By Claim 5, each cut C of size 3 or 4 in G is acyclic. Thus, one component of $G - C$ is a copy of K_2 (if $|C| = 4$) or a single vertex (if $|C| = 3$).

Let $E(v) = \{a, b, c, d\}$. If every even subset Y' of $E(v)$ can be extended to a good cycle of G , then we are done. Therefore, suppose that for some Y' , this is not the case.

If $Y' = E(v)$, then consider the cubic bridgeless graph $G(v, \{a, b\}, \{c, d\})$. By Theorem 4.1, $\{a, b\}$ can be extended to a 2-factor F of $G(v, \{a, b\}, \{c, d\})$. Note that F contains c and d . Thus, F corresponds to a good cycle of G that contains all the edges of Y' , a contradiction.

We may therefore assume that Y' is a 2-subset of $E(v)$, say $Y' = \{a, b\}$, and define $X = Y'$. Let Y be an even subset of $E(v)$ which crosses X . Since we have already observed that $E(v)$ extends to a good cycle of G , it may be assumed that $|Y| = 2$, say (without loss) $Y = \{a, d\}$. Consider the graph $G(v, \{a, c\}, \{b, d\})$. Let v_1, v_2 be the adjacent vertices into which v is split. Using Theorem 4.1, extend $\{a, v_1v_2\}$ to a 2-factor F of $G(v, \{a, c\}, \{b, d\})$. Notice that F contains precisely one of the edges b, d . It cannot be b , for otherwise we obtain a good cycle of G with $F(v) = X$, and this contradicts the choice of X . Thus, F must contain d . Since $F(v) = \{a, d\}$ and F is a good cycle of G , we obtain the right extension of Y , and we have established the theorem. $\square$

COROLLARY 4.4. *Every graph with maximum degree at most 3 has a $\{3, 4\}$ -covering cycle.*

Theorem 4.3 implies the following strengthening of Theorem 4.1.

COROLLARY 4.5. *Every cubic bridgeless graph has a 2-factor which intersects all cuts of size 3 and 4. Moreover, any two incident edges can be extended to such a 2-factor.*

5. An extension to arbitrary graphs. In this section, we generalize Corollary 4.4 to graphs with unrestricted degrees which, moreover, do not need to be bridgeless. We first prove a lemma that can be used to reduce coverability questions to the case of cubic graphs.

Let us call a class $\mathcal{Q}$ of graphs *splittable* if every graph $G \in \mathcal{Q}$ of maximum degree $\Delta(G) \geq 4$ contains a vertex v such that for some partition (E_1, E_2) of the set of edges incident with v , it holds that $G(v, E_1, E_2) \in \mathcal{Q}$ and $|E_1|, |E_2| \geq 2$. (Recall that the graph $G(v, E_1, E_2)$ is defined at the beginning of section 4.) As usual, the class $\mathcal{Q}$ is called *minor-closed* if every minor of a graph in $\mathcal{Q}$ is in $\mathcal{Q}$.

LEMMA 5.1. *Let $\mathcal{Q}$ be a splittable, minor-closed class of graphs and $A \subset \{3, 4, \dots\}$ a set of integers. Then A is coverable in $\mathcal{Q}$ if and only if A is coverable in the class of all cubic bridgeless graphs in $\mathcal{Q}$.*

Proof. The “only if” direction is clear. To prove the converse, suppose that a set A is coverable in the class of cubic bridgeless graphs in $\mathcal{Q}$ but not in $\mathcal{Q}$ itself. For a graph H , let $\Delta(H)$ denote the maximum degree of H and let $V_\Delta(H)$ be the set of vertices of degree $\Delta(H)$. Choose a graph $G \in \mathcal{Q}$ with no A -covering cycle and with the property that the triple $(\Delta(G), |V_\Delta(G)|, |V(G)|)$ is minimal in the lexicographic ordering. By our assumptions, G contains either a bridge or a vertex of degree different from 3. We distinguish three possible cases. In each case, we consider a suitable reduction of G to a “smaller” graph that preserves cuts whose cardinality is in A , which enables us to reach a contradiction.

Assume first that G contains a bridge e . Let G_1 and G_2 be the components of $G - e$. Since each G_i is in $\mathcal{Q}$, the induction hypothesis implies that it contains an A -covering cycle F_i . Furthermore, every cut in G except $\{e\}$ corresponds to a cut of the same size in G_1 or G_2 . Since $1 \notin A$, $F_1 \cup F_2$ is A -covering in G .

Next, assume that v is a vertex of degree 2 and let $E(v) = \{e_1, e_2\}$. Let G' be the graph obtained by suppressing v (and removing the resulting loop if e_1 and e_2 are parallel). Noting that $2 \notin A$, it is not difficult to see that A -covering cycles in G' (which exist by the induction hypothesis since G' is a minor of G) correspond to A -covering cycles in G .

Finally, let v be a vertex of degree at least 4. Using the assumption that $\mathcal{Q}$ is splittable, choose a partition of $E(v)$ into sets E_1 and E_2 with $|E_1|, |E_2| \geq 2$ such that $G^* = G(v, E_1, E_2)$ is in $\mathcal{Q}$. As above, the minimality of G implies that G^* contains an A -covering cycle F^* . Since every cut of G corresponds to a cut of the same size in G^* , F^* determines an A -covering cycle in G , a contradiction. $\square$

We can now derive Theorem 1.2, stated in section 1.

THEOREM 1.2. *Every graph G has a cycle intersecting all cuts of size 3 or 4.*

Proof. We apply Lemma 5.1 to the class $\mathcal{Q}$ of all graphs and $A = \{3, 4\}$. The result then follows from Corollary 4.4. $\square$

6. Concluding remarks. By Theorem 1.2, both the sets $\{3\}$ and $\{4\}$ are coverable. On the other hand, $\{1\}$ and $\{2\}$ are not. How about the other single-element sets?

QUESTION 6.1. *Is it true that for all $k \geq 3$, $\{k\}$ is coverable?*

We are unable to say anything for $k \geq 5$, except that Conjecture 1.7 clearly implies an affirmative answer to this question. On the other hand, since (as we noted in section 1) the conjecture is true for planar graphs, any set $\{k\}$ is coverable in the class of planar graphs (which will be denoted by $\mathcal{P}$ throughout this section).

Having determined which sets of size 1 are coverable in $\mathcal{P}$, we may attempt the same for sets of size 2. Let $A = \{a, b\}$ be a pair of positive integers with $a < b$. If $a \leq 2$, then A is not coverable in $\mathcal{P}$, and if $a \geq 4$, then the planar case of Conjecture 1.7 implies that A is coverable in $\mathcal{P}$. Thus, we may assume that $a = 3$. Since the set $2\mathbb{N} + 1 = \{3, 5, 7, \dots\}$ is coverable in $\mathcal{P}$ (by the Four Color Theorem), we may assume that b is even and $b \geq 6$.

QUESTION 6.2. *Let $k \geq 3$. Is $\{3, 2k\}$ coverable in $\mathcal{P}$?*

In fact, this is an equivalent form of a question posed by Broersma et al. [2] in connection with Theorem 1.1: For which $k \geq 3$ can one 2-color the vertices of every planar graph in such a way that there is no monochromatic circuit of length 3 or $2k$? To our knowledge, the question is open. It may even be that $\{3, 2k\}$ ($k \geq 3$) is coverable in the class of all graphs.

One might speculate that even the set consisting of 3 and all the numbers $2k$ ($k \geq 2$) is coverable. We show that this is not the case.

PROPOSITION 6.3. *The set $A = \{3, 4, 6, 8, 10, \dots\}$ is not coverable.*

Proof. Let G be a 3-connected, non-Hamiltonian, cubic bipartite graph. (Such graphs were first constructed by J. D. Horton; see [1, Exercise 4.2.14] or [6].) Let C be an A -covering cycle in G . As $3 \in A$, C is a 2-factor. Since C has more than one component, there exists a cut K contained in the complement of C . Let G_1 denote a component of $G \setminus K$. The size of K must be odd since $|K| \neq 2$ and C is A -covering. Thus, the number of vertices of G_1 is odd. However, C covers the vertices of G_1 by disjoint circuits of even length, a contradiction. $\square$

A computer-assisted investigation of a smallest known non-Hamiltonian bipartite cubic graph on 50 vertices constructed in [5] (see also [9]) shows that this graph in fact admits no $\{3, 4, 6, 8, 10\}$ -covering cycle. We are indebted to Ondřej Rucký for this information.

If we restrict our attention to the class $\mathcal{P}$, then the argument used in the proof of Proposition 6.3 no longer applies, for there is no known example of a 3-connected planar cubic bipartite graph which is not Hamiltonian. Indeed, a well-known conjecture of D. Barnette [7, section 2.12] states that there is no such graph. Thus, we conclude our paper with the following question.

QUESTION 6.4. *Is $\{3, 4, 6, 8, 10, \dots\}$ coverable in $\mathcal{P}$?*

Acknowledgment. We thank the anonymous referees for comments that helped improve the presentation of our results.

CHAINS IN THE NONCROSSING PARTITION LATTICE*

NATHAN READING†

Abstract. We establish recursions counting various classes of chains in the noncrossing partition lattice of a finite Coxeter group. The recursions specialize a general relation which is proven uniformly (i.e., without appealing to the classification of finite Coxeter groups) using basic facts about noncrossing partitions. We solve these recursions for each finite Coxeter group in the classification. Among other results, we obtain a simpler proof of a known uniform formula for the number of maximal chains of noncrossing partitions and a new uniform formula for the number of edges in the noncrossing partition lattice. All of our results extend to the m -divisible noncrossing partition lattice.

Key words. absolute order, Catalan number, chain enumeration, Coxeter element, Coxeter group, generalized cluster complex, noncrossing partition, parking function

DOI. 10.1137/07069777X

1. Introduction. The lattice of noncrossing partitions was defined and studied in 1972 by Kreweras [25]. For surveys of results on this lattice and on its mathematical applications, see [26, 30]. Through the results of [5, 6, 11, 29], the noncrossing partition lattice was recognized as a special case of a construction valid for an arbitrary finite Coxeter group. The notation L_W will stand for the noncrossing partition lattice of a finite Coxeter group W . In particular, when W is the symmetric group, L_W is the usual noncrossing partition lattice. Detailed enumeration of chains in L_W for various Coxeter groups W has been carried out in [1, 4, 7, 14, 15, 24, 25, 29, 32].

The key result of this paper is a formula relating certain rank-selected chain numbers for L_W to chain enumerations arising in parabolic subgroups. For a sequence $(j_1, j_2, \dots, j_{k+1})$ summing to $n = \text{rank}(W)$, let $C_{(j_1, j_2, \dots, j_{k+1})}(W)$ count multichains $x_1 \leq x_2 \leq \dots \leq x_k$ in L_W with $\ell_T(x_1) = j_1$, $\ell_T(x_k) = n - j_{k+1}$ and $\ell_T(x_i) = \ell_T(x_{i-1}) + j_i$ for $i = 2, \dots, k$. Here ℓ_T is the rank function of L_W . For each simple reflection $s \in S$, let $W_{\langle s \rangle}$ denote the parabolic subgroup generated by $S \setminus \{s\}$. The Coxeter number h is the order of a Coxeter element of W . The sequence $(j_1, j_2, \dots, \hat{j}_i, \dots, j_{k+1})$ is obtained by deleting j_i from $(j_1, j_2, \dots, j_{k+1})$.

THEOREM 1.1. *If (W, S) is a finite irreducible Coxeter system and $j_i = 1$, then*

$$C_{(j_1, j_2, \dots, j_{k+1})}(W) = \frac{h}{2} \sum_{s \in S} C_{(j_1, j_2, \dots, \hat{j}_i, \dots, j_{k+1})}(W_{\langle s \rangle}).$$

The theorem is proved uniformly in section 2 by a method similar to that used by Fomin and Zelevinsky to prove a recursive formula [18, Proposition 3.7] counting the facets of the cluster complex. In that context, one “rotates” a root by a modified Coxeter element (of order $h + 2$) until one obtains the negative of a simple root. This allows one to pass to a parabolic subgroup. Here, we rotate a reflection by an

†Department of Mathematics, North Carolina State University, Raleigh, NC 27695 (nathan.reading@ncsu.edu).

unmodified Coxeter element (of order h) until we obtain a simple reflection, which allows us to pass to a parabolic subgroup.

Theorem 1.1 is a broad generalization of what appears to be the only nontrivial enumerative fact about L_W previously known to have a uniform proof: the formula $nh/2$ for the number of atoms (or coatoms) of L_W . There are, however, uniform bijections to other sets, namely clusters [2, 23, 27] and sortable elements [23, 27], but no uniform proof is known for the enumeration of these other sets. (The results of [23] apply only to the crystallographic case. The proofs in [27] are made uniform by the results of [28].) There is also a uniform determination [3, Corollary 4.4] of the Möbius function of L_W in terms of positive clusters, but no uniform proof is known for the enumeration of positive clusters.

In section 3, we specialize Theorem 1.1 to provide recursions for some important classes of chains. In some cases, the recursion leads to a uniform formula. However, even in those cases, deriving the formula from the recursion requires a type-by-type approach. We now briefly summarize the results obtained.

We first consider the number $\text{MC}(W)$ of maximal chains in L_W . We obtain a recursion for $\text{MC}(W)$ and, by solving the recursion type-by-type, a uniform formula for $\text{MC}(W)$. As pointed out in [14], this uniform formula follows from previous type-by-type determinations of the zeta polynomial of L_W . In the exceptional types, the recursion on $\text{MC}(W)$ can be solved without a computer, thus providing the first verification of the formula for $\text{MC}(W)$ without brute-force computer counting.

We next give a recursion on the number of reduced words (in the alphabet of reflections) for elements of L_W . The recursion implies a relationship between the number of such words and the face numbers of the generalized cluster complexes of [17]. Another specialization of Theorem 1.1 leads to a uniform formula, which appears to be new, for the number of edges in L_W . More generally, we consider saturated chains in L_W of a fixed length. The number of such chains appears to exhibit the same odd behavior observed in [17] for the f - and h -numbers of generalized cluster complexes.

Theorem 1.1 and its corollaries are statements about h -fold symmetry. It is intriguing that one of the corollaries can be obtained, by taking leading coefficients, from a similar statement about the $(mh + 2)$ -fold symmetry of a generalized cluster complex, as explained in section 3.

We conclude the paper with a brief discussion, in section 4, of generalizations to m -divisible noncrossing partitions.

2. Proof of the main theorem. In this section, we define L_W and gather the simple facts about Coxeter groups and noncrossing partitions that are necessary to prove Theorem 1.1. We then prove the theorem and comment on the case where W is reducible. Much of the background material on L_W is due to Armstrong [1], Bessis [5], and Brady and Watt [12, 13].

We assume basic background on Coxeter groups and root systems, which is found, for example, in [8, 9, 22]. Let (W, S) be a finite Coxeter system of rank n . We fix a representation of W as a real reflection group acting on a Euclidean space V and make no distinction between an element of W and its action on V .

Let T be the set of reflections in W . For any reflection $t \in T$, let H_t be the reflecting hyperplane associated to t . Any element $w \in W$ can be written as a T -word—a word in the alphabet T . A *reduced* T -word for w is a T -word which has minimal length among all T -words for w . The *absolute length* of w is the length of a reduced T -word for w . This should not be confused with the more common notion

of length in W : the length of a reduced word for w in the alphabet S . The *absolute order* on W sets $u \leq v$ if and only if u has a reduced T -word that is a prefix of some reduced T -word for v . Note that since T is fixed as a set by conjugation, for any $u \leq v$ and any $w \in W$, the interval $[u, v]$ in the absolute order is isomorphic to the interval $[wuw^{-1}, wvw^{-1}]$.

Suppose $t_1 t_2 \cdots t_k$ is a reduced T -word for w . Then, for any $i \in [k-1]$, another reduced T -word for w can be obtained by replacing t_i with t_{i+1} and t_{i+1} with the reflection $(t_{i+1} t_i t_{i+1})$, while leaving all other letters of the word unchanged. Similarly, for $i \in [2, k]$, one can replace t_i with t_{i-1} and t_{i-1} with $(t_{i-1} t_i t_{i-1})$. This implies that $u \leq v$ if and only if u has a reduced T -word that is a subword of some reduced T -word for v . Furthermore, $u \leq v$ if and only if u has a reduced T -word that is a postfix of some reduced T -word for v .

A Coxeter element c is any element of W of the form $c = s_1 s_2 \cdots s_n$ with each element of S occurring exactly once. The order of c is the *Coxeter number* h . The primary object of study in this paper is the interval $[1, c]$ in the absolute order, often called the noncrossing partition lattice, and denoted here by L_W . Any two Coxeter elements are conjugate in W , so the isomorphism type of L_W does not depend on the choice of Coxeter element c . The fact that L_W is a lattice was given a uniform proof in [13] and later, with slightly less generality in [23].

The Coxeter diagram of W is a tree and thus a bipartite graph. Let $S = S_+ \cup S_-$ be a bipartition of the diagram. Define involutions

$$c_+ = \prod_{s \in S_+} s \quad \text{and} \quad c_- = \prod_{s \in S_-} s$$

so that $c = c_- c_+$ is a Coxeter element with $c_+ c c_+ = c_- c c_- = c_+ c_- = c^{-1}$. Thus conjugation by c_+ and conjugation by c_- are isomorphisms from $[1, c]$ to $[1, c^{-1}]$. Let $c_+^{(d)}$ be the $|d|$ -fold product $c_{(-1)^d} \cdots c_+ c_- c_+$ if $d \geq 0$ or $c_+ c_- c_+ \cdots c_{(-1)^d}$ if $d < 0$. We have $c_+^{(d)} c_+^{(-d)} = 1$ for any $d \in \mathbb{Z}$ and, furthermore, $c_+^{(2h)} = c^h = 1$.

The key to the proof of Theorem 1.1 is a result from Steinberg's 1959 paper [34] on finite reflection groups. (See also [22, sections 3.16–3.20] or [9, section V.6.2].)

PROPOSITION 2.1 (see Steinberg [34]). *Let (W, S) be an irreducible finite Coxeter system. The orbit of any reflection under the conjugation action of the dihedral group $\langle c_+, c_- \rangle$ either:*

- (i) *has $h/2$ elements and intersects S in a single element, or*
- (ii) *has h elements and intersects S in a two-element set.*

The proof of Theorem 1.1 uses some fundamental facts about absolute order which we now quote as Theorem 2.2. A clean seven-page exposition (with complete proofs) of these results can be obtained by reading Brady and Watt's paper [12] followed by section 2 of their paper [11]. We phrase these properties in terms of fixed spaces $F_w = \ker(w - I)$ of elements $w \in W$, rather than the *moved spaces* of [12]. This change is harmless because the moved space is the orthogonal complement of F_w . Note that $H_t = F_t$ for each $t \in T$.

THEOREM 2.2 (see Brady and Watt [11, 12]).

- (i) *If $t_1 t_2 \cdots t_k$ is a reduced T -word for $w \in W$, then $F_w = H_{t_1} \cap H_{t_2} \cap \cdots \cap H_{t_k}$.*
- (ii) *If $x, y \in [1, c]$, then $x \leq y$ if and only if $F_y \subseteq F_x$.*
- (iii) *If $t \in T$, then $t \leq c$.*

One useful consequence of Theorem 2.2 is the following lemma (cf. [11, Lemma 2.3]). Recall that $W_{\langle s \rangle}$ is the parabolic subgroup generated by $S \setminus \{s\}$, and let c' be the Coxeter element for $W_{\langle s \rangle}$ obtained by deleting s from the defining word for c . The

subword characterization of absolute order implies that $c' < c$, so $[1, c'] \subset [1, c]$. We write $[u, v]_{\langle s \rangle}$ for an interval in the absolute order on $W_{\langle s \rangle}$ and continue to write $[u, v]$ for an interval in the absolute order on W .

LEMMA 2.3. *The inclusion $W_{\langle s \rangle} \hookrightarrow W$ restricts to an isomorphism from $[1, c']_{\langle s \rangle}$ to $[1, c']$.*

Proof. Theorem 2.2(ii) implies that the inclusion $W_{\langle s \rangle} \hookrightarrow W$ restricts to an isomorphism from $[1, c']_{\langle s \rangle}$ to its image and, furthermore, that this image is contained in $[1, c']$. The parabolic subgroup $W_{\langle s \rangle}$ is the set of elements of W which fix the subspace $\cap_{s' \in \langle s \rangle} H_{s'}$. But $\cap_{s' \in \langle s \rangle} H_{s'} = F_{c'}$ by Theorem 2.2(i), so Theorem 2.2(ii) implies that $[1, c'] \subseteq W_{\langle s \rangle}$. Thus the inclusion of $[1, c']_{\langle s \rangle}$ in W is the entire interval $[1, c']$. $\square$

To simplify the proof of Theorem 1.1, we employ a basic result about counting multichains in L_W . (Cf. [1, Lemma 3.1.2].)

PROPOSITION 2.4. *If $(j'_1, \dots, j'_{k+1})$ is a permutation of $(j_1, \dots, j_{k+1})$, then*

$$C_{(j'_1, \dots, j'_{k+1})}(W) = C_{(j_1, \dots, j_{k+1})}(W).$$

Proof. It is sufficient to prove the proposition in the case where the two sequences agree except that $j'_i = j_{i+1}$ and $j'_{i+1} = j_i$ for some i . Setting $x_0 = 1$ and $x_{k+1} = c$, a multichain $x_1 \leq x_2 \leq \dots \leq x_k$ is uniquely encoded by the sequence

$$(\delta_0, \dots, \delta_k) = (x_0^{-1}x_1, x_1^{-1}x_2, \dots, x_k^{-1}x_{k+1}).$$

In [1], this is called the *delta sequence* of $x_1 \leq x_2 \leq \dots \leq x_k$. A sequence of elements of L_W is a delta sequence for some multichain in L_W if and only if the absolute lengths of the elements of the sequence sum to $n = \text{rank}(W)$ and the product, in order, of the sequence is c . A multichain is counted by $C_{(j_1, \dots, j_{k+1})}(W)$ if and only if its delta sequence has $\ell_T(\delta_{i-1}) = j_i$ for all i . Given a delta sequence $\delta = (\delta_0, \dots, \delta_k)$ with this property, define a new sequence $\delta' = (\delta'_0, \dots, \delta'_k)$ agreeing with δ except that $\delta'_{i-1} = \delta_{i-1}\delta_i\delta_{i-1}^{-1}$ and $\delta'_i = \delta_{i-1}$. It is immediate that δ' is the delta sequence for a multichain counted by $C_{(j'_1, \dots, j'_{k+1})}(W)$ and, furthermore, that the map $\delta \mapsto \delta'$ defines a bijection between the two sets of chains. $\square$

We now prove the main theorem.

Proof of Theorem 1.1. We continue to fix a particular Coxeter element $c = c_-c_+$. Proposition 2.4 implies that it is enough to consider the case where $i = k+1$. A multichain counted by $C_{(j_1, \dots, j_{k+1})}(W)$ consists of an element x covered by c and a multichain in $[1, x]$ with rank-differences given by $(j_1, \dots, j_k)$. In light of Theorem 2.2(iii) and the prefix/postfix characterization of absolute order, an element x is covered by c if and only if $x = ct$ for some $t \in T$.

For each $t \in T$, consider the orbit of $[1, ct]$ under the conjugation action of $\langle c_+, c_- \rangle$. Since conjugation by c_- is an involutive isomorphism from $[1, c]$ to $[1, c^{-1}]$, all intervals in this orbit are isomorphic. In light of Proposition 2.1, we can define $d = d(t)$ to be the smallest $d \geq 0$ such that $c_+^{(d)}tc_+^{(-d)} = c_+^{(d+1)}tc_+^{(-d-1)} = s$ for some $s \in S$. (Cf. the proof of [19, Lemma 4.1].) Let $s = s(t) = c_+^{(d)}tc_+^{(-d)}$. If d is even, then $c_+sc_+ = s$, or in other words, $s \in S_+$. Thus in this case

$$c_+^{(d)}(ct)c_+^{(-d)} = cs = \prod_{s' \in S_-} s' \prod_{s'' \in (S_+ \setminus \{s\})} s''.$$

If d is odd, then $s \in S_-$ and

$$c_+^{(d)}(ct)c_+^{(-d)} = c^{-1}s = \prod_{s' \in S_+} s' \prod_{s'' \in (S_- \setminus \{s\})} s''.$$

In either case $[1, ct]$ is isomorphic to $[1, c']$, where c' is some Coxeter element for $W_{\langle s \rangle}$.

By Lemma 2.3, we conclude that $C_{(j_1, \dots, j_k, 1)}(W)$ counts triples (t, s, μ) such that $t \in T$, $s = s(t)$ and μ is a multichain in $L_{W_{\langle s \rangle}}$ with rank-differences given by $(j_1, \dots, j_k)$. Alternately, we can count such pairs by first specifying s and applying Proposition 2.1. Each s belonging to an orbit of size $\frac{h}{2}$ contributes $\frac{h}{2} C_{(j_1, \dots, j_k)}(W_{\langle s \rangle})$ to the count. For each pair s, s' belonging to an orbit of size h , the lattices $L_{W_{\langle s \rangle}}$ and $L_{W_{\langle s' \rangle}}$ are isomorphic because they are isomorphic to conjugate intervals in L_W . Together s and s' contribute $h \cdot C_{(j_1, \dots, j_k)}(W_{\langle s \rangle}) = h \cdot C_{(j_1, \dots, j_k)}(W_{\langle s' \rangle})$ to the count. $\square$

In general, the parabolic subgroups $W_{\langle s \rangle}$ appearing in Theorem 1.1 are not irreducible. When W is reducible, L_W is a direct product. Thus by basic chain-counting techniques we have the following proposition.

PROPOSITION 2.5. *If $W = W_1 \times W_2$ with $\text{rank}(W_1) = n_1$, then*

$$C_{(j_1, \dots, j_{k+1})} = \sum C_{(j'_1, \dots, j'_{k+1})}(W_1) \cdot C_{(j_1 - j'_1, \dots, j_{k+1} - j'_{k+1})}(W_2),$$

where the sum is over all sequences $(j'_1, \dots, j'_{k+1})$ summing to n_1 and having $j'_i \leq j_i$ for all $i \in [k+1]$.

Remark 2.6. Stembridge [33] pointed out that Theorem 1.1 and Proposition 2.5 can be replaced by a single formula. Let W be a finite Coxeter group, not necessarily irreducible. For each $s \in S$, let h_s denote the Coxeter number of the irreducible component of W containing s . One factors c_+ as $(c_+)_1(c_+)_2 \cdots (c_+)_l$, where $(c_+)_i$ is in the i th irreducible component of W , and similarly for c_- . For each $s \in S$, let $(c_+)_s$ be $(c_+)_i$ if s is in the i th irreducible component of W , and similarly $(c_-)_s$. Replacing $c_{\pm}$ and h by $(c_{\pm})_s$ and h_s in the proof of Theorem 1.1, we obtain

$$C_{(j_1, j_2, \dots, j_{k+1})}(W) = \frac{1}{2} \sum_{s \in S} h_s \cdot C_{(j_1, j_2, \dots, \hat{j}_i, \dots, j_{k+1})}(W_{\langle s \rangle}).$$

Remark 2.7. We have seen that Proposition 2.1 describes a fundamental symmetry of L_W . In fact, the defining symmetry of cluster complexes also ultimately rests on Proposition 2.1. Specifically, [18, Theorem 2.6], which establishes the dihedral symmetry of the cluster complex, is a corollary of [18, Proposition 2.5], which in turn uses [18, Lemma 2.1], cited to [9, Exercise V.6.2]. Proposition 2.1 is not stated explicitly in [9], but is the key to the results which can be applied to solve [9, Exercise V.6.2]. And in fact, [18, Theorem 2.6] is an easy corollary of Proposition 2.1.

Remark 2.8. The concepts involved in the proof of Theorem 1.1 shed light on another similarity between noncrossing partitions and clusters. The definition of the cluster complex rests on a “compatibility” relation on certain roots. A negative simple root $-\alpha$ is compatible with a root β if and only if β belongs to the parabolic root subsystem obtained by deleting α . The rest of the compatibility relation is defined by requiring that compatibility be invariant under the dihedral action of $\langle \tau_+, \tau_- \rangle$, where $\tau_{\pm}$ is a modification of $c_{\pm}$. A similar approach can be made to noncrossing partitions. For $s \in S_-$ and $t \in T$, we have $st \in [1, c]$ if and only if $t \in W_{\langle s \rangle}$. When $s \in S_+$, we have $ts \in [1, c]$ if and only if $t \in W_{\langle s \rangle}$. This observation, together with the fact that the conjugation action of $\langle c_+, c_- \rangle$ acts by automorphisms, completely determines L_W .

3. Applications of the main theorem.

Maximal chains. The maximal chains in L_W are of particular interest for several reasons: For any finite Coxeter group, the maximal chains in L_W index the maximal faces in a CW-complex that is an Eilenberg–MacLane space (or “ $K(\pi, 1)$ ”) for the associated Artin group [10, 11]. Furthermore, maximal chains of classical noncrossing partitions are in bijection with parking functions [32]. In fact, the combinatorics of parking functions encodes rank-selected chain enumeration in the classical case [32, Proposition 3.2]. Generalizations to the case $W = B_n$ have been studied in [7, 21]. The number of maximal chains of classical noncrossing partitions also coincides with the dimension of the ring of diagonal coinvariants. (See, for example, [20, Theorem 4.2.4].)

Let $\text{MC}(W)$ denote the number of maximal chains in L_W . Since $\text{MC}(W) = C_{(1,1,\dots,1)}(W)$, Theorem 1.1 has the following corollary.

COROLLARY 3.1. *If (W, S) is a finite irreducible Coxeter system, then*

$$\text{MC}(W) = \frac{h}{2} \sum_{s \in S} \text{MC}(W_{\langle s \rangle}).$$

Proposition 2.5 becomes much simpler in this special case.

PROPOSITION 3.2. *If $W = W_1 \times W_2$ with $\text{rank}(W_1) = n_1$ and $\text{rank}(W_2) = n_2$, then*

$$\text{MC}(W) = \text{MC}(W_1) \text{MC}(W_2) \binom{n_1 + n_2}{n_1}.$$

The recursions in Corollary 3.1 and Proposition 3.2 can be solved to give formulas or values for each finite Coxeter group. The results are tabulated below, followed by examples illustrating how they were obtained.

A_n	B_n	D_n	E_6	E_7	E_8	F_4	H_3	H_4	$I_2(m)$
$(n+1)^{n-1}$	n^n	$2(n-1)^n$	41472	1062882	37968750	432	50	1350	m

Example 3.3. There is one maximal chain in L_W when W has rank zero. For $W = A_1$, since $h = 2$ we have $\text{MC}(A_1) = \frac{2}{2} \cdot 1 = 1$. For $W = I_2(m)$ we have $h = m$, so $\text{MC}(I_2(m)) = \frac{m}{2}(1+1) = m$.

Example 3.4. For $W = H_3$, $h = 10$ and the maximal parabolic subgroups are $I_2(5)$, $A_1 \times A_1$, and A_2 . Corollary 3.1 and Proposition 3.2 say that

$$\text{MC}(H_3) = \frac{10}{2} \left(5 + 1 \cdot 1 \cdot \binom{2}{1} + 3 \right) = 50.$$

Example 3.5. In each classical case, the formula for $\text{MC}(W)$ is proved by induction, applying Abel’s identity (see [16]). For $W = A_n$, the inductive step is

$$\sum_{i=0}^{n-1} \binom{n-1}{i} (i+1)^{i-1} (n-i)^{n-i-2} = 2(n+1)^{n-2}.$$

This is proved by rewriting the binomial coefficient in the left side as a sum of two binomial coefficients, splitting into two sums, and reversing the order of summation in one of the sums. The two summations are then identical and, by Abel’s identity, each equals $(n+1)^{n-2}$. For $W = B_n$, the inductive step is

$$\sum_{i=0}^{n-1} \binom{n-1}{i} i^i (n-i)^{n-i-2} = n^{n-1},$$

which is proved by reversing the order of summation and applying Abel's identity. For $W = D_n$, the inductive step is

$$\sum_{i=2}^{n-1} \binom{n-1}{i} (i-1)^i (n-i)^{n-i-2} = (n-1)^{n-1} - n^{n-2}.$$

This is proved by evaluating the left side from $i = 0$ to $n - 1$, reversing the order of summation, applying Abel's identity, and then subtracting off the $i = 0$ term.

The results tabulated above constitute a proof, without brute-force computer counting, of a uniform formula for $\text{MC}(W)$ pointed out in [14, Proposition 9].

THEOREM 3.6. *If W is a finite irreducible¹ Coxeter group, then*

$$\text{MC}(W) = \frac{n! h^n}{|W|}.$$

As explained in [14], Theorem 3.6 follows from a more general fact that has been verified type-by-type: For irreducible W , the zeta polynomial of L_W is the Fuss–Catalan number $\text{Cat}^{(m)}(W)$:

$$(3.1) \quad Z(L_W, m+1) = \text{Cat}^{(m)}(W) = \prod_{i=1}^n \frac{mh + e_i + 1}{e_i + 1}.$$

The numbers e_i are fundamental numerical invariants called the exponents of W . The zeta polynomial $Z(P, q)$ of a poset P counts, for each q , multichains $p_1 \leq p_2 \leq \dots \leq p_{q-1}$ in P . See [31, section 3.11] for details on zeta polynomials. By [31, Proposition 3.11.1], the leading term of $Z(P, q)$ is $(Mq^d)/d!$, where d is the length of the longest chain in P and M is the number of chains of length d . Maximal chains in L_W have length $n = \text{rank}(W)$, so the theorem follows by taking the coefficient of m^n in (3.1) and applying the fact that $|W| = \prod_{i=1}^n (e_i + 1)$.

The proof of Theorem 3.6 by zeta polynomials suggests an alternate proof of Corollary 3.1. By [17, Proposition 8.4], $\text{Cat}^{(m)}(W)$ also counts the facets of the generalized cluster complex associated to an irreducible W . A “rotation” of order $mh + 2$ on the generalized cluster complex leads to a recursion [17, Proposition 8.3] on $\text{Cat}^{(m)}(W)$ and thus on zeta polynomials of L_W :

$$(3.2) \quad Z(L_W, m+1) = \frac{mh+2}{2n} \sum_{s \in S} Z(L_{W_{\langle s \rangle}}, m+1).$$

Corollary 3.1 arises by extracting the coefficient of m^n in (3.2). The juxtaposition of this alternate proof with the proof via Theorem 1.1 is striking in that two different dihedral symmetries are related by passing to leading coefficients.

The proof of Corollary 3.1 via (3.2) can presumably be made uniform. The fact that $Z(L_W, 2)$ counts facets of the cluster complex (the case $m = 1$ of the generalized cluster complex) is proven uniformly in [2], based on results of [13]. Recently the results of [13] were extended [35] to the case $m \geq 1$, and presumably the analogous extension of [2] will eventually be undertaken. The recursion counting facets of the generalized cluster complex was proven uniformly, except for [17, Theorems 3.4 and 3.7]. However, the extension of the results of [2] to the case $m \geq 1$ can be expected

¹When W is reducible, the formula holds with h^n replaced by $\prod_{s \in S} h_s$. (See Remark 2.6.)

to provide uniform proofs of [17, Theorems 3.4 and 3.7]. It should be stressed that a uniform proof of (3.1), or even Theorem 3.6, is completely lacking. Indeed, a uniform proof of (3.1) would specialize to a uniform proof that the number of elements of L_W equals $\text{Cat}^{(1)}(W)$. This is an important open problem in W -Catalan combinatorics.

Reduced T -words. Let $\text{TW}_k(W)$ be the number of reduced T -words for elements of absolute length k in L_W . These are chains $x_0 < x_1 < x_2 < \cdots < x_k$ in L_W with $\ell_T(x_i) = i$ for each i , counted by $C_{(1, \dots, 1, n-k)}(W)$. Theorem 1.1 implies the following corollary.

COROLLARY 3.7. *If (W, S) is a finite irreducible Coxeter system, then*

$$\text{TW}_k(W) = \frac{h}{2} \sum_{s \in S} \text{TW}_{k-1}(W_{\langle s \rangle}).$$

Inspired by the alternate proof of Corollary 3.1, we notice a connection between TW_k and the generalized cluster complex. Let $f_k(W, m)$ be the number of k -vertex (i.e., $(k-1)$ -dimensional) simplices in the generalized cluster complex associated to W . When W is irreducible, [17, Proposition 8.3] says that

$$(3.3) \quad f_k(W, m) = \frac{mh + 2}{2k} \sum_{s \in S} f_{k-1}(W_{\langle s \rangle}, m).$$

Taking leading coefficients and interpreting the result as a recursion on $k!$ times the leading coefficient $\langle m^k | f_k(W, m) \rangle$, we obtain a recursion identical to Corollary 3.7. Using Proposition 2.5 and another assertion of [17, Proposition 8.3], one easily checks that $\text{TW}_k(W)$ also behaves like $k! \langle m^k | f_k(W, m) \rangle$ when W is reducible and when $k = 0$. Thus by induction on the rank of W , we have the following theorem.

THEOREM 3.8. *For any finite Coxeter group W ,*

$$\text{TW}_k(W) = k! \langle m^k | f_k(W, m) \rangle.$$

In particular, (nonuniform) formulas for $\text{TW}_k(W)$ can be obtained from [17, Theorem 8.5]. In light of the alternate proof of Theorem 3.6 via zeta polynomials, Theorem 3.8 suggests that $Z(L_W^{[0, k]}, m + 1) = f_k(W, m)$, where $L_W^{[0, k]}$ is the restriction of L_W to ranks $0, \dots, k$. However, this fails even in the smallest examples.

Edges. Let $E(W)$ be the number of edges in the Hasse diagram of L_W . Theorem 1.1 specializes to a recursion on cover relations $x < y$ in L_W with $\ell_T(x) = i$. The right side is a sum over $s \in S$ of the number of elements of $L_{W_{\langle s \rangle}}$ at rank i . Summing from $i = 0$ to $i = n - 1$, we obtain the following recursion on $E(W)$.

COROLLARY 3.9. *If (W, S) is a finite irreducible Coxeter system, then*

$$E(W) = \frac{h}{2} \sum_{s \in S} \text{NC}(W_{\langle s \rangle}).$$

Here $\text{NC}(W)$ stands for the number of elements of L_W . Setting $m = 1$ in (3.1), we see that for W irreducible,

$$(3.4) \quad \text{NC}(W) = \text{Cat}^{(1)}(W) = \prod_{i=1}^n \frac{h + e_i + 1}{e_i + 1}.$$

Furthermore, $\text{Cat}^{(1)}(W)$ counts facets of the cluster complex associated to W . By a recursion [18, Proposition 3.7] counting facets of the cluster complex,

$$(3.5) \quad \text{NC}(W) = \frac{h+2}{2n} \sum_{s \in S} \text{NC}(W_{\langle s \rangle}).$$

Comparing (3.5) with Corollary 3.9, we obtain a uniform formula for the number of edges of L_W .

THEOREM 3.10. *If (W, S) is a finite irreducible Coxeter system, then*

$$E(W) = \frac{nh}{h+2} \text{NC}(W) = \frac{nh}{|W|} \prod_{i=2}^n (h + e_i + 1).$$

The proof of Theorem 3.10 appears to be uniform, but is not, since there is no known uniform proof that $\text{NC}(W) = \text{Cat}^{(1)}(W)$.

Remark 3.11. Equation (3.5) can also be interpreted in terms of L_W . The equation can be rearranged to state that

$$(3.6) \quad \sum_{s \in S} (\text{NC}(W) - \text{NC}(W_{\langle s \rangle})) = \frac{h}{2} \sum_{s \in S} \text{NC}(W_{\langle s \rangle}).$$

The right side of the equation is $E(W)$. The left side of (3.6) counts pairs $(s, x) \in S \times L_W$ with $x \notin W_{\langle s \rangle}$. (Cf. the proof of Lemma 2.3.) A comparison of the expression for $E(W_1 \times W_2)$ arising from Proposition 2.5 with the left side of (3.6) in the case $W = W_1 \times W_2$ shows that, even in the reducible case, $E(W)$ counts pairs (s, x) as above. We have no explanation, within the combinatorics of noncrossing partitions, for the coincidence between these two counts.

Saturated chains. Theorem 1.1 specializes to a recursion on saturated chains $x_0 < x_1 < \cdots < x_k$ with $\ell_T(x_0) = i$. Summing over all possible i , we obtain the following recursion on the total number $\text{SC}_k(W)$ of saturated chains of length k (i.e., $k+1$ elements) in L_W .

COROLLARY 3.12. *If (W, S) is a finite irreducible Coxeter system and $k > 0$, then*

$$\text{SC}_k(W) = \frac{h}{2} \sum_{s \in S} \text{SC}_{k-1}(W_{\langle s \rangle}).$$

Corollaries 3.1 and 3.9 are special cases of Corollary 3.12 which lead to uniform formulas, and (3.4) is a uniform formula for $\text{SC}_0(W)$. One more special case leads to a uniform formula. When $k = n-1$, the recursion of Corollary 3.12 is solved in essentially the same manner as the recursion of Corollary 3.1 to obtain, for W irreducible,

$$(3.7) \quad \text{SC}_{n-1} = \frac{2n! h^n}{|W|}.$$

This is also a trivial corollary of Theorem 3.6, since L_W has a unique minimal and maximal element. Naturally, one seeks a formula for SC_k that generalizes Theorems 3.6 and 3.10 and (3.4) and (3.7). However, the obvious generalization

$$(3.8) \quad n(n-1) \cdots (n-k+1) \frac{h^k}{|W|} \prod_{i=k+1}^n (h + e_i + 1)$$

does not work beyond the cases $k \in \{0, 1, n-1, n\}$. It appears to fail in a way that is exactly analogous to the situation for f -numbers and h -numbers of cluster complexes, as explained in section 4.

4. m -divisible noncrossing partitions. This section is an extended remark about generalizing the results of this paper to the poset of m -divisible noncrossing partitions, as defined by Armstrong in [1]. We call this poset $L_W^{(m)}$. Armstrong names it $\text{NC}_{(m)}(W)$ and also considers the dual poset, under the name $\text{NC}^{(m)}(W)$. The m -divisible noncrossing partitions are the delta sequences of m -element multichains in L_W . (See the proof of Proposition 2.4.) In particular, $L_W^{(1)} = L_W$.

Let $\delta = (\delta_0, \dots, \delta_k)$ and $\delta' = (\delta'_0, \dots, \delta'_k)$ be delta sequences of multichains in L_W . The definition of $L_W^{(m)}$ sets $\delta \leq \delta'$ if and only if $\delta_i \leq \delta'_i$ for all $i = 1, \dots, k$. The poset $L_W^{(m)}$ is a graded meet-semilattice [1, Theorem 3.4.4] with rank function $\sum_{i=1}^n \ell_T(\delta_i)$. Let $C_{(j_1, j_2, \dots, j_{k+1})}^{(m)}(W)$ count multichains $x_1 \leq x_2 \leq \dots \leq x_k$ in $L_W^{(m)}$ with rank-differences given by $(j_1, j_2, \dots, j_{k+1})$. Theorem 1.1 generalizes as follows.

THEOREM 4.1. *If (W, S) is a finite irreducible Coxeter system and $j_i = 1$, then*

$$C_{(j_1, j_2, \dots, j_{k+1})}^{(m)}(W) = \frac{mh}{2} \sum_{s \in S} C_{(j_1, j_2, \dots, \hat{j}_i, \dots, j_{k+1})}^{(m)}(W_{\langle s \rangle}).$$

Theorem 4.1 is proved by a straightforward but notationally cumbersome generalization of the proof of Theorem 1.1, replacing the action of $\langle c_+, c_- \rangle$ with the action of $\langle L^*, R^* \rangle$, as defined in [1, section 3.4.6]. We omit the details.

Theorem 4.1 implies a formula for the number $\text{MC}^{(m)}(W)$ of maximal chains in $L_W^{(m)}$:

$$(4.1) \quad \text{MC}^{(m)}(W) = \frac{mh}{2} \sum_{s \in S} \text{MC}^{(m)}(W_{\langle s \rangle}).$$

The powers of m in the formula can be factored out trivially, so that this recursion is solved exactly as in the case $m = 1$. Thus for W irreducible we have $\text{MC}^{(m)}(W) = \frac{n!(mh)^n}{|W|}$, as was pointed out earlier by Armstrong [1, Corollary 3.6.10].

The analogue of Corollary 3.7 behaves similarly: powers of m can be factored out. Thus saturated chains $x_0 < x_1 < x_2 < \dots < x_k$ such that x_0 is the unique minimal element of $L_W^{(m)}$ are counted by $m^k \text{TW}_k(W)$. It is an easy exercise, given some familiarity with $L_W^{(m)}$, to construct an (m^k) -to-1 map from these “lower-saturated” chains in $L_W^{(m)}$ to lower-saturated chains in L_W . There are also m -analogues of the formulas given in Corollary 3.9, Theorem 3.10, and Remark 3.11, for the number $E^{(m)}(W)$ of edges in $L_W^{(m)}$. In each case, with h replaced by mh and with superscripts “ (m) ” in the appropriate places, the analogous proof works.

Corollary 3.12 generalizes, with similar modifications, to a recursion counting saturated chains in $L_W^{(m)}$. The resulting type-by-type formulas for $\text{SC}_k^{(m)}(W)$ are polynomials in m . Factoring these into irreducible factors reveals multiplicative formulas which seem to be loosely based on (3.8), with h replaced by mh throughout. These factorizations exhibit the odd phenomena first observed in formulas [17, Theorems 8.5 and 10.2] for the f - and h -numbers of generalized cluster complexes, including “levels” of exponents and single “mysterious” factors. The formulas for $\text{SC}_k^{(m)}(W)$ appear to be badly behaved exactly when $f_k(W, m)$ and $h_k(W, m)$ are badly behaved, and the bad behaviors take the same form.

Acknowledgments. I thank Drew Armstrong, Christos Athanasiadis, Jon McCammond, and John Stembridge for helpful comments on earlier versions of this paper.

ON THE FIRST-FIT CHROMATIC NUMBER OF GRAPHS*

JÓZSEF BALOGH[†], STEPHEN G. HARTKE[‡], QI LIU[†], AND GEXIN YU[§]

Abstract. The *first-fit chromatic number* of a graph is the number of colors needed in the worst case of a greedy coloring. It is also called the *Grundy number*, which is defined to be the maximum number of classes in an ordered partition of the vertex set of a graph G into independent sets $V_1, V_2, \dots, V_k$ so that for each $1 \leq i < j \leq k$ and for each $x \in V_j$ there exists a $y \in V_i$ such that x and y are adjacent. In this paper, we study the first-fit chromatic number of outerplanar and planar graphs as well as Cartesian products of graphs, and in particular we give asymptotically tight results for outerplanar graphs.

Key words. first-fit chromatic number, Grundy number, Grundy coloring, greedy coloring, random graph, planar graph, Cartesian product

1. Introduction. Given an ordering of the vertices of a simple graph G , a greedy (proper) coloring of G assigns to each vertex the first available color not used on a neighboring vertex earlier in the order. The first-fit chromatic number is the number of colors needed in the worst case of a greedy coloring. An equivalent definition of first-fit chromatic number is given below.

The *first-fit chromatic number* of G , written as $\chi_{FF}(G)$, is defined to be the maximum number of classes in an ordered partition of the vertex set of G into independent sets $V_1, V_2, \dots, V_k$ so that for each $1 \leq i < j \leq k$ and for each $x \in V_j$ there exists a $y \in V_i$ such that x and y are adjacent. A partition with this property is called a *first-fit partition*.

Historically, first-fit partitions and the first-fit chromatic number are also called Grundy colorings and the Grundy number, respectively. The study of Grundy coloring dates back to the 1930s [13], when Grundy used them in the study of kernels of directed graphs. Many researchers have studied this coloring under different names; see [8] for details. It is believed that Christen and Selkow [5] were the first to define and study the Grundy number as a graph parameter. Some recent results about it can be found, for example, in Füredi et al. [9], Zaker [21], Erdős et al. [7], and Germainian and Kheddouci [10].

Stemming from a natural connection with the classical dynamic storage allocation problem in computer science, Woodall [20] studied the first-fit chromatic number of an interval graph I_k with maximum clique size k and showed $\chi_{FF}(I_k) = O(k \log k)$. After a series of papers by Kierstead [15], Kierstead and Qin [16], and Pemmaraju, Raman, and Varadarajan [19], Brightwell, Kierstead, and Trotter [4] showed that

$\chi_{FF}(I_k) \leq 8k$. Kierstead and Trotter [17] improved the lower bound by showing that for every $\varepsilon > 0$, $\chi_{FF}(I_k) > (5 - \varepsilon)k$ when k is sufficiently large. We study the first-fit chromatic numbers of more general families of graphs.

THEOREM 1. *Let $\mathcal{F}$ be a family of graphs closed under taking subgraphs. Suppose that there exists a constant $d \geq 1$ such that $e(G) \leq dn(G)$ for every $G \in \mathcal{F}$. Then for every $G \in \mathcal{F}$,*

$$\chi_{FF}(G) \leq \log_{\frac{d+1}{d}}(n) - \log_{\frac{d+1}{d}}(d+4) + (2d+2).$$

Here, $e(G)$ denotes the number of edges of G , and $n(G)$ the number of vertices of G .

Irani [14] proved a similar result, showing that for the graphs above, $\chi_{FF}(G) = O(d \log n)$. However, our constants are slightly better and the proof techniques are different.

As a corollary, we obtain upper bounds of the first-fit chromatic numbers of planar and outerplanar graphs.

THEOREM 2. (i) *Let G be an n -vertex planar graph. Then*

$$\chi_{FF}(G) \leq \log_{4/3}(n) + 8 - \log_{4/3}(7).$$

(ii) *If G is additionally outerplanar, then*

$$\chi_{FF}(G) \leq \log_{3/2}(n) + 6 - \log_{3/2}(6).$$

For infinitely many integers n we construct planar graphs on n vertices with first-fit chromatic number $\log_{6^{1/6}} n$ (note that $6^{1/6} \approx 1.348$), and we show that the upper bound for outerplanar graphs is asymptotically best possible.

We also study the first-fit chromatic number of random graphs. The first results were proved by Grimmett and McDiarmid [11] and then improved by Bollobás and Erdős [2], who showed among other results that if $G \sim G_{n,1/2}$ is a random graph with edge density $1/2$, then with high probability (as $n \rightarrow \infty$),

$$\chi_{FF}(G) \geq \left(1 - 3\sqrt{\frac{\ln \ln n}{\ln n}}\right) \frac{n}{\log_2 n}.$$

Bollobás and Erdős [2] and McDiarmid [18] also showed that with high probability,

$$\chi_{FF}(G) \leq \left(1 + \frac{5 \ln \ln n}{\ln n}\right) \frac{n}{\log_2 n}.$$

In [11] and [2] much more was proven, including results about $G_{n,p}$. An excellent summary of these results appears in Bollobás's book *Random Graphs* [3, pp. 294–298].

We improve the lower bound on the first-fit chromatic number of $G_{n,1/2}$ by showing the following theorem.

THEOREM 3. *Let $G \sim G_{n,1/2}$ be a random graph with edge density $1/2$. Then with high probability (as $n \rightarrow \infty$),*

$$\chi_{FF}(G) \geq \left(1 - \frac{30(\ln \ln n)^2}{\log_2 n}\right) \frac{n}{\log_2 n}.$$

Note that the chromatic number of a random graph $G \sim G_{n,1/2}$ is asymptotically $n/(2 \log_2 n)$ almost surely (see Alon and Spencer [1]), and the ratio of the two chromatic numbers is asymptotically 2.

We discuss the first-fit chromatic number of Cartesian products of graphs in the last section. Effantin and Kheddouci [6] proved that if G is bipartite, then $\chi_{FF}(G \square P_3) \geq \chi_{FF}(G) + 2$. Using this, they proved that $\chi_{FF}(C_{m_1} \square C_{m_2} \square \cdots \square C_{m_k}) = 2k + 1$, where $k \geq 2$, $m_i \geq 4$, and m_i is even. (The case when all cycles are C_4 requires additional work.) Note that this result gives a short proof for the first-fit chromatic number of hypercubes which was originally obtained by Hoffman and Johnson [12]: A k -dimensional hypercube Q_k has first-fit chromatic number $k + 1$ for $k \geq 3$, and $\chi_{FF}(Q_2) = 2$.

Here we extend the above result to include odd cycles in the product and prove the same lower bound for $G \square P_3$ and $G \square P_4$, but we allow G to be nonbipartite as long as $\chi_{FF}(G)$ is even. As a result, $\chi_{FF}(C_{m_1} \square C_{m_2} \square \cdots \square C_{m_k}) = 2k + 1$ for all $k \geq 2$ and $m_i \geq 4$. For contrast, we construct graphs G with the property that $\chi_{FF}(G \square P_2)$ is as large as $2\chi_{FF}(G)$.

This paper is organized as follows: We prove the results on planar graphs in section 2, the lower bound of random graphs in section 3, and the results on products of graphs in section 4.

2. First-fit chromatic number of planar graphs. We begin with a technical, purely combinatorial lemma about sequences of integers. The proof is delayed until the end of the section.

LEMMA 4. *Given a sequence $a_1, a_2, \dots, a_t$ of positive integers and a constant $d \geq 1$ which satisfy*

- (i) $a_i \geq 1$ for $i = 1, \dots, t$,
- (ii) $\sum_{\ell=1}^t a_\ell = n$,
- (iii) $\sum_{\ell=i}^t (\ell - i) a_\ell \leq d(\sum_{\ell=i}^t a_\ell)$ for $i = 1, \dots, t - d$.

Then

$$t \leq \log_{\frac{d+1}{d}}(n) - \log_{\frac{d+1}{d}}(d+4) + (2d+2).$$

We now use Lemma 4 to prove Theorems 1 and 2.

Proof of Theorem 1. Suppose that $\chi_{FF}(G) = t$. Then there exists a first-fit partition $\langle V_1, V_2, \dots, V_t \rangle$ of $V(G)$. For $1 \leq i \leq t$, let G_i be the subgraph $G[V_i, V_{i+1}, \dots, V_t]$ induced by the last $t - i + 1$ parts. Since $\langle V_1, V_2, \dots, V_t \rangle$ is a first-fit partition,

$$e(G_i) \geq \sum_{\ell=i}^t (\ell - i) |V_\ell|.$$

Since G_i is a member of $\mathcal{F}$, G_i satisfies the edge bound

$$e(G_i) \leq d \left(\sum_{\ell=i}^t |V_\ell| \right).$$

Hence, the sequence $|V_1|, |V_2|, \dots, |V_t|$ satisfies the conditions of Lemma 4 where $a_i = |V_i|$, and so

$$\chi_{FF}(G) \leq \log_{\frac{d+1}{d}}(n) - \log_{\frac{d+1}{d}}(d+4) + (2d+2). \quad \square$$

Proof of Theorem 2. (i) If G is a planar graph with $n \geq 3$ vertices, then $e(G) \leq 3n - 6 < 3n$. Since planarity is preserved when taking subgraphs, the result then follows by applying Theorem 1.

FIG. 1. An 18-vertex graph H with first-fit chromatic number 9.

(ii) Since outerplanar graphs with n vertices have at most $2n-3$ edges, we similarly obtain the result. $\square$

PROPOSITION 5. *For every n_0 , there is an $n > n_0$ such that there exists an n -vertex planar graph with first-fit chromatic number at least $\log_{6^{1/6}} n$.*

Proof. A planar graph is called a *triangulation* if all of its faces are triangles. There exists a triangulation H (see Figure 1) with 18 vertices that has first-fit chromatic number at least 9. (The vertices with label i belong to the U_i in a first-fit partition $\cup_{i=1}^9 U_i$ of H .) The graph H has the additional property that the vertices of H can be covered by exactly 6 independent triangles (shown in gray in Figure 1).

Given a triangulation G_1 and a set $\mathcal{F}$ of triangles that cover every vertex of G_1 , we replace every triangle of $\mathcal{F}$ with a copy of H . This forms a new triangulation G_2 , where $n(G_2) \leq 6n(G_1)$. Suppose that $V(G_1)$ has an optimal first-fit partition $\langle V_1, V_2, \dots, V_t \rangle$. Then $V(G_2)$ has a first-fit partition $\langle U_1, U_2, \dots, U_{t+6} \rangle$, where $U_i = V_{i-6}$ when $i \geq 7$ and, for $i \leq 6$, U_i is the set of vertices labeled i from copies of H . Hence, $\chi_{FF}(G_2) \geq \chi_{FF}(G_1) + 6$. Note that G_2 has a set of $6|\mathcal{F}|$ triangles that cover every vertex of G_1 .

By iterating this procedure starting with $G_1 = C_3$, we obtain a sequence G_i of graphs with $3 \cdot 6^{i-1}$ vertices and first-fit chromatic number at least $3 + 6(i-1)$. Hence, we have constructed a series of planar graphs whose asymptotic first-fit chromatic number is at least $\log_{6^{1/6}} n$, where n is the number of the vertices of the graph. $\square$

By considering larger graphs H as a pattern, we may produce a better lower bound, but we do not believe this method can show that the upper bound is tight.

The following construction gives a lower bound for the first-fit chromatic number of outerplanar graphs.

PROPOSITION 6. *For every n_0 , there is an $n > n_0$ such that there exists an n -vertex outerplanar graph with first-fit chromatic number at least $\log_{3/2}(n+2) - \log_{3/2}(5) + 3$.*

Proof. We construct a sequence of outerplanar graphs as follows:

1. $G_0 = C_3$.

2. Suppose the outer face of G_i is $v_1 v_2 \dots v_{n_i}$ in order, where n_i is the number of vertices of G_i . Generate G_{i+1} by adding $k = \lceil n_i/2 \rceil$ vertices $u_1, \dots, u_k$ such that u_j is adjacent to v_{2j-1} and v_{2j} , where $j = 1, \dots, k$. (If n_i is odd, then u_k is adjacent to v_{n_i} and v_1 .)

Then G_{i+1} is also outerplanar and $\chi_{FF}(G_{i+1}) \geq \chi_{FF}(G_i) + 1$. As $\chi_{FF}(G_0) = 3$, we have $\chi_{FF}(G_i) \geq i + 3$. Since $n_i = n_{i-1} + \lceil n_{i-1}/2 \rceil \leq 3n_{i-1}/2 + 1$ and $n_0 = 3$, we have $n_i \leq 5(3/2)^i - 2$. Thus $\chi_{FF}(G_i) \geq i + 3 \geq \log_{3/2}(n_i + 2) - \log_{3/2}(5) + 3$. $\square$

So the upper bound given by Theorem 2 (ii) for outerplanar graphs is asymptotically sharp.

We conclude this section with the proof of Lemma 4.

Proof of Lemma 4. Given a sequence $a_1, a_2, \dots, a_t$ that satisfies the hypotheses of the lemma, we define a “shift” operation S_j for $1 \leq j \leq t-1$ on such a sequence as follows:

$$S_j(a_1, a_2, \dots, a_t) = a_1, \dots, a_{j-1}, a_j + 1, a_{j+1} - 1, a_{j+2}, \dots, a_t.$$

Clearly, if $a_1, a_2, \dots, a_t$ satisfies (i) and (ii), then $S_j(a_1, a_2, \dots, a_t)$ does as well if $a_{j+1} \geq 2$.

We repeatedly apply S_j to the sequence, where j is the largest index such that $a_{j+1} > 1$ and (iii) holds for $S_j(a_1, a_2, \dots, a_t)$. We stop when no such index j exists. After the process terminates, we obtain a new sequence $b_1, b_2, \dots, b_t$ that satisfies the conditions of the lemma for the same d , but, for each $j = 2, \dots, t$, either $b_j = 1$ or $b_j \geq 2$ and (iii) does not hold for $S_{j-1}(b_1, b_2, \dots, b_t)$.

Given the final sequence $b_1, b_2, \dots, b_t$, let i_0 be the unique index $j \geq 1$ such that

- (a) for any i with $j < i \leq t$, $b_i = 1$, and
- (b) if $j > 1$, then $b_j \geq 2$ and $S_{j-1}(b_1, b_2, \dots, b_t)$ violates (iii).

Note that the definition of i_0 includes the possibility that $i_0 = 1$. However, the next claim implies that $i_0 > 1$, since we may assume that $t > 2d + 2$. (Otherwise the conclusion of the lemma is trivially satisfied.)

Claim A. $2 \leq i_0 = t - (2d + 1)$.

Proof. Condition (iii) for $b_1, \dots, b_t$ with $i \geq i_0$ implies that

$$\left(\frac{t-i+1}{2} - d \right) (t-i) \leq db_i,$$

since $b_i = 1$ for $i > i_0$. Thus,

$$(1) \quad \text{if } \left(\frac{t-i+1}{2} - d \right) (t-i) \geq d+1, \text{ then } b_i > 1.$$

Define

$$f(x) = \left(\frac{x+1}{2} - d \right) x = \frac{1}{2}x^2 - (d-1/2)x.$$

Note that $f(x)$ is increasing on the interval $[d-1/2, \infty)$.

Since (iii) imposes no condition when $i > t-d$, we may always apply S_j for $j \geq t-d$ as long as $a_j \geq 2$. Thus we have $i_0 \leq t-d-1$, and so $t-i_0 \geq d+1$.

Since $b_i = 1$ for $i > i_0$ and by (1), we have that $f(t-i) < d+1$ for $i > i_0$. Since $f(2d+1) = 2d+1 > d+1$, we have that $i_0 \geq t-(2d+1) \geq 2$. Note that this rules out the possibility that $i_0 = 1$.

For the upper bound on i_0 , we first note that if any sequence $a'_1, a'_2, \dots, a'_t$ satisfies (iii), then $S_j(a'_1, a'_2, \dots, a'_t)$ satisfies (iii) for $i \neq j+1$. Thus, if $S_j(b_1, b_2, \dots, b_t)$ violates (iii), then the violation occurs for $i = j+1$:

$$(2) \quad 0 \cdot (b_{j+1} - 1) + \sum_{\ell=j+2}^t (\ell - j - 1)b_\ell \geq d \left(b_{j+1} - 1 + \sum_{\ell=j+2}^t b_\ell \right) + 1.$$

Since $i_0 > 1$, $b_{i_0} \geq 2$, and $S_{i_0-1}(b_1, b_2, \dots, b_t)$ does not satisfy (iii), and by (2), we have

$$(3) \quad \left(\frac{t - i_0 + 1}{2} - d \right) (t - i_0) = f(t - i_0) \geq db_{i_0} - d + 1 \geq d + 1,$$

where we use the fact that $b_i = 1$ for all $i_0 < i \leq t$. This implies

$$(4) \quad \left(\frac{t - i_0 + 1}{2} \right) (t - i_0) \geq d(t - i_0 + 1) + db_{i_0} - 2d + 1 > d(t - i_0 + 1),$$

where the first inequality is equivalent to (3). Hence, $i_0 < t - 2d$, and since i_0 is an integer, $i_0 \leq t - (2d + 1)$. $\square$

Claim B. $b_i \geq 2$ for all $i \leq i_0$, and as a consequence, $S_{i-1}(b_1, b_2, \dots, b_t)$ violates (iii) for all $i \leq i_0$.

Proof. We use downward induction on i . The base case is when $i = i_0$, which follows from the definition of i_0 .

Thus, we assume the inductive hypothesis is true for i , where $1 < i \leq i_0$. Hence

$$(5) \quad \sum_{\ell=i}^t (\ell - i)b_\ell \geq d \left(\sum_{\ell=i}^t b_\ell \right) - d + 1.$$

Condition (iii) for $i - 1$ states that

$$(6) \quad \sum_{\ell=i-1}^t (\ell - i + 1)b_\ell \leq d \left(\sum_{\ell=i-1}^t b_\ell \right).$$

Subtracting (5) from (6), we obtain

$$(7) \quad \sum_{\ell=i}^t b_\ell \leq db_{i-1} + d - 1,$$

which implies

$$\begin{aligned} db_{i-1} &\geq \sum_{\ell=i}^t b_\ell + 1 - d \geq (t - i + 2) + 1 - d && \text{since } b_i \geq 2, \\ &\geq t - d + 3 - i_0 && \text{since } i \leq i_0, \\ &\geq d + 4 && \text{since } i_0 = t - (2d + 1) \text{ by Claim A.} \end{aligned}$$

Hence $b_{i-1} \geq 2$, and additionally $S_j(b_1, b_2, \dots, b_t)$ violates (iii) when $j = i - 2$. This completes the induction. $\square$

By Claims A and B, for $b_1, b_2, \dots, b_t$ we have that (iii) holds and $b_i = 1$ for $i > i_0$ and $b_i \geq 2$ for $i \leq i_0$. We know from (7) that for $i = 1, \dots, i_0 - 1$,

$$db_i \geq \sum_{\ell=i+1}^t b_\ell - (d - 1).$$

Let $B_j := \sum_{\ell=j}^t b_\ell$. Then for $j \leq i_0 - 1$,

$$(8) \quad d(B_j - (d-1)) \geq (d+1)(B_{j+1} - (d-1)).$$

Thus, iterating the recurrence (8) starting with $j = 1$ until $j + 1 = i_0$, we have (note that $B_1 = n$)

$$n - (d-1) = B_1 - (d-1) \geq \left(\frac{d+1}{d}\right)^{i_0-1} (B_{i_0} - (d-1)).$$

Taking logarithms of both sides and solving for i_0 ,

$$i_0 \leq \log_{\frac{d+1}{d}}(n - (d-1)) - \log_{\frac{d+1}{d}}(B_{i_0} - (d-1)) + 1.$$

Note that $i_0 = t - (2d+1)$ and $b_{i_0} \geq 2$ implies $B_{i_0} = t - i_0 + b_{i_0} \geq 2d+3$, and from $i_0 = t - (2d+1)$ we have

$$\begin{aligned} t = i_0 + (2d+1) &\leq \log_{\frac{d+1}{d}}(n - (d-1)) - \log_{\frac{d+1}{d}}(d+4) + 1 + (2d+1) \\ &\leq \log_{\frac{d+1}{d}}(n) - \log_{\frac{d+1}{d}}(d+4) + (2d+2). \quad \square \end{aligned}$$

3. The first-fit chromatic number of random graphs. Recall that if G is a random graph on n labeled vertices in which every edge is chosen randomly and independently with probability p , then we say that $G \sim G_{n,p}$. Since n is large, for the sake of clarity of exposition, we will ignore the issue of integrality of the quantities.

For a vertex x in a graph G , let $\bar{N}(x)$ denote the set of nonneighbors of x in G . Let $\bar{N}(A) = \cap_{x \in A} \bar{N}(x) - A$. In our proof of Theorem 3 the key statements are Lemmas 8 and 9, whose proofs are based on repeated use of Chernoff's inequality. For a variant of Chernoff's inequality, see [1, p. 263]; we will use the following version.

LEMMA 7. *Let $G \sim G_{n,1/2}$ be a random graph, T a subset of $V(G)$ of size t , and x a vertex in $V(G) - T$. Then*

$$\mathbb{P} \left[|\bar{N}(x) \cap T| > \left(\frac{1}{2} + \gamma \right) t \right] < e^{-2\gamma^2 t}.$$

LEMMA 8. *Let $G \sim G_{n,1/2}$ be a random graph, and let $\delta_1 = 18/\sqrt{\log_2 n}$. Then for large n , G contains a maximal independent set C of size at most $(1 + \delta_1) \log_2 n$ with probability at least $1 - n^{-2}$. Note that during the process of choosing C no information is used about the graph spanned by $V(G) - C$.*

Proof. We construct a maximal independent set S iteratively in three phases. We start with $S_0 = \emptyset$. In each step of the first phase we extend this set by adding a vertex v_i so that $S_i = S_{i-1} \cup \{v_i\}$.

Phase I. This phase lasts for r iterations, until $|\bar{N}[S_r]| \leq (\ln n)^3$.

Let $\alpha := \alpha(n) = 2/\ln n$. Let x_1 be an arbitrarily chosen vertex of G ; set $S_1 := \{x_1\}$. We pick a sequence of vertices $x_2, x_3, \dots, x_r$ inductively as follows: let $A_i = \bigcap_{j=1}^i \bar{N}[x_j]$. (For convenience, let $A_0 = V(G)$.) While $|A_i| > (\ln n)^3$, arbitrarily choose x_{i+1} in A_i and set $S_i = S_{i-1} \cup \{x_i\}$.

Note that the selection of the vertices $x_1, x_2, \dots, x_i$ is independent of the edges in the subgraph of G induced by A_i . Hence, the subgraph induced by A_i is a random graph with distribution $G_{|A_i|,1/2}$, and we expect that x_{i+1} is adjacent to about half of the vertices in A_i . By Lemma 7 and using that $|A_i| > (\ln n)^3$,

$$(9) \quad \mathbb{P} [|\bar{N}(x_{i+1}) \cap A_i| > (1/2 + \alpha)|A_i|] < e^{-2\alpha^2|A_i|} < e^{-2\alpha^2(\ln n)^3} = e^{-8 \ln n} = n^{-8}.$$

Thus,

$$\mathbb{P} \left[|\overline{N}(x_{i+1}) \cap A_i| \leq (1/2 + \alpha)|A_i| \text{ for all } 1 \leq i < r \right] > 1 - rn^{-8} > 1 - n^{-7}.$$

As $|A_0| = n$ and for every $i \leq r$ we have $|A_{i+1}| \leq (1/2 + \alpha)|A_i|$, we conclude that

$$(10) \quad r \leq \log_{\frac{1}{\frac{1}{2} + \alpha}} n < \left[1 + \frac{2}{(\ln 2)^2} \frac{1}{\log_2 n} \right] \log_2 n < \left[1 + \frac{5}{\log_2 n} \right] \log_2 n.$$

The middle inequality follows from the inequalities $1 - x/2 > \frac{1}{1+x} > 1 - x$ and $\ln(1 - x) > -2x$.

Phase II. In the second phase we have the same process, but because $|\overline{N}[S_r]| = o(n)$, we shall have an estimate similar to (9) only after adding $m := \ln \ln n$ vertices at each iteration to the independent set. We proceed with this phase until $|\overline{N}[S_i]| \leq 180 \frac{\ln n}{\ln \ln n}$.

We will add m independent vertices $y_1^i, y_2^i, \dots, y_m^i$ to S_i , one at a time.

Subphase IIa. In this subphase we add the i th group of m vertices to S_{i-1} . Let

$$S_i(j) := S_{i-1} \cup \{y_1^i, y_2^i, \dots, y_j^i\}.$$

As before, pick y_j^i arbitrarily in $B^i(j-1) := \overline{N}[S_i(j-1)]$ (note that $S_i(0) = S_{i-1}$). While $j \leq m$ and $|B^i(j-1)| > \frac{180 \ln n}{\ln \ln n}$, arbitrarily choose y_j^i in $B^i(j-1)$, and set $S_i = S_{i-1} \cup \{y_1^i, y_2^i, \dots, y_m^i\}$. By Lemma 7 and using the fact that $|B^i(j-1)| > \frac{180 \ln n}{\ln \ln n}$,

$$\mathbb{P} \left[|B^i(j)| > \frac{2}{3} |B^i(j-1)| \right] < \exp \left[-\frac{1}{18} |B^i(j-1)| \right] \leq \exp \left[-10 \frac{\ln n}{\ln \ln n} \right].$$

These events are independent for different pairs of i and j . Thus, the probability that each pair (i, j) has more than $\frac{2}{3} |B^i(j-1)|$ nonneighbors in $B^i(j-1)$ is

$$\mathbb{P} \left[|\overline{N}(y_j^i) \cap B^i(j-1)| > \frac{2}{3} |B^i(j-1)| \text{ for all } 1 \leq i \leq m \right] < \left(e^{-\frac{10 \ln n}{\ln \ln n}} \right)^m = n^{-10}.$$

Since $|\overline{N}[S_i]| > \frac{2}{3} |\overline{N}[S_{i-1}]|$ implies that $|\overline{N}(y_j^i) \cap B^i(j-1)| > \frac{2}{3} |B^i(j-1)|$ for all $1 \leq j \leq m$, we have

$$(11) \quad \mathbb{P} \left[|\overline{N}[S_i]| \leq \frac{2}{3} |\overline{N}[S_{i-1}]| \right] > 1 - n^{-10}.$$

We repeat Subphase IIa while $|\overline{N}[S_i]| > \frac{180 \ln n}{\ln \ln n}$. If in the last iteration of Subphase IIa we cannot choose m vertices, then we simply add the vertices chosen so far to S . Suppose that Subphase IIa is repeated q times. By (11), $q \leq \log_{\frac{2}{3}} ((\ln n)^3) + 1$. The “+1” comes from the last possibly incomplete iteration of Subphase IIa. Hence, $(3 \log_{3/2} \ln n + 1) \ln \ln n$ vertices are added to S during Phase II.

Phase III. This phase occurs while $|\overline{N}[S]| \leq \frac{180 \ln n}{\ln \ln n}$. We choose any maximal independent set C in $\overline{N}[S]$ to add to S . As $\overline{N}[S]$ spans a random graph with edge-density $1/2$, it does not have an independent set of size $10\sqrt{\log_2 n}$ with probability at least

$$1 - \left(\frac{|\overline{N}[S]|}{10\sqrt{\log_2 n}} \right) 2^{-(\frac{10\sqrt{\log_2 n}}{2})} > 1 - n^{-3}.$$

Thus, $|C| \leq 10\sqrt{\log_2 n}$ with high probability.

Thus, after the completion of the three phases, S is a maximal independent set of G of size at most $\log_{1/(1/2+\alpha)} n + (3 \log_{3/2} \ln n + 1) \ln \ln n + 10\sqrt{\log_2 n}$ with probability greater than $(1 - n^{-3})^3 > 1 - n^{-2}$. Note that

$$\log_{\frac{1}{\frac{1}{2}+\alpha}} n + \left(3 \log_{3/2} \ln n + 1\right) \ln \ln n + 10\sqrt{\log_2 n} \leq (1 + \delta_1) \log_2 n$$

when $\delta_1 = 18/\sqrt{\log_2 n}$ and n is large. Hence the lemma is proved. $\square$

LEMMA 9. Let $G \sim G_{n,1/2}$ be a random graph, and let $\delta_2 = 10(\ln \ln n)^2 / \log_2 n$. Then for large n , G contains a maximal independent set C of size at most $(1 + \delta_2) \log_2 n$ with probability at least $(1 - n^{-3})^2(1 - p(n))$, where

$$2^{-(10 \log_2^2 \log_2 n)} \leq p(n) \leq \left(\frac{c}{\log_2 n}\right)^{30 \log_2 \log_2 n}$$

and c is a constant. Note that during the process of choosing C no information is used about the graph spanned by $V(G) - C$.

Proof. We construct a maximal independent set S iteratively in three phases, as in the proof of Lemma 8. Phases I and II are identical to those of Lemma 8.

Phase III. This phase occurs while $|\overline{N}[S]| \leq \frac{180 \ln n}{\ln \ln n}$. We choose any maximal independent set C in $\overline{N}[S]$ to add to S . As $\overline{N}[S]$ spans a random graph with edge-density $1/2$, it does not have an independent set of size $10 \log_2 \log_2 n$ with probability at least

$$1 - \binom{|\overline{N}[S]|}{10 \log_2 \log_2 n} 2^{-(10 \log_2^2 \log_2 n)}.$$

Thus, $|C| \leq 10 \log_2 \log_2 n$ with high probability. Let $p(n) := \binom{|\overline{N}[S]|}{10 \log_2 \log_2 n} 2^{-(10 \log_2^2 \log_2 n)}$.

First,

$$\begin{aligned} \binom{|\overline{N}[S]|}{10 \log_2 \log_2 n} 2^{-(10 \log_2^2 \log_2 n)} &\leq \left(\frac{e \cdot \frac{180 \ln n}{\ln \ln n}}{10 \log_2 \log_2 n}\right)^{10 \log_2 \log_2 n} \cdot 2^{-(10 \log_2^2 \log_2 n)} \\ &\leq \left[\frac{e \cdot \frac{180 \ln n}{\ln \ln n}}{10 \log_2 \log_2 n} \cdot 2^{-4 \log_2 \log_2 n}\right]^{10 \log_2 \log_2 n} \\ &= \left[\frac{e \cdot \frac{180 \ln n}{\ln \ln n}}{10 \log_2 \log_2 n} \cdot \frac{1}{(\log_2 n)^4}\right]^{10 \log_2 \log_2 n} \leq \left(\frac{c}{\log_2 n}\right)^{30 \log_2 \log_2 n}. \end{aligned}$$

Second,

$$\binom{|\overline{N}[S]|}{10 \log_2 \log_2 n} 2^{-(10 \log_2^2 \log_2 n)} \geq 2^{-(10 \log_2^2 \log_2 n)}.$$

$$\text{So } 2^{-(10 \log_2^2 \log_2 n)} \leq p(n) \leq \left(\frac{c}{\log_2 n}\right)^{30 \log_2 \log_2 n}.$$

Thus, after the completion of the three phases, S is a maximal independent set of G of size at most $\log_{1/(1/2+\alpha)} n + (3 \log_{3/2} \ln n + 1) \ln \ln n + 10 \log_2 \log_2 n$ with probability greater than $(1 - n^{-3})^2(1 - p(n))$. Note that

$$\log_{\frac{1}{1/2+\alpha}} n + (3 \log_{3/2} \ln n + 1) \ln \ln n + 10 \log_2 \log_2 n \leq (1 + \delta_2) \log_2 n$$

when $\delta_2 = 10(\ln \ln n)^2 / \log_2 n$ and n is large. Hence the lemma is proved. $\square$

Proof of Theorem 3. We create a first-fit partition by iteratively removing small maximal independent sets S_i generated by Lemmas 8 and 9 from G . Set $G_1 = G$, and for $i > 1$, $G_i = G - \cup_{j \leq i} S_j$. Let $n_i = |V(G_i)|$. We use the following important observation that G_i is a random graph distributed as $G_{n_i, 1/2}$ since the edges of G_i were never considered when the independent sets $S_1, S_2, \dots, S_i$ were constructed.

We iterate the process until $|V(G_t)| < n^{1/2} \log_2 n$. After that point, we greedily partition the remaining vertices into independent sets. Clearly, $\chi_{FF}(G) \geq t$.

By Lemma 8, there exists a maximal independent set S_i in G_i of size at most $(1 + \delta_1) \log_2 n_i$ with probability greater than $1 - n_i^{-2}$. Note that

$$\begin{aligned} \mathbb{P}[|S_i| < (1 + \delta_1) \log_2 n_i \text{ for all } 1 \leq i \leq t] &\geq 1 - t \left(n^{1/2} \log_2 n \right)^{-2} \\ &\geq 1 - n \left(\frac{1}{n (\log_2 n)^2} \right) = 1 - \frac{1}{(\log_2 n)^2}. \end{aligned}$$

Hence, with high probability,

$$t \geq \frac{n - n^{1/2} \log_2 n}{(1 + \delta_1) \log_2 n} = \frac{1}{1 + \delta_1} \left(\frac{n}{\log_2 n} \right) - \frac{1}{1 + \delta_1} n^{1/2} > (1 - 2\delta_1) \frac{n}{\log_2 n} > \frac{n}{2 \log_2 n}.$$

We will improve this lower bound on t by using Lemma 9 to show that many of the S_i are of a smaller size. However, since the probability in Lemma 9 is smaller, we can no longer use the union-sum bound as above. Instead, we will use Chernoff's inequality.

Let X_i be the indicator variable for the event that in Phase III during the construction of our maximal independent set S_i , G_i contains a maximal independent set of size larger than $10 \log_2 \log_2 n_i$. Then $X_i = 1$ with probability at most $p_i = p(n_i)$.

Next, we want to apply the following version of Chernoff's inequality to prove that, with high probability, $\sum_{i=1}^t X_i \leq 2pt$, where $p = \frac{\sum_{i=1}^t p_i}{t}$.

LEMMA 10 (see [1, pp. 263–265]). *Let $p_1, \dots, p_n \in [0, 1]$, and $\mathbb{P}[X_i = 1 - p_i] = p_i, \mathbb{P}[X_i = -p_i] = 1 - p_i$. If $X = \sum_{i=1}^n X_i$, then*

$$\mathbb{P}[X > a] < \exp(-2a^2/n).$$

Note that if $\mathbb{P}[X_i = 1]$ is smaller, then (10) remains true. So to get an upper bound of $\sum_{i=1}^t X_i$ with high probability, in the following proof we may assume that $\mathbb{P}[X_i = 1] = p_i = p(n_i)$.

Proof. Let $Y_i = X_i - p_i$ for $i = 1, \dots, t$. Then $\mathbb{P}[Y_i = 1 - p_i] = p_i$ and $\mathbb{P}[Y_i = -p_i] = 1 - p_i$. By Lemma 10 we have $\mathbb{P}[\sum_{i=1}^t Y_i > pt] < \exp(-2(pt)^2/t) = \exp(-2p^2t)$. Hence $\mathbb{P}[X > 2pt] < \exp(-2p^2t)$.

Since

$$p = \frac{\sum_{i=1}^t p_i}{t} \geq \frac{\sum_{i=1}^t 2^{-(10 \log_2 \log_2 n_i)}}{t} \geq 2^{-(10 \log_2 \log_2 n)} \geq 2^{-50(\log_2 \log_2 n)^2}$$

and $t \geq \frac{n}{2 \log_2 n}$,

$$\begin{aligned} \mathbb{P}[X > 2pt] &< \exp(-2p^2t) < \exp\left(-2 \cdot 2^{-100(\log_2 \log_2 n)^2} \cdot \frac{n}{2 \log_2 n}\right) \\ &= \exp(-2^{-100(\log_2 \log_2 n)^2 + \log_2 n - \log_2 \log_2 n}) \rightarrow 0 \text{ as } n \rightarrow \infty. \end{aligned}$$

So $\sum_{i=1}^t X_i \leq 2pt$ with high probability. $\square$

By Lemma 9, there exists a maximal independent set S_i in G_i of size at most $(1 + \delta_2) \log_2 n_i$ with probability greater than $(1 - n_i^{-3})^2(1 - p(n))$.

We have proved that with high probability, each S_i has size at most $(1 + \delta_1) \log_2 n_i$. Meanwhile, by the proof above we know that among these S_i 's, at most $2pt$ of them can have size greater than $(1 + \delta_2) \log_2 n_i$. Thus,

$$2pt \cdot (1 + \delta_1) \log_2 n + (t - 2pt)(1 + \delta_2) \log_2 n \geq n - n^{1/2} \log_2 n.$$

Hence,

$$\begin{aligned} \chi_{FF}(G) \geq t &\geq \frac{n - n^{1/2} \log_2 n}{[2p(1 + \delta_1) + (1 - 2p)(1 + \delta_2)] \log_2 n} \\ &= \left[\frac{1}{1 + \delta_2} \left(\frac{n}{\log_2 n} \right) - \frac{1}{1 + \delta_2} n^{1/2} \right] \frac{1 + \delta_2}{1 + \delta_2 + 2p(\delta_1 - \delta_2)} \\ &> (1 - 2\delta_2) \frac{n}{\log_2 n} \left(\frac{1 + \delta_2}{1 + \delta_2 + 2p\delta_1} \right) \\ &> (1 - 2\delta_2)(1 - 2p\delta_1) \frac{n}{\log_2 n} > (1 - 2p\delta_1 - 2\delta_2) \frac{n}{\log_2 n}. \end{aligned}$$

Since each $n_i \geq n^{1/2} \log_2 n > n^{1/2}$, we have

$$p = \frac{\sum_{i=1}^t p_i}{t} \leq \left(\frac{c}{\log_2(\sqrt{n})} \right)^{30 \log_2 \log_2(\sqrt{n})}.$$

When n is large, we have

$$\left(\frac{c}{\log_2(\sqrt{n})} \right)^{30 \log_2 \log_2(\sqrt{n})} < \frac{\log_2 \log_2 n}{\sqrt{\log_2 n}}$$

and so $2p\delta_1 < 2 \cdot \log_2 \log_2 n / \sqrt{\log_2 n} \cdot (18 / \sqrt{\log_2 n}) < \delta_2$.

Hence $\chi_{FF}(G) > (1 - 3\delta_2) \frac{n}{\log_2 n}$ for $\delta_2 = 10(\ln \ln n)^2 / \log_2 n$ and as $n \rightarrow \infty$. $\square$

3.1. Concentration. We next consider the concentration of the first-fit chromatic number of random graphs. We omit the proof of the following easy statement.

PROPOSITION 11. (i) Let G be a graph and H be a subgraph of G formed by deleting one edge from G . Then $|\chi_{FF}(G) - \chi_{FF}(H)| \leq 1$.

(ii) Let G be a graph and H be a subgraph of G formed by deleting one vertex from G . Then $\chi_{FF}(H) \leq \chi_{FF}(G) \leq \chi_{FF}(H) + 1$.

Note that there are graphs whose first-fit chromatic number drops when an edge is added. The smallest such example is P_4 , which has $\chi_{FF}(P_4) = 3$, while $\chi_{FF}(C_4) = 2$.

Since the first-fit chromatic number satisfies the vertex Lipschitz condition, we obtain a tight concentration via the vertex exposure martingale and Azuma's inequality (see [1, pp. 95–96]).

THEOREM 12. Let $G \sim G_{n,p}$ for any probability p . Then

$$\mathbb{P} [|\chi_{FF}(G) - \mathbb{E}[\chi_{FF}(G)]| > \lambda \sqrt{n-1}] < 2e^{-\lambda^2/2}.$$

This concentration result is analogous to the result of Shamir and Spencer [1] about the tight concentration of the chromatic number of the random graph.

4. First-fit chromatic number of product of graphs. In this section we discuss the first-fit chromatic number of $G \square P_2$, $G \square P_3$, and $G \square P_4$.

THEOREM 13. *Let $\chi_{FF}(G)$ be even. Then*

$$\chi_{FF}(G \square P_3) \geq \chi_{FF}(G) + 2.$$

Proof. For simplicity let $V(P_3) := \{1, 2, 3\}$. Suppose $\chi_{FF}(G) = 2k$. Then there exists a first-fit partition of $V(G)$ into $2k$ nonempty sets $\langle V_1, V_2, \dots, V_{2k} \rangle$. We construct a partition $\langle U_1, \dots, U_{2k+2} \rangle$ of $V(G \square P_3)$ as follows:

1. For $1 \leq i \leq k-1$, let

$$\begin{aligned} U_{2i-1} &= \{(u, 1) \mid u \in V_{2i-1}\} \cup \{(v, 2) \mid v \in V_{2i}\} \cup \{(u, 3) \mid u \in V_{2i-1}\}, \\ U_{2i} &= \{(v, 1) \mid v \in V_{2i}\} \cup \{(u, 2) \mid u \in V_{2i-1}\} \cup \{(v, 3) \mid v \in V_{2i}\}. \end{aligned}$$

2. For $k \leq i \leq k+1$, choose two adjacent vertices $u \in V_{2k-1}$ and $v \in V_{2k}$. Let $U_{2k-1} = \{(u, 3), (v, 1)\}$, $U_{2k} = \{(u, 1), (v, 3)\}$, $U_{2k+1} = \{(u, 2)\}$, $U_{2k+2} = \{(v, 2)\}$.

3. Add the remaining vertices to the previous parts greedily.

Since the V_i ($1 \leq i \leq 2k$) are all independent, it is easy to see that all U_i ($1 \leq i \leq 2k+2$) are also independent.

For each $1 \leq j < i \leq k-1$ and each $u \in V_{2i-1}$, $v \in V_{2i}$, there exist vertices $x_1, y_1 \in V_{2j-1}$ and vertices $x_2, y_2 \in V_{2j}$ such that x_1, x_2 are neighbors of u and y_1, y_2 are neighbors of v . Thus by the construction, (u, a) is adjacent to $(x_1, a) \in U_{2j-1}$ and $(x_2, a) \in U_{2j}$ for $a = 1, 3$, and $(u, 2)$ is adjacent to $(x_2, 2) \in U_{2j-1}$ and $(x_1, 2) \in U_{2j}$.

Similarly, (v, a) is adjacent to $(y_1, a) \in U_{2j-1}$ and $(y_2, a) \in U_{2j}$ for $a = 1, 3$, and $(v, 2)$ is adjacent to $(y_2, 2) \in U_{2j-1}$ and $(y_1, 2) \in U_{2j}$.

Similarly, we can check that any vertex in $U_{2k-1}, U_{2k}, U_{2k+1}, U_{2k+2}$ has a neighbor in the lower indexed subsets.

Thus $\langle U_1, \dots, U_{2k+2} \rangle$ is a first-fit partition of $G \square P_3$, so $\chi_{FF}(G \square P_3) \geq \chi_{FF}(G) + 2$ if $\chi_{FF}(G)$ is even. $\square$

We next consider the first-fit chromatic number of $G \square P_4$.

THEOREM 14. *For every graph G ,*

$$\chi_{FF}(G \square P_4) \geq \chi_{FF}(G) + 2.$$

Proof. Suppose $\chi_{FF}(G) = t$.

If t is even, since $G \square P_3$ is an induced subgraph of $G \square P_4$, then $\chi_{FF}(G \square P_4) \geq \chi_{FF}(G \square P_3) \geq \chi_{FF}(G) + 2$.

If $t = 2k-1$ is odd, then we can make a partition similar to the one in the proof of Theorem 13 as follows. Let $\{1, 2, 3, 4\}$ be the vertex set of P_4 . Then we have the following.

1. For $1 \leq i \leq k-1$, let

$$\begin{aligned} U_{2i-1} &= \{(u, 1) \mid u \in V_{2i-1}\} \cup \{(v, 2) \mid v \in V_{2i}\} \\ &\quad \cup \{(u, 3) \mid u \in V_{2i-1}\} \cup \{(v, 4) \mid v \in V_{2i}\}, \\ U_{2i} &= \{(v, 1) \mid v \in V_{2i}\} \cup \{(u, 2) \mid u \in V_{2i-1}\} \\ &\quad \cup \{(v, 3) \mid v \in V_{2i}\} \cup \{(u, 4) \mid u \in V_{2i-1}\}. \end{aligned}$$

2. Choose a vertex $u \in V_{2k-1}$. Let $U_{2k-1} = \{(u, 1), (u, 4)\}$, $U_{2k} = \{(u, 3)\}$, $U_{2k+1} = \{(u, 2)\}$.

3. For the remaining vertices, add them to the previous parts greedily.

It is easy to check that the above partition is a first-fit partition following an argument similar to the one in the proof of Theorem 13. $\square$

Effantin and Kheddouci [6] proved the following theorem for products of even cycles. We extend this result to include odd cycles in the product.

THEOREM 15 (see [6]). $\chi_{FF}(C_{m_1} \square C_{m_2} \square \dots \square C_{m_k}) = 2k + 1$, where $k \geq 2$, $m_i \geq 4$, and m_i is even.

COROLLARY 16. Let $C_{m_1}, C_{m_2}, \dots, C_{m_k}$ be cycles of size $m_1, m_2, \dots, m_k$, respectively, where $k \geq 2$ and $m_i \geq 4$. Then

$$\chi_{FF}(C_{m_1} \square C_{m_2} \square \dots \square C_{m_k}) = 2k + 1.$$

Proof. The upper bound follows from the obvious degree bound, $\chi_{FF}(G) \leq \Delta(G) + 1$. For the lower bound, we first reorder m_i 's to place the even m_i 's first, followed by the odd ones.

Case 1. If no m_i is odd, then the corollary follows from Theorem 15.

Case 2. If we have $k_1 \geq 2$ even m_i 's, then the product graph of k_1 even cycles has first-fit chromatic number $2k_1 + 1$ by Theorem 15. Then for the following odd cycles, since P_4 is an induced subgraph of any odd cycle of length at least 4, we can repeatedly apply Theorem 14.

If we have at most one even cycle which is not C_4 , then the fact that $\chi_{FF}(C_n) = 3$ for $n \geq 5$ and repeatedly applying Theorem 14 prove the corollary. If the sole even cycle is C_4 , then we use the fact that $\chi_{FF}(C_4 \square P_4) = 5$ and again repeatedly apply Theorem 14. $\square$

Note that a statement for $G \square P_2$ analogous to Theorems 13 and 14 does not hold because $\chi_{FF}(P_2 \square P_2) = 2 = \chi_{FF}(P_2)$. How large can $\chi_{FF}(G \square P_2)$ be? In the following example we show that $\chi_{FF}(G \square P_2)$ can be as large as $2\chi_{FF}(G)$. Since $G \square P_2$ is an induced subgraph of $G \square P_3$ and $G \square P_4$, $\chi_{FF}(G \square P_3)$ and $\chi_{FF}(G \square P_4)$ can be as large as $2\chi_{FF}(G)$ as well.

PROPOSITION 17. Let G be a graph formed by removing a perfect matching M from K_{2m} . Then $\chi_{FF}(G \square P_2) = 2\chi_{FF}(G)$.

Proof. Suppose $V(K_{2m}) = \{u_1, \dots, u_{2m}\}$ and the deleted matching is $M = \{u_1 u_2, \dots, u_{2m-1} u_{2m}\}$. Consider a first-fit partition $\langle V_1, \dots, V_t \rangle$ of $V(G)$, where $\chi_{FF}(G) = t$. Without loss of generality, suppose $u_1 \in V_1$. Then except u_2 , all other vertices are adjacent to u_1 , so they cannot be in V_1 . Then u_2 must be in V_1 ; otherwise it does not have any neighbor in V_1 . So $V_1 = \{u_1, u_2\}$. Inductively, we can see that $V_i = \{u_{2i-1}, u_{2i}\}$. So $\chi_{FF}(G) = t = m$. For $G \square P_2$, we can make a partition as follows:

For $1 \leq i \leq t$, $U_{2i-1} = \{(u_{2i-1}, 1), (u_{2i}, 2)\}$, $U_{2i} = \{(u_{2i-1}, 2), (u_{2i}, 1)\}$, where $\{1, 2\}$ is the vertex set of P_2 .

So $\chi_{FF}(G \square P_2) \geq 2\chi_{FF}(G)$. For the upper bound, $\chi_{FF}(G \square P_2) \leq \Delta(G \square P_2) + 1 = (2m - 1) + 1 = 2m$. Hence $\chi_{FF}(G \square P_2) = 2\chi_{FF}(G)$ in this case. $\square$

We believe that $\chi_{FF}(G \square P_2) \leq 2\chi_{FF}(G)$ for every graph G .

Acknowledgments. The authors thank Zoltán Füredi for his encouragement and helpful discussions and Weiting Cao for helpful discussions during the early stages of this project. The authors also thank the anonymous referee for an improvement to Lemma 4 and for comments that improved the readability of the paper, and Alan Frieze for pointing out reference [2].

NONLINEAR MATROID OPTIMIZATION AND EXPERIMENTAL DESIGN*

Yael Bernstein[†], Jon Lee[‡], Hugo Maruri-Aguilar[§], Shmuel Onn[†],
Eva Riccomagno[¶], Robert Weismantel^{||}, and Henry Wynn[§]

Abstract. We study the problem of optimizing nonlinear objective functions over matroids presented by oracles or explicitly. Such functions can be interpreted as the balancing of multicriteria optimization. We provide a combinatorial polynomial time algorithm for arbitrary oracle-presented matroids, that makes repeated use of matroid intersection and an algebraic algorithm for vectorial matroids. Our work is partly motivated by applications to minimum-aberration model-fitting in experimental design in statistics, which we discuss and demonstrate in detail.

1. Introduction. In this article, partly motivated by applications to minimum-aberration model-fitting in experimental design, which will be discussed briefly at the end of this introduction and in detail in section 5, we study the problem of optimizing an arbitrary nonlinear function over a matroid as follows.

Nonlinear matroid optimization. Given matroid M on ground set $N := \{1, \dots, n\}$, integer weight vectors $w_i = (w_{i,1}, \dots, w_{i,n}) \in \mathbb{Z}^n$ for $i = 1, \dots, d$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$, find a matroid base $B \in \mathcal{B}(M) \subset 2^N$ minimizing the “balancing” by f of

the d weights $w_i(B) := \sum_{j \in B} w_{i,j}$ of base B ,

$$f(w_1(B), \dots, w_d(B)) = f\left(\sum_{j \in B} w_{1,j}, \dots, \sum_{j \in B} w_{d,j}\right).$$

(All necessary basics about matroid theory are provided in section 2.1. For more details consult [14] or [17].)

Nonlinear matroid optimization can be interpreted as *multicriteria matroid optimization*: the d given weight vectors $w_1, \dots, w_d$ represent d different criteria, where the value of base $B \in \mathcal{B}(M)$ under criterion i is its i th weight $w_i(B) = \sum_{j \in B} w_{i,j}$, and where the objective is to minimize the “balancing” $f(w_1(B), \dots, w_d(B))$ of the d given criteria by the given function f .

In fact, we have a hierarchy of problems of increasing generality, parameterized by the number d of weight vectors. At the bottom of the hierarchy lies standard linear matroid optimization, recovered with $d = 1$ and f being the identity on $\mathbb{Z}$. At the top of the hierarchy lies the problem of maximizing an arbitrary function over the set of bases, with $d = n$ and $w_i = \mathbf{1}_i$, the i th standard unit vector in $\mathbb{Z}^n$ for all i ; see Proposition 2.4.

It will often be convenient to collect the weight vectors in a $d \times n$ matrix W . Thus, the i th row of this matrix is the i th weight vector $w_i = (w_{i,1}, \dots, w_{i,n})$. For each subset $S \subseteq N$ we define its W -image to be

$$W(S) := (w_1(S), \dots, w_d(S)) := \left(\sum_{j \in S} w_{1,j}, \dots, \sum_{j \in S} w_{d,j}\right) \in \mathbb{Z}^d,$$

which is the vector giving the value of S under each of the d weight vectors. The nonlinear matroid optimization then asks for a matroid base $B \in \mathcal{B}(M)$ minimizing the objective function $f(W(B))$.

The computational complexity of nonlinear matroid optimization depends on the number d of weight vectors, on the representation of weights (binary $\langle w_{i,j} \rangle$ versus unary $|w_{i,j}|$; see section 2.1), on the type of function f and its presentation, and on the type of matroid and its presentation. We will be able to handle an arbitrary function f presented by a *comparison oracle* that, queried on $u, v \in \mathbb{Z}^d$, asserts whether or not $f(u) \leq f(v)$, and an arbitrary matroid presented by an *independence oracle*, that, queried on $I \subseteq N$, asserts whether or not I is *independent* in M , that is, whether $I \subseteq B$ for some base $B \in \mathcal{B}(M)$; see section 2.1. These are very broad presentations that reveal little information (per query) on the function and matroid, making our problem setting rather expressive but difficult for achieving strong complexity results.

Standard linear matroid optimization is well known to be efficiently solvable by the greedy algorithm. Nonlinear matroid optimization with d fixed and f *concave* turns out to be solvable in polynomial time as well [8, 11]. In fact, using sophisticated geometric methods, the nonlinear optimization problem with d fixed and f concave has been recently shown to be efficiently solvable for bipartite matching [4] and for broader classes of combinatorial optimization problems [12]. Therein, maximization rather than minimization form is used; hence, convex rather than concave functions are considered.

However, generally, nonlinear matroid optimization is intractable, even for uniform matroids. In particular, if d is variable, then exponential time is needed even for $\{0, 1\}$ -valued weights, and if the weights are encoded in binary, then exponential

time is needed even for fixed dimension $d = 1$. See Propositions 2.3, 2.4, and 2.5 in what follows for various intractability statements.

In spite of these difficulties, we establish here the efficient solvability of the problem as follows.

THEOREM 1.1. *For every fixed d and p , there is an algorithm that, given a matroid M presented by an independence oracle on the n -element ground set N , integers $a_1, \dots, a_p \in \mathbb{Z}$, weight vectors $w_1, \dots, w_d \in \{a_1, \dots, a_p\}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the nonlinear matroid optimization problem in time that is polynomial in n and $\max\langle a_i \rangle$.*

We also state the following natural immediate corollary concerning $\{0, 1, \dots, p\}$ -valued weights.

COROLLARY 1.2. *For every fixed d and p , there is an algorithm that, given n -element matroid M presented by an independence oracle, $w_1, \dots, w_d \in \{0, 1, \dots, p\}^n$ and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the nonlinear matroid optimization problem in time polynomial in n .*

The algorithm establishing Theorem 1.1 is combinatorial and makes repeated use of matroid intersection (see, e.g., [9] or [10], and see [7] for another recent interesting application of matroid intersection). In fact, it invokes the matroid intersection algorithm roughly n^{p^d} times, and hence it is quite heavy. However, most matroids appearing in practice, including graphic matroids and those arising in the applications to experimental design to be discussed later, are vectorial. Therefore, we also provide another more efficient, linear-algebraic algorithm for vectorial matroids. Moreover, this algorithm applies to weights with an unlimited number (rather than a fixed number p) of different values $w_{i,j}$ of entries.

THEOREM 1.3. *For every fixed d , there is an algorithm that, given integer $m \times n$ matrix A , weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the nonlinear optimization problem over the (real) vectorial matroid of A in time polynomial in $\langle A \rangle$ and $\max |w_{i,j}|$.*

A specific application that can be solved by either the combinatorial algorithm underlying Theorem 1.1 or the more efficient linear-algebraic algorithm underlying Theorem 1.3 is the following example.

Example 1.4 (minimum-norm spanning tree). Fix any positive integer d . Let G be any connected graph with edge set $E = \{e_1, \dots, e_n\}$, and let $w_1, \dots, w_d \in \mathbb{Z}^n$ be weight vectors with $w_{i,j}$ representing the values of edge e_j under the i th criterion. Let A be the vertex-arc incidence matrix of an arbitrary orientation of G . Then the vectorial matroid of A is the graphic matroid of G whose bases are the spanning trees of G . Now fix also any q that is either a positive integer or ∞ , and let $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ be the l_q norm given by $\|u\|_q := (\sum_{i=1}^d |u_i|^q)^{\frac{1}{q}}$ for finite q and $\|u\|_\infty := \max_{i=1}^d |u_i|$. Note that a comparison oracle for $f(u) = \|u\|_q$ is easily and efficiently realizable. Then Theorems 1.1 and 1.3 assure that a spanning tree T of G minimizing the l_q norm of the multicriteria vector, given by

$$\|(w_1(T), \dots, w_d(T))\|_q = \|W(T)\|_q$$

is computable in time polynomial in n and $\max |w_{i,j}|$. Note that if $P \neq NP$, then the problem is *not* solvable in time polynomial in the binary length $\langle w_{i,j} \rangle$ even for the graph obtained from a path by replacing every edge by two parallel copies; see Proposition 2.5.

Experimental design. We conclude the introduction with a brief discussion of the application to experimental design, elaborated in detail in section 5. The general

framework is as follows. We are interested in learning an unknown system whose output y is an unknown function Φ of a multivariate input $x = (x_1, \dots, x_k) \in \mathbb{R}^k$. It is customary to call the input variables x_j *factors* of the system. In order to learn the system, we perform several experiments. Each experiment i is determined by a point $p_i = (p_{i,1}, \dots, p_{i,k})$ and consists of feeding the system with input $x := p_i$ and measuring the corresponding output $y_i = \Phi(p_i)$. Based on these experiments, we wish to *fit a model* for the system, namely, determine an estimation $\hat{\Phi}$ of the function Φ , that satisfies the following properties:

- It lies in a prescribed class of functions.
- It is consistent with the outcomes of the experiments.
- It minimizes the *aberration*—a suitable criterion—among models in the class.

More detailed discussion and precise definitions will be given in section 5. We have the following broad corollary of Theorems 1.1 and 1.3; see section 5 for the precise statement and its various practical specializations to concrete aberration criteria useful in optimal model-fitting in experimental design.

COROLLARY 1.5. *An aberration-minimum multivariate-polynomial model is polynomial time computable.*

The article proceeds as follows. In section 2 we set some notation and preliminaries, make some preparations for the algorithms in the following sections, and demonstrate various intractability limitations on nonlinear matroid optimization. In section 3 we discuss arbitrary matroids presented by oracles, and provide the combinatorial algorithm for nonlinear matroid optimization, thereby establishing Theorem 1.1. In section 4 we provide the more efficient algebraic algorithm for nonlinear optimization over vectorial matroids, thereby proving Theorem 1.3. We conclude in section 5 with a detailed discussion of the experimental design application and prove Corollary 5.2 (a refined version of Corollary 1.5) and its various practical specializations. Readers interested mostly in experimental design can go directly to section 5, where the minimum-aberration model-fitting problem is reduced to nonlinear optimization over a suitable matroid, and where each of the algorithms developed in sections 3 and 4 can be invoked as a black box.

2. Preliminaries, preparation, and limitations.

2.1. Preliminaries. We use $\mathbb{R}$ for the reals, $\mathbb{Z}$ for the integers, and $\mathbb{N}$ for the nonnegative integers. The i th standard unit vector in $\mathbb{R}^n$ is denoted by $\mathbf{1}_i$. The *support* of $x \in \mathbb{R}^n$ is the index set $\text{supp}(x) := \{j : x_j \neq 0\}$ of nonzero entries of x . The integer lattice $\mathbb{Z}^n$ is naturally embedded in $\mathbb{R}^n$. Vectors will be interpreted as either row or column vectors interchangeably—this will be relevant only when such vectors are multiplied by matrices—in which case the correct interpretation will be clear from the context. We often collect a sequence of vectors designated by a lower-case letter as the rows of a matrix designated by the corresponding upper case letter. Thus, our weight vectors $w_i = (w_{i,1}, \dots, w_{i,n})$, $i = 1, \dots, d$ are arranged in a $d \times n$ matrix W , and our design points $p_i = (p_{i,1}, \dots, p_{i,k})$, $i = 1, \dots, m$ are arranged in an $m \times k$ matrix P . The space $\mathbb{R}^n$ is endowed with the standard inner product which, for $w, x \in \mathbb{R}^n$, is $w \cdot x := \sum_{i=1}^n w_i x_i$. Vectors w in $\mathbb{R}^n$ are also regarded as linear functions on $\mathbb{R}^n$ via the inner product $w \cdot x$. Therefore, we refer to elements of $\mathbb{R}^n$ as points, vectors, or linear functions, as is appropriate from the context. We write $\mathbf{1}$ for the vector with all entries equal to 1, with the dimension being clear from the context.

Our algorithms are analyzed for rational data only, and the time complexity is as in the standard Turing machine model; see, e.g., [1, 6, 16]. The input typically

consists of rational (usually integer) numbers, vectors, matrices, and finite sets of such objects. The *binary length* of an integer number $z \in \mathbb{Z}$ is defined to be the number of bits in its binary representation, $\langle z \rangle := 1 + \lceil \log_2(|z| + 1) \rceil$ (with the extra bit for the sign). The length of a rational number presented as a fraction $r = \frac{p}{q}$ with $p, q \in \mathbb{Z}$ is $\langle r \rangle := \langle p \rangle + \langle q \rangle$. The length of an $m \times n$ matrix A (or a vector) is the sum $\langle A \rangle := \sum_{i,j} \langle a_{i,j} \rangle$ of the lengths of its entries. Note that the length of A is no smaller than the number of entries, $\langle A \rangle \geq mn$. Therefore, when A is, say, part of an input to an algorithm, with m and n not fixed, the length $\langle A \rangle$ already incorporates mn , and so we will typically not account additionally for m, n directly. But sometimes we will also emphasize n as part of the input length. Similarly, the length of a finite set S of numbers, vectors, or matrices is the sum of lengths of its elements and hence, since $\langle S \rangle \geq |S|$, automatically accounts for its cardinality. Some input numbers affect the running time of some algorithms through their unary presentation, resulting in so-called “pseudo-polynomial” running time. The *unary length* of an integer number $z \in \mathbb{Z}$ is the number $|z| + 1$ of bits in its unary representation (again, an extra bit for the sign). The unary length of a rational number, vector, matrix, or finite set of such objects is defined again as the sums of lengths of their numerical constituents, and is again no smaller than the number of such numerical constituents. Often part of the input is presented by oracles. Then the running time counts also the number of oracle queries. An oracle algorithm is *polynomial time* if its running time, including the number of oracle queries, is polynomial in the length of the input.

Next, we make some basic definitions concerning matroids and set some associated notation; for matroid theory, see [14] or [17]. A *matroid* M is described by giving a finite *ground set* $\mathcal{E}(M)$ and a nonempty set $\mathcal{B}(M)$ of subsets of $\mathcal{E}(M)$ called the set of *bases* of M , such that for every $B, B' \in \mathcal{B}(M)$ and $i \in B \setminus B'$ there is an $i' \in B'$ such that $B \setminus \{i\} \cup \{i'\} \in \mathcal{B}(M)$. A subset I of $\mathcal{E}(M)$ is *independent* in M if $I \subseteq B$ for some base $B \in \mathcal{B}(M)$. The set of independent sets of M is denoted by $\mathcal{I}(M)$. Often it is convenient to let $\mathcal{E}(M) = N = \{1, 2, \dots, n\}$ for some positive integer n . The *rank* $\text{rank}(S)$ of a subset $S \subseteq \mathcal{E}(M)$ is the maximum cardinality $|I|$ of an $I \in \mathcal{I}(M)$ that is contained in S . The *rank* of the matroid is $\text{rank}(M) := \text{rank}(\mathcal{E}(M))$ and is equal to the cardinality $|B|$ of every base $B \in \mathcal{B}(M)$. An *independence oracle* for M is one that, queried on $I \subseteq \mathcal{E}(M)$, asserts whether I is in $\mathcal{I}(M)$. An independence oracle allows us to compute the rank of every $S \subseteq \mathcal{E}(M)$ as follows. Start with $I := \emptyset$. For each $j \in S$ (in any order) do: if $I \cup \{j\}$ is in $\mathcal{I}(M)$, then set $I := I \cup \{j\}$. Output $\text{rank}(S) := |I|$.

An important example of a matroid is the *graphic matroid* $M(G)$ of a graph G with $\mathcal{E}(M(G))$ being the edge set of G and $\mathcal{B}(M(G))$ equal to the set of edge sets of spanning forests of G . A further key example is the *vectorial matroid* of an $m \times n$ matrix A (over a field $\mathbb{F}$) with $\mathcal{B}(M)$ the set of subsets of indices of maximal linearly-independent subsets of columns of A . Throughout, when treating complexity issues, we assume that $\mathbb{F}$ is the field $\mathbb{Q}$ of rationals, that A has integer components, and that we do arithmetic over $\mathbb{Q}$. A *uniform matroid* is any matroid that is isomorphic to the matroid $\mathcal{U}_{m,n}$ having ground set $N = \{1, \dots, n\}$ and having all m -subsets of N as bases. If M_1 and M_2 are matroids with disjoint ground sets, then their *direct sum* $M_1 \oplus M_2$ has $\mathcal{E}(M_1 \oplus M_2) := \mathcal{E}(M_1) \uplus \mathcal{E}(M_2)$ and $\mathcal{B}(M_1 \oplus M_2) := \{B_1 \uplus B_2 : B_1 \in \mathcal{B}(M_1), B_2 \in \mathcal{B}(M_2)\}$. A *partition matroid* is any matroid that is a direct sum of uniform matroids $\oplus_{i=1}^r \mathcal{U}_{m_i, n_i}$ (with the ground sets of the $\mathcal{U}_{m_i, n_i}$ labeled to be pairwise disjoint). If $m_i = m$ and all $n_i = k$ for all i , then we write $\mathcal{U}_{m,k}^r$ for this r -fold sum of $\mathcal{U}_{m,k}$.

It is well known that all graphic matroids and uniform matroids are vectorial. Furthermore, any partition matroid that is the direct sum $\oplus_{i=1}^r \mathcal{U}_{1,n_i}$ of rank-1 uniform matroids is graphic: it is the matroid of the graph obtained from any forest on r edges by replacing the i th edge by n_i parallel copies for $i = 1, \dots, r$. In particular, $\mathcal{U}_{1,k}^r$ is a graphic matroid for any positive k and r .

2.2. Preparation. Here we provide preparatory ingredients which will be used in algorithms in sections 3 and 4. First, we record for later the following statement, which follows directly from the definitions.

PROPOSITION 2.1. *Consider n -element matroid M , weights $w_1, \dots, w_d \in \mathbb{Z}^n$, and $f : \mathbb{Z}^d \rightarrow \mathbb{R}$. Put*

$$U := \{W(B) : B \in \mathcal{B}(M)\} = \{u \in \mathbb{Z}^d : u = W(B) \text{ for some base } B \in \mathcal{B}(M)\}.$$

Then the optimal objective value of the corresponding nonlinear matroid optimization problem satisfies

$$f^* = \min \{f(u) : u \in U\}.$$

In light of this viewpoint, with respect to the definitions of U and f^* from Proposition 2.1, an *optimal W -image* is any $u \in U$ satisfying $f(u) = f^*$.

Thus, the problem of computing f^* reduces to that of constructing the set U of W -images of bases, and then extracting an optimal W -image from U . This really is the crucial component of the solution of the nonlinear matroid optimization problem. While the cardinality of $U = \{W(B) : B \in \mathcal{B}(M)\}$ may be polynomial under suitable assumptions on the data, its direct computation by computing $W(B)$ for every base is prohibitive since the number of matroid bases is typically exponential in n . Instead, we will construct a finite superset Z of “potential” W -images of bases, satisfying $U \subseteq Z \subseteq \mathbb{Z}^d$, and then filter U out of Z . However, this is not an easy task either: deciding if a given $u \in \mathbb{Z}^d$ satisfies $u = W(B)$ for some base B is NP-complete already for fixed $d = 1$ and uniform matroids or partition matroids that are the direct sums of rank-1 uniform matroids; see Proposition 2.5. The way the filtration of U out of Z is done is precisely the key difference between our two algorithms for nonlinear matroid optimization in sections 3 and 4.

Next, we demonstrate that finding an optimal base for a nonlinear matroid optimization problem can be reduced to finding an optimal W -image for a small number of subproblems. Consider data for a nonlinear matroid optimization problem, consisting of a matroid M , weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$. Each subset $S \subseteq N$ gives a *subproblem* of nonlinear matroid optimization as follows. The matroid of the subproblem is the *restriction* of M to S ; that is, the matroid $M.S$ on ground set S in which a subset $I \subseteq S$ is independent if and only if it is independent in M . Note that an independence oracle for the restriction matroid $M.S$ is realizable at once from that of M . The weight vectors of the subproblem are the restrictions of the original weight vectors to S . The function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ in the subproblem is the same as in the original problem. We have the following useful statement.

LEMMA 2.2. *The nonlinear matroid optimization problem of finding an optimal base of an n -element matroid is reducible in time polynomial in n to finding an optimal W -image for $n + 1$ subproblems.*

Proof. Denote by $u^*(S)$ the optimal W -image for the subproblem on $S \subseteq N$. Now compute an optimal base for the original problem, by computing an optimal W -image for $n + 1$ such subproblems as follows.

```

Start with  $S := N$ ;
Compute  $m := \text{rank}(S)$ ;
Compute an optimal  $W$ -image  $u^* := u^*(N)$  of the original problem;
for  $j=1, 2, \dots, n$  do
    Compute  $\text{rank}(S \setminus \{j\})$ ;
    Compute an optimal  $W$ -image  $u^*(S \setminus \{j\})$ ;
    if  $\text{rank}(S \setminus \{j\}) = m$  and  $f(u^*(S \setminus \{j\})) = f(u^*)$  then set  $S := S \setminus \{j\}$ ;
end
return  $B := S$ ;

```

It is not hard to verify that the set B obtained is indeed an optimal base for the original problem. $\square$

2.3. Limitations. Here we provide various intractability statements about the nonlinear matroid optimization problem and some of its relatives. In particular, we show that, if the weights are encoded in binary, then even the 1-dimensional problem, namely with fixed $d = 1$, over any matroid given explicitly or by an oracle, requires examining the objective value of *every* base, and hence cannot be solved in polynomial time.

It is convenient to define a certain class of rank k matroids on $2k$ elements, so as to generalize the uniform matroid $\mathcal{U}_{k,2k}$ and the partition matroids $\mathcal{U}_{1,2}^k$. For some r , $1 \leq r \leq k$, partition $K = \{1, \dots, k\}$ into r parts as $\uplus_{i=1}^r K_i$. Correspondingly, let $\bar{K}_i := \{\bar{j} : j \in K_i\}$. Let $k_i = |K_i| = |\bar{K}_i|$. For $i = 1, \dots, r$, let $\mathcal{M}_i$ be a uniform matroid of rank k_i on ground set $K_i \cup \bar{K}_i$ (so $\mathcal{M}_i \cong \mathcal{U}_{k_i,2k_i}$). Let $\mathcal{M}_{r,k} := \oplus_{i=1}^r \mathcal{M}_i$. Observe that $\mathcal{M}_{1,k} \cong \mathcal{U}_{k,2k}$ (which is uniform) and $\mathcal{M}_{k,k} \cong \mathcal{U}_{1,2}^k$ (which is graphic), so *hardness results with respect to the matroid classes $\mathcal{M}_{r,k}$ apply to uniform and graphic matroids*. We note and will soon use that for any r , $1 \leq r \leq k$, $|\mathcal{B}(\mathcal{M}_{r,k})|$ is not bounded by any polynomial in $|\mathcal{E}(\mathcal{M}_{r,k})| = 2k$.

PROPOSITION 2.3. *Computing an optimal solution of the 1-dimensional nonlinear matroid optimization problem over any matroid M , given explicitly or by an oracle, on n -element ground sets, and a univariate function f presented by a comparison oracle, cannot be done in polynomial time. In particular, with the single weight vector $w := (1, 2, 4, \dots, 2^{n-1})$, solution of the nonlinear matroid optimization problem requires examining $f(W(B))$ for each of the $|\mathcal{B}(M)|$ bases of M . In particular, for each r , $1 \leq r \leq k$, the problem cannot be solved in polynomial time for the class of matroids $\mathcal{M}_{r,k}$.*

Proof. The weights $w(S) = \sum_{j \in S} 2^{j-1}$ of the 2^n subsets $S \subseteq N$ attain precisely all 2^n distinct values $0, 1, \dots, 2^n - 1$. Since the function f is arbitrary, this implies that the objective value $f(W(B))$ of each base B can be arbitrary. Therefore, if the value $f(W(B))$ of some base B is not compared against, it may be that this value is the unique minimum one and the nonlinear matroid optimization problem cannot be correctly solved. The final remark of the proposition follows since, for every r , $|\mathcal{B}(\mathcal{M}_{r,k})|$ is not bounded by any polynomial in $|\mathcal{E}(\mathcal{M}_{r,k})| = 2k$. $\square$

PROPOSITION 2.4. *Computing an optimal solution of the nonlinear matroid optimization problem in variable dimension $d = n$, over any matroid M , with $\{0, 1\}$ -valued weights, the i th weight being the standard unit vector $w_i := \mathbf{1}_i$ in $\mathbb{Z}^n$ for all i , and with $f : \mathbb{Z}^n \rightarrow \mathbb{R}$ a function presented by a comparison oracle, requires examining*

$f(W(B))$ for each of the $|\mathcal{B}(M)|$ bases of M . In particular, for each r , $1 \leq r \leq k$, the problem cannot be solved in polynomial time for the class of matroids $\mathcal{M}_{r,k}$.

Proof. The W -images $W(B) = (w_1(B), \dots, w_n(B))$ of the 2^n subsets $B \subseteq N$ attain precisely all 2^n distinct vectors in $\{0, 1\}^n$. Since the function f is arbitrary, this implies that the objective value $f(W(B))$ of each base can be arbitrary. The rest of the argument is as in the proof of Proposition 2.3. $\square$

Consider nonlinear matroid optimization with a matroid M , weights $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$. As explained in section 2.2, a crucial component in solving the problem is to identify W -images of bases; that is, points $u \in \mathbb{Z}^d$ satisfying $u = W(B)$ for some $B \in \mathcal{B}(M)$. The following proposition shows that, with binary-encoded weights, both the nonlinear matroid optimization problem with explicitly given univariate convex quadratic function f and the problem of deciding if a given u is a W -image of some base, are intractable already for fixed $d = 1$ and uniform matroids or partition matroids that are the direct sums of rank-1 uniform matroids.

PROPOSITION 2.5. *Given matroid M , a single nonnegative weight vector $w \in \mathbb{N}^n$, and nonnegative integer $u \in \mathbb{N}$, encoded in binary, the following problems are NP-complete, when already restricted to the class of matroids $\mathcal{M}_{r,k}$, for any r , $1 \leq r \leq k$:*

1. *Determining whether $u = W(B) = \sum_{j \in B} w_j$ for some base $B \in \mathcal{B}(M)$.*
2. *Determining whether the optimal objective value is zero for the 1-dimensional nonlinear matroid optimization problem over M , with the explicit convex univariate function $f(y) := (y - u)^2$.*

Proof. The NP-complete *subset-sum problem* is to decide, given $a_0, a_1, \dots, a_k \in \mathbb{N}$, whether there is a subset $S \subseteq K = \{1, \dots, k\}$ with $\sum_{j \in S} a_j = a_0$. Given such a_i , let $u := a_0$, and let $w := (a_1, \dots, a_k, 0, \dots, 0) \in \mathbb{N}^K \times \mathbb{N}^{\bar{K}}$. Then, for any r , a base B of $\mathcal{M}_{r,k}$ satisfies $W(B) = u$ if and only if $S := B \cap K$ satisfies $\sum_{j \in S} a_j = a_0$. This reduces the subset-sum problem to the problem considered in the first part of the proposition, showing that it is indeed NP-complete.

For the second part, note that the objective value $f(W(B)) = (W(B) - u)^2$ of every base B is nonnegative, and B has $f(W(B)) = 0$ if and only if $W(B) = u$. Thus, the optimal objective value is zero if and only if there is a base with $W(B) = u$. So the problem in the first part of the proposition reduces to the problem in the second part, showing the latter to be NP-complete as well. $\square$

3. Arbitrary matroids. In this section we develop a combinatorial algorithm for nonlinear matroid optimization that runs in polynomial time for any matroid presented by an independence oracle, provided that the number p of distinct values taken by the entries $w_{i,j}$ of the weight vectors is fixed. In particular, the algorithm applies to $\{0, 1\}$ -valued weight vectors as well as to $\{0, 1, \dots, p\}$ -valued weight vectors for any fixed p .

As explained in section 2.2, we will filter the set $U = \{W(B) : B \in \mathcal{B}(M)\}$ of W -images of bases out of a suitable superset Z . For this, we next show how to efficiently decide if a given $u \in \mathbb{Z}^d$ satisfies $u = W(B)$ for some $B \in \mathcal{B}(M)$. We start with $\{0, 1\}$ -valued W -images with pairwise-disjoint supports.

LEMMA 3.1. *There is an algorithm that, given matroid M presented by an independence oracle on the n -element ground set N , weight vectors $w_1, \dots, w_d \in \{0, 1\}^n$ with pairwise-disjoint supports, and $u \in \mathbb{N}^d$, determines if M has a base B with W -image $W(B) = u$, in time polynomial in n and $\langle u \rangle$.*

Proof. For each base B of M and for each $i = 1, \dots, d$ we have $w_i(B) = |B \cap \text{supp}(w_i)|$. Therefore, a base B has $W(B) = u$ if and only if $|B \cap \text{supp}(w_i)| = u_i$ for $i = 1, \dots, d$. So we may and do assume $\sum_{i=1}^d u_i \leq \text{rank}(M)$ and $u_i \leq |\text{supp}(w_i)|$ for

all i else M has no base with $W(B) = u$. Let

$$\mathcal{B}' := \left\{ B \subseteq N : |B \cap \text{supp}(w_i)| = u_i, \quad i = 1, \dots, d, \right. \\ \left. \left| B \cap \left(N \setminus \bigcup_{i=1}^d \text{supp}(w_i) \right) \right| = \text{rank}(M) - \sum_{i=1}^d u_i \right\}.$$

It is easy to see that $\mathcal{B}' = \mathcal{B}(M')$ is the set of bases of a partition matroid M' on ground set N , for which an independence oracle is efficiently realizable. Moreover, M has a base B with $W(B) = u$ if and only if $\mathcal{B}(M) \cap \mathcal{B}(M')$ is nonempty. These observations justify the following algorithm:

```

if  $\sum_{i=1}^d u_i \leq \text{rank}(M)$  or  $u_i > |\text{supp}(w_i)|$  for some  $i = 1, \dots, d$  then return
    NO;
    Determine if  $\mathcal{B}(M) \cap \mathcal{B}(M')$  is nonempty by computing a max-cardinality
     $S \in \mathcal{I}(M) \cap \mathcal{I}(M')$ ;
    if  $|S| = \text{rank}(M)$ ;
    then
        return YES and  $B := S$ ;
    else
        return NO;
    end
    
```

Computing a max-cardinality $S \in \mathcal{I}(M) \cap \mathcal{I}(M')$ can be efficiently carried out using a maximum-cardinality matroid-intersection algorithm; see, e.g., [9] or [10] and the references therein. $\square$

Next, we consider weight vectors for which the number p of distinct $w_{i,j}$ values is fixed. So, we assume that $w_1, \dots, w_d \in \{a_1, \dots, a_p\}^n$ for arbitrary given integer numbers $a_1, \dots, a_p$. Note that the a_i can vary and be very large, since they affect the running time through their binary length $\langle a_i \rangle$.

LEMMA 3.2. *For every fixed d and p , there is an algorithm that, given matroid M presented by an independence oracle on ground set N , integers $a_1, \dots, a_p$, weight vectors $w_1, \dots, w_d \in \{a_1, \dots, a_p\}^n$, and $u \in \mathbb{N}^d$, decides if M has a base B with $W(B) = u$ in time polynomial in n , $\max \langle a_i \rangle$, and $\langle u \rangle$.*

Proof. Let $V := \{a_1, \dots, a_p\}^d$, and let Q be the $d \times p^d$ pattern matrix having columns that are all of the p^d points in V . Let, as usual, W be the $d \times n$ matrix with rows $w_1, \dots, w_d$. For $j = 1, \dots, n$, let w^j denote the j th column of W . We will exploit the fact that, no matter how large n is, the columns w^j of W all lie in the fixed set V —so the number of distinct columns w^j of W is limited.

Define a $p^d \times n$ selector matrix $\widehat{W}$, having rows $\widehat{w}_v$ indexed by V , columns $\widehat{w}^j$ indexed by N , and

$$\widehat{w}_{v,j} := \begin{cases} 1 & \text{if } w^j = v, \\ 0 & \text{otherwise,} \end{cases}$$

for $v \in V$, $j \in N$. Note that each column $\widehat{w}^j$ of $\widehat{W}$ is a standard unit vector, selecting the unique pattern (i.e., column) of V that agrees with the column w^j of W . It should be clear that the rows of $\widehat{W}$, namely the $\widehat{w}_v$, lie in $\{0, 1\}^n$ and have pairwise-disjoint supports—this will enable us to appeal to Lemma 3.1. We observe and will make use of the fact that the weight matrix W factors as $W = Q\widehat{W}$. Therefore, the W -image and

$\widehat{W}$ -image of a base B satisfy $W(B) = Q\widehat{W}(B)$. This implies that there exists a base $B \in \mathcal{B}(M)$ with $W(B) = u$ if and only if for some p^d -dimensional vector $\widehat{u}$ satisfying $u = Q\widehat{u}$ there exists a base $B \in \mathcal{B}(M)$ satisfying $\widehat{W}(B) = \widehat{u}$. Since $\widehat{W}$ is $\{0, 1\}$ -valued, any such vector $\widehat{u} = \widehat{W}(B)$ must lie in $\{0, \dots, m\}^{p^d}$, where $m := \text{rank}(M)$. Therefore, checking if there is a base $B \in \mathcal{B}(M)$ with $W(B) = u$ reduces to going over all vectors $\widehat{u} \in \{0, \dots, m\}^{p^d}$, and for each vector $\widehat{u}$ checking if $Q\widehat{u} = u$ and if there is a base B satisfying $\widehat{W}(B) = \widehat{u}$. This justifies the following algorithm:

```

let  $Q$  be the  $d \times p^d$  pattern matrix, and let  $\widehat{W}$  be the selector matrix (both
determined by  $W$ );
for  $\widehat{u} \in \{0, 1, \dots, m\}^{p^d}$  do
  if  $Q\widehat{u} = u$  then
    if there is a base  $B \in \mathcal{B}(M)$  with  $\widehat{W}(B) = \widehat{u}$  then return  $B$ ;
  end
end
return NO;

```

Since d and p are fixed and $m \leq n$, the number $(m+1)^{p^d}$ of such potential vectors $\widehat{u}$ is polynomial in the data. For each such vector $\widehat{u}$, checking if $Q\widehat{u} = u$ is easily done by direct multiplication; and checking if there exists a base $B \in \mathcal{B}(M)$ satisfying $\widehat{W}(B) = \widehat{u}$ can be done in polynomial time using the algorithm of Lemma 3.1 applied to the matroid M , the $\widehat{d} := p^d$ weight vectors $\widehat{w}_v$, $v \in V$ (the $\{0, 1\}$ -valued rows of the matrix $\widehat{W}$, having pairwise-disjoint supports), and the vector $\widehat{u}$. $\square$

We are now in position to solve the nonlinear optimization problem over a matroid that is presented by an independence oracle.

THEOREM 1.1. *For every fixed d and p , there is an algorithm that, given a matroid M presented by an independence oracle on the n -element ground set N , integers $a_1, \dots, a_p \in \mathbb{Z}$, weight vectors $w_1, \dots, w_d \in \{a_1, \dots, a_p\}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the nonlinear matroid optimization problem in time that is polynomial in n and $\max\langle a_i \rangle$.*

Proof. We have three major steps.

1. First, under the hypotheses of the theorem, assume that in polynomial time we can calculate an optimal W -image for the problem. Then, for every subset $S \subseteq N$, an optimal W -image for the subproblem on S can be computed in polynomial time, since the entries of the restrictions of $w_1, \dots, w_d$ to S also attain values in $\{a_1, \dots, a_p\}$. By Lemma 2.2 this implies that an optimal base can be found and the nonlinear matroid optimization problem solved in polynomial time. So, it remains to show that in polynomial time we can calculate an optimal W -image for the problem.
2. To accomplish this, we first show how to compute the set U of W -images of bases of M , by working with an appropriately defined superset Z of U . Let $m := \text{rank}(M)$. Consider any $i = 1, \dots, d$ and any m -subset B of N . Then, since $w_{i,j} \in \{a_1, \dots, a_p\}$ for all j , we have that, for some nonnegative integers $\lambda_{i,1}, \dots, \lambda_{i,p}$ with $\sum_{k=1}^p \lambda_{i,k} = m$,

$$w_i(B) = \sum_{j \in B} w_{i,j} = \sum_{k=1}^p \lambda_{i,k} a_k.$$

Therefore, we find that the set U of W -images of bases satisfies

$$\begin{aligned} U &= \{W(B) : B \in \mathcal{B}(M)\} \\ &\subseteq \{W(B) : B \subseteq N, |B| = m\} \\ &\subseteq Z := \left\{ \sum_{k=1}^p \lambda_k a_k : \lambda \in \{0, 1, \dots, m\}^p, \sum_{k=1}^p \lambda_k = m \right\}^d. \end{aligned}$$

These observations justify the following algorithm to compute the set U of W -images of bases:

```

Compute  $m := \text{rank}(M)$  and let  $a := (a_1, \dots, a_p)$ ;
Start with  $Z := \emptyset$ ;
for  $\Lambda \in \{0, 1, \dots, m\}^{d \times p}$  do
  if  $\Lambda \mathbf{1} = m \mathbf{1}$  then let  $Z := Z \cup \{\Lambda a\}$ ;
end
Start with  $U := \emptyset$ ;
for  $u \in Z$  do
  if there is a base  $B \in \mathcal{B}(M)$  with  $W(B) = u$  then let
     $U := U \cup \{u\}$ ;
end
return  $U$ ;

```

Observe that, since d and p are fixed, $|Z| \leq |\{0, 1, \dots, m\}^{d \times p}| = (m+1)^{pd}$ is polynomially bounded in $m \leq n$ and hence so are the numbers of iterations in each of the “for” loops of the algorithm. Also note that, in each iteration of the second loop, we can apply the algorithm of Lemma 3.2 to determine, in polynomial time, whether there is a base $B \in \mathcal{B}(M)$ with $W(B) = u$. Therefore, we can efficiently determine U .

3. By repeatedly querying the comparison oracle of f on $|U| - 1$ suitable pairs of points in U , we obtain a $u^* \in U$ that satisfies $f(u^*) = \min\{f(u) : u \in U\}$, which by Proposition 2.1 is an optimal W -image.

Finally, by embedding steps 2 and 3 above as subroutines to solve the $n + 1$ restrictions of the problem to suitable subsets $S \subseteq N$ in step 1, we obtain our desired algorithm. $\square$

4. Vectorial matroids. In this section we develop an algebraic algorithm for nonlinear matroid optimization over vectorial matroids. It applies to any matroid that is vectorial over an ordered field. For matroids that are vectorial over the rationals $\mathbb{Q}$, it runs in time polynomial in the binary length $\langle A \rangle$ of the matrix A representing the matroid and in the unary length $\max |w_{i,j}|$ of the weights. It is much more efficient than the combinatorial algorithm of section 3 and applies to weights with an unlimited number of different values $w_{i,j}$ of entries.

First, we show that it suffices to deal with nonnegative weight vectors.

LEMMA 4.1. *The nonlinear matroid optimization problem with arbitrary integer weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$ is polynomial-time reducible to the special case of nonnegative vectors $w_1, \dots, w_d \in \mathbb{N}^n$.*

Proof. Consider a matroid M , integer weights $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$. Let $m := \text{rank}(M)$ and $\omega := \max |w_{i,j}|$. Define nonnegative weights by $w'_{i,j} := w_{i,j} + \omega$ for all i, j , and define a new function $f' : \mathbb{Z}^d \rightarrow \mathbb{R}$ by $f'(u_1, \dots, u_d) := f(u_1 - m\omega, \dots, u_d - m\omega)$ for every $u = (u_1, \dots, u_d) \in \mathbb{R}^d$. Note that the unary length

of each new weight $w'_{i,j}$ is at most twice the maximum unary length of the original weights $w_{i,j}$, and a comparison oracle for f' is easily realizable from a comparison oracle for f . Then for every base B and for each $i = 1, \dots, d$, we have

$$w'_i(B) = \sum_{j \in B} w'_{i,j} = \sum_{j \in B} (w_{i,j} + \omega) = \left(\sum_{j \in B} w_{i,j} \right) + m\omega = w_i(B) + m\omega,$$

implying the following equality between the new and original objective function values:

$$f'(w'_1(B), \dots, w'_d(B)) = f'(w_1(B) + m\omega, \dots, w_d(B) + m\omega) = f(w_1(B), \dots, w_d(B)).$$

Therefore, a base $B \in \mathcal{B}(M)$ is optimal for the nonlinear matroid optimization problem with data $M, w_1, \dots, w_d$ and f if and only if it is optimal for the problem with $M, w'_1, \dots, w'_d$ and f' . $\square$

So we assume henceforth that the weights are nonnegative. As explained in section 2.2 and carried out in section 3, we will filter the set $U = \{W(B) : B \in \mathcal{B}(M)\}$ of W -images of bases out of a suitable superset Z . However, instead of checking if $u \in U$ for one point $u \in Z$ after the other, we will filter here the entire set U out of Z at once. We proceed to describe this procedure.

Let A be an $m \times n$ integer matrix of full row rank m , and let M be the vectorial matroid of A . Note that $m = \text{rank}(M)$. Let $w_1, \dots, w_d \in \mathbb{N}^n$ be nonnegative integer weight vectors, and let $\omega := \max w_{i,j}$. Then for each $i = 1, \dots, d$ and each m -subset B of N , we have $w_i(B) \in \{0, 1, \dots, m\omega\}$, and therefore

$$\begin{aligned} U &= \{W(B) : B \in \mathcal{B}(M)\} \subseteq \{W(B) : B \subseteq N, |B| = m\} \\ &\subseteq Z := \{0, 1, \dots, m\omega\}^d \subseteq \mathbb{N}^d. \end{aligned}$$

We will show how to filter the set U out of the above superset Z of potential W -images of bases. For each base $B \in \mathcal{B}(M)$, let $A_{.B}$ denote the nonsingular $m \times m$ submatrix of A consisting of those columns indexed by $B \subseteq N$. Define the following polynomial in d variables $x_1, \dots, x_d$:

$$(1) \quad g = g(x) := \sum_{u \in Z} g_u x^u := \sum_{u \in Z} g_u \prod_{k=1}^d x_k^{u_k},$$

where the coefficient g_u corresponding to $u \in Z$ is the nonnegative integer

$$(2) \quad g_u := \sum \{\det^2(A_{.B}) : B \in \mathcal{B}(M), W(B) = u\}.$$

Now, $\det^2(A_{.B})$ is positive for every base $B \in \mathcal{B}(M)$. Thus, the coefficient g_u corresponding to $u \in Z$ is nonzero if and only if there exists a matroid base $B \in \mathcal{B}(M)$ with $W(B) = u$. So the desired set U is precisely the set of exponents of monomials x^u with nonzero coefficient in g . We record this for later use.

PROPOSITION 4.2. *Let M be the vectorial matroid of an $m \times n$ matrix A of rank m , let $w_1, \dots, w_d \in \mathbb{N}^n$, and let $g(x)$ be the polynomial in (1). Then $U := \{W(B) : B \in \mathcal{B}(M)\} = \{u \in Z : g_u \neq 0\}$.*

By Proposition 4.2, to compute U , it suffices to compute all coefficients g_u . Unfortunately, they cannot be computed directly from the definition (2), since this involves again checking exponentially many $B \in \mathcal{B}(M)$ —precisely what we are trying to avoid!

Instead, we will compute the g_u by interpolation. However, in order to do so, we need a way of evaluating $g(x)$ under numerical substitutions. We proceed to show how this can be efficiently accomplished.

Let X be the $n \times n$ diagonal matrix whose j th diagonal component is the monomial $\prod_{i=1}^d x_i^{w_{i,j}}$ in the variables $x_1, \dots, x_d$, that is, the matrix of monomials defined by

$$X := \text{diag} \left(\prod_{i=1}^d x_i^{w_{i,1}}, \dots, \prod_{i=1}^d x_i^{w_{i,n}} \right).$$

The following lemma will enable us to compute the value of $g(x)$ under numerical substitutions.

LEMMA 4.3. *For any $m \times n$ matrix A of rank m and nonnegative weights $w_1, \dots, w_d \in \mathbb{N}^n$ we have*

$$g(x) = \det(AXA^T).$$

Proof. By the classical Binet–Cauchy identity, for any two $m \times n$ matrices C, D of rank m we have $\det(CD^T) = \sum \{\det(C_{\cdot B}) \det(D_{\cdot B}) : B \in \mathcal{B}(M)\}$. Applying this to $C := AX$ and $D := A$, we obtain

$$\begin{aligned} \det(AXA^T) &= \sum_{B \in \mathcal{B}(M)} \det((AX)_{\cdot B}) \det(A_{\cdot B}) = \sum_{B \in \mathcal{B}(M)} \prod_{j \in B} \prod_{i=1}^d x_i^{w_{i,j}} \det(A_{\cdot B}) \det(A_{\cdot B}) \\ &= \sum_{B \in \mathcal{B}(M)} \prod_{i=1}^d x_i^{w_i(B)} \det^2(A_{\cdot B}) = \sum_{u \in Z} \sum_{\substack{B \in \mathcal{B}(M): \\ W(B)=u}} \det^2(A_{\cdot B}) \prod_{i=1}^d x_i^{u_i} \\ &= \sum_{u \in Z} g_u x^u = g(x). \quad \square \end{aligned}$$

Lemma 4.3 paves the way for computing the coefficients of the polynomial $g(x) = \sum_{u \in Z} g_u x^u$ by interpolation. We will choose sufficiently many suitable points on the moment curve in $\mathbb{R}^Z$, substitute each point into x , and evaluate $g(x)$ using the lemma. We will then solve the system of linear equations for the coefficients g_u . The next lemma describes the details and shows that this can be done efficiently.

LEMMA 4.4. *For every fixed d , there is an algorithm that, given any $m \times n$ matrix A of rank m and weights $w_1, \dots, w_d \in \mathbb{N}^n$, computes all coefficients g_u of $g(x)$ in time polynomial in $\max w_{i,j}$ and $\langle A \rangle$.*

Proof. Let $\omega := \max w_{i,j}$ and $s := m\omega + 1$. Then a superset of potential W -images of bases is $Z := \{0, 1, \dots, m\omega\}^d$ and satisfies $|Z| = s^d$. For $t = 1, 2, \dots, s^d$, let $X(t)$ be the numerical matrix obtained from X by substituting $t^{s^{i-1}}$ for x_i , $i = 1, \dots, d$. By Lemma 4.3 we have $g(x) = \det(AXA^T)$, and therefore we obtain the following system of s^d linear equations in the s^d variables g_u , $u \in Z$:

$$\begin{aligned} \det(AX(t)A^T) &= \det \left(A \text{diag}_j \left(\prod_{i=1}^d t^{w_{i,j} s^{i-1}} \right) A^T \right) = \sum_{u \in Z} g_u \prod_{i=1}^d t^{u_i s^{i-1}} \\ &= \sum_{u \in Z} t^{\sum_{i=1}^d u_i s^{i-1}} g_u, \quad t = 1, 2, \dots, s^d. \end{aligned}$$

As u runs through Z , the sum $\sum_{i=1}^d u_i s^{i-1}$ attains precisely all $|Z| = s^d$ distinct values $0, 1, \dots, s^d - 1$. This implies that, under the total order of the points u in Z by increasing value of $\sum_{i=1}^d u_i s^{i-1}$, the vector of coefficients of the g_u in the equation corresponding to t is precisely the point $(t^0, t^1, \dots, t^{s^d-1})$ on the moment curve in $\mathbb{R}^Z \cong \mathbb{R}^{s^d}$. Therefore, the equations are linearly independent and hence the system can be uniquely solved for the g_u .

These observations justify the following algorithm to compute the g_u , $u \in Z$:

```

Compute  $m := \text{rank}(A)$ ;
let  $\omega := \max w_{i,j}$ , and let  $s := m\omega + 1$ ;
let  $X := \text{diag}_j \left( \prod_{i=1}^d x_i^{w_{i,j}} \right)$ ;
for  $t = 1, 2, \dots, s^d$  do
    let  $X(t)$  be the numerical matrix obtained by substituting  $t^{s^{i-1}}$  for  $x_i$ ,
     $i = 1, 2, \dots, d$ , in  $X$ ; Compute  $\det(AX(t)A^T)$ ;
end
let  $Z := \{0, 1, \dots, m\omega\}^d$ ;
Compute and return the unique solution  $g_u$ ,  $u \in Z$ , of the square linear
system:

$$\det(AX(t)A^T) = \sum_{u \in Z} t^{\sum_{i=1}^d u_i s^{i-1}} g_u, \quad t = 1, 2, \dots, s^d.$$

```

We now show that this system can be solved in polynomial time. First, the number of equations and indeterminates is $s^d = (m\omega + 1)^d$ and hence polynomial in the data. Second, for each $i, j = 1, \dots, n$ and $t = 1, 2, \dots, s^d$, it is easy to see that the (i, j) th entry of $AX(t)A^T$ satisfies

$$\left| \sum_{h=1}^n a_{i,h} \prod_{k=1}^d t^{s^{k-1} w_{k,h}} a_{j,h} \right| \leq \sum_{h=1}^n |a_{i,h} a_{j,h}| p^{ds^d \max w_{k,h}},$$

implying that the binary length $\langle AX(t)A^T \rangle$ of $AX(t)A^T$ is polynomially bounded in the data as well.

It follows that $\det(AX(t)A^T)$ can be computed in polynomial time by Gaussian elimination for all t , and the system of equations can indeed be solved for the g_u in polynomial time. We further note that the system of equations is a Vandermonde system, so the number of arithmetic operations needed to solve it is just quadratic in its dimensions. $\square$

We can now efficiently solve the nonlinear optimization problem over vectorial matroids with unary weights.

THEOREM 1.3. *For every fixed d , there is an algorithm that, given integer $m \times n$ matrix A , weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the nonlinear optimization problem over the (real) vectorial matroid of A in time polynomial in $\langle A \rangle$ and $\max |w_{i,j}|$.*

Proof. Let M be the vectorial matroid of A . Recall that linear-algebraic operations on A can be done in polynomial time, say by Gaussian elimination. Dropping some rows of A if necessary without changing M , we may assume that A has rank m . An independence oracle for M is readily realizable since $S \subseteq N$ is independent in M precisely when the columns of A indexed by S are linearly independent. Applying, if necessary, the procedure of Lemma 4.1 and adjusting the weights while at most doubling the unary length of the maximum weight, we may also assume that the weights are nonnegative.

We will show how to compute an optimal W -image u^* in polynomial time. This will also imply that, for every subset $S \subseteq N$, an optimal W -image for the subproblem on S can be computed in polynomial time. By Lemma 2.2 this will show that an optimal base can be found and the nonlinear matroid optimization problem solved in polynomial time.

Let $\omega := \max w_{i,j}$ and consider the superset $Z := \{0, 1, \dots, m\omega\}^d$ of potential W -images of bases and the polynomial $g(x) = \sum_{u \in Z} g_u x^u$ as defined in (1) and (2). By Proposition 4.2 we have

$$U = \{W(B) : B \in \mathcal{B}(M)\} = \{u \in Z : g_u \neq 0\}.$$

Applying now the algorithm of Lemma 4.4, we can compute in polynomial time the right-hand side and hence the left-hand side, providing the filtration of the set U of W -images of bases out of Z . By repeatedly querying the comparison oracle of f on suitable pairs of points in U , we obtain a $u^* \in U$ satisfying $f(u^*) = \min\{f(u) : u \in U\}$, which by Proposition 2.1 is the desired optimal W -image. $\square$

5. Experimental design. We now discuss applications of nonlinear matroid optimization to experimental design. For general information on experimental design, see, e.g., the monograph [15] and the references therein. As outlined in the introduction, we consider the following rather general framework. We wish to learn an unknown system whose output y is an unknown function Φ of a multivariate input $x = (x_1, \dots, x_k) \in \mathbb{R}^k$. It is customary to call the input variables x_i *factors* of the system. We perform several experiments. Each experiment i is determined by a point $p_i = (p_{i,1}, \dots, p_{i,k})$ and consists of feeding the system with input $x := p_i \in \mathbb{R}^k$ and measuring the corresponding output $y_i := \Phi(p_i) \in \mathbb{R}$. Based on these experiments, we wish to *fit a model* for the system, namely, determine an estimation $\hat{\Phi}$ of Φ , that:

- lies in a prescribed class of functions;
- is consistent with the outcomes of the experiments;
- minimizes the *aberration*—a suitable criterion—among models in the class.

We concentrate on (multivariate) *polynomial models* defined as follows. Each nonnegative integer vector $\alpha \in \mathbb{N}^k$ serves as an *exponent* of a corresponding monomial $x^\alpha := \prod_{h=1}^k x_h^{\alpha_h}$ in the system input $x \in \mathbb{R}^k$. Each finite subset $B \subset \mathbb{N}^k$ of exponents provides a *model* for the system, namely a polynomial *supported on* B , i.e., having monomials with exponents in B only,

$$\Phi_B(x) = \sum_{\alpha \in B} c_\alpha x^\alpha,$$

where the c_α are real coefficients that need to be determined from the measurements by interpolation.

We assume that the set of design points $\{p_1, \dots, p_m\} \subset \mathbb{R}^k$ is prescribed. Indeed, in practical applications, it may be impossible or too costly to conduct experiments involving arbitrarily chosen points. The problem of choosing the design (termed the *inverse problem* in the statistics literature; see [2] and the references therein), is of interest in its own right, and its computational aspects will be considered elsewhere. We collect the design points in an $m \times k$ *design* matrix P . Thus, the i th row of this matrix is the i th design point p_i . A model $B \subset \mathbb{N}^k$ is *identifiable* by a design P if for any possible measurement values $z_i = \Phi(p_i)$ at the design points, there is a unique polynomial $\Phi_B(x)$ supported on B that interpolates Φ , that is, satisfies $\Phi_B(p_i) = z_i = \Phi(p_i)$ for every design point $p_i = (p_{i,1}, \dots, p_{i,k})$.

Among models identifiable by a given design, we wish to determine one that is best under a suitable criterion. Roughly speaking, common criteria ask for *low degree polynomials*. To make this precise, for each identifiable model B , consider the following *total degree vector* whose i th entry is the total degree of variable x_i over all monomials supported on B :

$$\sum_{\alpha \in B} \alpha = \left(\sum_{\alpha \in B} \alpha_1, \dots, \sum_{\alpha \in B} \alpha_k \right).$$

Now, given any function $f : \mathbb{Z}^k \rightarrow \mathbb{R}$, the *aberration* of model B induced by f is defined to be

$$\mathcal{A}(B) := f \left(\sum_{\alpha \in B} \alpha \right).$$

The term *aberration* is the one used in the statistics literature in this context; see, e.g., [5, 18] and the references therein. We now give some concrete examples of functions providing useful aberrations.

Example 5.1 (some concrete useful aberrations).

- Consider the function $f(u) := \frac{1}{|B|}(u_1 + \dots + u_k)$. Then the aberration of model B is

$$\mathcal{A}(B) = \frac{1}{|B|} \sum_{\alpha \in B} \alpha_1 + \dots + \frac{1}{|B|} \sum_{\alpha \in B} \alpha_k = \frac{1}{|B|} \sum_{\alpha \in B} \sum_{i=1}^k \alpha_i,$$

which is the average total degree of monomials supported on B .

- Consider $f(u) := \frac{1}{|B|}(\pi_1 u_1 + \dots + \pi_k u_k)$ for some real weights $\pi_1, \dots, \pi_k$. Then

$$\mathcal{A}(B) = \pi_1 \frac{1}{|B|} \sum_{\alpha \in B} \alpha_1 + \dots + \pi_k \frac{1}{|B|} \sum_{\alpha \in B} \alpha_k$$

is the weighted average degree, allowing for preferences of some variables over others.

- Consider the function $f(u) := \frac{1}{|B|}(\max\{u_1, \dots, u_k\})$. Then the aberration of B is

$$\mathcal{A}(B) = \max \left\{ \frac{1}{|B|} \sum_{\alpha \in B} \alpha_1, \dots, \frac{1}{|B|} \sum_{\alpha \in B} \alpha_k \right\},$$

and is the maximum over variables of the average variable degree of monomials supported on B .

- More generally, consider $f(u) := \frac{1}{|B|}(\|\pi \cdot u\|_q) = \frac{1}{|B|} \left(\left(\sum_{i=1}^k |\pi_i u_i|^q \right)^{\frac{1}{q}} \right)$. Then the aberration of B is

$$\mathcal{A}(B) = \left\| \pi \cdot \left(\frac{1}{|B|} \sum_{\alpha \in B} \alpha \right) \right\|_q,$$

which is the l_q -norm of the weighted average degree vector of monomials supported on B .

We can now formally define the minimum-aberration model-fitting problem.

Minimum-aberration model-fitting problem. Given a design $P = \{p_1, \dots, p_m\}$ of m points in $\mathbb{R}^k$, a set $N = \{\beta_1, \dots, \beta_n\}$ of n potential exponents in $\mathbb{N}^k$, and a function $f : \mathbb{Z}^k \rightarrow \mathbb{R}$, find a model $B \subseteq N$ that is identifiable by P and is of minimum aberration

$$\mathcal{A}(B) = f \left(\sum_{\beta_j \in B} \beta_j \right).$$

Next, we demonstrate how to formulate the minimum-aberration model-fitting problem as a nonlinear matroid optimization problem. Consider the following $m \times n$ matrix A having rows indexed by P and columns indexed by N , defined by

$$a_{i,j} := p_i^{\beta_j} = \prod_{h=1}^k p_{i,h}^{\beta_{j,h}}, \quad i = 1, \dots, m, j = 1, \dots, n.$$

It can be verified that a model $B \subseteq N$ is identifiable by a design P if and only if the $m \times m$ matrix A_B is invertible. (In the terminology of algebraic geometry, the model B is identifiable if the congruence classes of the monomials $x^{\beta_1}, \dots, x^{\beta_m}$ form a basis for the quotient of the algebra of polynomials $\mathbb{R}[x_1, \dots, x_k]$ modulo the ideal of polynomials vanishing on the design points; see [3, 13] and the references therein for more on this.) If B is identifiable, then, given any vector of measurements $y \in \mathbb{R}^m$ at the design points, the vector of coefficients $c \in \mathbb{R}^m$ of the unique polynomial $\Phi_B(x) = \sum_{j=1}^m c_j \prod_{h=1}^k x_h^{\beta_{j,h}}$ supported on B that is consistent with the measurements is given by $c := (A_B)^{-1} y$.

If the rank of A is less than m , then no $B \subseteq N$ is identifiable, and the set N of potential exponents should be augmented with more exponents. So assume that A has rank m . Let M be the vectorial matroid of A , so that

$$\mathcal{B}(M) := \{B \subseteq N : B \text{ is identifiable by } P\}.$$

Now define k weight vectors $w_1, \dots, w_k \in \mathbb{N}^n$ by $w_{i,j} := \beta_{j,i}$ for $i = 1, \dots, k, j = 1, \dots, n$. Then the aberration of model B is

$$\mathcal{A}(B) = f \left(\sum_{\beta_j \in B} \beta_j \right) = f \left(\sum_{\beta_j \in B} w_{1,j}, \dots, \sum_{\beta_j \in B} w_{k,j} \right).$$

Thus, the aberration of a model B identifiable by the design P is precisely the objective function value of the base B in the nonlinear matroid optimization problem over the matroid M above, with $d := k$ and the weights $w_1, \dots, w_k \in \mathbb{N}^n$ as above, and with the given function $f : \mathbb{Z}^k \rightarrow \mathbb{R}$. Assuming that a comparison oracle for the function f can be realized, which is practically always true, and that the design points are rational so that they can be input and processed on a digital computer, we obtain the following corollary of Theorems 1.1 and 1.3.

COROLLARY 5.2. *For every fixed k , there is an algorithm that, given a rational design $P = \{p_1, \dots, p_m\}$ in $\mathbb{R}^k$, a set $N = \{\beta_1, \dots, \beta_n\}$ in $\mathbb{N}^k$, and a function $f : \mathbb{Z}^k \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the minimum-aberration model-fitting problem in time polynomial in $m, n, \langle P \rangle$, and $\max \beta_{i,j}$.*

It is very natural and common in practice to consider *hierarchical models*; that is, models B with the property that $\beta \leq \alpha \in B$ implies $\beta \in B$. In [3, 13], in the

context of the theory of Gröbner bases in commutative algebra, it was shown that the smallest set containing all m -point hierarchical models B (termed *staircases* therein) in $\mathbb{N}^k$ is the following set, consisting of roughly $O(m \log m)$ points,

$$N := \left\{ \alpha \in \mathbb{N}^k : \prod_{h=1}^k (\alpha_h + 1) \leq m \right\}.$$

Thus, Corollary 5.2 will be typically applied with this set N as the set of potential monomial exponents.

We proceed to describe a more general useful class of aberrations that can be treated, which is naturally suggested by the nonlinear matroid optimization formulation. As before, we are given a design $P = \{p_1, \dots, p_m\}$ in $\mathbb{R}^k$ and a set $N = \{\beta_1, \dots, \beta_n\}$ of potential exponents in $\mathbb{N}^k$. But now we are also given d weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$. The function f is now defined on $\mathbb{R}^d$ rather than $\mathbb{R}^k$. The aberration induced by the weights and the function is now simply the objective function of the nonlinear matroid optimization problem, which for an identifiable model $B \subseteq N$ is given by

$$\mathcal{A}(B) := f(W(B)),$$

where W is the matrix with rows w_i . Note that aberrations of the type considered before can be recovered as a special case with $d := k$ and $w_{i,j} := \beta_{j,i}$ for all i, j . Here are a few useful examples.

Example 5.3 (some concrete useful generalized aberrations). Let $N = \{\beta_1, \dots, \beta_n\} \subset \mathbb{N}^k$ be any set of exponents. Let θ be a small positive integer, say $\theta = 1$ or $\theta = 2$, that will serve as a desired bound on the degrees of variables in monomials of the sought after models B contained in N .

- Let $d := 1$, and define the single weight vector $w_1 \in \mathbb{N}^n$ by

$$w_{1,j} := \begin{cases} 0 & \text{if } \beta_{j,i} \leq \theta \text{ for every } i = 1, \dots, k, \\ 1 & \text{otherwise,} \end{cases}$$

for $j = 1, \dots, n$. Then $\sum_{\beta_j \in B} w_{1,j}$ is the number of monomials supported on $B \subseteq N$ that do *not* meet the degree bound; in particular, for $\theta = 1$ it is the number of non square-free monomials. Taking $f : \mathbb{Z} \rightarrow \mathbb{R}$ to be the identity $f(u) := u$, the aberration $\mathcal{A}(B)$ of model B is the number of undesired monomials. In particular, an optimal model B has $\mathcal{A}(B) = 0$ if and only if the design admits an identifiable model with all variables in all monomials having degree at most θ .

- Now let $d := k$, and define weight vectors $w_1, \dots, w_k \in \mathbb{N}^n$ by

$$w_{i,j} := \begin{cases} 0 & \text{if } \beta_{j,i} \leq \theta, \\ 1 & \text{otherwise,} \end{cases}$$

for $i = 1, \dots, k$, $j = 1, \dots, n$. Then $\sum_{\beta_j \in B} w_{i,j}$ is the number of monomials supported on model $B \subseteq N$ for which variable x_i violates the degree bound θ . Defining $f : \mathbb{Z}^k \rightarrow \mathbb{R}$ by $f(u) := \max_{i=1}^k u_i$, we get that the aberration $\mathcal{A}(B)$ of model B is the maximum over variables of the number of monomials having x_i violating the degree bound θ . The optimal model will minimize the maximum violation.

We have the following generalized minimum-aberration model-fitting problem and corollary.

Generalized minimal-aberration model-fitting problem. Given a design $P = \{p_1, \dots, p_m\}$ in $\mathbb{R}^k$, a set $N = \{\beta_1, \dots, \beta_n\}$ of potential exponents in $\mathbb{N}^k$, weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$, and a function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$, find a model $B \subseteq N$ that is identifiable by P and is of minimum aberration

$$\mathcal{A}(B) = f(W(B)) = f\left(\sum_{\beta_j \in B} w_{1,j}, \dots, \sum_{\beta_j \in B} w_{d,j}\right).$$

COROLLARY 5.4. *For every fixed k and d , there is an algorithm that, given any rational design $P = \{p_1, \dots, p_m\}$ in $\mathbb{R}^k$, any set $N = \{\beta_1, \dots, \beta_n\}$ of potential exponents in $\mathbb{N}^k$, weight vectors $w_1, \dots, w_d \in \mathbb{Z}^n$, and function $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves the generalized minimum-aberration model-fitting problem in time polynomial in $m, n, \langle P \rangle, \max \beta_{j,i}$, and $\max |w_{i,j}|$.*

SPANNING TREES WITH MANY LEAVES IN GRAPHS WITH MINIMUM DEGREE THREE*

PAUL S. BONSMAT[†]

Abstract. We present two lower bounds for the maximum number of leaves over all spanning trees of a graph. For connected, triangle-free graphs on n vertices, with minimum degree at least three, we show that a spanning tree with at least $(n+4)/3$ leaves exists. For connected graphs with minimum degree at least three, without diamonds induced by vertices of degree three, we show that a spanning tree with at least $(2n+12)/7$ leaves exists. (A diamond is a K_4 minus one edge.) The proofs use the fact that spanning trees with many leaves correspond to small connected dominating sets. Both of these bounds are best possible for their respective graph classes. For both bounds, simple polynomial time algorithms that find spanning trees satisfying the bounds are given.

Key words. spanning tree, max leaf, connected dominating set, extremal graph theory

1. Introduction. For standard graph theoretic terminology we refer to [2]. A *tree* is a connected graph without cycles. A *spanning subgraph* of a graph G is a subgraph containing all vertices of G . A *spanning tree* of G is a spanning subgraph of G that is a tree. A *leaf* is a vertex with degree one. A subset $S \subseteq V(G)$ of the vertices of graph G is a *dominating set* if every vertex of G is in S or is adjacent to a vertex in S . $S \subseteq V(G)$ is a *connected set* if the graph it induces, denoted by $G[S]$, is connected. A set that is both a dominating set and a connected set will be called a *CD-set* for short. The minimum vertex degree of G is denoted by $\delta(G)$, or δ if there is no cause for confusion. See section 2 for additional definitions.

In this paper we study spanning trees with many leaves and the closely related concept of small CD-sets. The well-known relation between these concepts is as follows: a graph $G \neq K_2$ on n vertices has a spanning tree with at least k leaves if and only if G has a CD-set of size at most $n - k$.

Much research has been done on the corresponding optimization problems, where the goal is to maximize the number of leaves of a spanning tree (resp., to minimize the number of vertices in a CD-set). The problems are known to be $\mathcal{NP}$ -hard [9]. For both problems approximation algorithms exist. For finding spanning trees with many leaves, approximation algorithms have been found by Lu and Ravi [15] and Solis-Oba [17], with approximation guarantees of 3 (resp., 2). When the input is restricted to cubic graphs, a $5/3$ -approximation recently has been presented by Correa et al. [7]. Approximation algorithms for finding small CD-sets have been found by Guha and Khuller [12] and Ruan et al. [16]. These algorithms do not have constant factor approximation guarantees, and in [12] it is shown that it is unlikely that such algorithms exist.

A second branch of results on these problems is in the area of extremal graph theory. We are interested in statements of this type: every graph on n vertices that

FIG. 1.1. *Theorem 1 is best possible.*

satisfies a certain set of properties has a spanning tree with at least $\alpha n + \beta$ leaves ($0 < \alpha < 1$). Even though the focus in this area of research is often not on algorithms, many of these results are constructive and correspond to polynomial time algorithms.

Linial conjectured that every graph on n vertices with minimum degree δ has a spanning tree with at least $n - 3n/(\delta + 1) + c_\delta$ leaves, for some appropriate constant c_δ . For sufficiently large δ , it was observed in [6] that a result by Alon [1] disproves this conjecture. However, for small values of δ the conjecture has been shown to be true. For $\delta = 3$, Linial and Sturtevant [14] and Kleitman and West [13] independently proved the conjecture.

THEOREM 1 (Linial and Sturtevant, Kleitman and West). *Every connected graph on n vertices with $\delta \geq 3$ has a spanning tree with at least $\lceil \frac{1}{4}n + 2 \rceil$ leaves.*

For $\delta = 4$, a proof appears in [13]. For $\delta = 5$, Griggs and Wu [11] gave a proof. For small values of δ greater than five, little is known. For more information, see [6].

The result in Theorem 1 is best possible for every n . For $n = 4k$, an extremal example is constructed as follows; see Figure 1.1. Start with k disjoint *diamonds*, which is a K_4 minus an edge. Add k edges such that the graph becomes connected and cubic. A *cubic graph* is a graph in which all vertices have degree three. The resulting graph has no spanning tree with more than $k + 2$ leaves. For other values of n , similar constructions can be found. An immediate question is whether the bound can be improved when diamonds are forbidden. One result in this direction is by Griggs, Kleitman, and Shastri [10].

THEOREM 2 (see Griggs, Kleitman, and Shastri). *Every connected cubic graph without diamonds on n vertices has a spanning tree with at least $(n + 4)/3$ leaves.*

The bound in Theorem 2 is the best possible linear bound for this graph class: There exist cubic graphs without diamonds that admit no more than $n/3 + 2$ leaves, for every $n = 6k$ [10]. The single graph Q_3 shows that the additive term $\frac{4}{3}$ cannot be increased. (Q_3 is the 3-dimensional cube graph, which has eight vertices and no spanning tree with more than four leaves.) However, for other values of n no examples that show that this bound is sharp are known. See section 8 for a discussion on the sharpness of this bound and the other bounds in this paper.

New results. Our first question is what kind of bounds can be obtained when we consider graphs with $\delta \geq 3$ instead of cubic graphs but still forbid (certain types of) diamonds. In this paper, we present one best possible bound for these graphs. In addition, even though the proof of Kleitman and West for Theorem 1 is very short and elegant, the proof of Theorem 2 uses the same techniques but consists mainly of a very long and intricate case study. Therefore it is useful to develop new techniques for proving results of this kind. In section 3, the ideas behind our new method are introduced.

As a first application of these techniques, in section 4 we first prove that the bound from Theorem 2 also holds for graphs with $\delta \geq 3$ without triangles.

THEOREM 3. *Every connected, triangle-free graph on n vertices with $\delta \geq 3$ has a spanning tree with at least $(n + 4)/3$ leaves.*

Our second result is that for graphs with $\delta \geq 3$, the following statement holds. Here a *cubic diamond* is a diamond induced by vertices of degree three. (Similarly, a *cubic triangle* is a triangle induced by vertices of degree three.)

THEOREM 4. *Every connected graph on n vertices with $\delta \geq 3$, without cubic diamonds, has a spanning tree with at least $(2n + 12)/7$ leaves.*

In fact we prove the following stronger version of the statement.

THEOREM 5. *Every connected graph on n vertices with $\delta \geq 3$ that contains D cubic diamonds has a spanning tree with at least $(2n - D + 12)/7$ leaves.*

Because of space considerations, we do not give the details of the proof of Theorem 5 in this paper, but a proof sketch is given in section 5. Details can be found in [3]. See also section 5 for a slightly sharper formulation of Theorem 5. The bounds in Theorem 3 and Theorem 5 are best possible, in the same sense as explained above. This is shown in section 6.

Our proofs are constructive and correspond to efficient and simple algorithms: Spanning trees that satisfy the bound from Theorem 3 can be found with an algorithm that repeatedly adds vertices or pairs of vertices to a leaf set (according to some simple rules) until no more leaves can be added, and then constructs a spanning tree with those leaves. Spanning trees that satisfy the bound from Theorem 5 can be found using a similar algorithm that also involves local search on these leaf sets. These algorithms are discussed in section 7. We end in section 8 with a discussion of the results.

One important application of our bounds lies in the area of *fixed parameter tractable (FPT) algorithms*. These algorithms answer the following decision problem: does a graph G on n vertices have a spanning tree with at least k leaves? k is often chosen as the *parameter*, and then an algorithm for this problem is an FPT algorithm if its time complexity is bounded by a function $g(n)f(k)$, where $g(n)$ is a polynomial in the input size n , and the *parameter function* $f(k)$ may be any function. For designing fast FPT algorithms, the main goal is to find an algorithm where the parameter function $f(k)$ grows slowly. After a long line of improvements in this direction, two of the current best FPT algorithms in this respect appear in [4] and [8]. Bonsma, Brueggemann, and Woeginger [4] used the bound from Theorem 1 to construct an FPT algorithm with $f(k) \in O(9.49^k) \approx O(\binom{4k}{k})$. The factor 4 here comes from the factor $\frac{1}{4}$ in Theorem 1. Since our new Theorem 4 improves this factor to $\frac{2}{7}$, while adding only a minor extra restriction on the graph class, this can easily be used to improve the FPT algorithm given in [4]. The resulting algorithm has $f(k) \in O(\binom{3.5k}{k}) \approx O(8.12^k)$ and is the new fastest FPT algorithm. For details we refer to [3].

Another application of bounds of this type lies in the area of approximation algorithms, as demonstrated recently by Correa et al. [7]. They used the bound from Theorem 2 to deduce a bound similar to the one in Theorem 5: their bound states that every cubic graph has a spanning tree with at least $(3n - 2c + 14)/10$ leaves, where c is the number of components that result from deleting all internal vertices of diamonds (vertices that have all of their neighbors in the diamond itself). Combined with a suitable upper bound, this gives the $5/3$ -approximation algorithm for finding leafy trees in cubic graphs.

We also remark that apart from a small difference of $\frac{2}{7}$ in the constant, Theorem 5 can be seen as a generalization of Theorem 1: since $D \leq \frac{1}{4}n$ (cubic diamonds are vertex disjoint), it follows directly from Theorem 5 that connected graphs with $\delta \geq 3$ have a spanning tree with at least $(2n - D + 12)/7 \geq (\frac{7}{4}n + 12)/7 = \frac{1}{4}n + \frac{12}{7}$ leaves.

2. Preliminaries. We distinguish between $\subseteq$ and $\subset$: subset and proper subset, respectively. A graph G is called k -connected if $|V(G)| > k$ and there is no set $S \subset V(G)$ with $|S| < k$ such that $G - S$ is disconnected. For a nonempty set $S \subset V(G)$, $[S, \bar{S}]$ denotes the set of edges with exactly one end vertex in S . A set of this form is called an *edge cut*. If the single edge e forms an edge cut, e is called a *bridge*. K_n denotes a complete graph on n vertices. K_3 is called a *triangle*. A graph with no triangles as subgraphs is called *triangle-free*.

In this paper, the *blocks* of a graph are maximal 2-connected subgraphs. So unlike in the usual definition, a K_2 is not a block, and bridges are not contained in any block of the graph. The following lemma is an easy-to-prove variant of a well-known lemma.

LEMMA 6. *A connected graph without leaves and with cut vertices has at least two blocks that contain exactly one cut vertex.*

A set S is called minimal (maximal) for property ϕ if it satisfies property ϕ and no elements can be removed (added) such that ϕ is still satisfied. Minimal and maximal subgraphs are defined similarly. For a set $S \subseteq V(G)$, $G[S]$ denotes the subgraph of G induced by S ; this is the unique maximal subgraph of G with vertex set S . We will write $S - x$ and $S + x$ instead of $S \setminus \{x\}$ and $S \cup \{x\}$, respectively. If w is a function that assigns values to elements of S , then for $T \subseteq S$, $w(T) = \sum_{v \in T} w(v)$.

If $S \subseteq V(G)$, then a vertex $v \in S$ will be called an S -vertex. A neighbor v of u with $v \in S$ is called an S -neighbor of u . Similarly, a neighbor that is part of a CD-set that is currently considered is called a CD-set neighbor, etc.

Leafy spanning trees and small CD-sets. The following close relation between spanning trees and CD-sets is well known. If T is a spanning tree for $G = (V, E)$ with leaf set L , then $V \setminus L$ is a CD-set, unless $G = K_2$. Similarly, for every CD-set S , we can find in polynomial time a spanning tree for which $V \setminus S$ is a subset of the leaf set.

In the remainder of the paper, we will consider CD-sets instead of leaf sets of spanning trees. We feel that this is more practical for our purposes, which is illustrated by our methods, and discussed in section 8. If S is a CD-set, we will still call the vertices in $V \setminus S$ the *leaves* of S . If S is a CD-set for G and $G[S - v]$ is not connected, v is called a *connector*. If S is a CD-set for G and $S - v$ is not dominating, v is called a *dominator*. Observe that if S and $S' \subset S$ are CD-sets for G , and $v \in S$ is a dominator or connector, then $v \in S'$. A leaf v is called an *i-leaf* if it has i CD-set neighbors. A CD-set is called a *2-CD-set* if all its leaves are 1-leaves or 2-leaves.

Since we will consider CD-sets in the remainder of this paper, we state our main results in terms of CD-sets. Theorem 3 is equivalent to the following theorem.

THEOREM 7. *Every connected, triangle-free graph on n vertices with $\delta \geq 3$ has a CD-set S with $|S| \leq (2n - 4)/3$.*

Theorem 7 will be proved in section 4. Theorem 5 is equivalent to the following theorem.

THEOREM 8. *Every connected graph on n vertices with $\delta \geq 3$ that contains D cubic diamonds has a CD-set S with $|S| \leq (5n - 12 + D)/7$.*

In section 5, a slightly stronger variant of Theorem 8 is stated and proved.

3. Introduction to the method. We give a simple example to explain our proof technique.

DEFINITION 9. *$S \subseteq V(G)$ is a standard CD-set for graph G if the following properties hold:*

1. S is a 2-CD-set for G .
2. Every $v \in S$ has $d_G(v) \geq 3$.

Suppose that S is a standard CD-set for graph G and that $G[S]$ is a tree. We show that $|S|$ is roughly bounded from above by $\frac{2}{3}n$. For this it is sufficient to show that $|S| \leq 2|\bar{S}|$. This is easy when $G[S]$ is a tree: vertices with degree one or two in $G[S]$ have at least two, resp., one $\bar{S}$ -neighbors in G , since these vertices have degree at least three in G . A tree has average degree less than two, so there are at least $|S|$ edges in $[S, \bar{S}]$. Combining this with the fact that vertices in $\bar{S}$ are incident with at most two of these edges (S is a 2-CD-set), we obtain $|S| \leq 2|\bar{S}|$. This is the basic counting method behind the bounds we deduce. The next question is of course how to find a CD-set with the above properties, or similar properties.

Since we consider only graphs with minimum degree at least three, the property that vertices in S have degree at least three is easily satisfied. Finding a small 2-CD-set is not always possible, however. Fortunately, for our counting techniques, we may ignore edges between two vertices of high degree. More precisely, when u is an i -leaf with $i \geq 3$, we may delete incident edges to make it a 2-leaf, as long as this does not reduce the minimum degree of vertices in S below three. This leads to the following definition of *potential standard CD-sets*.

DEFINITION 10. $S \subseteq V(G)$ is a potential standard CD-set for G if there exists a spanning subgraph G' of G such that S is a standard CD-set for G' . Such a graph G' is called a realization of S . G' is a maximal realization of S if there is no other realization of S of which G' is a subgraph.

Observe that for a given potential standard CD-set S , every maximal realization has the same number of edges.

In the counting method example above, we required one additional property, namely that $G[S]$ is a tree. We cannot always find a potential standard CD-set S such that $G[S]$ is a tree, but we will show below that as long as we require S to be a *minimal* potential standard CD-set, the blocks of $G[S]$ have useful properties that can be used in our counting method to give similar bounds. In the next section we extend the above counting method to prove Theorem 7. In section 5, we prove Theorem 8. To prove this second bound, we impose three additional restrictions on the minimal potential standard CD-set we consider, and we slightly change the counting method.

4. Small CD-sets for graphs without triangles. In this section we state three properties for a pair consisting of a potential standard CD-set S and a realization G' . Below we will prove a bound for pairs S and G' that satisfy these properties. But first we will show that such a pair S and G' exists for every connected graph G with $\delta(G) \geq 3$.

Theorem 12 below states the essential properties of the pair S and G' that are needed to prove the bound. Property 1 is added to allow an easier formulation of properties 2 and 3 and to facilitate the later analysis, although it is not necessary for the method. Properties 2 and 3 are needed to ensure that S is relatively small.

To prove the existence of a pair S and G' with these properties, we can simply consider any *minimal* potential standard CD-set S ; for every such S a realization G' can be found such that the three properties are satisfied. However, it is not trivial to prove that a minimal potential standard CD-set can easily be found, and therefore we prove the statement using a potential standard CD-set S that is defined differently. This will be more convenient when we consider constructive algorithms in section 7.

DEFINITION 11. A potential standard CD-set S for graph G is 2-optimal if there is no potential standard CD-set $S' \subset S$ with $|S'| \geq |S| - 2$.

Clearly, any minimal potential standard CD-set is 2-optimal. It can also be shown that any 2-optimal potential standard CD-set is a minimal potential standard CD-set, but since we do not need this statement and the proof is not trivial, we omit this proof. Note that for Theorem 12, we do not yet need to assume that G contains no triangles.

THEOREM 12. *A connected graph G with $\delta(G) \geq 3$ has a potential standard CD-set S , with realization G' , with the following properties. Degrees, neighbors, and all other graph-related notions are taken with respect to G' .*

1. *If $u, v \in S$, $d(u) \geq d(v) \geq 4$, and $uv \in E(G')$, then uv is a bridge of $G'[S]$.*
2. *Every vertex $v \in S$ that is neither a dominator nor a connector has at least three neighbors in S , and all of its neighbors in S have degree three.*
3. *If $\{u, v\} \subseteq S$, $uv \in E(G')$, and u and v are both neither dominators nor connectors, then $G'[S] - u - v$ is not connected.*

Proof. Consider a 2-optimal potential standard CD-set S for graph G , with realization G'' . Consider a realization G' that is obtained from G'' as follows. First let $G' = G''$. If there is an edge $uv \in E(G'[S])$ that is not a bridge in $G'[S]$, with $d_{G'}(u) \geq 4$ and $d_{G'}(v) \geq 4$, remove uv from G' . Repeat this until no such edges exist anymore.

This procedure of removing edges does not destroy the connectivity of $G'[S]$, and it maintains the property that all vertices in S have degree at least three in S . So clearly G' is again a realization of S . By removing edges like this, it is now obvious that property 1 holds for S and G' .

To prove the remaining two properties, we will use the fact that S is a 2-optimal potential standard CD-set for G . Let v be a vertex in S that is not a dominator or connector. If v has at most two neighbors in S , then $S - v$ is again a potential standard CD-set, with realization G' , a contradiction with the 2-optimality of S . Now suppose v has at least three neighbors in S , and one of these neighbors $u \in S$ has $d_{G'}(u) \geq 4$. Since v is not a connector, uv is not a bridge of $G'[S]$, so by property 1, $d(v) = 3$. Then $S - v$ is a potential standard CD-set with realization $G' - uv$, again a contradiction. We conclude that any vertex v that is not a dominator or connector has at least three S -neighbors in G' and that all of these neighbors have degree three in G' , which proves property 2.

Now we will prove property 3. Suppose that u and v in S are neighbors in G' , and both are neither connectors nor dominators. By property 2, u and v have at least three neighbors in S , and all of those neighbors have degree three. It follows that u and v both have degree three, and therefore they have no neighbors outside of S . So $S - u - v$ is again a dominating set. If $G'[S] - u - v$ is connected, then u and v are 2-leaves with respect to $S - u - v$ and G' , so $S - u - v$ is a potential standard CD-set, a contradiction with the 2-optimality of S . We conclude that $G'[S] - u - v$ is not connected, which proves property 3. $\square$

Now that we have proved the existence of a CD-set with these properties, we can use them to establish upper bounds on the size of such a CD-set, assuming that the given graph G has no triangles.

To prove the bound in Theorem 13 below, we consider a potential standard CD-set S and realization G' having the properties stated in Theorem 12, and use an extension of the counting technique sketched before in section 3: leaves distribute a weight of 1 to their CD-set neighbors, and we show that these weights can be redistributed over the CD-set such that every vertex receives a weight of at least $\frac{1}{2}$. Previously we assumed that $G'[S]$ was a tree. Now we will allow $G'[S]$ to have blocks, and we

require only that these blocks do not contain triangles.

Observe that when $G'[S]$ is not a tree, there may be vertices in S that are not connectors or dominators. In this case a minimal CD-set $S' \subset S$ exists. It is for this set S' that we prove the bound. To improve the clarity of the exposition, we first state the theorem which yields this bound and then prove the two lemmas that are used in its proof.

THEOREM 13. *Let $G = (V, E)$ be a connected graph on n vertices with $\delta(G) \geq 3$. Let S be a potential standard CD-set for G with realization G' that satisfy the properties from Theorem 12 such that in addition no block of $G'[S]$ contains a triangle. If $S' \subseteq S$ is a minimal CD-set, then $|S'| \leq (2n - 4)/3$.*

Proof. In order to prove this theorem, we assign weights w to the vertices of S such that the total weight $w(S)$ is $|V \setminus S| + \frac{3}{2}|S \setminus S'|$. We show that $w(S) \geq \frac{1}{2}|S| + 2$. Then we can combine these equations to obtain the result.

The weight assignment is as follows: all leaves of S distribute a weight of 1 equally among their neighbors in S' (vertices in $S \setminus S'$ receive no weight yet). This means we have assigned a total weight of $|V \setminus S|$. Next, we assign a weight of $\frac{3}{2}$ to each vertex in $S \setminus S'$.

In order to show that $w(S) \geq \frac{1}{2}|S| + 2$, we prove three lower bounds for this weight assignment w .

1. A vertex v with degree two in $G'[S]$ is a dominator or connector (property 2 from Theorem 12), so $v \in S'$. Since v has at least one leaf neighbor $u \notin S$ (S is a standard CD-set for G'), and u has at most two neighbors in $G'[S']$, u assigns at least $\frac{1}{2}$ to v . This shows that for a vertex v with degree two in $G'[S]$, $w(v) \geq \frac{1}{2}$.
2. A vertex v with degree one in $G'[S]$ is not a connector, so it is a dominator (property 2). From the 1-leaf adjacent to it, it receives a weight of 1. In addition, since v has degree at least three and leaves have at most two CD-set neighbors, it gains an additional weight of at least $\frac{1}{2}$. So for a vertex v with degree one in $G'[S]$, $w(v) \geq \frac{3}{2}$.
3. Let $G'[B]$ be a block of $G'[S]$; let L denote the set of vertices in B with two neighbors in B , and $H = B \setminus L$ denote the set of vertices in B with at least three neighbors in B . Then $|L| \geq |H| + 1$ (which is shown below in Lemma 14). Let $C \subseteq S$ denote the set of connectors, which are the cut vertices of $G'[S]$. We will show that $w(B \setminus C) \geq \frac{1}{2}|B| + 2 - |C \cap B|$. A vertex in L that is not a connector also has degree two in $G'[S]$, and therefore must be a dominator (property 2). A dominator in B has weight at least 1. We consider two cases:

- (a) Suppose $|(S \setminus S') \cap B| \geq 1$. Then one of the vertices in H has an additional weight of at least $\frac{3}{2}$. We have $w(B \setminus C) \geq \frac{3}{2} + |L \setminus C| \geq \frac{3}{2} + |L| - |C \cap B|$. Since $|L| \geq |H| + 1$, we have $|L| \geq \frac{1}{2}|B| + \frac{1}{2}$. Hence $w(B \setminus C) \geq 2 + \frac{1}{2}|B| - |C \cap B|$.
- (b) Suppose $(S \setminus S') \cap B = \emptyset$. Suppose B contains a vertex v that is not a dominator or connector with respect to S . Since $v \in S'$, it is a connector or dominator with respect to S' . But $(S \setminus S') \cap B = \emptyset$, so v is also not a connector for S' . Therefore, in S , v is adjacent to a 2-leaf u , and the other CD-set neighbor of u is in $S \setminus S'$. In this case, v receives a weight of 1 from u . Recall that dominators also receive a weight of at least 1. So all vertices in $B \setminus C$ receive a weight of at least 1. It follows that $w(B \setminus C) \geq |B \setminus C| = |B| - |C \cap B|$. Since $G'[B]$ is not a triangle, $|B| \geq 4$. Hence $w(B \setminus C) \geq \frac{1}{2}|B| + 2 - |C \cap B|$.

If $G'[S] \neq K_1$, Lemma 15 below now shows that $w(S) \geq \frac{1}{2}|S| + 2$. In that case we have

$$\frac{3}{2}|S \setminus S'| + |V \setminus S| = w(S) \geq \frac{1}{2}|S| + 2 \Leftrightarrow$$

$$\frac{3}{2}|S| - \frac{3}{2}|S'| + |V| - |S| \geq \frac{1}{2}|S| + 2 \Leftrightarrow$$

$$|V| - 2 \geq \frac{3}{2}|S'| \Leftrightarrow |S'| \leq (2|V| - 4)/3.$$

If $G'[S] = K_1$, then this final inequality follows easily since $|V| \geq 4$. $\square$

We continue to prove the two lemmas that were used in the above proof. We adopt the notation from the proof. In particular, for a block $G'[B]$ of $G'[S]$, the set L is the set of vertices in B that have two neighbors in B , and $H = B \setminus L$ is the set of vertices with at least three neighbors in B . The first lemma gives a lower bound for the number of L -vertices in a block of $G'[S]$.

LEMMA 14. *Let CD -set S and graph G' have the properties stated in Theorem 12. For every block $G'[B]$ in $G'[S]$, $|L| \geq |H|$. If $G'[B]$ contains no triangles, then $|L| \geq |H| + 1$.*

Proof. Let $G'' = G'[B]$. Consider two neighbors $u, v \in H$. If $d_{G'}(u) \geq 4$, then $d_{G'}(v) = 3 = d_{G''}(v)$, since uv is not a bridge of $G'[S]$ (property 1 from Theorem 12). Then v is not a dominator or connector since all its neighbors are in B . This is a contradiction with property 2. So both u and v have degree three in G' and therefore are not dominators or connectors. So by property 3, they form a 2-cut in $G'[S]$ and also in G'' . This shows that all neighbor pairs $u, v \in H$ form a 2-cut in G'' and have degree three in G' .

We show that it follows that every vertex in H has at most one neighbor in H . Suppose $u \in H$ has two neighbors v and w in H . $G'' - u - v$ is disconnected, and u and v both have exactly one neighbor in both components. Therefore, if u and v share a neighbor, this must be a vertex in L since G'' is 2-connected. So w is not a neighbor of v . Now it can be checked that $G'' - u - w$ is still connected, a contradiction with the statement from the previous paragraph.

So every vertex in H has at most one neighbor in H and therefore at least two neighbors in L . Clearly, every vertex in L has at most two neighbors in H . It follows that $|L| \geq |H|$.

In addition, if $|L| = |H|$, then every vertex in H has exactly one neighbor in H , and every vertex in L has two neighbors in H . We show that it follows that G'' contains a triangle. Consider two neighbors $u, v \in H$. Let C_1 and C_2 be the two components of $G'' - u - v$, such that $|V(C_1)| \leq |V(C_2)|$. If C_1 contains vertices of H , then let u' and v' be two neighbors in $H \cap V(C_1)$. Let C'_1 and C'_2 be the components of $G'' - u' - v'$, such that $|V(C'_1)| < |V(C_1)|$. We can continue to find new neighbor pairs in H like this, until the smallest component no longer contains vertices of H . Since every vertex in L has two neighbors in H , this component consists of a single vertex, and we have found a triangle. $\square$

In the proof of Theorem 13, we started with a certain weight assignment and proved three properties for this. We anticipated in the proof of Theorem 13 that this yields that the total weight of S is at least $\frac{1}{2}|S| + 2$, so slightly more than $\frac{1}{2}$ on average. The following lemma proves this statement.

LEMMA 15. Let $G = (V, E) \neq K_1$ be a connected graph with nonnegative weights w on the vertices such that the following hold:

1. If $d(v) = 2$, then $w(v) \geq \frac{1}{2}$.
2. If $d(v) = 1$, then $w(v) \geq \frac{3}{2}$.
3. If $G[B]$ is a block of G , and C is the set of cut vertices of G , then $w(B \setminus C) \geq \frac{1}{2}|B| + 2 - |C \cap B|$.

For this graph, $w(V) \geq \frac{1}{2}|V| + 2$.

Proof. We prove the statement by induction on $|V|$. If G is 2-connected, then the statement follows immediately from property 3. If $G = K_2$, then the statement is clearly true.

In any other case, G has at least one leaf u such that $G - u$ is not K_1 , or it has at least one block with exactly one cut vertex (Lemma 6). We consider these two cases.

Suppose first that u is a leaf of G , with neighbor v . Consider the graph $G' = G - u$ with weight function $w'(v) = w(v) + w(u) - \frac{1}{2}$, and $w'(x) = w(x)$ for all other vertices. We prove that for G' and w' , the three properties hold again, so we can use induction. Note that since $w(u) \geq \frac{3}{2}$, $w'(v) \geq w(v) + 1$.

If v has degree two in G' , then since $w'(v) \geq 1$, the first property holds for v . If v has degree one in G' , then $w(v) \geq \frac{1}{2}$ (since v has degree two in G), so $w'(v) \geq \frac{3}{2}$, and the second property holds for v . For all other vertices, the weights and degrees do not change, so these two properties hold for all vertices.

For a block $G'[B]$, it is obvious that property 3 still holds, unless $v \in B$ and v is not a cut vertex anymore in G' . In this case, let C_G (resp., $C_{G'}$) denote the set of cut vertices of G and G' ($C_G = C_{G'} + v$):

$$w'(B \setminus C_{G'}) \geq w(B \setminus C_G) + 1 \geq \frac{1}{2}|B| - |C_G \cap B| + 3 = \frac{1}{2}|B| - |C_{G'} \cap B| + 2,$$

so property 3 holds.

We conclude that if G has a leaf u , then we can construct a new graph $G' = G - u$ with weight function w' such that $w'(V(G')) = w(V(G)) - \frac{1}{2}$, for which the three properties hold. $G' \neq K_1$ and G' is connected, so by induction, $w(V(G)) = w'(V(G')) + \frac{1}{2} = \frac{1}{2}|V(G')| + \frac{5}{2} = \frac{1}{2}|V(G)| + 2$, which proves the lemma for this case.

Now we consider the case that G has no leaves. Then G has a block B which contains only a single cut vertex u . Consider the graph $G' = G - (B - u)$ with weight function $w'(u) = \frac{3}{2}$ and $w'(x) = w(x)$ for all other vertices. $G' \neq K_1$, so if we can show that the three properties hold for G' and w' , we can use induction.

If $d_{G'}(u) = 1$ or $d_{G'}(u) = 2$, then w' clearly satisfies the corresponding properties. For a block $G'[B']$, property 3 clearly holds when $u \notin B'$ or u is still a cut vertex in G' . In the other case, let C_G (resp., $C_{G'}$) denote the set of cut vertices of G and G' . Now

$$w'(B' \setminus C_{G'}) = w(B' \setminus C_G) + \frac{3}{2} \geq \frac{1}{2}|B'| - |C_G \cap B'| + \frac{7}{2} > \frac{1}{2}|B'| - |C_{G'} \cap B'| + \frac{5}{2},$$

which is even better than necessary.

Now for G' all weight properties are satisfied and we can use induction: let $V = V(G)$ and $V' = V(G')$:

$$\begin{aligned} w(V) &\geq w'(V') + w(B - u) - \frac{3}{2} \geq \left(\frac{1}{2}|V'| + 2 \right) + \left(\frac{1}{2}|B| + 1 \right) - \frac{3}{2} \\ &= \frac{1}{2}|V'| + \frac{1}{2}|B| + \frac{3}{2} = \frac{1}{2}(|V| - |B| + 1) + \frac{1}{2}|B| + \frac{3}{2} = \frac{1}{2}|V| + 2. \end{aligned}$$

This proves the lemma for the case where G has no leaves, so the lemma is true in all cases. $\square$

In Theorem 13, there is an additional condition that no block of $G'[S]$ contains triangles. Unfortunately, such a G' and S do not always exist for every connected graph G with $\delta(G) \geq 3$. In the following text a potential standard CD-set S that has a realization G' such that $G'[S]$ contains no triangles will be called a *potential standard CD-set without triangles*.

First consider a graph G that contains a cubic triangle consisting of three cut vertices. Every potential standard CD-set S for G contains these three vertices, and every realization contains all incident edges, so G has no potential standard CD-set without triangles. We can even construct planar, 3-connected, cubic graphs that have no potential standard CD-set without triangles. In fact, we prove a stronger statement; we show that it is $\mathcal{NP}$ -complete to decide whether a given graph with these properties has a potential standard CD-set without triangles.

THEOREM 16. *Deciding whether a planar, cubic, 3-connected graph G has a potential standard CD-set S with realization G' such that $G'[S]$ contains no triangles is $\mathcal{NP}$ -complete.*

Proof. The problem of deciding whether a given graph has a spanning subgraph that is a path is called the Hamilton path problem. This problem is $\mathcal{NP}$ -complete even when restricted to planar, cubic, 3-connected graphs [9]. Let $G = (V, E)$ be such a Hamilton path instance. Replacing every vertex with a cubic triangle gives a graph G' , which is again planar, cubic, and 3-connected. Suppose S is a CD-set for G' such that $G'[S]$ contains no triangles (a *CD-set without triangles*). Define $F \subset E$ as follows: if the edge corresponding to $uv \in E$ is part of $G'[S]$, add uv to F . Since S contains at most two vertices of every triangle in G' , $\Delta((V, F)) \leq 2$. Suppose a vertex v with $d(v) = 0$ exists in (V, F) . Then, because S is a dominating set, every neighbor of v has degree one in (V, F) . So (V, F) has maximum degree two and at least three vertices with degree one and therefore has multiple nontrivial components, contradicting the fact that $G'[S]$ is connected. Therefore (V, F) has minimum degree one and maximum degree two and is connected, which gives a Hamilton path for G . Similarly, a Hamilton path for G can be used to find a CD-set without triangles for G' . This shows that it is $\mathcal{NP}$ -complete to decide whether a planar, cubic, 3-connected graph G' has a CD-set without triangles.

For the constructed graph G' , it can be checked that a CD-set without triangles exists if and only if a potential standard CD-set without triangles exists, which proves the $\mathcal{NP}$ -completeness of the given problem. $\square$

So we cannot hope to improve our CD-set construction method to always find potential standard CD-sets without triangles. However, for graphs without triangles, Theorem 12 and Theorem 13 together immediately prove Theorem 7.

THEOREM 7. *Every connected, triangle-free graph on n vertices with $\delta \geq 3$ has a CD-set S with $|S| \leq (2n - 4)/3$.*

5. Small CD-sets for graphs with few cubic diamonds. In order to give a clear overview of the new ideas in this section, we will be a little sloppy; we will, for instance, omit the constants from the bounds we discuss. The correct and detailed reasoning can be found in the proof sketches.

In the previous section we showed that every connected graph with $\delta \geq 3$ without triangles, on n vertices, has a CD-set containing at most $\frac{2}{3}n$ vertices. This bound was proved by letting leaves distribute a weight of 1 among their CD-set neighbors, and showing that these weights can be distributed over the CD-set such that every CD-set

FIG. 5.1. $G[S]$ contains one cubic diamond block.

FIG. 5.2. A diamond necklace.

vertex receives a weight of at least $\frac{1}{2}$. Triangles in the given graph G caused a problem only when they appeared in blocks of $G'[S]$, where S is the potential standard CD-set that was considered, and G' its realization.

In this section we will construct a CD-set with at most $\frac{5}{7}n$ vertices for graphs that may have triangles. For this, we use the same counting method, but instead we have only to assign a weight of $\frac{2}{5}$ to each CD-set vertex. With this more relaxed goal, only two possible blocks of $G'[S]$ cannot be handled with (a slightly more detailed analysis of) the method from the previous section: we have a weight deficiency for blocks of $G'[S]$ that are cubic triangles in G' and blocks of $G'[S]$ that are cubic diamonds in G' .

DEFINITION 17. A subgraph H of G is a cubic diamond if H is a diamond that is induced by four vertices of degree three in G .

Let $S \subseteq V(G)$. Subgraph H of $G[S]$ is a cubic diamond block of $G[S]$ if H is a cubic diamond with respect to G and a block with respect to $G[S]$. (Vertices of H may have degree two in $G[S]$.)

Figure 5.1 shows an illustration of cubic diamond blocks: H_1 is a cubic diamond block of $G[S]$ that contains one vertex with degree two in $G[S]$, but H_2 and H_3 are not cubic diamond blocks.

In the previous section, we used an arbitrary minimal potential standard CD-set S to find a CD-set that satisfied the bound, using three properties we deduced for such a set S , and the chosen realization G' . In this section, we consider a potential standard CD-set S that has these properties plus some additional properties, which enables us to account for triangle and diamond blocks in $G'[S]$.

We consider again the examples from section 1 that show that Theorem 1 is best possible. Recall that these are graphs that have no CD-set with fewer than $\frac{3}{4}n$ vertices, and that these examples contain many cubic diamonds. So when G contains many cubic diamonds, we cannot prove the desired bound of $\frac{5}{7}n$. Instead we show that a CD-set exists that contains at most $\frac{5}{7}n + \frac{1}{7}D$ vertices, where D is the number of cubic diamonds in the given graph G . This is equal to $\frac{3}{4}n$ when D is maximum (when $D = n/4$).

To prove this bound, we need to ensure that for the potential standard CD-set S of G and realization G' we consider, cubic diamond blocks in $G'[S]$ only occur when they cannot be avoided. It turns out that we can always avoid cubic diamond blocks in $G'[S]$, except those that are part of a *diamond necklace* of G (see Figure 5.2).

DEFINITION 18. An induced subgraph H of G is a diamond necklace in G if

for some $k \geq 1$, the vertices of H can be labeled $u_1, \dots, u_{k+1}, v_1, \dots, v_k, w_1, \dots, w_k$, such that the edge set of H consists exactly of $u_i v_i, u_i w_i, v_i w_i, v_i u_{i+1}, w_i u_{i+1}$ for $i = 1, \dots, k$, and such that $u_2, \dots, u_k$ have degree four in G , and all other vertices of H have degree three in G .

Note that a cubic diamond is also a diamond necklace. The new property 4 in Theorem 21 below shows that the only cubic diamond blocks that occur in $G'[S]$ are part of a diamond necklace of G .

The next new property in Theorem 21 is introduced to solve the weight deficiency of triangle blocks of $G'[S]$ in our counting method. Observe that for every triangle block in $G'[S]$, there is one 1-leaf in $\bar{S}$; the number of 1-leaves is at least $T + 2$, where T is the number of triangle blocks in $G'[S]$. If these additional 1-leaves assign a weight of $\frac{6}{5}$ instead of 1 to their CD-set neighbors, the weight deficiency for triangle blocks can be solved. A more detailed analysis of our counting method shows that not all 1-leaves need to assign $\frac{6}{5}$, only those directly related to blocks in some way. These will be called *block-leaves* and are defined as follows.

DEFINITION 19. A vertex $v \in S$ is a simple CD-set vertex with respect to the CD-set S for graph G if $d(v) = 3$ and

- $G[S - v]$ has two components, and $S - v$ is a dominating set for G , or
- $G[S - v]$ is connected, and v has exactly one 1-leaf neighbor.

Simple CD-set vertices are those vertices that do not receive additional weight in our counting method.

DEFINITION 20. A 1-leaf v is a block-leaf with respect to the CD-set S for graph G if there is a path P in $G[S]$ with end vertices x and y ($x = y$ is possible), consisting only of simple CD-set vertices, such that

- x is a neighbor of v .
- y is part of a block of $G[S]$, but none of the other vertices of P are part of a block.

Of course we still need to ensure that the total weight assigned is at most equal to the number of leaves, and therefore we compensate this additional weight by letting non-block-leaves (a *non-block-leaf* is a leaf but not a block-leaf) assign only a weight of $\frac{4}{5}$ and choosing a CD-set S such that the number of block-leaves (that assign $\frac{6}{5}$) is at most half of the total number of leaves. This is ensured by property 5 of Theorem 21.

THEOREM 21. A connected graph G with $\delta(G) \geq 3$ has a potential standard CD-set S , with realization G' , with the following properties. Degrees, neighbors, and all other graph related notions are taken with respect to G' .

1. If $u, v \in S$, $d(u) \geq d(v) \geq 4$ and $uv \in E(G')$, then uv is a bridge of $G'[S]$.
2. Every vertex $v \in S$ that is neither a dominator nor a connector has at least three neighbors in S , and all of its neighbors in S have degree three.
3. If $\{u, v\} \subseteq S$, $uv \in E(G')$, and u and v are both neither dominators nor connectors, then $G'[S] - u - v$ is not connected.
4. The number of cubic diamond blocks in $G'[S]$ is at most the number of diamond necklaces in G .
5. The number of block-leaves is at most half the total number of leaves.

In addition, if $|S| = 2$, then $|\bar{S}| \geq 4$.

Proof sketch. The main idea is to consider a potential standard CD-set S and realization G' that are optimal according to the following priorities:

- Minimize $|S|$.
- Maximize the number of 2-leaves in $\bar{S}$.
- Minimize the number of cubic diamond blocks in $G'[S]$.

- Minimize $|E(G'[S])|$.
- Maximize $|E(G')|$.

By this we mean that among all pairs of S and G' that minimize $|S|$, we consider pairs that maximize the number of 2-leaves. Among all these pairs, we choose one that minimizes the number of cubic diamond blocks in $G'[S]$, etc. For S and G' chosen this way, it can be shown that the above properties hold.

The proof of properties 1–3 is very similar to that in the proof of Theorem 12. The proof of the last two properties is more involved; unlike the other properties, these properties do not hold for just any minimal potential standard CD-set. However it can be shown that if these properties do not hold, a small change can be made to the standard CD-set S and realization G' , such that an improved S_2 and G'_2 are found, according to the priorities. By “small change” we mean that $|S_2 \setminus S| \leq 3$ in every case. For details, we refer to [3]. $\square$

Analogous to the use of Theorems 12 and 13, now that the existence of a CD-set with the properties stated in Theorem 21 has been established, we will use these properties to determine an upper bound on the size of such a CD-set.

THEOREM 22. *Let S be a potential standard CD-set for graph $G = (V, E)$, with realization G' , satisfying the properties from Theorem 21. If $S' \subseteq S$ is a minimal CD-set, then $|S'| \leq (5|V| - 12 + D)/7$, where D is the number of cubic diamond blocks in $G'[S]$.*

Proof sketch. In order to prove this theorem, we assign weights w to the vertices of S such that the total weight is at most $|V \setminus S| + \frac{7}{5}|S \setminus S'| + D/5$, and then show that $w(S) \geq \frac{2}{5}|S| + \frac{12}{5}$. Then we can combine the two inequalities to obtain the result.

The weight assignment is as follows: block-leaves assign a weight of $\frac{6}{5}$ to their CD-set neighbor, and all other leaves distribute a weight of $\frac{4}{5}$ equally among their neighbors in S' (vertices in $S \setminus S'$ receive no weight yet). Since at most half of the leaves are block-leaves (property 5 of Theorem 21), we have assigned a total weight of not more than $|V \setminus S|$. Next, we assign a weight of $\frac{7}{5}$ to each vertex in $S \setminus S'$. Vertices in $S \setminus S'$ that are part of a cubic diamond block of $G'[S]$ receive an additional weight of $\frac{1}{5}$.

When $G'[S]$ is not a tree, it can be shown that $w(S) \geq \frac{2}{5}|S| + \frac{12}{5}$ for this weight assignment, using a proof similar to that of Lemma 15. For details we refer to [3]. It follows that

$$\begin{aligned} \frac{7}{5}|S \setminus S'| + D/5 + |V \setminus S| &\geq w(S) \geq \frac{2}{5}|S| + \frac{12}{5} \Leftrightarrow \\ \frac{7}{5}|S| - \frac{7}{5}|S'| + D/5 + |V| - |S| &\geq \frac{2}{5}|S| + \frac{12}{5} \Leftrightarrow \\ |V| + D/5 - \frac{12}{5} &\geq \frac{7}{5}|S'| \Leftrightarrow |S'| \leq (5|V| - 12 + D)/7. \end{aligned}$$

If $G'[S]$ is a tree, then this last inequality can be proved by assigning the weights as we did in the proof of Theorem 13: every leaf distributes a weight of 1 equally among its CD-set neighbors. For details we again refer to [3]. $\square$

In the bound from Theorem 22, the term D is equal to the number of cubic diamond blocks in $G'[S]$. Using property 4 from Theorem 21, we know that for the S and G' we consider, all cubic diamond blocks are part of diamond necklaces in G , so the number of diamond necklaces is an upper bound for D . In the theorem

FIG. 5.3. Reducing a necklace containing multiple diamonds.

FIG. 5.4. Reversing the necklace reduction.

below, we show that diamond necklaces can be reduced when they consist of more than one diamond, and therefore this term D can even be bounded by the number of cubic diamonds in G (diamond necklaces consisting of one diamond). This yields the desired theorem. Theorem 23 is actually formulated slightly stronger than Theorem 8, where D is the number of cubic diamonds in G . The stronger formulation was used to obtain the improved FPT algorithm [3] (see section 1).

THEOREM 23. *Let G be a connected graph on n vertices with $\delta \geq 3$. G has a CD-set S with $|S| \leq (5n - 12 + D)/7$, where D is the number of cubic diamonds in G that contain three vertices of S .*

Proof. First we reduce diamond necklaces that are not cubic diamonds in G : replace every diamond necklace containing at least two diamonds by a single cubic diamond as shown in Figure 5.3. These are called the *new* cubic diamonds, and the other cubic diamonds are called the *original* cubic diamonds. The resulting graph G_1 is again a simple, connected graph with $\delta(G_1) \geq 3$.

Consider a potential standard CD-set S of G_1 and realization G' that satisfy the properties from Theorem 21. Let D and D' denote the number of original (resp., new) cubic diamonds of G_1 that are a block of $G'[S]$. Since all diamond necklaces are now cubic diamonds, the number of cubic diamond blocks in $G'[S]$ is $D + D'$ (property 4). By Theorem 22, any minimal CD-set $S' \subseteq S$ has $|S'| \leq (5|V(G_1)| - 12 + D + D')/7$. Note that for any minimal CD-set $S' \subseteq S$, the cubic diamonds in G' that contain three vertices of S' are exactly those that are blocks in $G'[S]$.

From S' we can construct a CD-set for G : we can reconstruct G from G_1 by applying the operation illustrated in Figure 5.4 a number of times for every new cubic diamond. This operation introduces three new vertices. At the same time, we can maintain a CD-set by adding at most two new vertices to the CD-set every time we apply the operation: if u and v in Figure 5.4 are not in the previous CD-set, then we add v and x . If one of u and v is in the previous CD-set, then we add w and x . Let k be the number of times this operation has to be applied in order to reconstruct G from G_1 , and construct the corresponding CD-set S'' . Using $k \geq D'$, we can bound $|S''|$ as follows:

$$\begin{aligned} |S''| &\leq |S'| + 2k \leq (5|V(G_1)| - 12 + D + D')/7 + 2k \\ &\leq (5(|V(G)| - 3k) - 12 + D + k)/7 + 2k = (5|V(G)| - 12 + D)/7. \end{aligned}$$

The reconstruction does not affect the original cubic diamonds and also does not affect which vertices of these diamonds are in the CD-set. So D is the number of cubic diamonds in G that contain three vertices of S'' . $\square$

FIG. 6.1. The bound of Theorem 7 is best possible.

FIG. 6.2. Building block for the worst case examples for Theorem 8.

6. Worst case examples for the CD-set size. In this section we show that the bounds in Theorems 7 and 8 are best possible linear bounds. Throughout this section, n denotes the number of vertices of G .

Theorem 7 shows that every connected, triangle-free graph on n vertices with $\delta \geq 3$ has a CD-set S with $|S| \leq (2n - 4)/3$. We use examples very similar to those mentioned by Griggs, Kleitman, and Shastri [10] to show that this bound is best possible: for $n = 6k$, take k copies of the graph shown in Figure 6.1(a) and connect them in a cyclic form as shown in Figure 6.1(b). The resulting graph is cubic and connected and contains no triangles. It can be checked that it has no CD-set with fewer than $\frac{2}{3}n - 2 = \lfloor (2n - 4)/3 \rfloor$ vertices. This shows that for a linear bound $\alpha n - \beta$, $\alpha = \frac{2}{3}$ is best possible. When we consider the graph Q_3 on eight vertices which has no CD-set with fewer than four vertices, we see that $\beta = \frac{4}{3}$ cannot be increased.

Theorem 8 shows that every connected graph G with $\delta \geq 3$ has a CD-set S with $|S| \leq (5n - 12 + D)/7$, where D is the number of cubic diamonds in G . To prove that this bound is best possible we use the graph shown in Figure 6.2 as a building block, together with diamonds. For any D and $n = 4D + 7k$, take D diamonds and k copies of the graph in Figure 6.2, and connect them in a cyclic form similar to before. The resulting graph is connected, has $\delta = 3$, and has D cubic diamonds. It can be checked that it has no CD-set with fewer than $5k + 3D - 2 = \frac{5}{7}n + \frac{1}{7}D - 2 = \lfloor (5n + D - 12)/7 \rfloor$ vertices. It follows that for a bound of the form $\alpha n + \gamma D - \beta$, the choices $\alpha = \frac{5}{7}$ and $\gamma = \frac{1}{7}$ are best possible. Q_3 again shows that $\beta = \frac{12}{7}$ cannot be improved.

7. An algorithmic viewpoint. Let S be a potential standard CD-set for graph G , with realization G' , that satisfy the properties from Theorem 12, such that $G'[S]$ contains no triangles, and let $S' \subseteq S$ be a minimal CD-set. Theorem 13 then states that $|S'| \leq (2n - 4)/3$ holds, with $n = |V(G)|$. In the proof of Theorem 12, it is shown that for every 2-optimal potential standard CD-set S with realization, a new realization G' can be found such that the properties from Theorem 12 hold. Now we will show that in polynomial time, we can find a 2-optimal potential standard CD-set S in a connected graph with minimum degree at least three. First we show that potential standard CD-sets can be recognized in polynomial time.

LEMMA 24. *It can be checked in polynomial time whether $S \subseteq V(G)$ is a potential standard CD-set for G , and if so, a maximal realization G' of S can be found in polynomial time.*

Proof. We construct an auxiliary bipartite graph H with vertex set $A \cup B$: for every vertex $v \in S$, we add $d(v) - 3$ vertices to A (only vertices with degree at least four will correspond to vertices in A). For every i -leaf in $\bar{S}$ with $i > 2$, we add $i - 2$ vertices to B . We join vertices in A to vertices in B if in G edges exist between the corresponding vertices.

We show that a realization G' of S exists if and only if H has a matching M that saturates every vertex in B . If M is such a matching, delete every edge in G that corresponds to an edge of M , to obtain G' . For every former i -leaf (with $i > 2$), $i - 2$ incident edges are deleted since M saturates B , so only 1-leaves and 2-leaves remain. For every vertex in S with original degree d , at most $d - 3$ incident edges are deleted, so vertices in S still have degree at least three. Clearly, S is still a CD-set in G' .

Similarly, every maximal realization of S corresponds to a B -saturating matching in H .

The existence of polynomial time algorithms now follows from the well-known fact that polynomial time algorithms exist for finding a maximum matching (in fact, for bipartite graphs a specialized algorithm exists) and that if a B -saturating matching exists, every maximum matching saturates B . $\square$

THEOREM 25. *For a connected, triangle-free graph G on n vertices with $\delta(G) \geq 3$, in polynomial time a CD-set S' for G with $|S'| \leq (2n - 4)/3$ can be constructed.*

Proof. The algorithm is as follows. Start with $S = V(G)$. Since G is connected and $\delta(G) \geq 3$, this S is a potential standard CD-set for G . Repeatedly remove one or two vertices from S while maintaining a potential standard CD-set. Since we remove only at most two vertices at a time, and potential standard CD-sets can be recognized in polynomial time (Lemma 24), this can be done in polynomial time. When we have a 2-optimal potential standard CD-set, set $S' = S$ and then repeatedly remove vertices from S until a minimal CD-set S' is obtained.

At this point, S is a 2-optimal potential standard CD-set for G , and $S' \subseteq S$ is a minimal CD-set for G . In the proof of Theorem 12 it is shown that a realization G' can be constructed for S such that S and G' satisfy the properties stated in Theorem 12. Since G contains no triangles, $G'[S]$ contains no triangles. Then by Theorem 13, $|S'| \leq (2n - 4)/3$. $\square$

A CD-set that satisfies the bound from Theorem 23 can also be found in polynomial time, since the proof of Theorem 21 is constructive. However, in this case a local search procedure is needed. The main idea of this local search procedure is as follows: for a given standard CD-set S and realization G' , we can check in polynomial time whether there is an improved standard CD-set S_2 and realization G'_2 with $|S_2 \setminus S| \leq 3$, according to the priorities stated in the proof of Theorem 21. When considering the detailed proof of Theorem 21, it can be seen that considering this neighborhood is enough to find a standard CD-set and realization that satisfy the desired properties. For details we again refer to [3].

THEOREM 26. *Let G be a connected graph with $\delta(G) \geq 3$. We can find in polynomial time a CD-set S for G with $|S| \leq (5|V(G)| - 12 + D)/7$, where D is the number of cubic diamonds in G that contain three vertices of S .*

8. Discussion. In this paper, we introduced new techniques to find small CD-sets, and spanning trees with many leaves. We feel that our methods show that considering small CD-sets is more practical for this purpose than looking at leafy spanning trees, which was previously done to deduce bounds of this kind. For instance, the concept of minimality of a CD-set proves to be very useful, but no similar concept exists for spanning trees. In addition, there are simple but powerful ways of doing

local search on minimal CD-sets, which again have no easy and equally powerful equivalent in the world of leafy trees. To put it differently, spanning trees contain too much information for our purposes: it does not matter which leaves are connected to which CD-set vertices or which tree is chosen to connect the CD-set vertices. These techniques may be useful to prove other similar results: for instance the conjecture of Linial (see section 1) for other small values of δ , or the conjecture from [7] that for cubic graphs a $3/2$ -approximation exists for finding leafy trees.

We mentioned that for our two bounds (Theorem 7 and 8) and the bound in Theorem 2, Q_3 is the only known example that prevents us from finding a stronger linear bound. If we exclude this graph and a few other small graphs (in [10], $K_2 \times C_5$ and another graph on ten vertices are mentioned), it may be possible to show that the bounds become $|S'| \leq \frac{2}{3}n - 2$ (resp., $|S'| \leq \frac{5}{7}n + \frac{1}{7}D - 2$). We have shown in section 6 that these two bounds cannot be improved any further unless we exclude infinitely many graphs. Again we do not expect an easy proof for these improved bounds.

Addendum. Recently, together with Florian Zickfeld we have been able to improve the results from the current paper; see [5]. Previously we conjectured that all graphs with $\delta \geq 3$ without diamond necklaces have a spanning tree with at least $(2n - 4)/3$ leaves [3]. In [5] it is shown that this is not true, but the bound does hold when one more special subgraph is forbidden, which is called a *2-blossom*. It is shown that graphs without diamond necklaces and 2-blossoms have a spanning tree with at least $(2n_{\geq 3} - 4)/3$ leaves, where $n_{\geq 3}$ is the number of vertices in the graph with degree at least three. This result is used to find an FPT algorithm for the problem mentioned in the introduction, with parameter function $f(k) = O(\binom{3k}{k}) \approx O(6.75^k)$.

NEAR-UNANIMITY FUNCTIONS AND VARIETIES OF REFLEXIVE GRAPHS*

RICHARD C. BREWSTER[†], TOMAS FEDER[‡], PAVOL HELL[§], JING HUANG[¶], AND
GARY MACGILLIVRAY[¶]

Abstract. Let H be a graph and $k \geq 3$. A *near-unanimity function of arity k* is a mapping g from the k -tuples over $V(H)$ to $V(H)$ such that $g(x_1, x_2, \dots, x_k)$ is adjacent to $g(x'_1, x'_2, \dots, x'_k)$ whenever $x_i x'_i \in E(H)$ for each $i = 1, 2, \dots, k$, and $g(x_1, x_2, \dots, x_k) = a$ whenever at least $k - 1$ of the x_i 's equal a . Feder and Vardi proved that, if a graph H admits a near-unanimity function, then the homomorphism extension (or retraction) problem for H is polynomial time solvable. We focus on near-unanimity functions on reflexive graphs. The best understood are reflexive chordal graphs H : they always admit a near-unanimity function. We bound the arity of these functions in several ways related to the size of the largest clique and the leafage of H , and we show that these bounds are tight. In particular, it will follow that the arity is bounded by $n - \sqrt{n} + 1$, where $n = |V(H)|$. We investigate substructures forbidden for reflexive graphs that admit a near-unanimity function. It will follow, for instance, that no reflexive cycle of length at least four admits a near-unanimity function of any arity. However, we exhibit nonchordal graphs which do admit near-unanimity functions. Finally, we characterize graphs which admit a conservative near-unanimity function. This characterization has been predicted by the results of Feder, Hell, and Huang. Specifically, those results imply that, if $P \neq NP$, the graphs with conservative near-unanimity functions are precisely the so-called bi-arc graphs. We give a proof of this statement without assuming $P \neq NP$.

Key words. graph homomorphism, near unanimity function, homomorphism extension, retraction, dichotomy

1. Introduction. We consider finite undirected graphs without multiple edges, but with loops allowed. A graph in which no vertex has a loop is called *irreflexive*, and a graph in which every vertex has a loop is called *reflexive*. When we say a graph satisfies a property, such as being connected, a tree, a cycle, etc., we mean that the underlying irreflexive graph (i.e., the graph obtained from it by deleting all loops if there are any) has the property.

Given graphs G and H , with lists $L(v) \subseteq V(H)$, for each $v \in V(G)$, a *list homomorphism* of G to H with respect to the lists L is a function $f : V(G) \rightarrow V(H)$ which satisfies the following two properties:

- (i) $f(v) \in L(v)$ for all $v \in V(G)$;
- (ii) $f(u)f(v) \in E(H)$ for all $uv \in E(G)$.

Note that a list homomorphism can map two adjacent vertices of G to the same vertex of H only if the vertex of H has a loop, and, in particular, it must map any vertex

of G with a loop to a vertex of H with a loop. List homomorphisms are introduced in [9].

For a fixed graph H , the *list homomorphism problem*, LIST-HOM H , asks whether an input graph G , together with lists L , admits a list homomorphism to H with respect to the given lists. The complexity of all list homomorphism problems has recently been classified [11]: LIST-HOM H is polynomial time solvable when H is a *bi-arc graph* and is NP-complete when H is not a bi-arc graph. (The definition of bi-arc graphs appears in section 5.)

In the case when the input lists $L(v) = V(H)$ for all $v \in V(G)$, the list homomorphism problem is the *homomorphism problem*, HOM H , or the *H -coloring problem*. When $H = K_n$, the irreflexive complete graph on n vertices, the homomorphism problem HOM H becomes the *n -coloring problem*, which is polynomial time solvable when $n \leq 2$ and NP-complete when $n \geq 3$. The complexity of all HOM H problems has been classified by Hell and Nešetřil [16]: HOM H is polynomial time solvable when H is bipartite or contains a loop and is NP-complete if H is irreflexive and not bipartite.

The *homomorphism extension problem*, EXTH, another special case of list homomorphisms, is of particular interest. In EXTH the inputs are restricted so that each list is either a singleton set or the entire set $V(H)$. Extension problems obviously correspond to questions of extending a given partial mapping (“precoloring”) to a homomorphism and have been historically studied under an equivalent formulation called *retract problems*, RETH; cf. [7, 3, 15, 21, 30]. The *retract problem*, RETH, for a fixed graph H takes as an input a graph G containing H as a subgraph and asks whether or not there is a homomorphism f of G to H such that $f(v) = v$ for all $v \in V(H)$. Such a homomorphism f is called a *retraction* of G to H . If there is a retraction of G to H , then H is called a *retract* of G .

It seems difficult to classify the complexity of all extension problems. In particular, Feder and Vardi [13] have shown that extension problems capture the complexity of the much larger class of all constraint satisfaction problems (CSPs) in the following sense: for each CSP, say, Π , there exists a reflexive graph H such that Π and EXTH are polynomially equivalent. This means that even proving that each extension problem is NP-complete or is solvable in polynomial time would answer a difficult open question in complexity theory [13]. Recall that, by contrast, for list homomorphism problems, we know the exact classification of the complexity [9, 10, 11]. In particular, by techniques similar to [13] it can be seen that if a graph H admits a conservative near-unanimity function (as defined below), then LIST-HOM H is polynomial time solvable. In turn, this implies that RETH and EXTH are also polynomial time solvable. See [17].

Let H be a graph and $k \geq 3$ be an integer. A *near-unanimity function of arity k* (or NUF $_k$ for short) on H is a mapping $g : V(H)^k \rightarrow V(H)$ which satisfies the following properties:

- (i) $g(x_1, x_2, \dots, x_k)$ is adjacent to $g(x'_1, x'_2, \dots, x'_k)$ whenever $x_i x'_i \in E(H)$ for each $i = 1, 2, \dots, k$, and
- (ii) $g(x_1, x_2, \dots, x_k) = a$ whenever at least $k - 1$ of the x_i 's equal a .

Early papers on near-unanimity functions include [1, 20]. Near-unanimity functions of arity 3, also called *majority functions*, are much studied [2, 17, 31]. A near-unanimity function g of arity k on H is a *conservative near-unanimity function* if $g(x_1, x_2, \dots, x_k) \in \{x_1, x_2, \dots, x_k\}$ for all vertices of H^k . It is shown in [11] that all bi-arc graphs admit a conservative near-unanimity function, implying that the corresponding list homomorphism problems can be solved in polynomial time via the

results mentioned above. It is also shown in [11] that graphs H which are not bi-arc graphs have NP-complete list homomorphism problems. Hence, if we assume that $P \neq NP$, then bi-arc graphs are precisely the graphs which admit a conservative near-unanimity function. We will prove this is the case without the assumption $P \neq NP$.

The *categorical product* of a family of graphs, $\{H_i\}_{i \in I}$, denoted $\prod_{i \in I} H_i$, has as its vertex set the Cartesian product $\prod_{i \in I} V(H_i)$. (We restrict our attention to finite products, i.e., $|I| < \infty$.) Two vertices $(g_i)_{i \in I}$ and $(h_i)_{i \in I}$ are adjacent if g_i and h_i are adjacent in each H_i , $i \in I$. We may write $H_1 \times H_2 \times \cdots \times H_k$ for the product of the k graphs, $H_1, H_2, \dots, H_k$, and H^k for the product of k copies of H . Thus, a near-unanimity function of arity k is a homomorphism of H^k to H that is *nearly unanimous*, i.e., satisfies condition (ii) above. Finally, a *graph variety* is a class $\mathcal{V}$ of graphs which contains all products and all retracts of members of $\mathcal{V}$. Given a class of graphs C , the *variety generated by C* is the smallest variety containing all of C . (The intersection of two varieties is itself a variety, and thus the concept of smallest is well defined.)

By abuse of notation we also denote by NUF_k the *class of all graphs that admit a NUF_k* . We let $\text{NUF} = \bigcup_{k=1}^{\infty} \text{NUF}_k$, i.e., the class of graphs each of which admits a near-unanimity function of some arity. We show that, for each fixed $k \geq 3$, the class NUF_k is a variety and that this collection of varieties is strictly monotone, i.e., $\text{NUF}_3 \subset \text{NUF}_4 \subset \cdots$ (with strict inclusions). We show the class of chordal graphs is contained in NUF . It follows that the *variety generated by chordal graphs*, i.e., the smallest variety containing all chordal graphs, is also contained in NUF ; the variety generated by chordal graphs has been further investigated in [27]. The variety generated by *cop-win* or *dismantable* reflexive graphs (see [29]) contains the variety generated by chordal graphs. We give an example of a dismantable graph which does not belong to NUF . An extended examination of the inclusions described here (and of other varieties) is developed in [27]. In particular, NUF is strictly contained in the variety generated by dismantable graphs, and the variety generated by chordal graphs is strictly contained in the variety NUF [27, 25]. A polynomial time algorithm for recognizing graphs in NUF based on dismantability is given in [25].

We give two bounds on the arity of a near-unanimity function of a chordal graph with n vertices, in terms of its clique-size and its *leafage* (defined in section 3.1), respectively. It follows, in particular, that the arity is at most $n - \sqrt{n} + 1$. We present some forbidden substructures for graphs to have a NUF . It follows from these conditions that no reflexive cycle of length at least four admits a near-unanimity function. However, we shall exhibit nonchordal graphs which do admit near-unanimity functions. Finally, we give a proof, without assuming $P \neq NP$, of the result predicted by [11], that the graphs which admit a conservative near-unanimity function are precisely the bi-arc graphs. See also [5, 23].

2. Basic properties.

PROPOSITION 2.1. *For each $k \geq 3$, a graph H admits a NUF_k if and only if each connected component of H admits a NUF_k .*

Proof. Let $H_1, H_2, \dots, H_p$ be the connected components of H . Suppose that $g : H^k \rightarrow H$ is a NUF_k on H . We begin by defining for each H_i a NUF_k , say, f_i , on H_i . Note that by definition g is a homomorphism of H^k to H , and hence any restriction $h = g|_X$ of g to a subgraph X of H^k is a homomorphism $h : X \rightarrow H$.

A vertex of H^k with at least $k - 1$ coordinates equal is called a *nearly unanimous* vertex. For each connected component C of H_i^k , we define f_i on C as follows. If C has a nearly unanimous vertex $x = (x_1, x_2, \dots, x_k)$, define $f_i = g|_C$. By near-unanimity, we

have $f_i(x) \in H_i$. Since $f_i(C)$ is also connected, $f_i(C)$ is a subgraph of H_i . On the other hand, if C contains no such vertex, then define $f_i : C \rightarrow H_i$ by $f_i(z_1, z_2, \dots, z_k) = z_1$. It is easily seen that each f_i is a NUF_k on H_i .

Conversely, suppose $g_i : H_i^k \rightarrow H_i$ is a NUF_k on H_i for each $i = 1, 2, \dots, p$. Let C be a component of H^k , and let $x = (x_1, x_2, \dots, x_k)$ and $y = (y_1, y_2, \dots, y_k)$ be two vertices in C . Since C is connected, there is a walk from x to y in C and, thus, a walk from x_s to y_s in H for each s , where $1 \leq s \leq k$. That is, for each component C of H^k and each coordinate s , there exists a component H_j of H such that $x_s \in H_j$ if and only if $y_s \in H_j$. Hence exactly one of the following conditions holds for all of the vertices of C :

- (i) all k coordinates belong to the same H_j ; i.e., C is a subgraph of H_j^k ;
- (ii) exactly $k - 1$ coordinates belong to the same H_j , and the other coordinate belongs to H_m , $m \neq j$; or
- (iii) at most $k - 2$ coordinates belong to any H_j .

Let $x = (x_1, x_2, \dots, x_k)$ be a vertex in C . In case (i), define $g(x) = g_j(x)$. In case (ii), choose some coordinate t such that $x_t \in H_j$. Define $g(x) = x_t$. (We fix t for the entire component C ; thus, g is simply the projection of C onto its t th coordinate.) Finally, in case (iii), let $g(x) = x_1$.

In all cases, g is a homomorphism. Moreover, g satisfies the near-unanimity condition. In case (i), g inherits the property from g_j . In case (ii), any nearly unanimous vertex in C must have all $k - 1$ coordinates from H_j , including x_t , equal. Finally, in case (iii) there are no nearly unanimous vertices. $\square$

PROPOSITION 2.2. *For each $k \geq 3$, if a graph H admits a NUF_k , then H admits a NUF_{k+1} .*

Proof. Let $g : H^k \rightarrow H$ be a NUF_k on H . Then the function $h : H^{k+1} \rightarrow H$ defined as $h(x_1, x_2, \dots, x_k, x_{k+1}) = g(x_1, x_2, \dots, x_k)$ is a NUF_{k+1} on H . $\square$

The argument above also proves the following.

COROLLARY 2.3. *For each $k \geq 3$, if a graph H admits a conservative NUF_k , then H admits a conservative NUF_{k+1} .*

We provide examples of graphs in $\text{NUF}_{k+1} - \text{NUF}_k$ for each $k \geq 3$ in section 4.1. Thus the converse of Proposition 2.2 does not hold. On the other hand, we will show that the converse of Corollary 2.3 does hold; i.e., H admits a conservative NUF_k for some $k \geq 3$ if and only if H admits a conservative NUF_3 .

PROPOSITION 2.4. *Let G be a graph that admits a NUF_k , and let H be a retract of G . Then H also admits a NUF_k .*

Proof. Let g be a NUF_k on G , and let $r : G \rightarrow H$ be a retraction. Then it is easy to verify that $g' = r \circ (g|_{V(H)^k})$ is a NUF_k on H . $\square$

The above result shows that the class of graphs which admit a NUF_k are closed under retractions. In the case of conservative functions, the class is also closed under taking induced subgraphs.

PROPOSITION 2.5. *Suppose the graph G admits a conservative NUF_k and H is an induced subgraph of G . Then H admits a conservative NUF_k .*

Proof. Let g be a conservative NUF_k for G . The restriction of g to H^k is a near-unanimity homomorphism of H^k to G , and to H as well since g is a conservative NUF . $\square$

PROPOSITION 2.6. *Let $X_1, X_2, \dots, X_n$ be graphs in NUF_k . Then the product $X_1 \times X_2 \times \dots \times X_n$ is also in NUF_k .*

Proof. By associativity of the product, it suffices to verify the claim for two graphs. It is easy to check that if g_X and g_Y are near-unanimity functions of arity k for X

and Y , respectively, then

$$g((x_1, y_1), (x_2, y_2), \dots, (x_k, y_k)) = (g_X(x_1, x_2, \dots, x_k), g_Y(y_1, y_2, \dots, y_k))$$

is a NUF_k for $X \times Y$. $\square$

COROLLARY 2.7. *For each $k \geq 3$, the class NUF_k is a variety.*

A *dominating vertex* of a graph G is one adjacent to all other vertices of G . We make the following observation.

PROPOSITION 2.8. *If the reflexive graph H has a dominating vertex v , then H admits a NUF_k for all $k \geq 3$.*

Proof. By Proposition 2.2 it suffices to show that H admits a NUF_3 . The function

$$g(a, b, c) = \begin{cases} x & \text{if at least two of } a, b, c \text{ equal } x, \\ v & \text{otherwise} \end{cases}$$

is a NUF_3 . $\square$

A graph is *chordal* if it does not contain an induced cycle of length greater than three. We shall show that each chordal graph belongs to NUF , and we shall show that each reflexive cycle of length at least four does not. However, Proposition 2.8 allows us to find examples of nonchordal graphs with a NUF . The *wheel* w_n is the graph obtained from a cycle of length n by adjoining one (new) vertex adjacent to all other vertices.

COROLLARY 2.9. *Each reflexive wheel $w_n, n \geq 4$, is a nonchordal graph in NUF_3 .*

Since NUF_3 is the variety generated by finite paths [2, 17, 19], we see that each reflexive wheel is in the variety generated by finite paths and thus in the variety generated by chordal graphs. In [27] it is shown that the variety generated by chordal graphs is in fact strictly contained in the variety NUF .

3. Reflexive chordal graphs. In this section and the next section, all graphs are assumed to be reflexive unless otherwise stated. We show in this section that every reflexive chordal graph admits a near-unanimity function. (By contrast, in section 4.2 we shall show that no reflexive cycle of length greater than three admits a near-unanimity function.) We provide two bounds on the arity of the NUF . One bound is based on the *leafage* of the graph, and the second is based on the clique-size and is obtained through the study of *tree obstructions*. We remark that the two approaches, leafage and tree obstructions, often allow us to compute the minimum k for which a graph admits a NUF_k . Typically the leafage is used to demonstrate the existence of a NUF_k , and tree obstructions are used to prove the nonexistence of a NUF_{k-1} .

3.1. Arity bounds based on leafage. Let T be a tree. A *subtree* of T is a connected subgraph of T . A *rooted subtree* R of T is a subtree of T with a distinguished vertex called the *root* of R , denoted $r(R)$.

It is well known that a graph H is chordal if and only if it is the *intersection graph* of a family $\mathcal{F}$ of subtrees of a tree; that is, there is a one-to-one correspondence between $V(H)$ and $\mathcal{F}$ such that two vertices of $V(H)$ are adjacent in H if and only if the corresponding subtrees of $\mathcal{F}$ have at least one vertex in common; see [14]. The family $\mathcal{F}$, together with the underlying tree, is called an *intersection representation* of H by subtrees. The *leafage* $l(H)$ of a chordal graph H is the minimum number of leaves of a tree in which H has an intersection representation; cf. [26].

In the following H is a chordal graph. We use $\mathcal{F}$ to denote a (fixed) family of subtrees of a tree T which gives an intersection representation of H . Further, let $\mathcal{T}$

be the set of all rooted subtrees R of T such that $R - r(R)$ is the union of some (zero, one, or more) components of $T - r(R)$, and if $R - r(R)$ is the union of zero components of $T - r(R)$, then $r(R)$ is a leaf of T . For a rooted subtree R , we denote by l_R the number of leaves of T contained in R ; note that these definitions ensure that $l_R \geq 1$ for any rooted subtree R .

Given a collection S of $k + 1$ (not necessarily distinct) subtrees in $\mathcal{F}$, we say that a rooted subtree $R \in \mathcal{T}$ is *critical with respect to S* if it satisfies the following two properties:

1. there are at least $k - l_R + 1$ subtrees of S , each of which contains a vertex of R ;
2. for each $R' \in \mathcal{T}$ contained in $R - r(R)$, there are at most $k - l_{R'}$ subtrees of S , each of which contains a vertex in R' .

The two conditions above are referred to as Properties 1 and 2.

LEMMA 3.1. *Let S be a family of $k + 1$ (not necessarily distinct) members of $\mathcal{F}$. Then*

- (a) *every rooted subtree in $\mathcal{T}$ satisfying Property 1 contains a rooted subtree which is critical with respect to S ; and*
- (b) *there are pairwise vertex disjoint critical rooted subtrees $R_1, \dots, R_p$ such that $T - \bigcup_{i=1}^p R_i$ does not contain any critical rooted subtrees.*

Proof. Let the rooted subtree X satisfy Property 1. If X also satisfies Property 2, then X is critical with respect to S , and we are done. Otherwise, $X - r(X)$ contains another rooted subtree X' which satisfies Property 1. Again, if X' also satisfies Property 2, then X' is critical; otherwise, $X' - r(X')$ contains a third rooted subtree X'' which satisfies Property 1. Continuing this way, we will find a critical subtree with respect to S . A subtree consisting of a single vertex which satisfies Property 1 trivially satisfies Property 2.

To see statement (b), note that the entire tree T (with an arbitrary root) satisfies Property 1. In addition, a rooted tree R which does not satisfy Property 1 cannot contain a subtree R' which satisfies Property 1, since $k - l_R + 1 \leq k - l_{R'} + 1$ in the case that R' is a subtree of R . $\square$

THEOREM 3.2. *Every chordal graph H of leafage k admits a NUF_{k+1} .*

Proof. Let $\mathcal{F}$ be an intersection representation of H by subtrees of a tree T with $k \geq 2$ leaves. We shall show that the intersection graph H of $\mathcal{F}$ admits a NUF_{k+1} . By Proposition 2.1, we may assume that H is connected. Further, we assume that every vertex of T belongs to a subtree in $\mathcal{F}$. For convenience, we shall not distinguish between the vertices of H and the subtrees of $\mathcal{F}$.

Let S be a collection of $k + 1$ subtrees of $\mathcal{F}$. Although some of the $k + 1$ subtrees of S may be the same, we treat them as distinct in the counting below.

By Lemma 3.1, there exist $R_1, R_2, \dots, R_p$ pairwise vertex-disjoint critical rooted subtrees with respect to S such that $T - \bigcup_{i=1}^p R_i$ does not contain any critical rooted subtrees. We claim that there is a subtree in $\mathcal{F}$ containing all the roots $r(R_i)$, $i = 1, 2, \dots, p$. When $p = 1$, this is clearly true as by assumption every vertex of T is in a subtree of $\mathcal{F}$. So assume that $p \geq 2$. In this case, we prove the stronger statement that in fact there is a subtree in S which contains all the roots. Suppose to the contrary that none of the $k + 1$ subtrees of S contains all the roots. Then each subtree of S has vertices in at most $p - 1$ critical rooted subtrees R_i . (Observe that any subtree of S that contains vertices in any two rooted subtrees must in fact contain both roots of the subtrees.) Denote by c_i ($i = 1, 2, \dots, p$) the number of subtrees of S , each of which has a vertex in R_i . Then we have $(p - 1)|S| = (p - 1)(k + 1) \geq \sum_{i=1}^p c_i$.

By Property 1, $c_i \geq k - l_{R_i} + 1$. Thus we have

$$\begin{aligned} (p-1)(k+1) &\geq \sum_{i=1}^p c_i \\ &\geq \sum_{i=1}^p (k - l_{R_i} + 1) \\ &= p(k+1) - \sum_{i=1}^p l_{R_i}, \end{aligned}$$

which gives $\sum_{i=1}^p l_{R_i} \geq (k+1)$. This implies that some leaf of T must be contained in at least two critical rooted subtrees, contradicting the assumption that the critical rooted subtrees are pairwise vertex-disjoint.

Ultimately the goal is to define a NUF on these families of subtrees. Suppose at least k subtrees of S are the same subtree X . We claim X contains all the roots. In fact, a rooted subtree $R \in \mathcal{T}$ is critical with respect to S if and only if $V(R) \cap V(X) = \{r(R)\}$. To see this, observe that R satisfying Property 1 requires $V(X) \cap V(R) \neq \emptyset$ and R satisfying Property 2 ensures $V(X) \cap V(R - r(R)) = \emptyset$. On the other hand, $V(X) \cap V(R) = \{r(R)\}$ implies that R contains vertices from at least $k \geq k - l_R + 1$ elements of S , since $l_R \geq 1$. Also, $R - r(R)$ contains no vertices from the k copies of X , which implies that $R - r(R)$ contains vertices from at most $k - l_{R-r(R)}$ subtrees of S , as $l_{R-r(R)} \geq 1$. Consequently, X contains all the roots.

It remains to define the near-unanimity function g on H . Given $k+1$ vertices of H , consider the corresponding family S of subtrees in $\mathcal{F}$. Decompose T into p critical rooted subtrees $\{R_i\}_{i=1}^p$ as described in Lemma 3.1. Define $g(S)$ as follows: When at least k subtrees of S are the same subtree X , let $g(S) = X$; otherwise, let $g(S)$ be any subtree of $\mathcal{F}$ which contains all the roots $r(R_i)$. It remains to verify that g is a homomorphism from H^{k+1} to H . Thus consider two adjacent vertices in H^{k+1} . That is, let $S = \{U_1, U_2, \dots, U_{k+1}\}$ and $S' = \{V_1, V_2, \dots, V_{k+1}\}$ be two collections of $k+1$ subtrees (from $\mathcal{F}$) such that U_j intersects with V_j for each $j = 1, 2, \dots, k+1$. Again, let $R_1, R_2, \dots, R_p$ be the decomposition of T into critical subtrees *with respect to* S . Suppose to the contrary that $g(S)$ and $g(S')$ do not intersect. Let $P : z_0 z_1 \dots z_d$ be the shortest path from $g(S)$ to $g(S')$ where $z_0 \in V(g(S))$ and $z_d \in V(g(S'))$. Let C be the component of $T - z_d$ containing z_0 and C' be the component of $T - z_0$ containing z_d . Let A be the rooted subtree consisting of C with $r(A) = z_{d-1}$. Then A is a rooted subtree containing $g(S)$ but no vertex from $g(S')$. Similarly, $B = C'$ with $r(B) = z_1$ is a rooted subtree containing $g(S')$ but no vertex from $g(S)$. Since each leaf of T is either in A or in B , we must have $l_A + l_B \geq k$. Since $g(S)$ does not intersect with B , B contains none of the roots of $R_1, R_2, \dots, R_p$. Thus, B cannot satisfy Property 1 with respect to S . This means that S contains at most $k - l_B$ subtrees such that each of them has a vertex in B . In other words, S contains at least $k+1 - (k - l_B) = l_B + 1$ subtrees, none of which has a vertex in B . Thus, these $l_B + 1$ subtrees must all be contained in A . Each of these subtrees intersects a member of S' . Hence S' must contain at least $l_B + 1$ subtrees, each of which contains a vertex in A . On the other hand, a similar argument shows that S' contains at most $k - l_A$ subtrees, each of which has a vertex in A . So we must have $l_B + 1 \leq k - l_A$, i.e., $l_A + l_B \leq k - 1$, in contradiction to the fact that $l_A + l_B \geq k$. $\square$

Lin, McKee, and West [26] proved that for every chordal graph H with n vertices, the leafage is at most $n - \lg n - \frac{1}{2} \lg \lg n + O(1)$. Hence, each chordal graph with n

vertices admits a NUF of arity $n - \lg n - \frac{1}{2} \lg \lg n + O(1)$. We improve this bound in the next section.

The upper bound on the arity in Theorem 3.2 is sharp in the sense that there are chordal graphs of leafage l which do not admit a NUF_l . In section 4.1, we construct families of graphs useful for showing lower bounds, including the one just mentioned.

3.2. Arity bounds based of tree certificates. We recall the problem EXTH from the introduction. An instance of EXTH consists of a graph G together with lists $L(v) \subseteq V(H)$, where each $L(v)$ is either a singleton set or all of $V(H)$. Let $X \subseteq V(G)$ be the set of vertices x for which $L(x)$ is a singleton. Then we may view the function $p : X \rightarrow V(H)$ defined by $p(x) = h \in L(x)$ as a preassignment of images (in H) to the vertices in X . The vertices in X are called *preassigned* vertices. The EXTH problem asks if there exists a homomorphism $f : G \rightarrow H$ which extends the preassignment p (i.e., satisfies $f(x) = p(x)$ for $x \in X$). In the case of a yes instance, we say that p is *extendible (in H)*. In the following we shall use the language of lists, or of extending preassignments, as is convenient.

Before entering the technical details of our work, we outline some key ideas used in the development. (We use the standard notation for $X \subseteq V(G)$, and $G[X]$ denotes the induced subgraph of G with vertex set X .) First, it is clear that, given a preassignment $p : X \rightarrow V(H)$, if p is not a homomorphism of $G[X]$ to H , then p is not extendible. On the other hand, if p is a homomorphism $G[X] \rightarrow H$, then a natural algorithmic idea is to successively extend p by one vertex, i.e., select $v \in V(G) \setminus X$, and define $f(v) = h \in L(v)$ (and set $f(u) = p(u)$ for all $u \in X$) such that $f : G[X \cup \{v\}] \rightarrow H$ is a homomorphism. Clearly the condition we must verify is that $f(u)f(v) \in E(H)$ whenever $uv \in E(G)$ for each $u \in X$. Such a value h is an *allowed image* for v . On the other hand, in searching $L(v)$ for an allowed image for v , we may remove from $L(v)$ any value h' such that $p(u)h' \notin E(H)$ for some $u \in X$, where $uv \in E(G)$. Below we will talk about u *causing* h' to be removed from $L(v)$. Finally, if some $L(v)$ becomes empty by removing nonallowed images, then $p : X \rightarrow V(H)$ cannot extend to a homomorphism of G to H . (The image of v under any homomorphism $\phi : G \rightarrow H$ extending p will always be an allowed image, and thus $\phi(v)$ is never removed from $L(v)$.) This process of removing nonallowed images is known as a *consistency check*; see, for example, [17].

Testing all possible extensions of p to all of G is an exponential process; however, for certain graphs H , as identified below, the extendability of p can be determined by considering only a polynomial number of possible extensions. In particular, for such a graph H and a given instance (G, p) of EXTH, the preassignment $p : X \rightarrow V(H)$ is not extendible to H if and only if there exists a *certificate of nonextendability* in the form of a tree with at most k preassigned leaves (where k is a constant depending on H). The existence of such algorithmically well-behaved NO-certificates yields that EXTH is polynomial.

We begin with the concept of a conflict.

DEFINITION 3.3. Let G and H be graphs. A set $X \subseteq V(G)$ with a preassignment $p : X \rightarrow V(H)$ which is not extendible, such that the restriction of p to any proper subset X' of X is extendible, is called a *conflict in G with respect to H* . The size of the conflict is $|X|$. A graph H has *strict extension-width k* if every conflict (in any graph G with respect to H) has size at most k .

Feder and Vardi [13] give several equivalent descriptions of graphs that admit a NUF_k . In particular, the following connection between strict extension-width and near-unanimity is presented.

THEOREM 3.4 (Feder and Vardi [13]). *A graph H admits a NUF_k if and only if it has strict extension-width $k - 1$.*

A graph has *bounded strict extension-width* if it has strict extension-width k for some integer k . Thus the theorem implies that NUF is precisely the class of graphs with bounded strict extension-width. See [17] for more details on this connection.

Reflexive graphs with a NUF_3 have been most carefully investigated. (Irreflexive graphs with a NUF_3 are characterized in [2].) The class of reflexive graphs with a NUF_3 is known to be the smallest variety containing all reflexive paths [28]. It is also known to be precisely the class of all reflexive graphs H such that H is a retract of any G of which it is an isometric subgraph [19, 28]. What this means in the language of extensions and conflicts is the following. Given a graph G containing H as a subgraph, let $p : X \rightarrow V(H)$ be a preassignment where $X = V(H)$ and p is the identity function. Note that in this context (G, p) is naturally viewed as an instance of the retraction problem for H . Either p is extendible (in the case that H is isometric) or there is a conflict of size two (otherwise). Such a conflict yields a *certificate of nonextendability*. In particular, the certificate is a path P with end vertices u and v preassigned as $p'(u) = a, p'(v) = b$, where a, b are vertices of $X = V(H)$. By taking P so that $d_P(u, v) = d_G(a, b) < d_H(a, b)$, we see that p' is extendible in G but $p \circ p'$ is not extendible in H . Hence, p is not extendible to a homomorphism of G to H ; i.e., H is not a retract of G . (For a description of NUF_k , $k \geq 3$, as a variety generated by some starting set of building blocks, see [12]. See also [19] and [4].)

We have just observed that graphs in NUF_3 have certificates of nonextendability in the form of a path whose end points have been preassigned. We now extend this concept to larger certificates.

DEFINITION 3.5. *A reflexive graph H has extension-width one if for any G and any preassignment $p : X \rightarrow V(H)$, where $X \subseteq V(G)$, either p is extendible or there exist a tree T and a set of vertices $X' \subseteq V(T)$ preassigned by a mapping $p' : X' \rightarrow X$ such that p' is extendible in G but $p \circ p'$ is not extendible in H . The tree T together with the preassignment p' is called a *tree-certificate*. Furthermore, the tree T is minimal if the preassigned vertices are precisely the leaves of T and they form a conflict (in H with respect to T).*

Thus, by the comments above the reflexive graphs with a NUF_3 are precisely the reflexive graphs of extension-width one, where the (minimal) tree-certificates can be chosen to be paths.

In [18] the concept of width one is defined as *tree duality*. A graph H has tree duality if for all G either $G \rightarrow H$ or there exists a tree T such that $T \rightarrow G$ and $T \not\rightarrow H$. The notion of extension-width defined here differs slightly from that in [13]; it has been adapted to extensions (and implicitly to retractions). Thus our condition is that either a preassignment p extends to a homomorphism of G to H or there is a tree T and a preassignment p' from T to the preassigned vertices of G (under p) such that p' extends to a homomorphism of T to G but $p \circ p'$ does not extend to a homomorphism of T to H . Clearly, the existence of a tree-certificate demonstrates that p is not extendible. The proposition below shows that each tree-certificate contains a minimal tree-certificate.

PROPOSITION 3.6. *Let (G, p) be an instance of EXT_H where $X \subseteq V(G)$ is the set of preassigned vertices. Suppose T is a tree and $p' : X' \rightarrow X$ is a preassignment, where $X' \subseteq V(T)$, such that p' is extendible (in G) but $p \circ p'$ is not extendible (in H). Then T contains, as a subtree, a minimal tree-certificate.*

Proof. Let T' be a minimal subtree of T with respect to nonextendibility in H , and let $X'' \subseteq X'$ be the set of preassigned vertices of in T' . We first claim that each vertex in X'' is a leaf. Suppose to the contrary that some vertex $v \in X''$ is not a leaf. Let $T_1, \dots, T_k$ be the subtrees of $T' - v$. Consider $T_i + v$. By the minimality of T' , $T_i + v$ is extendible in H . Moreover, since v is preassigned the same value in $T_i + v$ for all i , we obtained that the preassignment X'' of T' is extendible in H , which is a contradiction.

We claim that all the leaves in T' are preassigned. Suppose to the contrary that some leaf $v \in T'$ is not preassigned. By minimality, the preassignment from $T' - v$ to $V(H)$ is extendible. In particular, the parent of v receives an image. Since H is reflexive, v can receive the same image. Thus this preassignment of X'' to H is extendible, which is a contradiction.

Therefore, T' is a tree whose leaves are preassigned and the leaves form a conflict. That is, T' together with the preassignment is a minimal tree-certificate. $\square$

Tree-certificates are used implicitly in [9] but are first formally defined and studied in [27]. Finally, we remark that K_2 is an example of a graph with width two. That is, for the $\text{HOM}K_2$ problem, i.e., testing if a graph is bipartite, the NO-certificates are odd cycles, i.e., partial two-trees.

A special type of tree-certificate is introduced in [19]. A *hole* in a reflexive graph H is a set Z of vertices with a mapping $\delta : Z \rightarrow \{0, 1, 2, \dots\}$ such that no h in H has the distances $d_H(h, x) \leq \delta(x)$ for all $x \in Z$, but for each proper subset Z' of Z , there is an h satisfying these inequalities for all x in Z' . A *k-hole* is a hole in which the set Z has exactly k vertices. A *unit hole* is a hole in which δ is the constant mapping with range $\{1\}$. If $Z = \{x_1, x_2, \dots, x_k\}$, we may refer to the hole as a $(\delta(x_1), \delta(x_2), \dots, \delta(x_k))$ *k-hole*.

Equivalently, a hole in H is a tree T with exactly one branch vertex (vertex of degree greater than two), together with a precoloring $p : X \rightarrow V(H)$, where X is the set of leaves of T . The length of the path from the branch vertex to the leaf x is precisely $\delta(x)$. Further, (X, p) is a conflict in T with respect to H ; i.e., p is not extendible in H , but any proper subtree of T , with the same precoloring (restricted to the subtree), is extendible in H .

From the above discussion, we obtain the following corollaries of Theorem 3.4.

COROLLARY 3.7. *A reflexive graph that admits a minimal tree-certificate with k preassigned leaves cannot have a NUF_k .*

Proof. The minimal tree-certificate contains a conflict with k vertices, showing the strict extension-width is at least k . $\square$

COROLLARY 3.8. *A reflexive graph with a k -hole cannot have a NUF_k .*

It turns out that the reflexive graphs with a NUF_3 are also characterized as the class of reflexive graphs which do not have holes [19, 28]. Thus a reflexive chordal graph which is not in NUF_3 must have a hole. We shall elaborate on this fact in section 4. Specifically, such graphs must have a unit hole of a particular kind.

We now return our attention to improving the bounds on the strict extension-width of reflexive chordal graphs. In Figure 1 is an algorithm from [9]. This algorithm solves the *connected list homomorphism problem*, denoted by the $\text{CLIST-HOM}H$ problem, where H is a reflexive chordal graph and the lists of any instance induce connected subgraphs of H . The proof of correctness for the algorithm follows from properties of the perfect elimination ordering of H ; see [9]. We present the algorithm with the addition that we explicitly construct a tree-certificate for G in H when G is a NO-instance of the problem. A digraph D is used in the algorithm to retain information

CLIST-HOMH Algorithm [9]

Input: A graph G with lists $L : V(G) \rightarrow \mathcal{P}(V(H))$ such that $L(v)$ induces a connected subgraph of H .

Output: A homomorphism $f : G \rightarrow H$ such that $f(v) \in L(v)$ for all v , or a tree-certificate T proving $G \not\rightarrow H$.

1. Let $h_1, h_2, \dots, h_n$ be a perfect elimination ordering of H (an ordering such that any two neighbors of h_i among $h_{i+1}, h_{i+2}, \dots, h_n$ are adjacent).
2. Set $V(D) = \{t_g : g \in V(G)\}$; $E(D) = \emptyset$.
3. For $i = 1$ to n
 - 3.1 Remove h_i from all lists $L(g)$ in which it is not the only member.
 - 3.2 For those g which have $L(g) = \{h_i\}$:
 - 3.2.1 assign $f(g) = h_i$;
 - 3.2.2 for each g' adjacent to g , remove from $L(g')$ all vertices that are not adjacent to h_i ; and add the arc $t_{g'}t_g$ to D if some vertex is removed from $L(g')$;
 - 3.2.3 delete g from G .
 - 3.3 If some list $L(x) = \emptyset$, then let T be the subgraph of D consisting of descendants of t_x . Answer NO; return T together with the lists L_T where $L_T(t_g)$ equals the original $L(g)$ (provided as input).
4. Answer YES; return f .

FIG. 1. An algorithm for CLIST-HOMH, where H is a reflexive chordal graph, and each list induces a connected subgraph of H .

about which vertices cause the removal of elements from lists (of other vertices). In the case of a NO-instance we prove below, the digraph D contains a tree-certificate (T, p') ; thus, H has extension-width one. Also, we provide bounds on the size of the conflict contained in T , thus providing bounds on the strict extension-width of H . That is, we prove the following.

THEOREM 3.9. *Each reflexive chordal graph H has extension-width one and bounded strict extension-width.*

The proof of the theorem appears below after the development of some preliminary results.

LEMMA 3.10. *At any step of the CLIST-HOMH Algorithm in Figure 1, the digraph D is acyclic.*

Proof. If $t_{g'}t_g$ is an arc of D , then g is removed from G before g' is removed from G . $\square$

LEMMA 3.11. *Suppose the CLIST-HOMH Algorithm in Figure 1 answers NO and returns (T, L_T) for some instance (G, L) of CLIST-HOMH. Then for each vertex $t_g \in V(T)$ other than the root, the corresponding vertex $g \in V(G)$ is assigned to some h_i , i.e., $f(g) = h_i$, by the algorithm. Furthermore, this assignment is injective.*

Proof. Suppose t_{g_1} and t_{g_2} are both children of some vertex t_g in T . The arcs $t_g t_{g_1}$ and $t_g t_{g_2}$ in T are created in D after each t_{g_1} and t_{g_2} are assigned an image at step 3.2.2 of the algorithm. Thus, assume that the assignments $f(g_1) = h_i$ and $f(g_2) = h_j$ are made by the algorithm. Without loss of generality we may assume that h_i precedes h_j in the perfect elimination ordering, or $h_i = h_j$. The arc in T from t_g to t_{g_2} was added to T when the assignment $f(g_2) = h_j$ caused some vertex, say, h , to be removed from $L(g)$. In particular, $h_j h \notin E(H)$ and h appears later in the perfect elimination ordering than h_j . Also, $h_i h \in E(H)$; otherwise, h_i causes h to be removed from $L(g)$ before t_{g_2} is assigned h_j , and thus $t_g t_{g_2}$ would not appear in D .

In addition, note that t_g cannot be assigned h_j . Since h_j caused h to be removed from the list, there must be a vertex in the elimination ordering after both h_j and h that will remain in the list for g (after the current round). Recall that the lists are connected. In particular, adjacent vertices receive unique images.

We claim that h_i and h_j are nonadjacent in H . This is immediate from properties of the elimination ordering and the observations $h_i h \in E(H)$, $h_j h \notin E(H)$. The same argument shows there is no path $h_i = u_1, u_2, \dots, u_m = h_j$ in H where each u_ℓ precedes $u_{\ell+1}$ in the perfect elimination ordering. Indeed, for such a path, $h_j h \notin E(H)$ implies $u_{m-1} h \notin E(H)$, which in turn implies $u_{m-2} h \notin E(H)$. Continuing back to h_i , we conclude $h_i h \notin E(H)$, which is a contradiction.

Finally, there is no vertex h' in the perfect elimination ordering with paths $h = u_1, u_2, \dots, u_{m_1} = h_i$ and $h = w_1, w_2, \dots, w_{m_2} = h_j$ such that each u_ℓ precedes $u_{\ell+1}$ and each w_ℓ precedes $w_{\ell+1}$ in the perfect elimination ordering. Suppose to the contrary that such paths exist. Then u_2 and w_2 are common neighbors of h' and must be adjacent. Without loss of generality u_2 precedes w_2 in the elimination ordering. Thus the paths $u_2, u_3, \dots, u_{m_1} = h_i$ and $u_2, w_2, w_3, \dots, w_{m_2} = h_j$ are paths with the property above, and the first path has been shortened by one vertex. We thus repeatedly shorten the paths until one has length zero, say, the first path, at which point we have a path from h_i to h_j , which is the case analyzed in the previous paragraph.

This last result about two paths ending at h_i and h_j , respectively, shows that the descendants of t_{g_1} and t_{g_2} , respectively, receive images that are disjoint sets of vertices in H , completing the proof that the function f defined in the algorithm is indeed injective. $\square$

We now establish that in the case of a NO-instance, the CLIST-HOMH algorithm does indeed return a tree. Recall that for a list homomorphism problem vertices with lists of size one are called preassigned.

LEMMA 3.12. *If the CLIST-HOMH Algorithm in Figure 1 answers NO and returns (T, L_T) , then T is a tree rooted at t_x , where x is the vertex whose list becomes empty in step 3.3. Moreover, the preassigned vertices are leaves in T , and the preassigned images form an independent set in H .*

Proof. Every vertex in T other than the root t_x has in-degree one. Suppose to the contrary that some vertex t has predecessors t_1 and t_2 . Using the proof of Lemma 3.11, one can easily show that the descendants of t_1 and t_2 are disjoint sets and thus derive a contradiction.

To see that preassigned vertices in T are leaves, observe that internal vertices of T are assigned a value from their list and have something removed from their list by a child. Thus, the list of an internal vertex cannot be a singleton.

Suppose t_{g_1} and t_{g_2} are leaves of T , neither of which is the root. Then they have a common ancestor, say, t_g , such that the (t_g, t_{g_1}) -path and the (t_g, t_{g_2}) -path in T are internally disjoint. Let $t_{g'_1}$ and $t_{g'_2}$ be the first vertex after t_g on the two paths, respectively, with $t_{g_i} = t_{g'_i}$ possible. Without loss of generality, $f(g_1)$ precedes $f(g_2)$ in the perfect elimination ordering. If $f(g_1)f(g_2) \in E(H)$, then there are paths in H from $f(g_1)$ to $f(g'_1)$ and $f(g_1)$ to $f(g'_2)$, contrary to the proof of Lemma 3.11.

Finally, suppose that the root t' is a preassigned vertex. Then the unique child of the root, say, t_g , causes the single element from $L(t')$, say, h' , to be removed when the algorithm makes the assignment $f(g) = h$. Consider some other leaf, say, t_{g_1} , in the tree, including the possibility that t_g is a leaf. Suppose further that the assignment $f(g_1) = h_1$ is made by the algorithm. Then there is a path from h_1 to h in H whose vertices are in increasing order with respect to the perfect elimination ordering. Each vertex on this path is nonadjacent to h' . In particular, $h_1 h' \notin E(H)$. Therefore, the set of all leaves is independent. $\square$

COROLLARY 3.13. *Suppose (G, L) is an instance of EXTH where $X \subseteq V(G)$ is the set of preassigned vertices. Further, suppose the CLIST-HOMH Algorithm in Figure 1 answers NO and returns (T, L_T) . Then T contains as a subtree a minimal tree-certificate.*

Proof. Suppose (T, L_T) is returned by the CLIST-HOMH Algorithm. Because the lists L_T come from L , each is either a singleton or the entire set $V(H)$. Hence (T, L_T) is also an instance of EXTH, in particular, a NO-instance. Note the mapping $t_g \mapsto g$ is an embedding of T in G . Thus, T is extendible in G but not in H . By Proposition 3.6, T contains as a subtree a minimal tree-certificate. $\square$

Proof of Theorem 3.9. Let (G, L) be a NO-instance of EXTH. We will establish that there is a tree-certificate for G with respect to H . Moreover, this tree contains a conflict of size at most $|V(H)|$.

If H is not connected, we consider two cases. First, if some component of G has preassigned vertices in different components of H , then a path between two such vertices is a tree-certificate containing a conflict of size two. On the other hand, if for each component of G its preassigned vertices appear in the same component of H , then (G, L) is a NO-instance if and only if some component of G is a NO-instance for some component of H . Thus, we may restrict our attention to connected graphs G and H . Hence, any instance of EXTH can be viewed as an instance of CLIST-HOMH where each list is a singleton or $V(H)$, and since H is connected, we can apply the algorithm in Figure 1. Given that (G, L) is a NO-instance, the algorithm returns a tree-certificate by Corollary 3.13. Furthermore, this tree has at most $n = |V(H)|$ leaves by Lemma 3.11. The former statement shows that H has extension-width one; the latter statement shows that H has strict extension-width n . $\square$

Theorem 3.9 shows that each reflexive chordal graph with n vertices belongs to NUF_{n+1} . We now improve the bound.

THEOREM 3.14. *Let H be a reflexive chordal graph with n vertices and maximum clique-size $\omega \geq 3$. Then H admits a NUF_k with $k \leq \min\{n - \omega + 1, n - n/(\omega - 1) + 1\}$. In particular, $k \leq n - \sqrt{n} + 1$.*

Proof. First observe that $n - \sqrt{n} \geq \min\{n - n/(\omega - 1), n - \omega\}$. Hence it suffices to prove that the strict extension-width of H is less than or equal to both $n - n/(\omega - 1)$ and $n - \omega$.

Suppose G is a NO-instance of EXTH. By Corollary 3.13, there is a tree-certificate for G . In particular, there is a tree T with lists L from $V(H)$ that is nonextendible in H . Moreover, the preassigned vertices of T are precisely the leaves of T , and they form a conflict.

Suppose s vertices of T are preassigned values in H . These s vertices can only be leaves of T , including possibly the root t of T , if the root has only one child. Also, by Lemma 3.12, the preassigned values form an independent set in H . Thus, a clique with ω vertices in H contains at most one of the s preassigned images; therefore, the remaining vertices in the clique are not among the s vertices, showing that the strict extension-width is at most $s \leq n - \omega + 1$. This establishes that H admits a NUF_k for $k \leq n - \omega + 2$. In the case that $s = n - \omega + 1$, we note that H must be a split graph with s independent vertices and a clique of size $n - s$. However, such a chordal graph has an intersection representation with $s - 1$ leaves. Thus the leafage of H is at most $s - 1$, and we conclude from Theorem 3.2 that H admits a NUF_k where $k \leq n - \omega + 1$.

Let r be the number of children of t , the root of T . The r children eliminate at least r values from the list for t . If $r \neq 1$, then each of these r vertices must remove at least one value from $L(t)$ which is not among the preassigned images for the leaves

of T . Suppose to the contrary that this is not the case. Let t_g be a child of t that removes only values from $L(t)$ that come from the set of preassigned images. Then we can remove the subtree rooted at t_g from T and obtain a smaller tree-certificate, contrary to our assumption that T is minimal. Indeed, each preassigned image, say, h_i , will be removed from the list of all vertices in T at iteration i of the for-loop in the algorithm. Hence, the values that t_g removes from $L(v)$ will all be removed by the algorithm anyway, without the subtree rooted at t_g being present. (Observe that all of the preassigned vertices form an independent set, but the lists are connected. Hence $L(v)$ must contain a vertex that appears later in the perfect elimination ordering than all of the preassigned vertices. Thus v will not be assigned a preassigned image, and they will indeed all be removed from $L(v)$.)

Let i be the number of internal vertices of T (other than the root). Each of these internal vertices is assigned an image which again is not among the preassigned images for the leaves of T . There are l remaining vertices in H that are not one of the $s + i$ assigned images nor one of the r images removed from $L(t)$. Define $p = r + l + i$, unless $r = 1$, in which case $p = l + i$. Thus, $n - s = p$. We will establish the result by showing that $p \geq n/(\omega - 1)$.

Let d be the maximum number of children of a vertex in T other than the root. The number of vertices in H assigned as images to vertices in T other than the root is at most $r + id$, since the root has r children and each of the i internal vertices has at most d children. The r eliminated values from the list for the root t , and the l additional elements counted above, are the only other vertices of H , giving $n \leq 2r + l + id$.

Note finally that $\omega \geq d + 1$. If $d = 1$, the claim is trivial. Suppose $d \geq 2$. Consider the d neighbors of an internal vertex t_g (other than the root) of T . Call these neighbors $t_{g_1}, t_{g_2}, \dots, t_{g_d}$. Further, suppose the algorithm makes the assignments $f(g) = h$ and $f(g_i) = h_i$ for $i = 1, 2, \dots, d$, and suppose these assignments occur in the order $i = 1, 2, \dots, d$. The d children remove d vertices from $L(t_g)$. In particular, say that the assignment $f(g_i) = h_i$ causes x_i to be removed from $L(t_g)$. Each of $x_2, x_3, \dots, x_d$ must appear later in the perfect elimination ordering (by the construction of T) than h_1 . Also, each x_i for $2 \leq i \leq d$ must be adjacent to h_1 ; otherwise, h_1 would have caused x_i to be removed from $L(t_g)$. Hence h_1 is adjacent to h and each of x_i for $2 \leq i \leq d$. Since h_1 precedes the other vertices in the perfect elimination ordering, $h_1, h, x_2, \dots, x_d$ form a clique of size $d + 1$.

We claim $p(\omega - 1) = (p - i)(\omega - 1) + i(\omega - 1) \geq 2r + l + id \geq n$. To see this note that $\omega - 1 \geq d$, and by hypothesis $\omega - 1 \geq 2$. If $r \neq 1$, then $p - i = r + l$, and the claim follows. When $r = 1$ we have $p - i = l$, giving $l(\omega - 1) \geq 2 + l$ (and the claim), except for $l = 1$ and $\omega = 3$, or $l = 0$. First, note that $l \geq 1$; otherwise, the root t and its only child in T would map to the last two vertices in the perfect elimination ordering, which are adjacent.

Hence, assume that $l = 1$ and $\omega = 3$. If some internal vertex of T other than the root has $d' \leq d$ children, then we claim that $n \leq 2r + l + id - (d - d')$. In this final case the difference of one is accounted for unless $d = d' = 2$. This is not possible since the child of the root t would have two children that remove two values from its list, giving $l \geq 2$, contrary to $l = 1$. Therefore, $p(\omega - 1) \geq n$, or $p \geq n/(\omega - 1)$, completing the proof. $\square$

4. Reflexive graphs without NUF.

4.1. Graphs without NUF_k for some k . Having established in the previous sections that each reflexive chordal graph belongs to NUF_k for some k , we now turn our attention to providing lower bounds on the arity of the NUF.

We first show that reflexive chordal graphs without NUF_3 must have a unit hole of a particularly simple kind.

DEFINITION 4.1. *The reflexive chordal graph R_k is formed by constructing a clique on vertices $y_1, \dots, y_k$ and adding independent vertices $x_1, \dots, x_k$ and edges $x_i y_j$ for $i \neq j$.*

THEOREM 4.2. *Let H be a reflexive chordal graph which is not in NUF_3 . There exists $k \geq 3$ such that R_k is an induced subgraph of H . Furthermore, the set $X = \{x_1, x_2, \dots, x_k\} \subseteq V(R_k)$ is the vertex set of a $(1, 1, \dots, 1)$ k -hole in H .*

Proof. It suffices to show that H does indeed contain an induced copy of R_k with no vertex adjacent to all the x_i 's. Clearly, such a copy of R_k is a $(1, 1, \dots, 1)$ k -hole in H .

Since $H \notin \text{NUF}_3$, there exist a graph G and a preassignment $p : X \rightarrow V(H)$, where $X \subseteq V(G)$, $|X| \geq 3$, and X is a conflict. As described in the proof of Theorem 3.9, we may assume that G and H are connected. (A conflict must belong to a single component of G , and conflicts receiving their images in two components of H have size two.) Hence, by Corollary 3.13, there is a tree-certificate (T, p') for G with respect to H . In particular, $p' : X' \rightarrow X$, where X' is the set of leaves of T . Furthermore, $|X'| = |X|$. Suppose to the contrary that $|X'| < |X|$. Since X is a conflict, $p'(X')$ is extendible in H (as it is a proper subset of X). This contradicts the fact that (T, p') is a tree-certificate.

Hence, T is a tree, with at least three leaves which form a conflict with respect to H under the preassignment $p \circ p'$. Without loss of generality, assume T is the smallest tree whose leaves form a conflict of size $|X'|$.

We consider two cases, depending on the degree in T of the root t .

Case 1. $\deg_T(t) = r \geq 3$. Let the children of t be $t_1, t_2, \dots, t_r$. In the execution of the CLIST-HOMH Algorithm in Figure 1 these are mapped to vertices $x_1, x_2, \dots, x_r$ of H , respectively. By (the proof of) Lemma 3.12, $X = \{x_1, x_2, \dots, x_r\}$ is an independent set. Since t is the root of T (meaning that it arose from the first vertex of G whose list became empty), the vertices $x_1, x_2, \dots, x_r$ have no common neighbor in H . By the minimality of T , for $j = 1, 2, \dots, r$ the vertices in $X - \{x_j\}$ have a common neighbor y_j in H .

By the minimality of T , for $j \neq i$ the vertex y_i occurs after x_j in the perfect elimination ordering of $V(H)$. Suppose to the contrary that some child of the root, say, x_i , removes a set of images, say, Y_i , from the list of the root, all of which occur before x_j in the perfect elimination ordering. Then we may remove x_i and all of its descendants from T . The algorithm will remove all elements of Y_i from the list of the roots in Step 3.1 before the assignment $f(t_j) = x_j$ is made. Hence, there is no need to include x_i in the tree, contrary to our assumption of minimality. In particular (since $r \geq 3$), any two of $y_1, y_2, \dots, y_r$ have a common neighbor x_j occurring before them in the perfect elimination ordering. Therefore, $\{y_1, y_2, \dots, y_r\}$ induces a clique in H , and $\{x_1, x_2, \dots, x_r\} \cup \{y_1, y_2, \dots, y_r\}$ induces a copy of R_r , with no vertex in H adjacent to all the x_i 's.

Case 2. $\deg_T(t) = r \leq 2$. Since T has $s \geq 3$ leaves, at least one child of the root, say, t_{g_1} , is the root of a subtree of T consisting of a path from t_{g_1} to a vertex t' with at least two children (where $t_{g_1} = t'$ is possible). Let the children of t' be $t_2, \dots, t_k$ ($k \geq 3$), and assume these vertices have been mapped to $x_2, \dots, x_k$, respectively, by the algorithm.

If $r = 2$, then let t_{g_2} be the other child of t . Further, let h be the image assigned to t_{g_2} in the algorithm, and define v to be the vertex $v = t_{g_2}$. On the other hand,

if $r = 1$, then t is a leaf, and by Corollary 3.13 the original list for t , $L(t)$, must be a singleton, say, $\{h\}$. In this case, define the vertex v to be $v = t$.

Consider the $k - 1$ assigned images $x_2, \dots, x_k$. A vertex x_1 will be defined below. Let y_1 be the value in H assigned to t' by the algorithm. As before, for each i , the $k - 2$ vertices x_j , $j \neq i$, have a common neighbor y_i following y_1 in the perfect elimination ordering, with y_i not adjacent to x_i . Hence, for each $i = 2, \dots, k$, y_1 and y_i have a common neighbor, x_j , $j \neq i$, preceding them in the perfect elimination ordering. Thus, the y_i 's, $i = 1, 2, \dots, k$, form a clique.

Let $d = d_H(y_1, h)$ be the distance in H from y_1 to h . Since T does not map to H , $d_T(t', v) < d_H(y_1, h)$. Let $d' = d_T(t', v)$. Furthermore, for $i \neq 1$, the distance $d_i = d_H(y_i, h)$ must satisfy the inequality $d - 1 \leq d_i \leq d'$. To see the inequality, note that y_1 is adjacent to y_i ; hence, $d - 1 \leq d_i$. Also, by the minimality of T , $T - \{x_i\}$ maps to H with t' mapping to y_i . Hence, $d_i \leq d'$.

Consider a tree T' (whose leaves are vertices in H) consisting of a vertex y^* adjacent to each y_i for $i \geq 2$ together with a path of length $d - 2$ from y^* to h . If T' does not map to H , then, since T' has distances between its leaves at least their distance in H , the tree T' is another example of a tree like T , but smaller, which is a contradiction. Hence, T' maps to H , and, in particular, y^* maps to a vertex x_1 . By the distance inequalities, x_1 is not adjacent to y_1 , but it is adjacent to all y_i with $i \neq 1$.

Finally, consider x_i with $i \neq 1$. The vertex x_i is distance at least d from h in H . This follows from the algorithm and properties of the perfect elimination ordering. If h comes after y_1 in the perfect elimination ordering, then a path from x_i to h in H of length at most $d - 1$ easily yields a path of length at most $d - 1$ from y_1 to h in H , which is a contradiction. Similarly, h preceding y_1 also leads to a contradiction. Since x_1 is at distance $d - 2$ from h in H , it follows that x_1 is not adjacent to any x_i with $i \neq 1$. Furthermore, no vertex w in H is adjacent to all x_i , since otherwise we could map T to H by mapping t' to w at distance $d - 1 = d'$ from h in H . This completes the proof. $\square$

We continue our examination of holes from page 947, where we defined holes and provided a correspondence to trees with one branch point. The above proof shows that for chordal graphs H without NUF_3 , there is an instance of $\text{EXT}H$ whose tree-certificate is a $(1, 1, \dots, 1)$ hole. Historically, holes have been studied in the (equivalent) language of retractions. We adopt the retraction language for this next result. Given a graph G with a subgraph H , we say a hole in H is *filled* if G contains a vertex g whose distances to the vertices of the hole are within the distance given in the definition of the hole, i.e., $d_G(g, x) \leq \delta(x)$ for each x in the hole. Thus, a filled hole corresponds to a tree-certificate where the tree is a subdivision of a star. On the other hand, we now provide a graph G that does not retract to a reflexive chordal graph H , yet G does not fill a hole in H . In essence, the tree-certificate for G is necessarily more complex than a subdivision of a star.

THEOREM 4.3. *There is a reflexive chordal graph H with a NUF_5 (but not a NUF_4) and an instance G of RETH that does not retract to H , yet no vertex of G fills a hole in H .*

Proof. The graph H has ten vertices a_i, b_i, c_i, d_i, e_i for $i = 1, 2$ and edges $a_i c_i, a_i d_i, b_i c_i, b_i e_i, c_i d_i, c_i e_i, d_i e_i, d_1 d_2, e_1 e_2, d_1 e_2$, and $e_1 d_2$. The instance G is H together with three vertices x_1, x_2, y and edges $x_i a_i, x_i b_i, x_i y$. None of x_1, x_2, y fills a hole in H , and yet G does not retract to H . To see that no hole is filled, observe that $d(x_1, v) \geq d(c_1, v)$ for all $v \in V(H)$. Hence x_1 cannot fill a hole in H . A similar

FIG. 2. A G containing a subgraph H induced by the black vertices. The graph H is in $\text{NUF}_5 - \text{NUF}_4$. The graph G is a NO -instance of RETH yet fills no holes in H .

argument shows that neither x_2 nor y fills a hole. Figure 2 contains a drawing of H (with black vertices) and G (consisting of H plus the three white vertices).

To establish that H admits a NUF_5 and not a NUF_4 , we first observe that it is easy to construct an intersection representation for H with leafage 4. Hence, by Theorem 3.2, H admits a NUF_5 . Suppose to the contrary that g is a NUF_4 for H . Then $g(a_1, a_1, a_1, c_1) = a_1$ and $g(c_1, b_1, b_1, b_1) = b_1$. Since (a_1, a_1, a_1, c_1) and (c_1, b_1, b_1, b_1) are both adjacent to (d_1, c_1, c_1, e_1) , we must have $g(d_1, c_1, c_1, e_1)$ adjacent to both a_1 and b_1 . Namely, $g(d_1, c_1, c_1, e_1) = c_1$. However, (d_1, c_1, c_1, e_1) is adjacent to (d_2, d_1, e_1, e_2) . Thus, $g(d_2, d_1, e_1, e_2)$ is adjacent to c_1 . A similar argument shows that $g(d_2, d_1, e_1, e_2)$ is adjacent to c_2 . In particular (a_2, a_2, c_2, a_2) and (b_2, c_2, b_2, b_2) are both adjacent to (c_2, d_2, e_2, c_2) . Hence, $g(c_2, d_2, e_2, c_2) = c_2$ and $g(d_2, d_1, e_1, e_2)$ is adjacent to c_2 (as well as c_1), which is a contradiction. $\square$

We complete this section by establishing that the bounds in Theorems 3.2 and 3.14 are tight.

THEOREM 4.4. *For each $i \geq 0$ and $\omega \geq 3$, there exists a reflexive chordal graph $LB(\omega, i)$ with $n = 2\omega + i(\omega - 1)$, strict extension-width $s = \omega + i(\omega - 2)$, and leafage s .*

Proof. Fix $\omega \geq 3$.

For the case $i = 0$, $LB(\omega, 0)$ is the chordal graph with vertices $x_1, \dots, x_\omega, y_1, \dots, y_\omega$, a clique on the y_l , all edges $x_k y_l$ with $k \neq l$, and all loops, i.e., a copy of R_ω as defined above. To see that $LB(\omega, 0)$ has strict extension-width at least $s = \omega$, consider an instance T (a tree defined below) of $\text{EXTLB}(\omega, 0)$. The tree T has root t adjacent to ω leaves, each assigned to a unique x_k in $LB(\omega, 0)$. Clearly, the preassignment does not extend to a homomorphism $T \rightarrow H$, but if one of the ω leaves in T is deleted, say, the leaf mapped to x_1 , then the root t can be mapped to y_1 . Thus the x_k 's form a conflict of size $s = \omega$. On the other hand, there is an intersection representation of $LB(\omega, 0)$ with s leaves. Hence, by Theorem 3.2, $LB(\omega, 0)$ belongs to NUF_{s+1} . We have $n = 2\omega$, strict extension-width $s = \omega$, and leafage s .

For the case $i = 1$, consider the element x_1 in the preceding construction, with $\omega - 1$ neighbors y_j with $j \neq 1$. To construct $LB(\omega, 1)$, add vertices $z_2, z_3, \dots, z_\omega$ adjacent to x_1 , plus edges $z_k y_l$ for $k \neq l$ and $l \neq 1$. Similarly, replace the leaf in T that is preassigned to x_1 with a vertex t' having the $\omega - 1$ children each preassigned to a unique z_k . Thus n has increased by $\omega - 1$, and the fact that T does not map to $LB(\omega, 1)$ depends on $\omega - 1$ new leaves in T but no longer depends on t' (which is no longer preassigned to x_1). Hence the size of the conflict has increased by at least $\omega - 2$;

however, it is easy to see that the leafage has increased by at most $\omega - 2$. Therefore, s has increased by $\omega - 2$.

Note that the new vertices z_k have $\omega - 1$ neighbors in $LB(\omega, 1)$ as before for the x_k in $LB(\omega, 0)$. We may repeat the process of enlarging each $LB(\omega, i)$ and changing T as follows. In $LB(\omega, i)$ add $\omega - 1$ new vertices, the $z_2, \dots, z_\omega$ above, and join each to some vertex and $\omega - 2$ of its neighbors, as for x_1 above, ensuring that no two of the new vertices have the same neighborhood. In T , select a leaf, say, u , as before, for the preimage of x_1 ; add $\omega - 1$ leaves each adjacent to u , and map each (injectively) to the new $\omega - 1$ vertices, say, $z_2, \dots, z_\omega$, as above. Thus each time we increase n by $\omega - 1$ and s by $\omega - 2$. This completes the construction. $\square$

The bound in Theorem 3.2 is tight.

COROLLARY 4.5. *For each $l \geq 3$, there is a reflexive chordal graph H with $\omega = 3$, and leafage l , such that $H \in \text{NUF}_{l+1} - \text{NUF}_l$.*

Proof. The graph $LB(3, l - 3)$ is such a graph. $\square$

The bounds in Theorem 3.14 are tight.

COROLLARY 4.6. *For each $\omega \geq 2$ there is a reflexive chordal graph $H \in \text{NUF}_k - \text{NUF}_{k-1}$, where $k = n - \omega + 1$.*

Proof. The graph $LB(\omega, 0)$ is such a graph. $\square$

COROLLARY 4.7. *For each $i \geq 0$, there is a reflexive chordal graph $H \in \text{NUF}_k - \text{NUF}_{k-1}$ with $\omega = 3$, where $k = n - n/(\omega - 1) + 1$.*

Proof. The graph $LB(3, i)$ is such a graph. $\square$

4.2. Graphs without NUF_k for any k . We now construct classes of reflexive graphs that do not admit a near-unanimity function of any arity. Given a vertex v and a subgraph S of a graph H , we use the notation $d(v, H)$ to denote the minimum distance from the vertex v to a vertex in the subgraph H , where the minimum is taken over all vertices of H . We are working with reflexive graphs; however, $N(v)$ denotes the vertices other than v that are adjacent to v , i.e., $v \notin N(v)$.

LEMMA 4.8. *Let H be a connected reflexive graph and t, b be two nonadjacent vertices of H . Suppose that for each $x \in N(t)$ there is a complete subgraph $K(x)$, which is either a maximal clique or a single vertex, with the property that $d(x, K(x)) > \max\{d(t, K(x)), d(b, K(x))\}$. Then H does not admit a NUF_k for any $k \geq 3$.*

(The hypotheses are illustrated in Figure 3, where t is the top vertex, b is the bottom vertex, and for each $x \in N(t)$, $K(x)$ is one of the middle four vertices which is not adjacent to x .)

Proof. Suppose to the contrary that g is a NUF_k on H . For each $j = 1, 2, \dots, k$, let $\bar{x}_j$ be a vertex, say, $(x_1, x_2, \dots, x_k)$, of H^k with the property that $x_i = t$ for all $i < j$, $x_i = b$ for all $i > j$, and x_j is an arbitrary vertex of H . Thus $\bar{x}_j = (t, \dots, t, x_j, b, \dots, b)$. Consider any vertex $x \in N(t)$. By hypothesis there exists a complete subgraph $K(x)$ with $d(x, K(x)) > \max\{d(t, K(x)), d(b, K(x))\}$. Thus there exist $y, z \in V(K(x))$ with $d(x, K(x)) > d(t, y)$ and $d(x, K(x)) > d(b, z)$. Hence in H^k the distance between $\bar{x}_j$, and $(y, \dots, y, x_j, z, \dots, z)$ is less than $d(x, K(x))$. For each $v \in K(x)$ the vertex $(y, \dots, y, x_j, z, \dots, z)$ is adjacent to $(v, \dots, v, x_j, v, \dots, v)$. Hence $g(y, \dots, y, x_j, z, \dots, z)$ must be adjacent to v , and as $K(x)$ is either a single vertex or a maximal complete subgraph of H , $g(y, \dots, y, x_j, z, \dots, z)$ must be a vertex of $K(x)$. We have

$$\begin{aligned} d(x, K(x)) &> d(\bar{x}_j, (y, \dots, y, x_j, z, \dots, z)) \\ &\geq d(g(\bar{x}_j), g(y, \dots, y, x_j, z, \dots, z)) \end{aligned}$$

FIG. 3. A dismantable reflexive graph without a NUF_k .

and, consequently, $g(\bar{x}_j) \neq x$. Since x was an arbitrary member of $N(t)$, we conclude that $g(\bar{x}_j) \notin N(t)$.

Since H is a connected graph, there is a (t, b) -path $(t =)v_1, v_2, \dots, v_l(= b)$. Thus, in H^k , we have the following path, say, P :

$$\begin{aligned} (t, b, b, b, \dots, b, b) &\sim (t, v_{l-1}, b, b, \dots, b, b) \sim (t, v_{l-2}, b, b, \dots, b, b) \sim \dots \\ &\sim (t, v_2, b, b, \dots, b, b) \sim (t, t, b, b, \dots, b, b) \sim (t, t, v_{l-1}, b, \dots, b, b) \sim \dots \\ &\sim (t, t, t, b, \dots, b, b) \sim (t, t, t, v_{l-1}, \dots, b, b) \dots \sim (t, t, t, \dots, t, b). \end{aligned}$$

Since $g(t, b, b, b, \dots, b) = b$ and $g(t, t, \dots, t, t, b) = t$, we must have that $g(P)$ is a (b, t) -walk in H . Since t and b are nonadjacent, some interior vertex of P must map to a neighbor of t , contrary to our claim above. $\square$

COROLLARY 4.9. *No reflexive cycle of length at least 4 admits a NUF_k for any $k \geq 3$.*

Proof. Let $C : v_1 v_2 \dots v_n v_1$ ($n \geq 4$) be a cycle. We show that C satisfies the assumption of Lemma 4.8: Set $t = v_1$, $b = v_3$, $K_1 = \langle \{v_{\lceil \frac{n-1}{2} \rceil}, v_{\lceil \frac{n}{2} \rceil}\} \rangle$, and $K_2 = \langle \{v_{\lceil \frac{n+3}{2} \rceil}, v_{\lceil \frac{n+4}{2} \rceil}\} \rangle$. Then $N(t) = \{v_2, v_n\}$ and

$$\begin{aligned} d(v_n, K_1) &= \left\lfloor \frac{n}{2} \right\rfloor > \left\lfloor \frac{n}{2} \right\rfloor - 1 = \max\{d(t, K_1), d(b, K_1)\}, \\ d(v_2, K_2) &= \left\lfloor \frac{n}{2} \right\rfloor > \left\lfloor \frac{n}{2} \right\rfloor - 1 = \max\{d(t, K_2), d(b, K_2)\}. \quad \square \end{aligned}$$

We have established that all chordal graphs belong to NUF . Recall that it is proved in [27] that the variety generated by chordal graphs is properly contained in NUF . The corollary below shows that some dismantable graphs do not admit a NUF . It has subsequently been established in [25] that NUF is properly contained in the variety generated by dismantable graphs.

COROLLARY 4.10. *The dismantable reflexive graph in Figure 3 does not admit a NUF_k for any $k \geq 3$.*

COROLLARY 4.11. *There is a reflexive graph H that does not admit a NUF of any arity such that every nonidentity retract of H admits a NUF_3 .*

We complete this section by observing for irreflexive graphs that if H admits a NUF_k , then H must be bipartite. The proof is analogous to Corollary 4.9.

PROPOSITION 4.12. *Let H be an irreflexive graph. If H is not bipartite, then H does not admit a NUF_k for any $k \geq 3$.*

5. Conservative NUF. We complete the paper by examining a special type of near-unanimity functions called conservative functions. Recall that $g \in \text{NUF}_k$ is a *conservative near-unanimity function* if $g(x_1, x_2, \dots, x_k) \in \{x_1, x_2, \dots, x_k\}$ for all $(x_1, \dots, x_k)$. Conservative near-unanimity functions have also been called *choice* or *projective* and are of particular interest since if H admits a conservative NUF, then the *list-homomorphism problem* for H is polynomial time solvable.

The computational complexity of LIST-HOMH has been determined for any fixed (general) graph H . In [11] a new class of intersection graphs called *bi-arc* graphs is introduced. The LIST-HOMH problem is polynomial time solvable if H is a bi-arc graph and is NP-complete if H is not a bi-arc graph. This result generalizes the work of [9, 10] since a reflexive graph is a bi-arc graph if and only if it is an interval graph, and an irreflexive graph is a bi-arc graph if and only if it is a complement of a circular arc graph of clique covering number two.

The polynomial time algorithm of [11] is established by showing that every bi-arc graph admits a conservative NUF_3 . Under the assumption that $P \neq \text{NP}$, the bi-arc graphs are precisely the graphs with a conservative NUF_3 . We now establish this result without the assumption $P \neq \text{NP}$.

Let C be a circle with two specified points p and q . A *bi-arc* is an ordered pair of arcs (N, S) on C such that N contains p but not q , and S contains q but not p . A graph G is a *bi-arc graph* if there is a family of bi-arcs $\{(N_x, S_x) : x \in V(G)\}$ such that, for any not necessarily distinct vertices $x, y \in V(G)$, the following hold:

- (i) if x and y are adjacent, neither N_x intersects S_y nor N_y intersects S_x ;
- (ii) if x and y are not adjacent, both N_x intersects S_y and N_y intersects S_x .

(Note that there cannot be bi-arcs $(N, S), (N', S')$ such that N intersects S' but S does not intersect N' or vice versa.)

We begin by showing that the irreflexive graphs that admit a conservative NUF_3 are precisely the complements of circular arc graphs of clique covering number two.

An *edge-asteroid* in a bipartite graph with the bipartition (X, Y) is a set of $2k+1$ edges $u_0v_0, u_1v_1, \dots, u_{2k}v_{2k}$ ($k \geq 1$ and each $u_i \in X$ and $v_i \in Y$) and $2k+1$ paths, $P_{0,1}, P_{1,2}, \dots, P_{2k,0}$, where each $P_{i,i+1}$ joins u_i to u_{i+1} , such that for each $i = 0, 1, \dots, 2k$ there is no edge between $\{u_i, v_i\}$ and $\{v_{i+k}, v_{i+k+1}\} \cup V(P_{i+k, i+k+1})$ (subscripts are modulo $2k+1$). We refer to the (odd) integer $2k+1$ as the *order* of the edge-asteroid. An edge-asteroid which has no edge between $\{u_0, v_0\}$ and $\{v_1, v_2, \dots, v_{2k}\} \cup V(P_{1,2}) \cup V(P_{2,3}) \cup \dots \cup V(P_{2k-1, 2k})$ is called a *special edge-asteroid*.

We will use the following structural characterization.

THEOREM 5.1 (see [10]). *An irreflexive bipartite graph H is the complement of a circular arc graph if and only if H is chordal bipartite and contains no special edge-asteroids.*

THEOREM 5.2. *Let H be an irreflexive graph. The following are equivalent:*

- (a) H is bipartite and the complement of a circular arc graph;
- (b) H admits a conservative NUF_3 ;
- (c) H admits a conservative NUF_k for some $k \geq 3$.

Proof. In [11], it is shown that every complement of a circular arc graph of clique covering number two has a conservative NUF_3 . Clearly, if H has a conservative NUF_3 , then H has a conservative NUF_k for some k .

To complete the proof, assume to the contrary that H is not the complement of a circular arc graph of clique covering number two, but H does admit a conservative NUF_k , say, g . If H is not bipartite, then by Proposition 4.12 H does not admit a NUF_k for any k . Therefore, H is bipartite.

Suppose H contains an induced (even) cycle, say, C , of length at least six with vertex set $0, 1, 2, \dots, 2n - 1$. In light of Proposition 2.5, g is a conservative NUF_k on the cycle C . Consider the following path in C^k :

$$\begin{aligned} (0, 0, \dots, 0, 0, 2) &\sim (2n - 1, \dots, 2n - 1, 1, 3) \sim (0, \dots, 0, 2, 2) \\ &\sim (2n - 1, \dots, 2n - 1, 1, 3, 3) \sim (0, \dots, 0, 2, 2, 2) \\ &\sim \dots \sim (2n - 1, 1, 3, \dots, 3, 3) \sim (0, 2, 2, \dots, 2, 2). \end{aligned}$$

By near unanimity, the first vertex of the path must map to 0. The vertices of the form $(2n - 1, \dots, 2n - 1, 1, 3, \dots, 3)$ cannot map to 1, since such vertices are distance $n - 2$ from $(n + 1, \dots, n + 1, n - 1, n + 1, \dots, n + 1)$ and 1 is distance n from $n + 1$. Thus the second vertex of the path must map to $2n - 1$, the third to 0, the fourth to $2n - 1$, etc. By parity, the final vertex maps to 0, which is a contradiction.

Hence H is chordal bipartite. We conclude that H contains a special edge-asteroid. Let the path $P_{0,1}$ be $u_0, p_1, p_2, \dots, p_t, u_1$. Consider the following path in H^k :

$$\begin{aligned} (u_0, \dots, u_0, u_0, u_{k+1}) &\sim (v_0, \dots, v_0, p_1, v_{k+1}) \\ &\sim (u_0, \dots, u_0, p_2, u_{k+1}) \sim (v_0, \dots, v_0, p_3, v_{k+1}) \\ &\sim \dots \sim (u_0, \dots, u_0, u_1, u_{k+1}). \end{aligned}$$

Notice that, in this path, all coordinates with the exception of coordinate $k - 1$ alternate between u_i and v_i . We will describe this situation by saying that *coordinate $k - 1$ traverses that path $P_{0,1}$ while all other coordinates alternate*.

We claim $g(u_0, \dots, u_0, u_1, u_{k+1}) = u_0$. Clearly the first vertex of the path is mapped to u_0 . Since g is a conservative function and there is no edge between $\{u_{k+1}, v_{k+1}\}$ and $\{v_0, v_1\} \cup P_{0,1}$, we know that no vertex in the above path is mapped to $\{u_{k+1}, v_{k+1}\}$. If $g(u_0, \dots, u_0, u_1, u_{k+1}) = u_1$, then we look at the path from $(u_0, \dots, u_0, u_1, u_{k+1})$ to $(u_0, \dots, u_0, u_1, u_{k+2})$ where the last coordinate traverses the path $P_{k+1,k+2}$ while all other coordinates alternate. Since there is no edge from $\{u_1, v_1\}$ to $\{v_{k+1}, v_{k+2}\} \cup P_{k+1,k+2}$, the image of the entire path must alternate between u_1 and v_1 , and thus $g(u_0, \dots, u_0, u_1, u_{k+2}) = u_1$. Similarly, we consider the path from $(u_0, \dots, u_0, u_1, u_{k+2})$ to $(u_0, \dots, u_0, u_2, u_{k+2})$ where coordinate $k - 1$ traverses $P_{1,2}$ while all other coordinates alternate. Again there is no edge between $\{u_{k+2}, v_{k+2}\} \cup \{u_0, v_0\}$ and $\{v_1, v_2\} \cup P_{1,2}$. Thus $g(u_0, \dots, u_0, u_2, u_{k+2}) = u_2$. Continuing in this manner, we can move coordinate k down to u_0 and coordinate $k - 1$ up to u_k . We find that $g(u_0, \dots, u_0, u_k, u_0) = u_k$, which is a contradiction. This proves the claim.

Consider the path from $(u_0, \dots, u_0, u_1, u_{k+1})$ to $(u_0, \dots, u_0, u_{k+1}, u_{k+1})$, where the $(k - 1)$ st coordinate traverses all the paths $P_{1,2}, P_{2,3}, \dots, P_{k,k+1}$ while the other coordinates alternate. Since there is no edge from $\{u_0, v_0\}$ to any of these paths $P_{i,i+1}$, the image of the entire path must alternate between u_0 and v_0 , and thus, $g(u_0, \dots, u_0, u_{k+1}, u_{k+1}) = u_0$. Continuing in this manner, we can show that $g(u_0, \dots, u_0, u_{k+1}, \dots, u_{k+1}) = u_0$ and thus $g(u_0, u_{k+1}, \dots, u_{k+1}) = u_0$, which is a contradiction. $\square$

We conclude by characterizing all graphs that admit a conservative near-unanimity function.

THEOREM 5.3. *Let H be a graph. The following are equivalent.*

- (a) H is a bi-arc graph;
- (b) H admits a conservative NUF_3 ;

(c) H admits a conservative NUF.

Proof. Assume H is a bi-arc graph. In [11], it is shown that H admits a conservative NUF_3 . Clearly, if H admits a conservative majority function, then it admits a conservative NUF.

Thus assume H admits a conservative NUF. Let $H^* = H \times K_2$. Note that H^* is irreflexive since K_2 is irreflexive. We have established how to construct a NUF for the product of two graphs given that both factors admit a NUF (see Proposition 2.7). This construction preserves the conservative property. Consequently, H^* is bipartite and the complement of a circular arc graph by Theorem 5.2. Using Proposition 3.1 of [11], we have H is a bi-arc graph. $\square$

Note that by Corollary 2.3 and Theorem 5.3, H admits a conservative NUF_3 if and only if H admits a conservative NUF_k for all $k \geq 3$.

It is shown in [11] that the reflexive bi-arc graphs are precisely the interval graphs and the irreflexive bi-arc graphs are precisely the complement of circular arc graphs of clique covering number two. Thus we have the following.

COROLLARY 5.4. *A reflexive graph admits a conservative NUF if and only if it is an interval graph and an irreflexive graph admits a conservative NUF if and only if it is the complement of a circular arc graph of clique covering number two.*

It is easy to construct a conservative NUF for a reflexive (resp., irreflexive) bi-arc graph using an interval (resp., a circular arc) representation of the graph. In [11], a direct construction of a conservative NUF is given for bi-arc trees. However, a direct construction for general bi-arc graphs still remains elusive.

Acknowledgment. The authors wish to thank the referees for a very careful reading of the manuscript and many helpful suggestions.

COMBINATORICS OF PEDIGREES I: COUNTEREXAMPLES TO A RECONSTRUCTION QUESTION*

BHALCHANDRA D. THATTE†

Abstract. A pedigree is a finite directed acyclic graph in which all vertices other than the founder vertices have two outgoing arcs each (to their parents), while the founder vertices have no outgoing arcs. The primary motivation to study pedigrees comes from population biology. The main result in this paper is a construction of an infinite family of counterexamples to a reconstruction problem on pedigrees, thus negatively answering a question of Steel and Hein.

Key words. pedigrees, reconstruction

AMS subject classification. 05C60

1. Introduction. Informally speaking, a *pedigree* is a structure that represents ancestral relationships between individuals in a population. A motivation to study pedigrees comes from population biology, where one ambitious goal is to reconstruct pedigrees of populations as far into the past as possible. The purpose of this paper is to study a reconstruction question on pedigrees. It is hoped that the main result in this paper—the nonreconstructibility of pedigrees from the pedigrees of subpopulations—will also be of interest to combinatorialists interested in the well-known reconstruction conjectures.

We now introduce the definitions and the terminology and formulate the problem.

A *general pedigree* $\mathcal{T}(X_0)$ on a set X_0 is a finite directed acyclic graph on a vertex set $V \supseteq X_0$ that satisfies the following conditions:

1. each vertex has out-degree 0 or 2; and
2. each vertex in X_0 has in-degree 0.

The vertices with out-degree 0 are called the *founders*. The vertices in X_0 are referred to as the *extant* vertices. The cardinality of X_0 is called the *order* of the pedigree. The vertices with no descendants in X_0 are called the *redundant* vertices.

A *discrete generation pedigree* on X_0 is a pedigree on vertex set $V = \cup_{i=0}^d X_i$, where X_i are disjoint sets, X_d is the set of founders, and every vertex u in $X_i, i < d$, has outgoing arcs uv and uw to vertices v and w , respectively, in X_{i+1} . In this case, d is the *depth* of the pedigree.

If there is an arc from a vertex u to a vertex v , then v is called a parent of u , and u is called a child of v . If there is a directed path from a vertex u to a vertex v in a pedigree, then v is said to be an *ancestor* of u , and u is said to be a *descendent* of v . Trivially, each vertex is its own ancestor as well as its own descendent but not its own parent or child.

A pedigree $\mathcal{P}(X_0)$ with vertex set U is said to be *isomorphic* to a pedigree $\mathcal{Q}(Y_0)$ with vertex set V if there is a one-one map $f : U \rightarrow V$ such that $u_1 - u_2$ is an arc in $\mathcal{P}(X_0)$ if and only if $f(u_1) - f(u_2)$ is an arc in $\mathcal{Q}(Y_0)$. Although this is a

standard definition of graph isomorphism, we will be interested in pedigrees in which the extant vertices are labeled. Therefore, if $X_0 = Y_0 = \{x_i, 1 \leq i \leq n\}$, then we will be interested only in isomorphisms π for which $\pi(x_i) = x_i$ for all $1 \leq i \leq n$.

Steel and Hein [3] posed and partially solved reconstruction and enumeration questions about pedigrees. It is well known in phylogenetics that a leaf labeled tree can be constructed up to isomorphism from the collection of pairwise distances between leaves. See, for example, [4]. This fact is a basis of many phylogenetic tree reconstruction algorithms. Motivated by such results in phylogenetics, it is natural to ask the following question: Is a pedigree determined up to isomorphism from the pairwise distances between extant vertices? A pair of extant vertices x and y in a pedigree may have several common ancestors or several paths to a common ancestor. Therefore, it is assumed that all possible distances (in the undirected sense) between all pairs of extant vertices are given. Such a question is not expected to have a positive answer, as demonstrated by a counterexample in [3]. Despite the counterexample, variations of this question are definitely significant in evolutionary biology. Steel and Hein considered the following weaker question.

Let $\mathcal{P}(X_0)$ be a pedigree without redundant vertices. A *subpedigree* $\mathcal{P}(Y)$ of $\mathcal{P}(X_0)$ is obtained by deleting every vertex in $\mathcal{P}(X_0)$ that has no descendent in Y . If the subpedigrees on all two-element subsets of X_0 are given up to isomorphism, can we construct the pedigree on X_0 up to isomorphism? Steel and Hein demonstrated that in general the collection of subpedigrees of order 2 is not sufficient to reconstruct a pedigree. They posed the following problem.

PROBLEM 1. *Is there an integer $r > 2$ such that every pedigree of order $n > r$ that has no redundant vertices is determined up to isomorphism if all its subpedigrees of order r are given up to isomorphism?*

The reason for considering only those pedigrees that have no redundant vertices is that redundant vertices do not appear in subpedigrees, so no structural information about them can be reconstructed.

It must be pointed out that the extant vertices in a pedigree are labeled, and the extant vertices in each subpedigree retain their original label. The following definitions are introduced to make this assumption precise.

Let $n > r > 2$ be positive integers. Let $\mathcal{T}(X_0)$ and $\mathcal{U}(X_0)$ be two pedigrees of order n that have no redundant vertices. The two pedigrees are said to be *r -hypomorphic* to each other if for every $Y \subset X_0, |Y| = r$, there is an isomorphism π_Y from the subpedigree $\mathcal{T}(Y)$ of $\mathcal{T}(X_0)$ to the subpedigree $\mathcal{U}(Y)$ of $\mathcal{U}(X_0)$ such that $\pi_Y(x) = x$ for all $x \in X_0$. A pedigree $\mathcal{T}(X_0)$ is said to be *r -reconstructible* if, for every pedigree $\mathcal{U}(X_0)$ that is r -hypomorphic to $\mathcal{T}(X_0)$, there is an isomorphism π from $\mathcal{T}(X_0)$ to $\mathcal{U}(X_0)$ such that $\pi(x) = x$ for all $x \in X_0$.

PROBLEM 2. *Is there an integer $r > 2$ such that all pedigrees of order $n > r$ are r -reconstructible?*

Since the extant vertices are labeled, many more vertices in a pedigree effectively receive a unique label. Therefore, a reconstruction question on pedigrees is expected to be simpler than the well-known reconstruction conjectures in graph theory.

In section 2, we construct an infinite family of nonreconstructible pedigrees. In particular, we prove that, for every $n \geq 3$, there are pedigrees of order n that are not even $(n - 1)$ -reconstructible. The problem of classification of nonreconstructible pedigrees remains open, and we suspect that it might have an algebraic structure similar to the Nash-Williams lemma in edge reconstruction theory; see [2]. We also present a few positive results on constant population size pedigrees.

2. Counterexamples to pedigree reconstruction. In this section we construct an infinite family of pairs of nonisomorphic pedigrees that have correspondingly isomorphic subpedigrees. That is, we prove the following theorem.

THEOREM 1. *For every $n > 2$, there are nonisomorphic pedigrees $\mathcal{T}(X_0)$ and $\mathcal{U}(X_0)$ of order n that are $(n - 1)$ -hypomorphic.*

Proof. The proof is divided into two cases. The case $n = 3$ gives the basic idea, which is then generalized to arbitrary values of n .

Case $n = 3$. Consider the nonisomorphic graphs $K_{1,3}$ and K_3 . Let the edges of both graphs be arbitrarily labeled e_1, e_2, e_3 , where, following the standard graph theoretic convention, an edge is a set of two vertices. It is clear that $K_{1,3} - e_i \cong K_3 - e_i$ for all i , where $-e_i$ denotes deletion of the edge e_i and the resulting isolated vertices. Now suppose that the end vertices of each edge e_i are parents of the vertex $x_i \in X_0$ in each of the pedigrees $\mathcal{T}(X_0)$ and $\mathcal{U}(X_0)$. Then the pedigrees $\mathcal{T}(\{x_i, x_j\})$ and $\mathcal{U}(\{x_i, x_j\})$ are isomorphic for all i, j , but the pedigrees $\mathcal{T}(X_0)$ and $\mathcal{U}(X_0)$ are not isomorphic. This example proves the theorem for $n = 3$. The pedigrees $\mathcal{T}(X_0)$, $\mathcal{U}(X_0)$ and their subpedigrees are shown in Figure 1.

FIG. 1. Pedigrees based on $K_{1,3}$ and K_3 .

Case $n > 3$. We have to construct hypergraphs that play the role that $K_{1,3}$ and K_3 play above. We construct a hypergraph G with edge set $\{g_i, 1 \leq i \leq n\}$ and a hypergraph H with edge set $\{h_i, 1 \leq i \leq n\}$ such that the following conditions are satisfied.

1. $G \not\cong H$.
2. For each $i, 1 \leq i \leq n$, $G - g_i \cong H - h_i$; moreover, there is an isomorphism between $G - g_i$ and $H - h_i$ that *preserves the edge order*; that is, vertices in an edge g_j in $G - g_i$ are mapped to vertices in h_j under such an isomorphism for each $j \neq i$.

Once such hypergraphs are constructed, we treat each edge in each hypergraph as a founder set. We construct pedigrees T_i on founder sets g_i and pedigrees U_i on founder sets h_i such that

1. pedigrees $T_i, 1 \leq i \leq n$, are vertex-disjoint except possibly for their founder sets g_i ;
2. pedigrees $U_i, 1 \leq i \leq n$, are vertex-disjoint except possibly for their founder sets h_i ;
3. pedigrees T_i and U_i are correspondingly isomorphic; moreover, for all $i, j, i \neq j$, an isomorphism between $G - g_j$ and $H - h_j$ that preserves the edge order extends to an isomorphism between T_i and U_i ; and
4. each of the pedigrees T_i and U_i contains exactly one extant vertex x_i .

The resulting pedigrees $\cup_{i=1}^n T_i$ and $\cup_{i=1}^n U_i$ are nonisomorphic (since the hypergraphs G and H are nonisomorphic), but their subpedigrees are correspondingly isomorphic.

Construction of hypergraphs G and H . The required hypergraphs are constructed by a simple application of linear algebra.

Let each integer in $\{0, 2^n - 1\}$ be written in base 2 as an n -digit number by padding sufficiently many zeros on the left. We count its digits from the right. The set of n -digit binary numbers is denoted by $[2^n]$. The i th digit of a number k is denoted by $k(i)$, and the number obtained by setting the i th digit of k to 0 (or 1) is denoted by $k(i \leftarrow 0)$ (or, respectively, $k(i \leftarrow 1)$). The number of 1's and the number of 0's in k are denoted by $\#1(k)$ and $\#0(k)$, respectively.

The isomorphism class of a hypergraph G with edge set $\{g_i, 1 \leq i \leq n\}$ may be represented by a list of integers $a(k), k \in [2^n]$, where $a(k)$ is the number of vertices in $\cap_{i=1}^n f_i$, where $f_i = g_i$ if $k(i) = 1$, and $f_i = \bar{g}_i$ (that is, the complement of g_i) if $k(i) = 0$. In other words, we have to specify only the number of vertices in each region of the Venn diagram of $g_i, 1 \leq i \leq n$. Let the list of integers $b(k), k \in [2^n]$, similarly denote the isomorphism class of H .

The condition $G - g_i \cong H - h_i$ for $1 \leq i \leq n$, with an isomorphism between them that preserves the edge order, may be expressed as

$$(1) \quad a(k(i \leftarrow 0)) + a(k(i \leftarrow 1)) = b(k(i \leftarrow 0)) + b(k(i \leftarrow 1)), \quad k \in [2^n].$$

Since we are interested in nonisomorphic hypergraphs G and H , we must find solutions to the above equations so that $a(k) \neq b(k)$ for some $k \in [2^n]$.

We verify that

$$\begin{aligned} a(k) &= 1 \text{ and } b(k) = 0 \text{ when } k \text{ has even number of 1's,} \\ a(k) &= 0 \text{ and } b(k) = 1 \text{ when } k \text{ has odd number of 1's} \end{aligned}$$

satisfy (1).

It can be easily verified that $K_{1,3}$ and $K_3 \cup K_1$ do in fact satisfy the above solutions, where we include an isolated vertex in one of the graphs purely for algebraic convenience.

From now on we write $[2^n] = [2^n]_e \cup [2^n]_o$, where $[2^n]_e$ is the set of integers having an even number of 1's in their binary representation, and $[2^n]_o$ is the set of integers having an odd number of 1's in their binary representation. In this notation, the hypergraphs G and H are described as follows: the set $[2^n]_e$ is the set of vertices of G , and a vertex $k \in [2^n]_e$ is in g_i if and only if $k(i) = 1$. Similarly, the set $[2^n]_o$ is the vertex set of H , and a vertex $k \in [2^n]_o$ is in edge h_i if and only if $k(i) = 1$.

The vertex $k = 0$ is in G but is an isolated vertex and is included at this stage only for algebraic convenience. It may be deleted after completing the construction of nonreconstructible pedigrees.

It is clear that G and H are nonisomorphic, since each of them has 2^{n-1} vertices, but G has the isolated vertex 0, while H has no isolated vertex. What is an isomorphism between $G - g_i$ and $H - h_i$? An edge order preserving isomorphism from $G - g_i$ to $H - h_i$ must map vertices in a region of the Venn diagram of $\cup_{j|j \neq i} g_j$ to the corresponding region of the Venn diagram of $\cup_{j|j \neq i} h_j$. Consider any $k \in [2^n]$. The vertex $k(i \leftarrow 0)$ is in g_j for some $j \neq i$ if and only if the vertex $k(i \leftarrow 1)$ is in h_j , because the two vertices differ only in their i th digit. Therefore, if $k(i \leftarrow 0)$ is in G , then an edge order preserving isomorphism between $G - g_i$ and $H - h_i$ must map the vertex $k(i \leftarrow 0)$ to the vertex $k(i \leftarrow 1)$. Similarly, if the vertex $k(i \leftarrow 1)$ is in G , then an edge order preserving isomorphism between $G - g_i$ and $H - h_i$ must map the vertex $k(i \leftarrow 1)$ to the vertex $k(i \leftarrow 0)$. Moreover, this isomorphism is unique. On the standard hypercube on $[2^n]$, each vertex in $G - g_i$ is mapped to its neighbor along the i th axis, which is in $H - h_i$.

Example 1. Let $n = 4$, and let the hypergraphs G and H be defined on vertex sets $[2^4]_e$ and $[2^4]_o$ as follows:

$$\begin{aligned} g_1 &= \{0011, 0101, 1001, 1111\}, \\ g_2 &= \{0011, 0110, 1010, 1111\}, \\ g_3 &= \{0101, 0110, 1100, 1111\}, \\ g_4 &= \{1001, 1010, 1100, 1111\}, \\ h_1 &= \{0001, 0111, 1011, 1101\}, \\ h_2 &= \{0010, 0111, 1011, 1110\}, \\ h_3 &= \{0100, 0111, 1101, 1110\}, \\ h_4 &= \{1000, 1011, 1101, 1110\}, \end{aligned}$$

where g_i are the edges of G , and h_i are the edges of H . The isomorphism π_1 from $G - g_1$ to $H - h_1$ that preserves the edge order is given by $\pi_1(0000) = 0001$, $\pi_1(0011) = 0010$, $\pi_1(0101) = 0100$, $\pi_1(1001) = 1000$, $\pi_1(0110) = 0111$, $\pi_1(1010) = 1011$, $\pi_1(1100) = 1101$, $\pi_1(1111) = 1110$. Observe that $\pi_1(g_2) = h_2$, $\pi_1(g_3) = h_3$, and $\pi_1(g_4) = h_4$ under this map.

Construction of T_i and U_i . As stated earlier, for each i , pedigrees T_i and U_i must be so constructed that the edge order preserving isomorphism between $G - g_j$ and $H - h_j$ extends to an isomorphism between T_i and U_i for all $j \neq i$.

Let a balanced binary tree T_i be defined so that x_i is its root and g_i is its set of leaves. By convention, the root x_i is the lowest vertex (at depth 0) in T_i , and the leaves are the highest vertices (at depth $n-2$) in T_i . For a vertex t in T_i , let $T_i(t)$ be the subtree of T_i induced by t and all vertices in T_i that are above t . Let t_0 and t_1 be the parents of t . The subtree $T_i(t)$ is a union of subtrees $L(t)$ and $R(t)$, where $L(t)$ is induced by vertices t, t_0 , and all vertices above t_0 , and the subtree $R(t)$ is induced by vertices t, t_1 , and all vertices above t_1 . We call $L(t)$ the *left subtree* at t and $R(t)$ the *right subtree* at t .

Let $i_1, i_2, \dots, i_{n-1}$ be the integers $1 \leq j \leq n, j \neq i$, in arbitrary order. The vertices in g_i are grouped in such a way that for each vertex t at depth $k, 0 \leq k \leq n-3$, if a vertex $p \in g_i$ is a leaf of $L(t)$, then $p(i_{k+1}) = 0$, and if a vertex $p \in g_i$ is a leaf of $R(t)$, then $p(i_{k+1}) = 1$.

The vertices in h_i are partitioned, and a binary tree U_i is constructed analogously for the same ordering $i_j, 1 \leq j \leq n-1$.

For $n = 5$ and $i = 5$ and the ordering $i_1 = 2, i_2 = 3, i_3 = 1, i_4 = 4$, the trees T_5 and U_5 are shown in Figure 2.

We show that for every $j \neq i$, the unique isomorphism between $G - g_j$ and $H - h_j$ extends to an isomorphism between T_i and U_i .

Let $\bar{b} = (b_1, \dots, b_j), 0 \leq j \leq n-2$, be a j -tuple of 0's and 1's. Extending notation introduced earlier, let $g_i(\bar{b})$ denote the set $\{k \in g_i | k(i_1) = b_1, k(i_2) = b_2, \dots, k(i_j) = b_j\}$, which is the set of leaves of a binary subtree of T_i rooted at the vertex $t(\bar{b})$ at depth j . For example, when $\bar{b} = (0)$, $g_i(\bar{b})$ is the set of leaves above the left parent of x_i , and $t(\bar{b})$ is the left parent of x_i . The set $h_i(\bar{b})$ and the vertex $u(\bar{b})$ are analogously defined for U_i . By convention, an empty tuple $\bar{b}$ defines the sets g_i and h_i , and the trees T_i and U_i , rooted at x_i ; and a tuple $\bar{b}$ of length $n-2$ defines singleton subsets $\{t(\bar{b})\}$ of g_i and $\{u(\bar{b})\}$ of h_i . A tuple $\bar{b}$ of length $n-2$ also uniquely determines the digits $t(\bar{b})(i_{n-1})$ and $u(\bar{b})(i_{n-1})$, since we know that $\#1(t(\bar{b}))$ is even and $\#1(u(\bar{b}))$ is odd. Also, if $t(\bar{b})(i_{n-1}) = 1$, then $u(\bar{b})(i_{n-1}) = 0$, and if $t(\bar{b})(i_{n-1}) = 0$, then $u(\bar{b})(i_{n-1}) = 1$. Therefore, the map $t(\bar{b}) \rightarrow u(\bar{b})$ for all tuples of length at most $n-2$ extends the isomorphism between $G - g_{i_{n-1}}$ and $H - h_{i_{n-1}}$.

Let $\bar{b}$ be a tuple as above. Extending the notation $k(i \leftarrow 0)$ to $\bar{b}$, we define $\bar{b}(i \leftarrow 0)$ to be the tuple obtained by setting $b_i = 0$ in $\bar{b}$, and $\bar{b}(i \leftarrow 1)$ to be the tuple obtained by setting $b_i = 1$ in $\bar{b}$.

Let $\bar{b}$ be a tuple of length $n-2$ and $j \leq n-2$. By an argument as in the above paragraph, we have

1. if $t(\bar{b}(j \leftarrow 0))(i_{n-1}) = 1$, then $u(\bar{b}(j \leftarrow 1))(i_{n-1}) = 1$;
2. if $t(\bar{b}(j \leftarrow 0))(i_{n-1}) = 0$, then $u(\bar{b}(j \leftarrow 1))(i_{n-1}) = 0$;
3. if $t(\bar{b}(j \leftarrow 1))(i_{n-1}) = 1$, then $u(\bar{b}(j \leftarrow 0))(i_{n-1}) = 1$; and
4. if $t(\bar{b}(j \leftarrow 1))(i_{n-1}) = 0$, then $u(\bar{b}(j \leftarrow 0))(i_{n-1}) = 0$.

Therefore, for each $j, 1 \leq j \leq n-2$, the map defined by

1. $t(\bar{b}) \rightarrow u(\bar{b})$ for all tuples of length at most $j-1$,
2. $t(\bar{b}(j \leftarrow 0)) \rightarrow u(\bar{b}(j \leftarrow 1))$ for all tuples of length at least j , and
3. $t(\bar{b}(j \leftarrow 1)) \rightarrow u(\bar{b}(j \leftarrow 0))$ for all tuples of length at least j

extends the isomorphism between $G - g_j$ and $H - h_j$. Observe that this map sends the vertices in the left subtree $L(t(\bar{b}))$ in T_i to the vertices in the right subtree $R(u(\bar{b}))$ in U_i , and the vertices in the right subtree $R(t(\bar{b}))$ in T_i to the vertices in the left subtree $L(u(\bar{b}))$ in U_i , for each tuple $\bar{b}$ of length j . Since the trees T_i and T_j (and trees U_i and U_j) are disjoint except for their founders for all $i \neq j$, the isomorphism between

FIG. 2. Binary pedigrees T_5 and U_5 for $n = 5$.

$G - g_j$ and $H - h_j$ extends to an isomorphism between pedigrees $\mathcal{T}(X_0 \setminus \{x_j\})$ and $\mathcal{U}(X_0 \setminus \{x_j\})$ for all j .

An isomorphism between $G - g_{i_2}$ and $H - h_{i_2}$ that extends to an isomorphism between T_i and U_i , $i \neq i_2$, is schematically shown in Figure 3. $\square$

Remark 1. The pedigrees constructed above do not admit a valid gender labeling. That is, we cannot assign labels m (male) and f (female) to all vertices so that each vertex (except founders) has one male parent and one female parent. For example, in the $n = 3$ case, K_3 is not a bipartite graph, so a valid gender labeling is impossible.

FIG. 3. Isomorphism between $G - g_{i_2}$ and $H - h_{i_2}$ extends to an isomorphism between T_i and U_i .

But the examples can be easily modified to create nonreconstructible pedigrees that also admit valid gender labels. Each vertex in a pedigree constructed above may be duplicated, and one vertex may be treated male and the other female, as shown in Figure 4. At the bottom of the tree T_i (or U_i), the vertex x_i is duplicated as vertices x_i^m and x_i^f , and the new vertex x_i is a child of x_i^m and x_i^f .

Remark 2. Let $k, k' \in [2^n]$ be any two adjacent vertices on the hypercube. From (1), if $a(k) - b(k) = p > 0$ for some p , then $b(k') - a(k') = p$, regardless of which digit k and k' differ at. In fact, by connectivity of the hypercube, we have $a(r) - b(r) = p$ for all vertices $r \in [2^n]$ that are at even distance from k on the hypercube and $b(r) - a(r) = p$

FIG. 4. Construction of a pedigree with a valid gender labeling.

for all vertices $r \in [2^n]$ that are at odd distance from k on the hypercube. This further implies that the hypergraphs G and H constructed in the above counterexample have a special structure: for each $i, 1 \leq i \leq n$, $|g_i| = |h_i| \geq 2^{n-2}$. Let $G(d)$ be the hypergraph with edge set $\{g_i(d), 1 \leq i \leq n\}$, where $g_i(d)$ is the set of ancestors of x_i at depth d in the pedigree $\mathcal{T}(X_0)$, and let $H(d)$ and $h_i(d)$ be similarly defined for the pedigree $\mathcal{U}(X_0)$; then the hypergraphs $G(d)$ and $H(d)$ must be isomorphic whenever $d < n-2$.

We end this section with a conjecture motivated by the observations made in Remark 2.

CONJECTURE 1. *The counterexample constructed in Theorem 1 is minimal. In other words, if a pedigree $\mathcal{T}(X_0)$ of order n is not $(n-1)$ -reconstructible, then it has depth at least $n-2$, and there are at least 2^{n-1} ancestors at depth $n-2$.*

Remark 3. Let G and H be simple graphs with edge sets $E(G) = \{g_i, 1 \leq i \leq m\}$ and $E(H) = \{h_i, 1 \leq i \leq m\}$, respectively, such that $G - g_i \cong H - h_i$ for all $1 \leq i \leq m$. Then the edge reconstruction conjecture states that $G \cong H$ provided $m > 3$. The condition $m > 3$ is required since $K_{1,3}$ and K_3 —the graphs used as the base case of our construction of nonreconstructible pedigrees—are not *edge reconstructible*. Although no counterexamples are yet known, Nash-Williams [2] proved a characterization of (hypothetical) counterexamples to edge reconstruction. His characterization was based on a generalization of ideas earlier introduced by Lovász [1]. Without going into detail, we note that the counterexamples presented here have certain similarities to the characterization by Nash-Williams. It may be possible to exploit such similarities to prove Conjecture 1.

3. A positive reconstruction result. Let $\mathcal{T}(X_0)$ be a discrete generation pedigree on X_0 , where $|X_0| = n > 2$. Let $S_{n-1}(\mathcal{T}) = \{\mathcal{T}(Y) | Y \subset X_0, |Y| = n-1\}$. Consider the edge labeled (multi-) graph G_1 whose vertex set is X_1 (that is, the set

of vertices at depth 1), and vertices $x, y \in X_1$ are joined by an edge e_i if they are the parents of x_i .

LEMMA 1. *If there are vertices x_i and x_j in X_0 that have the same parents, then $\mathcal{T}(X_0)$ is uniquely determined by $S_{n-1}(\mathcal{T})$.*

Proof. The situation in the lemma is recognized by looking at $\mathcal{T}(X_0 \setminus x_k)$, where $x_k \notin \{x_i, x_j\}$. Now $\mathcal{T}(X_0)$ is uniquely obtained from $\mathcal{T}(X_0 \setminus x_i)$ by joining x_i to the parents of x_j . $\square$

LEMMA 2. *If $n > 3$ and if G_1 contains a cycle, then $\mathcal{T}(X_0)$ is uniquely determined by $S_{n-1}(\mathcal{T})$.*

Proof. Let e_i be an edge in a cycle in G_1 . The end vertices of e_i are the two parents of x_i . Since the set of half brothers of x_i is known from the collection S_{n-1} , the parents of x_i are uniquely recognized in $\mathcal{T}(X \setminus x_i)$. Note that we need the condition $n > 3$ because otherwise we would get a counterexample based on $G_1 \cong K_3$ or $G_1 \cong K_{1,3}$. $\square$

COROLLARY 1. *If $|X_1| \leq n$ and $n > 3$, then $S_{n-1}(\mathcal{T})$ determines $\mathcal{T}(X_0)$ up to congruence.*

Proof. If no two vertices in X_0 have the same two parents, then G_1 has n simple edges (that is, no two edges are parallel edges), and there is a cycle in G_1 . $\square$

We end this section with another conjecture.

CONJECTURE 2. *Discrete generation pedigrees of order n that have the same number of vertices in each generation are r -reconstructible for $r > \log n$.*

This conjecture is true if Conjecture 1 is true. For suppose that Conjecture 1 is true but Conjecture 2 is not true, and that there is a constant population size pedigree of order n that is not r -reconstructible for some $r > \log n$. Therefore, for some $r > \log n$, there is a subpedigree of order $r + 1$ that is not r -reconstructible. Such a subpedigree must have depth at least $r - 1$ and must have at least 2^r vertices at depth $r - 1$, implying that $r \leq \log n$. Thus, if $r > \log n$, then we have a contradiction; therefore, all subpedigrees of order $r + 1$ are r -reconstructible when $r > \log n$, and we can complete the reconstruction inductively.

Acknowledgments. I would like to thank Mike Steel for many useful conversations and for hosting me at the University of Canterbury. Oliver Will and Mike Steel read the manuscript carefully and made many helpful comments.

RESONANCE GRAPHS AND A BINARY CODING FOR THE 1-FACTORS OF BENZENOID SYSTEMS*

HEPING ZHANG[†], PETER CHE BOR LAM[‡], AND WAI CHEE SHIU[‡]

Abstract. Applying the recently obtained distributive lattice structure on the set of 1-factors, we show that the resonance graphs of any benzenoid systems G , as well as of general plane (weakly) elementary bipartite graphs, are median graphs and thus extend greatly Klavžar et al.'s result. The n -dimensional vectors of nonnegative integers as a labelling for the 1-factors of G with n inner faces are described. The labelling preserves the partial ordering of the above-mentioned lattice and can be transformed into a binary coding for the 1-factors. A simple criterion for such a labelling being binary is given. In particular, Klavžar et al.'s algorithm is modified to generate this binary coding for the 1-factors of a cata-condensed benzenoid system.

1. Introduction. A hexagonal system is a finite connected plane graph with no cut-vertices in which every interior region is bounded by a regular hexagon of side length 1. A hexagonal system with a 1-factor is regarded as a molecular graph (carbon-skeleton) of a benzenoid hydrocarbon. Hence these kinds of graphs are called *benzenoid systems* and have been extensively investigated; cf. a detailed review [23] due to Randić with the references therein. A benzenoid system is classified into two types: peri-condensed if it has an interior vertex and cata-condensed if it has none. For example, a well-known coronene is peri-condensed, while Dibenzo[a,c]anthracene is cata-condensed; both are illustrated in Figure 1.

A 1-factor or perfect matching M of a graph G is a set of pairwise nonadjacent edges (i.e., no two edges share a common endvertex) such that every vertex of G is incident with an edge in M . This graph-theoretical concept coincides with a Kekulé structure of chemical molecules. One research approach is to compute the number of Kekulé structures of a benzenoid system [5]. Another approach is to study individual Kekulé structures and relationships between them. For example, Gutman [10] and Gutman, Teodorović, and Kolaković [11] found different contributions of a leaf and a nonleaf in the tree structure on the set of 1-factors to the resonance energy of a benzenoid hydrocarbon and obtained a more accurate estimate for the resonance energy.

A graph was established on the set of 1-factors of a benzenoid system G : Every 1-factor of G is for a vertex, and a pair of 1-factors is for an edge if they can be transformed into each other by interchanging double and single bonds in an alternating hexagon. This new graph associated with a benzenoid system is called the

Z-transformation graph in mathematics by Zhang, Guo, and Chen [28] and the *resonance graph* in chemistry by Randić [22]. Chemical explanation for this concept can be found in [16, 22, 23]. In 1997, Randić [22] showed that the leading eigenvalues (λ) of the resonance graphs correlate with the resonance energy of benzenoids and gave a quite satisfactory regression formula.

For cata-condensed benzenoid systems with n hexagons, Chen and Zhang [2] discovered that the resonance graphs contain Hamilton paths, which can be generated by an algorithm [15]; Randić [22, 23] and Randić et al. [24] showed that some of the resonance graphs can be constructed by proposing a procedure and embedded in n -dimensional Cartesian coordinate grids; Klavžar, Žigert, and Brinkmann [17] proved that the resonance graphs are median graphs. As applications of the latter result, the resonance graphs of cata-condensed benzenoid systems can be isometrically embedded in hypercubes; an algorithm was designed [16] to give each 1-factor a sequence of ones and zeros with length n as a binary coding; a simple method was used to determine the Clar number [18].

Benzenoid systems are a kind of weakly-elementary plane bipartite graphs. In addition, the molecular graphs of most alternate compounds are also plane bipartite graphs. For example, a *coronoid* [4] is a connected subgraph of a hexagonal system such that every edge belongs to at least one hexagon and it contains at least one nonhexagonal interior face (called a corona hole); a boron-nitride (BN) fullerene [3, 8] is a cubic graph embedded on the surface of a sphere so that all faces are (exactly 6) squares and hexagons; see Figure 2. As a unified framework, the resonance graph has already been extended [30, 31, 32] in a natural way on the set of 1-factors of a plane bipartite graph. It was independently shown [7, 33] that the resonance graph of a plane bipartite graph G is connected if and only if G is weakly elementary.

The acyclic orientation of the resonance graph not only enables one to prove [31] that the block graph of the resonance graph of a plane (weakly) elementary bipartite graph G is a path, but also implies a partial ordering on the set of 1-factors of G . Lam and Zhang [20], two of the present authors, showed that this poset associated

with G is a finite distributive lattice by embedding it into an n -dimensional Cartesian coordinate grid with the usual partial ordering, where n is the number of inner faces of G , which implies that each 1-factor is assigned a sequence of nonnegative integers with length n as its labelling.

As applications of the above distributive lattice on the set of 1-factors, in this paper we mainly prove that all connected resonance graphs are median graphs and thus give a significant extension to Klavžar et al.'s result (see Klavžar, Vesel, and Žigert [15], Klavžar et al. [16], Klavžar, Žigert, and Brinkmann [17], Klavžar, Žigert, and Gutman [18]), and we further investigate the labelling for the 1-factors that preserves partial ordering. In the next section, we will introduce the distributive lattice with labelling and give a procedure for generating them. In section 3, by the established distributive lattice structure and the developed techniques, we show that the resonance graph of a plane weakly-elementary bipartite graph is a median graph. In section 4, we give a criterion that such a labelling is a binary coding for all 1-factors of a benzenoid system: it has no coronene as its nice subgraph. In general, the labelling can be transformed into a binary coding so that its length is the diameter of the resonance graph. In section 5, a simple algorithm is designed for generating the binary coding for the 1-factors of a cata-condensed benzenoid system, without producing 1-factors. We conclude this paper with two open problems.

2. Preliminaries and distributive lattices. We now introduce some concepts and notations. A *bipartite* graph means a graph for which every vertex is colored by white or black so that two adjacent vertices receive different colors; such a 2-coloring (white-black) is always given. A bipartite graph G is called *elementary* if G is connected and every edge belongs to a 1-factor of G . For example, coronene, cata-condensed benzenoid systems and boron-nitride fullerenes are plane elementary bipartite graphs.

Let G be a plane bipartite graph with a 1-factor M . A cycle C is *M -alternating* if the edges of C appear alternately in and off the M . An M -alternating cycle C of G is said to be *proper* (*improper*) [30] if every edge of C belonging to M goes from white (black) endvertex to black (white) endvertex by the clockwise orientation of C .

THEOREM 2.1 (see [32]). *A nontrivial plane bipartite graph is elementary if and only if every face is resonant, i.e., every facial boundary is an alternating cycle with some 1-factor.*

Elementary components of G mean components of the subgraph obtained from G by removing all fixed single edges (those edges not contained in any 1-factors). G is called *weakly elementary* [19, 25, 32] if every inner face of every elementary component of G is still a face of the original G . For instance, benzenoid systems are these kinds of graphs.

The symmetry difference of finite sets A and B is defined as $A \oplus B := (A \cup B) \setminus (A \cap B)$. This operation can be defined among many finite sets in a natural way and is associative and commutative. If C is an M -alternating cycle of G , then $M \oplus C$ is also a 1-factor, where C may be regarded as its edge-set. It is obvious that a cycle C is proper M -alternating if and only if it is improper $M \oplus C$ -alternating. For two 1-factors M and M' of G , $M \oplus M'$ consists of pairwise disjoint M and M' -alternating cycles of G .

A partially ordered set (poset) is a set P with a binary relation $\preceq$ satisfying the reflexivity, antisymmetry, and transitivity. If $x, y \in P$, then we say y covers x if $x \prec y$ and no element z satisfies $x \prec z \prec y$. A poset $(P, \preceq)$ is determined by its covering relation and often denoted by the Hasse diagram. A one-to-one mapping ϕ from P_1 to

FIG. 3. Pyrene G , 1-factors M_1 to M_6 , and Z-transformation digraph $\vec{Z}(G)$.

P_2 is an embedding of lattice $(P_1; \vee, \wedge)$ into lattice $(P_2; \vee, \wedge)$ if $\phi(x \vee y) = \phi(x) \vee \phi(y)$ and $\phi(x \wedge y) = \phi(x) \wedge \phi(y)$ for any x and y in P_1 . Other terms on posets and lattices used in this paper can be found in [1, 9, 26].

Let G be a plane bipartite graph with a 1-factor. Let $\mathcal{M}(G)$ denote the set of all 1-factors of G and $\mathcal{F}$ the set of all inner faces of G . The *Z-transformation digraph* or *resonance digraph*, denoted by $\vec{Z}(G)$, of 1-factors of G is defined as a digraph on $\mathcal{M}(G)$ such that there exists an arc from M_1 to M_2 provided that $M_1 \oplus M_2$ is a proper M_1 - (thus improper M_2 -) alternating cycle that is an inner facial boundary of G . Ignoring all directions of arcs of $\vec{Z}(G)$, we get the usual Z-transformation graph or resonance graph, denoted by $Z(G)$.

For example, the Z-transformation digraph of pyrene is constructed in Figure 3. Note that a benzenoid system considered is always drawn so that an edge-direction is vertical and the peaks are colored black (see Figure 1). Accordingly, a proper and an improper alternating hexagon with respect to a 1-factor are the usual proper and improper *sextet*, respectively.

The property that $\vec{Z}(G)$ has no directed cycle implies a partial ordering: $M_1 \preceq M_2$, $M_1, M_2 \in \mathcal{M}(G)$, if and only if $\vec{Z}(G)$ has a directed path from M_2 to M_1 . Then $(\mathcal{M}(G), \preceq)$ is a poset. From now on we simply denote it by $\mathcal{M}(G)$.

THEOREM 2.2 (see [20, 29]). *For a plane bipartite graph G , $\vec{Z}(G)$ is the Hasse diagram of $\mathcal{M}(G)$.*

The plane bipartite graph G has a unique 1-factor M_0 such that G has no proper M_0 -alternating cycles [30]. Then M_0 is a minimal element of the poset $\mathcal{M}(G)$ and called the *root 1-factor* of G . Likely, G has a unique 1-factor M_1 such that G has no improper M_1 -alternating cycles. For each $M \in \mathcal{M}(G)$, we define a *function* ϕ_M on $\mathcal{F}$ as follows: For any $f \in \mathcal{F}$, $\phi_M(f)$ is the number of cycles in $M \oplus M_0$ with f in their interiors. In fact, such cycles are all proper M -alternating and pairwise disjoint if they exist. In particular, ϕ_{M_0} is constantly zero, i.e., every value on the inner faces is 0.

For example, we consider 1-factors M_0 (left) and M_1 (middle) of the coronene in Figure 4. Since $M_1 \oplus M_0$ consists of two proper M_1 -alternating cycles—the boundary and the central hexagon of the coronene (see the rightmost diagram in Figure 4), ϕ_{M_1} is easily computed and represented by the integers indicated in hexagons. As for the pyrene (see Figure 3), the functions ϕ_M of 1-factors $M_1, \dots, M_6$ are denoted, respectively, by 1111, 1101, 1100, 1001, 1000, 0000 in such an order of hexagons: h_1, h_2, h_3, h_4 .

$\mathbb{Z}^+ = \{0, 1, 2, \dots\}$ is a linear order with the usual order. $(\mathbb{Z}^+)^{\mathcal{F}}$ is the Cartesian product of $|\mathcal{F}|$ copies of $\mathbb{Z}^+$; each one is indexed by an inner face in $\mathcal{F}$. That is, $(\mathbb{Z}^+)^{\mathcal{F}} = \{(a_1, a_2, \dots, a_{|\mathcal{F}|}) : \text{each } a_i \in \mathbb{Z}^+ \text{ is indexed by the } i\text{th inner face in } \mathcal{F}\}$. It

 FIG. 4. Examples of function ϕ_M for the coronene.

is well known that $(\mathbb{Z}^+)^{\mathcal{F}}$ is an infinite distributive lattice under the usual partial ordering (i.e., for $a, b \in (\mathbb{Z}^+)^{\mathcal{F}}$, $a \leq b$ if and only if $(a)_i \leq (b)_i$ for each $i \in \mathcal{F}$).

In the following, we are given a plane (weakly) elementary bipartite graph G . Each function ϕ_M can be regarded as a vector $\phi_M(\mathcal{F})$ in $(\mathbb{Z}^+)^{\mathcal{F}}$. It was shown in [20] that $\phi : M \mapsto \phi_M$ defines an isomorphism between the poset $\mathcal{M}(G)$ and $\phi(\mathcal{M}(G))$, and the latter is a sublattice of $(\mathbb{Z}^+)^{\mathcal{F}}$.

THEOREM 2.3 (see [20]). *Let G be a plane (weakly) elementary bipartite graph. Then $\mathcal{M}(G)$ is a finite distributive lattice.*

The embedding ϕ of $\mathcal{M}(G)$ into $(\mathbb{Z}^+)^{\mathcal{F}}$ not only enables one to prove the above result, but also gives a labelling for all 1-factors of G . We now turn to discussing a generation of $\mathcal{M}(G)$ with such a labelling.

In obtaining Theorem 2.3, *unit region* and *unit decomposition* of a cycle system $M \oplus M'$ each play a crucial role. For convenience, we now introduce an equivalent form. For $M, M' \in \mathcal{M}(G)$, $\mathcal{C} := M \oplus M'$ consists of pairwise disjoint M and M' -alternating cycles. Let $\psi_{MM'}(f)$ be the number of proper M -alternating cycles in $\mathcal{C}$ with f in their interiors minus the number of improper M -alternating cycles in $\mathcal{C}$ with f in their interiors.

In a sense that $\psi_{MM'}(f)$ here may be allowed to be negative, it is slightly different from the original definition. Accordingly, by Lemmas 4.1 and 4.7 in [20], a relation among the functions $\phi_M, \phi_{M'}$, and $\psi_{MM'}$ can be expressed as follows.

LEMMA 2.4. *For $M, M' \in \mathcal{M}(G)$, $\phi_M - \phi_{M'} = \psi_{MM'}$.*

From the lemma, as a special case we immediately arrive at the following result, which will play an important role in the rest of this paper.

LEMMA 2.5. *For $M, M' \in \mathcal{M}(G)$, M covers M' if and only if $\phi_M(f) - \phi_{M'}(f) = 1$ for $f = f_0$, where f_0 is an inner face bounded by the cycle $M \oplus M'$, and 0 for the other faces in $\mathcal{F}$.*

Based on Theorems 2.2 and 2.3, we can give a generation procedure of lattice $\mathcal{M}(G)$. The main principle is the well-known Jordan–Dedekind theorem in finite distributive lattices: all maximal chains between a pair of elements have the same length. That is, all directed paths between any pair of vertices $\vec{Z}(G)$ are of the same length whenever they exist. Further, Lemma 2.5 also enables one to give the embedding ϕ of $\mathcal{M}(G)$ into $(\mathbb{Z}^+)^{\mathcal{F}}$.

We now describe an outline. First, construct the root 1-factor M_0 and let $\phi_{M_0} \equiv 0$. The inductive procedure is as follows: Suppose that a 1-factor M and its labelling ϕ_M have been already given. For each improper M -alternating face f_0 , $M \oplus f_0$ is another 1-factor covering M , while $\phi_{M \oplus f_0}(f_0) = \phi_M(f_0) + 1$ and the others remain unchanged. Note in the $M \oplus f_0$ operation, f_0 is always regarded as the set of edges bounding the face. A detailed procedure is given as follows.

ALGORITHM 2.6. Input: *A benzenoid system or plane weakly-elementary bipartite graph G .*

Output: *Lattice $\mathcal{M}$, and labelling list L for all 1-factors of G .*

FIG. 5. The coronene and the distributive lattice on the 1-factors with labelling.

Step 0. Set $\mathcal{M} := \emptyset, L := \emptyset$, and $i = 0$; construct the root 1-factor M of G and set $S_i := \{M\}$ and $\phi_M \equiv 0$.

Step 1. Set $\mathcal{M} := \mathcal{M} \cup S_i, L := L \cup \{\phi_M : M \in S_i\}$.

Step 2. If S_i has exactly one element M and there is no improper M -alternating face, stop.

Step 3. Set $S_{i+1} := \{M \oplus f_0 : M \in S_i, f_0 \text{ is an improper } M\text{-alternating face of } G\}$. For each $M \oplus f_0$ in S_{i+1} ($M \oplus f_0$ covers M), compute $\phi_{M \oplus f_0} : \phi_{M \oplus f_0}(f_0) := \phi_M(f_0) + 1$ and $\phi_{M \oplus f_0}(f) := \phi_M(f)$ for the other faces f in $\mathcal{F}$.

Step 4. Set $i := i + 1$, then go to step 1.

When this algorithm stops, it also gives the height of $\mathcal{M}(G)$ (it is equal to the diameter of the resonance graph of G ; see Corollary 3.5). In fact, S_i consists of all 1-factors with height i . As for step 0, the root 1-factor can be obtained in the following way: First, find any 1-factor of G with the Hungarian algorithm, then repeatedly twist proper alternating inner faces. Finally, we arrive at the root 1-factor. This procedure can be completed in $O(n^2)$ steps, where n is the number of inner faces of G . This is because [29] the height is no more than $\lceil \frac{n(n+2)}{4} \rceil$.

For example, we now implement Algorithm 2.6 to the coronene. The enumeration $h_1, \dots, h_7$ of its hexagons and the root 1-factor are referred to in Figure 5 (left). When we accomplish the algorithm, the distributive lattice associated with the coronene is produced in Figure 5 (right). For convenience, all of the 1-factors are replaced with their labels. For example, 0000000 corresponds to the root 1-factor, while 1111112 represents the maximum element $M_{\hat{1}}$. In general, the following result shows that such a label can determine uniquely a 1-factor.

PROPOSITION 2.7. For any given ϕ_M , let $\phi_M \cdot \mathcal{F} := \bigoplus_{f \in \mathcal{F}} \phi_M(f)f$. Then

$$(1) \quad M = M_{\hat{0}} \oplus (\phi_M \cdot \mathcal{F}).$$

Proof. $\mathcal{M}(G)$ has a sequence $M_t (= M) \cdots M_0 (= M_{\hat{0}})$ such that each M_i covers

M_{i-1} for $1 \leq i \leq t$. By Lemma 2.5, $M_i \oplus M_{i-1}$ is a proper M_i -alternating face f_i and $\phi_{M_i}(f) - \phi_{M_{i-1}}(f) = 1$ if $f = f_i$, 0, otherwise. That is, $M_i \oplus M_{i-1} = \bigoplus_{f \in \mathcal{F}} (\phi_{M_i}(f) - \phi_{M_{i-1}}(f))f = (\phi_{M_i} - \phi_{M_{i-1}}) \cdot \mathcal{F}$. Hence $M \oplus M_0 = \bigoplus_{i=1}^t (M_i \oplus M_{i-1}) = \bigoplus_{i=1}^t (\phi_{M_i} - \phi_{M_{i-1}}) \cdot \mathcal{F} = \sum_{i=1}^t (\phi_{M_i} - \phi_{M_{i-1}}) \cdot \mathcal{F} = \phi_M \cdot \mathcal{F}$. Here the symmetry difference agrees with addition module 2 and every face $f \in \mathcal{F}$ can be always regarded as the set of edges bounding it. $\square$

Given two labels 1111112 and 1111111, for example, we shall determine their corresponding 1-factors of coronene. For the former, $M_0 \oplus (h_1 \oplus h_2 \oplus h_3 \oplus h_4 \oplus h_5 \oplus h_6 \oplus 2h_7) = M_0 \oplus (h_1 \oplus h_2 \oplus h_3 \oplus h_4 \oplus h_5 \oplus h_6) = M_0 \oplus (C \oplus h_7) = M_1$, where C denotes the boundary of the coronene. For the latter, $M_0 \oplus (h_1 \oplus h_2 \oplus h_3 \oplus h_4 \oplus h_5 \oplus h_6 \oplus h_7) = M_1 \oplus h_7$.

3. Median graph. Klavžar, Žigert, and Brinkmann [17] showed that the resonance graphs of cata-condensed benzenoid systems, or a subclass of bipartite outplane graphs, are median graphs. By the established distributive lattices and the developed techniques, we now show that the above results hold generally for benzenoid systems, or more general, plane weakly-elementary bipartite graphs G .

Given a connected graph H with vertices u and v , the *interval* $I_H(u, v)$ (or simply $I(u, v)$) between u and v consists of all vertices on shortest paths between u and v . A *median* of vertices u, v , and w is a vertex that lies in $I(u, v) \cap I(u, w) \cap I(v, w)$. A graph is called a *median graph* if every triple of its vertices has a unique median (cf. [12]). We now give the main result of this section as follows.

THEOREM 3.1. *The resonance graph of a plane weakly-elementary bipartite graph G is a median graph.*

To prove the theorem we first give three explicit formulae on distance $d_{Z(G)}(M, M')$, the length of a shortest path between a pair of vertices M and M' , in the resonance graph $Z(G)$.

THEOREM 3.2 (distance formula 1). $d_{Z(G)}(M, M') = \sum_{f \in \mathcal{F}} |\phi_M(f) - \phi_{M'}(f)|$.

Proof. Let $P = M_0 (= M)M_1 \cdots M_t (= M')$ be a path in $Z(G)$ between M and M' . Then the length

$$\begin{aligned} l(P) &= t = \sum_{i=0}^{t-1} \sum_{f \in \mathcal{F}} |\phi_{M_{i+1}}(f) - \phi_{M_i}(f)| \quad (\text{by Lemma 2.5}) \\ &= \sum_{f \in \mathcal{F}} \sum_{i=0}^{t-1} |\phi_{M_{i+1}}(f) - \phi_{M_i}(f)| \\ (2) \quad &\geq \sum_{f \in \mathcal{F}} |\sum_{i=0}^{t-1} (\phi_{M_{i+1}}(f) - \phi_{M_i}(f))| \\ &= \sum_{f \in \mathcal{F}} |\phi_M(f) - \phi_{M'}(f)|. \end{aligned}$$

We now choose a special path $P_* := N_s (= M) \cdots N_1 N_0 N_{-1} \cdots N_{-s'} (= M')$ through the *meet* $N_0 := M \wedge M'$ such that N_i covers N_{i-1} and N_{-j} covers $N_{-(j-1)}$ for all $s \geq i \geq 1$ and $s' \geq j \geq 1$. Recall that $\phi : \mathcal{M}(G) \rightarrow \phi(\mathcal{M}(G))$ is an isomorphism and $\phi(\mathcal{M}(G))$ is a sublattice of $(\mathbb{Z}^+)^{\mathcal{F}}$. Then $\phi_{N_0} = \phi_{M \wedge M'} = \phi_M \wedge \phi_{M'}$, and $\phi_{N_0}(f) = \min(\phi_M(f), \phi_{M'}(f))$ for each $f \in \mathcal{F}$. Hence by Lemma 2.5 and similar arguments as above (2) we have that

$$\begin{aligned} l(P_*) &= s + s' = \sum_{f \in \mathcal{F}} (\phi_M(f) - \phi_{N_0}(f)) + \sum_{f \in \mathcal{F}} (\phi_{M'}(f) - \phi_{N_0}(f)) \\ &= \sum_{f \in \mathcal{F}} (\phi_M(f) + \phi_{M'}(f) - 2\phi_{N_0}(f)) \\ (3) \quad &= \sum_{f \in \mathcal{F}} \{\phi_M(f) + \phi_{M'}(f) - 2\min(\phi_M(f), \phi_{M'}(f))\} \\ &= \sum_{f \in \mathcal{F}} |\phi_M(f) - \phi_{M'}(f)| \\ &\leq l(P). \end{aligned}$$

This implies that P_* is a shortest path of $Z(G)$ and therefore the theorem holds. $\square$

The above distance formula shows that the embedding $\phi : \mathcal{M}(G) \rightarrow (\mathbb{Z}^+)^{\mathcal{F}}$ is also distance-preserving.

COROLLARY 3.3 (distance formula 2). $d_{Z(G)}(M, M') = d_{Z(G)}(M \vee M', M \wedge M')$.

Proof. By Theorem 3.2 we have that

$$\begin{aligned}
 & d_{Z(G)}(M \vee M', M \wedge M') \\
 &= \sum_{f \in \mathcal{F}} \{ \phi_{M \vee M'}(f) - \phi_{M \wedge M'}(f) \} \\
 (4) \quad &= \sum_{f \in \mathcal{F}} \{ \max(\phi_M(f), \phi_{M'}(f)) - \min(\phi_M(f), \phi_{M'}(f)) \} \\
 &= \sum_{f \in \mathcal{F}} |\phi_M(f) - \phi_{M'}(f)| = d_{Z(G)}(M, M'). \quad \square
 \end{aligned}$$

Combining Lemma 2.4 with Theorem 3.2, we have the following third formula.

COROLLARY 3.4 (distance formula 3). $d_{Z(G)}(M, M') = \sum_{f \in \mathcal{F}} |\psi_{MM'}(f)|$.

The *height* (or *rank*) of $\mathcal{M}(G)$ is the length of a maximal chain between the greatest and least elements, that is, the length of a directed path of $\vec{Z}(G)$ from the source to sink. Corollary 3.3 shows that $d_{Z(G)}(M_0, M_1)$ is the diameter (i.e., the largest distance between all pairs of vertices) of $Z(G)$. So we have the following result.

COROLLARY 3.5. *The diameter of $Z(G)$ is equal to the height of $\mathcal{M}(G)$.*

LEMMA 3.6. *For any $M_1, M_2 \in \mathcal{M}(G)$, $I_{Z(G)}(M_1, M_2) = I_{\mathcal{M}(G)}(M_1 \vee M_2, M_1 \wedge M_2)$.*

Proof. For any $M \in \mathcal{M}(G)$, by Theorem 3.2 we have that

$$\begin{aligned}
 d_{Z(G)}(M_1, M_2) &= \sum_{f \in \mathcal{F}} |\phi_{M_1}(f) - \phi_{M_2}(f)| \\
 &= \sum_{f \in \mathcal{F}} |(\phi_{M_1}(f) - \phi_M(f)) + (\phi_M(f) - \phi_{M_2}(f))| \\
 (5) \quad &\leq \sum_{f \in \mathcal{F}} \{ |\phi_{M_1}(f) - \phi_M(f)| + |\phi_M(f) - \phi_{M_2}(f)| \} \\
 &= \sum_{f \in \mathcal{F}} |\phi_{M_1}(f) - \phi_M(f)| + \sum_{f \in \mathcal{F}} |\phi_M(f) - \phi_{M_2}(f)| \\
 &= d_{Z(G)}(M_1, M) + d_{Z(G)}(M, M_2).
 \end{aligned}$$

Then $M \in I_{Z(G)}(M_1, M_2) \iff$ for all f , $\phi_{M_1}(f) - \phi_M(f)$ and $\phi_M(f) - \phi_{M_2}(f)$ have the same sign $\iff$ for all f , $\min(\phi_{M_1}(f), \phi_{M_2}(f)) \leq \phi_M(f) \leq \max(\phi_{M_1}(f), \phi_{M_2}(f)) \iff \phi_{M_1 \wedge M_2} \leq \phi_M \leq \phi_{M_1 \vee M_2} \iff M_1 \wedge M_2 \preceq M \preceq M_1 \vee M_2$. $\square$

Proof of Theorem 3.1. It is sufficient to show that any triple of 1-factors M_1, M_2 , and M_3 in $\mathcal{M}(G)$ have a unique median. If M_1, M_2 , and M_3 have a median M_0 , then by Lemma 3.6 we have that $M_1 \wedge M_2 \preceq M_0 \preceq M_1 \vee M_2$, $M_2 \wedge M_3 \preceq M_0 \preceq M_2 \vee M_3$ and $M_1 \wedge M_3 \preceq M_0 \preceq M_1 \vee M_3$, which imply that

$$(6) \quad (M_1 \wedge M_2) \vee (M_2 \wedge M_3) \vee (M_1 \wedge M_3) \preceq M_0 \preceq (M_1 \vee M_2) \wedge (M_2 \vee M_3) \wedge (M_1 \vee M_3).$$

Since $\mathcal{M}(G)$ is a distributive lattice (Theorem 2.3), by [1, Theorem 8, Chapter 2] both equalities in (6) hold. This also implies that $(M_1 \wedge M_2) \vee (M_2 \wedge M_3) \vee (M_1 \wedge M_3)$ is a unique median of M_1, M_2 , and M_3 . $\square$

4. Binary coding for the 1-factors. Theorem 3.1 shows that any connected resonance graph is a median graph. Hence it can be isometrically embedded into hypercubes [12]. That is, every 1-factor can be assigned a 0,1-sequence (binary coding) of a given length so that the distance between two 1-factors is equal to the number

of positions for which both of the corresponding sequences differ. In this section, we first give a criterion when ϕ_M itself is such a binary coding for all 1-factors M of a benzenoid system, or a plane weakly-elementary bipartite graph. Then, in a general situation we show how ϕ can be transformed into a binary coding.

Let G be a plane bipartite graph with a 1-factor. A subgraph H of G is said to be *nice* if $G - V(H)$ has a 1-factor. A set S of pairwise disjoint inner faces of G is called a *resonant pattern* of G if G has a 1-factor M such that the boundary of each face in S is an M -alternating cycle. Let $c(G)$ and $k(G)$ denote the numbers of resonant patterns and 1-factors of G , respectively.

LEMMA 4.1 (see [13, 25]). *Let G be a plane bipartite graph with a 1-factor. Then $c(G) \leq k(G)$, and equality holds if and only if G is weakly elementary and for any pair of disjoint cycles that form a nice subgraph, their interiors are disjoint.*

LEMMA 4.2 (see [27]). *For a benzenoid system G , $c(G) = k(G)$ if and only if G has no coronene as its nice subgraph.*

THEOREM 4.3. *Let G be a plane weakly-elementary bipartite graph. Then ϕ is an embedding of $\mathcal{M}(G)$ into $\{0, 1\}^{\mathcal{F}}$ if and only if $c(G) = k(G)$; equivalently, for any pair of disjoint cycles that form a nice subgraph their interiors are disjoint.*

Proof. If $\phi_M(f) \geq 2$ for some $M \in \mathcal{M}(G)$ and $f \in \mathcal{F}$, then there exist two disjoint proper M -alternating cycles C_1 and C_2 such that f lies in both interiors of C_1 and C_2 . Conversely, suppose that G has a 1-factor M and a pair of disjoint proper M -alternating cycles C_1 and C_2 such that the interior of C_1 is contained in the interior of C_2 . Then $M' := M \oplus C_1 \oplus C_2 \in \mathcal{M}(G)$. Since $M \oplus M' = C_1 \cup C_2$, and both C_1 and C_2 are proper M and improper M' -alternating cycles, $\psi_{MM'}(f) = 2$ for any inner face f of G contained in the interior of C_1 . By Lemma 2.4, $\phi_M(f) - \phi_{M'}(f) = \psi_{MM'}(f) = 2$. This implies that $\phi_M(f) \geq 2$. Further, the other equivalency is implied by Lemma 4.1. $\square$

The following result is an immediate consequence of Lemma 4.2 and Theorem 4.3.

COROLLARY 4.4. *Let G be a benzenoid system. Then ϕ is an embedding of $\mathcal{M}(G)$ into $\{0, 1\}^{\mathcal{F}}$ if and only if G has no coronene as its nice subgraph.*

COROLLARY 4.5. *Let G be a benzenoid system. If G has no coronene as its nice subgraph, then the height of $\mathcal{M}(G)$ is equal to the number of resonant hexagons of G .*

Proof. Recall that M_1 is the maximum element of $\mathcal{M}(G)$. Then by distance formula 1 the height $d = \sum_{f \in \mathcal{F}} \phi_{M_1}(f)$. Since G has no coronene as its nice subgraph, by Corollary 4.4 $\phi_{M_1}(f) = 0$ or 1 for each $f \in \mathcal{F}$. For a resonant hexagon h , there exists a 1-factor M such that h is proper M -alternating. Further, by Lemma 2.5 we have that $\phi_M(h) - \phi_{M'}(h) = 1$, where $M' := M \oplus h$, which implies that $1 \leq \phi_M(h) \leq \phi_{M_1}(h) \leq 1$. Hence $\phi_{M_1}(h) = 1$. But for a nonresonant hexagon h , the $\phi_M(h)$ remain unchanged (zero). Hence d is equal to the number of resonant hexagons of G . $\square$

We have already given a criterion that every ϕ_M is a binary coding of M . In a general situation we show how ϕ can be transformed into an embedding $\bar{\phi}$ of $\mathcal{M}(G)$ into Boolean algebra $B_d = \{0, 1\}^d$, where $d = \sum_{f \in \mathcal{F}} \phi_{M_1}(f)$. In fact such an embedding gives a binary coding of length d for all 1-factors of G .

For each $M \in \mathcal{M}(G)$, the function ϕ_M on $\mathcal{F}$ is naturally transformed into the function $\bar{\phi}_M$ on $\mathcal{F}$ as follows: For each $f \in \mathcal{F}$, $\bar{\phi}_M(f)$ is a sequence of length $\phi_{M_1}(f)$ such that the first $\phi_M(f)$ positions from the left side are all placed 1 and the others 0. Since $0 \leq \phi_M(f) \leq \phi_{M_1}(f)$, $\bar{\phi}_M(f)$ is well defined. For the coronene, for example, $\phi_{M_1}(h_7) = 2$ and $\phi_{M_1}(h_i) = 1 (1 \leq i \leq 6)$. Then $\bar{\phi}_{M_1}(h_7) = 11$ and $\bar{\phi}_{M_1}(h_i) = 1 (1 \leq i \leq 6)$ (see Figure 6); while for 1-factor M with $\phi_M = 1111111$, $\bar{\phi}_M(h_7) = 10$ and $\bar{\phi}_M(h_i) = 1 (1 \leq i \leq 6)$.

FIG. 6. The transformation of ϕ_M into a binary coding $\bar{\phi}_M$.

FIG. 7. Proper and improper positions of a hexagon.

The following result follows immediately from the property of distance-preserving embedding ϕ .

THEOREM 4.6. $\bar{\phi} : \mathcal{M}(G) \rightarrow \{0, 1\}^d$ is a distance-preserving embedding, where d is the height of $\mathcal{M}(G)$.

5. An algorithm. For a cata-condensed benzenoid system G with d hexagons, there are 2^d different ways by which the resonance graph can be isometrically embedded into a d -hypercube; for example, [15, 16] gave different binary codings. In fact such embeddings are all equivalent under the sense that they can be transformed into each other by permutating the coordinates; though, only ϕ is both order-preserving and distance-preserving embedding. In general, Algorithm 2.6 gives a generation procedure for all ϕ_M . For this special case, we now design a simpler algorithm by modifying Klavžar et al.'s method [16].

If $d \geq 2$, then G has a hexagon that shares exactly one edge with the remainder of G when removing the hexagon. This hexagon corresponds to a monovalency vertex of its inner dual graph (tree). Hence G has a sequence of hexagons $h_1, h_2, \dots, h_d$, so that each h_j shares one edge (say e_j) with exactly one hexagon (say $h_{a(j)}$) of $h_1, \dots, h_{j-1}$. We call it a *normal* sequence of hexagons of G .

For a given hexagon, the three thick edges in Figure 7 are said to be in *proper* positions, the other thin edges in *improper* positions. So the common edge of two adjacent hexagons is in a proper position of one hexagon and in an improper position of the other one.

ALGORITHM 5.1. Input: A cata-condensed benzenoid system G with a normal sequence of hexagons $h_1, h_2, \dots, h_d$ ($d \geq 1$).

Output: A binary coding ϕ for all 1-factors of G : L_d .

Step 0. $i := 1, L_i := \{0, 1\}$.

Step 1. If $i = d$, stop.

Step 2. Let e_{i+1} be the common edge of h_{i+1} with one (say $h_{a(i+1)}$) of $h_1, \dots, h_i$. If e_{i+1} lies in a proper position of $h_{a(i+1)}$, then set $L_{i+1} := \{x0 : x \in L_i\} \cup \{x1 : x \in L_i \text{ and } (x)_{a(i+1)} = 1\}$; otherwise, set $L_{i+1} := \{x1 : x \in L_i\} \cup \{x0 : x \in L_i \text{ and } (x)_{a(i+1)} = 0\}$.

Step 3. $i := i + 1$, go to step 1.

As an example, we implement the algorithm to Dibenz[a,c]anthracene. For a given normal sequence of hexagons $h_1, \dots, h_5$ (see Figure 8), e_2 and e_3 are in proper

FIG. 8. An example for implementing Algorithm 5.1.

FIG. 9. Illustration for the proof of Theorem 5.2.

positions of h_1 and h_2 respectively; both e_4 and e_5 are in improper positions of h_3 . Figure 8 illustrates a process of implementing Algorithm 5.1. The binary coding for all of the 1-factors of Dibenz[a,c]anthracene with lattice structure is denoted in the last one. The following theorem gives the correctness of this algorithm.

THEOREM 5.2. *Algorithm 5.1 determines the binary coding ϕ_M for all 1-factors M of a cata-condensed benzenoid system G .*

Proof. We proceed by induction on the number d of hexagons of G . If $d = 1$, it is trivial because 1 and 0 correspond to two 1-factors entirely lying in the proper and improper positions of h_1 , respectively (see Figure 7).

From now on we suppose that $d \geq 2$. Recall that e_d is the common edge of h_d and some hexagon $h_{a(d)}$. Then $P := h_d - e_d$ is a path of length 5, denoted by $v_1 v_2 \cdots v_6$. Let G' be the graph obtained from G by removing the hexagon h_d , i.e., $G' = G - \{v_2, v_3, v_4, v_5\}$; see Figure 9. Then G' has a normal sequence $h_1, \dots, h_{d-1}$ of hexagons. We claim that the restrictions of all ϕ_M on the hexagons $h_1, \dots, h_{d-1}$ become the coding $\phi_{\widetilde{M}}$ for all 1-factors $\widetilde{M}$ of G' .

Let $\mathcal{M}_0 := \{M \in \mathcal{M}(G) : \{v_2 v_3, v_4 v_5\} \subseteq M\}$. For each $M \in \mathcal{M}_0$, $\widetilde{M} := M \setminus \{v_2 v_3, v_4 v_5\}$ is a 1-factor of G' . This naturally produces a one-to-one correspondence from the 1-factors in $\mathcal{M}_0$ to the 1-factors of G' . For any $M \in \mathcal{M}(G) \setminus \mathcal{M}_0$, $\{v_1 v_2, v_3 v_4, v_5 v_6\} \subseteq M$ and $M \oplus h_d \in \mathcal{M}_0$; by Lemma 2.5 $\phi_M(h_i) = \phi_{M \oplus h_d}(h_i)$ for all $1 \leq i \leq d-1$. Hence the above claim means that

$$(7) \quad \phi_M(h_i) = \phi_{\widetilde{M}}(h_i) \text{ for all } 1 \leq i \leq d-1 \text{ and for all } M \in \mathcal{M}_0.$$

Let $\widetilde{M}_0$ denote the minimum element of $\mathcal{M}(G')$. It follows that $\phi_{\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\}}(h_i) = \phi_{\widetilde{M}_0}(h_i) = 0$ for all $1 \leq i \leq d-1$. If $M_0 = \widetilde{M}_0 \cup \{v_2v_3, v_4v_5\}$, it is trivial. Otherwise, every cycle in $M_0 \oplus (\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\})$ is improper M_0 -alternating and thus proper $(\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\})$ -alternating. Therefore such a cycle must pass through P ; otherwise it is a proper $\widetilde{M}_0$ -alternating cycle in G' , a contradiction. Hence such a cycle is unique and denoted by C . In fact $C = h_d$; otherwise, $C + e_d$ contains a proper $\widetilde{M}_0$ -alternating cycle of G' , a contradiction. Hence $\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\}$ covers M_0 and $M_0 \oplus h_d = \widetilde{M}_0 \cup \{v_2v_3, v_4v_5\}$. So Lemma 2.5 implies the required result.

For any $M \in \mathcal{M}_0$, by Lemma 2.4 we have

$$\phi_M - \phi_{\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\}} = \psi_{M(\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\})},$$

and

$$\phi_M(h_i) = \psi_{M(\widetilde{M}_0 \cup \{v_2v_3, v_4v_5\})}(h_i) = \psi_{\widetilde{M}\widetilde{M}_0}(h_i) = \phi_{\widetilde{M}}(h_i) - \phi_{\widetilde{M}_0}(h_i) = \phi_{\widetilde{M}}(h_i)$$

for all $1 \leq i \leq d-1$. Claim (7) is verified.

Suppose that Algorithm 5.1 has already determined the binary coding $\phi_{\widetilde{M}}(h_i)$, $1 \leq i \leq d-1$, for all 1-factors $\widetilde{M}$ of G' . Hence for each $x \in L_{d-1}$, the corresponding $\widetilde{M} \in \mathcal{M}(G')$ has $\phi_{\widetilde{M}}(h_1, \dots, h_{d-1}) = x$. For each $M := \widetilde{M} \cup \{v_2v_3, v_4v_5\} \in \mathcal{M}_0$, we have $\phi_M(h_1, \dots, h_{d-1}) = x$ by the above claim verified.

We now consider the case that e_d is in a proper position of $h_{a(d)}$. Then both v_2v_3 and v_4v_5 are in improper positions of h_d . Therefore $\{v_2v_3, v_4v_5\} \subseteq M_0$; otherwise, h_d is a proper M_0 -alternating, a contradiction. Hence h_d lies outside all cycles in $M \oplus M_0$. This implies that $\phi_M(h_d) = 0$ and $\phi_M = x0$. Since e_d is always contained in an improper $\widetilde{M}_0$ -alternating cycle, $e_d \notin \widetilde{M}_0$. This implies that $e_d \in \widetilde{M}$ if and only if e_d is contained in a cycle C in $\widetilde{M}_0 \oplus \widetilde{M}$; that is, $h_{a(d)}$ is contained in the interior of C . If $\phi_{\widetilde{M}}(h_{a(d)}) = 1$, then, equivalently, $e_d \in M$, h_d is an improper M -alternating hexagon and $\phi_{M \oplus h_d} = x1$.

For the other case that e_d is in an improper position of $h_{a(d)}$, analogous arguments can be made. We have that $\phi_M(h_d) = 1$ and $\phi_M = x1$. If $\phi_{\widetilde{M}}(h_{a(d)}) = 0$, then, equivalently, $e_d \in M$, h_d is a proper M -alternating hexagon and $\phi_{M \oplus h_d} = x0$. These conform to step 2 in Algorithm 5.1. Therefore Algorithm 5.1 determines the binary coding ϕ_M for all 1-factors M of G . $\square$

Theorem 5.2 shows that the binary coding ϕ_M for the 1-factors M of a cata-condensed benzenoid system can be accomplished by Algorithm 5.1. Hence such a binary coding produced by Algorithm 5.1 is independent of its constructive process (i.e., choices for a normal sequence of hexagons) in a sense that each bit corresponds to a specific hexagon. This algorithm is still valid for outplane bipartite graphs.

6. Conclusion. If a plane bipartite graph G is weakly elementary, then from the distributive lattice structure on the 1-factors we know that the resonance graph is a median graph. If G is nonweakly elementary, then we can see that each component of the poset $\mathcal{M}(G)$ is a distributive lattice [29] and each component of the resonance graph is a median graph.

For the weakly-elementary case, the mapping $\phi : \mathcal{M}(G) \rightarrow (\mathbb{Z}^+)^{\mathcal{F}}$ is both order-preserving and distance-preserving embedding. When ϕ is transformed into an embedding $\bar{\phi}$ of $\mathcal{M}(G)$ into the Boolean algebra B_d , $\bar{\phi}$ gives an isometric embedding of the resonance graph $Z(G)$ into a d -hypercube—the covering graph of the Boolean

algebra B_d of rank d . Here d is equal to both the height of $\mathcal{M}(G)$ and the diameter of resonance graph $Z(G)$. We conclude by proposing two open problems.

Open problem 1. Determine the smallest integer m such that $\mathcal{M}(G)$ can be embedded into $(\mathbb{Z}^+)^m$. We may conjecture that such smallest integer m is equal to the *resonant number* or *Clar number* in benzenoid systems (i.e., the maximum size of resonant patterns). In Figure 5 we can see that the conjecture is true for the coronene since both smallest m and Clar number are equal to 3, much less than the number 7 of hexagons.

A similar problem was considered recently [6, 14]: If a graph can be isometrically embedded into the m -dimensional integer lattice $\mathbb{Z}^m$ (an infinite graph), then we find such minimum possible dimension m , called the *lattice dimension* of the graph. The lattice dimension of benzenoid systems was determined by Klavžar and Kovše [14] in terms of fundamental trees. Substantially, open problem 1 is to determine the lattice dimension of the resonance graph.

Both embeddings ϕ and $\bar{\phi}$ can be regarded as labellings for the 1-factors, which can be generated by Algorithm 2.6. For the special case of cata-condensed benzenoid system, such two labellings become the same binary coding for all 1-factors, which can be generated by Algorithm 5.1 without involving the generation of all 1-factors; its encoding gives the corresponding 1-factors (see (1)).

Open problem 2. For a general benzenoid system G , how can one design an algorithm to generate the binary coding for all 1-factors, avoiding the generation of $\mathcal{M}(G)$?

Acknowledgment. The authors are grateful to the referee for giving valuable suggestions to the improvement of this manuscript.

LARGEST NUMBER OF SUBTREES OF TREES WITH A GIVEN MAXIMUM DEGREE*

RUSSELL KIRK[†] AND HUA WANG[‡]

Abstract. We characterize trees, given a size and maximum vertex degree, which have the greatest number of subtrees. This generalizes the recent result of Szekely and Wang. These trees coincide with those which were shown by Fischermann et al., and independently Jelen and Triesch, to minimize the Wiener index.

Key words. tree, subtree, Wiener index, maximum degree

AMS subject classifications. 05C05, 05C90

DOI. 10.1137/070687736

1. Terminology. All graphs in this paper will be finite, simple, and undirected. A *tree* $T = (V, E)$ is a connected, acyclic graph. $V(T)$ denotes the vertex set of a tree T . We refer to vertices of degree 1 of T as *leaves*. The unique path connecting two vertices v, u in T will be denoted by $P_T(v, u)$. For a tree T and two vertices v, u of T , the *distance* $d_T(v, u)$ between them is the number of edges on the path $P_T(v, u)$. For a vertex v of T , define the *distance of the vertex* as $g_T(v) = \sum_{u \in V(T)} d_T(v, u)$. Then $\sigma(T) = \frac{1}{2} \sum_{v \in V(T)} g_T(v)$ denotes the *Wiener index* of T .

We call a tree (T, r) *rooted at the vertex* r (or just T if it is clear what the root is) by specifying a vertex $r \in V(T)$. For any two different vertices u, v in a rooted tree (T, r) , we say that v is a *successor* of u if $P_T(r, u) \subset P_T(r, v)$. Furthermore, if u and v are adjacent to each other and $d_T(r, u) = d_T(r, v) - 1$, we say that u is a *parent* of v and v is a *child* of u . A subtree T' of a tree T will often be described by its vertex set, $T \setminus T'$ denotes the tree resulting from removing the edges of T' (and the resulting isolated vertices) from T .

If v is any vertex of a rooted tree (T, r) , let $T(v)$, *the subtree induced by* v , denote the rooted subtree of T that is induced by v and all of its successors in T and is rooted at v .

The *height* of a vertex v of a rooted tree T with root r is $h_T(v) = d_T(r, v)$, and the *height* of a rooted tree T is $h(T) = \max_{v \in T} h_T(v)$, the maximum height of vertices.

(T, r, k) denotes a tree T rooted at r , where the degree of any vertex is less than or equal to k . For a rooted tree T , $C_T(v)$ denotes the set of children of a vertex v .

For a tree T and vertices $v_1, v_2, \dots, v_{n-1}, v_n$ of T , let $f_T(v_1, v_2, \dots, v_{n-1}, v_n)$ denote the number of subtrees of T that contain the vertices $v_1, v_2, \dots, v_{n-1}$ and v_n , and let $F(T)$ denote the number of nonempty subtrees (connected subgraphs with at least one vertex) of T .

For a tree (T, r, k) , label the vertices in $C_T(r)$ as $r_1, r_2, \dots, r_m$ such that

$$f_{T(r_1)}(r_1) \leq f_{T(r_2)}(r_2) \leq \dots \leq f_{T(r_m)}(r_m).$$

Similarly, for $T(r_j)$, label the vertices in $C_T(r_j)$ as $r_{j1}, r_{j2}, \dots, r_{jl}$ according to the same rule (Figure 1). Hence for any vertex $r_{i_1 i_2 \dots i_s}$, we always have

$$(1) \quad f_{T(r_{i_1 \dots i_{s1}})}(r_{i_1 \dots i_{s1}}) \leq f_{T(r_{i_1 \dots i_{s2}})}(r_{i_1 \dots i_{s2}}) \leq \dots \leq f_{T(r_{i_1 \dots i_{st}})}(r_{i_1 \dots i_{st}}).$$

For convenience, we will use $i^{[n]}$ to denote a character i repeated n times in the subscripts, i.e., $\underbrace{i \dots i}_n$. Also, we use $T_{i_1 i_2 \dots i_n}$ to denote the tree $T(r_{i_1 i_2 \dots i_n})$ induced by $r_{i_1 i_2 \dots i_n}$.

A tree (T, r, k) is *complete* if and only if all of its vertices of height less than $h(T)$ are of maximum degree k (by abuse of the terminology, we also refer to an induced subtree as complete if all nonleaf vertices except the root are of maximum degree).

2. Introduction. To present our main result, we give more definitions.

DEFINITION 2.1. We are given a tree (T, r, k) with the following properties:

- (1) $\deg(r) = c$.
- (2) The height of any two leaves of T differs by at most 1.
- (3) For any v in T , let $v_1, v_2, \dots \in C_T(v)$, at most one $T(v_i)$ is incomplete, in which case $T(v)$ is incomplete. Then for $c = k, k-1$, and $k-2$, T is called k -good, k -rgood, and semi- k -good, respectively.

Remark. An unrooted tree T is k -good if there exists $r \in V(T)$ such that when T is considered as rooted at r , the above conditions are satisfied.

Intuitively, we get the graphs described above by simply filling the distance levels as long as there are still vertices available. In particular, a single vertex or a star rooted at the center is also considered as a “good” tree. For a *complete k -rgood (semi- k -good) tree* T , the vertices of height less than $h(T)$ are of maximum degree except the root.

FIG. 1. A 4-good tree on 40 vertices with labels.

Note that k -good, k -rgood, and semi- k -good trees are unique in the following sense: if we have two k -good (k -rgood, semi- k -good) trees with same number of vertices, then we can label their vertices such that they are isomorphic to each other.

The Wiener index is one of the mostly wide used chemical indices in biochemistry. Since most applications under consideration have acyclic molecular structures, the Wiener index of trees has received great attention in the recent years; see [1] for a survey of related research. Although stated differently due to different terminology, Fischermann et al. [2], and independently Jelen and Triesch [4], proved the following theorem.

THEOREM 2.2. Among trees of the same size with maximum vertex degree k , precisely the k -good tree minimizes the Wiener index.

Theorem 2.2 considers trees with a general maximum vertex degree. For binary trees (with vertex degree 1 or 3) with a given number of vertices, the extremal tree that maximizes (minimizes) the number of subtrees is studied in [9]. In a related paper [7], formulas are given to calculate the number of subtrees of these extremal binary

trees. These formulas use a new representation of integers as a sum of powers of 2. Number theorists have already started investigating this new binary representation [3]. Also, the sequence of the number of subtrees of these extremal binary trees (with 2^n leaves, $n = 1, 2, \dots$) appears to be new [6].

An interesting fact is that among binary trees of the same size, the extremal one that minimizes the Wiener index is exactly the one that maximizes the number of subtrees, and vice versa. Recent work of Wagner [10] also implies a strong relation between the Wiener index and the number of subtrees, through a generating function approach. It is then natural to conjecture that for binary trees with a given number of vertices, the larger the Wiener index, the fewer the subtrees. In [7], this phenomenon is further studied, and a counterexample is presented showing that there is no such relation between the Wiener index and the number of subtrees. Yet we lack a better understanding of this relationship.

In [8], a similar question is studied for the number of subtrees that contain at least one leaf of the original tree. It turns out that the same kind of extremal trees, the ones that minimize the Wiener index and maximize the number of subtrees among binary trees of the same size, also maximize the number of leaf-containing subtrees. This was first investigated by Knudsen [5] to provide an upper bound for the time complexity of his multiple parsimony alignment with affine gap cost using a phylogenetic tree. This result on the number of leaf-containing subtrees [8] can be used to provide an upper bound for the number of acceptable residue configurations (the leaf-containing subtrees, in our terms) and helps to decide the time complexity of Knudsen's algorithm; for details see [9].

In this paper, we extend the result in [9] to general trees with a given maximum degree. We will prove the following theorem.

THEOREM 2.3. *Among trees with maximum vertex degree k and a given size, precisely the k -good tree maximizes the number of subtrees.*

Combined with Theorem 2.2, we see that the yet-to-understand relation between the Wiener index and the number of subtrees also holds for general trees, given the maximum vertex degree.

In section 3, some basic lemmas related to the number of subtrees are introduced. Then the properties of k -good, k -r-good, and semi- k -good trees are explored in section 4. We will further characterize the structure of the extremal trees that maximize the number of subtrees in section 5; these lemmas may be interesting on their own. Section 6 completes the proof of Theorem 2.3.

3. Lemmas about arbitrary trees. Two key lemmas are proved in [9]; they can be easily generalized to the following:

FIG. 2. Path $P_W(x, y)$ connecting vertices x and y .

Consider the tree W in Figure 2, with vertices x and y , and

$$P_W(x, y) = x_0(x)x_1 \dots x_n z y_n \dots y_1 y_0(y)(x_0(x)x_1 \dots x_n y_n \dots y_1 y_0(y))$$

if $d_W(x, y)$ is even (odd) for any $n \geq 0$.

After the deletion of all the edges of $P_W(x, y)$ from W , some connected components will remain. Let X_i (X_0) denote the component that contains x_i ($x_0 = x$), let Y_i (Y_0) denote the component that contains y_i ($y_0 = y$), for $i = 1, 2, \dots, n$, and let Z denote the component that contains z .

LEMMA 3.1. *In the above situation, if $f_{X_i}(x_i) \geq f_{Y_i}(y_i)$ for $i = 0, 1, \dots, n$, then $f_W(x) \geq f_W(y)$. Furthermore, $f_W(x) = f_W(y)$ if and only if $f_{X_i}(x_i) = f_{Y_i}(y_i)$ for all i .*

Idea of the proof. We can write $f_W(x)$ ($f_W(y)$) in terms of $f_{X_i}(x_i)$ and $f_{Y_i}(y_i)$; then the result follows by simple algebra.

A similar approach also leads to the next lemma.

FIG. 3. Switching subtrees rooted at x and y .

If we have a tree W with vertices x and y , and two rooted trees X and Y , then we can build two new trees: first T' by identifying the root of X with x (later will simply be referred to as “attaching X to x ” or “adding $X \setminus x$ to x ” when there is no confusion) and the root of Y with y ; and second T'' by identifying the root of X with y and the root of Y with x (Figure 3). Under the circumstances below we can tell which composite tree has more subtrees.

LEMMA 3.2. *In the above situation, if $f_W(x) > f_W(y)$ and $f_X(x) < f_Y(y)$, then we have $F(T'') > F(T')$.*

Remark. When x, y are leaves, Lemmas 3.1 and 3.2 become the original lemmas in [9].

We also list the following obvious observation for our convenience.

LEMMA 3.3. *Given T rooted at r , if $v \in V(T)$ and $v \neq r$, then $f_T(r) > f_{T(v)}(v)$.*

4. Properties of the “good” trees. A few nice properties follow from the definitions of k -good, k -rgood, and semi- k -good trees; we leave the proofs of them to the reader.

LEMMA 4.1. *If T is a k -good or k -rgood tree, then for any vertex $v \in V(T)$ that is not the root, $T(v)$ is k -rgood.*

LEMMA 4.2. *If T is a k -rgood tree, $v \in V(T)$ is not a leaf, and $v' \in C_T(v)$, then $T(v) \setminus T(v')$ is semi- k -good.*

LEMMA 4.3. *For any two k -rgood or semi- k -good trees T and T' with roots r and r' , respectively, we have*

$$(2) \quad h(T) > h(T') \Rightarrow |V(T)| > |V(T')|,$$

$$(3) \quad |V(T)| \geq |V(T')| \Rightarrow h(T) \geq h(T'),$$

$$(4) \quad f_T(r) > f_{T'}(r') \Leftrightarrow |V(T)| > |V(T')|; f_T(r) = f_{T'}(r') \Leftrightarrow |V(T)| = |V(T')|.$$

We introduce the next lemma for technical reasons.

LEMMA 4.4. *Let two k -good trees T' and T'' be rooted at v' and v'' , respectively, such that $k \leq |V(T')| \leq |V(T'')|$. If T'' is not complete, then*

$$f_{T' \setminus T'_{(k-1)}}(v') < f_{T'' \setminus T''_1}(v'').$$

Proof. Consider $|V(T'_{(k-1)})|$ and $|V(T''_1)|$.

(i) If $|V(T'_{(k-1)})| > |V(T''_1)|$, then $|V(T')| - |V(T'_{(k-1)})| < |V(T'')| - |V(T''_1)|$.

(ii) If $|V(T'_{(k-1)})| \leq |V(T''_1)|$ (note that $|V(T''_1)| < |V(T''_{(k-1)})|$ as T'' is incomplete), then

$$\begin{aligned} |V(T')| - |V(T'_{(k-1)})| &= 1 + \sum_{i=1}^{k-2} |V(T'_i)| \leq 1 + (k-2)|V(T'_{(k-1)})| \\ &\leq 1 + (k-2)|V(T''_1)| < \sum_{i=2}^{k-1} |V(T''_i)| = |V(T'')| - |V(T''_1)|. \end{aligned}$$

Either way, we have

$$|V(T' \setminus T'_{(k-1)})| = |V(T')| - |V(T'_{(k-1)})| < |V(T'')| - |V(T''_1)| = |V(T'' \setminus T''_1)|.$$

The conclusion follows from Lemma 4.2 and (4). $\square$

The next two lemmas follow from the definitions; they provide a better understanding of the structures of “good” trees.

LEMMA 4.5. *Given (T, r, k) , if $\deg(r) = k-1$ and $T(v_i)$ is k -good for any $v_i \in C_T(r)$ ($1 \leq i \leq k-1$), then T is k -good if and only if one of the following conditions holds:*

(1) *For $i = 1, 2, \dots, k-2$, $h(T(v_i)) = h(T(v_{i+1}))$ and $T(v_{i+1})$ is complete.*

(2) *There exists $l \in \{1, \dots, k-1\}$ such that*

for $i = 1, 2, \dots, l-1$, $h(T(v_i)) = h(T) - 2$ and $T(v_i)$ is complete;

for $j = l, \dots, k-1$, $h(T(v_j)) = h(T(v_{j+1})) = h(T) - 1$ and $T(v_{j+1})$ is complete.

LEMMA 4.6. *Let T' and T'' be two k -good trees with $h(T'') - 1 \leq h(T') \leq h(T'')$, and let T be the tree resulting from connecting (with an edge) the roots of T' and T'' .*

If $h(T') = h(T'')$, then T is k -good if and only if one of T' and T'' is complete.

If $h(T') = h(T'') - 1$, then T is k -good if and only if T' is complete.

5. Properties of optimal trees. For convenience, we will call a tree *optimal* if it is a tree of a given size with maximum vertex degree k and it maximizes the number of subtrees. First we show that almost all vertices in an optimal tree have the maximum degree.

LEMMA 5.1. *If (T, r, k) is an optimal tree, then there is at most one nonleaf vertex that has degree not equal to k . Furthermore, if such a vertex exists, all but one of its neighbors must be leaves.*

Proof. First, suppose (for contradiction) that v_1 and v_2 are two nonleaf vertices whose degrees are less than k . Without loss of generality, assume $f_T(v_1) \geq f_T(v_2)$.

Let v_L be a neighbor of v_2 that is not on $P_T(v_1, v_2)$, and T_{v_L} is the component that contains v_L after the removal of the edge $v_2 v_L$ in T . Let T' be the tree resulting from removing a T_{v_L} from T . Notice that $f_T(v_2, v_L) > f_T(v_1, v_2, v_L) = f_T(v_1, v_L)$ as every subtree counted in $f_T(v_1, v_2, v_L)$ is counted in $f_T(v_2, v_L)$, while the subtree induced by the edge $v_2 v_L$ is counted only in $f_T(v_2, v_L)$.

Now we have

$$f_{T'}(v_1) = f_T(v_1) - f_T(v_1, v_L) > f_T(v_2) - f_T(v_L, v_2) = f_{T'}(v_2).$$

Note that, for T' , adding T_{v_L} to v_2 yields T and adding T_{v_L} to v_1 yields a new tree T'' ; by Lemma 3.2, we have $F(T) < F(T'')$ —contradicting the optimality of T .

Thus there is at most one nonleaf vertex that has degree less than k , say v ; suppose (for contradiction) that v_1 and v_2 are neighbors of v that are not leaves. Let T_1 (T_2) denote the component that contains v_1 (v_2) after the removal of the edge vv_1 (vv_2) from T .

Without loss of generality, assume $f_{T_1}(v_1) \geq f_{T_2}(v_2)$. Let T' denote the tree resulting from removing a T_u from T , where u is a neighbor of v_2 that is not on $P_T(v_1, v_2)$, and T_u is the component that contains u after the removal of the edge $v_2 u$ from T . Notice that $f_{T' \setminus T_2}(v) = f_{T \setminus T_2}(v) > f_{T_1}(v_1) \geq f_{T_2}(v_2) > f_{T_2 \setminus T_u}(v_2)$; applying Lemma 3.1 to vv_2 in T' yields that

$$f_{T'}(v) > f_{T'}(v_2).$$

Note that, for T' , adding T_u to v_2 yields T and adding T_u to v yields a new tree T'' ; by Lemma 3.2, we have $F(T) < F(T'')$ —contradicting the optimality of T . $\square$

The reader can refer to Figure 4 for the remaining lemmas in this section.

FIG. 4. T' and T'' after the removal of the edge $v'v''$ or the path $P_T(v', v'')$.

We introduce the next two lemmas for technical reasons.

LEMMA 5.2. *Let (T, r, k) be an optimal tree that is divided into two trees (T', v') and (T'', v'') by the removal of the edge $v'v''$. If $T''(v)$ is k -rgood for any $v \in C_{T''}(v'')$ and $f_{T'}(v') \geq f_{T''_{(k-1)1}}(v''_{(k-1)1})$, then, for any $n \geq 1$ such that $v''_{1[n]}$ and $v''_{(k-1)[n+1]}$ exist, we have*

$$(5) \quad |V(T''_{1[n]})| \geq |V(T''_{(k-1)[n+1]})|.$$

Proof. By induction on n , for the base case $n = 1$, we prove the following claim.

CLAIM 5.1. *Under the condition of Lemma 5.2, we must have*

$$(6) \quad |V(T''_i)| \geq |V(T''_{(k-1)j})|$$

for any $i = 1, 2, \dots, k-2$ and $j = 2, 3, \dots, k-1$.

Proof of Claim 5.1. Take the $2(k-2)$ subtrees T''_i for $i = 1, 2, \dots, k-2$ and $T''_{(k-1)j}$ for $j = 2, 3, \dots, k-1$. Put them in a sequence in the descending order of the

number of vertices; we will show that T''_i ($i = 1, 2, \dots, k-2$) must be the first half of this sequence of subtrees (which implies (6)).

Otherwise, suppose $T''_1, T''_2, \dots, T''_s$ are in the second half of the sequence; then we must have $T''_{(k-1)(k-1)}, \dots, T''_{(k-1)(k-s)}$ in the first half. Then

$$|V(T''_i)| > |V(T''_{(k-1)(k-i)})|$$

for $i = s+1, s+2, \dots, k-2$ and

$$|V(T''_j)| < |V(T''_{(k-1)(k-j)})|$$

for $j = 1, 2, \dots, s$.

By the assumption of k -rgoodness and Lemmas 4.2 and 4.3, we have

$$(7) \quad f_{T''_i}(v''_i) > f_{T''_{(k-1)(k-i)}}(v''_{(k-1)(k-i)}) \quad \text{for } i = s+1, s+2, \dots, k-2,$$

$$(8) \quad f_{T''_j}(v''_j) < f_{T''_{(k-1)(k-j)}}(v''_{(k-1)(k-j)}) \quad \text{for } j = 1, 2, \dots, s.$$

We intend to show that this contradicts the optimality of T by applying Lemmas 3.1 and 3.2 in the following setting:

$X = \bigcup_{i=1}^s T''_i \cup \{v''\}; Y = \bigcup_{i=1}^s T''_{(k-1)(k-i)} \cup \{v''_{(k-1)}\}; x = x_0 = v''; y = y_0 = v''_{(k-1)}$.

Consequently we have $W = T \setminus (X \cup Y) \cup \{x, y\}$.

Note that now $X_0 = \bigcup_{i=s+1}^{k-2} T''_i \cup T' \cup \{v''\}$ is a result of joining $T', T''_{s+1}, \dots, T''_{(k-2)}$ with v'' , and $Y_0 = \bigcup_{i=s+1}^{k-2} T''_{(k-1)(k-i)} \cup T''_{(k-1)1} \cup \{v''_{(k-1)}\}$ is a result of joining $T(v''_{(k-1)1}), \dots, T(v''_{(k-1)(k-s-1)})$ with $v''_{(k-1)}$.

By (7) and the assumption that $f_{T'}(v') \geq f_{T''_{(k-1)1}}(v''_{(k-1)1})$, we have

$$f_{X_0}(x_0) = (1 + f_{T'}(v')) \prod_{i=s+1}^{k-2} (1 + f_{T''_i}(v''_i)) > \prod_{i=1}^{k-s-1} (1 + f_{T''_{(k-1)i}}(v''_{(k-1)i})) = f_{Y_0}(y_0).$$

Similarly, note that X is a result of joining $T''_1, \dots, T''_s$ with v'' , and Y is the result of joining $T(v''_{(k-1)(k-s)}), \dots, T(v''_{(k-1)(k-1)})$ with $v''_{(k-1)}$. Equation (8) implies that

$$f_X(x) = \prod_{i=1}^s (1 + f_{T''_i}(v''_i)) < \prod_{i=k-s}^{k-1} (1 + f_{T''_{(k-1)i}}(v''_{(k-1)i})) = f_Y(y).$$

Thus, Lemma 3.1 implies that $f_W(x) > f_W(y)$, but we have $f_X(x) < f_Y(y)$. Lemma 3.2 yields that switching X and Y will increase $F(T)$, in contradiction to the optimality of T .

Hence we must have (6), in particular, $|V(T''_1)| \geq |V(T''_{(k-1)(k-1)})|$.

This completes the proof of Claim 5.1. $\square$

For the inductive step, suppose (5) holds for all values up to n . In particular, $|V(T''_{1[n]})| \geq |V(T''_{(k-1)[n+1]})|$ implies that

$$(9) \quad \sum_{j=1}^{k-1} |V(T''_{1[n]j})| = |V(T''_{1[n]})| - 1 \geq |V(T''_{(k-1)[n+1]})| - 1 = \sum_{j=1}^{k-1} |V(T''_{(k-1)[n+1]j})|.$$

For the sake of contradiction, suppose that the hypothesis does not hold for $n + 1$, yielding

$$(10) \quad |V(T''_{1[n+1]})| < |V(T''_{(k-1)[n+2]})|.$$

Now we have (we superscript some of the inequalities for reference to their proofs)

$$(11) \quad \sum_{i=2}^{k-1} |V(T''_{1[n]_i})| \stackrel{(9)-(10)}{>} \sum_{i=1}^{k-2} |V(T''_{(k-1)[n+1]_i})|.$$

We intend to show that this contradicts the optimality of T by applying Lemma 3.1 and Lemma 3.2 in the following setting:

$$W = T \setminus (X \cup Y) \cup \{x, y\}; X = T(v''_{1[n+1]}); Y = T(v''_{(k-1)[n+2]});$$

$$x = v''_{1[n+1]}; y = v''_{(k-1)[n+2]};$$

$$x_l = v''_{1[n-l+1]}; X_l = T(v''_{1[n-l+1]}) \setminus T(v''_{1[n-l+2]}) \text{ for } l = 1, 2, \dots, n,$$

$$X_{n+1} = T \setminus (T''_{(k-1)} \cup T''_1),$$

$$y_l = v''_{(k-1)[n-l+2]}; Y_l = T(v''_{(k-1)[n-l+2]}) \setminus T(v''_{(k-1)[n-l+3]}) \text{ for } l = 1, 2, \dots, n+1.$$

Note that each X_l and Y_l for $l < n + 1$ is semi- k -good by the assumption of k -rgoodness and Lemma 4.2. Also, we have

$$|V(X_l)| = |V(T''_{1[n-l+1]})| - |V(T''_{1[n-l+2]})| \geq |V(T''_{(k-1)[n-l+2]})| - |V(T''_{(k-1)[n-l+3]})| = |V(Y_l)|$$

for $l = 1, 2, \dots, n$ by induction hypothesis and (1); in addition, strict inequality holds for $l = 1$ by (11).

Hence we have $f_{X_l}(x_l) \geq f_{Y_l}(y_l)$ for $l = 2, \dots, n$ and $f_{X_1}(x_1) > f_{Y_1}(y_1)$ by Lemma 4.3.

Notice that $X_{n+1} = T \setminus (T''_{(k-1)} \cup T''_1)$ is a result of joining $T', T''_2, \dots, T''_{(k-2)}$ with v'' , while $Y_{n+1} = T(v''_{(k-1)}) \setminus T(v''_{(k-1)(k-1)})$ is the result of joining $T(v''_{(k-1)1}), \dots, T(v''_{(k-1)(k-2)})$ with $v''_{(k-1)}$. Compare these “branches”:

$$(12) |V(T''_{(k-1)j})| \stackrel{(1)}{\leq} |V(T''_{(k-1)(k-1)})| \stackrel{(5)}{\leq} |V(T''_1)| \stackrel{(1)}{\leq} |V(T''_j)| \text{ for } j = 2, \dots, k-2.$$

Equation (12) implies, with Lemma 4.3, that $f_{T''_j}(v''_j) \geq f_{T''_{(k-1)j}}(v''_{(k-1)j})$ for $j = 2, \dots, k-2$.

With the assumption that $f_{T'}(v') \geq f_{T''_{(k-1)1}}(v''_{(k-1)1})$, we have

$$f_{X_{n+1}}(x_{n+1}) = (1 + f_{T'}(v')) \prod_{i=2}^{k-2} (1 + f_{T''_i}(v''_i)) \geq \prod_{i=1}^{k-2} (1 + f_{T''_{(k-1)i}}(v''_{(k-1)i})) = f_{Y_{n+1}}(y_{n+1}).$$

Thus we have $f_{X_l}(x_l) \geq f_{Y_l}(y_l)$ for $l = 2, 3, \dots, n+1$ and $f_{X_1}(x_1) > f_{Y_1}(y_1)$, which implies that $f_W(x) > f_W(y)$ by Lemma 3.1. We also have that $f_X(x) < f_Y(y)$ by assumption of k -rgoodness, Lemma 4.3, and (10).

Note that T is the tree resulting from attaching X to x and Y to y , and let T^* be the tree resulting from attaching X to y and Y to x . Now applying Lemma 3.2 to X, Y , and W , we have $F(T^*) > F(T)$, which contradicts the optimality of T , thus proving Lemma 5.2 by induction. $\square$

Let $v'a_1 \dots a_c(z)b_c \dots b_1v''$ denote the path that connects the roots of two disjoint k -rgood trees T' and T'' in an optimal tree T . After the deletion of the edges of $P_T(v', v'')$, some connected components will remain. Let A_i denote the component

that contains a_i and B_i denote the one that contains b_i (and Z the one that contains z).

LEMMA 5.3. *As described above, if $|V(T')| \leq |V(T'')|$, $h(T') = h(T'') = m$, and $f_{A_i}(a_i) \leq f_{B_i}(b_i)$ for $i = 1, 2, \dots, c$, then T'' is complete.*

Proof. Suppose (for contradiction) that T'' is not complete.

CLAIM 5.2. $|V(T'_{(k-1)[n]})| \leq |V(T''_{1[n]})|$ for $n = 1, 2, \dots, m-1$.

Proof of Claim 5.2. By contradiction, let s be the smallest integer such that

$$(13) \quad |V(T'_{(k-1)[s]})| > |V(T''_{1[s]})|.$$

We intend to show that this contradicts the optimality of T by applying Lemmas 3.1 and 3.2 in the following setting:

$$X = T'(v'_{(k-1)[s]}); x = v'_{(k-1)[s]}; Y = T''(v''_{1[s]}); y = v''_{1[s]}.$$

We have $f_X(x) > f_Y(y)$ by (13) and Lemma 4.3.

For $l = 1, 2, \dots, s$,

$$x_l = v'_{(k-1)[s-l]}; X_l = T'_{(k-1)[s-l]} \setminus T'_{(k-1)[s+1-l]}; y_l = v''_{1[s-l]}; Y_l = T''_{1[s-l]} \setminus T''_{1[s+1-l]}.$$

$|V(T'_{(k-1)[s-l]})| \leq |V(T''_{1[s-l]})|$ by hypothesis; then $f_{X_l}(x_l) < f_{Y_l}(y_l)$ by Lemma 4.4.

For $l = s+1, \dots, s+c$,

$$x_l = a_{l-s}; X_l = A_{l-s}; y_l = b_{l-s}; Y_l = B_{l-s}.$$

We have $f_{X_l}(x_l) \leq f_{Y_l}(y_l)$ by assumption.

Let $W = T \setminus (T' \cup T'')$; then $f_W(x) < f_W(y)$ by Lemma 3.1, and thus we can switch X, Y and increase the number of subtrees by Lemma 3.2. This is a contradiction.

This completes the proof of Claim 5.2. $\square$

Now by Claim 5.2, we have

$$(14) \quad |V(T'_{(k-1)[m-1]})| \leq |V(T''_{1[m-1]})|.$$

Notice that $1 \geq h(T''_{1[m-1]}) \geq^{(14)} h(T'_{(k-1)[m-1]}) = h(T') - (m-1) = 1$. By Lemma 5.1, at least one of $v'_{(k-1)[m-1]}$ and $v''_{1[m-1]}$ is of degree k . Then $v''_{1[m-1]}$ must be of degree k by (14); hence T'' is complete. $\square$

Now we show that, after “dividing” an optimal tree into two rooted trees, if one of them is sufficiently “large,” then the other one has to be “good.”

LEMMA 5.4. *For an optimal tree (T, r, k) , assume that T is divided into two rooted subtrees (T', v') and (T'', v'') by the removal of the edge $v'v''$. Then, if for $n \geq 2$,*

$$(15) \quad f_{T'}(v') > f_{T''_{a_1 a_2 \dots a_n}}(v''_{a_1 a_2 \dots a_n}) \quad (1 \leq a_i \leq k-1 \text{ for } i = 1, 2, \dots, n)$$

hold as long as the vertex $v''_{a_1 a_2 \dots a_n}$ exists, then T'' is k -rgood.

Proof. First notice that, by Lemma 5.1, v'' must be of degree k or all of its children are leaves (in which case T'' is k -rgood).

Now we prove the lemma; by induction on $|V(T'')|$, the base case, $|V(T'')| = 1$, is trivial by definition. Now suppose Lemma 5.4 is true for any induced subtree in place of T'' with fewer vertices.

CLAIM 5.3. T''_i is k -rgood for $i = 1, 2, \dots, k-1$.

Proof of Claim 5.3. Consider T as being divided into T''' and T^* , where $T''' = (T''_i, v''_i)$ and $T^* = (T \setminus T''_i, v'')$. Now, for any $1 \leq a_i \leq k-1, i = 1, 2, \dots, n \geq 2$, by using Lemma 3.3, we have

$$f_{T^*}(v'') > f_{T''_i}(v''_i) > f_{T''_{i a_2 \dots a_n}}(v''_{i a_2 \dots a_n}) = f_{(T''''_{a_1 a_2 \dots a_n})}(v''_{i a_1 a_2 \dots a_n});$$

thus (15) holds for T^* and T''' , and then T''_i is k -rgood by hypothesis.

This completes the proof of Claim 5.3. $\square$

Now all induced subtrees of T'' are k -rgood by Lemma 4.1; consider two cases.

Case I. $h(T''_i) = h(T''_{i+1})$ for $i = 1, 2, \dots, k-2$.

In this case, we have, for $i = 1, 2, \dots, k-2$, that

$$h(T''_i) = h(T''_{i+1}) \quad \text{and} \quad |V(T''_i)| \leq^{(1)} |V(T''_{i+1})|.$$

Applying Lemma 5.3 to T''_i and T''_{i+1} yields that T''_{i+1} is complete for $i = 1, \dots, k-2$.

Since each T''_i is of the same height, we have by Lemma 4.5 that T'' is k -rgood.

Case II. There exists c , $1 \leq c \leq k-2$, such that $h(T''_c) < h(T''_{c+1})$.

Then, on the one hand, we must have $h(T''_1) < h(T''_{k-1})$.

On the other hand, by Lemma 5.2 we have

$$|V(T''_1)| \geq |V(T''_{(k-1)(k-1)})| \Rightarrow^{(3)} h(T''_1) \geq h(T''_{(k-1)(k-1)}) = h(T''_{k-1}) - 1.$$

Thus, $h(T''_1) = \dots = h(T''_c) = h(T''_{c+1}) - 1 = \dots = h(T''_{k-1}) - 1$.

Let $m = h(T''_1)$. Lemma 5.2 implies that $|V(T''_{1[m-1]})| \geq |V(T''_{(k-1)[m]})|$, coupled with Lemma 5.1, yields that $v''_{1[m-1]}$ is of degree k , which implies that T''_1 is complete.

Since each T''_i is of the same height, T''_i is complete for $i = 1, 2, \dots, c$ by (1).

Also, for $i = c+1, \dots, k-2$, T''_{i+1} is complete by applying Lemma 5.3 to T''_i and T''_{i+1} .

Thus each T''_i except T''_{c+1} is complete. T'' is k -rgood by Lemma 4.5. $\square$

Next we show that an optimal tree can be “divided” into two trees such that each of them is “large” enough to make the other one “good.”

LEMMA 5.5. *Divide an optimal tree (T, r, k) into two rooted trees (T', v') and (T'', v'') by removing an edge $v'v''$. If $|h(T'') - h(T')| \leq 1$, then both T' and T'' are k -rgood.*

Proof. Note that if we choose a longest path P and choose (v', v'') as the closest to middle edge on P , we obtain such T' and T'' .

Without loss of generality, assume $f_{T''}(v'') \geq f_{T'}(v')$; then

$$f_{T''}(v'') \geq f_{T'}(v') >^{Lemma\ 3.3} f_{T'_{a_1 a_2 \dots a_n}}(v'_{a_1 a_2 \dots a_n}).$$

So (15) holds for T'' and T' , and T' is k -rgood by Lemma 5.4.

Now, since T' is k -rgood, it contains a copy of a complete k -rgood tree (denote by T^* , $h(T^*) = h(T') - 1$) rooted at v' . Note that

$$h(T^*) = h(T') - 1 \geq h(T'') - 2 \geq h(T''_{a_1 a_2 \dots a_n})$$

for any $1 \leq a_i \leq k-1$ for $i = 1, 2, \dots, n \geq 2$. Then

$$f_{T'}(v') >^{(4)} f_{T^*}(v') \geq^{Lemma\ 3.3} f_{T''_{a_1 a_2 \dots a_n}}(v''_{a_1 a_2 \dots a_n}).$$

Thus (15) holds for T' and T'' , and T'' is k -rgood by Lemma 5.4. $\square$

6. Proof of Theorem 2.3.

Proof. Let (T, r, k) be an optimal tree. By Lemma 5.5, we can divide T into two k -rgood trees (T', v') and (T'', v'') with

$$h(T'') - 1 \leq h(T') \leq h(T'').$$

Further assume that $|V(T')| \leq |V(T'')|$. If T' is complete, T is k -good by Lemma 4.6. Now suppose T' is not complete, and consider two cases.

Case I. $h(T') = h(T'')$.

Apply Lemma 5.3 to T' and T'' ; then T'' is complete, and T is k -good by Lemma 4.6.

Case II. $h(T') = h(T'') - 1 = m$.

Note that $h(T''_{(k-1)}) = h(T') = m$, and applying Lemma 5.3 to T' and $T''_{(k-1)}$, together with the assumption that T' is not complete, we have that $T''_{(k-1)}$ must be complete.

Now considering T as being divided by the removal of the edge $v''v''_{(k-1)}$, we have $(T''', v''_{(k-1)}) = T''_{(k-1)}$ of height m being complete and $(T^*, v'') = T \setminus T''_{(k-1)}$ of height $m + 1$. Then T^* is k -good by Lemma 5.5, and T is k -good by Lemma 4.6. $\square$

Acknowledgments. The authors want to thank the referees for carefully reading such a tedious proof and providing many valuable suggestions that greatly improved the quality of this paper. The authors also want to thank the editor/typesetter for their help.

REAL NUMBER CHANNEL ASSIGNMENTS FOR LATTICES*

JERROLD R. GRIGGS[†] AND XIAOHUA TERESA JIN[†]

Abstract. We consider the problem of assigning a numerical channel to each transmitter in a large regular array such that multiple levels of interference, which depend on the distance between transmitters, are avoided by sufficiently separating the channels. The goal is to find assignments that minimize the span of the labels used. A previous paper of the authors introduced a model for this problem using real number labelings of (possibly infinite) graphs G . Given reals $k_1, k_2, \dots, k_p \geq 0$, one denotes by $\lambda(G; k_1, k_2, \dots, k_p)$ the infimum of the spans of the labelings f of the vertices v of G , such that for any two vertices v and w , the difference in their labels is at least k_i , where i is the distance between v and w in G . When $p = 2$, it is enough to determine $\lambda(G; k, 1)$ for reals $k \geq 0$; for G of bounded maximum degree, this will be a continuous, piecewise linear function of k . Here we consider this function for infinite regular lattices that model large planar networks, building on earlier efforts by other researchers. For the triangular lattice, we determine the function for $k \geq 1$, which had previously been found for rational $k \geq 3$ by Calamoneri. We also give bounds for $0 \leq k \leq 1$. For the square lattice and the hexagonal lattice, we completely determine the function for $k \geq 0$, which had been given for rational $k \geq 3$ and $k \geq 2$, respectively, by Calamoneri. Portions of it have been obtained by other researchers for infinite regular lattices that model large planar networks. Here we present the complete function $\lambda(G; k, 1)$ for $k \geq 1$ when G is the triangular, square, or hexagonal lattice.

Key words. channel assignment, generalized graph coloring, planar lattice graphs

1. Introduction. Efficient channel assignment algorithms in wireless networks are increasingly important. There is usually a large network of transmitters in the plane, and a numerical channel must be assigned to each transmitter, where channels for nearby vertices must be assigned so as to avoid interference. The goal is to minimize the portion of the frequency spectrum that must be allocated to the problem, so it is desired to minimize the span of a feasible labeling.

In 1980 Hale [22] formulated such channel assignment problems in network engineering as graph labeling problems: each transmitter is represented by a vertex, and any pair of vertices that may interfere is represented by an edge in the graph. All labels are integers.

In 1988 Lanfear proposed to Roberts [33] a new 2-level channel assignment problem of interest to NATO, in which integer labels are assigned to transmitters in the plane, with two levels of interference, depending on the distance between transmitters; e.g., say labels differ by at least two (resp., one) when the transmitters are within some fixed distance A (resp., $2A$). Griggs introduced the analogous “lambda-labeling” problem for graphs and made the initial investigation of this graph theory problem

with Yeh [21]. They extended the problem in a natural way by specifying separations $k_1, \dots, k_p$ for vertices at distances $1, \dots, p$, defining an $L(k_1, k_2, \dots, k_p)$ -labeling of a graph G to be an assignment of nonnegative numbers $f(v)$ to the vertices v of G , such that $|f(u) - f(v)| \geq k_i$ if u and v are at distance i in G . The labeling f is said to belong to the set $L(k_1, k_2, \dots, k_p)(G)$. One denotes by $\lambda(G; k_1, k_2, \dots, k_p)$ the minimum span over such f , where the span is the difference between the largest and smallest labels $f(v)$. Griggs and Yeh concentrated on the fundamental case of $L(2, 1)$ -labelings, and many authors have subsequently contributed to the literature on these $L(2, 1)$ and more general labelings. For an online survey and annotated bibliography of work with conditions at distance $p = 2$, see [7]. For an overview of the recent progress and state of the general theory, refer to the recent survey [20].

In applications the frequency channel separations k_i for two transmitters are often taken to be inversely proportional to the physical distance i between them [3]. Most articles assume that the separations are nonincreasing, $k_1 \geq k_2 \geq \dots \geq k_p$. But this is not required in the theory. Since in applications one can in principle use any frequencies (channels) in the available continuous frequency spectrum, not only from a discrete set, Griggs and Jin [17] proposed extending integer graph labelings to allow the labels and separations k_i to be nonnegative *real* numbers. They used the same notation as before, $L(k_1, \dots, k_p)(G)$ and $\lambda(G; k_1, \dots, k_p)$, but now the span of a real labeling is the difference between the supremum and the infimum of the labels used, and λ is the infimum of the spans of such labelings. The authors [19] first explored this concept for simple graphs, such as paths and cycles, and then began to study optimal labelings for the lattices considered in this paper. Their early results led to the discovery of properties for general graphs, which were included in the first, foundational paper [17]. The new insights and tools developed in that project are applied to lattices in this paper. The methods described here for lattices in turn are potentially applicable to other classes of graphs.

For graphs of bounded maximum degree, the authors proved the existence of an optimal labeling of a nice form, in which all labels belong to a discrete set, denoted by $D(k_1, k_2, \dots, k_p)$, of linear combinations $\sum_i a_i k_i$, with nonnegative integer coefficients a_i .

THEOREM 1.1 (the D -Set Theorem [17]). *Let G be a graph, possibly infinite, with finite maximum degree. Let p be a positive integer, and let k_i , $1 \leq i \leq p$, be real numbers ≥ 0 . Then there exists a finite optimal $L(k_1, k_2, \dots, k_p)$ -labeling $f^* : V(G) \rightarrow [0, \infty)$ in which the smallest label is 0 and all labels belong to the set $D(k_1, k_2, \dots, k_p)$. Hence, $\lambda(G; k_1, k_2, \dots, k_p)$ belongs to $D(k_1, k_2, \dots, k_p)$.*

Due to the D -Set Theorem, previous optimal integer labeling results are compatible with new optimal real number labeling results. Some natural properties of distance-constrained labelings become more evident in the setting of real number labelings. In particular, the authors made the following observation, which was evident already in earlier work of Georges and Mauro on integer labelings.

LEMMA 1.2 (Scaling). *For real numbers $d, k_i \geq 0$, $i = 1, 2, \dots, p$,*

$$\lambda(G; d \cdot k_1, d \cdot k_2, \dots, d \cdot k_p) = d \cdot \lambda(G; k_1, k_2, \dots, k_p).$$

More subtle is the result of the authors [17, 23] that $\lambda(G; k_1, k_2, \dots, k_p)$ is a continuous function of the separations k_i for any graph G (possibly infinite) with finite maximum degree. Hence, results about the minimum spans $\lambda(G; k_1, k_2, \dots, k_p)$ for k_i being rational numbers can often be extended into the results for k_i being real numbers. Indeed, by the Scaling Lemma, it is usually enough to obtain results for

integer k_i . The analysis is often more clear when considering real number labelings. For any fixed p and any graph G with finite maximum degree, the authors conjectured [17] that $\lambda(G; k_1, k_2, \dots, k_p)$ is a piecewise linear function of real numbers k_i , where the pieces have nonnegative integer coefficients and where there are only finitely many pieces. The authors proved this if G is finite or if $p = 2$ [17]. Subsequently, Král' proved the full conjecture [25].

For the $p = 2$ case, the Scaling Lemma implies that for $k_2 > 0$, $\lambda(G, k_1, k_2) = k_2 \lambda(G; k, 1)$, where $k = k_1/k_2$. This reduces the two-parameter function to a one-parameter function, $\lambda(G; k, 1)$, $k \geq 0$. As just discussed, it is a continuous, nondecreasing, piecewise linear function with finitely many pieces. Further, each piece has the form $ak + b$ for some nonnegative integers $a, b \geq 0$. This paper concerns the function $\lambda(G; k, 1)$, $k \geq 0$, for the most natural infinite regular planar lattices (also called grid graphs), which are the triangular (6-regular), square (4-regular), and hexagonal (3-regular) lattices. The optimal span function is completely determined in the range of natural application, $k \geq 1$. It is solved as well for $0 \leq k \leq 1$ for the square and hexagonal lattice. For the triangular lattice, the problem appears to be much tougher for $0 \leq k \leq 1$, but here portions of it are solved and bounds are given in the remaining intervals. (See the last section for an update on this work.) Despite their nice properties, the optimal span function turns out to be surprisingly complicated for these three regular lattices.

Section 2 introduces some of the general methods used to obtain optimal lattice labelings. It also reviews some of the known results for labeling infinite trees with conditions at distance two, which are closely related to the lattice results. Sections 3, 4, and 5 contain the results for the triangular, square, and hexagonal lattices, respectively. The detailed proofs, which make up most of the paper, are presented in sections 6, 7, and 8, respectively. The paper concludes with ideas for future research directions.

2. Methods. Upper bounds on $\lambda(G; k_1, k_2, \dots, k_p)$ are generally achieved by constructing an efficient labeling, sometimes discovered by computer search. Typically this can be achieved by coordinating the vertices of the lattice, giving an explicit labeling for a small piece, and repeating the pattern, tiling the whole lattice with congruent pieces. Lower bound proofs are generally more difficult. For these we identify crucial particular values of k where we need to prove a lower bound on $\lambda(G; k, 1)$. Such k are rational, say $k = a/b$ for some integers $a, b > 0$. By scaling, it is then equivalent to bound $\lambda(G; a, b)$ below, which has the advantage that we need only consider integer $L(a, b)$ -labelings, which have integer spans. We then seek to prove an integer bound, say $\lambda(G; a, b) \geq c$, by contradiction: If it is not true, then $\lambda(G; a, b) \leq c - 1$, and there must exist a labeling f of G using labels from the set $\{0, 1, \dots, c - 1\}$. We restrict f to an appropriate finite induced subgraph of G , and argue that some label, call it L , must be avoided by f . We continue to eliminate possible labels, until there remains a set of labels for which it can be shown that in fact no feasible labeling exists. In some cases we had to write a computer program to check all possible labelings from a specified label set of a particular induced subgraph.

We begin by recording a simple way to expand the set of avoided labels by using symmetry (which was introduced for the triangular lattice in [4, 14]).

LEMMA 2.1 (Symmetry). *Let S , L , and $k_1, k_2, \dots, k_p$ be nonnegative integers, and let G be a graph. If every $L(k_1, k_2, \dots, k_p)(G)$ -labeling f into $\{0, \dots, S\}$ avoids (resp., uses) label L , then every such labeling f avoids (resp., uses) label $S - L$.*

We next describe a simple method for general graphs G that is surprisingly useful,

 FIG. 1. The bound on $\lambda(G; k, 1)$.

for it permits us to extend a bound at some particular value to general values of k .

LEMMA 2.2. Let a, b be reals with $a > 0$.

If $\lambda(G; a, 1) \leq b$, then

$$\lambda(G; k, 1) \leq \begin{cases} b & \text{if } 0 \leq k \leq a, \\ \frac{b}{a}k & \text{if } k \geq a. \end{cases}$$

If $\lambda(G; a, 1) \geq b$, then

$$\lambda(G; k, 1) \geq \begin{cases} \frac{b}{a}k & \text{if } 0 \leq k \leq a, \\ b & \text{if } k \geq a. \end{cases}$$

In particular, if $\lambda(G; a, 1) = b$, then

- for $0 \leq k \leq a$, $\frac{b}{a}k \leq \lambda(G; k, 1) \leq b$;
- for $k \geq a$, $b \leq \lambda(G; k, 1) \leq \frac{b}{a}k$.

Proof. If $\lambda(G; a, 1) \leq b$, we have the following:

- For $0 \leq k \leq a$, the result follows from the fact that $\lambda(G; k, 1)$ is nondecreasing.
- For $k \geq a$, we also use the scaling lemma to obtain $\lambda(G; k, 1) \leq \lambda(G; k, \frac{k}{a}) = \frac{k}{a} \lambda(G; a, 1) \leq \frac{b}{a}k$.

The proof is similar if $\lambda(G; a, 1) \geq b$. $\square$

It is interesting to compare the lattice problems to those for infinite trees. For integer $d > 0$, let T_d denote the tree that is regular of degree d . Note that T_d is infinite for $d \geq 2$ and T_2 is an infinite path. For the path P_n on n vertices, $n \geq 7$, the authors [19] determined the minimum span $\lambda(P_n; k, 1)$, $n \geq 7$ (see Figure 2).

Georges and Mauro [12] obtained the values of $\lambda(T_d; k_1, k_2)$ for integers $k_1 \geq k_2 \geq 0$. In a subsequent paper (with the same title!) Calamoneri, Pelc, and Petreschi [8] gave the values for integers $0 \leq k_1 \leq k_2$. By continuity and scaling, these can be restated in terms of $\lambda(T_d; k, 1)$ for reals $k \geq 0$, which is neater, so we use this format here. For $k \geq 1$ the functions get increasingly complicated as d grows, so we state formulas only for the values required here, $d = 3, 4$.

THEOREM 2.3 (see [12]). For real $k \geq 1$ we have

$$\lambda(T_3; k, 1) = \begin{cases} 3k & \text{if } 1 \leq k \leq \frac{3}{2}, \\ k + 3 & \text{if } \frac{3}{2} < k \leq 2, \\ 2k + 1 & \text{if } 2 \leq k \leq 3, \\ k + 4 & \text{if } k \geq 3. \end{cases}$$

FIG. 2. The minimum span $\lambda(P_n; k, 1)$ for path $P_n, n \geq 7$.

THEOREM 2.4 (see [12]). For real $k \geq 1$, we have

$$\lambda(T_4; k, 1) = \begin{cases} 4k & \text{if } 1 \leq k \leq \frac{4}{3}, \\ k+4 & \text{if } \frac{4}{3} < k \leq \frac{3}{2}, \\ 3k+1 & \text{if } \frac{3}{2} \leq k \leq \frac{5}{3}, \\ 6 & \text{if } \frac{5}{3} \leq k \leq 2, \\ 3k & \text{if } 2 \leq k \leq \frac{5}{2}, \\ k+5 & \text{if } \frac{5}{2} \leq k \leq 3, \\ 2k+2 & \text{if } 3 \leq k \leq 4, \\ k+6 & \text{if } k \geq 4. \end{cases}$$

THEOREM 2.5 (see [8]). For real k , $0 \leq k \leq 1$, and integer $d \geq 2$, we have

$$\lambda(T_d; k, 1) = \begin{cases} k + (d-1) & \text{if } 0 \leq k \leq \frac{1}{2}, \\ (2d-1)k & \text{if } \frac{1}{2} < k \leq \frac{d}{2d-1}, \\ d & \text{if } \frac{d}{2d-1} \leq k \leq 1. \end{cases}$$

Next we give two results that relate the optimal spans of regular trees T_d to that of general d -regular graphs G .

THEOREM 2.6 (see [13]). Let G be a regular graph of degree $d \geq 2$. Then for all real $k \geq 1$, we have $\lambda(G; k, 1) \geq \lambda(T_d; k, 1)$.

The idea of the proof is that T_d is a universal cover of G , so that we can easily define a graph homomorphism h from T_d to G . Then if f is an optimal $L(k, 1)$ -labeling of G , $f \circ h$ is an $L(k, 1)$ -labeling of T_d , so that

$$\lambda(T_d; k, 1) \leq \text{span}(f) \leq \text{span}(f') = \lambda(G; k, 1).$$

The condition $k \geq 1$ above is certainly necessary, since it could be for vertices s and t at distance two that $h(s)$ and $h(t)$ are adjacent, and we would only be certain

FIG. 3. The hexagonal cell covering and the triangular lattice Γ_Δ .

that $|f(s) - f(t)| \geq k$, which is not strong enough if $k < 1$. For instance, let $k < 1$. If $d = 2$, then T_d is an infinite path, and we may consider the 2-regular graph $G = C_3$. It is easily seen (by examining the two neighbors of a vertex with label 0) that $\lambda(T_2; k, 1) \geq 1 + k$, which exceeds $\lambda(C_3; k, 1) = 2k$.

However, if G is triangle-free, then it cannot be that $h(s)$ and $h(t)$ are adjacent in the problematic case above. We obtain the following result.

THEOREM 2.7. *Let G be a triangle-free regular graph of degree $d \geq 2$. Then for all real $k \geq 0$, we have $\lambda(G; k, 1) \geq \lambda(T_d; k, 1)$.*

3. The triangular lattice. In a radio mobile network, the large service areas are often covered by a network of nearly congruent polygonal cells, with each transmitter at the center of a cell that it covers. A honeycomb of hexagonal cells provides the most economic covering of the whole plane [11] (i.e., covers the plane with smallest possible transmitter density), where the transmitters are placed in the triangular lattice Γ_Δ (see Figure 3). We fix a point to be the original point o and impose an xy coordinate system so that we can name each point by its xy coordinate.

This problem has some history, owing to the fundamental nature of the triangular lattice for channel assignment problems. Griggs [15] formulated an integer $L(k, 1)$ -labeling problem on the triangular lattice Γ_Δ for the 2000 International Math Contest in Modeling (MCM). Among the 271 teams which worked on this problem for four days and wrote papers, five teams [4, 10, 14, 29, 34] won the contest and got their papers published. As pointed out in the last section, two student teams observed what became the Symmetry Lemma, Lemma 2.1. All winners found $\lambda(\Gamma_\Delta; k, 1)$ for $k = 2, 3$, and some gave labelings for $k = 1$ or for integers $k \geq 4$ that turn out to be optimal, but without proving the lower bound. The team of Goodwin, Johnston, and Marcus [14] proved the optimality for integers $k \geq 4$ (quite an achievement in such a short time) and considered the more general problem of $\lambda(\Gamma_\Delta; k_1, k_2)$ for integers k_1, k_2 . Subsequently, researchers Jin and Yeh [24] and Zhu and Shi [36] took over, each solving some special cases for integers $k_1 \geq k_2$. Calamoneri [6] gave the minimum span for integers $k_1 \geq 3k_2$, and she gave bounds for $k_2 \leq k_1 \leq 3k_2$.

Here we describe the solution of the $L(k, 1)$ -labeling problem for the triangular lattice for real numbers $k \geq 1$, and we give bounds for $0 \leq k \leq 1$ (see Figure 4), where considerable effort has not yet led to a full solution.

THEOREM 3.1. *For $k \geq 0$ the minimum span of any $L(k, 1)$ -labeling of the*

FIG. 4. $\lambda(\Gamma_{\Delta}; k, 1)$ for $k \geq 0$.

triangular lattice is given by

$$\lambda(\Gamma_{\Delta}; k, 1) \left\{ \begin{array}{ll} = 2k + 3 & \text{if } 0 \leq k \leq \frac{1}{3}, \\ \in [2k + 3, 11k] & \text{if } \frac{1}{3} \leq k \leq \frac{9}{22}, \\ \in [2k + 3, \frac{9}{2}] & \text{if } \frac{9}{22} \leq k \leq \frac{3}{7}, \\ \in [9k, \frac{9}{2}] & \text{if } \frac{3}{7} \leq k \leq \frac{1}{2}, \\ \in [\frac{9}{2}, \frac{16}{3}] & \text{if } \frac{1}{2} \leq k \leq \frac{2}{3}, \\ \in [\frac{16}{3}, \frac{23}{4}] & \text{if } \frac{2}{3} \leq k \leq \frac{3}{4}, \\ \in [\frac{23}{4}, 6] & \text{if } \frac{3}{4} \leq k \leq \frac{4}{5}, \\ = 6 & \text{if } \frac{4}{5} \leq k \leq 1, \\ = 6k & \text{if } 1 \leq k \leq \frac{4}{3}, \\ = 8 & \text{if } \frac{4}{3} \leq k \leq 2, \\ = 4k & \text{if } 2 \leq k \leq \frac{11}{4}, \\ = 11 & \text{if } \frac{11}{4} \leq k \leq 3, \\ = 3k + 2 & \text{if } 3 \leq k \leq 4, \\ = 2k + 6 & \text{if } k \geq 4. \end{array} \right.$$

For the proof of this theorem, go to section 6. We can use Lemma 2.2 to give a slight improvement to the stated bounds in the interval that is not yet resolved, $\frac{1}{3} \leq k \leq \frac{4}{5}$: having the exact values of lambda at $k = \frac{2}{3}, \frac{3}{4}, \frac{4}{5}$ means that there is a linear lower bound for k just below these values, of $8k$ if $k \in [\frac{9}{16}, \frac{2}{3}]$; of $\frac{23k}{3}$ if $k \in [\frac{16}{23}, \frac{3}{4}]$; and of $\frac{15k}{2}$ if $k \in [\frac{23}{30}, \frac{4}{5}]$. Similarly, there is a linear upper bound for k just above these values, of $9k$ if $k \in [\frac{1}{2}, \frac{16}{27}]$; of $8k$ if $k \in [\frac{2}{3}, \frac{23}{32}]$; and of $\frac{23k}{3}$ if $k \in [\frac{3}{4}, \frac{18}{23}]$. We conjecture that the upper bound on $\lambda(\Gamma_{\Delta}; k, 1)$ is the actual value for $\frac{1}{3} \leq k \leq \frac{1}{2}$. For $\frac{1}{2} \leq k \leq \frac{4}{5}$, we conjecture that $\lambda(\Gamma_{\Delta}; k, 1) = 5k + 2$, a formula which works already in this interval at $k = \frac{1}{2}, \frac{2}{3}, \frac{3}{4}$, and $\frac{4}{5}$. Incidentally, we compared the formulas for the triangular lattice (which is 6-regular) to that of the regular infinite tree, T_6 , and found they are quite different and not worth stating explicitly here.

 FIG. 5. A Manhattan network and the square lattice $\Gamma_{\square}$.

4. The square lattice. In cities, tall buildings can be obstacles in the signal path and limit the range of a cell phone. A Manhattan cellular system [3] can be used that is modeled by the square lattice $\Gamma_{\square}$ (see Figure 5). Many graphs corresponding to cellular systems are the induced subgraphs of the square lattice and the triangular lattice.

Theorem 4.1 is the complete determination of $\lambda(\Gamma_{\square}; k, 1)$ for real numbers $k \geq 0$ (see Figure 6). Previously, Calamoneri [6] independently gave the minimum (integer) span $\lambda(\Gamma_{\square}; k_1, k_2)$ for integers $k_1 \geq 3k_2$, as well as bounds when $k_2 \leq k_1 \leq 3k_2$. (It should be noted that the stated bounds in the earlier extended abstract [5] are not entirely correct, such as the claim that $\lambda(\Gamma_{\square}; 3, 2) = 12$, which is contradicted by the $L(3, 2)$ -labeling of span only 11 from [35]. However, the bounds in the subsequent preprint [6] appear to be correct.)

THEOREM 4.1. *For $k \geq 0$ the minimum span of any $L(k, 1)$ -labeling of the square lattice is given by*

$$\lambda(\Gamma_{\square}; k, 1) = \begin{cases} k + 3 & \text{if } 0 \leq k \leq \frac{1}{2}, \\ 7k & \text{if } \frac{1}{2} < k \leq \frac{4}{7}, \\ 4 & \text{if } \frac{4}{7} \leq k < 1, \\ 4k & \text{if } 1 \leq k \leq \frac{4}{3}, \\ k + 4 & \text{if } \frac{4}{3} < k \leq \frac{3}{2}, \\ 3k + 1 & \text{if } \frac{3}{2} < k \leq \frac{5}{3}, \\ 6 & \text{if } \frac{5}{3} \leq k \leq 2, \\ 3k & \text{if } 2 < k \leq \frac{8}{3}, \\ 8 & \text{if } \frac{8}{3} \leq k \leq 3, \\ 2k + 2 & \text{if } 3 \leq k \leq 4, \\ k + 6 & \text{if } k \geq 4. \end{cases}$$

This theorem, which is proven in section 7, allows us to answer a question posed by Georges and Mauro (private communication): does $\lambda(\Gamma_{\square}; k, 1)$ agree with $\lambda(T_4; k, 1)$ for all $k \geq 0$, as stated in Theorems 2.4 and 2.5? Since $\Gamma_{\square}$ is a triangle-free regular graph of degree 4, Theorem 2.7 is applicable and tells us that $\lambda(\Gamma_{\square}; k, 1) \geq \lambda(T_4; k, 1)$ for all $k \geq 0$. Indeed, they almost always agree. However, there is one interval in which they differ: when $\frac{5}{2} < k < 3$, $\lambda(\Gamma_{\square}; k, 1) = \min\{3k, 8\}$ is strictly larger than $\lambda(T_4; k, 1) = k + 5$.

FIG. 6. The minimum span $\lambda(\Gamma_{\square}; k, 1)$.FIG. 7. The equilateral triangle cell covering and the hexagonal lattice Γ_H .

5. The hexagonal lattice. Another interesting fundamental planar array is the hexagonal lattice Γ_H (see Figure 7), which is the dual of the triangular lattice. We are not aware of its being used in real life for wireless networks, but it is mentioned in the engineering literature.

We designate a point o to be the origin, and we impose an xoy coordinate system so that we can name each point by its xoy coordinate, where (i, j) are vertices (see Figure 7). Vertices (i, j) and $(i + 1, j)$ are always adjacent, while vertices (i, j) and $(i, j + 1)$ are adjacent if and only if $i \equiv j \pmod{2}$. Calamoneri [6] gives the minimum span for the hexagonal lattice for integers $k_1 \geq 2k_2$ and bounds for $k_2 \leq k_1 \leq 2k_2$. Here we resolve the remaining open cases and completely determine the span $\lambda(\Gamma_H; k, 1)$ for real numbers $k \geq 0$ (see Figure 8).

THEOREM 5.1. For $k \geq 0$ the minimum span of any $L(k, 1)$ -labeling of the

 FIG. 8. The minimum span $\lambda(\Gamma_H; k, 1)$ for $k \geq 0$.

hexagonal lattice is given by

$$\lambda(\Gamma_H; k, 1) = \begin{cases} k+2 & \text{if } 0 \leq k \leq \frac{1}{2}, \\ 5k & \text{if } \frac{1}{2} \leq k \leq \frac{3}{5}, \\ 3 & \text{if } \frac{3}{5} \leq k \leq 1, \\ 3k & \text{if } 1 \leq k \leq \frac{5}{3}, \\ 5 & \text{if } \frac{5}{3} \leq k \leq 2, \\ 2k+1 & \text{if } 2 \leq k \leq 3, \\ k+4 & \text{if } k \geq 3. \end{cases}$$

The proof is given in section 8. We may now compare the spans of the hexagonal lattice and the regular tree of the same degree, T_3 . As before, the fact that Γ_H is triangle-free allows us to apply Theorem 2.7 to see that $\lambda(\Gamma_H; k, 1) \geq \lambda(T_3; k, 1)$ for all $k \geq 0$. Comparing the formula above for Γ_H to those from Theorems 2.3 and 2.5, we see that Γ_H agrees with T_3 except in the range $\frac{3}{2} < k < 2$, where $\lambda(\Gamma_H; k, 1) = \min\{3k, 5\}$ is strictly larger than $\lambda(T_3; k, 1) = k + 3$.

6. The proof of the Triangular Lattice Theorem (Theorem 3.1). Generally, we get upper bounds by constructing feasible labelings. For lower bounds we derive contradictions on induced subgraphs for labelings of smaller span. Especially, we denote by B_7 (resp., B_{19} , B_{37}) the induced subgraph of Γ_Δ on all 7 (resp., 19, 37) vertices at distance at most one (resp., two, three) from a fixed vertex. Lemma 2.2 is particularly useful for obtaining lower and upper bounds.

To find an upper bound on $\lambda(\Gamma_\Delta; k, 1)$, one construction method is to tile the whole lattice by a labeled parallelogram described by a matrix of labels. We de-

FIG. 9. The matrix labeling.

fine a doubly periodic labeling of the triangular lattice by an $m \times n$ labeling matrix $A := [a_{i,j}]$, such that we label point (i, j) by $a_{m-(j \bmod m), (i \bmod n)+1}$, where i, j are integers. For example, the following labeling (see Figure 9) is defined by the labeling matrix A :

$$A = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}.$$

Then Figure 9 shows how the labels are assigned, where $a_{3,1}$ is at the vertex with coordinates $(0, 0)$ in the triangular lattice. The whole lattice is tiled with copies of the 3×3 tile as shown.

A special case of matrix labeling is defined simply by “arithmetic progressions”: For positive integers k_1, k_2 , we construct a labeling $f \in L(k_1, k_2)$ by taking $f(i, j) = (ai + bj) \bmod l$ for positive integers a, b, l . When such f is feasible, we obtain $\lambda(\Gamma_\Delta; k_1, k_2) \leq l - 1$. Some labelings of this kind were given for the triangular and square lattices in [35]. We found some new arithmetic progression labelings by computer search. We begin our constructions at $k = 0$.

PROPOSITION 6.1. *For $0 \leq k \leq \frac{1}{3}$, we have $\lambda(\Gamma_\Delta; k, 1) \leq 2k + 3$. For $\frac{1}{3} \leq k \leq \frac{9}{22}$, we have $\lambda(\Gamma_\Delta; k, 1) \leq 11k$.*

Proof. We get the upper bound $\lambda(\Gamma_\Delta; k, 1) \leq 2k + 3$ for $0 \leq k \leq \frac{1}{3}$ by defining the labeling matrix

$$A = \begin{bmatrix} k+1 & 2k & 0 & k+3 & 2k+2 & 2 \\ 2k+1 & 1 & k & 2k+3 & 3 & k+2 \\ 0 & k+3 & 2k+2 & 2 & k+1 & 2k \\ k & 2k+3 & 3 & k+2 & 2k+1 & 1 \\ 2k+2 & 2 & k+1 & 2k & 0 & k+3 \\ 3 & k+2 & 2k+1 & 1 & k & 2k+3 \end{bmatrix}.$$

In particular, $\lambda(\Gamma_\Delta; \frac{1}{3}, 1) \leq \frac{11}{3}$, and Lemma 2.2 implies that $\lambda(\Gamma_\Delta; k, 1) \leq 11k$ for $k \geq \frac{1}{3}$. $\square$

Next, we can improve upon the $11k$ upper bound for k between $\frac{9}{22}$ and $\frac{1}{2}$.

PROPOSITION 6.2. *For $\frac{9}{22} \leq k \leq \frac{1}{2}$, we have $\lambda(\Gamma_\Delta; k, 1) \leq \frac{9}{2}$.*

Proof. The upper bound $\lambda(1, 2) \leq 9$ is given in [24] by an arithmetic progression labeling in $L(1, 2)$: Label point (i, j) by $(i + 4j) \bmod 10$. By scaling, this gives the bound on $\lambda(\Gamma_\Delta; \frac{1}{2}, 1)$, which then extends to $k \leq \frac{1}{2}$ by Lemma 2.2. $\square$

The upper bound for k between $\frac{1}{2}$ and $\frac{3}{4}$ follows from the bounds at $k = \frac{2}{3}$ and $\frac{3}{4}$ by the fact that $\lambda(\Gamma_\Delta; k, 1)$ is nondecreasing (Lemma 2.2).

PROPOSITION 6.3. 1. We have $\lambda(\Gamma_\Delta; 2, 3) \leq 16$. Hence, $\lambda(\Gamma_\Delta; \frac{2}{3}, 1) \leq \frac{16}{3}$.

2. We have $\lambda(\Gamma_\Delta; 3, 4) \leq 23$. Hence, $\lambda(\Gamma_\Delta; \frac{3}{4}, 1) \leq \frac{23}{4}$.

Proof. By computer search of arithmetic progression labelings, we discovered $f_1 \in L(2, 3)(\Gamma_\Delta)$ given by $f_1(i, j) = (2i + 7j) \bmod 17$ and $f_2 \in L(3, 4)(\Gamma_\Delta)$ given by $f_2(i, j) = (3i + 10j) \bmod 24$. Hence, $\lambda(\Gamma_\Delta; 2, 3) \leq 16$ and $\lambda(\Gamma_\Delta; 3, 4) \leq 23$. $\square$

Next we extend the upper bound out to $k = \frac{4}{3}$ by applying Lemma 2.2 with the upper bound on $\lambda(\Gamma_\Delta; 1, 1)$. Note that the upper bounds we are giving here for $k = \frac{1}{2}, \frac{2}{3}, \frac{3}{4}$, and 1 are matched by the lower bounds, and so give the correct values of $\lambda(\Gamma_\Delta; k, 1)$ for these k .

PROPOSITION 6.4 (see [4, 14]). We have $\lambda(\Gamma_\Delta; 1, 1) = 6$. Hence,

$$\lambda(G; k, 1) \leq \begin{cases} 6 & \text{if } \frac{3}{4} \leq k \leq 1, \\ 6k & \text{if } 1 \leq k \leq \frac{4}{3}. \end{cases}$$

Proof. We get the upper bound, $\lambda(B_7; 1, 1) \leq 6$, from the arithmetic progression labeling $f(i, j) = (i + 3j) \bmod 7$. The rest follows from Lemma 2.2. $\square$

We now use the construction of numerous MCM teams at $k = 2$ to extend our upper bound out to $k = \frac{11}{4}$, and another construction out to $k = 4$.

PROPOSITION 6.5 (see [4, 10, 14, 29, 34]). We have $\lambda(\Gamma_\Delta; 2, 1) \leq 8$. Hence,

$$\lambda(G; k, 1) \leq \begin{cases} 8 & \text{if } \frac{4}{3} \leq k \leq 2, \\ 4k & \text{if } 2 \leq k \leq \frac{11}{4}. \end{cases}$$

Proof. Label point (i, j) by $(2i + 5j) \bmod 9$. $\square$

PROPOSITION 6.6 (see [14, 29]). For $3 \leq k \leq 4$, we have $\lambda(\Gamma_\Delta; k, 1) \leq 3k + 2$.

Proof. We get the bound by defining the labeling matrix

$$A = \begin{bmatrix} 3k & 0 & k & 2k \\ 1 & k+1 & 2k+1 & 3k+1 \\ k+2 & 2k+2 & 3k+2 & 2 \end{bmatrix}. \quad \square$$

Using $\lambda(\Gamma_\Delta; 3, 1) \leq 11$, this bound of 11 extends down to $k = \frac{11}{4}$ by Lemma 2.2. A construction from the winning MCM papers takes care of all large k .

PROPOSITION 6.7 (see [4, 10, 14, 29, 34]). For $k \geq 4$, we have $\lambda(\Gamma_\Delta; k, 1) \leq 2k + 6$.

Proof. We get the labeling from the matrix

$$A = \begin{bmatrix} 2k+5 & 0 & k+4 \\ 1 & k+2 & 2k+6 \\ k+3 & 2k+4 & 2 \end{bmatrix}. \quad \square$$

We verify the lower bounds using proofs by contradiction (which can be rather complicated) and Lemma 2.2. We shall postpone the small values, $k \leq \frac{3}{4}$. We demonstrate two main methods of proof. The first method, for integers k_1, k_2 , involves the successive elimination of possible labels, until a contradiction is reached. This method was used in the contest paper of Goodwin, Johnston, and Marcus [14] to handle the case of integers $k \geq 4$ (see our comments before Proposition 6.11). We also drew ideas from [36] for the proof of the following important case.

FIG. 10. The subgraphs B_7 and B_{19} of the triangular lattice.

PROPOSITION 6.8. We have $\lambda(\Gamma_\Delta; 4, 3) \geq 24$. Hence,

$$\lambda(\Gamma_\Delta; k, 1) = \begin{cases} 6k & \text{if } \frac{3}{4} \leq k \leq \frac{4}{3}, \\ 8 & \text{if } \frac{4}{3} \leq k \leq 2. \end{cases}$$

Proof. The first statement implies the second by Lemma 2.2. It suffices to prove that $\lambda(\Gamma_\Delta; 4, 3) \geq 24$. Assume to the contrary that there exists a labeling $f \in L(4, 3)(\Gamma_\Delta)$ with its labels in $\{0, 1, \dots, 23\}$. The series of claims that follows restricts the labels f one can use until we find that no such f can exist at all, proving the proposition.

CLAIM 1. The labeling f cannot use label 3 or 20.

Proof. Assume f uses label 3 at v . By the separation conditions, the six labels around v belong to $\{7, 8, \dots, 23\}$, and the difference between any pair of them is at least 3.

Among all 49 possible labelings of B_7 with central label 0 by symmetry, we found by computer that there are just five feasible labelings of subgraph B_{19} that use 3 at the center (B_7 , B_{19} are shown in Figure 10), and none of these can be extended to B_{37} . Full details are in [23]. By the Symmetry Lemma, Lemma 2.1, f is also excluded from using the complementary label $23 - 3 = 20$, and the claim follows.

CLAIM 2. The labeling f cannot use label 7 or 16.

Proof. Assume f uses label 7 at $v \in V(\Gamma_\Delta)$. Denote the six labels around v by $x_1 < x_2 < \dots < x_6$. By the separation conditions, $x_{i+1} \geq x_i + 3$ for $i = 1, 2, \dots, 5$, and each $x_i \in \{0, 1, 2, 11, 12, \dots, 19, 21, 22, 23\}$ (recall we cannot use 3 or 20). Then even if $x_1 \leq 2$, we must have $x_2 \geq 11$, $x_3 \geq 14$, $x_4 \geq 17$, $x_5 \geq 21$, $x_6 \geq 24$, a contradiction proving the claim.

Now f has no label 3, 7, 16, 20. The proofs of Claims 3, 4, and 5 are similar to the proof of Claim 2, so we omit the details.

CLAIM 3. The labeling f cannot use label 6 or 17.

CLAIM 4. The labeling f cannot use label 10 or 13.

CLAIM 5. The labeling f cannot use label 11 or 12.

Now the set of all possible labels is $\{0, 1, 2, 4, 5, 8, 9, 14, 15, 18, 19, 21, 22, 23\}$. We cannot find seven distinct labels, such that the difference between any two of them is at least 3. So we cannot label B_7 , which is a contradiction. Thus, $\lambda(\Gamma_\Delta; 4, 3) \geq 24$. $\square$

By similar proofs, we have the following bounds (see [23] for full details).

PROPOSITION 6.9. 1. We have $\lambda(\Gamma_\Delta; 11, 4) \geq 44$. Hence,

$$\lambda(\Gamma_\Delta; k, 1) \geq \begin{cases} 4k & \text{if } 2 \leq k \leq \frac{11}{4}, \\ 11 & \text{if } \frac{11}{4} \leq k \leq 3. \end{cases}$$

2. We have $\lambda(\Gamma_\Delta; 1, 2) \geq 9$. Hence,

$$\lambda(\Gamma_\Delta; k, 1) \geq \begin{cases} 9k & \text{if } \frac{3}{7} \leq k \leq \frac{1}{2}, \\ \frac{9}{2} & \text{if } k \geq \frac{1}{2}. \end{cases}$$

3. We have $\lambda(\Gamma_\Delta; 2, 3) \geq 16$. Hence, $\lambda(\Gamma_\Delta; k, 1) \geq \frac{16}{3}$ for $k \geq \frac{2}{3}$.

4. We have $\lambda(\Gamma_\Delta; 3, 4) \geq 23$. Hence, $\lambda(\Gamma_\Delta; x, 1) \geq \frac{21}{4}$ for $k \geq \frac{3}{4}$.

5. We have $\lambda(\Gamma_\Delta; 4, 5) \geq 30$. Hence, $\lambda(\Gamma_\Delta; x, 1) \geq 6$ for $k \geq \frac{4}{5}$.

The next result takes care of all k in the interval $(3, 4)$. It can be derived by continuity and scaling from the corresponding result by Calamoneri [6] for integer labelings that give $\lambda(\Gamma_\Delta; k_1, k_2)$ for integers k_1, k_2 with $3k_2 \leq k_1 \leq 4k_2$. Her lower bound method involves looking at a small induced subgraph of the lattice and checking cases according to the numerical order of the labels. This is similar to the method devised independently by Georges and Mauro for labeling trees [12]. We discovered the result independently (but waited on the rest of this project before writing it up here). Because our proof illustrates a different method with some potential for future value, we include it here. It involves the successive removal of intervals of possible labels until there is a contradiction.

PROPOSITION 6.10. For $3 < k < 4$, we have $\lambda(\Gamma_\Delta; k, 1) = 3k + 2$.

Proof. The upper bound comes from Proposition 6.6. We prove the lower bound by contradiction: Assume $\lambda(\Gamma_\Delta; k, 1) = l < 3k + 2$. By the D -Set Theorem, there is an optimal labeling $f \in L(k, 1)(\Gamma_\Delta)$ with $\text{span}(f) = l < 3k + 2$ and $f(u) = 0$ for some $u \in V(\Gamma_\Delta)$.

CLAIM 1. The labeling f cannot use labels in $[k - 1, k) \cup (l - k, l - k + 1]$.

Proof. Assume $f(v) \in [k - 1, k)$ for some $v \in V(\Gamma_\Delta)$. The neighbors of v induce a C_6 subgraph, and their labels are all $\geq f(v) + k$. Hence, $\lambda(\Gamma_\Delta; k, 1) \geq f(v) + k + \lambda(C_6; k, 1) \geq (k - 1) + k + (k + 3) = 3k + 2$ (because $\lambda(C_6; k, 1) = k + 3$ for $k \geq 3$; see [23]). This gives a contradiction. Thus $f(v) \notin [k - 1, k)$ for all $v \in V(\Gamma_\Delta)$. By symmetry of the labels, $f(v) \notin (l - k, l - k + 1]$ for all $v \in V(\Gamma_\Delta)$, which proves the claim.

Now, $f(v) \in I_1 \cup I_2 \cup I_3$ for all $v \in V(\Gamma_\Delta)$, where $I_1 = [0, k - 1)$, $I_2 = [k, l - k]$, $I_3 = (l - k + 1, l]$. Then $|I_1| = k - 1 < k$, $|I_2| = l - 2k < k + 2$, $|I_3| = k - 1 < k$.

CLAIM 2. The labeling f cannot use labels in $[k, k + 1) \cup (l - k - 1, l - k]$.

Proof. Assume $f(v) \in [k, k + 1)$ for some $v \in V(\Gamma_\Delta)$. Among the six distinct labels around v , at most one label is in $I_1 = [0, k - 1)$ (because this label is $\leq f(v) - k < 1$), at most two labels are in $I_2 = [k, l - k]$ (because these two labels are $\geq f(v) + k \geq 2k$ and $||2k, l - k|| = l - 3k < 2$), and at most three labels are in $I_3 = (l - k + 1, l]$ (because $|I_3| < k$, these labels cannot be adjacent). Thus, one label is in I_1 , two labels are in I_2 , and three labels are in I_3 . The three labels in I_3 are for vertices that aren't adjacent. The smallest of the three labels then must be next to at least one of the labels in I_2 . This smallest label in I_3 is $\leq l - 2 < 3k$. But the two labels in I_2 are $\geq f(v) + k \geq 2k$, and the smallest label in I_3 , being next to one of these, must then be at least $3k$, a contradiction.

Thus, $f(v) \notin [k, k + 1)$ for all $v \in V(\Gamma_\Delta)$. By symmetry of the labels, $f(v) \notin (l - k - 1, l - k]$, proving the claim.

Now, $f(v) \in I_1 \cup I_2' \cup I_3 = [0, k - 1) \cup [k + 1, l - k - 1] \cup (l - k + 1, l]$, where $I_2' = [k + 1, l - k - 1]$. Then $|I_2'| \leq l - 2k - 2 < k$.

CLAIM 3. The labeling f cannot use labels in $[k + 1, k + 2) \cup (l - k - 2, l - k - 1]$.

Proof. Assume $f(v) \in [k + 1, k + 2)$ for some $v \in V(\Gamma_\Delta)$. Among the six labels around v , at most two labels are in $I_1 = [0, k - 1)$ (because these two labels are

$\leq f(v) - k < 2$), no label is in $I'_2 = [k + 1, l - k - 1]$ (because if it exists, it would be $\geq f(v) + k \geq 2k + 1 > l - k - 1$, a contradiction), and at most three labels are in $I_3 = (l - 2, l]$. We cannot label all six vertices.

Thus $f(v) \notin [k + 1, k + 2]$ for all $v \in V(\Gamma_\Delta)$. By symmetry of the labels, $f(v) \notin (l - k - 2, l - k - 1]$, proving the claim.

Now, $f(v) \in I_1 \cup I''_2 \cup I_3 = [0, k - 1] \cup [k + 2, l - k - 2] \cup (l - k + 1, l]$ for all $v \in V(\Gamma_\Delta)$, where $I''_2 = [k + 2, l - k - 2]$. Then $|I''_2| = l - 2k - 4 < k - 2 < 2$ for $k < 4$.

Since $f(u) = 0$, among the six distinct labels around u (the difference between any pair of them is at least 1), no label is in I_1 , at most two labels are in I''_2 (because $|I''_2| < 2$), and at most three labels are in $I_3 = (l - 2, l]$ (because $|I_3| < k$ means no two of its labels are for adjacent vertices). So we cannot label all six neighbors of u , a contradiction. $\square$

We next address $k \geq 4$. The modeling team of Goodwin, Johnston, and Marcus [14] obtained the correct values for the integer cases, that is, for integers $k \geq 4$. It is a pity that, due to space limitations, the elegant proof in their contest paper was omitted from the published version! It is the same method we used to prove Proposition 6.8 above.

Moreover, Goodwin et al. gave what is equivalent to the correct formula, $\lambda(\Gamma_\Delta; k_1, k_2) = 2k_1 + 6k_2$, for arbitrary integers k_1, k_2 with $k_1 > 6k_2 + 1$. By scaling and continuity, this implies $\lambda(\Gamma_\Delta; k, 1) = 2k + 6$ for all real $k \geq 6$. There appear to be some technical errors in their lower bound proof (quite understandable, since they had just four days to produce their entire paper from scratch!). However, we discovered that if one uses the D -Set Theorem, some small changes will fix their proof. We present below our own verification of the lower bound, which we need more generally for all real $k \geq 4$. We follow this with the much shorter proof for $k \geq 6$ based on the method of Goodwin et al. that does not depend on the structure of the triangular lattice, so that it can be used on other graphs for sufficiently large real k , provided that there is a linear bound for all large integers k .

PROPOSITION 6.11. *For $k \geq 4$ we have $\lambda(\Gamma_\Delta; k, 1) \geq 2k + 6$.*

Proof. Assume for contradiction that $\lambda(\Gamma_\Delta; k, 1) = l < 2k + 6$ for some $k \geq 4$. By the D -Set Theorem, there is an optimal labeling $f \in L(k, 1)(\Gamma_\Delta)$ with span and largest label l and smallest label 0.

CLAIM 1. *The labeling f cannot use labels in $[3, k]$.*

Proof. If some $f(v) \in [3, k]$, then the labels on the vertices of the C_6 neighboring v are all at least $f(v) + k$. The largest of these labels is then at least $f(v) + k + \lambda(C_6; k, 1) \geq 3 + k + (k + 3) = 2k + 6 > l$, a contradiction since $\lambda(C_6; k, 1) = k + 3$ [23, 19]), proving the claim.

By symmetry, none of the labels in f belongs to $(l - k, l - 3]$. So all labels belong to the union $I_1 \cup I_2 \cup I_3$, where $I_1 = [0, 3]$, $I_2 = [k, l - k]$, and $I_3 = (l - 3, l]$.

CLAIM 2. *The labeling f cannot use labels in $[k, k + 1]$.*

Proof. Assume some label $f(v) \in [k, k + 1]$. At most one of the six vertices next to v has a label in I_1 because any such label is $\leq f(v) - k < 1$. At most three of the six vertices have labels in I_3 as any two must be at least one apart.

First suppose that three of these labels are in I_3 . They cannot be at adjacent vertices, so suppose they are at vertices v_1, v_3 , and v_5 , with reference to the graph B_7 in Figure 10. Two of the other labels next to v must belong to $[f(v) + k, l - k]$, so the larger of the two, say it is at v_2 , must be at least $f(v) + k + 1 \geq 2k + 1$. Then both $f(v_1)$ and $f(v_3)$ are at least $f(v_2) + k$, and the larger of the two is at least $f(v_2) + k + 1 \geq 3k + 2 \geq 2k + 6 > l$, a contradiction with $k \geq 4$.

Next suppose just two of these labels next to v lie in I_3 . The two vertices are not adjacent. There must be at least three labels next to v in $[f(v) + k, l - k]$, and, because this interval has length $< k$, no two of the three are adjacent—say they are at v_1, v_3, v_5 . The largest of the three labels is at least $f(v) + k + 2$, and its neighbor with label in I_3 has label at least $f(v) + k + 2 + k \geq 3k + 2$, which is again a contradiction.

Finally, suppose at most one label next to v lies in I_3 . Then at least four labels next to v are in $[f(v) + k, l - k]$, so some two are adjacent—but this is impossible since they must differ by at least k (as $(l - k) - (f(v) + k) \leq l - 3k < 2 < k$). This proves the claim.

Hence, f has no labels in $[k, k + 1)$ or, by symmetry, in $(l - k - 1, l - k]$. So all of its labels belong to $I_1 \cup I'_2 \cup I_3$, where here $I'_2 = [k + 1, l - k - 1]$.

CLAIM 3. *The labeling f cannot use labels in $[k + 1, k + 2)$.*

Proof. Suppose some $f(v) \in [k + 1, k + 2)$. Then labels used next to v in I_1 are at most $f(v) - k < 2$, so there can be at most two such labels. On the other hand, at most three labels next to v can come from I_3 . Then some label used next to v lies in I'_2 . But such a label must be at most $l - k - 1$ and at least $f(v) + k \geq 2k + 1 \geq k + 5 > l - k - 1$, a contradiction proving the claim.

By symmetry, no label of f belongs to $(l - k - 2, l - k - 1]$. Then all of its labels belong to $I_1 \cup I''_2 \cup I_3$, where $I''_2 = [k + 2, l - k - 2]$. Let u be a vertex with $f(u) = 0$. Then its six neighbors all have labels in $I''_2 \cup I_3$. But I_3 can contain at most three of the labels, as they must be at least one apart from each other. So some three of the labels are in I''_2 . However, $(l - k - 2) - (k + 2) = l - 2k - 4 < 2$, so I''_2 can contain at most two of the labels, a contradiction, so no such f exists. $\square$

Here is the shorter proof of the restriction of the proposition above to $k \geq 6$.

PROPOSITION 6.12. *For $k \geq 6$ we have $\lambda(\Gamma_\Delta; k, 1) \geq 2k + 6$.*

Proof. Let us assume the result of Goodwin et al. that $\lambda(\Gamma_\Delta; k, 1) \geq 2k + 6$ for integers $k \geq 4$. Now consider any noninteger $k > 6$. Let $m = \lceil k \rceil - k$, so that $m \in (0, 1)$ and $k + m = \lceil k \rceil \geq 7$. Hence, $\lambda(\Gamma_\Delta; k + m, 1) \geq 2k + 2m + 6$.

Assume for contradiction that $\lambda(\Gamma_\Delta; k, 1) < 2k + 6$. Let f be an optimal labeling in $L(k, 1)(\Gamma_\Delta)$ as in the D -Set Theorem, with minimum value 0 at some vertex u and maximum value $\text{span}(f)$ at some vertex w . Define a labeling f_1 by $f_1(v) = f(v) + m \lfloor f(v)/k \rfloor$. We can check that $f_1 \in L(k + m, 1)(\Gamma_\Delta)$. Further, the minimum value of f_1 is 0, which occurs at u , and its maximum occurs at w , which thus has value $f_1(w) = \text{span}(f_1) < (2k + 6) + m \lfloor (2k + 6)/k \rfloor = 2k + 6 + 2m$ (since $k > 6$ by assumption). This contradicts the lower bound in the previous paragraph. $\square$

We cannot see how to extend the argument in the last proof to work for k between 4 and 6. It remains to do the lower bound for small k . Similar to the proof of Proposition 6.10, we can show the following (see [23]).

PROPOSITION 6.13. *For $0 < k \leq \frac{1}{2}$, we have $\lambda(\Gamma_\Delta; k, 1) \geq 2k + 3$. Hence $\lambda(\Gamma_\Delta; k, 1) = 2k + 3$ for $0 \leq k \leq \frac{3}{7}$.*

This completes the proof of Theorem 3.1.

7. The proof of the Square Lattice Theorem (Theorem 4.1). We begin by establishing the claimed upper bounds on $\lambda(\Gamma_\square; k, 1)$ for reals $k \geq 0$. In many cases, there is an explicit construction based on a modular construction, in which a particular matrix of labels is used for a rectangle of lattice points and then repeated over and over. We define a doubly periodic labeling of the square lattice by an $m \times n$ labeling matrix $A := [a_{i,j}]$, such that we label point (i, j) by $a_{m-(j \bmod m), (i \bmod n)+1}$, where i, j are integers.

PROPOSITION 7.1. *For $0 \leq k \leq \frac{1}{2}$, we have $\lambda(\Gamma_\square; k, 1) \leq k + 3$.*

Proof. Starting from an optimal $L(0, 1)$ -labeling and shifting up some labels by k , in order to satisfy the $L(k, 1)$ conditions, we constructed with the following labeling matrix that attains the upper bound:

$$A = \begin{bmatrix} 0 & k & 1 & k+1 \\ k+3 & 2 & k+2 & 3 \\ 1 & k+1 & 0 & k \\ k+2 & 3 & k+3 & 2 \end{bmatrix}. \quad \square$$

Next, applying the result above at $k = \frac{1}{2}$, Lemma 2.2 yields this upper bound for larger k .

PROPOSITION 7.2. *For $\frac{1}{2} \leq k \leq \frac{4}{7}$, we have $\lambda(\Gamma_{\square}; k, 1) \leq 7k$.*

Van den Heuvel, Leese, and Shepherd [35] gave a circular integer labeling result which is helpful for our real number labelings, as it suggests some arithmetic progression labelings that turn out to be optimal for our problem.

PROPOSITION 7.3. *We have*

$$\begin{aligned} \lambda(\Gamma_{\square}; 1, 1) &= 4, \\ \lambda(\Gamma_{\square}; 2, 1) &\leq 6, \\ \lambda(\Gamma_{\square}; 3, 1) &\leq 8, \\ \lambda(\Gamma_{\square}; 3, 2) &\leq 11. \end{aligned}$$

Proof. From [35], we have these labelings:

$\lambda(\Gamma_{\square}; 1, 1) \leq 4$ by labeling f with $f(i, j) = (i + 2j) \bmod 5$.

$\lambda(\Gamma_{\square}; 2, 1) \leq 6$ by labeling f with $f(i, j) = (2i + 3j) \bmod 7$.

$\lambda(\Gamma_{\square}; 3, 1) \leq 8$ by labeling f with $f(i, j) = (3i + 4j) \bmod 9$.

$\lambda(\Gamma_{\square}; 3, 2) \leq 11$ by labeling f with $f(i, j) = (3i + 5j) \bmod 12$.

It is easy to show $\lambda(\Gamma_{\square}; 1, 1) \geq 4$. $\square$

Applying the preceding two propositions and Lemma 2.2, we have the following upper bounds.

PROPOSITION 7.4. *We have*

$$\lambda(\Gamma_{\square}; k, 1) \leq \begin{cases} 4 & \text{if } \frac{4}{7} \leq k \leq 1, \\ 4k & \text{if } 1 \leq k \leq \frac{5}{3}, \\ 6 & \text{if } \frac{5}{3} \leq k \leq 2, \\ 3k & \text{if } 2 \leq k \leq \frac{8}{3}, \\ 8 & \text{if } \frac{8}{3} \leq k \leq 3. \end{cases}$$

The upper bounds in the proposition above are weaker than the known lower bounds for $\frac{4}{3} < k < \frac{5}{3}$. Let us consider one value in this gap, $k = \frac{11}{8}$. By Proposition 7.4, we get the upper bound $\lambda(\Gamma_{\square}; \frac{11}{8}, 1) \leq \frac{11}{2}$, so by the Scaling Lemma, $\lambda(\Gamma_{\square}; 11, 8) \leq 44$. To determine whether this is the best possible, we searched for a better labeling: We managed to construct an $L(11, 8)$ -labeling based on a matrix A in which the entries are elements of the D -set in $[0, 43]$. Since 43 can be expressed in terms of 11 and 8 in just one way, $43 = 11 + 4 \times 8$, we were able to extend this matrix labeling to cases in the range $\frac{4}{3} \leq k \leq \frac{3}{2}$, as given in the following proposition. We next took the resulting labeling at $k = \frac{3}{2}$ and found a way to extend it to the range $\frac{3}{2} \leq k \leq \frac{5}{3}$ in a way that maintains the order of the labels, while expanding

their pairwise differences, to maintain feasibility as k grows, giving Proposition 7.6. Notice that these formulas for $\lambda(\Gamma_{\square}; k, 1)$ around $k = 11/8$ are not of the simple form ck for some c , so we could not simply apply Lemma 2.2.

PROPOSITION 7.5. *For $\frac{4}{3} \leq k \leq \frac{3}{2}$, we have $\lambda(\Gamma_{\square}; k, 1) \leq k + 4$.*

Proof. The upper bound is attained by the following labeling matrix:

$$\begin{bmatrix} 5 & k & 4 & 0 & 3 & k+4 & 2 & k+3 & 1 & k+2 & 0 & k+1 \\ 0 & 3 & k+4 & 2 & k+3 & 1 & k+2 & 0 & k+1 & 5 & k & 4 \\ 2 & k+3 & 1 & k+2 & 0 & k+1 & 5 & k & 4 & 0 & 3 & k+4 \\ k+2 & 0 & k+1 & 5 & k & 4 & 0 & 3 & k+4 & 2 & k+3 & 1 \end{bmatrix}. \quad \square$$

PROPOSITION 7.6. *For $\frac{3}{2} \leq k \leq \frac{5}{3}$, we have $\lambda(\Gamma_{\square}; k, 1) \leq 3k + 1$.*

Proof. The upper bound is attained by the following labeling matrix:

$$\begin{bmatrix} 2k+2 & k & 2k+1 & 0 & 2k & 3k+1 & 2 & 3k & 1 & k+2 & 0 & k+1 \\ 0 & 2k & 3k+1 & 2 & 3k & 1 & k+2 & 0 & k+1 & 2k+2 & k & 2k+1 \\ 2 & 3k & 1 & k+2 & 0 & k+1 & 2k+2 & k & 2k+1 & 0 & 2k & 3k+1 \\ k+2 & 0 & k+1 & 2k+2 & k & 2k+1 & 0 & 2k & 3k+1 & 2 & 3k & 1 \end{bmatrix}. \quad \square$$

For larger k , we first adapt the construction given by Calamoneri for integers k_1, k_2 with $3k_2 \leq k_1 \leq 4k_2$. We then present a simple matrix $L(k, 1)$ -labeling that is optimal for all $k \geq 4$.

PROPOSITION 7.7. *For $3 \leq k \leq 4$ we have $\lambda(\Gamma_{\square}; k, 1) \leq 2k + 2$.*

Proof. Adapting the construction in [6], the upper bound is attained by the $L(k, 1)$ -labeling matrix:

$$A = \begin{bmatrix} 2k+2 & k & 2k+1 & 2 & 2k & 1 & k+2 & 0 & k+1 \\ k+2 & 0 & k+1 & 2k+2 & k & 2k+1 & 2 & 2k & 1 \\ 2 & 2k & 1 & k+2 & 0 & k+1 & 2k+2 & k & 2k+1 \end{bmatrix}. \quad \square$$

PROPOSITION 7.8. *For $k \geq 0$ we have $\lambda(\Gamma_{\square}; k, 1) \leq k + 6$.*

Proof. The upper bound is attained by the following labeling matrix:

$$A = \begin{bmatrix} 0 & k+3 & 1 & k+4 \\ k+6 & 2 & k+5 & 3 \\ 1 & k+4 & 0 & k+3 \\ k+5 & 3 & k+6 & 2 \end{bmatrix}. \quad \square$$

We now consider the lower bounds to complete the proof of the formulas. It is helpful to compare our graph to T_4 , the regular infinite tree of degree 4 discussed in section 2. By Theorem 2.7 we get that for all $k \geq 0$, $\lambda(\Gamma_{\square}; k, 1) \geq \lambda(T_4; k, 1)$. From the values of $\lambda(T_4; k, 1)$ presented in Theorems 2.4 and 2.5, we obtain the claimed values of $\lambda(\Gamma_{\square}; k, 1)$ for all k outside the interval $[\frac{5}{2}, 3]$. In this remaining interval, we must improve the lower bound on $\lambda(\Gamma_{\square}; k, 1)$. In view of Lemma 2.2, all that remains to prove the theorem is to establish the lower bound at $k = \frac{8}{3}$.

PROPOSITION 7.9. *We have $\lambda(\Gamma_{\square}; 8, 3) \geq 24$. Consequently, for $2 \leq k \leq 3$, we have*

$$\lambda(\Gamma_{\square}; k, 1) \geq \begin{cases} 3k & \text{if } 2 \leq k \leq \frac{8}{3}, \\ 8 & \text{if } \frac{8}{3} \leq k \leq 3. \end{cases}$$

Proof. The second statement follows from the first by Lemma 2.2.

FIG. 11. The subgraph B_{12} of the square lattice.

Assume for contradiction that the first statement fails. Then there exists a labeling $f \in L(8, 3)(\Gamma_{\square})$ with all labels in $\{0, \dots, 23\}$. The series of claims that follows restricts the labels f one can use until we find that no such f can exist at all, proving the proposition.

Let $v_0 = (i_0, j_0) \in V(\Gamma_{\square})$. Let B_{12} be the induced subgraph as in Figure 11.

CLAIM 1. *The labeling f cannot use label 7 or 16.*

Proof. Assume $f(v_0) = 16$. Since no label can exceed 23, the four distinct labels around v_0 are each $\leq f(v_0) - 8 = 8$, which is impossible since any two must be at least 3 apart. By the Symmetry Lemma, labeling f does not use the complementary label $23 - 16 = 7$, and the claim follows.

CLAIM 2. *The labeling f cannot use label 8 or 15.*

Proof. Assume some $f(v_0) = 8$. The four labels around v_0 are each $\geq f(v_0) + 8 = 16$ or $\leq f(v_0) - 8 = 0$, and hence are 0 or ≥ 17 (because by Claim 1, f cannot use 16). Suppose they are labels $x < y < z < w$. Since the difference between any pair of the four labels is ≥ 3 , it must be that $x = 0, y = 17, z = 20, w = 23$. Suppose without loss of generality that $f(v_7) = y = 17$. Since $f(v_7) + 8 = 25$ is too large, it must be that the neighboring labels $f(v_6), f(v_8), f(v_{10})$ are all $\leq f(v_7) - 8 = 9$, and hence all $\leq f(v_0) - 3 = 8 - 3 = 5$. But this is impossible since the difference between any pair of the three labels must be at least 3. By symmetry, we can also exclude 15. This proves the claim.

Now f has no label 7, 8, 15, 16. The proofs of Claims 3 and 4 are similar to the proof of Claim 2, so we omit the details.

CLAIM 3. *The labeling f cannot use label 9 or 14.*

CLAIM 4. *The labeling f cannot use label 11 or 12.*

By the D -Set Theorem, there exists optimal labeling $f^* \in L(8, 3)(\Gamma_{\square})$ with smallest label 0 and all labels in $D_{8,3} \cap [0, 23] = \{0, 3, 6, 8, 9, 11, 12, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23\}$. Applying the claims above to f^* , we find that $f^*(v) \in \{0, 3, 6, 17, 18, 19, 20, 21, 22, 23\}$ for all $v \in V(\Gamma_{\square})$.

Let $f(v_0) = 0$. The four labels around v_0 are each $\geq f(v_0) + 8 = 8$. Their labels belong to $\{17, 18, 19, 20, 21, 22, 23\}$, a contradiction since the difference between any pair of them is ≥ 3 . Thus, it must be that $\lambda(\Gamma_{\square}; 8, 3) \geq 24$. $\square$

This completes the proof of the formulas for the square lattice, Theorem 4.1.

8. The proof of the Hexagonal Lattice Theorem (Theorem 5.1). We will find the upper bound on $\lambda(\Gamma_H; k, 1)$, $k \geq 0$, by constructions and Lemma 2.2. One construction method is to tile the whole lattice by a labeled parallelogram described by a matrix of labels. We define a doubly periodic labeling of the hexagonal lattice by an $m \times n$ labeling matrix $A := [a_{i,j}]$ for m, n even, such that we label point (i, j) by $a_{m-(j \bmod m), (i \bmod n)+1}$, where i, j are integers. For example, the following labeling

 FIG. 12. The doubly periodic labeling by matrix A .

(see Figure 12) is defined by the labeling matrix A , where

$$A = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} & a_{15} & a_{16} \\ a_{21} & a_{22} & a_{23} & a_{24} & a_{25} & a_{26} \\ a_{31} & a_{32} & a_{33} & a_{34} & a_{35} & a_{36} \\ a_{41} & a_{42} & a_{43} & a_{44} & a_{45} & a_{46} \end{bmatrix}.$$

Then Figure 12 shows how the labels are assigned, where $a_{4,1}$ is at the vertex with coordinates $(0, 0)$ in the hexagonal lattice. The whole lattice is tiled with copies of the 4×6 tile as shown.

PROPOSITION 8.1. For $0 \leq k \leq \frac{1}{2}$, we have $\lambda(\Gamma_H; k, 1) \leq k + 2$.

Proof. We use the labeling matrix below, also shown in Figure 13, with the values a, b, c taken to be $k, k + 1, k + 2$, respectively:

$$A = \begin{bmatrix} 0 & a & 1 & b & 2 & c \\ b & 2 & c & 0 & a & 1 \end{bmatrix}.$$

Incidentally, this labeling was obtained by doing a first-fit labeling on one row, then on the next row, and so on. $\square$

We have $\lambda(\Gamma_H; \frac{1}{2}, 1) \leq \frac{5}{2}$. By Lemma 2.2, the following proposition holds.

PROPOSITION 8.2. For $\frac{1}{2} \leq k \leq \frac{3}{5}$, we have $\lambda(\Gamma_H; k, 1) \leq 5k$.

Next we consider $k = 1$.

PROPOSITION 8.3. We have $\lambda(\Gamma_H; 1, 1) \leq 3$. Hence,

$$\lambda(\Gamma_H; k, 1) \leq \begin{cases} 3 & \text{if } \frac{3}{5} \leq k \leq 1, \\ 3k & \text{if } 1 \leq k \leq \frac{5}{3}. \end{cases}$$

FIG. 13. Optimal $L(k, 1)$ -labeling of Γ_H for $0 \leq k \leq \frac{1}{2}$ or $k \geq 3$.FIG. 14. Optimal $L(1, 1)$ -labeling of Γ_H .

Proof. Because of Lemma 2.2, it is enough to prove the upper bound at $k = 1$.

We will prove $\lambda(\Gamma_H; 1, 1) \leq 3$ by using either of the following labeling matrices. Each was obtained by a first-fit labeling process, doing one row at a time (see Figure 14).

$$A = \begin{bmatrix} 0 & 2 & 1 & 3 \\ 1 & 2 & 0 & 3 \\ 1 & 3 & 0 & 2 \\ 0 & 3 & 1 & 2 \end{bmatrix} \quad \text{or} \quad A = \begin{bmatrix} 0 & 2 & 1 & 3 \\ 1 & 3 & 0 & 2 \end{bmatrix}. \quad \square$$

PROPOSITION 8.4. For $2 \leq k \leq 3$, we have $\lambda(\Gamma_H; k, 1) \leq 2k + 1$. For $\frac{5}{3} \leq k \leq 2$, we have $\lambda(\Gamma_H; k, 1) \leq 5$.

Proof. The second statement follows immediately from the first at $k = 2$. For $2 \leq k \leq 3$, one can prove $\lambda(\Gamma_H; k, 1) \leq 2k + 1$ by the matrix labeling with entries shown in Figure 15 (top). A simpler construction can be obtained by adapting a construction of Calamoneri [6], originally given for the corresponding integer labeling. This gives the following matrix labeling, shown in Figure 15 (bottom):

$$A = \begin{bmatrix} 1 & k+1 & 2k+1 & 1 & k+1 & 2k+1 \\ 2k & 0 & k & 2k & 0 & k \end{bmatrix}. \quad \square$$

Next we treat large k .

PROPOSITION 8.5. For $k \geq 3$, we have $\lambda(\Gamma_H; k, 1) \leq k + 4$.

 FIG. 15. Optimal $L(k, 1)$ -labelings of Γ_H for $2 \leq k \leq 3$.

Proof. Following the construction in [6] for the corresponding integer labeling, we again have the matrix labeling as in Figure 13, where this time $a = k + 4, b = k + 3, c = k + 2$:

$$A = \begin{bmatrix} 0 & a & 1 & b & 2 & c \\ b & 2 & c & 0 & a & 1 \end{bmatrix}. \quad \square$$

We next verify the lower bounds. By Theorem 2.7 we get that for all $k \geq 0$, $\lambda(\Gamma_{\square}; k, 1) \geq \lambda(T_3; k, 1)$. From the values of $\lambda(T_3; k, 1)$ presented in Theorems 2.3 and 2.5, we obtain the claimed values of $\lambda(\Gamma_{\square}; k, 1)$ for all k outside the interval $(\frac{3}{2}, 2)$. In this remaining interval, we must improve the lower bound on $\lambda(\Gamma_{\square}; k, 1)$. In view of Lemma 2.2, all that is needed to complete the proof is to establish the lower bound at $k = 5/3$.

PROPOSITION 8.6. *We have $\lambda(\Gamma_H; 5, 3) \geq 15$. Hence,*

$$\lambda(\Gamma_H; k, 1) \leq \begin{cases} 3k & \text{if } 1 \leq k \leq \frac{5}{3}, \\ 5 & \text{if } \frac{5}{3} \leq k \leq 2. \end{cases}$$

Proof. It suffices to prove the first statement, due to Lemma 2.2. We will show $\lambda(\Gamma_H; 5, 3) \geq 15$.

Assume otherwise, $\lambda(\Gamma_H; 5, 3) < 15$. Then there exists an $L(5, 3)$ -labeling f with all labels in the set $\{0, \dots, 14\}$.

CLAIM 1. *The labeling f cannot use labels 4 or 10.*

Proof. Assume $f(v) = 4$ for some $v \in V(\Gamma_H)$. The three distinct labels around v are $\geq f(v) + 5 = 9$. Suppose they are labels $x_1 < x_2 < x_3$. Since any pair of the three labels differs by at least 3 (because they are at distance two from each other),

FIG. 16. The $L(5, 3)$ -labeling of a subgraph of Γ_H .

one of them is ≥ 15 , a contradiction. By the Symmetry Lemma, f cannot use label $14 - 4 = 10$. This proves the claim.

CLAIM 2. *The labeling f cannot use labels 5 or 9.*

Proof. Assume $f(v) = 5$ for some $v \in V(\Gamma_H)$. The three labels around v are $\leq f(v) - 5 = 0$ or $\geq f(v) + 5 = 10$. But 10 is excluded by the previous claim. Since any pair of the three labels differs by at least 3 it must be that the three labels used are 0, 11, 14. Then the three neighbors of the label 11 are each $\leq 11 - 5 = 6$ and any two are at least 3 apart, so they need to be 0, 3, and 6. But this is a contradiction since one of them is $f(v) = 5$. By symmetry, we must also exclude label 9, and the claim follows.

Now f has no label 4, 5, 9, 10. The proofs of Claims 3 and 4 are similar to the proof of Claim 2, so we omit the details.

CLAIM 3. *The labeling f cannot use label 7.*

CLAIM 4. *The labeling f cannot use labels 1, 2, 12, or 13.*

Now all labels of f belong to $\{0, 3, 6, 8, 11, 14\}$; call this set L .

CLAIM 5. *The labeling f cannot use labels 3 or 11.*

Proof. Assume $f(v) = 3$ for some $v \in V(\Gamma_H)$. The three labels around v are $\geq f(v) + 5 = 3 + 5 = 8$. They are 8, 11, 14 as in Figure 16. The three neighbors of the label 11 are ≤ 6 , with one of them $f(v) = 3$ and the others 0, 6. By the separation conditions and set L , we have $c, d \in \{0, 14\}$. We have two cases.

Case 1. $a = 0, b = 6$. Since $a = 0$, then $c = 14$. We cannot find a feasible label g in L , a contradiction.

Case 2. $a = 6, b = 0$. Since $b = 0$, then $e \in \{6, 8\}, f = 0$, so that $d = 14$. We cannot find a feasible label h in L , a contradiction proving the claim.

Now all labels of f belong to $\{0, 6, 8, 14\}$. We cannot label the induced subgraph $K_{1,3}$, a contradiction. $\square$

This completes the proof of the span formulas for Γ_H .

9. Concluding remarks. Despite considerable effort, we failed to complete the determination of all values $\lambda(\Gamma_\Delta; k, 1)$ for $\frac{1}{2} < k < \frac{4}{5}$. We believed that our upper bounds would be the correct values for $k \in [\frac{1}{3}, \frac{1}{2}]$, while the line $5k+2$ would be correct for $k \in [\frac{1}{2}, \frac{4}{5}]$. However, while preparing our revision of this manuscript, Král' and Škoda (building on our earlier version in circulation) found that this is not entirely the case [26]. They completed the determination of $\lambda(\Gamma_\Delta; k, 1)$. Altogether, the graph has eleven linear pieces in the interval $[0, 1]$.

As with the graphs of $\lambda(\Gamma_\square; k, 1)$ and $\lambda(\Gamma_H; k, 1)$, the graph of $\lambda(\Gamma_\Delta; k, 1)$ has the property that successive linear pieces alternately turn up and down; that is, though continuous and nondecreasing in k , the concavity keeps alternating between up and down. We continue to be puzzled why this is so.

It is natural now to extend this investigation to conditions at distance three, where very little is known. One definite result in this direction is given by Bertossi, Pinotti, and Tan [3], who determined that $\lambda(\Gamma_\Delta; 2, 1, 1) = 11$. Their construction that achieves the optimal value, 11, can be described by a labeling matrix:

$$A = \begin{bmatrix} 0 & 10 & 2 & 6 & 1 & 9 \\ 4 & 8 & 5 & 11 & 3 & 7 \\ 2 & 6 & 1 & 9 & 0 & 10 \\ 5 & 11 & 3 & 7 & 4 & 8 \\ 1 & 9 & 0 & 10 & 2 & 6 \\ 3 & 7 & 4 & 8 & 5 & 11 \end{bmatrix}.$$

On the other hand, it is easy to find 12 vertices in Γ_Δ such that the maximum distance is three, and so $\lambda(\Gamma_\Delta; 1, 1, 1) \geq 11$. It follows that $\lambda(\Gamma_\Delta; k, 1, 1) = 11$ for $1 \leq k \leq 2$.

Several papers in engineering consider labelings with conditions at distance at most p with $k_1 = k \geq k_2 = k_3 = \dots = k_p = 1$. Bertossi, Pinotti, and Tan [3] and then Panda, Kumar, and Das [30] independently obtained a lower bound for the square lattice, $\lambda(\Gamma_\square; 1, 1, \dots, 1) \geq \lfloor \frac{p^2+2p}{2} \rfloor$. This problem corresponds to integer channel assignments such that identical channels must be at least distance $p + 1$ apart in the lattice. Investigating graph models of wireless networks, Dubhashi et al. [9] presented bounds on the minimum span for $L(2, 1, 1, \dots, 1)$ -labeling of the p -dimensional square lattice (grid), in which $V(G) = \mathbb{Z}^p$, and two vertices, say $(x_1, x_2, \dots, x_p)$ and $(y_1, y_2, \dots, y_p)$, are joined by an edge whenever $\sum_{i=1}^p |x_i - y_i| = 1$.

We are continuing this project by seeking to describe *all* optimal $L(k, 1)$ -labelings of the three regular lattices, and by searching for optimal labelings with nice symmetry properties, such as being periodic or doubly periodic.

For further progress on the general theory of real number graph labelings, the reader is recommended to check the paper of Král' [25]. For an overview of the recent progress and state of the theory, refer to the recent survey [20].

Acknowledgments. The authors need to acknowledge the encouragement and sharing of ideas by their international research colleagues during this long-running project. Particular thanks go to Tiziana Calamoneri, Gerard Chang, John Georges, Dan Král', Jan Kratochvíl, Daphne Liu, David Mauro, Fred Roberts, and Roger Yeh. We are indebted to the dedicated and diligent referees for their many thoughtful editorial suggestions.

COMPUTING COMMON INTERVALS OF K PERMUTATIONS, WITH APPLICATIONS TO MODULAR DECOMPOSITION OF GRAPHS*

ANNE BERGERON[†], CEDRIC CHAUVE[‡], FABIEN DE MONTGOLFIER[§], AND
MATHIEU RAFFINOT[§]

Abstract. We introduce a new approach to compute the common intervals of K permutations based on a very simple and general notion of generators of common intervals. This formalism leads to simple and efficient algorithms to compute the set of all common intervals of K permutations that can contain a quadratic number of intervals, as well as a linear space basis of this set of common intervals. Finally, we show how our results on permutations can be used for computing the modular decomposition of graphs.

Key words. common interval, permutation, PQ -tree, modular decomposition

DOI. 10.1137/060651331

1. Introduction. The notion of *common interval* was introduced by Uno and Yagiura [19] in order to model the fact that, when comparing genomes, a group of genes can be rearranged but still remain connected. They proposed a first algorithm that computes the set of common intervals of a permutation P with the identity permutation in time $O(n + N)$, where n is the length of P , and N is the number of common intervals. However, N can be of size $O(n^2)$, thus the algorithm of Uno and Yagiura has an $O(n^2)$ time complexity. Heber and Stoye [12] defined a subset of size $O(n)$ of the common intervals of K permutations, called *irreducible intervals*, that forms a basis of the set of all common intervals: every common interval is a chain overlapping irreducible intervals. They proposed an $O(Kn)$ time algorithm to compute the set of irreducible intervals of K permutations, based on Uno and Yagiura's pioneering work.

One of the drawbacks of these algorithms is that properties of Uno and Yagiura's algorithm are not obvious [5]. Even the authors describe their $O(n + N)$ algorithm as “quite complicated,” and, in practice, simpler $O(n^2)$ algorithms run faster on randomly generated permutations [19]. On the other hand, Heber and Stoye's algorithms rely on a complex data structure that mimics what is known, in the theory of modular decomposition of graphs, as the PQ -trees of *strong intervals*. An incentive to revisit this problem is the central role that these PQ -trees seem to play in the field of comparative genomics. Strong intervals can be used to identify significant groups of genes that are conserved between genomes [13] or as guides to reconstruct evolution scenarios [1, 10].

In order to design alternative efficient algorithms to compute common intervals, we propose a theoretical framework for common intervals based on generating families of intervals. For two permutations, these families can be computed by straightforward $O(n)$ algorithms that use only tables and stacks as data structures and that upgrade trivially to the case of K permutations. Using these families, we compute common intervals with simple $O(n + N)$ and $O(n)$ algorithms whose properties can be readily verified. We also propose a new canonical representation of the family of common intervals that is simpler than the PQ -trees. We then link this work to previous studies on common intervals and show how our new representation can be transformed in linear time into classical ones, namely PQ -trees and irreducible intervals. Conversely, generating families can be linearly built from these representations.

Finally, we extend our approach to the classical graph problem of *modular decomposition* that aims to efficiently compute a compact representation of the modules of a graph. The first linear time algorithms that were developed [8, 15] are rather complex, and many efforts have been put into the design of decomposition algorithms that are efficient in practice, even if they do not run in linear time but in quasi-linear time [9, 16].

The article is structured as follows. In section 2, we describe the notion of generators of common intervals and how to compute generators of K permutations of size n in $O(Kn)$ time. Section 3 explains how to generate the set of all N common intervals in $O(n + N)$ using a generator. Section 4 describes a new linear space basis of common intervals, called the canonical generator. Section 5 links this new representation to classical ones, namely strong intervals, irreducible intervals, and PQ -trees. Finally, in section 6, we extend our results to the modular decomposition of graphs. An extended abstract of this article appeared in [2].

2. Common intervals and generators. A *permutation* P on n elements is a complete linear order on the set of integers $\{1, 2, \dots, n\}$. We denote Id_n the identity permutation $(1, 2, \dots, n)$. An *interval* of a permutation $P = (p_1, p_2, \dots, p_n)$ is a set of consecutive elements of permutation P . An interval of the identity permutation will be denoted by giving the indices of its left and right bounds $(i..j)$.

DEFINITION 2.1. Let $\mathcal{P} = \{P_1, P_2, \dots, P_K\}$ be a set of K permutations on n elements. A *common interval* of $\mathcal{P}$ is a set of integers that is an interval in each permutation of $\mathcal{P}$.

The set $\{1, 2, \dots, n\}$ and all singletons are always common intervals of any non-empty set of permutations; they are called *trivial* intervals. In what follows, we assume, without loss of generality, that the set $\mathcal{P}$ contains the identity permutation Id_n . A common interval of $\mathcal{P}$ can thus be denoted as an interval $(i..j)$ of the identity permutation.

Algorithms that identify common intervals such as those in [12, 19] use a bottom-up approach that constructs the common intervals by extending small intervals until they form a common interval and then form longer common intervals by taking unions of common intervals that share elements. Here we adopt a dual approach of constructing common intervals as intersections of intervals that are not necessarily common. This had two major impacts on the rest of the theory. First, it allowed us to exploit the symmetric properties of minima and maxima of intervals, and it provided the natural notion of two families of intervals of size n . Moreover, by removing the need to maintain common intervals, the design of the algorithms was much easier, and the data structures became trivial.

DEFINITION 2.2. Let $\mathcal{P} = \{\text{Id}_n, P_2, \dots, P_K\}$ be a set of K permutations on n

elements. A generator for the common intervals of $\mathcal{P}$ is a pair (R, L) of vectors of size n such that

1. $R[i] \geq i$ and $L[j] \leq j$ for all $i, j \in \{1, 2, \dots, n\}$,
2. $(i..j)$ is a common interval of $\mathcal{P}$ if and only if $(i..j) = (i..R[i]) \cap (L[j]..j)$.

Definition 2.2 has the following easy property that will turn out very useful in proving results on the structure of generators.

PROPOSITION 2.3. *For any generator (R, L) , $(i..j) = (i..R[i]) \cap (L[j]..j)$ if and only if $L[i] \leq i \leq j \leq R[i]$.*

Proof. If $(i..j) = (i..R[i]) \cap (L[j]..j)$, then $(i..j) \subseteq (i..R[i])$ and $(i..j) \subseteq (L[j]..j)$, which yields $L[i] \leq i \leq j \leq R[i]$. The converse is immediate. $\square$

The following proposition shows how to construct a generator for the common intervals of a union of sets of permutations, given generators for the common intervals of each set. If X and Y are two vectors, we denote by $\min(X, Y)$ the vector $\min(X[1], Y[1]), \dots, \min(X[n], Y[n])$.

PROPOSITION 2.4. *Let (R_1, L_1) and (R_2, L_2) be generators for the common intervals of two sets $\mathcal{P}_1$ and $\mathcal{P}_2$ of permutations, both containing the identity permutation. The pair $(\min(R_1, R_2), \max(L_1, L_2))$ is a generator for the common intervals of $\mathcal{P}_1 \cup \mathcal{P}_2$.*

Proof. Interval $(i..j)$ is a common interval of $\mathcal{P}_1 \cup \mathcal{P}_2$ if and only if it is a common interval of both $\mathcal{P}_1$ and $\mathcal{P}_2$, which is equivalent, by Proposition 2.3, to $L_1[j] \leq i \leq j \leq R_1[i]$ and $L_2[j] \leq i \leq j \leq R_2[i]$ and finally to $\max(L_1[j], L_2[j]) \leq i \leq j \leq \min(R_1[i], R_2[i])$. $\square$

Proposition 2.4 implies that, given an $O(n)$ algorithm for computing generators for the common intervals of two permutations, we can easily deduce an $O(Kn)$ algorithm for computing a generator for the common intervals of K permutations.

Generators are far from unique, but some are easier to compute than others. Identifying good generators is a crucial step in the design of efficient algorithms to compute common intervals. The remainder of this section focuses on particular classes of generators that turn out to have interesting properties with respect to computations.

DEFINITION 2.5. *Let $P = (p_1, \dots, p_n)$ be a permutation on n elements. For each element p_i , we define two intervals containing p_i :*

$\text{IMax}[p_i]$ *is the largest interval of P containing p_i and whose elements are all $\geq p_i$;*

$\text{IMin}[p_i]$ *is the largest interval of P containing p_i and whose elements are all $\leq p_i$. And we define the following two integers:*

$\text{Sup}[p_i]$ *is the largest integer such that $(p_i.. \text{Sup}[p_i]) \subseteq \text{IMax}[p_i]$;*

$\text{Inf}[p_i]$ *is the smallest integer such that $(\text{Inf}[p_i]..p_i) \subseteq \text{IMin}[p_i]$.*

Remark that $(p_i.. \text{Sup}[p_i])$ and $(\text{Inf}[p_i]..p_i)$ are intervals of the identity permutation but not necessarily intervals of permutation P . For example, if $P = (1, 4, 7, 5, 9, 6, 2, 3, 8)$, we have $\text{IMax}[5] = (7, 5, 9, 6)$ and $\text{Sup}[5] = 7$, and $\text{IMin}[8] = (6, 2, 3, 8)$ and $\text{Inf}[8] = 8$.

PROPOSITION 2.6. *The pair of vectors (Sup, Inf) is a generator for the common intervals of P and Id_n .*

Proof. Suppose that $(i..j)$ is a common interval of P and Id_n ; then $\text{Sup}[i] \geq j$ and $\text{Inf}[j] \leq i$ since all elements in the set $(i..j)$ are consecutive in permutation P . Thus $(i..j) = (i.. \text{Sup}[i]) \cap (\text{Inf}[j]..j)$. On the other hand, suppose that $\text{Sup}[i] \geq j$ and $\text{Inf}[j] \leq i$; then $\text{IMax}[i]$ contains j and $\text{IMin}[j]$ contains i . Since both $\text{IMax}[i]$ and $\text{IMin}[j]$ are intervals of P , their intersection is an interval and is equal to $(i..j)$. $\square$

Example. Let $\mathcal{P} = \{\text{Id}_8, P_2\}$ and $\mathcal{Q} = \{\text{Id}_8, P_3\}$ with

FIG. 1. The top two diagrams show the generators (Sup, Inf) of the common intervals of the set $\mathcal{P}$ in solid lines and of set $\mathcal{Q}$ in dashed lines. A line in row i of the left diagram extends from column i to column $\text{Sup}(i)$, and a line in row i of the right diagram extends from column $\text{Inf}(i)$ to column i . The bottom diagrams show a generator for the common intervals of $\mathcal{P} \cup \mathcal{Q}$ constructed using Proposition 2.4.

$$\text{Id}_8 = (1, 2, 3, 4, 5, 6, 7, 8), \quad P_2 = (1, 3, 2, 4, 5, 7, 6, 8), \quad P_3 = (2, 8, 3, 4, 5, 6, 1, 7).$$

The generators (Sup, Inf) for the common intervals of $\mathcal{P}$ and $\mathcal{Q}$ are shown in Figure 1. This figure also shows a generator for $\mathcal{P} \cup \mathcal{Q}$.

ALGORITHM 1. COMPUTING THE GENERATOR (Sup, Inf).

```

Inf[1] ← 1, Sup[n] ← n.
For k from 1 to n, m[k] ← k, M[k] ← k.
For k from 2 to n
  While m[k] - 1 is in IMin[k], m[k] ← m[m[k] - 1]
  Inf[k] ← m[k]
For k from n - 1 to 1
  While M[k] + 1 is in IMax[k], M[k] ← M[M[k] + 1]
  Sup[k] ← M[k]

```

PROPOSITION 2.7. Let P be a permutation on n elements. If the bounds of intervals $\text{IMax}[k]$ and $\text{IMin}[k]$ are known for all k , then Algorithm 1 computes (Sup, Inf) in $O(n)$ time.

Proof. We first show that Algorithm 1 is correct. Suppose that, at the beginning of the k th iteration of the second For loop, $\text{Inf}[k'] = m[k']$ for all $k' < k$, and $m[k] \in \text{IMin}[k]$. This is the case at the beginning of iteration $k = 2$, since $\text{Inf}[1] = 1$. By definition, $\text{Inf}[k] \leq k$, thus before entering the While loop, we have $\text{Inf}[k] \leq m[k]$. If the test $m[k] - 1 \in \text{IMin}[k]$ of the While loop is true, then $\text{Inf}[k] \leq m[k] - 1$, implying that $\text{Inf}[k] \leq \text{Inf}[m[k] - 1]$. Since $\text{Inf}[m[k] - 1] = m[m[k] - 1]$ by hypothesis, the instruction in the While loop preserves the invariant $\text{Inf}[k] \leq m[k]$. When the test of the While loop becomes false, then $\text{Inf}[k]$ is greater than $m[k] - 1$, thus $\text{Inf}[k] = m[k]$. The proof of correctness for Sup is similar.

Using the inverse of permutation P , the tests in the While loops can be done in

constant time. The total time complexity follows from the fact that the instruction within the *While* loop is executed exactly $n - 1$ times. Indeed, consider, at any point of the execution of the algorithm, the collection I of intervals $(m[k]..k)$ of the identity permutation that are not contained in any other interval of this type. After the initialization loop, we have n such intervals, that is, $I = \{(1..1), (2..2), \dots, (n..n)\}$, and at the completion of the algorithm, there is only one, namely $(m[n]..n) = (1..n)$, since $\text{Inf}[n] = 1$. The instruction in the *While* loop merges two consecutive intervals $(m[m[k] - 1]..m[k] - 1)$ and $(m[k]..k)$ of I into one, since the current value of $m[k]$ becomes $m[m[k] - 1]$. Since there were n intervals to start with, there can be at most $n - 1$ of these merges. $\square$

The computation of the bounds of intervals $\text{IMax}[k]$ and $\text{IMin}[k]$, as well as the computation of the inverse of permutation P , are quite straightforward. As an example, Algorithm 2 shows how to compute the left bound of $\text{IMax}[p_i]$.

PROPOSITION 2.8. *Let $P = (p_1, \dots, p_n)$ be a permutation on n elements. Algorithm 2 computes the left bound of all intervals $\text{IMax}[p_i]$ in $O(n)$ time.*

Proof. The time complexity of Algorithm 2 is immediate since each position is stacked once. Its correctness relies on the fact that, at the beginning of the i th iteration, the position j of the nearest left element such that $p_j < p_i$ must be in the stack. If it was not the case, then an element smaller than p_j was found between the positions j and i , contradicting the definition of position j . $\square$

ALGORITHM 2. COMPUTING THE LEFT BOUND OF $\text{IMax}[p_i]$ FOR ALL p_i .

S is a stack of positions; s denotes the top of S .
 Push 0 on S
 $p_0 \leftarrow 0$
 For i from 1 to n
 While $p_i < p_s$ Pop the top of S
 left bound of $\text{IMax}[p_i] \leftarrow s + 1$
 Push i on S

To summarize the results of this section, we have the following theorem.

THEOREM 2.9. *Let $\mathcal{P} = \{\text{Id}_n, P_2, \dots, P_K\}$ be a set of K permutations on n elements. A generator for the common intervals of $\mathcal{P}$ can be computed in $O(Kn)$ time.*

3. Common intervals of K permutations in optimal time. We now turn to the problem of generating all common intervals of K permutations in $O(N)$ time, where N is the number of such common intervals, given a generator satisfying the following property, based on the notion of *commuting* sets. Note that commuting families are also known as *laminar* families [18] in the field of combinatorial optimization.

DEFINITION 3.1. *Two sets A and B commute if either $A \subseteq B$, or $B \subseteq A$, or A and B are disjoint, and otherwise they overlap. A collection $\mathcal{C}$ of sets is commuting if, for any pair of sets A and B in $\mathcal{C}$, A and B commute. A generator (R, L) for the common intervals of $\mathcal{P} = \{\text{Id}_n, P_2, \dots, P_K\}$ is commuting if both the collections $\{(i..R[i])\}_{i \in (1..n)}$ and $\{(L[i]..i)\}_{i \in (1..n)}$ are commuting. If (R, L) is a commuting generator, we define $\text{Support}[i]$, for $i > 1$, to be the greatest integer $j < i$ such that $R[i] \leq R[j]$. (Similar values can be defined for L , but we will not refer to them explicitly.)*

It turns out that generators defined in section 2 are commuting. Indeed, generators defined in Proposition 2.4 are commuting if they are constructed with generators (R_1, L_1) and (R_2, L_2) that are commuting. This is a consequence of the fact that if

$a < b$ and $a' < b'$, then $\min(a, a') < \min(b, b')$ and $\max(b, b') > \max(a, a')$. For the generator (Sup, Inf) , we have the following proposition.

PROPOSITION 3.2. *The generator (Sup, Inf) for the common intervals of permutations $\mathcal{P}$ and Id_n is commuting.*

Proof. Suppose that $(k.. \text{Sup}[k])$ contains k' ; we will show that it must also contain $\text{Sup}[k']$. If k' is in $(k.. \text{Sup}[k])$, then k' is in $\text{IMax}[k]$, and $k' > k$; therefore, $\text{IMax}[k'] \subseteq \text{IMax}[k]$, and the interval $(k'.. \text{Sup}[k'])$ is included in $\text{IMax}[k]$, thus in $(k.. \text{Sup}[k])$ also. Since $\text{Sup}[k]$ is maximal, we must have $\text{Sup}[k] \geq \text{Sup}[k']$. A similar argument holds for Inf . $\square$

PROPOSITION 3.3. *Given a commuting generator (R, L) , Algorithm 3 computes the values $\text{Support}[i]$, for all $i > 1$, in linear time.*

Proof. The time complexity of Algorithm 3 is immediate. At iteration i the stack contains the left bounds of all intervals of $(j.. R[j])$ such that $R[j] \geq i$ and $j < i$, sorted in decreasing size order. It is then easy to see when equality holds. Note that $\text{Support}[1]$ is undefined and should not be used by subsequent algorithms. $\square$

THEOREM 3.4. *Given a commuting generator (R, L) , Algorithm 4 outputs all common intervals of a set $\mathcal{P}$ of K permutations on n elements in $O(n + N)$ time, where N is the number of common intervals of the set $\mathcal{P}$.*

Proof. The time complexity of Algorithm 4 is immediate. Suppose that interval $(i..j)$ is identified by the algorithm. At the start of the j th iteration of the *For* loop, $i = j$, thus $j \leq R[i]$. If the test of the *While* loop is true, then $i \geq L[j]$, and $(i..j)$ is a common interval. If $i' = \text{Support}[i]$, then $R[i'] \geq R[i]$, thus $j \leq R[i']$ at the end of the *While* loop.

On the other hand, if $(i..j)$ is a common interval of $\mathcal{P}$, with $i < j$, then $\text{Support}[j] \geq i$, since $R[i] \geq R[j]$. Let i' be the smallest integer such that $i < i'$ and $(i'..j)$ is identified by Algorithm 4 as a common interval. Such an interval exists, since $(j..j)$ is a common interval. Finally, $\text{Support}[i'] = i$ since $\text{Support}[i']$ must be greater than or equal to i . If it is greater, then $(\text{Support}[i']..j)$ is a common interval, contradicting the definition of i' . $\square$

ALGORITHM 3. COMPUTING $\text{Support}[i]$ FOR A COMMUTING GENERATOR (R, L) .

S is an empty stack; s denotes the top of S .
 Push 1 on S
 For i from 2 to n
 While $R[s] < i$ Pop the top of S
 $\text{Support}[i] \leftarrow s$
 Push i on S

ALGORITHM 4. COMMON INTERVALS OF A SET $\mathcal{P}$ GIVEN A GENERATOR (R, L) .

For j from n to 1
 $i \leftarrow j$
 While $i \geq L[j]$
 Output $(i..j)$ (* Interval $(i..j)$ is a common interval of the set $\mathcal{P}$ *)
 $i \leftarrow \text{Support}[i]$

4. A new canonical representation of closed families. The set of common intervals of a set of permutations is an example of more general families of intervals, the *closed* families. Closed families can have a quadratic number of elements, but a classical result establishes a bijection between PQ -trees with n leaves and closed families of Id_n , thus allowing a representation of size $O(n)$ ([3]—see also Proposition 5.3). In this section, we develop a new canonical representation for such families, based

FIG. 2. Two overlapping common intervals determine four more common intervals.

on the generators of the previous section. We will discuss the relations between this representation and PQ -trees in section 5.

DEFINITION 4.1. A closed family $\mathcal{F}$ of intervals of a permutation σ on n elements is a family that contains all singletons and the interval $(1..n)$ and that has the following property: if $(i..k)$ and $(j..l)$ are in $\mathcal{F}$, and $i < j \leq k < l$, then $(i..j-1)$, $(j..k)$, $(k+1..l)$, and $(i..l)$ belong to $\mathcal{F}$.

In what follows, we will suppose, for simplicity, that the permutation σ is the identity permutation, thus every interval of the family $\mathcal{F}$ is an interval of the form $(i..j)$. The closure properties of Definition 4.1 are well-known properties of the set of common intervals of a set of permutations and are illustrated in Figure 2. Conversely, it is easy to extend the definition of generators (Definition 2.2) to the more general case of closed families, and we will refer to a *generator of a closed family* $\mathcal{F}$ as a pair (R, L) that satisfies the conditions of Definition 2.2 with respect to the members of $\mathcal{F}$. Among all possible generators, the following one provides a representation of size $O(n)$ for any closed family.

DEFINITION 4.2. A generator (R, L) for a closed family $\mathcal{F}$ is canonical if, for all $i \in (1..n)$, intervals $(i..R[i])$ and $(L[i]..i)$ belong to $\mathcal{F}$.

PROPOSITION 4.3. Let $\mathcal{F}$ be a closed family. The canonical generator of $\mathcal{F}$ always exists, and it is unique and commuting.

Proof. Let $\mathcal{F}$ be a closed family. For $1 \leq i \leq n$, define $R[i]$ as the largest integer such that $(i..R[i]) \in \mathcal{F}$, and define $L[i]$ as the smallest integer such that $(L[i]..i) \in \mathcal{F}$.

If an interval $(i..j) \in \mathcal{F}$, then $(i..j) \subseteq (i..R[i])$, and $(i..j) \subseteq (L[j]..j)$, thus (R, L) is a generator. It is canonical since we picked elements of $\mathcal{F}$. Suppose that there exists a second canonical generator (R', L') , with $R \neq R'$; then there exists $1 \leq i \leq n$ such that $R'[i] < R[i]$. Since $(i..R[i])$ is in $\mathcal{F}$, it should be generated by (R', L') , but $(i..R'[i]) \cap (L'[R[i]]..R[i])$ does not contain $R[i]$. A similar argument holds if $L \neq L'$. Finally, suppose that two intervals $(i..R[i])$ and $(j..R[j])$ overlap with $i < j < R[i] < R[j]$. Then $(i..R[j])$ is in $\mathcal{F}$, which contradicts the maximality of $(i..R[i])$. $\square$

The following elementary property of canonical generators states that if two intervals of a generator overlap, they always do it correctly, in the sense that an $(L[j]..j)$ interval is always at the left of an $(i..R[i])$ interval.

PROPOSITION 4.4. For a canonical generator (R, L) , if $(i..R[i])$ and $(L[j]..j)$ overlap, then $L[j] \leq i \leq j \leq R[i]$.

Proof. Suppose that $i \leq L[j] \leq R[i] \leq j$; then $(i..j)$ is in $\mathcal{F}$ since both $(i..R[i])$ and $(L[j]..j)$ are. Then, by definition, $(i..j) = (i..R[i]) \cap (L[j]..j)$, thus $(i..R[i]) \cup (L[j]..j) = (i..R[i]) \cap (L[j]..j)$, implying $(i..R[i]) = (L[j]..j)$, contrary to the assumption that these intervals overlap. $\square$

THEOREM 4.5. Given a commuting generator (R', L') , Algorithm 5 computes the canonical generator (R, L) of a closed family $\mathcal{F}$ in $O(n)$ time.

Proof. The time complexity of Algorithm 5 follows from the fact that testing if an interval belongs to $\mathcal{F}$ can be computed in $O(1)$ time with the generator (R', L') . Its correctness relies on the following observation: if $R[k] \neq k$, then there exists an

integer $k' > k$ such that

$$(4.1) \quad \text{Support}[k'] = k \quad \text{and} \quad R[k'] = R[k],$$

where $\text{Support}[k']$ is defined (Definition 3.1) as the greatest integer smaller than k' such that $R'[\text{Support}[k']] \geq R'[k']$. Statement (4.1) implies that, since the values of $R[k]$ are computed in decreasing order, the value of $R[k]$ will be known at the start of iteration k .

In order to prove statement (4.1), let k' be the smallest integer such that $R[k'] = R[k]$. The hypothesis $R[k] \neq k$, and the fact that (R, L) is a commuting generator, imply that $k' > k$. We must show that $\text{Support}[k'] = k$. Since (R', L') is a commuting generator, and (R, L) is the canonical generator, we must have $R'[k] \geq R'[k']$. Thus, $\text{Support}[k'] \geq k$, implying that $R[\text{Support}[k']] \leq R[k]$. Since $R[k] = R[k']$, this would imply $R[\text{Support}[k']] = R[k]$, contradicting the definition of k' . $\square$

ALGORITHM 5. CANONICAL GENERATOR (R, L) GIVEN A COMMUTING GENERATOR (R', L') .

The vector *Support* is obtained from R' using Algorithm 3
 $R[1] \leftarrow n$
 For k from 2 to n
 $R[k] \leftarrow k$
 For k from n to 2
 If $(\text{Support}[k], R[k]) \in \mathcal{F}$
 $R[\text{Support}[k]] \leftarrow \max(R[k], R[\text{Support}[k]])$
 (* Computation of L is similar, by defining the vector *Support* with respect to L' *)

Example (continued). Let $\mathcal{R} = \{\text{Id}_8, P_2, P_3\}$ with

$$\text{Id}_8 = (1, 2, 3, 4, 5, 6, 7, 8), \quad P_2 = (1, 3, 2, 4, 5, 7, 6, 8), \quad P_3 = (2, 8, 3, 4, 5, 6, 1, 7).$$

Two generators for the common interval of $\mathcal{R}$ are shown in Figure 3. The second one is canonical.

5. Transformations of canonical representations. There exist many representations of closed families, and this variety is useful. Indeed, some are better suited for algorithmic purposes [12], and others yield nice graphical representations of the organization and nesting properties of a set of common intervals [3, 14]. In this section, we present algorithms that allow the conversion between the canonical generators of the preceding section and the classic representation using PQ -trees.

5.1. Canonical representations of closed families. Let T be a tree whose n leaves are labeled with n different labels. The *frontier* of a node is the set of labels of the leaves of the subtree rooted at this node.

DEFINITION 5.1. Let $\mathcal{F}$ be a closed family. A strong interval of $\mathcal{F}$ is an interval of $\mathcal{F}$ that commutes with each interval of $\mathcal{F}$.

A proper commuting family $\mathcal{F}$ of subsets of a set V is a commuting family such that $V \in \mathcal{F}$, all the singletons are in $\mathcal{F}$, and $\emptyset \notin \mathcal{F}$. In particular, the strong common intervals of K permutations form a proper commuting family. A proper commuting family $\mathcal{F}$ can be represented by its *inclusion tree* in which the frontiers of the nodes are in bijection with the members of the family. Its root is V and its leaves are the singletons of $\mathcal{F}$. Conversely, the frontiers of a tree with V as leaf labels define a

FIG. 3. The top two diagrams show a generator for the common intervals of $\mathcal{R}$ constructed using Proposition 2.4 (see Figure 1). The bottom diagrams shows the canonical generator constructed by Algorithm 5.

proper commuting family. The inclusion trees on V are thus in bijection with the proper commuting families on V .

For closed families, PQ -trees play the same role as the inclusion trees for proper commuting families.

DEFINITION 5.2. A PQ -tree on finite set V is a tree whose leaves are labeled from 1 to $|V|$ and whose internal nodes are labeled P -nodes or Q -nodes. A P -node must have at least two children, and a Q -node must have at least three children. The children of a P -node are unordered, and the children of a Q -node are totally ordered.

The reversal of a Q node consists in reversing the total order of its children. An extended frontier of a PQ -tree is either the frontier of a P node, the union of frontiers of consecutive children of a Q node, or a singleton.

PROPOSITION 5.3 (see [3, 7]). Given a closed family $\mathcal{F}$, there exists a PQ -tree such that the intervals of the family are exactly the extended frontiers. The strong intervals of the family are exactly the frontiers of this tree. Furthermore, the PQ -tree is unique up to Q node reversals.

Example. Let $\mathcal{P}_2 = \{\text{Id}_9, P_4, P_5, P_6\}$ with

$$\begin{aligned} \text{Id}_9 &= (1, 2, 3, 4, 5, 6, 7, 8, 9), & P_5 &= (6, 5, 7, 8, 9, 1, 2, 3, 4), \\ P_4 &= (9, 8, 7, 5, 6, 4, 3, 2, 1), & P_6 &= (1, 3, 2, 4, 5, 6, 9, 8, 7). \end{aligned}$$

Figure 4 shows the canonical generator of the set $\mathcal{P}_2$ and the corresponding PQ -tree.

Compared to PQ -trees, the canonical generator of a closed family $\mathcal{F}$ is much simpler since it uses only two arrays. Moreover, some operations, for example testing whether an interval $(i..j)$ belongs to the family $\mathcal{F}$, are also simpler using this representation. However, PQ -trees have the advantage of being recursive structures.

Another canonical representation, the family of *irreducible intervals*, was introduced in [12]. The links between PQ -trees and irreducible intervals have been studied in [13] that present linear-time algorithms for the conversion.

FIG. 4. The canonical generator and the associated PQ-tree for the set of permutations $\mathcal{P}_2 = \{\text{Id}_9, P_4, P_5, P_6\}$.

5.2. From canonical generators to strong intervals. Strong intervals of a closed family $\mathcal{F}$ are associated with *overlap classes*: let us consider the canonical generator (R, L) of $\mathcal{F}$. The transitive closure of the overlap relation on all intervals of $R \cup L$ is an equivalence relation, and its equivalence classes are henceforth called *overlap classes*. We will prove, in Theorem 5.8, that once the overlap classes are identified, the task of identifying the strong intervals is almost complete.

A *trivial* overlap class contains only a single interval $(i..R[i])$ or $(L[j]..j)$. We have the following lemma.

LEMMA 5.4. *A trivial overlap class is a strong interval of $\mathcal{F}$.*

Proof. Consider a trivial overlap class $\{(i..j)\}$. Either $j = R[i]$ or $L[j] = i$. Suppose that $j = R[i]$ and that $(i..j)$ is not strong. Then it is overlapped by an interval $(i'..j')$ belonging to $\mathcal{F}$ but not to the generator. If $i \leq i' \leq j \leq j'$, then the interval $(i..j')$ is in $\mathcal{F}$ but larger than $(i..R[i])$ in violation with the fact that $j' \leq R[i]$ (see Proposition 2.3). Let us then suppose $i' \leq i \leq j' \leq j$. Since $(L[j']..j')$ does not overlap $(i..R[i])$, we have $i \leq L[j'] \leq j'$. Since $i' \leq i \leq L[j']$, $(i'..j')$ is larger than $(L[j']..j')$ and thus does not belong to $\mathcal{F}$. Interval $(i..j)$ is therefore strong. The other case is similar. $\square$

For nontrivial overlap classes, we need to explain the relations between the various intervals that belong to the classes. Note that any nontrivial overlap class must contain intervals of R and L since intervals of R (resp., L) do not overlap each other. Figure 5 shows a typical nontrivial class: the number of left and right intervals is the same, left and right bounds are nicely aligned, and the left and right intervals are nested. The following lemmas establish these properties formally and can be skipped at the first reading.

LEMMA 5.5. *Let (R, L) be the canonical generator of a closed family $\mathcal{F}$. We have the following: (1) if $(i..R[i])$ overlaps $(L[j]..j)$ and $(L[j']..j')$, then $L[j] = L[j']$; and (2) if $(L[j]..j)$ overlaps $(i..R[i])$ and $(i'..R[i'])$, then $R[i] = R[i']$.*

Proof. Note that if $(i..R[i])$ overlaps $(L[j]..j)$, then $(i..j)$ belongs to $\mathcal{F}$ and, by Proposition 4.4, $i \geq L[j]$. The hypothesis that $(i..R[i])$ overlaps $(L[j]..j)$ implies fur-

FIG. 5. Structure of a nontrivial overlap class $\mathcal{C}$ with $k = 3$. Dashed lines represent the strong intervals corresponding to the class.

ther that $i < L[j]$; otherwise we would have $(L[j]..j) \subseteq (i..R[i])$. A similar argument shows that $(i..R[i])$ overlapping $(L[j']..j')$ implies that $j' < R[i]$.

Now suppose $L[j] \neq L[j']$ and $j' > j$; then $L[j'] < L[j]$, since L is commuting. This implies that $L[j'] < L[j] < i \leq j < j' < R[i]$. Interval $(L[j']..i-1)$ belongs to $\mathcal{F}$ since it is $(L[j']..j') \setminus (i..R[i])$. Thus $(L[j']..j)$ is also in $\mathcal{F}$ since it is the union of overlapping $(L[j']..i-1)$ and $(L[j]..j)$. Applying Proposition 4.4 to interval $(L[j']..j)$ implies that $L[j'] \geq L[j]$, which yields a contradiction. Therefore $L[j] = L[j']$.

Statement (2) is proved in a similar way. $\square$

Lemma 5.5 implies that, in a nontrivial class $\mathcal{C}$, all intervals of the form $(i..R[i])$ share the same right bound, and all intervals of the form $(L[j]..j)$ share the same left bound. We will henceforth denote $L[\mathcal{C}]$ and $R[\mathcal{C}]$ these common bounds. Moreover, the interval $(L[\mathcal{C}]..R[\mathcal{C}])$ is necessarily strong.

LEMMA 5.6. *Let $\mathcal{C}$ be a nontrivial overlap class of a closed family $\mathcal{F}$. Then $(L[\mathcal{C}]..R[\mathcal{C}])$ is a strong interval of $\mathcal{F}$.*

Proof. Since $\mathcal{C}$ is a nontrivial class, it contains at least two overlapping intervals $(L[\mathcal{C}]..j)$ and $(i..R[\mathcal{C}])$. The interval $(L[\mathcal{C}]..R[\mathcal{C}])$ is an interval of $\mathcal{F}$ since it is the union of those two overlapping intervals. Suppose that $(i..j) \in \mathcal{F}$ overlaps $(L[\mathcal{C}]..R[\mathcal{C}])$ and $i < L[\mathcal{C}] \leq j < R[\mathcal{C}]$; then $(L[j]..j)$ contains $(i..j)$ and overlaps $(L[\mathcal{C}]..R[\mathcal{C}])$, thus it overlaps at least one member of $\mathcal{C}$, and therefore it belongs to $\mathcal{C}$ and $L[j] = L[\mathcal{C}]$. On the other hand, if $L[\mathcal{C}] < i \leq R[\mathcal{C}] < j$, then $(i..R[i])$ overlaps $(L[\mathcal{C}]..R[\mathcal{C}])$, thus it overlaps at least one member of $\mathcal{C}$. Thus no interval overlaps $(L[\mathcal{C}]..R[\mathcal{C}])$, and therefore it is a strong interval. $\square$

LEMMA 5.7. *Let (R, L) be the canonical generator of a closed family $\mathcal{F}$, and let $\mathcal{C}$ be a nontrivial overlap class containing $(i_1..R[\mathcal{C}]), \dots, (i_k..R[\mathcal{C}])$ and $(L[\mathcal{C}]..j_1), \dots, (L[\mathcal{C}]..j_l)$, with $i_1 < \dots < i_k$ and $j_1 < \dots < j_l$. Then $k = l$, and for all $a \in (1..k)$, $(i_a..j_a)$ is a strong interval of $\mathcal{F}$.*

Proof. We first show the result for $k = l = 1$. In this case, there are only two intervals $(i_1..R[\mathcal{C}])$ and $(L[\mathcal{C}]..j_1)$, and they overlap to form interval $(i_1..j_1)$. To show that this interval is strong, suppose that it contains more than one element and that $(i..j)$ overlaps it with $i < i_1 \leq j < j_1$. Then $(L[j]..j)$ also overlaps $(i_1..R[\mathcal{C}])$, and the class must have more than two intervals. If $(i..j)$ overlaps $(i_1..j_1)$ with $i_1 < i \leq j_1 < j$, then we obtain a similar contradiction using interval $(i..R[i])$.

Now suppose that, up to index $a \geq 1$, $(i_a..j_a)$ is a strong interval of $\mathcal{F}$, $k > a$ if and only if $l > a$, and all intervals are consecutive; that is, $i_{b+1} = i_b + 1$ when $b < a$. We will show that these statements are true for $a + 1$.

First, note that the interval $(j_a + 1..R[\mathcal{C}])$ always belongs to $\mathcal{F}$, being the difference $(i_a..R[\mathcal{C}]) \setminus (L[\mathcal{C}]..j_a)$, and since the generator is commuting, this implies that $R[j_a + 1] = R[\mathcal{C}]$. If $k > a$, then $l > a$ since $(i_{a+1}..R[\mathcal{C}])$ does not overlap any interval already processed. If $l > a$, then $(L[\mathcal{C}]..j_{a+1})$ overlaps $(j_a + 1..R[\mathcal{C}])$ and both are in $\mathcal{C}$, implying that $k > a$ and $i_{a+1} = j_a + 1$, since the hypothesis that $(i_a..j_a)$ is strong

implies that $i_{a+1} > j_a$.

To finish the proof, we must show that $(i_{a+1}..j_{a+1})$ is strong. Suppose that $(i..j) \in \mathcal{F}$ overlaps $i_{a+1}..j_{a+1}$ and $i < i_{a+1} \leq j < j_{a+1}$; then $(L[j]..j)$ overlaps $(i_{a+1}..R[\mathcal{C}])$, thus it overlaps at least one member of $\mathcal{C}$, and therefore it belongs to $\mathcal{C}$. But $i_{a+1} \leq j < j_{a+1}$ and $i_{a+1} = j_a + 1$ implies that $j_a < j < j_{a+1}$, which contradicts the fact that the list of j indices is totally ordered.

On the other hand, if $i_{a+1} < i \leq j_{a+1} < j$, then $(i..R[i])$ belongs to $\mathcal{C}$, implying that $(L[\mathcal{C}]..i-1)$ is in $\mathcal{F}$, thus $(L[i-1]..i-1)$ is in $\mathcal{C}$. Since we have that $i_{a+1} - 1 < i - 1 < j_{a+1}$, thus $j_a < i - 1 < j_{a+1}$, $i - 1$ is again out of order in the list of j indices. $\square$

Let (R, L) be the canonical generator of a closed family $\mathcal{F}$, and define the set of *traces* of overlap classes as the set $\mathcal{T}$ of intervals containing the following:

- For each nontrivial overlap class $\mathcal{C} = \{(i_1..R[\mathcal{C}]), \dots, (i_k..R[\mathcal{C}]), (L[\mathcal{C}]..j_1), \dots, (L[\mathcal{C}]..j_k)\}$
 - $(L[\mathcal{C}]..R[\mathcal{C}])$,
 - $(i_a..j_a)$ for each $1 \leq a \leq k$.
- $(i..j)$ if $\mathcal{C} = \{(i..j)\}$ is trivial.

THEOREM 5.8. *The set $\mathcal{T}$ of traces of overlap classes of the canonical generator of a closed family $\mathcal{F}$ is equal to the family of strong intervals of $\mathcal{F}$.*

Proof. The fact that all intervals of $\mathcal{T}$ are strong is proved in Lemmas 5.4, 5.6, and 5.7.

Conversely, let $S = (i..j)$ be a strong interval. If either $R[i] = j$ or $L[j] = i$, then S is in the generator and forms a trivial overlap class. Otherwise $(i..R[i])$ and $(L[j]..j)$ overlap and thus belong to an overlap class $\mathcal{C}$. Using the same notation as above we have $i = i_a$ and $j = j_b$ for some a and b . We showed in the proof of Lemma 5.7 that we must have $a \leq b$. If $a < b$, S is overlapped by $(i_b..R[\mathcal{C}])$ and thus is not strong. Therefore $a = b$. $\square$

Theorem 5.8 implies that computing the strong intervals of $\mathcal{F}$ amounts to computing $\mathcal{T}$. This can be done by a classical parenthesis-matching algorithm using a stack since we proved that the left and right bounds of the strong intervals defined by an overlap class form a balanced expression. Namely, for nontrivial classes, the corresponding expression is

$$(\dots (\dots) (\dots) \dots (\dots) \dots)$$

and for trivial classes is $(\dots)$.

More formally, let (R, L) be the canonical generator. Consider the $4n$ bounds of intervals of the families $(i..R[i])$ and $(L[j]..j)$ for $i, j \in (1..n)$. Let $(a_1, \dots, a_{4n})$ be the list of these $4n$ bounds sorted in increasing order, with the left bounds placed before the right bounds when they are equal. For the example of Figure 3 this list is

$$(1, 1, 1, \bar{1}, 2, 2, \bar{2}, \bar{2}, 3, 3, 3, \bar{3}, \bar{3}, 4, \bar{4}, 5, 5, \bar{5}, \bar{5}, \bar{5}, 6, 6, \bar{6}, \bar{6}, 7, 7, \bar{7}, \bar{7}, 8, \bar{8}, \bar{8}),$$

where $\bar{i}$ denotes a right bound. Such a list can be constructed easily by scanning the two vectors R and L and by noting that each $i \in (1..n)$ is a left bound at least once and a right bound at least once. The following algorithm takes this sorted list as input and outputs the strong intervals sorted by increasing left bounds.

ALGORITHM 6. COMPUTATION OF THE STRONG INTERVALS.

S is a stack of bounds; *s* denotes the top of *S*.
 For *i* from 1 to $4n$
 If a_i is a left bound
 Push a_i on *S*
 Else
 Output $(s..a_i)$ (* Interval $(s..a_i)$ is strong *)
 Pop the top of *S*

PROPOSITION 5.9. *Given the ordered list $(a_1, \dots, a_{4n})$ of the $4n$ bounds of a canonical generator (R, L) , Algorithm 6 computes $\mathcal{T}$ in $O(n)$ time.*

Proof. Algorithm 6 will correctly match left and right bounds of a balanced expression. Since the left and right bounds of the strong intervals defined by each overlap class are balanced, and two overlap classes are either nested or disjoint, the list $(a_1, \dots, a_{4n})$ is balanced, and a correct matching of corresponding bounds will generate all the strong intervals. Since $2n$ intervals are identified by Algorithm 6, and the number of strong intervals is between $n + 1$ and $2n - 1$, some of them may be output several times. A suitable sorting algorithm, bucket-sort for example, will allow the identification of duplicates in $O(n)$ time. $\square$

5.3. From strong intervals to PQ -trees. By Proposition 5.3, the PQ -tree of a family $\mathcal{F}$ can be generated from its canonical generator by first computing the set of strong intervals of $\mathcal{F}$, ordering them into a tree structure, and finally labeling them as P or Q nodes.

Consider the example of Figure 4; Algorithm 6 produces the stack

$(1, 1, 1, 1, 1, \bar{1}, 2, 2, \bar{2}, 3, \bar{3}, \bar{3}, 4, \bar{4}, \bar{4}, 5, 5, 5, \bar{5}, 6, \bar{6}, \bar{6}, 7, 7, 7, \bar{7}, 8, \bar{8}, 9, \bar{9}, \bar{9}, 9, \bar{9})$

and outputs the set of strong intervals

$(1..1), (2..2), (3..3), (2..3), (4..4), (1..4), (1..4), (5..5), (6..6),$
 $(5..6), (5..6), (7..7), (8..8), (9..9), (7..9), (7..9), (1..9), (1..9).$

Each of these intervals corresponds to a node of the PQ -tree.

Given a proper commuting family of $n \leq m < 2n$ intervals, the following well-known algorithm computes its inclusion tree. To upgrade an inclusion tree to a PQ -tree, it is necessary to label the nodes as P or Q and to order the children of Q -nodes. Theorem 5.10 explains how to do these last tasks.

ALGORITHM 7. BUILDING THE INCLUSION TREE OF A PROPER COMMUTING FAMILY $\mathcal{F}$.

Bucket-sort in decreasing order the intervals of $\mathcal{F}$ according to their right bound
 Bucket-sort in increasing order the intervals of $\mathcal{F}$ according to their left bound
 Let $I_1..I_m$ be the list of sorted intervals
 $F \leftarrow I_1$ (* $I_1 = V$ is the root *)
 $k \leftarrow 2$
 While $k \leq m$
 If $I_k \subset F$
 $\text{Parent}(I_k) \leftarrow F$
 $F \leftarrow I_k$
 $k \leftarrow k + 1$
 else
 $F \leftarrow \text{Parent}(F)$

Let $I_1 = (l_1..r_1), \dots, I_k = (l_k..r_k)$ be the children of a Q node. For every i , $I_i \cup I_{i+1}$ is an interval of the family $\mathcal{F}$. Intervals I_i and I_{i+1} are disjoint, thus $r_i + 1 = l_{i+1}$ or $r_{i+1} = l_i + 1$. The *canonical PQ-tree* is the one where all Q nodes are sorted in increasing order, i.e., $r_i + 1 = l_{i+1}$.

THEOREM 5.10. *Let (R, L) be the canonical generator of a closed family $\mathcal{F}$. The canonical PQ-tree of $\mathcal{F}$ can be computed from (R, L) in $O(n)$ time.*

Proof. Algorithm 7 computes the inclusion tree in $O(n)$ time. The bucket sort is a stable linear-time sorting algorithm, thus intervals with the same left bound are sorted by their right bounds. The overall time complexity is obviously $O(n)$.

Given the inclusion tree of the strong intervals of a closed family $\mathcal{F}$, a PQ -tree of $\mathcal{F}$ can be built by labeling as P or Q the internal nodes of the inclusion tree and by ordering the children of the Q nodes. Fortunately, Algorithm 7 directly orders the children of every node (including the upcoming Q nodes) by increasing values of the first bounds of their frontiers. The resulting PQ -tree is therefore the canonical one. Thus, it is necessary only to label the nodes.

Each internal node of the inclusion tree has at least two children, since a node and its only child would have the same frontier. Every node with two children is labeled P . To test whether a node with at least three children is a P or Q node, it suffices to probe its two first children: if their union is an interval of the family $\mathcal{F}$, the node is labeled Q ; otherwise it is labeled P . This can be done in $O(1)$ time per node, using the generator. $\square$

5.4. From PQ-trees to canonical generators. Given a PQ -tree T , $\sigma(T)$ is the permutation of the leaves of T obtained by a left-to-right traversal of the tree. We may always assume that $\sigma(T) = \text{Id}_n$ by renaming the leaves of T . In this section we explain how to compute the canonical generator of the closed family represented by T .

Let N be a node with children $I_1, \dots, I_k$. Let l_i and r_i be the indices of the left and right bounds of I_i . Let $\text{imin}(N)$ and $\text{imax}(N)$ be the indices, respectively, of the minimum element of N and of the maximal element of N . Computing imin and imax can be done in $O(n)$ by a simple bottom-up traversal of T .

ALGORITHM 8. COMPUTING THE CANONICAL GENERATOR FROM A PQ -TREE.

For each internal node N of T taken bottom-up

 If N is a Q node

 For i from 1 to k

$L[\text{imax}(I_i)] \leftarrow \text{imin}(N)$

$R[\text{imin}(I_i)] \leftarrow \text{imax}(N)$

 Else

$R[\text{imin}(I_1)] \leftarrow \text{imax}(N)$

$L[\text{imax}(I_1)] \leftarrow \text{imin}(N)$

$R[\text{imin}(I_k)] \leftarrow \text{imax}(N)$

$L[\text{imax}(I_k)] \leftarrow \text{imin}(N)$

 For i from 2 to $k - 1$

$L[\text{imax}(I_i)] \leftarrow \text{imin}(I_i)$

$R[\text{imin}(I_i)] \leftarrow \text{imax}(I_i)$

PROPOSITION 5.11. *Algorithm 8 computes the canonical generator of a closed family in $O(n)$ time.*

Proof. The time complexity of the algorithm is obvious because the PQ -tree T has $O(n)$ nodes. Let us prove that the algorithm computes the canonical generator.

First, for all i , the value of $R[i]$ and $L[i]$ will be determined because, for the node N that bears the leaf i as j th node, $i = \text{imin}(I_j)$ and $i = \text{imax}(I_j)$.

When $R[\text{imin}(I_i)]$ is determined, $(\text{imin}(I_i)..R[\text{imin}(I_i)])$ is an interval of $\mathcal{F}$ because if N is a P node, then $(\text{imin}(I_i)..R[\text{imin}(I_i)]) = I_i$ and if N is a Q node, then $(\text{imin}(I_i)..R[\text{imin}(I_i)])$ is the union of all consecutive children of Q from i to k . The other cases are similar.

Let $R_t[1], \dots, R_t[i]$ be the values taken by the variable $R[i]$ during the execution of the algorithm. Since the nodes are visited bottom-up, the intervals $(i..R_t[i])$ are a nested sequence of intervals. We shall now prove that this sequence ends with the largest interval starting at i (resp., ending at j). Let us suppose that $(i..R_t[i]) \neq (i..R[i])$. Then $R_t[i] < R[i]$ since $(i..R_t[i])$ belongs to $\mathcal{F}$. Let us suppose $(i..R_t[i])$ is not strong. Then it is the union of children $I_a, \dots, I_b$ of some Q -node N . The algorithm sets $R_t[i]$ to the left bound of the last child of N . Since $(i..R[i])$ is larger, it overlaps the strong interval N , which is impossible. Now let us suppose that $(i..R_t[i])$ is strong. It corresponds to a node I of the PQ -tree whose parent is N . Either $(i..R[i])$ contains N , or N is a Q -node and $(i..R[i])$ is a union of children of N . In the first case, $i = \text{imin}(N)$ and thus $R_t[i] \geq \text{imax}(N)$, a contradiction. In the second case, $R_t[i] = \text{imax}(N)$, which also contradicts $R_t[i] < R[i] = \text{imax}(N)$.

We proved that the sequence of $R_t[i]$ converges toward $R[i]$ for all i . The case for $L_t[j]$ is similar. $\square$

6. Modular decomposition. Let $G = (V, E)$ be a directed, finite, loopless graph, with $|V| = n$ and $|E| = m$. Undirected graphs may be seen as symmetrical directed graphs in this context. A *module* is a subset M of V that behaves like a single vertex: for $x \notin M$ either there are $|M|$ arcs that join x to all vertices of M , or no arc joins x to M , and conversely either there are $|M|$ arcs that join all vertices of M to x , or no arc joins M to x . A *strong* module does not overlap any other module. There may be up to 2^n modules in a graph (in the complete graph for instance), but there are at most $O(n)$ strong modules, and the *modular decomposition tree* based on the strong modules' inclusion tree is sufficient to represent all modules [17]. The modular decomposition tree is indeed the PQ -tree of the family of modules.

Modular decomposition is the first step in many graph algorithms such as graph recognition (e.g., cographs, interval graphs, permutation graphs, and other classes of perfect graphs; see [4] for a survey) and transitive orientation computation [15].

Linear-time decomposition algorithms have been discovered [8, 15] but remain rather complex. Simpler algorithms work in two steps: computing a factorizing permutation and then building a tree representation on it. The first step was published in [11]. In this paper, we simplify the second step.

A *factorizing permutation* of a graph [6] is a permutation of the vertices of the graph in which every strong module of the graph is a *factor*, that is, an interval of the permutation. Since the strong modules are a commuting family, every graph admits a factorizing permutation. A factorizing permutation of a graph can be computed in linear time [11]. In the following we assume, without loss of generality, that the vertex-set V is the set $\{1, \dots, n\}$ and that the identity permutation is a factorizing permutation of the graph.

Given an interval $(u..v)$ of the factorizing permutation, a vertex $x \notin (u..v)$ is a *splitter* of the interval if there are between 1 and $v - u$ arcs going from x to $(u..v)$, or if there are between 1 and $v - u$ arcs going from $(u..v)$ to x . A *right-module* is an interval $(u..v)$ with no splitters greater than v . A *left-module* is an interval $(u..v)$

with no splitters smaller than u . An *interval-module* is an interval $(u..v)$ with no splitters. Clearly, interval-modules are modules. However, some modules are not interval-modules, but, according to the definition of a factorizing permutation, the strong modules of the graph are interval-modules. It is well known that modules behave like intervals: unions, intersections, or differences of two overlapping modules are modules. Thus we have the following proposition.

PROPOSITION 6.1 (see [17]). *The interval-modules of a factorizing permutation of a graph G are a closed family. The strong intervals of this family are exactly the strong modules of the graph G .*

DEFINITION 6.2. *For a vertex v let $R[v]$ be the greatest integer such that $(v..R[v])$ is a left-module and $L[v]$ the smallest integer such that $(L[v]..v)$ is a right-module.*

It can be proved that, for every $w \in (L[v]..v)$, $(w..v)$ is a right-module and, for every $w < L[v]$, $(w..v)$ is not a right-module. For this reason $(L[v]..v)$ is called the maximal right-module ending at v . In a similar way, we can define the maximal left-module beginning at v . We have the following proposition.

PROPOSITION 6.3. *The pair (R, L) is a commuting generator of the interval-modules' family.*

Proof. Interval $(u..v)$ is an interval-module if and only if $R[u] \geq v$ and $L[v] \leq u$, thus (R, L) is a generator. The family defined by R is commuting because if $(u..R[u])$ overlaps $(v..R[v])$, and if, without loss of generality, $u < v$, then $(u..R[v])$ is a left-module starting at u greater than the maximal left-module $(u..R[u])$, which is a contradiction. A similar argument shows that L also is commuting. $\square$

In order to compute the maximal right-strong modules, we use a simplified version of an algorithm due to Capelle and Habib [6]. The algorithm to compute the maximal left-modules is similar.

Let us consider the maximal right-module $(L[v]..v)$ ending at v . If $L[v] > 1$, then there exists an $x > v$ that splits $(L[v] - 1..v)$; otherwise this right-module would not be maximal, and x therefore splits $(L[v] - 1..L[v])$ but does not split $(y - 1, y)$ for all $L[v] < y \leq v$. Based on this observation, Capelle and Habib's algorithm proceeds in two steps. First, for every vertex v the *rightmost splitter* $s[v]$ is computed. It is the greatest vertex, if any, that splits the pair $(v - 1..v)$. Then a loop for v from n to 2 computes all the maximal right-modules $(L[x]..x)$ such that $v = L[x]$. Computing $s[v]$ can be done by a simultaneous scan of the adjacency lists of v and $v - 1$: the greatest element occurring in only one adjacency list is kept. This can be done in time proportional to the size of the adjacency lists. The computation of $s[v]$ for all v can therefore be done in $O(n + m)$ time, that is, linear in the size of the graph. The second step is Algorithm 9. It clearly runs in $O(n)$ time, and its correctness relies on the following invariant.

INVARIANT. *At step v , for all vertices x in the stack, $(v..x)$ is a right-module, and for all $x > v$ not in the stack, $L[v] > v$.*

Proof. The invariant is initially true. Every step maintains it: if $s[v]$ does not exist, then for all x in the stack $(v - 1..x)$ is a right-module, and $(v - 1..v)$ is also a right-module. And if $s[v]$ exists, (v) is the maximal right-module ending at v . For all $x < s[v]$, $(v - 1..x)$ is not a right-module, and $(v..x)$ is therefore the maximal right-module ending at x . For all $x \geq s[v]$, $(v - 1..x)$ is still a right-module, because $s[v]$ is the greatest of the splitters of $(v - 1, v)$. $\square$

We thus have the following theorem.

THEOREM 6.4. *Given a graph G and a factorizing permutation of G , it is possible to compute the modular decomposition tree of G in time $O(n + m)$ and in a simple way.*

ALGORITHM 9. COMPUTING ALL MAXIMAL RIGHT-MODULES GIVEN $s[v]$.

```

S is a stack of vertices; t denotes the top of S.
for v from n to 2
  if  $s[v]$  exists
     $L[v] \leftarrow v$ 
    While  $t < s[v]$ 
       $L[t] \leftarrow v$ 
      Pop the top of S
  else
    Push v on S

```

7. Conclusion. In the present work, we formalized two concepts about common intervals, namely generators and canonical representation, that proved to have important algorithmic implications. Indeed, the combinatorial properties of these objects, and in particular the different links between them, are central in the design and the analysis of the simple optimal algorithms for computing the common intervals of permutations we presented. It is important to highlight that our algorithms are really “optimal” since they are based on very elementary manipulations of stacks and arrays. This is, we believe, a significant improvement over the existing algorithms that are based on intricate data structures, both in terms of ease of implementation and time efficiency and in terms of understanding the underlying concepts [12, 19].

Moreover, we showed how, transposed in the more general context of modular decomposition of graphs, our results have a similar impact and lead to a significant simplification of some existing algorithms. Indeed, modular decomposition algorithms are quite complex algorithms, but using the factorizing permutation algorithm of [11] and the right-modules identification algorithm of section 6, a generator of the interval-modules can easily be computed in linear time; tools from section 5.2 can then be used to compute the strong interval-modules, that are also the strong modules, and the *PQ*-tree, called *modular decomposition tree* in this context.

STRUCTURE AND COLORING OF GRAPHS WITH ONLY SMALL ODD CYCLES*

SUSAN S. WANG[†]

Abstract. In this paper we investigate the role that odd cycles play in graph structure and in graph coloring. We focus on graphs with only small odd cycles and examine how the absence of large odd cycles affects graph structure. For a number of classes of such graphs, we provide full structural characterizations. Based on this structural analysis, we develop efficient and optimal graph coloring algorithms. For example, for graphs whose only odd cycles are 3-cycles and 5-cycles, we show how to color them optimally using 3, 4, 5, or 6 colors in $O(E)$ time.

Key words. structural characterization of graphs, odd cycles, graph coloring, chromatic number, algorithms

1. Introduction. In this paper we investigate the role that odd cycles play in graph structure and in graph coloring. We focus on graphs with only small odd cycles—graphs with one odd cycle size k and graphs with two odd cycle sizes, 3 and 5. A theme of the paper is *structural analysis*. For certain classes of graphs, we are able to characterize the structure of graphs directly. For others, we first use breadth-first search to decompose the graphs into components and then analyze the structure of the graphs in terms of the components. We provide full structural characterizations for those biconnected graphs with minimum degree at least three, with at least seven vertices, and with only 3-cycles and 5-cycles in odd cycles; that is, 3-cycles and 5-cycles are the only odd cycles that are present in the graphs. Characterizing graph structures enables us to identify important graph properties and to solve many problems, including graph recognition and graph coloring.

To *color* a graph means to assign a color to each vertex of the graph so that no two adjacent vertices have the same color. The graph coloring problem is to determine the minimum number of colors—denoted by the chromatic number $\chi(G)$ —needed to color a given graph G . This problem is considered hard not only because it is hard to arrive at an exact solution, even when the graph under consideration is restricted, but also because it is hard to arrive at an approximately optimal solution. Graph coloring, in its general form, in which one asks whether a graph G is k -colorable, has been shown to be NP-complete by Karp [10]. It remains NP-complete in the special case when $k = 3$ [6], even if the graph is restricted to be 4-regular planar [2]. As regards nonapproximability, Lund and Yannakakis [12] proved that there exists a fixed $c > 0$ such that approximating the chromatic number to within a factor of n^c , where n is the number of vertices, is NP-hard. Feige and Kilian [5] improved this nonapproximability result by showing that the chromatic number is hard to approximate to within a factor

of $n^{1-\epsilon}$, for any positive ϵ , under the assumption that $\text{NP} \neq \text{ZPP}$.¹ Khanna, Linial, and Safra [11] showed that coloring 3-colorable graphs with 4 colors is NP-hard.

Graph coloring is solvable in polynomial time for bipartite graphs ($k = 2$) but is NP-complete for nonbipartite graphs ($k \geq 3$). The property that distinguishes nonbipartite from bipartite graphs is the presence of odd cycles. In this paper we investigate the role that odd cycles play in graph coloring by focusing on a special class of graphs—graphs without large odd cycles. The author has also investigated the problem for graphs with only large odd cycles; see [17].

TABLE 1

Graphs with various structure, their chromatic numbers, and the number of colors used (optimal in all cases) via algorithms developed in this paper.

G is biconnected, nonbipartite, with:	$\chi(G)$	Number of colors used
One odd cycle size, 3, and		
No K_4	3	3
With K_4	4	4
One odd cycle size, k , $k \geq 5$	3	3
Two odd cycle sizes, 3 and 5, and		
No K_4 and no W_5	3	3
No K_4 and with W_5	4	4
With K_4 but no K_5	4	4
With K_5 but no K_6	5	5
With K_6	6	6

In [3], Bollobás and Erdős posed the following conjecture: If a graph G has s different odd cycle sizes, then $\chi(G) \leq 2s + 2$, with equality if and only if G contains a complete subgraph on $2s + 2$ vertices. Gyárfás proved this conjecture in [8] and a stronger theorem showing that every biconnected graph G with s odd cycle sizes is either K_{2s+2} or contains a vertex of degree at most $2s$, implying that $\chi(G)$ is at most $2s + 2$. In this paper, we shall provide structural characterizations of biconnected graphs for the case of $s = 1$, and for the case of $s = 2$ where the odd cycle sizes are 3 and 5. In particular, we shall provide full structural characterizations for graphs that are biconnected and with one odd cycle size, 3, and for graphs that are biconnected, with minimum degree at least three, with at least seven vertices, and with two odd cycle sizes, 3 and 5. Based on the structural analysis, we shall present linear-time algorithms that optimally color all such graphs. Table 1 summarizes the graph coloring results of this paper. All the algorithms are optimal, in terms of the number of colors used, and efficient— $O(E)$ in complexity. Some of the results of this paper constituted a part of author's doctoral dissertation in [17] and were briefly summarized in [13, p. 149] and in [14, p. 28].

The paper is organized as follows. In section 2, we provide some background and then derive some graph-theoretic bounds on cycle sizes and the chromatic number for graphs with only small odd cycles. In section 3, we focus on graphs with only one odd cycle size, say k , treating first the case $k = 3$ and then the case $k \geq 5$. In section 4, we focus on graphs with two odd cycle sizes, 3 and 5. In section 5, we pose some open problems.

2. Odd cycles, even cycles, and the chromatic number. In this paper $G = (V, E)$ denotes a simple, connected, finite, and undirected graph with $|V|$ vertices and $|E|$ edges. The *size* of a graph is the number of vertices in the graph. The *degree*

¹ZPP denotes the class of languages decidable by a random expected polynomial-time algorithm that makes no errors. See [9] for a precise definition.

of a vertex is the number of edges incident with it. The *minimum degree* of a graph is the minimum degree of vertices of the graph. We denote a *path* by the edges on the path: $v_1 - v_2 - \cdots - v_i$, where $v_1 - v_2$ represents an edge (a path of length one) from v_1 to v_2 . The *length* of a path P , $|P|$, is the number of edges on path P . If P is a path in G , and if v_1, v_2 are two vertices on the path, then $v_1 \xrightarrow{P} v_2$ denotes that part of path on P that goes from v_1 to v_2 . A complete graph on n vertices is denoted by K_n . An n -wheel, W_n , is an n -cycle together with another vertex that is adjacent to all vertices of the n -cycle. If H_1, H_2 are two subgraphs of G , each with at least one edge, then $H_1 \Delta H_2$ denotes the *symmetric difference* of H_1 and H_2 , that is, $H_1 \Delta H_2 = (H_1 \cup H_2) - (H_1 \cap H_2)$.

Breadth-first search is a procedure of visiting the vertices of a graph in a specific order. We begin the search procedure at a vertex r called the *root* (often the root is chosen arbitrarily). First, we search r , that is, we visit all neighbors of r , then we search all neighbors of r , and then we search all of neighbors of neighbors of r , and so on. Each vertex in G is searched exactly once, and the breadth-first search procedure halts after all vertices have been searched. It is clear that the breadth-first search procedure takes time $O(E)$, when the graph is given in terms of its adjacency list.

Let $BFS(G_r)$ denote the breadth-first search graph of G rooted at r ; that is, $BFS(G_r)$ is a leveled graph isomorphic to G . The *level* $l_r(v)$ of a vertex v of a graph is defined as follows: the level of the root of $BFS(G_r)$ is 0 ($l_r(r) = 0$); the level of all other vertices is defined inductively as follows: if vertex v is first visited through the edge (u, v) , then $l_r(v) = l_r(u) + 1$. A vertex u is a *parent* of a vertex v in $BFS(G_r)$ if $(u, v) \in E$ and $l_r(u) = l_r(v) - 1$. If u is a parent of v , then v is a *child* of u . A vertex u is an *ancestor* of a vertex v if either u is a parent of v , or u is an ancestor of a parent of v . A vertex w is a *common ancestor* of vertices u and v if w is an ancestor of both u and v . A vertex w is a *nearest-common ancestor* of vertices u and v if w is a common ancestor of u and v , and the distance between w and u ($l_r(u) - l_r(w)$) is no greater than that of any other common ancestor of u and v .

Here is a useful characterization of *biconnected* graphs.

THEOREM 1 (see [1]). *The following properties are equivalent in a graph G of size at least three:*

- (A) G is biconnected.
- (B) Any two vertices of G lie on a common simple cycle.
- (C) Every vertex and edge of G lies on a common simple cycle.
- (D) Any two edges of G lie on a common simple cycle.

In studying graphs with only small odd cycles, we are interested in knowing whether the size of a largest odd cycle determines or bounds the chromatic number. There are some interesting and rather curious results concerning this question. On the one hand, a $2p$ -chromatic graph—as exemplified by K_{2p} , the complete graph on $2p$ vertices—need not contain odd cycles of size $2p + 1$ or longer. On the other hand, Erdős and Hajnal [4] proved that every $(2p + 1)$ -chromatic graph must contain an odd cycle of size at least $2p + 1$.

THEOREM 2. *If G does not contain odd cycles of size more than $2p - 1$ ($p \geq 1$), then G is $2p$ -colorable, that is, $\chi(G) \leq 2p$.*

Hence, the size plus one of a largest odd cycle of a graph provides an upper bound for the chromatic number of the graph. The Erdős–Hajnal result is tight. Unfortunately their proof is nonconstructive.

One may wonder whether limiting the size of odd cycles affects the size of even cycles of a graph. It has been observed that if G is biconnected, nonbipartite, and does

not contain large odd cycles, then G does not contain large even cycles. Theorem 5 below describes this result more precisely. Before proving Theorem 5, we first establish two lemmas.

LEMMA 3. *Let G be a biconnected graph, and let D be a simple even cycle that edge-overlaps some simple odd cycle. Then there exists a simple odd cycle C such that $C\Delta D$ is a simple odd cycle.*

Proof. Consider the set of all simple odd cycles that edge-overlap D (this set is nonempty by assumption). In this set, choose a cycle C such that $|C - D|$ is minimal (a cardinality argument shows that this is possible). Now we claim that $C\Delta D$ is a simple odd cycle. First, $C\Delta D$ is odd, because $|C\Delta D| = |C| + |D| - 2|C \cap D|$. We use an argument by contradiction to show that $C\Delta D$ is a simple cycle. If $C\Delta D$ is not simple, then it is the disjoint union of simple cycles. Since $C\Delta D$ is odd, at least one of the simple cycles, say C' , is odd. Because $C' \subset C\Delta D$ and C is simple, C' edge-overlaps D . Since both C and C' edge-overlap D , and since $C' \subset C\Delta D$, it follows that $|C' - D| < |C - D|$, which contradicts the minimality of C . $\square$

LEMMA 4. *In a biconnected, nonbipartite graph G , every edge of G lies on a simple odd cycle.*

Proof. Since G is biconnected, every edge in G lies on a simple cycle (Theorem 1). Let e_1 be one of the edges under consideration, and suppose that e_1 lies on the simple cycle C . If C is odd, then we are done. Suppose C is even. Since G is nonbipartite, there exists a simple odd cycle D in G . Let e_2 be an edge on D . Since G is biconnected, there exists a simple cycle E that contains edges e_1 and e_2 (Theorem 1). If E is odd, then again we are done. Suppose E is even. Since E and D edge-overlap (in e_2) and D is odd, there exists a simple odd cycle F such that $F\Delta E$ is a simple odd cycle, by Lemma 3. Either e_1 lies on F or on $F\Delta E$. $\square$

THEOREM 5.²

(A) *In a biconnected, nonbipartite graph G , if there exists a simple even cycle of size $2m$, then there exists a simple odd cycle of size at least $m + 1$. Equivalently, the following holds:*

(B) *In every biconnected, nonbipartite graph G , we have*

$$l_o \leq l \leq 2(l_o - 1),$$

where l_o is the size of a maximum odd cycle and l is the size of a maximum cycle.

Proof. Let D be a simple even cycle of size $2m$ in G . Then D edge-overlaps some simple odd cycle, by Lemma 4. Hence, by Lemma 3, there is a simple odd cycle C such that $C\Delta D$ is a simple odd cycle. If $|C| \geq m + 1$, then we are done. Suppose $|C| \leq m$. Since D is a simple cycle, C is not contained in D . Hence, $|C \cap D| \leq m - 1$. It follows that the size of $C\Delta D$ is at least $m + 1$, because $|C\Delta D| = |C| + |D| - 2|C \cap D| \geq |D| - |C \cap D| \geq 2m - (m - 1) = m + 1$. This proves (A).

To establish the equivalence of (A) and (B), we first form the contrapositive of (A); it says that in every biconnected, nonbipartite graph, if $l_o < m + 1$, then $l_e < 2m$, where l_e is the size of a maximum even cycle. To show that (A) implies (B), set $m = l_o$. Then the hypothesis of the contrapositive is satisfied, so $l_e < 2l_o$. Since l_e is even, this means $l_e \leq 2(l_o - 1)$ ($l_o \geq 3$). Therefore, $l_o \leq l \leq 2(l_o - 1)$. To show that (B) implies (A), assume that (B) holds and that $l_o < m + 1$. By simple arithmetic, $2(l_o - 1) < 2m$, so $l < 2m$ by (B). Therefore, $l_e < 2m$. $\square$

Let G_i denote the graph obtained from G by iteratively deleting vertices of degree less than i . Thus, the minimum degree of G_i is at least i .

²Theorem 5 was found by the author and published in [17]. Subsequently a proof was published in [16].

LEMMA 6. *If we can k -color G_i in time T , then we can k -color G in time $T + O(E)$ for all $k \geq i$.*

*Proof.*³ Once G_i is k -colored, we can k -color G by adding the deleted vertices back to G_i , one at a time, in reverse order. Each time we add a vertex to G_i , its degree is less than i (due to the way G_i is created); therefore it can be (legally) colored with one of the k colors, since $k \geq i$. The above condition holds for all vertices added back to G_i . Hence, we can k -color G .

To create G_i , we use a queue to keep track of vertices of degree less than i . As we delete vertices of degree less than i , we keep them on a stack so that later we can color them in reverse order. In the process of coloring G , we go through the adjacency list of G a constant number of times: first to determine the initial degrees of the vertices; then to update the degrees as vertices are deleted; and finally to color the vertices when they are added back to G_i . Hence, the total running time of the algorithm is $T + O(E)$, where T is the amount of time it takes to color G_i . $\square$

3. Odd cycles = k -cycles. In studying graphs with only small odd cycles, we first focus on graphs with only one odd cycle size k , i.e., graphs with no odd cycles other than k -cycles. We show that the restriction of having only one odd cycle size in the context of biconnected graphs gives rise to tightly structured graphs. Being able to characterize the structure of graphs enables us to recognize the graphs and color them optimally.

3.1. $k = 3$.

LEMMA 7. *If a biconnected graph G contains no odd cycles other than 3-cycles, then G does not contain two edge-disjoint 3-cycles.*

Proof. Suppose that G contains two edge-disjoint 3-cycles, say $C_1 = v_1 - v_2 - v_3 - v_1$ and $C_2 = v_a - v_b - v_c - v_a$. Since G is biconnected, the edges (v_1, v_2) and (v_a, v_b) lie on a common simple cycle (Theorem 1), say C_3 . The size of C_3 is either three or four by Theorem 5. If the size of C_3 is three, then cycles C_1 and C_2 have a common vertex. Without loss of generality, assume that $v_2 = v_b$. The edge on C_3 that connects C_1 and C_2 must then be (v_1, v_a) , and therefore the cycle $v_1 - v_a - v_c - v_b - v_3 - v_1$ is a 5-cycle, which is a contradiction. Hence, the size of C_3 must be four. But then the cycle $C_1 \Delta C_3$ is a 5-cycle, which again is a contradiction. $\square$

THEOREM 8. *If G is a biconnected graph that contains no odd cycles other than 3-cycles, then G is either K_4 or belongs to the family of graphs of Figure 1. This family can be recognized in $O(E)$ time.*

Proof. First, we show that if G contains a 4-clique $K_4 = (v_1, v_2, v_3, v_4)$, then G coincides with K_4 . Argue by contradiction: suppose v_a is a vertex in G that is not in K_4 , and let (v_a, v_b) be an edge incident with v_a for some vertex v_b in G . From Lemma 4, we know that every edge in G lies on a 3-cycle. In particular, (v_a, v_b) lies on some 3-cycle, say $C = v_a - v_b - v_c - v_a$. According to Lemma 7, C shares an edge with every 3-cycle in K_4 . But this is not possible for any combination of v_b and v_c . Thus, no vertex $v_a \in G - K_4$ can exist; i.e., $G = K_4$.

Next we show that if G is not a 4-clique, then it must belong to the family of graphs illustrated in Figure 1. First, we know that G contains a 3-cycle, by assumption. Second, every edge of G lies on a 3-cycle, by Lemma 4. Third, since G does not contain a 4-clique, all 3-cycles in G must share the same edge, by Lemma 7. Thus, every vertex not on the shared edge is on some 3-cycle containing the shared edge. Fourth, if we delete the two vertices associated with the shared edge from the graph, then all the

³The algorithm presented in the proof is a well-known heuristic for graph coloring.

FIG. 1. A family of graphs containing only 3-cycles in odd cycles and no K_4 .

vertices remaining in the graph are independent. Indeed, if an edge exists in the remaining graph, then that edge must lie on a 3-cycle, and the 3-cycle must contain the shared edge, which is not possible (since the two edges have four distinct vertices).

Due to the restricted structure of graphs satisfying the hypotheses of Theorem 8, we can recognize such graphs in $O(E)$ time (using breadth-first search, for example). $\square$

THEOREM 9. *If G is a biconnected graph that contains no odd cycles other than 3-cycles, then G can be optimally colored in $O(E)$ time.*

Proof. We have established in Theorem 8 that G is either K_4 or a member of the family of graphs shown in Figure 1. In the first case, the chromatic number of G is 4; in the second case, it is 3. Observe that all vertices except the two on the shared edge in Figure 1 have degree two. This observation implies that a biconnected graph with minimum degree at least three and containing no odd cycles other than 3-cycles must coincide with K_4 . Thus, one way of optimally coloring G is as follows. First, iteratively delete vertices of degree less than three from G to obtain G_3 . If G_3 is nonempty, then G must be K_4 and we can 4-color it in $O(E)$ time. If G_3 is empty, then G is 3-colorable in $O(E)$ time, by Lemma 6. $\square$

The proof of Theorem 9 shows that if a graph G contains no odd cycles other than 3-cycles, then G is perfect;⁴ that is, the chromatic number is the same as the clique number for G and every induced subgraph of G .

3.2. $k \geq 5$. All graphs that contain only k -cycles in odd cycles for some fixed $k \geq 5$, can be 3-colored in time $O(E)$. To prove this assertion, we first recall the following theorem.

THEOREM 10 (see [16]). *Every biconnected, nonbipartite graph of size at least seven and with minimum degree at least three contains an odd cycle with at least two diagonals.*

THEOREM 11. *If G is a biconnected graph that contains only k -cycles in odd cycles for some fixed $k \geq 5$, then G can be 3-colored in $O(E)$ time.*

Proof. We iteratively delete vertices of degree at most two from G to obtain biconnected components each with minimum degree at least three. All of these biconnected components G' must be bipartite. Indeed, for $|V(G')| < 7$, this can be established without difficulty, by a case argument, using the fact that any odd cycle has to be a 5-cycle by our assumption and that G' has minimum degree three. For $|V(G')| \geq 7$,

⁴Graph coloring for perfect graphs is solvable in polynomial time using the ellipsoid method for linear programming [7].

we argue by contradiction. If G' were nonbipartite, then by Theorem 10, it would contain an odd cycle with at least two diagonals. This would force G' , and hence also G , to have odd cycles of different sizes, which contradicts the hypotheses of the theorem. All of the biconnected bipartite components G' can be colored in $O(E')$ time. Combining Lemma 6 with the fact that biconnected components of a graph can be found in $O(E)$ time [15], we see that G can be 3-colored in $O(E)$ time. $\square$

The preceding argument actually proves that biconnected graphs containing only k -cycles in odd cycles, for some fixed $k \geq 5$, with minimum degree at least three do not exist.

The author has recently obtained a complete characterization of graphs that are biconnected and contain only k -cycles in odd cycles for all $k \geq 5$. This result will be published elsewhere.

4. Odd cycles = 3-cycles + 5-cycles. We now move on to consider graphs with two odd cycle sizes, more specifically, to graphs with only 3-cycles and 5-cycles in odd cycles. We focus on graphs that are biconnected with minimum degree at least three and with at least seven vertices. We analyze their structures and present full structural characterizations of these graphs in Theorems 13, 15, and 16 and an $O(E)$ -time graph recognition algorithm in Algorithm 1. With regards to coloring, graphs with only 3-cycles and 5-cycles in odd cycles may contain a K_6 —a 6-clique—as a subgraph and hence may require at least six colors. However, as Theorem 2 indicates, they are 6-colorable. Based on the structural analysis, we develop an algorithm, Algorithm 2, that optimally colors all graphs with only 3-cycles and 5-cycles in odd cycles in $O(E)$ time.

From the graph structure perspective, it is of interest to focus on the quintessential aspects of the structure that exhibit the characteristics of the graph. For that reason we focus on biconnected graphs, as every edge of a biconnected graph lies on an odd cycle (Lemma 4). In addition, all graphs can be decomposed into biconnected components in $O(E)$ time [15]. In connection with graph coloring, since all nonbipartite graphs require at least three colors and in consideration of Lemma 6, we chose to examine graphs with minimum degree at least three.

LEMMA 12. *If G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, then G contains no K_5 .*

Proof. Suppose for a contradiction that G contains a K_5 . Since G is of size at least seven, $G - K_5$ is of size at least two. If $G - K_5$ contains an edge, say e_1 , then since G is biconnected, there exists a simple cycle C that contains the edge e_1 and an edge of K_5 (Theorem 1). Because K_5 is a complete graph on five vertices, it is not hard to construct an odd cycle of size at least seven from C and K_5 . Thus, $G - K_5$ must be an independent set. Let v_1 and v_2 be two vertices in $G - K_5$. Because the degrees of v_1 and v_2 are both at least three, each of v_1, v_2 must be adjacent to three vertices of K_5 . It is not hard to construct a 7-cycle from v_1, v_2 , and K_5 . $\square$

Since the graphs that satisfy the hypotheses of Lemma 12 do not contain a K_5 , we may partition them into two classes: those that contain a K_4 and those that do not. A full structural characterization of the first class is given in Theorem 13, and a full structural characterization of the second class is given in Theorems 15 and 16.

THEOREM 13. *Assume G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices. If G contains a K_4 , then G belongs to one of the two families of graphs shown in Figure 2.*

FIG. 2. Two families of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, with at least seven vertices, and containing a K_4 .

Proof. Suppose that we have a 4-clique in G , say $K_4 = (v_1, v_2, v_3, v_4)$. First, we argue that all vertices in $G - K_4$ are distance one from K_4 . Suppose not. Without loss of generality, let v_a be a vertex that is (shortest) distance two or more from K_4 . Since G is biconnected, there exists a simple cycle C that contains v_a and an edge of K_4 (Theorem 1). Because v_a is distance two or more from K_4 , the total length of paths on C that connect v_a with K_4 is at least four. Thus, from C and K_4 we can easily construct a simple odd cycle of size at least seven, which is a contradiction.

Second, we argue that $G - K_4$ does not contain any paths of length two. Suppose, to the contrary, that it does; say $v_a - v_b - v_c$ is a path of length two in $G - K_4$. Both v_a and v_c must be adjacent to exactly one and the same vertex of K_4 . If not, then, in view of the first observation, v_a and v_c are adjacent to distinct vertices of K_4 , say v_1 and v_2 , respectively. Then $v_a - v_b - v_c - v_2 - v_3 - v_4 - v_1 - v_a$ is a 7-cycle, which is not possible. Hence, we can and do assume that v_a and v_c are adjacent to the same vertex v_1 . Since the degree of v_c is at least three, at least one of the following is true: (a) v_c is adjacent to v_a ; or (b) v_c is adjacent to some vertex v_d such that v_d is not in K_4 (and $v_d \neq v_a$). In either case, we claim that v_b is adjacent to v_1 but not to v_2, v_3 , or v_4 . According to our first observation, v_b is adjacent to a vertex of K_4 . In case (a), if v_b were adjacent to v_2, v_3 , or v_4 , then it would be easy to construct a 7-cycle. (For example, if v_b were adjacent to v_2 , then we would obtain the 7-cycle $v_a - v_b - v_2 - v_3 - v_4 - v_1 - v_c - v_a$.) In case (b), using similar arguments as those used to show that v_a and v_c are adjacent to exactly one and the same vertex (v_1) of K_4 , we conclude that the same is true for v_a and v_d , and for v_b and v_d . Hence, we have established our claim. The above argument shows that, for any path of length two or more outside of K_4 , the vertices on the path are all adjacent to exactly one and the same vertex of K_4 . Hence, any such path must enter K_4 (in either direction) through the same vertex of K_4 . But G is biconnected, and we have a contradiction.

From the first observation we know that every vertex in $G - K_4$ is adjacent to at least one vertex of K_4 . From the second observation we know that each connected component of $G - K_4$ is either a vertex or a path of length one. Note that each vertex in $G - K_4$ is adjacent to at most three vertices of K_4 , because G does not contain a K_5 (Lemma 12). Since the minimum degree of G is at least three, an independent vertex in $G - K_4$ is adjacent to exactly three vertices of K_4 , and a vertex on a path of length one in $G - K_4$ is adjacent to either two or three vertices of K_4 . Hence,

$G - K_4$ cannot contain an independent vertex and a path of length one; otherwise it would be easy to construct a 7-cycle. Thus, the connected components of $G - K_4$ are either all independent vertices or all paths of length one. A similar argument shows that if $G - K_4$ contains all independent vertices, then all the independent vertices are adjacent to the same three vertices of K_4 (recall we have assumed that G has at least seven vertices); and if $G - K_4$ contains paths of length one, then all vertices in $G - K_4$ are adjacent to the same two vertices of K_4 (otherwise we could construct a 7-cycle). This completely characterizes the structure of G : it belongs to one of the two families of graphs shown in Figure 2. $\square$

Next we shall consider graphs that do not contain K_4 . We use breadth-first search to decompose the graphs and obtain additional structural results.

LEMMA 14. *Assume G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices. If G contains no K_4 , then a breadth-first-search graph of G — $BFS(G)$ —has the following properties:*

- (A) $BFS(G)$ contains at most four levels.
- (B) If level 1 is not independent, then $BFS(G)$ contains at most three levels.
- (C) Levels 3 and 4 of $BFS(G)$ are independent.
- (D) Levels 1 and 2 of $BFS(G)$ are bipartite; moreover, level 2 is a forest.

Proof. We shall prove each part individually.

- (A) $BFS(G)$ contains at most four levels.

Suppose, to the contrary, that $BFS(G_r)$ has more than four levels, where r is the root. Let u be a vertex at level 5. Since G is biconnected, u and r lie on a common simple cycle (Theorem 1), say C . The size of C is at least ten because u is at level 5 and r is at level 0. The size of C cannot be odd, by our assumption about odd cycle sizes, and it cannot be even (of size ten or more), by Theorem 5. Thus, we have a contradiction.

- (B) If level 1 is not independent, then $BFS(G)$ contains at most three levels.

Assume, to the contrary, that $BFS(G_r)$ has more than three levels, where r is a vertex on a 3-cycle. Let u be a vertex at level 4 and (v_a, v_b) a cross edge at level 1 forming a 3-cycle with r . Since G is biconnected, u and (v_a, v_b) lie on a common simple cycle (Theorem 1), say C . The size of C is at least seven because u is at level 4 and (v_a, v_b) is at level 1. The size of C cannot be odd, by our assumption on odd cycle sizes, and it cannot be even (of size ten or more), by Theorem 5. Thus, the size of C must be eight. Since C contains the edge (v_a, v_b) and is of size eight, C does not contain the root r . Because edge (v_a, v_b) forms a 3-cycle with the root, we can construct a 9-cycle from C by replacing edge (v_a, v_b) by edges (v_a, r) and (r, v_b) . This contradicts the assumption about odd cycle sizes.

- (C) Levels 3 and 4 of $BFS(G)$ are independent.

We first show that level 4 is independent, using an argument by contradiction. Suppose (v_1, v_2) is a cross edge at level 4 and r is the root. Since G is biconnected, r and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C . The size of C is at least nine. The size of C cannot be odd, by our assumption about odd cycle sizes, and it cannot be even (of size ten or more), by Theorem 5. The desired contradiction has arrived.

To show that level 3 is independent, we consider two cases: (i) root r is on a 3-cycle, and (ii) root r is not on a 3-cycle.

Case (i). Root r is on a 3-cycle; that is, there are cross edges at level 1.

Suppose, for a contradiction, that level 3 is not independent. Let (v_1, v_2) be a cross edge at level 3, and let (v_a, v_b) be a cross edge at level 1 that forms a 3-cycle

with r . Since G is biconnected, (v_a, v_b) and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C . The size of C is at least six, which means that it must be even, by our assumption about odd cycle sizes. If C does not contain the root, then we construct an odd cycle of size at least seven from C by replacing edge (v_a, v_b) by edges (v_a, r) and (r, v_b) . If C contains the root, then the size of C must be eight, by Theorem 5. Thus, C contains exactly two cross edges, including (v_a, v_b) , and either (r, v_a) or (r, v_b) . Without loss of generality, assume that C contains (r, v_a) . Then we obtain a 7-cycle from C by replacing edges (r, v_a) and (v_a, v_b) by edge (r, v_b) . This contradicts the assumption about odd cycle sizes.

Case (ii). Root r is not on a 3-cycle; that is, level 1 is independent.

Suppose the contrary, and let (v_1, v_2) be a cross edge at level 3. Since G is biconnected, r and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C . The size of C is at least seven. The size of C cannot be odd, by our assumption about odd cycle sizes, and it cannot be even of size ten or more, by Theorem 5. Thus, the size of C must be eight, which means that C contains two cross edges. Since level 1 is independent by assumption and level 4 is independent as shown above, the second cross edge of C lies either at level 3 or at level 2. The argument now breaks down into several subcases.

Suppose, for a contradiction, that the second cross edge of C lies at level 3; without loss of generality, assume that it is (v_2, v_3) . Then cycle C is of the form $r - g_1 - p_1 - v_1 - v_2 - v_3 - p_3 - g_3 - r$, where g_1, g_3 and p_1, p_3 are vertices at levels 1 and 2, respectively. If p_1 is a parent of v_2 , then we arrive at a 7-cycle, namely $r - g_1 - p_1 - v_2 - v_3 - p_3 - g_3 - r$. Similarly, if p_3 is a parent of v_2 , then we have the 7-cycle $r - g_1 - p_1 - v_1 - v_2 - p_3 - g_3 - r$. Thus, v_2 must have a parent other than p_1, p_3 ; call it p_2 . Exploring the possible parents of p_2 , we find a similar situation: If g_1 is a parent of p_2 , we get the 7-cycle $r - g_1 - p_2 - v_2 - v_3 - p_3 - g_3 - r$; if g_3 is a parent of p_2 , we obtain the 7-cycle $r - g_1 - p_1 - v_1 - v_2 - p_2 - g_3 - r$. Thus, p_2 must have a parent other than g_1, g_3 ; call it g_2 . But now we have the 7-cycle $r - g_1 - p_1 - v_1 - v_2 - p_2 - g_2 - r$, which yields the desired contradiction.

Next suppose the second cross edge of C lies at level 2. Without loss of generality, assume that (p_2, p_3) is the second cross edge and cycle C is of the form $r - g_1 - p_1 - v_1 - v_2 - p_2 - p_3 - g_3 - r$, where g_1, g_3 and p_1, p_2, p_3 are vertices at levels 1 and 2, respectively. Note that g_1 is the unique grandparent of v_1 and v_2 (if not, then it would be easy to construct a 7-cycle that contains edge (v_1, v_2) and root r). Thus, g_1 is the unique parent of p_1 and p_2 . For the rest of the analysis, we shall focus on vertices v_1, v_2 , and p_1 . We shall use the fact that all of them have degree at least three to analyze possible structures that can exist at each vertex and show that no combination of these structures is possible.

Focusing on v_1 . Since the degree of v_1 is at least three, at least one of the following is true: (a) v_1 has another parent besides p_1 ; (b) v_1 is incident with another cross edge besides (v_1, v_2) ; (c) v_1 has a child. Suppose (a) holds. Observe that v_1 does not have p_2 as a parent; otherwise we would obtain the 7-cycle $r - g_1 - p_1 - v_1 - p_2 - p_3 - g_3 - r$. Nor does v_1 have p_3 as a parent, because v_1 has a unique grandparent. It is possible that v_1 has p_4 as a parent for some $p_4 \neq p_1, p_2, p_3$. Since g_1 is the unique grandparent of v_1 , it is the unique parent of p_4 . We call this Structure (1) (see Figure 3).

We now take up the case when (b) holds; that is, suppose v_1 is incident with cross edge (v_1, v_3) , $v_3 \neq v_2$. Note that v_3 does not have p_3 as a parent; otherwise we would get the 7-cycle $r - g_1 - p_1 - v_1 - v_3 - p_3 - g_3 - r$. Nor does v_3 have a parent, say p , that is different from p_2 and p_3 ; otherwise it would be easy to construct an odd cycle

FIG. 3. Structure (1).

Structure (2).

of size at least seven from path $p - v_3 - v_1 - v_2 - p_2 - p_3$ and two paths from p and p_3 to their nearest-common ancestor in $BFS(G_r)$. It is possible that v_3 has p_2 as a parent. We call this Structure (2) (see Figure 3).

We now turn to the case when (c) holds; that is, suppose v_1 has a child, say u . Since G is biconnected, (r, g_1) and (v_1, u) lie on a common simple cycle (Theorem 1), say C_2 . In view of our assumption about odd cycle sizes and Theorem 5, the size of C_2 is eight, because r is at level 0 and u is at level 4. Thus, C_2 does not contain cross edges. Combining this observation with the fact that g_1 is the unique grandparent of v_1 , we see that C_2 must contain a path—call it P_1 —of length two from v_1 to g_1 . This implies that C_2 does not contain p_2 or v_2 ; if it did, then the fact that g_1 is the unique parent of p_2 and the unique grandparent of v_2 would imply that cycle C_2 is closed at g_1 instead of at r . We can replace P_1 by $g_1 - p_2 - v_2 - v_1$ in C_2 and arrive at a 9-cycle, which is a contradiction.

Thus, if we focus on v_1 , Structures (1) and (2) are possible.

Focusing on v_2 . Since the degree of v_2 is at least three, at least one of the following is true: (a) v_2 has another parent besides p_2 ; (b) v_2 is incident with another cross edge besides (v_1, v_2) ; (c) v_2 has a child. Suppose (a) holds. Note that v_2 does not have p_3 as a parent, since v_2 has a unique grandparent. Nor does v_2 have a parent p_i different from p_2 and p_3 , since if it did, then p_i would have g_1 as its parent (because v_2 has a unique grandparent), and we would have the 7-cycle $r - g_1 - p_i - v_2 - p_2 - p_3 - g_3 - r$. Thus, v_2 does not have any other parent besides p_2 .

Next suppose (b) holds; that is, suppose v_2 is incident with cross edge (v_2, v_4) for some $v_4 \neq v_1$. Observe that v_4 does not have p_2 as a parent; otherwise we would obtain the 9-cycle $r - g_1 - p_1 - v_1 - v_2 - v_4 - p_2 - p_3 - g_3 - r$. It follows that g_1 is the unique grandparent of v_4 ; if not, then it would be easy to construct a 7-cycle that contains edge (v_2, v_4) and the root r . This implies that v_4 does not have p_3 as a parent. Also, v_4 does not have p_1 as a parent; if it did, then in combination with Structure (1), we would have the 7-cycle $g_1 - p_4 - v_1 - p_1 - v_4 - v_2 - p_2 - g_1$; and in combination with Structure (2), we would have the 7-cycle $g_1 - p_1 - v_4 - v_2 - v_1 - v_3 - p_2 - g_1$. The only possibility left is that v_4 has a parent p_5 that is different from p_1, p_2 , and p_3 . Note that g_1 is the unique parent of p_5 . Having p_5 as a parent for v_4 is not compatible with Structure (2); if it were compatible, we would arrive at the 7-cycle

FIG. 4. *Structure (3).*

$g_1 - p_2 - v_3 - v_1 - v_2 - v_4 - p_5 - g_1$. It is possible for v_4 to have p_5 as a parent, in combination with Structure (1), and this leads to Structure (3) (see Figure 4).

We now turn to the case when (c) holds; that is, suppose v_2 has a child. Arguments analogous to those which showed that v_1 does not have any children now show that v_2 does not have any children.

Hence, if we focus on both v_1 and v_2 , we see that Structure (2) is not possible, but Structure (3), which includes Structure (1) as a subgraph, is possible.

Focusing on p_1 . We shall now base our discussions on Structure (3). Since the degree of p_1 is at least three, at least one of the following is true: (a) p_1 has another parent besides g_1 ; (b) p_1 is incident with a cross edge; (c) p_1 has another child besides v_1 . Possibility (a) cannot hold because p_1 has a unique parent, namely g_1 . Nor can (b) hold. Indeed, suppose, to the contrary, that p_1 is incident with a cross edge. If p_1 is adjacent to p_2 , we have the 7-cycle $g_1 - p_2 - p_1 - v_1 - v_2 - v_4 - p_5 - g_1$. If p_1 is adjacent to p_3 , we get the 7-cycle $g_1 - p_1 - p_3 - p_2 - v_2 - v_4 - p_5 - g_1$. If p_1 is adjacent to some p_j different from p_2 and p_3 via a cross edge, then it is easy to construct an odd cycle of size at least seven from path $p_j - p_1 - v_1 - v_2 - p_2 - p_3$ and two paths from p_j and p_3 to their nearest-common ancestor in $BFS(G_r)$. Thus, possibility (b) leads to a contradiction in every case.

We now turn to possibility (c). Suppose p_1 has a child, say v_i , that is different from v_1 . Note that $v_i \neq v_2$, since v_2 does not have another parent besides p_2 . Also $v_i \neq v_4$; otherwise we would obtain the 7-cycle $g_1 - p_4 - v_1 - p_1 - v_4 - v_2 - p_2 - g_1$. Since the degree of v_i is at least three, v_i is adjacent to at least two other vertices. We consider three possible adjacency structures: (i) v_i has another parent; (ii) v_i is incident with a cross edge; (iii) v_i has a child. We proceed to show that none of the possibilities can actually occur. As regards (i), observe that v_i does not have p_2 as a parent; otherwise we would have the 7-cycle $r - g_1 - p_1 - v_i - p_2 - p_3 - g_3 - r$. Nor does v_i have p_k as a parent for some $p_k \neq p_1, p_2$, as it would be easy to construct an odd cycle of size at least seven from the path $p_k - v_i - p_1 - v_1 - v_2 - p_2$ and the two paths from p_k and p_2 to their nearest-common ancestor in $BFS(G_r)$. Thus, v_i has a unique parent, namely p_1 .

To see that (ii) cannot hold; suppose v_i is incident with a cross edge (v_i, v_j) . Since G is biconnected, r and (v_i, v_j) lie on a common simple cycle (Theorem 1), say C_3 .

Using similar arguments as those presented in earlier paragraphs, we see that C_3 is of size eight and contains two cross edges with the second cross edge lying at level 2. This implies that v_i and v_j have distinct parents and a unique grandparent g_1 . Since v_i has p_1 as its unique parent, v_j must have a parent other than p_1 , say p_m . This leads to the 7-cycle $g_1 - p_4 - v_1 - p_1 - v_i - v_j - p_m - g_1$, which is impossible.

To dispose of possibility (iii), assume v_i has a child, say u . Since G is biconnected, r and (v_i, u) lie on a common simple cycle (Theorem 1), say C_4 . Again using arguments similar to those presented in earlier paragraphs, we see that C_4 is of size eight. Hence, C_4 does not contain cross edges. Observe that C_4 contains the path $r - g_1 - p_1 - v_i - u$, because p_1 is the unique parent of v_i , and g_1 is the unique parent of p_1 . In addition, C_4 does not contain vertices v_1 , v_2 , or p_2 (if it did and since C_4 does not contain cross edges, C_4 would have to contain a path from v_1 , v_2 , or p_2 to g_1 , closing the cycle C_4 at g_1 instead of at r). We can replace edge $g_1 - p_1$ on C_4 by path $g_1 - p_2 - v_2 - v_1 - p_1$ to obtain an 11-cycle, which is not possible.

The assumption that (c) holds led to three subcases (i), (ii), (iii), each of which has been shown to be impossible. Thus, (c) cannot hold. Therefore, Structure (3) is not possible.

In summary, in consideration of the degree requirements of v_1, v_2 , and p_1 , none of the structures in support of the degree requirements is possible. Therefore, level 3 is independent.

(D) Levels 1 and 2 of $BFS(G)$ are bipartite; moreover, level 2 is a forest.

To show that levels 1 and 2 are bipartite, we break up the proof into two parts, showing, respectively, that levels 1 and 2 do not contain 5-cycles and 3-cycles. We then proceed to show that level 2 is a forest (i.e., a collection of trees).

Claim D.1. Levels 1 and 2 do not contain 5-cycles.

First, we show that if there exists a 5-cycle at level 2, then the vertices on the 5-cycle have the same unique parent. Label the vertices on the 5-cycle v_1 through v_5 , and assume, to the contrary, that two vertices, say v_1 and v_3 , have distinct parents. There then exist two disjoint paths from v_1 and v_3 to their common ancestor r , which is two levels above them. The cycle that consists of path $v_1 - v_5 - v_4 - v_3$ plus the two disjoint paths from v_1 and v_3 to r is a 7-cycle, which is not possible.

Second, we show that G cannot contain a W_5 as a subgraph. (Recall that W_5 is a 5-cycle together with another vertex that is adjacent to all vertices of the 5-cycle.) Suppose, to the contrary, that there is such a W_5 . Since G contains at least seven vertices, there is a vertex u in G that is not part of W_5 . Because G is biconnected, u and an edge of W_5 lie on a common simple cycle (Theorem 1), say C . Due to the structure and symmetry of W_5 , there exist paths of length two, three, four, and five between any two vertices of W_5 . Consequently, it is not hard to construct an odd cycle of size at least seven from C and W_5 , which is not possible.

The above two observations immediately imply Claim D.1.

Claim D.2. Levels 1 and 2 do not contain 3-cycles.

Since G does not contain K_4 as a subgraph, level 1 does not contain 3-cycles. Suppose, for a contradiction, that level 2 contains a 3-cycle $C_1 = v_1 - v_2 - v_3 - v_1$. The three vertices on the cycle cannot have the same parent; otherwise we would obtain a K_4 . Thus, two of the vertices, say v_1 and v_2 , have different parents, say p_1 and p_2 , respectively.

Since the degree of r is at least three, r must have a third child, say p_3 . Since G is biconnected, (r, p_3) and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C_2 . Let P_1 be the path on C_2 containing edge (r, p_3) with two endpoints v_a and v_b on C_1

such that if we traverse C_2 from edge (r, p_3) in one direction, we enter C_1 for the first time at v_a ; and if we traverse C_2 from edge (r, p_3) in the other direction, we enter C_1 for the first time at v_b . Since P_1 contains (r, p_3) and two vertices on C_1 , its length must be four or more. In fact, its length must be exactly four, because if it were five or more, then we could easily construct an odd cycle of size at least seven from P_1 and C_1 . This means that p_3 must be adjacent to a vertex on C_1 .

We claim that p_3 is not incident with a cross edge. Indeed, suppose, to the contrary, that p_3 is adjacent to p_i via a cross edge. Note that $p_i \neq p_1$; otherwise we would have the 7-cycle $r - p_3 - p_1 - v_1 - v_3 - v_2 - p_2 - r$. An analogous argument shows that $p_i \neq p_2$. Recall that p_3 is adjacent to a vertex on C_1 (i.e., either v_1, v_2 , or v_3). If p_3 is adjacent to v_1 , then we obtain the 7-cycle $r - p_i - p_3 - v_1 - v_3 - v_2 - p_2 - r$. Symmetrically, if p_3 is adjacent to v_2 , then we arrive at another 7-cycle. If p_3 is adjacent to v_3 , then we get the 7-cycle $r - p_i - p_3 - v_3 - v_2 - v_1 - p_1 - r$. Thus, all possibilities lead to contradictions.

Since the degree of p_3 is at least three and p_3 is not incident with a cross edge, p_3 must have at least two children. From the above discussion, it follows that at least one child of p_3 belongs to the set $\{v_1, v_2, v_3\}$. We claim that exactly one child of p_3 belongs to this set. Suppose, to the contrary, that two children of p_3 belong to the set $\{v_1, v_2, v_3\}$. If v_1 and v_3 are children of p_3 , then we get the 7-cycle $r - p_1 - v_1 - p_3 - v_3 - v_2 - p_2 - r$. Similarly, if v_2 and v_3 are children of p_3 , we again obtain a 7-cycle. The third possibility is that v_1 and v_2 are children of p_3 . In this case, if p_1 is a parent of v_3 , we have the 7-cycle $r - p_1 - v_3 - v_1 - p_3 - v_2 - p_2 - r$; and if p_j is a parent of v_3 for some $p_j \neq p_1, p_3$, we arrive at the 7-cycle $r - p_1 - v_1 - p_3 - v_2 - v_3 - p_j - r$. In all cases, we arrive at a contradiction.

Because p_3 has at least two children, and exactly one of them belongs to the set $\{v_1, v_2, v_3\}$, it follows that at least one child of p_3 is distinct from v_1, v_2, v_3 . Let v_4 be such a child. Since the degree of v_4 is at least three, v_4 must be adjacent to at least two other vertices. Assume w is one of them (thus $w \neq p_3$). Certainly w is different from each of v_1, v_2, v_3, p_1, p_2 ; otherwise it would be easy to construct a 7-cycle. Also note that w is not adjacent to vertices v_1, v_2, v_3 ; otherwise it would again be easy to construct a 7-cycle (for example, if w were adjacent to v_2 , then we would have the 7-cycle $r - p_3 - v_4 - w - v_2 - v_1 - p_1 - r$). Since G is biconnected, (v_4, w) and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C_3 . Let P_2 be the path on C_3 containing edge (v_4, w) with two endpoints v_c and v_d on C_1 such that if we traverse C_3 from edge (v_4, w) in one direction, we enter C_1 for the first time at v_c ; and if we traverse C_3 from edge (v_4, w) in the other direction, we enter C_1 for the first time at v_d . The length of P_2 cannot be less than five; this would imply that at least one of v_4, w is adjacent to v_1, v_2 , or v_3 . The length of P_2 cannot be five or more; then we could easily construct an odd cycle of size at least seven from P_2 and C_1 (for example, if the length of P_2 were five and $v_c = v_1, v_d = v_2$, then we would have the 7-cycle $v_1 \xrightarrow{P_2} v_2 - v_3 - v_1$). The desired contradiction has arrived. We conclude that level 2 does not contain 3-cycles.

Claim D.3. Level 2 is a forest.

Assume, to the contrary, that level 2 is not a forest; then it contains even cycles of size four, six, or eight (Theorem 5). Suppose it contains a 4-cycle, say $v_1 - v_2 - v_3 - v_4 - v_1$. If two adjacent vertices v_i and v_{i+1} , where $v_{4+1} = v_1$, have different parents, then we obtain a 7-cycle; for example, if v_2 and v_3 have different parents p_2 and p_3 , respectively, then we get the 7-cycle $v_3 - v_4 - v_1 - v_2 - p_2 - r - p_3 - v_3$. Thus, all vertices v_1 through v_4 have exactly one and the same parent, say p_1 . Since G is

FIG. 5. A family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, and $BFS(G_r)$ has three levels.

biconnected, (r, p_1) and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C . It is easy to construct a 7-cycle from C and vertices v_1 through v_4 and vertex p_1 , and this leads to a contradiction. Using similar arguments, we can also show that level 2 does not contain 6-cycles or 8-cycles. Therefore, level 2 is a forest. $\square$

THEOREM 15. Assume G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, with at least seven vertices, and with no K_4 . If a breadth-first-search graph of G from a vertex on a 3-cycle contains three levels, then G belongs to the family of graphs shown in Figure 5.

Proof. Let r be a vertex on a 3-cycle such that $BFS(G_r)$ has three levels. Let (v_1, v_2) be a cross edge at level 1 of $BFS(G_r)$ forming a 3-cycle with r . Let u_1 be a vertex at level 3 of $BFS(G_r)$. Since the degree of u_1 is at least three and since $BFS(G_r)$ has at most three levels, with the third level being independent (properties (B) and (C) of Lemma 14), the vertex u_1 has at least three parents. We prove that $BFS(G_r)$ has the following properties, which reflect the structure shown in Figure 5:

- (A) Level 1 contains exactly one cross edge.
- (B) Level 2 is independent.
- (C) All vertices at level 2 have degree exactly three.
- (D) Level 1 contains exactly three vertices.

We begin with the first property.

- (A) Level 1 contains exactly one cross edge.

This property is proved by establishing two claims.

Claim A.1. There exists a 5-cycle containing u_1 and (v_1, v_2) .

Since G is biconnected, u_1 and (v_1, v_2) lie on a common simple cycle (Theorem 1), say C . By Theorem 5 and our assumptions that (v_1, v_2) is a cross edge at level 1 and u_1 a vertex at level 3, the size of C is at least five and at most eight. We first argue by contradiction that the size of C cannot be eight. Suppose, to the contrary, that it is. Then r must lie on C ; otherwise we could replace edge (v_1, v_2) by edges

(v_1, r) and (r, v_2) to obtain a 9-cycle. Also, C contains neither (r, v_1) nor (r, v_2) ; if C contained, say (r, v_1) , then we could replace edges (r, v_1) and (v_1, v_2) by edge (r, v_2) and arrive at a 7-cycle. In order for C to be of size eight, to contain u_1, r , and (v_1, v_2) , and not to contain (r, v_1) or (r, v_2) , it must contain a path from cross edge (v_1, v_2) to another cross edge and then to r . Without loss of generality, assume that C contains cross edge (v_2, v_3) . We then get a 7-cycle by replacing edges (v_2, v_3) and (v_3, r) by edge (v_2, r) in C . We conclude that the size of C is less than eight. This size cannot be seven, by our assumption on odd cycle sizes. Nor can it be six; otherwise we could replace edge (v_1, v_2) by edges (v_1, r) and (r, v_2) to get a 7-cycle. Thus, the size of C must be five.

Claim A.2. v_1 and v_2 are the only grandparents of u_1 .

From Claim A.1 we see that v_1 and v_2 are two grandparents of u_1 . Suppose, for a contradiction, that v_3 is a third grandparent of u_1 through child p_1 (i.e., p_1 is a child of v_3 and a parent of u_1). Since there exists a 5-cycle containing u_1 and (v_1, v_2) (Claim A.1), there exists a parent of u_1 , say p_2 , distinct from p_1 , such that p_2 is a child of v_1 or v_2 . If p_2 is a child of v_1 , then we get the 7-cycle $u_1 - p_1 - v_3 - r - v_2 - v_1 - p_2 - u_1$; a similar contradiction arises if p_2 is a child of v_2 . Thus, no third grandparent of u_1 can exist.

Now we are ready to show that level 1 contains exactly one cross edge. Suppose that (v_a, v_b) is any cross edge at level 1. Using analogous arguments as those in Claims A.1 and A.2, we conclude that v_a and v_b are the only grandparents of u_1 . Thus, the edge (v_a, v_b) coincides with the edge (v_1, v_2) .

(B) Level 2 is independent.

Consider a vertex p at level 2; there are three possibilities:

- (1) p is a child of v_1 or v_2 and a parent of a vertex at level 3;
- (2) p is a child of v_1 or v_2 but not a parent of a vertex at level 3;
- (3) p is neither a child of v_1 nor of v_2 .

We shall prove that, in each case, p is not incident with a cross edge.

Claim B.1. If a vertex at level 2 is a child of v_1 or v_2 and a parent of a vertex at level 3, then it is not incident with a cross edge.

Suppose the contrary. Without loss of generality, let p_1 be a parent of u_1 and a child of v_1 such that p_1 is incident with a cross edge (p_1, p_a) . Since there exists a 5-cycle containing u_1 and (v_1, v_2) (Claim A.1), there exists a vertex p_2 , distinct from p_1 , such that p_2 is a parent of u_1 and a child of v_2 . If p_a has a parent other than v_2 , say v_p , then we have the 7-cycle $u_1 - p_1 - p_a - v_p - r - v_2 - p_2 - u_1$. Hence, the only parent of p_a is v_2 . Since u_1 has at least three parents, let p_3 be a third parent of u_1 . Note that v_1 is not a parent of p_3 ; otherwise we would get the 7-cycle $u_1 - p_1 - p_a - v_2 - r - v_1 - p_3 - u_1$. Hence, the only parent of p_3 is v_2 by Claim A.2. Similarly, the only parent of p_2 is v_2 . It is not possible that $p_a = p_2$ (or p_3); otherwise we would arrive at the 7-cycle $u_1 - p_2 - p_1 - v_1 - r - v_2 - p_3 - u_1$.

We now focus on possible structures surrounding p_2 . Since the degree of p_2 is at least three (note p_2 is adjacent to v_2 and u_1), p_2 must either (i) be incident with a cross edge or (ii) have another child besides u_1 . Suppose, for a contradiction, that (i) holds; say p_2 is incident with cross edge (p_2, p_b) . Observe that $p_b \neq p_a$; otherwise we would have the 7-cycle $u_1 - p_2 - p_a - v_2 - r - v_1 - p_1 - u_1$. Either v_1 is a parent of p_b or it is not. If it is, then we obtain the 7-cycle $u_1 - p_2 - p_b - v_1 - v_2 - p_a - p_1 - u_1$. If it is not, then p_b has a parent v_3 different from v_1 , and we get the 7-cycle $u_1 - p_2 - p_b - v_3 - r - v_1 - p_1 - u_1$. Thus, both possibilities lead to a contradiction, so (i) cannot hold. Suppose now that (ii) holds. Let u_2 , different from u_1 , be a child of p_2 . Since u_2 is a vertex at level 3,

it has the same structure as u_1 ; that is, u_2 has at least three parents, and v_1 and v_2 are the only grandparents of u_2 . Without loss of generality, assume p_c is a parent of u_2 and a child of v_1 . Observe that $p_c \neq p_a$, since p_a has exactly one parent, namely v_2 . If $p_c = p_1$, then we arrive at the 7-cycle $u_1 - p_2 - u_2 - p_1 - v_1 - v_2 - p_3 - u_1$; if $p_c \neq p_1$, we get the 7-cycle $u_2 - p_c - v_1 - p_1 - p_a - v_2 - p_2 - u_2$. Both possibilities lead to contradictions, so (ii) cannot hold either. Thus, p_2 cannot have degree at least three, and therefore, by our assumption, it cannot exist. It follows that p_1 cannot be incident with a cross edge.

Claim B.2. If a vertex at level 2 is a child of v_1 or v_2 but not a parent of a vertex at level 3, then it is not incident with a cross edge.

Suppose, to the contrary, that p_a is a child of v_2 , has no children, and is incident with cross edge (p_a, p_b) . Since there exists a 5-cycle containing u_1 and (v_1, v_2) (Claim A.1), there exist vertices p_1, p_2 such that they are parents of u_1 and children of v_1, v_2 , respectively. Let v_i be a parent of p_b . If $v_i = v_1$, we get the 7-cycle $u_1 - p_2 - v_2 - p_a - p_b - v_1 - p_1 - u_1$. If $v_i \neq v_2$, then since $v_i \neq v_1$, we obtain the 9-cycle $u_1 - p_2 - v_2 - p_a - p_b - v_i - r - v_1 - p_1 - u_1$. Thus, $v_i = v_2$; in other words, p_b has v_2 as its only parent. The same arguments apply to p_a ; that is, p_a has v_2 as its only parent. Having v_2 as a parent, and being incident with a cross edge, p_b has no children by Claim B.1. Since p_a and p_b do not have children, they must be incident with other cross edges, because the degrees of both vertices are at least three. Assume that p_a is incident with cross edge (p_a, p_c) and p_b incident with cross edge (p_b, p_d) . Using the same arguments as before, we conclude that v_2 is the unique parent of p_c and p_d , that p_c and p_d do not have any children, and that p_c and p_d are incident with other cross edges. Repeat this argument to conclude that all paths from p_a to r must include v_2 , which contradicts the assumption that G is biconnected.

Claim B.3. All vertices at level 2 are children of v_1 or v_2 .

Suppose, for a contradiction, that there exists a vertex p at level 2 such that p is a child of neither v_1 nor v_2 . Since G is biconnected, u_1 and p lie on a common simple cycle (Theorem 1), say C . Since the parents of u_1 are not incident with cross edges (Claim B.1) and since the grandchildren of v_1 and v_2 do not have a third grandparent (Claim A.2), C must contain a path from u_1 to v_1 and another path from u_1 to v_2 . Thus, C consists of a path from u_1 to v_1 plus a path from v_1 to p plus a path from p to v_2 plus the path v_2 to u_1 . Since neither v_1 nor v_2 is a parent of p , since (v_1, v_2) is the only cross edge at level 1 (property (A)), and since a child of v_1 or v_2 is not incident with a cross edge (Claim B.2), the length of the path from v_1 (v_2) to p in C is at least three. Hence, the size of C is at least ten, which contradicts the fact the size of C is at most eight (Theorem 5).

It follows from Claim B.3 that case (3)— p is neither a child of v_1 nor v_2 —does not exist. Combine Claims B.1 and B.2 to conclude that level 2 is independent.

(C) All vertices at level 2 have degree exactly three.

We consider two cases: those vertices at level 2 with children and those without.

Claim C.1. If a vertex at level 2 has children, then it has exactly one child and exactly two parents, namely v_1 and v_2 .

Suppose, for a contradiction, that a vertex at level 2 has more than one child. Without loss of generality, let p_1 be a vertex at level 2 such that p_1 is a parent of u_1 and a child of v_1 (Claim A.2), and let u_2 be a second child of p_1 . Because there exists a 5-cycle containing u_1 and (v_1, v_2) (Claim A.1), there exists a vertex p_2 , distinct from p_1 , such that p_2 is a parent of u_1 and a child of v_2 . Since u_2 is a vertex at level 3, u_2 has the same structure as u_1 . In particular, u_2 has at least

three parents, so one of them is different from p_1 and p_2 ; say it is p_3 . Note that p_3 has v_1 or v_2 as a parent, by Claim A.2. If v_1 were a parent of p_3 , then we would obtain the 7-cycle $u_2 - p_3 - v_1 - v_2 - p_2 - u_1 - p_1 - u_2$. Hence, v_2 is the only parent of p_3 . A symmetric argument shows that v_2 is the only parent of p_2 . Since the degree of p_2 is at least three and p_2 is not incident with a cross edge (Claim B.1), p_2 must have another child, say u_3 . Observe that $u_3 \neq u_2$; otherwise we would arrive at the 7-cycle $u_2 - p_2 - u_1 - p_1 - v_1 - v_2 - p_3 - u_2$. Since u_3 is a vertex at level 3, u_3 has the same structure as u_1 . In particular, u_3 has at least three parents, so one of them is different from p_1 and p_2 ; say it is p_4 . Note that $p_4 \neq p_3$; otherwise we would get the 7-cycle $u_3 - p_3 - u_2 - p_1 - v_1 - v_2 - p_2 - u_3$. By Claim A.2, p_4 has v_1 or v_2 as a parent. If v_1 were a parent of p_4 , then we would get the 9-cycle $u_3 - p_4 - v_1 - v_2 - p_3 - u_2 - p_1 - u_1 - p_2 - u_3$; if v_2 were a parent of p_4 , then we would obtain the 7-cycle $u_3 - p_4 - v_2 - v_1 - p_1 - u_1 - p_2 - u_3$. These contradictions imply that the degree of p_2 cannot be at least three. Consequently, the vertex p_1 cannot have more than one child. In other words, if a vertex p at level 2 has children, then it has just one child, say u . Since p has degree at least three and is not incident with a cross edge (Claim B.1), it must have at least two parents, and these parents are the grandparents of u . Apply Claim A.2 (with “ u_1 ” replaced by “ u ”) to conclude that v_1 and v_2 are the only parents of p .

Claim C.2. If a vertex at level 2 has no children, then it has exactly three parents, including v_1 and v_2 .

Let p_1 be a vertex at level 2 such that p_1 has no children. Since p_1 has degree at least three, is not incident with a cross edges (Claim B.2), and has no children, it must have at least three parents, and therefore one of them, say v_3 , is different from v_1 and v_2 . Since the degree of v_3 is at least three and (v_1, v_2) is the only cross edge at level 1 (property (A)), v_3 must have another child, say p_2 . From Claim B.3 we know that v_1 or v_2 is a parent of p_2 . Without loss of generality, suppose it is v_1 . It is not possible for p_1 to have parent v_4 that is different from v_1, v_2 , and v_3 ; that would yield the 7-cycle $r - v_4 - p_1 - v_3 - p_2 - v_1 - v_2 - r$. Therefore, the parents of p_1 are exactly v_1, v_2 , and v_3 .

(D) Level 1 contains exactly three vertices.

Since r has degree at least three, it has at least three children: v_1, v_2 , and, say, v_3 . From Claim C.1, we know that v_3 has no grandchildren. We claim that r must have exactly three children. If r had a fourth child, say v_4 , then the structure of v_4 and its children must be similar to that of v_3 and its children (see Claim C.2); namely the children of v_4 have exactly three parents: v_1, v_2 , and v_4 . This would lead to the 7-cycle $r - v_3 - p_1 - v_1 - v_2 - p_2 - v_4 - r$, where p_1, p_2 are children of v_3, v_4 , respectively.

We are now in a position to show that $BFS(G_r)$ belongs to the family of graphs shown in Figure 5. Level 1 contains exactly three vertices (property (D))— v_1, v_2 , and, say, v_3 . Since the degree of v_3 is at least three and (v_1, v_2) is the only cross edge at level 1 (property (A)), v_3 has at least two children, each of which has degree exactly three with v_1, v_2 , and v_3 as its parents (Claim C.2). All the other vertices on level 2 have degree exactly three—one child and the two parents v_1 and v_2 (Claim C.1). We have completely characterized the structure of G when a BFS graph of G from a vertex on a 3-cycle contains three levels: it belongs to the family of graphs shown in Figure 5. $\square$

THEOREM 16. Assume G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, with at least seven vertices, and with no K_4 . If

a breadth-first-search graph of G from a vertex on a 3-cycle contains two levels, then G belongs to one of the families of graphs shown in Figures 6–10.

Proof. Let r be a vertex on a 3-cycle such that $BFS(G_r)$ has two levels. We shall prove that $BFS(G_r)$ has the following properties:

- (A) Level 2 does not contain paths of length two or more.
- (B) If level 2 contains paths of length one, then the graph belongs to the family of graphs shown in Figure 6.
- (C) Level 1 does not contain paths of length three or more.
- (D) If level 1 contains paths of length two and level 2 is independent, then the graph belongs to one of the families of graphs shown in Figures 7 and 8.
- (E) If level 1 contains paths of length one only and level 2 is independent, then the graph belongs to one of the families of graphs shown in Figures 9 and 10.

We begin with the first property.

- (A) Level 2 does not contain paths of length two or more.

We proceed by eliminating the possibilities of paths of length five or more and then length four, length three, and finally length two.

Claim A.1. Level 2 does not contain paths of length five or more.

Let P_1 be a maximum-length path at level 2 and m be its length. Since the degree of every vertex is at least three, since $BFS(G_r)$ contains 2 levels, and since level 2 contains no cycles (property (D) of Lemma 14), each of the endpoints of P_1 must have at least two parents. Thus, there exists a cycle in $BFS(G_r)$ that contains the path P_1 and the root r and has length $m + 4$. From Theorem 5 we know that maximum cycle length in G is eight. Therefore, m is at most four.

Claim A.2. Level 2 does not contain paths of length four.

Suppose, for a contradiction, that level 2 contains a path of length four, say $v_1 - v_2 - v_3 - v_4 - v_5$. Argue as in the proof of Claim A.1 and use Claim A.1 to conclude that v_1 and v_5 must have at least two parents. Let p_1 be a parent of v_1 , and let p_2 , distinct from p_1 , be a parent of v_5 . If v_2 had a parent different from p_2 , say p_3 , we would get a 7-cycle $r - p_3 - v_2 - v_3 - v_4 - v_5 - p_2 - r$. Thus, the only parent of v_2 is p_2 . Similarly, the only parent of v_4 is p_1 . The second parent of v_1 must be p_2 ; otherwise if p_4 were a parent of v_1 , then we would have the 7-cycle $r - p_4 - v_1 - p_1 - v_4 - v_5 - p_2 - r$. Similarly, the second parent of v_5 must be p_1 . But then we arrive at the 7-cycle $p_1 - v_5 - v_4 - v_3 - v_2 - p_2 - v_1 - p_1$, which is a contradiction.

Claim A.3. Level 2 does not contain paths of length three.

Suppose, for a contradiction, that level 2 contains a path of length three, say $v_1 - v_2 - v_3 - v_4$. As before, and in view of Claim A.2, v_1 and v_4 must have at least two parents. If p_1 is a parent of v_1 , and p_2 , distinct from p_1 , is a parent of v_4 , then $r - p_1 - v_1 - v_2 - v_3 - v_4 - p_2 - r$ is a 7-cycle, which is not possible.

Claim A.4. Level 2 does not contain paths of length two.

Suppose, for a contradiction, that level 2 contains a path of length two, say $v_1 - v_2 - v_3$. As before, and in view of Claim A.3, v_1 and v_3 must have at least two parents. We now consider three cases: (i) v_1 and v_3 share two or more parents, (ii) v_1 and v_3 share exactly one parent, and (iii) v_1 and v_3 share no parents, and we show that in each case we have a contradiction.

Case (i). v_1 and v_3 share two or more parents.

Let p_1 and p_2 be two parents that v_1 and v_3 share. If v_2 had a parent other than p_1, p_2 , say p_3 , then we would arrive at the 7-cycle $r - p_3 - v_2 - v_1 - p_2 - v_3 - p_1 - r$. Thus, v_2 must have p_1 and/or p_2 as parents. Since the degree of r is at least three, r

has a third child, say p_4 . Because G is biconnected, there exists a simple cycle C that contains (r, p_4) and p_1 (Theorem 1). Due to the multiple number of edges that exist among vertices p_1, p_2, v_1, v_2, v_3 , it is not hard to use these edges and the cycle C to build an odd cycle of size seven or greater, leading to a contradiction.

Case (ii). v_1 and v_3 share exactly one parent.

Let p_1 be the parent that v_1 and v_3 share, and let p_2 and p_3 be the second parents of v_1 and v_3 , respectively. We now focus on possible parents of v_2 and show that in each case we reach a contradiction. If p_1 is a parent of v_2 , we get the 7-cycle $r - p_2 - v_1 - p_1 - v_2 - v_3 - p_3 - r$. If p_2 is a parent of v_2 , we arrive at the 7-cycle $r - p_2 - v_2 - v_1 - p_1 - v_3 - p_3 - r$. If some vertex p_4 , different from p_1 and p_2 , is a parent of v_2 , then we obtain the 7-cycle $r - p_4 - v_2 - v_3 - p_1 - v_1 - p_2 - r$.

Case (iii). v_1 and v_3 share no parents.

Since v_1 and v_3 each has at least two parents, let p_1 and p_2 be parents of v_1 , and let p_3 and p_4 be parents of v_3 . Note that none of p_1, p_2, p_3 , and p_4 can be a parent of v_2 ; otherwise we would get a 7-cycle (for instance, if p_1 were a parent of v_2 , then we would have the 7-cycle $r - p_2 - v_1 - p_1 - v_2 - v_3 - p_3 - r$). Thus, a parent of v_2 , say p_5 , is different from p_1, p_2, p_3, p_4 . Since the degree of p_1 is at least three, p_1 is either incident with a cross edge or has another child. If p_1 were incident with cross edge (p_1, p_6) , we would arrive at the 7-cycle $r - p_6 - p_1 - v_1 - v_2 - v_3 - p_3$ (or p_4) $- r$. Thus, p_1 must have another child, say v_4 . Observe that $v_4 \neq v_2$ because v_2 does not have p_1 as a parent, and $v_4 \neq v_3$ because v_1 and v_3 share no parents. In fact, v_4 has exactly one parent, namely p_1 ; if v_4 had another parent, say p_7 , then we would have the 7-cycle $r - p_7 - v_4 - p_1 - v_1 - v_2 - p_5 - r$ (in the case where $p_7 = p_5$ we would get the 7-cycle $r - p_1 - v_4 - p_5 - v_2 - v_3 - p_3 - r$). Since the degree of v_4 is at least three and since v_4 has exactly one parent, v_4 must be incident with two cross edges, say (v_4, v_5) and (v_4, v_6) . Now $v_5 - v_4 - v_6$ is a path of length two on level 2, so the argument at the beginning of Claim A.4 shows that v_5 must have at least two parents. Let p_8 be a parent of v_5 such that $p_8 \neq p_1$. If $p_8 = p_2$, we arrive at the 9-cycle $r - p_2 - v_5 - v_4 - p_1 - v_1 - v_2 - v_3 - p_3 - r$; if not, we obtain the 7-cycle $r - p_8 - v_5 - v_4 - p_1 - v_1 - p_2 - r$. Both of these situations are impossible.

(B) If level 2 contains paths of length one, then the graph belongs to the family of graphs shown in Figure 6.

Suppose that $v_1 - v_2$ is a path of length one at level 2. The usual argument and property (A) show that v_1 and v_2 must each have at least two parents. We now consider three cases: (i) v_1 and v_2 share no parents, (ii) v_1 and v_2 share exactly one parent, and (iii) v_1 and v_2 share two or more parents, and we show that cases (i) and (ii) are not possible, and case (iii) leads to the family of graphs shown in Figure 6.

Case (i). v_1 and v_2 share no parents.

Let p_1, p_2 be parents of v_1 , and let p_3, p_4 be parents of v_2 . Since the degree of p_1 is at least three, p_1 must either have another child or be incident with a cross edge. Suppose p_1 has a child v_3 ; clearly, $v_3 \neq v_2$ because v_1 and v_2 share no parents. Since the degree of v_3 is at least three and level 2 does not contain paths of length two (property (A)), v_3 must have a second parent; call it p_5 . But this leads to the 7-cycle $r - p_5 - v_3 - p_1 - v_1 - v_2 - p_3$ (or p_4) $- r$. Thus, p_1 cannot have another child beside v_1 , so it must be incident with a cross edge, say (p_1, p_6) . A similar argument shows that all parents of v_1 and v_2 have exactly one child and are incident with cross edges. In particular, this is true of p_3 ; say (p_3, p_7) is the cross edge. If p_6 is a parent of v_2 , we have the 7-cycle $r - p_2 - v_1 - p_1 - p_6 - v_2 - p_4 - r$; if not, we arrive at the 7-cycle

FIG. 6. A family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, $BFS(G_r)$ has two levels, and level 2 is not independent.

$r - p_6 - p_1 - v_1 - v_2 - p_3 - p_7 - r$. We conclude that case (i) leads to a contradiction, so it is not possible.

Case (ii). v_1 and v_2 share exactly one parent.

Let p_1 be the parent that v_1 and v_2 share, and let p_2 and p_3 be second parents of v_1 and v_2 , respectively. Since the degree of p_2 is at least three, p_2 must either have another child or be incident with a cross edge. Suppose p_2 has a child v_3 ; clearly, $v_3 \neq v_2$ because v_1 and v_2 share exactly one parent. Since the degree of v_3 is at least three and level 2 does not contain paths of length two (property (A)), v_3 must have a second parent; call it p_4 . But this leads to the 7-cycle $r - p_4 - v_3 - p_2 - v_1 - v_2 - p_1$ (or p_3) $- r$. Thus, p_2 cannot have another child beside v_1 , so it must be incident with a cross edge, say (p_2, p_5) . For the same reasons, p_3 has exactly one child, namely v_2 , and is incident with a cross edge, say (p_3, p_6) . If $p_5 \neq p_1, p_3$, we obtain the 7-cycle $r - p_5 - p_2 - v_1 - p_1 - v_2 - p_3 - r$. If $p_5 = p_1$ and $p_6 = p_1$, then we have a W_5 , which does not exist in G , as shown in property (D) of Lemma 14. The only possibility left is $p_5 = p_3$ and hence $p_6 = p_2$ (i.e., we have the cross edge (p_2, p_3)). Observe that now v_1 and v_2 have exactly two parents. If p_7 were, say, a third parent of v_1 , then we would arrive at the 7-cycle $r - p_7 - v_1 - p_2 - p_3 - v_2 - p_1 - r$. In particular, the degrees of the vertices v_1, v_2, p_2, p_3 are exactly three.

Let us focus on a seventh vertex of G , which could be a third child of p_1 (recall that p_2 and p_3 have exactly one child each) or a fourth child of r . Suppose p_1 has a third child v_4 . Since the degree of v_4 is at least three and level 2 does not contain paths of length two (property (A)), v_4 must have a second parent. This second parent cannot be p_2 or p_3 , so it must be another child of r ; call it p_8 . This leads to the 7-cycle $r - p_8 - v_4 - p_1 - v_1 - v_2 - p_3 - r$. Thus, p_1 cannot have a third child, so r must have a fourth child; call it p_9 . Since G is biconnected, there exists a simple cycle C containing p_9 and p_1 . Let us focus on the path from p_9 to p_1 on C without going through r ; call it P . The second to last vertex on P (just before reaching p_1) must be another child of r (call it p_{10} (p_{10} could be p_9)), since p_1 does not have a third child and p_2, p_3, v_1, v_2 have degrees exactly three. This leads to the 7-cycle $r - p_{10} - p_1 - v_1 - v_2 - p_3 - p_2 - r$, which is not possible. We conclude that case (ii) leads to a contradiction and is therefore not possible.

Case (iii). v_1 and v_2 share two or more parents.

Let p_1 and p_2 be two parents that v_1 and v_2 share. Recall that G has no K_4 ; thus, p_1 is not adjacent to p_2 via a cross edge. Since the degree of r is at least three and since r is on a 3-cycle, r must have a third child, say p_3 , such that p_3 is on a 3-cycle with r . Since G is biconnected, there exists a path P from p_3 to the subgraph induced by the vertices v_1, v_2, p_1, p_2 that does not pass through r . If P had length two or more, then we could use P and the edges among vertices $r, v_1, v_2, p_1, p_2, p_3$ to build an odd cycle of size seven or more. Consequently, P has length one; i.e., all paths from p_3 to the subgraph induced by the vertices v_1, v_2, p_1, p_2 not going through r are of length one (or edges). Note that p_3 is not incident with a cross edge (p_3, p_i) for some $p_i \neq p_1, p_2$; otherwise it would be easy to construct a 7-cycle from the path $r - p_i - p_3$ and a path from p_3 back to r of length five involving intermediate vertices v_1, v_2, p_1, p_2 . In addition, p_3 does not have children that are different from v_1 and v_2 . Suppose, to the contrary, that v_i is a child of p_3 , different from v_1 and v_2 . Since the degree of v_i is at least three and since level 2 does not contain paths of length two (property (A)), v_i must have a second parent; call it p_j . If $p_j = p_1$, we have the 7-cycle $r - p_3 - v_i - p_1 - v_1 - v_2 - p_2 - r$; if $p_j = p_2$, we obtain a similar 7-cycle. If $p_j \neq p_1, p_2$, we can build a 7-cycle from the path $r - p_j - v_i - p_3$ and a path from p_3 back to r of length four involving three intermediate vertices from the set $\{v_1, v_2, p_1, p_2\}$. We conclude that if p_3 is adjacent to a vertex different from r , that vertex must be in the set $\{v_1, v_2, p_1, p_2\}$. Since p_3 has degree at least three, it must be adjacent to at least two vertices in this set.

The graph G has at least seven vertices; a seventh vertex could be a fourth child of r , or a child of p_1 or p_2 . Suppose r has a fourth child; call it p_4 . Using arguments analogous to those above, we see that the structure for p_4 is the same as that for p_3 ; that is, p_4 is not incident with a cross edge (p_4, p_k) for some $p_k \neq p_1, p_2$; p_4 has no children different from v_1 and v_2 ; and p_4 is adjacent to at least two of the vertices in the set $\{v_1, v_2, p_1, p_2\}$. Recall that p_3 is on a 3-cycle with r . Hence, p_3 is adjacent to at least one of p_1, p_2 . Without loss of generality, assume p_3 is adjacent to p_1 . Note that there exist paths of length three from p_1 to each of v_1, v_2, p_2 . It is easy now to construct a 7-cycle: take the path $r - p_3 - p_1$, plus a path from p_1 to p_4 of length four involving intermediate vertices v_1, v_2, p_2 , plus the path $p_4 - r$. We conclude that r cannot have a fourth child. In other words, the only vertices on level 1 are p_1, p_2 , and p_3 .

A seventh vertex—call it v_3 —must therefore be a child of p_1 or p_2 , and say it is a child of p_1 . Since v_3 has degree at least three and level 2 has no paths of length two (property (A)), v_3 must have another parent besides p_1 . That parent cannot be p_3 , because p_3 has no children different from v_1 and v_2 , so it must be p_2 . Since level 1 has exactly three vertices, the third adjacency of v_3 must be a cross edge. There are no paths of length two at level 2, so that cross edge must be to a new vertex on level 2, say v_4 . The vertex v_4 has degree at least three, and level 2 contains no paths of length two, so v_4 must have two parents. Neither of these parents can be p_3 (which has no children different from v_1 and v_2), so p_1 and p_2 must be the parents of v_4 as well. The existence of v_3 and v_4 imply that p_3 cannot be adjacent to v_1 or v_2 ; that would lead to a 7-cycle (for instance, if p_3 were adjacent to p_1 and v_1 , then we would get the 7-cycle $r - p_3 - v_1 - v_2 - p_1 - v_3 - p_2 - r$). Thus, p_3 must be incident with both p_1 and p_2 via cross edges. Note that the structures of v_3 and v_4 are identical to those of v_1 and v_2 . Similarly, if p_1 has additional children (they must come in pairs), then their structures must be the same as those of v_1 and v_2 . Thus, we arrive at the family of graphs shown in Figure 6.

(C) Level 1 does not contain paths of length three or more.

Claim C.1. Level 1 does not contain paths of length four or more.

Since each vertex on level 1 is adjacent to r , level 1 does not contain paths of length five or more; otherwise it would be easy to build a 7-cycle using a length-five path together with r . Now suppose, for a contradiction, that level 1 contains a path of length four, say $v_1 - v_2 - v_3 - v_4 - v_5$. Since G contains at least seven vertices, there exists a seventh vertex (call it u) that is either a child of r or a child of a vertex on level 1. In either case, since G is biconnected, there exist two paths from u to the subgraph induced by the vertices $r, v_1, v_2, v_3, v_4, v_5$. Due to the multiple number of edges that exist among vertices $r, v_1, v_2, v_3, v_4, v_5$, it is not hard to construct an odd cycle of size seven or more from those two paths and the edges among vertices $r, v_1, v_2, v_3, v_4, v_5$, which gives the desired contradiction.

Claim C.2. Level 1 does not contain paths of length three.

Suppose, for a contradiction, that level 1 contains a path of length three, say $v_1 - v_2 - v_3 - v_4$. Note that level 2 must be independent, because we have shown in property (A) that level 2 does not contain paths of length two or more, and the only family of graphs where level 2 contains paths of length one is shown in Figure 6. Also note that the family of graphs shown in Figure 6 does not contain paths of length three on level 1. We now consider two cases: (i) v_1 and v_4 have no children, and (ii) v_1 and v_4 have children, and we show that they are not possible.

Case (i). v_1 and v_4 have no children.

Because the degrees of v_1 and v_4 are at least three and v_1 and v_4 have no children, v_1 and v_4 must each be incident with at least two cross edges. Since level 1 is bipartite (property (D) of Lemma 14) and since level 1 does not contain paths of length four or more (Claim C.1), v_1 must be adjacent to v_4 (i.e., (v_1, v_4) must be the second cross edge). Since G has at least seven vertices, a sixth vertex can either be a child of r or a child of a vertex on level 1. Suppose, for a contradiction, that r has a fifth child; call it v_5 . Since level 1 does not contain paths of length four or more (Claim C.1), v_5 is not adjacent to any of v_1, v_2, v_3, v_4 . Because G is biconnected, there must exist a path of length two or more from v_5 to the subgraph induced by the vertices v_1, v_2, v_3, v_4 that does not pass through r . Due to the multiple number of edges that exist among vertices r, v_1, v_2, v_3, v_4 , it is not hard to construct an odd cycle of size seven or more using that path and the edges among vertices $r, v_1, v_2, v_3, v_4, v_5$. Thus, r has only four children. Next suppose that, say, v_2 has a child; call it w . Since the degree of w is at least three and level 2 is independent, w must have three parents. But we have just shown that r has only four children, and v_1 and v_4 have no children by assumption. Thus, it is not possible for w to have three parents, which implies that a sixth vertex cannot exist.

Case (ii). v_1 and v_4 have children.

As usual, we argue by contradiction to show that this cannot occur. First, consider the case where v_1 and v_4 have at least two children between them; say w_1 is a child of v_1 , and w_2 is a child of v_4 , and $w_1 \neq w_2$. Since G is biconnected, (v_1, w_1) and (v_4, w_2) lie on a common simple cycle (Theorem 1); call it C . Due to the multiple number of edges that exist among vertices r, v_1, v_2, v_3, v_4 , it is not hard to construct an odd cycle of size seven or more from C and the edges among vertices r, v_1, v_2, v_3, v_4 , leading to a contradiction.

Now consider the case where v_1 and v_4 have exactly one child between them; call it w . Since G has at least seven vertices, a seventh vertex, say u , can either be a child of r or a child of a vertex on level 1. Suppose, for a contradiction, that u is a fifth child

of r . Because G is biconnected, there must exist a path of length one or more from u to the subgraph induced by the vertices v_1, v_2, v_3, v_4, w that does not pass through r . Due to the multiple number of edges that exist among vertices r, v_1, v_2, v_3, v_4, w , it is not hard to construct an odd cycle of size seven or more from that path and the edges among vertices $r, v_1, v_2, v_3, v_4, w, u$. Thus, r has only four children. It follows that u must be a child of a vertex on level 1. Since the degree of u is at least three and since level 2 is independent, u must have three parents. But r has only four children, and v_1 and v_4 have exactly one child (w) between them, so it is not possible for u to have three parents.

(D) If level 1 contains paths of length two and level 2 is independent, then the graph belongs to one of the families of graphs shown in Figure 7 or 8.

Suppose that level 1 contains a path of length two, say $v_1 - v_2 - v_3$. Since the degree of v_1 is at least three, since level 1 is bipartite (property (D) of Lemma 14), and since level 1 does not contain paths of length three (property (C)), v_1 must have at least one child. A similar argument and conclusion apply to v_3 . We consider two cases: (i) v_1 and v_3 together have two or more children, and (ii) v_1 and v_3 have exactly one and the same child.

Case (i). v_1 and v_3 together have two or more children.

Without loss of generality, let w_1 be a child of v_1 , and w_2 a child of v_3 , such that $w_1 \neq w_2$. Since the degree of w_1 is at least three and since level 2 is independent, w_1 must have at least two other parents besides v_1 ; and similarly for w_2 . We consider now two subcases: (a) w_1 and w_2 have v_1, v_2, v_3 only as parents, (b) at least one of w_1 and w_2 has a parent outside of v_1, v_2, v_3 .

Subcase (a). w_1 and w_2 have v_1, v_2, v_3 only as parents.

Since G has at least seven vertices and is biconnected, there must exist two paths from the seventh vertex to the subgraph induced by the vertices $r, v_1, v_2, v_3, w_1, w_2$. It is then easy to build an odd cycle of size at least seven from those two paths and the subgraph induced by $r, v_1, v_2, v_3, w_1, w_2$. Hence, this subcase cannot happen.

Subcase (b). At least one of w_1 and w_2 has a parent outside of v_1, v_2, v_3 .

In this subcase, we shall explore the structure of vertices and work toward building up the family of graphs shown in Figure 7. Without loss of generality, let v_4 be a parent of w_1 . We focus on potential (second and third) parents of w_2 . First, we show that v_1, v_2, v_4 cannot be parents of w_2 . If v_1 were a parent of w_2 , we would get the 7-cycle $r - v_4 - w_1 - v_1 - w_2 - v_3 - v_2 - r$. If v_2 were a parent of w_2 , we would have the 7-cycle $r - v_4 - w_1 - v_1 - v_2 - w_2 - v_3 - r$. If v_4 were a parent of w_2 , we would obtain the 7-cycle $r - v_1 - w_1 - v_4 - w_2 - v_3 - v_2 - r$. Thus, w_2 must have a new vertex (different from v_1, v_2, v_4) as a second parent. Similarly, the third parent of w_2 must also be a new vertex, and the same is true for the third parent of w_1 .

We now explore the structure of the parents of w_1 (or w_2), such as v_4 . Since the degree of v_4 is at least three, v_4 must have another child or be incident with a cross edge. Suppose, for a contradiction, that v_4 has another child; call it w_3 . Note that $w_3 \neq w_2$, since v_4 cannot be a parent of w_2 . If w_3 has a parent other than v_1, v_2 , say v_i , then we obtain the 7-cycle $r - v_i - w_3 - v_4 - w_1 - v_1 - v_2 - r$. If not, then since the degree of w_3 is at least three and level 2 is independent, w_3 must have v_1 and v_2 as parents. This yields the 7-cycle $r - v_4 - w_1 - v_1 - w_3 - v_2 - v_3 - r$. It follows from this observation that v_4 must be incident with a cross edge, say (v_4, v_5) . Note that $v_5 \neq v_1, v_3$, since level 1 does not contain paths of length three (property (C)). If v_5 were different from v_2 , we would get the 7-cycle $r - v_5 - v_4 - w_1 - v_1 - v_2 - v_3 - r$. Consequently, $v_5 = v_2$ (i.e., v_4 is adjacent to v_2). The same arguments

can be applied to all parents of w_1 and w_2 , including v_1 and v_3 , to conclude that all parents of w_1 and w_2 have degree exactly three, are adjacent to v_2 , and have only one child.

With regard to the structure of v_2 , observe that v_2 does not have any children. Indeed, if v_2 has a child w_j , then $w_j \neq w_1, w_2$, because (as noted earlier) v_2 cannot be a parent of w_1 or w_2 . Since the degree of w_j is at least three and level 2 is independent, w_j must have another parent (call it v_k), different from v_1 and v_3 , since v_1 and v_3 have exactly one child. This leads to the 7-cycle $r - v_k - w_j - v_2 - v_1 - w_1 - v_4 - r$.

Next we explore the structure of the children of r that are not parents of w_1 or w_2 . Let v_m be such a child. Let G' represent the subgraph induced by the vertices v_2, w_1, w_2 , and the parents of w_1 and w_2 . So v_m is outside of G' . Because G is bi-connected, there must exist a path P from v_m to G' that does not pass through r . Since the parents of w_1 and w_2 have degree exactly three and since w_1 and w_2 are not incident with cross edges, the only way to enter G' from outside not through r is via a cross edge to v_2 . Thus, the last two vertices on P are v_n and v_2 , where v_n is a child of r (v_n could be v_m). Observe that the length of the path from v_m to v_n on P is either zero (that is, $v_m = v_n$) or two, because there exist paths from v_m to v_n through r of length three ($v_m - r - v_2 - v_n$), of length four ($v_m - r - v_1 - v_2 - v_n$), and of length six ($v_m - r - v_1 - w_1 - v_4 - v_2 - v_n$) (so if there existed paths of lengths one, three, or more from v_m to v_n on P , we would have an odd cycle of size seven or more). Since the degree of v_n is at least three, v_n must either be incident with a second cross edge or have a child. It cannot be incident with a second cross edge, because level 1 is bipartite (property (D) of Lemma 14) and level 1 does not contain paths of length three (property (C)). It follows that v_n must have a child, say w_3 . Observe that $v_1 - v_2 - v_n$ is a path of length two on level 1, v_1 and v_n have two children (w_1 and w_3), and these two children have parents outside of v_1, v_2, v_3 . Thus, the parents of w_3 , such as v_n , must have the structure described earlier; namely they have degree exactly three, are adjacent to v_2 , and have only one child. If $v_m \neq v_n$, then v_m is also a parent of w_3 , because v_n has exactly one child and the path from v_m to v_n is of length two (via child w_3). Therefore, the structure of v_m (a child of r but not a parent of w_1 or w_2) is the same as that of v_n ; that is, v_m has degree exactly three, is adjacent to v_2 , and has only one child. Thus, we arrive at the family of graphs shown in Figure 7.

Case (ii). v_1 and v_3 have exactly one and the same child.

Notice that in Case (i) Subcase (b), $v_1 - v_2 - v_4$ is a path of length two on level 1, and v_1 and v_4 have exactly one and the same child. Hence, some of the graphs of Case (ii) are subgraphs of the family of graphs shown in Figure 7. For the discussion that follows, we shall focus on graphs that do not belong in Case (i), that is, graphs G such that $BFS(G_r)$ contains paths of length two on level 1 and all endpoints of the paths of length two have exactly one and the same child. Again, we shall explore the structure of vertices and work toward building up the family of graphs shown in Figure 8.

Let w_1 be the unique child of v_1 and v_3 . We make several observations.

First, v_2 does not have a child, except possibly for w_1 . Indeed, suppose, to the contrary, that w_2 is a child of v_2 different from w_1 . Since the degree of w_2 is at least three and level 2 is independent, w_2 must have at least two other parents besides v_2 . Let v_p be a parent of w_2 ; certainly $v_p \neq v_1, v_3$ since v_1 and v_3 have exactly one child, namely w_1 . Therefore, we obtain the 7-cycle $r - v_1 - w_1 - v_3 - v_2 - w_2 - v_p - r$.

FIG. 7. A family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, $BFS(G_r)$ has two levels, level 2 is independent, and level 1 contains paths of length two.

Second, all parents of w_1 have only one child, namely w_1 itself. Suppose, to the contrary, that v_q is a parent of w_1 and v_q has a child w_3 different from w_1 . Since the degree of w_3 is at least three and level 2 is independent, w_3 must have at least two other parents besides v_q . Let v_r be a parent of w_3 ; then $v_r \neq v_1, v_3$ since v_1 and v_3 have w_1 as their only child, and $v_r \neq v_2$ by the first observation. This leads to the 7-cycle $r - v_r - w_3 - v_q - w_1 - v_1 - v_2 - r$.

Third, all parents of w_1 are adjacent to v_2 but not incident with other cross edges. Suppose, indeed, that v_s is a parent of w_1 such that $v_s \neq v_1, v_3$, and v_s is adjacent to a vertex v_t on level 1 with $v_t \neq v_2$. Then we arrive at the 7-cycle $r - v_t - v_s - w_1 - v_1 - v_2 - v_3 - r$, which is a contradiction. Thus, v_s is not adjacent to a level 1 vertex different from v_2 . Since v_s has degree at least three and has just one child, by the second observation, it follows that v_s must be adjacent to v_2 . In particular, the degree of v_s is exactly three.

Fourth, due to our assumption that endpoints of paths of length two on level 1 have one and the same child, if v_2 is incident with a cross edge, say with a vertex v_t (so now $v_1 - v_2 - v_t$ is a path of length two), then v_t has exactly one child, namely w_1 .

Since G contains at least seven vertices, since w_1 is the only child of v_1, v_3 , and since w_1 is the only possible child of v_2 , a sixth vertex of G must be a child of r ; call it v_4 . We now explore the structure of v_4 . Let G' represent the subgraph induced by the vertices v_1, v_2, v_3, w_1 . Because G is biconnected, there exists a path P from v_4 to G' that does not pass through r . The ways for P to enter G' from outside, not going through r , are via v_2 through a cross edge or via w_1 through a parent-child edge. Let us focus on the second to last vertex on P ; call it u . Because the degree of u is at least three, observations two through four above imply that u must be adjacent to v_2 via a cross edge, must be a parent of w_1 , and must have degree exactly three (so $u = v_4$).

Using analogous arguments as above, we see that a seventh vertex must be a child of r with degree exactly three and adjacent to v_2 and w_1 . If G has more than seven vertices, they must also have the same structure as the sixth and the seventh vertices. Hence, the graph belongs to the family of graphs in Figure 8, with the edge (v_2, w_1) being optional.

FIG. 8. A second family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, $BFS(G_r)$ has two levels, level 2 is independent, and level 1 contains paths of length two.

We have completely characterized the structure of G when level 1 of $BFS(G_r)$ contains paths of length two, where r is a vertex on a 3-cycle. If there is a path of length two such that the endpoints of the path have two or more children, then G belongs to the family of graphs shown in Figure 7; otherwise it belongs to the family of graphs shown in Figure 8.

(E) If level 1 contains paths of length one only, and if level 2 is independent, then the graph belongs to one of the families of graphs in Figure 9 or 10.

We consider two cases: (i) level 1 contains two or more paths of length one, and (ii) level 1 contains exactly one path of length one.

Case (i). Level 1 contains two or more paths of length one.

Let $v_1 - v_2$ and $v_3 - v_4$ be two paths of length one on level 1. Since the degree of v_1 is at least three and since level 1 does not contain paths of length two or more by assumption, v_1 must have at least one child. A similar conclusion holds for vertices v_2, v_3 , and v_4 . We now argue that v_1, v_2, v_3 , and v_4 together cannot have two or more children. Suppose, to the contrary and without loss of generality, that v_1 and v_3 have distinct children; say, w_1 is a child of v_1 , and w_2 is a child of v_3 . Since G is biconnected, there exists a simple cycle that contains the edges (v_1, w_1) and (r, v_3) (Theorem 1), which means there exists a path from w_1 to v_3 without going through r ; call it P . Since the maximum cycle length in G is eight (Theorem 5) and since there is a path from w_1 to v_3 through r of length three ($w_1 - v_1 - r - v_3$), the length of P is at most five. We shall examine various possible paths of P according to length and show that no such path can exist. Keep in mind that since level 2 is independent and since the degrees of w_1 and w_2 are at least three, w_1 and w_2 must both have at least three parents.

Suppose the length of P is one, that is, $P = w_1 - v_3$. If v_1 and v_2 are both parents of w_2 , then we have the 7-cycle $r - v_2 - w_2 - v_1 - w_1 - v_3 - v_4 - r$; if not, we obtain the 7-cycle $r - v_2 - v_1 - w_1 - v_3 - w_2 - v_i - r$, where v_i is a parent of w_2 different from v_1 and v_2 . Suppose, next, that the length of P is two. Since level 2 is independent and since level 1 contains paths of length one only by assumption, P must be $w_1 - v_4 - v_3$. If v_1 and v_4 are both parents of w_2 , then we get the 7-cycle $r - v_2 - v_1 - w_1 - v_4 - w_2 - v_3 - r$; if not, then we arrive at the 7-cycle $r - v_1 - w_1 - v_4 - v_3 - w_2 - v_j - r$, where v_j is a parent of w_2 different from v_1 and v_4 .

If the length of P is three, then either P contains v_2 , in which case it does not contain v_4 and we get the 7-cycle $r - v_1 - w_1 \xrightarrow{P} v_3 - v_4 - r$; or P does not contain v_2 and we have the 7-cycle $r - v_2 - v_1 - w_1 \xrightarrow{P} v_3 - r$. If the length of P is four, then we arrive at the 7-cycle $r - v_1 - w_1 \xrightarrow{P} v_3 - r$. Finally, suppose the length of P is five. If P does not contain v_4 , then we obtain the 9-cycle $r - v_1 - w_1 \xrightarrow{P} v_3 - v_4 - r$. If P contains v_4 , let P_1 represent the path in P from w_1 to v_4 . The length of P_1 is four or less. If the length of P_1 is four, we get the 7-cycle $r - v_1 - w_1 \xrightarrow{P_1} v_4 - r$. If the length of P_1 is three or less, then the path $P_1 - v_3$ is a path from w_1 to v_3 of length four or less, which we have already shown does not exist.

The preceding argument shows that it is not possible for v_1, v_2, v_3 , and v_4 together to have two or more children. They must therefore all have exactly one and the same child, say w . Note that in this case v_1, v_2, v_3 , and v_4 have degree exactly three. Since G contains at least seven vertices, a seventh vertex of G must be a child of r ; call it v_5 . Because G is biconnected, there exists a simple cycle that contains the edges (v_1, w) and (r, v_5) (Theorem 1), which means there exists a path from w to v_5 that does not go through r . Since level 2 is independent, the first vertex after w on the path from w to v_5 must be a parent of w ; call it v_p (it is possible that $v_5 = v_p$). Note that v_p does not have another child besides w ; if it did, say w_k , then we would obtain the 7-cycle $r - v_1 - v_2 - w - v_p - w_k - v_s - r$, where v_s is a parent of w_k . Thus, in order for v_p to have degree at least three, v_p must be incident with a cross edge, say (v_p, v_q) . By taking v_1, v_2, v_p, v_q instead of v_1, v_2, v_3, v_4 and using the argument of the preceding paragraphs, it follows that v_q must have w as its only child. Both v_p and v_q , like v_1 through v_4 , have degrees exactly three and have identical structure. Since all paths on level 1 have length one, it is the case that either v_p or v_q is v_5 .

If G has additional vertices, using analogous arguments we see that those vertices must have the same structure as v_5 ; that is, they have degree exactly three, they have w as a child, and they are incident with a cross edge. We now arrive at the family of graphs shown in Figure 9.

Case (ii). Level 1 contains exactly one path of length one.

Let $v_1 - v_2$ be a path of length one on level 1. We shall mostly use the degree requirement to analyze the rest of the graph. Since the degree of v_1 is at least three and since level 1 does not contain paths of length two or more by assumption, v_1 must have at least one child, say w_1 . Because the degree of w_1 is at least three and level 2 is independent, w_1 must have a parent on level 1 that is different from v_1 and v_2 ; call it v_3 . Since the degree of v_3 is at least three and since level 1 contains exactly one path of length one, v_3 must have another child (besides w_1); call it w_2 . Again, because the degree of w_2 is at least three and level 2 is independent, w_2 must have at least three parents. Note that if w_2 has a parent other than v_1, v_2, v_3 , say v_p , then we obtain a 7-cycle $r - v_2 - v_1 - w_1 - v_3 - w_2 - v_p - r$. Hence, w_2 must have v_1, v_2 , and v_3 as its parents. Similarly, w_1 must have v_2 as its third parent; if w_1 has a parent v_q different from v_1, v_2, v_3 , then we get the 7-cycle $r - v_2 - v_1 - w_2 - v_3 - w_1 - v_q - r$. This argument shows that w_1 and w_2 have exactly three parents, namely v_1, v_2, v_3 . The same structure applies to all the children of v_3 : they all have exactly three parents, namely v_1, v_2, v_3 . If r had additional children, say v_4 , then using analogous arguments as above, we could show that v_4 has at least two children, and all of v_4 's children have exactly three parents, namely v_1, v_2, v_4 . But we would arrive at the 7-cycle $r - v_4 - w_3 - v_1 - v_2 - w_1 - v_3 - r$, where w_3 is a child of v_4 different from w_1 . We conclude that r does not have a fourth child; in other words, r has

FIG. 9. A family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, $BFS(G_r)$ has two levels, level 2 is independent, and level 1 contains paths of length one only.

FIG. 10. A second family of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices, where root r is on a 3-cycle, $BFS(G_r)$ has two levels, level 2 is independent, and level 1 contains paths of length one only.

exactly three children. Since G contains at least seven vertices, a seventh vertex and any additional vertices of G must be children of v_1, v_2, v_3 . Thus, G belongs to the family of graphs shown in Figure 10. $\square$

Theorems 13, 15, and 16 provide a complete structural characterization of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices: the graph belongs to one of the family of graphs shown in Figures 2, 5–10. Observe that some of these families of graphs are *equivalent*, in the sense that they contain the same graphs but are drawn differently. In fact, families of graphs in Figures 5 and 7 are equivalent, as are those in Figures 6 and 9, and in Figures 8 and 10.

FIG. 11. Two families of biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, with at least seven vertices, and in which level 1 of $BFS(G)$ is independent.

Also notice that every vertex of the family of graphs shown in Figures 2, 6, and 9 is on a 3-cycle, while some vertices of the families of graphs shown in Figures 5, 7, 8, and 10 lie on 5-cycles only. After doing breadth-first searches on those vertices that lie on 5-cycles only, we arrive at the two families of graphs shown in Figure 11, with the first family equivalent to the families in Figures 8 and 10 and the second family equivalent to the families in Figures 5 and 7. Observe that the first family is a subgraph of the second family. The graphs in Figure 11 have an independent level 1 with structures consistent with the properties in Lemma 14; that is, $BFS(G)$ contains at most four levels; levels 3 and 4 of $BFS(G)$ are independent; and level 2 of $BFS(G)$ is bipartite. We state this structural characterization as Corollary 17.

COROLLARY 17. *Assume G is a biconnected graph with two odd cycle sizes, 3 and 5, with minimum degree at least three, with at least seven vertices, and with no K_4 . If level 1 of a breadth-first-search graph of G is independent, then G belongs to one of the family of graphs shown in Figure 11.*

Another important point regarding the families of graphs in Figures 2, 5–10 is that a vertex of maximum degree is always on a 3-cycle. In addition, if we do breadth-first searches on maximum degree vertices only, then the structures we get are those in Figure 2 (modified by breadth-first search) and in Figures 7, 8, and 9. This observation simplifies the number of cases we need to consider when approaching problems such as graph recognition and graph coloring.

We now present a simple and efficient graph recognition algorithm (Algorithm 1) for biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices.

Input. A biconnected graph G with minimum degree at least three and with at least seven vertices.

Output. *Accept* if G contains only 3-cycles and 5-cycles in odd cycles; *Reject* otherwise.

1. Let r be a vertex of maximum degree in G .
2. Build the breadth-first-search graph of G rooted at r — $BFS(G_r)$.
3. If $BFS(G_r)$ has one level, then do
 4. If G belongs to the families of graphs shown in Figure 2, then accept.
5. Else if $BFS(G_r)$ has two levels, then do
 6. If there are two or more independent vertices at level 2 of $BFS(G_r)$, then do
 7. If G belongs to the family of graphs shown in Figure 7, then accept.
 8. Else if there is a single vertex at level 2 of $BFS(G_r)$, then do
 9. If level 1 of $BFS(G_r)$ has paths of length two, then do
 10. If G belongs to the family of graphs shown in Figure 8, then accept
 11. Else if level 1 of $BFS(G_r)$ has paths of length one only, then do
 12. If G belongs to the family of graphs shown in Figure 9, then accept.
13. Reject.

ALGORITHM 1. An $O(E)$ -time graph recognition algorithm for biconnected graphs with two odd cycle sizes, 3 and 5, with minimum degree at least three, and with at least seven vertices.

THEOREM 18. If G is a biconnected graph with minimum degree at least three, with at least seven vertices, and with two odd cycle sizes, 3 and 5, then Algorithm 1 recognizes G in $O(E)$ time.

Proof. Graph biconnectivity can be checked in $O(E)$ time [15]. In the following analysis, we assume that G is a biconnected graph with minimum degree at least three and at least seven vertices. As observed earlier, if G contains two odd cycle sizes, 3 and 5, and we perform breadth-first search of G on a vertex of maximum degree, then we get one of the structures shown in Figure 2 (modified by breadth-first search) and in Figures 7, 8, and 9. Thus, the tasks associated with verifying that G contains only 3-cycles and 5-cycles in odd cycles are the following: first, find a maximum degree vertex r ; second, build $BFS(G_r)$; and, third, check to see if $BFS(G_r)$ belongs to one of the families of graphs in Figure 2 (modified by breadth-first search) and in Figures 7, 8, and 9. This is basically Algorithm 1.

Note that when breadth-first search is performed on graphs in Figure 2 with root r being a maximum degree vertex, the breadth-first-search graph has only one level. Thus, verifying that G belongs to the first family of graphs in Figure 2 involves the following: check if level 1 contains exactly two vertices also of the maximum degree, and check if all other vertices on level 1 have degree exactly three and are adjacent to the three maximum degree vertices. Verifying that G belongs to other families of graphs involves similar checks and is graph specific. For instance, to check if G belongs to the family of graphs in Figure 7, we first check if level 1 contains a vertex that is adjacent to all other vertices on level 1 but has no children, and then we check whether each of the other vertices on level 1 has degree exactly three and has exactly one child. Verification for each of the families of graphs can be done in $O(E)$ time. Breadth-first search takes $O(E)$ time. Therefore, Algorithm 1 runs in $O(E)$ time. $\square$

Using the same framework as Algorithm 1, we present, in Algorithm 2, a simple

and efficient algorithm that colors G optimally in time $O(E)$.

Input. A biconnected graph G , with two odd cycle sizes, 3 and 5, and with minimum degree at least three.

Output. A p -coloring of G (see Table 1 for the value of p).

1. If G contains no more than six vertices, then color G using $\chi(G)$ colors.
2. Else do (G contains no K_5)
 3. Let r be a vertex of maximum degree in G .
 4. Build the breadth-first-search graph of G rooted at r — $BFS(G_r)$.
 5. Color root vertex r with color A.
 6. If $BFS(G_r)$ has one level, then do
 7. If level 1 of $BFS(G_r)$ contains two vertices of degree greater than three, then color them with colors B and C, and color the other vertices on level 1 with color D.
 8. Else color the vertex that has degree greater than three at level 1 of $BFS(G_r)$ with color B, and color the other vertices on level 1 with colors C and D.
 9. Else ($BFS(G_r)$ has two levels) do
 10. Color vertices at level 1 of $BFS(G_r)$ with colors B and C.
 11. Color vertices at level 2 of $BFS(G_r)$ with color A.

ALGORITHM 2. An optimal p -coloring algorithm (see Table 1 for the value of p) for graphs with two odd cycle sizes, 3 and 5.

THEOREM 19. If G is a biconnected graph with two odd cycle sizes, 3 and 5, then Algorithm 2 optimally colors G in $O(E)$ time.

Proof. In the following analysis, we assume that G is a graph with minimum degree at least three and then use Lemma 6 to relax the degree restriction. We also assume that the size of G is at least seven (if G contains no more than six vertices, we optimally color G by exhaustive search in step 1). Based on these assumptions, G does not contain a K_5 (Lemma 12). As noted in the proof of Theorem 18, $BFS(G_r)$ belongs to one of the families of graphs in Figure 2 (modified by breadth-first search) and in Figures 7, 8, and 9, where r is a maximum degree vertex in G .

Since the graphs in Figure 2 contain a K_4 and $BFS(G_r)$ has only one level, three colors are needed for the vertices on level 1 (steps 6–8). The graphs in Figures 7, 8, and 9 contain two levels and are straightforward to color: the root r gets one color; level 1 is bipartite, so it needs two colors; and level 2 is independent, so one color suffices (steps 5, 9–11). Breadth-first search takes $O(E)$ time. Therefore, Algorithm 2 runs in $O(E)$ time. $\square$

5. Summary and open problems. In this paper we have shown that biconnected graphs containing only small odd cycles possess many special structures. We have used breadth-first search to identify various structures and to show that certain structures do not exist. We have completely characterized the structure of graphs that are biconnected, with minimum degree at least three, with at least seven vertices, and with two odd cycle sizes, 3 and 5. Knowing the structure of these graphs enables us, among other things, to recognize them and to color them. We have developed graph coloring algorithms that are simple, efficient, and optimal in the number of colors used.

One direction of future work is to focus on graphs with different combinations of two odd cycle sizes, for example, 3 and 7, 3 and 9, 5 and 13, etc. Another direction is to consider graphs with three different odd cycle sizes (such as 3, 5, and 7), four different odd cycle sizes, and so on.

We have used case analysis to study the structure of graphs with only small odd cycles. As the number s of different odd cycle sizes increases, the complexity of the structure and the number of cases to be considered increase. For large s , case analysis becomes infeasible. It would be very desirable to find a more uniform and general method of analyzing and identifying the global structure of graphs.

Acknowledgments. I thank my advisor Andrea LaPaugh for helpful discussions and comments, for carefully reading earlier drafts of this paper, and for her advice and support. I thank an anonymous referee for helpful, detailed comments and for suggestions on how to improve the paper.

ON THE GRAPH BISECTION CUT POLYTOPE*

MICHAEL ARMBRUSTER[†], CHRISTOPH HELMBERG[†], MARZENA FÜGENSCHUH[‡],
AND ALEXANDER MARTIN[‡]

Abstract. Given a graph $G = (V, E)$ with node weights $\varphi_v \in \mathbb{N} \cup \{0\}$, $v \in V$, and some number $F \in \mathbb{N} \cup \{0\}$, the convex hull of the incidence vectors of all cuts $\delta(S)$, $S \subseteq V$, with $\varphi(S) \leq F$ and $\varphi(V \setminus S) \leq F$ is called the *bisection cut polytope*. We study the facial structure of this polytope which shows up in many graph partitioning problems with applications in VLSI design or frequency assignment. We give necessary and in some cases sufficient conditions for the knapsack tree inequalities introduced in [C. E. Ferreira et al., *Math. Programming*, 74 (1996), pp. 247–267] to be facet-defining. We extend these inequalities to a richer class by exploiting the fact that each cut intersects each cycle in an even number of edges. Finally, we present a new class of inequalities that are based on nonconnected substructures yielding nonlinear right-hand sides. We show that the supporting hyperplanes of the convex envelope of this nonlinear function correspond to the faces of the so-called *cluster weight polytope*, for which we give a complete description under certain conditions.

1. Introduction. Let $G = (V, E)$ be an undirected graph with $V = \{1, \dots, n\}$ and $E \subseteq \{\{i, j\} : i, j \in V, i < j\}$. For given vertex weights $\varphi_v \in \mathbb{N} \cup \{0\}$ for all $v \in V$ and edge costs $w_{\{i, j\}} \in \mathbb{R}$ for all $\{i, j\} \in E$, a partition of the vertex set V into two disjoint clusters S and $V \setminus S$ with sizes $\varphi(S) \leq F$ and $\varphi(V \setminus S) \leq F$ for fixed $F \in [\frac{1}{2}\varphi(V), \varphi(V)] \cap (\mathbb{N} \cup \{0\})$ is called a *bisection*. Finding a bisection such that the total cost of edges in the cut $\delta(S) := \{\{i, j\} \in E : i \in S, j \in V \setminus S\}$ is minimal is the *minimum bisection problem* (MB). Its decision form is known to be NP-complete [10].

In this paper we investigate the *bisection cut polytope* P_B associated with MB. To define P_B note that a cut $\delta(S)$ can be described by its incidence vector $\chi^{\delta(S)}$ with respect to the edge set E . Then

$$P_B := \text{conv}\{y \in \mathbb{R}^{|E|} : y = \chi^{\delta(S)}, S \subseteq V, \varphi(S) \leq F, \varphi(V \setminus S) \leq F\}.$$

MB as well as P_B are related to other problems and polytopes in the literature. Obviously, the bisection cut polytope is contained in the *cut polytope* [2, 6]

$$(1) \quad P_C := \text{conv}\{y \in \mathbb{R}^{|E|} : y = \chi^{\delta(S)}, S \subseteq V\}.$$

If $F = \varphi(V)$, then MB is equivalent to the maximum cut problem (using the negative cost function) and $P_B = P_C$. For $F = \lceil \frac{1}{2}\varphi(V) \rceil$ MB is equivalent to the *equipartition problem* [5] and the bisection cut polytope equals the *equipartition polytope* [3, 4, 14]

$$P_E := \text{conv}\{y \in \mathbb{R}^{|E|} : y = \chi^{\delta(S)}, S \subseteq V, |\varphi(S) - \varphi(V \setminus S)| \leq 1\}.$$

Furthermore, MB is a special case of the minimum node capacitated graph partitioning problem (MNCGP) [8], where two or more clusters are available for the partition of the node set and each cluster has a limited capacity. The objective in MNCGP is the same as in MB, i.e., to minimize the total cost of edges having endpoints in distinct clusters. Finally, we mention the *knapsack polytope* [17]

$$(2) \quad P_K := \text{conv} \left\{ x \in \{0, 1\}^{|V|} : \sum_{v \in V} \varphi_v x_v \leq F \right\}.$$

P_K plays a fundamental role in the inequalities which we derive for the bisection cut polytope.

Graph partitioning problems in general have numerous applications, for instance, in numerics [12], VLSI design [15], compiler design [13], and frequency assignment [7].

The main contribution of this paper is threefold. First, in [8] the so-called knapsack tree inequalities have been introduced. These inequalities relate the knapsack conditions on the nodes with the edge variables defining the cuts and turn out to be computationally very effective. However, no theoretical justification has been found so far for this behavior. In this paper, we give necessary conditions for the knapsack tree inequality to be facet-defining, which turn out to be also sufficient in certain cases. Second, we can generalize the knapsack tree inequalities in the case of bisections by exploiting the well-known fact that any cut intersects a cycle an even number of times. This new class of inequalities, called *bisection knapsack walk inequalities*, subsume the knapsack tree inequalities and yield computationally more flexibility in finding strong inequalities. The third class of inequalities, called *capacity reduced bisection knapsack walk inequalities*, extend both classes of inequalities to nonconnected substructures. The idea is to exploit the weights of the nodes that are not end-nodes of walks to reduce the capacity of the corresponding knapsack inequality, yielding in this way stronger right-hand sides for the knapsack tree and bisection knapsack walk inequalities. These stronger conditions result in nonlinear right-hand sides. We consider the convex envelope of this nonlinear function and show that the supporting hyperplanes are in one-to-one correspondence to the faces of a certain polytope, called *cluster weight polytope*. For the case of a star without capacity restriction we are able to give a complete description of the cluster weight polytope yielding in this case the tightest strengthening possible for the capacity reduced bisection knapsack walk inequalities.

The outline of the paper is as follows. In section 2 we introduce an integer programming formulation for MB building on the formulation of MNCGP given in [8]. Section 3 treats the known knapsack tree inequalities valid for both MB and MNCGP, while section 5 introduces the new bisection knapsack walk inequalities which are only valid for MB and which subsume the knapsack tree inequalities. Section 4 shows a strengthening applicable only to knapsack tree inequalities. Furthermore, we state necessary and sufficient conditions for knapsack tree inequalities to define facets of P_B . Finally, section 6 introduces a strengthening of the bisection knapsack walk inequalities. For this purpose we investigate the facial structure of the cluster weight polytope on stars.

We frequently denote an edge $\{i, j\}$ by ij . Let A and B be discrete sets such that $A \subseteq B$. The incidence vector of A with respect to B is a vector $\chi^A \in \{0, 1\}^{|B|}$ with

$$\chi_a^A = \begin{cases} 1 & \text{if } a \in A, \\ 0 & \text{if } a \in B \setminus A. \end{cases}$$

For a vector $x \in \mathbb{R}^{|B|}$ we define $x(A) = \sum_{a \in A} x_a$. The vector $0^{|A|}$ is the zero vector of dimension $|A|$ and e_a is the unit vector of dimension $|A|$, which is indexed by the elements of A and has entry 1 in coordinate $a \in A$. For a graph $G = (V, E)$ the edge set of the subgraph induced by $\bar{V} \subseteq V$ will be denoted by $E(\bar{V})$ and the node set of the subgraph induced by $\bar{E} \subseteq E$ by $V(\bar{E})$. The convex hull of a set $A \subseteq \mathbb{R}^n$ will be denoted by $\text{conv}\{A\}$.

2. An integer programming formulation of MB. The integer programming formulation for MB given below is based on the formulation for MNCGP presented in [8]. We introduce variables z_i^k for each node $i \in V$ and each cluster $k = 1, 2$ and edge variables y_{ij} for each edge $ij \in E$. z_i^k is set to 1 if node i is in cluster k and 0 otherwise. Variable y_{ij} is set to 1 if edge ij is in the cut, i.e., i and j are not in the same cluster. Then MB can be written as

$$\begin{aligned}
 \text{(MB)} \quad & \min \sum_{e \in E} w_e y_e \\
 \text{s.t.} \quad & z_i^1 + z_i^2 = 1 \quad \forall i \in V, \\
 & \sum_{i \in V} \varphi_i z_i^k \leq F, \quad k = 1, 2, \\
 & y_{ij} \geq z_i^1 - z_j^1 \quad \forall ij \in E, \\
 & y_{ij} \geq z_j^1 - z_i^1 \quad \forall ij \in E, \\
 & y_{ij} \leq 2 - z_i^1 - z_j^1 \quad \forall ij \in E, \\
 & y_{ij} \leq 2 - z_i^2 - z_j^2 \quad \forall ij \in E, \\
 & y_{ij} \in \{0, 1\} \quad \forall ij \in E, \\
 & z_i^k \in \{0, 1\} \quad \forall i \in V, k = 1, 2.
 \end{aligned}$$

The first constraints assure that each node i is packed into exactly one cluster k . The second constraints enforce the capacity restriction on each cluster k . Together with the first set of equations, the next four constraints transmit for each edge $ij \in E$ the values of variables z_i^1 and z_j^1 to the edge variable y_{ij} in the sense that $y_{ij} = 1$ if and only if $z_i^1 \neq z_j^1$ and $y_{ij} = 0$ otherwise. The last two constraints are the binary restrictions on the variables.

Noting that the variables z_i^k do not appear in the objective function, we can consider model

$$\begin{aligned}
 \min \quad & \sum_{e \in E} w_e y_e \\
 \text{s.t.} \quad & y \in Y_{\text{MB}},
 \end{aligned}$$

where $Y_{\text{MB}} \subseteq \mathbb{R}^{|E|}$ is the projection onto the y -space of the feasible region of model (MB). It can be worked out that $P_B = \text{conv}(Y_{\text{MB}})$.

3. Known valid inequalities for MNCGP and MB. A large variety of valid inequalities for the polytope associated to MNCGP is known and, since MB is a special case of MNCGP, all those inequalities are also valid for P_B : cycle inequalities of the cut polytope [2], tree inequalities [3], star inequalities [3], cycle inequalities of capacitated graph partitioning [4], cycle with tails inequalities [8], suspended tree inequalities [14], path block cycle inequalities [14], cycle with ear inequalities [8], strengthened cycle

with ear inequalities [8], knapsack tree inequalities [8], and strengthened knapsack tree inequalities [8].

In the remainder of the paper we specialize and improve the knapsack tree inequality for MB. First we recall its definition for MNCGP from [8].

DEFINITION 1 (knapsack tree inequality [8]). *Let $\sum_{v \in V} a_v x_v \leq a_0$ be a valid inequality for the knapsack polytope P_K with $a_v \geq 0$ for all $v \in V$. For a fixed node $r \in V$ and a subtree (T, E_T) of G rooted at r we define the knapsack tree inequality*

$$(3) \quad \sum_{v \in T} a_v \left(1 - \sum_{e \in P_{rv}} y_e \right) \leq a_0,$$

where for each $v \in T$ the edge set of the path joining node v to root r in (T, E_T) is denoted by P_{rv} .

If (T, E_T) is a star rooted at r , i.e., $E_T = \{\{r, t\} : t \in T, t \neq r\}$, then we call inequality (3) the knapsack star inequality.

In general, there is an exponential number of these knapsack tree inequalities, since for each combination of a valid knapsack inequality with a choice of a rooted tree there is one knapsack tree inequality.

PROPOSITION 2 (see [8]). *The knapsack tree inequality (3) is valid for the polytope P_B .*

The above statement follows from the fact that MB is a special case of MNCGP.

It will be useful to write inequality (3) in the form

$$(4) \quad \sum_{e \in E_T} \left(\sum_{v: e \in P_{rv}} a_v \right) y_e \geq \sum_{v \in T} a_v - a_0.$$

The term on the right-hand side may be interpreted as the excess if all vertices $v \in T$ are packed into the cluster containing the root node r , while we are only allowed to pack a total weight of a_0 . The left-hand side has to compensate for this; i.e., it has to force some edges into the cut so that not all vertices are placed into the same cluster as the current root. We use this reformulation to apply a folklore approach to strengthen coefficients in general binary programs and obtain

$$(5) \quad \sum_{e \in E_T} \min \left\{ \sum_{v: e \in P_{rv}} a_v, \sum_{v \in T} a_v - a_0 \right\} y_e \geq \sum_{v \in T} a_v - a_0.$$

We call this inequality the *truncated knapsack tree inequality*.

Remark 3. Note that this strengthening was already proposed in Proposition 3.12 in [8] applied to the knapsack tree inequality for MNCGP. For MNCGP those authors also proposed a second case of strengthening, namely (in our notation) to reduce α_e to a_0 . However, for MB we always have $\alpha_0 \leq a_0$ due to the following reason. In the bisection case if $\bar{x} = (\bar{x}_1, \dots, \bar{x}_n)^T \in P_K \cap \{0, 1\}^n$, then also $\hat{x} = (1 - \bar{x}_1, \dots, 1 - \bar{x}_n)^T$ lies in $P_K \cap \{0, 1\}^n$. This follows from the fact that the total node weight of each of the clusters $\{v \in V : \bar{x}_v = 1\}$ and $\{v \in V : \bar{x}_v = 0\}$ cannot exceed F . If $\sum_{i \in V} a_v \bar{x}_v \leq a_0$, then also $\sum_{v \in V} a_v \hat{x}_v = \sum_{v \in V} a_v (1 - \bar{x}_v) \leq a_0$. Summing up these two inequalities yields $\sum_{v \in V} a_v \leq 2a_0$ and thus $\alpha_0 = \sum_{v \in V} a_v - a_0 \leq a_0$.

4. Minimum root strengthening of knapsack tree inequalities. Given a knapsack inequality $\sum_{v \in V} a_v x_v \leq a_0$ with $a_v \geq 0$, $v \in V$, let a corresponding knapsack tree inequality be defined on a tree (T, E_T) rooted at r . If we replace r by another node from T , the paths change. The corresponding change of the coefficients

of the inequality will be exploited in the strengthening of the truncated knapsack tree inequality presented in this section. Our strengthening aims at reducing the coefficients of the left-hand side while keeping the value of the right-hand side. We are going to show that the strongest or in some cases even facet-defining inequality is achieved if r enforces a sort of balance with respect to the cumulated node weights on the paths to r . To emphasize that the coefficients in (5) depend on the root node r we introduce the notation

$$(6) \quad \alpha_0 := \sum_{v \in T} a_v - a_0, \quad \alpha_e^r := \min \left\{ \sum_{v: e \in P_{rv}} a_v, \alpha_0 \right\}, \quad e \in E_T,$$

and consider (5) in the form

$$(7) \quad \sum_{e \in E_T} \alpha_e^r y_e \geq \alpha_0.$$

Note that if we change the root of (T, E_T) , the right-hand side of (7) remains the same, since by this operation we do not eliminate nodes of (T, E_T) .

At first we derive some relations based on the definition of the coefficients α_e^r , $r \in T$, $e \in E_T$, which we will exploit in the proofs of the results presented in this section. The following lemma states that along a path from the root to some node the coefficients cannot increase.

LEMMA 4. *Let (T, E_T) be a tree in G rooted at node r and let e and f be two edges on a path to r such that e is closer to r than f with respect to the number of edges. Then*

$$(8) \quad \alpha_e^r \geq \alpha_f^r.$$

Proof. It suffices to consider incident edges e and f . Setting $e := ij$ and $f := jk$ we obtain

$$\sum_{v: e \in P_{rv}} a_v = \sum_{v: f \in P_{rv}} a_v + a_j + \sum_{\bar{e} \in \bar{E}} \left(\sum_{v: \bar{e} \in P_{rv}} a_v \right) \geq \sum_{v: f \in P_{rv}} a_v,$$

where $\bar{E}$ contains edges incident to j except e and f . Hence if $\alpha_f^r = \alpha_0$, then also $\alpha_e^r = \alpha_0$; otherwise $\alpha_f^r \leq \min\{\sum_{v: e \in P_{rv}} a_v, \alpha_0\} = \alpha_e^r$. $\square$

In the next lemma we investigate the change of coefficients if the root is moved from a node r to an adjacent node s .

LEMMA 5. *Let (T, E_T) be a tree in G and let $r, s \in T$ be two adjacent nodes with $\bar{e} = rs$. We have*

- (a) $\alpha_e^r = \alpha_e^s$ for all $e \in E_T$ such that $e \neq rs$;
- (b) $\alpha_{\bar{e}}^r = \min\{a_s + \sum_{e \in \delta(\{s\}) \setminus \{\bar{e}\}} \alpha_e^s, \alpha_0\}$;
- (c) if $\alpha_{\bar{e}}^r \leq \alpha_{\bar{e}}^s$, then $\alpha_e^r \leq \alpha_e^s$ for all $\bar{v} \in V_{\bar{e}}^r := \{v \in T : \bar{e} \in P_{rv}\}$ and all $e \in E_T$.

Proof. (a) For $e \neq rs$ we have $\{v : e \in P_{rv}\} = \{v : e \in P_{sv}\}$ and thus $\sum_{v: e \in P_{rv}} a_v = \sum_{v: e \in P_{sv}} a_v$.

(b) Using the notation from (6) we have

$$\sum_{v: \bar{e} \in P_{rv}} a_v = a_s + \sum_{e \in \delta(\{s\}) \setminus \{\bar{e}\}} \left(\sum_{v: e \in P_{sv}} a_v \right).$$

(c) Consider a $\bar{v} \in T$ with $\bar{e}$ on the path $\Pi = P_{r\bar{v}}$ with $V_\Pi = \{v_1, \dots, v_p\}$, $p \geq 2$, where $v_1 = r$, $v_2 = s$, $v_p = \bar{v}$, and v_k, v_{k+1} , $1 \leq k \leq p-1$, are adjacent in T . Applying (a) recursively to nodes v_i, v_{i+1} , $i = 1, \dots, p-1$, we obtain

$$(9) \quad \alpha_e^r = \alpha_e^{\bar{v}} \quad \forall e \in E_T \setminus E_\Pi.$$

As $\bar{e}$ is outside the path from s to $\bar{v}$, the same argument for root s and the assumption yield

$$(10) \quad \alpha_{\bar{e}}^{\bar{v}} = \alpha_{\bar{e}}^s \geq \alpha_{\bar{e}}^r.$$

By Lemma 4, coefficients cannot increase along paths from the root, so

$$(11) \quad \begin{aligned} \alpha_{\bar{v}v_{p-1}}^{\bar{v}} &\geq \alpha_{v_{p-1}v_{p-2}}^{\bar{v}} \geq \dots \geq \alpha_{v_3v_2}^{\bar{v}} \geq \alpha_{v_2r}^{\bar{v}} = \alpha_{\bar{e}}^{\bar{v}}, \\ \alpha_{\bar{e}}^r &= \alpha_{rv_2}^r \geq \alpha_{v_2v_3}^r \geq \dots \geq \alpha_{v_{p-2}v_{p-1}}^r \geq \alpha_{v_{p-1}\bar{v}}^r. \end{aligned}$$

Thus, putting (9)–(11) together, the claim is proved. $\square$

This allows us to characterize exactly the set of roots giving the best coefficients.

LEMMA 6. *Let (T, E_T) be a tree in G . The set of minimal roots*

$$\mathcal{R} := \{r \in T : \alpha_e^r \leq \alpha_e^v \quad \forall v \in V_T \text{ and } e \in E_T\}$$

is nonempty and induces a connected subtree in T . A node $r \in T$ satisfies $r \in \mathcal{R}$ if and only if $\alpha_e^r \leq \alpha_e^s$ for all $e = rs \in E_T$.

Proof. To see that $\mathcal{R}$ is nonempty, orient the edges $e = uv \in T$ with $\alpha_e^u < \alpha_e^v$ towards v ; do not orient edges with $\alpha_e^u = \alpha_e^v$. As T contains no cycle, there must be a node $r \in T$ so that all incident edges are either not oriented or point towards r , i.e., $\alpha_e^r \leq \alpha_e^s$ for all $e = rs \in E_T$. By Lemma 5(c) and using the notation defined there, this r is in $\mathcal{R}$, because $V = \bigcup_{rs \in E_T} V_{rs}^r \cup \{r\}$.

Next, we show connectedness for $r, s \in \mathcal{R}$. These satisfy $\alpha_e^r = \alpha_e^s$ for all $e \in E_T$. Assume there is some inner vertex $\bar{v} \in T$ on the path between r and s . Apply Lemma 5(a) on the edges outside the paths $P_{r\bar{v}}$ and $P_{s\bar{v}}$ to see that $\alpha_e^r = \alpha_e^{\bar{v}}$ for all $e \in E_T$ and so $\bar{v} \in \mathcal{R}$.

The characterization of the elements of $\mathcal{R}$ is obtained via Lemma 5(c) directly. $\square$

For each choice of a roots out of R we obtain the same coefficient for each edge. Thus, the strongest truncated knapsack tree inequality is independent of the choice of $r \in R$.

THEOREM 7. *Let (T, E_T) be a tree in G and $\mathcal{R}$ as defined in Lemma 6. The strongest truncated knapsack tree inequality, with respect to the knapsack inequality $\sum_{v \in V} a_v x_v \leq a_0$, $a_v \geq 0$, $v \in V$, defined on (T, E_T) is obtained for a root $r \in \mathcal{R}$; i.e., if $r \in \mathcal{R}$, then*

$$(12) \quad \sum_{e \in E_T} \alpha_e^s y_e \geq \sum_{e \in E_T} \alpha_e^r y_e \geq \alpha_0$$

holds for all $s \in T$ and all $y \in P_B$. In particular,

$$(13) \quad \sum_{e \in E_T} \alpha_e^r y_e = \sum_{e \in E_T} \alpha_e^s y_e$$

holds for all $r, s \in \mathcal{R}$ and all $y \in P_B$.

Proof. The proof is obtained directly by Lemma 6. $\square$

In what follows the elements of the set $\mathcal{R}$ will be called *minimal roots* of a given tree (T, E_T) . In order to obtain the strongest truncated knapsack tree inequality it is sufficient, by Theorem 7, to identify any minimal root. Given a tree (T, E_T) rooted at some node r one can find a minimal root along the lines of the proof of Lemma 6 by proceeding iteratively as follows. Select a node $s \in T$ adjacent to r such that $\alpha_{rs}^r = \max\{\alpha_{rv}^r : rv \in E_T\}$. If $\alpha_{rs}^r > \alpha_{rs}^s$, then also $\sum_{e \in E_T} \alpha_e^r > \sum_{e \in E_T} \alpha_e^s$ by Lemma 5(c). Hence r can be discarded and s is marked as the next root of (T, E_T) . Otherwise $\sum_{e \in E_T} \alpha_e^r y_e \geq \alpha_0$ is the strongest truncated knapsack tree inequality with respect to all possible choices of roots in (T, E_T) .

In the remainder of this section we show that the assumption on r to be a minimal root is not only a necessary condition for a truncated knapsack tree inequality to be facet-defining for the polytope P_B , which follows from Theorem 7, but in some cases is also sufficient.

For this purpose we assume that $G = (T, E_T)$ is a tree and $\varphi_v = 1$ for all $v \in T$. Then the knapsack polytope P_K is defined by the inequality $\sum_{v \in T} x_v \leq F$, and the corresponding knapsack tree inequality (3) defined on (T, E_T) takes the form

$$\sum_{v \in T} \left(1 - \sum_{e \in P_{rv}} y_e \right) \leq F.$$

Applying the strengthening (5) and notation (6) we obtain $\alpha_0 = |T| - F$ and $\alpha_e^r = \min\{|V_e^r|, |T| - F\}$, for all $e \in E$, where V_e^r is the set of nodes whose path to $r \in T$ contains the edge e ; see, e.g., Figure 3. To emphasize the special case that we treat in what follows we set $\kappa_e^r := \alpha_e^r$, $\bar{F} := \alpha_0$ and consider the inequality $\sum_{e \in E_T} \kappa_e^r y_e \geq \bar{F}$, or $(\kappa^r)^T y \geq \bar{F}$ for short. For ease of exposition we call κ_e^r the *knapsack weight* of $e \in E$ with respect to the root r of (T, E_T) . If $\kappa_e^r = \bar{F}$ and $\bar{F} < |V_e^r|$, we say that e has the *reduced knapsack weight*. Furthermore, we introduce the term *branchless path*, which is a path in (T, E_T) whose inner nodes are all of degree 2. We consider a path consisting of an edge and both its end-nodes as a trivial case of a branchless path. We call an edge a *leaf* if one of its endpoints is of degree 1.

THEOREM 8. *Assume that $G = (T, E_T)$ is a tree rooted at a node $r \in T$, $\varphi_v = 1$ for all $v \in T$ and $\frac{|T|}{2} + 1 \leq F < |T|$. The truncated knapsack tree inequality $(\kappa^r)^T y \geq \bar{F}$ is facet-defining for P_B if and only if one of the following conditions is satisfied:*

- (a) r is a minimal root and (T, E_T) satisfies the following branchless path condition: each branchless path with F nodes has one end-edge that is a leaf in (T, E_T) ;
- (b) $F = |T| - 1$.

Remark 9. Note the following:

- (1) Given a graph $G = (V, E)$, P_B is full-dimensional under the assumptions that $\varphi_v = 1$ for all $v \in V$ and $F \geq \frac{|V|}{2} + 1$; see [8]. If $F = \frac{|V|}{2}$, the bisection cut polytope is not full-dimensional, and hence this case needs a special treatment which can be found in [9].
- (2) In case $F = |V|$ the knapsack inequality $\sum_{v \in V} x_v \leq F$ is redundant for P_K and thus the corresponding truncated knapsack tree inequalities are redundant for P_B . Therefore we assume that $F < |V|$, in particular, $\bar{F} > 0$.

Due to the complexity of the proof of Theorem 8, we complete it in several steps. First we outline the general idea of the sufficiency part. Let $\mathcal{F}$ be a face of P_B induced by $(\kappa^r)^T y \geq \bar{F}$ and let $\mathcal{F}_b$ be the facet of P_B defined by the inequality $b^T y \geq b_0$ such that $\mathcal{F} \subseteq \mathcal{F}_b$. To show that $(\kappa^r)^T y \geq \bar{F}$ is a facet-defining inequality for P_B , we prove

that $\mathcal{F} = \mathcal{F}_b$; i.e., there exists $\gamma \in \mathbb{R} \setminus \{0\}$ such that

$$(14) \quad \begin{aligned} b_e &= \gamma \kappa_e^r \quad \forall e \in E, \\ b_0 &= \gamma \bar{F} \end{aligned}$$

hold.

We introduce now further definitions and lemmas required to prove the above relations. Given a partition of the node set T , we denote by V_r the cluster containing r ; see, e.g., Figure 3. We say that two edges $e, f \in E$ are *related* if there exists a path to the root containing both e and f . An edge e is related to itself. For an edge e we set $B_e = \{f \in E : f \text{ is related to } e\}$ and call the graph $(\bigcup_{f \in B_e} f, B_e)$ a *branch* (induced by e); it is a subtree of (T, E_T) and is said to be incident on r if e and r are incident. If any two edges e and f are incident and related and such that e is closer to the root than f (with respect to the number of edges), then f is a *child* of e . We denote the set of children of e by

$$S_e = \{f \in E_T : f \text{ is a child of } e\}.$$

With this, the recursive construction rule of Lemma 5(b) specialized to κ_e^r reads

$$(15) \quad \kappa_e^r = \min \left\{ 1 + \sum_{\bar{e} \in S_e} \kappa_{\bar{e}}^r, \bar{F} \right\}.$$

We say that a bisection cut $\delta(V_r)$ is *tight* for $(\kappa^r)^T y \geq \bar{F}$ if it satisfies $(\kappa^r)^T \chi^{\delta(V_r)} = \bar{F}$. As we will show soon, $|V_r| = F$ holds if $\delta(V_r)$ is tight for $(\kappa^r)^T y \geq \bar{F}$ and all $e \in \delta(V_r)$ satisfy $\kappa_e^r = |V_e^r| \leq \bar{F}$, i.e., all edges in the cut do not have reduced knapsack weights. In this case we will call the cut $\delta(V_r)$ *double-tight* for $(\kappa^r)^T y \geq \bar{F}$.

Next, we derive some properties of bisection cuts tight for $(\kappa^r)^T y \geq \bar{F}$.

LEMMA 10. *No two edges in a bisection cut tight for $(\kappa^r)^T y \geq \bar{F}$ are related.*

Proof. Assume, for contradiction, that $\delta(V_r)$ is a bisection cut tight for $(\kappa^r)^T y \geq \bar{F}$ containing two related edges $e = v_{j-1}v_j$ and $f = v_{k-1}v_k$ on some path $P_{v_k}^r = \{v_1v_2, v_2v_3, \dots, v_{j-1}v_j, \dots, v_{k-1}v_k\}$ with $r = v_1$ and $1 < j < k$. Without loss of generality (w.l.o.g.), we may assume that $v_{j-1} \in V_r$ and no further edge $v_{i-1}v_i$ is in the cut for $j < i < k$. Then $\{v_j, \dots, v_{k-1}\} \subset T \setminus V_r$ and $v_k \in V_r$. The cut induced by $\bar{V}_r = V_r \cup \{v_j\} \setminus \{v_k\}$ is again a bisection cut with $\delta(\bar{V}_r) \subseteq (\delta(V_r) \setminus \{e, f\}) \cup S_e \cup S_f$; we know $e \notin \delta(\bar{V}_r)$ (this will not hold for f if $f \in S_e$). Note that e and f must be unreduced because $\delta(V_r)$ is tight, $(\kappa^r)^T \chi^{\delta(V_r)} = \bar{F}$. Thus, by (15),

$$(\kappa^r)^T \chi^{\delta(V_r)} - (\kappa^r)^T \chi^{\delta(\bar{V}_r)} \geq \kappa_e^r + \kappa_f^r - \sum_{\bar{e} \in S_e \cup S_f} \kappa_{\bar{e}}^r \geq 1,$$

and that yields $(\kappa^r)^T \chi^{\delta(\bar{V}_r)} + 1 \leq (\kappa^r)^T \chi^{\delta(V_r)} = \bar{F}$. This contradicts $(\kappa^r)^T \chi^{\delta(\bar{V}_r)} \geq \bar{F}$, which holds because $\delta(\bar{V}_r)$ is a bisection cut and $(\kappa^r)^T y \geq \bar{F}$ is feasible for P_B . $\square$

LEMMA 11. *Let (T, E_T) be rooted at $r \in T$. A bisection cut $\delta(V_r)$ is double-tight for $(\kappa^r)^T y \geq \bar{F}$ if and only if $|V_r| = F$ and $(V_r, E(V_r))$ is connected.*

Proof. Assume first that $\delta(V_r)$ is double-tight for $(\kappa^r)^T y \geq \bar{F}$. By Lemma 10 any two edges in $\delta(V_r)$ are not related. This implies that V_r induces a connected subgraph of (T, E_T) . Hence $T \setminus V_r = \bigcup_{e \in \delta(V_r)} V_e^r$ and $V_e^r \cap V_f^r = \emptyset$ for any $e, f \in \delta(V_r)$. Furthermore, $\kappa_e^r = |V_e^r|$ holds for each $e \in \delta(V_r)$ and we obtain $|T \setminus V_r| = \sum_{e \in \delta(V_r)} \kappa_e^r = \bar{F}$, i.e., $|V_r| = F$.

Now consider a bisection $(V_r, T \setminus V_r)$ such that $(V_r, E(V_r))$ is connected and $|V_r| = F$ (i.e., $|T \setminus V_r| = \bar{F}$). We show first that $\delta(V_r)$ contains only edges whose knapsack weights are not reduced. Assume for contradiction that $\delta(V_r)$ contains an edge f with a reduced knapsack weight. Since $\kappa_f^r = \bar{F}$, this is the only edge in $\delta(V_r)$; otherwise $\delta(V_r)$ is not tight for $(\kappa^r)^T y \geq \bar{F}$. Hence $\delta(V_r) = \{f\}$, and since f has a reduced knapsack weight, $|T \setminus V_r| = |V_f^r| > \bar{F}$ holds, contradicting the assumption that $|V_r| = F$. To show that $\delta(V_r)$ is tight for $(\kappa^r)^T y \geq \bar{F}$, we use the assumption that $(V_r, E(V_r))$ is connected. We have

$$\sum_{e \in \delta(V_r)} \kappa_e^r = \sum_{e \in \delta(V_r)} |V_e^r| = \left| \bigcup_{e \in \delta(V_r)} V_e^r \right| = \bar{F}.$$

Hence $\delta(V_r)$ is double-tight for $(\kappa^r)^T y \geq \bar{F}$. $\square$

Next, we provide some results following from the assumption that (T, E_T) is rooted at a minimal root. As we will show in the following lemmas, this ensures the existence of bisection cuts tight for $(\kappa^r)^T y \geq \bar{F}$, which we will consider in the proof of further lemmas preceding the proof of Theorem 8.

LEMMA 12. *Let $B = (V_B, E_B) \subseteq (T, E_T)$ be a branch incident on root $r \in T$. If r is a minimal root of (T, E_T) , then $|V_B \setminus \{r\}| \leq F$.*

FIG. 1. Node set V_B .

FIG. 2. Node sets V_f^s and V_f^r .

Proof. Let $B = (V_B, E_B)$ be a branch incident on r and assume that $|V_B \setminus \{r\}| > F$. We are going to show that in this case r cannot be a minimal root. Let s be the node in V_B adjacent to r , and let $f = rs \in E_B$; see Figures 1 and 2. Note that $V_f^r \cup V_f^s = T$. Since $|V_f^r| = |V_B \setminus \{r\}| > F > \bar{F}$, we have $\kappa_f^r = \bar{F}$ on the one hand. On the other hand, $\kappa_f^s = \min\{|T \setminus V_f^r|, \bar{F}\} < \bar{F}$. Hence $\kappa_f^s < \kappa_f^r$, and by Lemma 6, r is not a minimal root. $\square$

LEMMA 13. *Assume (T, E_T) , rooted at a minimal root r , has an edge $e \in E_T$ such that $\kappa_e^r = \bar{F}$. The cut $\delta(V_e^r) = \{e\}$ is a bisection cut tight for $(\kappa^r)^T y \geq \bar{F}$.*

Proof. Note that in the considered case we have $V_r = T \setminus V_e^r$. We show that the cut $\delta(V_r)$, which is obviously tight for $(\kappa^r)^T y \geq \bar{F}$, is also a bisection cut. Assume that $\delta(V_r)$ is not a bisection cut. Then either $|V_r| < \bar{F}$ or $|T \setminus V_r| < \bar{F}$. In the first case, let s be a node incident to e such that the path $\Pi_{rs} = (V_{rs}, E_{rs})$ joining r and s contains e ; see Figure 3. For all $f \in E_T \setminus E_{rs}$ there holds $\kappa_f^r = \kappa_f^s$ due to Lemma 5(a). For $f \in E_{rs}$ we obtain by Lemma 4 that $\kappa_f^r \geq \kappa_e^r = \bar{F} > |V_r| \geq |V_f^s| = \kappa_f^s$. By Lemma 6 this contradicts the assumption that r is a minimal root. One can show in a similar way that $|T \setminus V_r| < \bar{F}$ not possible either. $\square$

The following result exhibits the central structural property required for cross-connecting double-tight cuts of which one contains edge e and the next contains its children S_e .

LEMMA 14. *Given (T, E_T) with minimal root r . For each unreduced $e \in E_T$ that is not a leaf there exists a double-tight cut $\delta(V_r)$ that contains e , S_f , and S_g for two*

FIG. 3. Node sets V_r , V_e^r , and V_f^r .FIG. 4. Node sets V_r and $\bar{V}_r$ (Lemma 15(b)).

further unreduced edges f and g with $\{e, f, g\}$ unrelated if and only if (T, E_T) satisfies the branchless path condition.

Proof. First suppose that in (T, E_T) the branchless path condition does not hold, so there is a branchless path on nodes $\bar{V} = \{v_1, \dots, v_F\}$ with $\{v_i, v_{i+1}\} \in E_T$ for $1 \leq i < F$ and neither $\{v_1, v_2\}$ nor $\{v_{F-1}, v_F\}$ are leaves. By the minimality of r and Lemma 12 we must have $r \in \bar{V}$. One of the edges $\{v_1, v_2\}$ and $\{v_{F-1}, v_F\}$ must be unreduced (otherwise one of them would cut the graph into two parts, one containing more than F and one at least $\bar{F}+1$ nodes). W.l.o.g., let $e = \{v_1, v_2\}$ be unreduced and satisfy $\kappa_e^r \leq \kappa_{v_{F-1}v_F}^r$. For this e there exist no further two unrelated edges f and g satisfying the requirements, because at least one of them must be located on the path (by Lemma 11 we need $|V_r| = F$) and must thus be related either to e or to the other edge.

Now suppose that (T, E_T) satisfies the branchless path conditions. Let e be an unreduced edge that is not a leaf. Edge e is contained in some branch incident on r ; call this branch $B = (V_B, E_B)$. By Lemmas 11 and 12 we may construct a bisection $(V_r, T \setminus V_r)$ with $e \in \delta(V_r)$ and $\delta(V_r)$ double-tight by extending $V_B \setminus V_e^r$ to V_r via successively adding adjacent points from $V \setminus V_B$ so that $|V_r| = F$ and the subgraph $\bar{T} = (V_r, E_r)$ induced by V_r is a tree. Note that by Lemma 12 root r can be a leaf of $\bar{T}$ only if it is incident to e . First suppose $\bar{T}$ has two leaves so that the corresponding nodes of degree 1 are not incident to e , then take these for f and g . Otherwise $\bar{T}$ forms a path $\{v_1, \dots, v_F\}$ with v_i adjacent to v_{i+1} in $\bar{T}$ for $1 \leq i < F$ with e incident to one of its endpoints, say $v_1 \in e$. By the branchless path condition at least one of the nodes v_i , $1 \leq i < F-1$, has degree at least 3 in T (otherwise one can find a branchless path with F nodes not having one end edge a leaf); pick one and call it $\bar{v}$. Incident to this $\bar{v}$ there is an edge $f \in \delta(V_r)$ with $f \neq e$. Now observe that, by Lemma 11, $\delta(V_r \cup f \setminus \{v_F\})$ is a double-tight cut that contains e , S_f , and S_g for $g = \{v_{F-2}, v_{F-1}\}$ and e, f , and g are unrelated. $\square$

LEMMA 15. Given (T, E_T) satisfying the branchless path condition and a minimal root $r \in T$, let $\mathcal{F}, \mathcal{F}_b$ be faces of P_B defined by $(\kappa^r)^T y \geq \bar{F}$ and $b^T y \geq b_0$, respectively, such that $\mathcal{F} \subseteq \mathcal{F}_b$. For each branch $B = (V_B, E_B)$ in (T, E_T) incident on r there is a $\gamma_B \geq 0$ such that

- (a) $b_e = b_0$ holds for any edge $e \in E_T$ with $\kappa_e^r = \bar{F}$;
- (b) $b_e = b_f =: \gamma_B$ holds for any two leaves $e, f \in E_B$ of T ;
- (c) $b_e = \gamma_B \kappa_e^r$ holds for unreduced $e \in E_B$;
- (d) $\gamma_B = b_0/\bar{F}$ and $b_e = \gamma_B \kappa_e^r$ holds for $e \in E_B$.

Proof. (a) Let e be an edge in E_T with $\kappa_e^r = \bar{F}$. By Lemma 13 the cut $\delta(V_e^r) = \{e\}$ is a bisection cut tight for $(\kappa^r)^T y \geq \bar{F}$. Since $\chi^{\{e\}}$ is in $\mathcal{F}_b$, we obtain $b_e = b_0$.

(b) Let e and f be leaves in E_B and denote by s, v their respective end-nodes of degree 1. $|V_B \setminus \{s\}| \leq F$ follows from Lemma 12. Hence there exists a bisection $(V_r, T \setminus V_r)$ with V_r connected such that $V_B \setminus \{s\} \subseteq V_r$, $s \notin V_r$, and $|V_r| = F$. Then, by Lemma 11, $\bar{V}_r = V_r \cup \{s\} \setminus \{v\}$ also yields a double-tight bisection cut, so $b_0 = \sum_{\bar{e} \in \delta(V_r)} b_{\bar{e}} = \sum_{\bar{e} \in \delta(\bar{V}_r)} b_{\bar{e}}$ and therefore $b_e = b_f =: \gamma_B$; see Figure 4.

(c) We use induction by distance of the edges in E_B to the deepest leaves in their induced branches. By (b) the claim holds for the leaves. Let e be an unreduced edge in E_B that is not a leaf. By Lemma 14 there exists a double-tight cut $\delta(V_r)$ and unreduced edges f, g unrelated to e and to each other so that $e \in \delta(V_r)$, $S_f \subset \delta(V_r)$, and $S_g \subset \delta(V_r)$. Pick some $h \in S_e$. Lemma 4 implies that h is unreduced and hence (15) combined with the induction hypothesis yields

$$(16) \quad b_h - \sum_{\bar{e} \in S_h} b_{\bar{e}} = \gamma_B \left(\kappa_h^r - \sum_{\bar{e} \in S_h} \kappa_{\bar{e}}^r \right) = \gamma_B.$$

Denote by v_e (v_f, v_g, v_h) that node of e (f, g, h) whose distance to r is greater. Then by Lemma 11

$$\bar{V}_f = V_r \cup \{v_e\} \setminus \{v_f\}, \quad \bar{V}_g = V_r \cup \{v_e\} \setminus \{v_g\}, \quad \text{and} \quad \bar{V}_h = V_r \cup \{v_e, v_h\} \setminus \{v_f, v_g\}$$

(see Figure 5) also yield double-tight cuts with edge sets (for appropriately chosen $D \subset E_T$)

$$\begin{aligned} \delta(V_r) &= \{e\} \dot{\cup} S_f \dot{\cup} S_g \dot{\cup} D, \\ \delta(\bar{V}_f) &= S_e \dot{\cup} \{f\} \dot{\cup} S_g \dot{\cup} D, \\ \delta(\bar{V}_g) &= S_e \dot{\cup} S_f \dot{\cup} \{g\} \dot{\cup} D, \\ \delta(\bar{V}_h) &= (S_e \setminus \{h\}) \dot{\cup} S_h \dot{\cup} \{f\} \dot{\cup} \{g\} \dot{\cup} D. \end{aligned}$$

FIG. 5. Node sets V_r , $\bar{V}_f$, $\bar{V}_g$, and $\bar{V}_h$.

Exploiting

$$b_0 = \sum_{\bar{e} \in \delta(V_r)} b_{\bar{e}} = \sum_{\bar{e} \in \delta(\bar{V}_f)} b_{\bar{e}} = \sum_{\bar{e} \in \delta(\bar{V}_g)} b_{\bar{e}} = \sum_{\bar{e} \in \delta(\bar{V}_h)} b_{\bar{e}}$$

one obtains after a few rearrangements together with (16)

$$b_e - \sum_{\bar{e} \in S_e} b_{\bar{e}} = b_f - \sum_{\bar{e} \in S_f} b_{\bar{e}} = b_g - \sum_{\bar{e} \in S_g} b_{\bar{e}} = b_h - \sum_{\bar{e} \in S_h} b_{\bar{e}} = \gamma_B.$$

By induction, $b_{\bar{e}} = \gamma_B \kappa_{\bar{e}}^r$ for all $\bar{e} \in S_e$, so $b_e = \gamma_B(1 + \sum_{\bar{e} \in S_e} \kappa_{\bar{e}}^r) = \gamma_B \kappa_e^r$.

(d) We first show $\gamma_{\bar{B}} = \gamma_B$ for all branches $\bar{B}$ incident on r with respect to a special branch B incident on r . Observe that there is always a branch $B = (V_B, E_B)$ incident on r with $|V_B \setminus \{r\}| < F$ (because there exist at least two branches by minimality of r and because $|T| \leq 2F$), so let B be this branch. Let $\bar{B} = (\bar{V}, \bar{E})$ be

some other branch incident on r . Denote by $\bar{S} \subset \bar{E}$ the set of unreduced edges in $\bar{E}$ that have no unreduced predecessors, i.e.,

$$\bar{S} = \{\bar{e} \in \bar{E} : |V_e^r| = \kappa_e^r \text{ and if } \bar{e} \in S_{e'} \text{ for some } e' \in \bar{E}, \text{ then } |V_{e'}^r| > |\bar{F}|\}.$$

Next, the set $\hat{V} = V_B \cup \bar{V} \cup \bigcup_{\bar{e} \in \bar{S}} V_e^r$ induces a tree $\hat{T} = (\hat{V}, \hat{E})$ with $|\hat{V}| \leq F$ ($|V_B| \leq F$ by construction and removing any leaf $v \in \hat{V} \setminus V_B$ corresponds to cutting a reduced edge f in $\bar{B}$ so that $|\hat{V} \setminus \{v\}| \leq |T| - |V_f^r| < |T| - \bar{F} = F$). Thus, we may extend $\hat{V}$ by nodes from $V \setminus (V_B \cup \bar{V})$ to a set V_r with $|V_r| = F$ so that $\delta(V_r)$ is a double-tight cut with $\bar{S} \subseteq \delta(V_r)$ and $E_B \cap \delta(V_r) = \emptyset$. Take a leaf $e \in E_B$, an edge $f \in \bar{S}$, and denote by v_e and v_f those of the two nodes of e and f whose distance to r is greater. Then $V_e = V_r \cup \{v_f\} \setminus \{v_e\}$ yields another double-tight cut $\delta(V_e) = \delta(V_r) \cup \{e\} \cup S_f \setminus \{f\}$, and therefore $\gamma_B = b_e = b_f - \sum_{\bar{e} \in S_f} b_{\bar{e}} = \gamma_{\bar{B}}$.

As $\gamma_{\bar{B}} = \gamma_B$ for all branches $\bar{B}$ and B , any double-tight cut $\delta(V_r)$ yields with (c)

$$b_0 = \sum_{e \in \delta(V_r)} b_e = \gamma_B \sum_{e \in \delta(V_r)} \kappa_e^r = \gamma_B \bar{F}.$$

Thus, $\gamma_B = \frac{b_0}{\bar{F}}$. $\square$

Proof of Theorem 8. (a) Because of (b) we require $\bar{F} \geq 2$ within the proof of (a). For sufficiency assume that the branchless path condition is satisfied. Given a face $\mathcal{F}_b$ of P_B defined by $b^T y \geq b_0$ that contains all roots of $(\kappa^r)^T y \geq \bar{F}$, Lemma 15 shows that $b^T y \geq b_0$ is a nonnegative multiple of $(\kappa^r)^T y \geq \bar{F}$, so the latter is facet-inducing.

Necessity of the minimal root condition is a consequence of Theorem 7, so consider the case that r is a minimal root but the branchless path condition does not hold. In this case (T, E_T) contains a path on nodes $\bar{V} = \{v_1, \dots, v_F\}$ with $\{v_i, v_{i+1}\} \in E_T$ for $1 \leq i < F$ and neither $\{v_1, v_2\}$ nor $\{v_{F-1}, v_F\}$ is a leaf. By the minimality of r and Lemma 12 there must be some $k \in \{1, \dots, F\}$ with $r = v_k$. Split (T, E_T) at r into two edge disjoint subtrees (V_1, E_1) and (V_2, E_2) with $V_1 \cap V_2 = \{r\}$, $E_T = E_1 \cup E_2$ and set

$$\begin{aligned} S_1 &:= \delta(\{v_1\}) \setminus \{v_1 v_2\}, \\ S_2 &:= \delta(\{v_F\}) \setminus \{v_{F-1} v_F\}, \\ P_1 &:= \{v_i v_{i+1} : 1 \leq i < k\}, \\ P_2 &:= \{v_i v_{i+1} : k \leq i < F\}, \\ D_i &:= E_i \setminus P_i \quad \text{for } i \in \{1, 2\}, \\ n_i &:= \sum_{e \in S_i} |V_e^r| \quad \text{for } i \in \{1, 2\}. \end{aligned}$$

Note that $1 \leq n_i < \bar{F}$ for $i \in \{1, 2\}$, because otherwise the cut S_i would induce a partition requiring at least $n_i + F + 1 > \bar{F} + F = |T|$ nodes. Furthermore, $n_1 + n_2 = \bar{F}$ because $S_1 \cup S_2$ induces a double-tight cut by Lemma 11. We show that all roots of $(\kappa^r)^T y \geq \bar{F}$ also satisfy the equation

$$(17) \quad n_2 \sum_{e \in D_1} \kappa_e^r y_e + n_1 \sum_{e \in P_1} (\bar{F} - \kappa_e^r) y_e - n_2 \sum_{e \in P_2} (\bar{F} - \kappa_e^r) y_e - n_1 \sum_{e \in D_2} \kappa_e^r y_e = 0.$$

Indeed, let V_r be a node set inducing a bisection cut tight for $(\kappa^r)^T y \geq \bar{F}$ and consider the number of times the path can be cut in view of Lemma 10:

$|\delta(V_r) \cap (P_1 \cup P_2)| = 0$: This implies $\delta(V_r) = S_1 \cup S_2$ by Lemma 11 and (17) holds.
 $|\delta(V_r) \cap (P_1 \cup P_2)| = 1$: By symmetry it suffices to consider the case $\delta(V_r) \cap P_1 = \{f\}$.
 By Lemma 10 we have $\delta(V_r) \cap D_1 = \emptyset$ and as the cut is tight, $\sum_{e \in D_2} \kappa_e^r y_e = \bar{F} - \kappa_f^r$, so (17) holds.
 $|\delta(V_r) \cap (P_1 \cup P_2)| \geq 2$: By Lemma 10 it cannot be greater than two, but even two is impossible for a tight cut. Indeed, Lemma 10 ensures $\delta(V_r) \cap (P_1) = \{e_1\}$, $\delta(V_r) \cap (P_2) = \{e_2\}$, and $\delta(V_r) \cap (D_1 \cup D_2) = \emptyset$. Since $n_i < \bar{F}$ we obtain $\kappa_{e_i}^r \geq n_i + 1$ for $i \in \{1, 2\}$, so $(\kappa^r)^T \chi^{\delta(V_r)} = \kappa_{e_1}^r + \kappa_{e_2}^r \geq n_1 + n_2 + 2 > \bar{F}$ yields the desired contradiction.

As (17) is not a scalar multiple of $(\kappa^r)^T y \geq \bar{F}$, the latter cannot be a facet if $\bar{F} \geq 2$ and the branchless path condition is not fulfilled.

(b) If $\bar{F} = 1$, then $\kappa_e^r = 1$ for all $e \in E_T$ and each e alone forms a bisection cut that is tight for $(\kappa^r)^T y \geq \bar{F}$. As these are $|E_T|$ affinely independent roots, the inequality is facet-inducing. $\square$

Remark 16. The statements of Theorem 8 cannot be easily carried forward for graphs denser than trees. So far, we observed that if there are cycles in the graph, then not all trees in this graph yield a facet-defining truncated knapsack tree inequality, even if conditions (a) in Theorem 8 are satisfied. Some additional assumptions must be figured out. For instance, it can be shown that if $F = |T| - 1$ (condition (b) in Theorem 8) and the graph G contains at least one cycle, then $(\kappa^r)^T y \geq \bar{F}$ does not define a facet of P_B .

5. The bisection knapsack walk inequalities for MB. In this section we exploit the special structure of MB in order to derive an improved version of the knapsack tree inequality. Note that in the MNCGP case with $K > 2$ a walk $\{e_1 = \{v_1, v_2\}, e_2 = \{v_2, v_3\}\}$ with $y_{e_1} = y_{e_2} = 1$ does not imply any relation between nodes v_1 and v_3 , while in the MB case where $K = 2$ it follows from $y_{e_1} = y_{e_2} = 1$ that v_1 and v_3 belong to the same cluster.

More generally, whenever there is a walk (for ease of exposition we assume throughout that a walk traverses an edge at most once; for the general case, see [1]) between two nodes of the graph with an even number of edges in the cut, we know in the case of MB that the two end-nodes of the walk have to be in the same cluster. We may therefore replace the indicator term $1 - \sum_{e \in P_{rv}} y_e$ of (3) by

$$(18) \quad 1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e),$$

where $H_v \subseteq P_{rv}$ with even cardinality. So if $y \in \{0, 1\}^{|E|}$ is a valid solution of MB and P_{rv} is a walk from r to v in G with $H_v = \{e \in P_{rv} : y_e = 1\}$ and $|H_v|$ even, then expression (18) is equal to one, indicating that r and v belong to the same cluster. If, however, $H_v \neq \{e \in P_{rv} : y_e = 1\}$, the value of (18) is less than or equal to zero.

LEMMA 17. *Given a root node $r \in V$, walks $P_{rv} \subseteq E$, and even subsets $H_v \subseteq P_{rv}$ for all $v \in V$, let $y = \chi^{\delta(S)}$ for some $S \subseteq V$ with $r \in S$ and put $z = \chi^S$. Then for all $v \in V$*

$$(19) \quad 1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e) \leq z_v.$$

Proof. For $v \in S$ we have $z_v = 1$ and inequality (19) is satisfied, because $y_e \geq 0$ and $1 - y_e \geq 0$ for all $e \in E$. If $v \notin S$, the set $C = \{e \in P_{rv} : y_e = 1\}$ must be of odd

cardinality (otherwise r and v would be together in S_1). Since H_v is of even cardinality and both C and H_v are subsets of P_{rv} , there exists an $e \in P_{rv}$ with $e \in C \setminus H_v$ or $e \in H_v \setminus C$. If $e \in C \setminus H_v$, then $y_e = 1$ and the left-hand side of (19) is smaller or equal to $1 - y_e = 0 = z_v$. If $e \in H_v \setminus C$, then $y_e = 0$ and the left-hand side of (19) is smaller than or equal to $1 - (1 - y_e) = 0 = z_v$. $\square$

Now we are ready to sum up all the evaluation terms.

DEFINITION 18 (bisection knapsack walk inequality). *Let $\sum_{v \in V} a_v x_v \leq a_0$ be a valid inequality for the knapsack polytope P_K with $a_v \geq 0$ for all $v \in V$. For a subset $V' \subseteq V$, a fixed root node $r \in V'$, walks $P_{rv} \subseteq E$, and sets $H_v \subseteq P_{rv}$ with $|H_v|$ even, the bisection knapsack walk inequality reads*

$$(20) \quad \sum_{v \in V'} a_v \left(1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e) \right) \leq a_0.$$

Lemma 17 directly implies the following proposition.

PROPOSITION 19. *The bisection knapsack walk inequality (20) is valid for the polytope P_B .*

Note that knapsack tree inequalities are a special case of the bisection knapsack walk inequalities where the walks P_{rv} form a tree, all nodes on these walks are contained in V' , and all $H_v = \emptyset$. Again, we may rewrite the bisection knapsack walk inequality so as to pronounce its strength in forcing cut variables to increase:

$$\sum_{e \in E} \left(\sum_{v \in V': e \in P_{rv}} a_v - \sum_{v \in V': e \in H_v} 2a_v \right) y_e \geq \sum_{v \in V'} a_v - a_0 - \sum_{v \in V'} a_v |H_v|.$$

Remark 20. For $y = \chi^{\delta(S)}$ with $r \in S \subseteq V$, $z = \chi^S$, and $U_v \subseteq P_{rv}$ with $|U_v|$ odd ($v \in V \setminus \{r\}$), one can show $\sum_{e \in P_{rv} \setminus U_v} y_e + \sum_{e \in U_v} (1 - y_e) \geq z_v$ for $v \in V \setminus \{r\}$. In case of (MB), a valid knapsack inequality $\sum_{v \in V} a_v x_v \leq a_0$ implies the validity of $\sum_{v \in V'} a_v z_v \geq a(V') - a_0$ for all $V' \subseteq V$. Thus the so-called *odd bisection knapsack walk inequality*

$$a_r + \sum_{v \in V' \setminus \{r\}} a_v \left(\sum_{e \in P_{rv} \setminus U_v} y_e + \sum_{e \in U_v} (1 - y_e) \right) \geq a(V') - a_0$$

is valid for P_B , too. Due to their close relation to the (even) bisection knapsack walk inequalities (20) we will not treat these inequalities further in this paper but refer the interested reader to [1].

Remark 21. The bisection knapsack walk inequalities are closely linked to the cycle inequalities [2], which are defined for cycles $C = (V_C, E_C)$ in G and subsets $U \subseteq E_C$ with $|U|$ odd by

$$\sum_{e \in E_C \setminus U} y_e - \sum_{e \in U} y_e \geq 1 - |U|.$$

Indeed, consider the case that in a bisection knapsack walk inequality a path P_{rv} with even subset H_v can be shortcut by the edge rv ; put $E_C = P_{rv} \cup \{rv\}$ and $U = H_v \cup \{rv\}$ and rewrite the corresponding cycle inequality in the form

$$(21) \quad 1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e) \leq 1 - y_{rv}.$$

If $1 - y_{rv}$ is interpreted as z_v (indicating whether v is in the same set as the root r), this is just (19). Thus, whenever all cycle inequalities are enforced and a direct edge rv exists between roots r and v , then $P_{rv} = \{rv\}$ is always the best possible choice. It is, however, not true in general that in the presence of all cycle inequalities a shorter path (with respect to the number of edges) dominates longer paths; see Example 22.

Example 22. Let G be the cycle on five nodes of Figure 6. The solution $y = (y_{12}, y_{23}, y_{34}, y_{45}, y_{15})^T = (0.5, 0.5, 0, 0, 0)^T$ fulfills all cycle inequalities because it is a convex combination of the two cuts $(0, 0, 0, 0, 0)^T$ and $(1, 1, 0, 0, 0)^T$. Now look at the bisection knapsack walk inequalities with $V' = \{1, 3\}$ and $r = 1$. The shorter path P_{13}^s from root node 1 to node 3 uses the edge set $\{\{1, 2\}, \{2, 3\}\}$ with $H_3^s = \emptyset$ or $H_3^s = \{\{1, 2\}, \{2, 3\}\}$, and the longer path P_{13}^l uses the edge set $\{\{3, 4\}, \{4, 5\}, \{1, 5\}\}$ with $H_3^l = \emptyset$, $H_3^l = \{\{3, 4\}, \{4, 5\}\}$, $H_3^l = \{\{3, 4\}, \{1, 5\}\}$, or $H_3^l = \{\{4, 5\}, \{1, 5\}\}$. For the shorter path of the two possible bisection knapsack walk inequalities the left-hand side value is $a_3 \cdot 0$, whereas the best possible bisection knapsack walk inequality on the longer path uses $H_3^l = \emptyset$ and yields left-hand side value $a_3 \cdot 1$.

FIG. 6. Graph for the counterexample of Example 22.

6. Capacity improved bisection knapsack walk inequalities and the lower envelope for stars. To motivate another strengthening for bisection knapsack walk inequalities consider the case of a disconnected graph with two components, one of them being a single edge $\{u, v\}$, the other connected one being $V' = V \setminus \{u, v\}$. Even though one cannot include the edge $\{u, v\}$ directly in a bisection knapsack walk inequality rooted at some $r \in V'$, one can at least improve the inequality if $y_{uv} = 1$. In this case u and v belong to different clusters, and therefore the capacity F of both clusters can be reduced by $\min\{\varphi_u, \varphi_v\}$. Since F is the right-hand side of the inequality $\sum_{v \in V} \varphi_v x_v \leq F$ used to define the knapsack polytope P_K , this reduction may help to derive stronger bisection knapsack walk inequalities. For instance, one can look at a given valid inequality $\sum_{v \in V} a_v x_v \leq a_0$ for the original knapsack polytope with capacity F , and in case $y_{uv} = 1$ we are allowed to reduce the right-hand side a_0 by $\min\{a_u, a_v\}$, thus also improving the bisection knapsack walk inequality.

To generalize this idea we define for $\bar{G} \subseteq G$ with $\bar{V} \subseteq V$, $\bar{E} \subseteq E(\bar{V})$ and $a \in \mathbb{R}_+^{|\bar{V}|}$ a function $\beta_{\bar{G}} : \{0, 1\}^{|\bar{E}|} \rightarrow \mathbb{R} \cup \{\infty\}$ with

$$(22) \quad \beta_{\bar{G}}(y) = \inf \left\{ a(S), a(\bar{V} \setminus S) : S \subseteq \bar{V}, \max \{a(S), a(\bar{V} \setminus S)\} \leq a_0, y = \chi^{\delta_G(S)} \right\}.$$

Now we look at the lower convex envelope $\check{\beta}_{\bar{G}} : \mathbb{R}^{|\bar{E}|} \rightarrow \mathbb{R} \cup \{\infty\}$ of $\beta_{\bar{G}}(y)$, i.e.,

$$(23) \quad \check{\beta}_{\bar{G}}(x) = \sup \left\{ \check{\beta}(x) : \check{\beta} : \mathbb{R}^{|\bar{E}|} \rightarrow \mathbb{R}, \check{\beta} \text{ convex}, \check{\beta}(y) \leq \beta_{\bar{G}}(y), y \in \{0, 1\}^{|\bar{E}|} \right\}.$$

Notice that $\check{\beta}_{\bar{G}}$ is a piecewise linear function on its domain. We will see that given a bisection knapsack walk inequality (20) on some $V' \subseteq V$ and $\bar{V} \subseteq V \setminus V'$, subtracting

any affine minorant $c_0 + \sum_{e \in \bar{E}} c_e y_e$ of $\check{\beta}_{\bar{G}}$, i.e.,

$$(24) \quad c_0 + \sum_{e \in \bar{E}} c_e y_e \leq \check{\beta}_{\bar{G}}(y),$$

on the right-hand side of (20) yields again a valid inequality for P_B . It yields an improvement with respect to a given y if the minorant is positive for this y . For convenience, the next proposition states this for several disjoint subsets $\bar{V}$.

PROPOSITION 23. *Let $\sum_{v \in V} a_v x_v \leq a_0$ with $a_v \geq 0$ for all $v \in V$ be a valid inequality for the knapsack polytope P_K . Choose a nonempty $V' \subseteq V$ and subgraphs $(\bar{V}_l, \bar{E}_l) = \bar{G}_l \subset G$ with $\bar{V}_l \cap V' = \emptyset$, $\bar{E}_l \subseteq E(\bar{V}_l)$ for $l = 1, \dots, L$ and pairwise disjoint sets $\bar{V}_l$. Find for each l an affine minorant $c_0^l + \sum_{e \in \bar{E}_l} c_e y_e$ for the convex envelope $\check{\beta}_{\bar{G}_l}$ so that (24) holds for all y in P_B . Then the capacity reduced bisection knapsack walk inequality*

$$(25) \quad \sum_{v \in V'} a_v \left(1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in P_{rv} \cap H_v} (1 - y_e) \right) \leq a_0 - \sum_{l=1}^L \left(c_0^l + \sum_{e \in \bar{E}_l} c_e y_e \right)$$

is valid for P_B .

Proof. Let $y \in P_B$ such that $y = \chi^{\delta(S)}$ with $S \subseteq V$; then $\varphi(S) \leq F$ and $\varphi(V \setminus S) \leq F$. W.l.o.g., let $r \in S$ and put $z = \chi^S$. Then for all $l = 1, \dots, L$

$$c_0^l + \sum_{e \in \bar{E}_l} c_e y_e \leq \check{\beta}_{\bar{G}_l}(y) \leq \beta_{\bar{G}_l}(y) = \min \{a(\bar{V}_l \cap S), a(\bar{V}_l \setminus S)\} \leq \sum_{v \in \bar{V}_l \cap S} a_v = \sum_{v \in \bar{V}_l \cap S} a_v z_v.$$

Furthermore, by Lemma 17 we have $1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e) \leq z_v$ for $v \in V'$. Thus

$$\begin{aligned} & \sum_{v \in V'} a_v \left(1 - \sum_{e \in P_{rv} \setminus H_v} y_e - \sum_{e \in H_v} (1 - y_e) \right) + \sum_{l=1}^L \sum_{e \in \bar{E}_l} c_e y_e \\ & \leq \sum_{v \in V'} a_v z_v + \sum_{l=1}^L \sum_{v \in \bar{V}_l} a_v z_v \leq \sum_{v \in V} a_v z_v \leq a_0. \quad \square \end{aligned}$$

FIG. 7. Graph considered in Example 24 (1). $F = 4$, $\varphi_i = 1$ for all $i \in V$, $\sum_{i \in V} x_i \leq 4$.

Example 24. For the graph G displayed in Figure 7 with $\varphi_v = 1$ for all $v \in V$ the polytope P_B has 74 facets (computed by *polymake* [11]). Among these are 14 trivial facets, only 2 pure bisection knapsack walk facets, 19 truncated bisection knapsack walk facets, 16 capacity reduced bisection knapsack walk facets (some truncated), 4 capacity reduced odd bisection knapsack walk facets, and 19 facets for which we are not yet able to recognize a construction rule. Here we want to give a first simple example for a capacity reduced bisection knapsack walk inequality. Two more involved examples will follow at the end of this section. We use the knapsack inequality $\sum_{v \in V} x_v \leq 4$ in all three examples; thus $a_v = 1$ for all $v \in V$:

- (1) For $V' = \{1, 3, 4, 5\}$, root node $r = 3$ and $H_v = \emptyset$ for all $v \in V'$ the bisection knapsack walk inequality is $1 + (1 - y_{13}) + (1 - y_{34}) + (1 - y_{34} - y_{45}) \leq 4$. We choose $\bar{G} = (\bar{V}, \bar{E})$ with $\bar{V} = \{6, 7\}$ and $\bar{E} = \{67\}$. We will see that the unique best minorizing function for $\check{\beta}_{\bar{G}}$ is y_{67} , and thus the bisection knapsack walk inequality can be strengthened to $1 + (1 - y_{13}) + (1 - y_{34}) + (1 - y_{34} - y_{45}) \leq 4 - y_{67}$. Now rewrite this inequality to $y_{13} + 2y_{34} + y_{45} - y_{67} \geq 0$ and observe that, as in (5), the coefficient of y_{34} can be strengthened to 1 in order to find the facet $y_{13} + y_{34} + y_{45} - y_{67} \geq 0$ of P_B .

To find inequalities (24) to apply in Proposition 23 we take a closer look at the lower envelope defined in (23). In certain cases, e.g., for the case of $\bar{G} = (\bar{V}, \bar{E})$ being a star with $a(\bar{V}) \leq a_0$, we are able to give a full description of $\check{\beta}_{\bar{G}}$ by giving a complete description of the cluster weight polytope defined below. This will provide the tightest improvement possible in (25).

DEFINITION 25. Given a graph $G = (V, E)$ with node weights $a_v \geq 0$ for $v \in V$, for a set $S \subseteq V$ we define the following point in $\mathbb{R}^{|E|+1}$:

$$h_G^S = \begin{pmatrix} a(S) \\ \chi^{\delta(S)} \end{pmatrix}.$$

With respect to a given nonnegative $a_0 \in \mathbb{R}$ we define

$$P_{CW}(G) = \text{conv}\{h_G^S : S \subseteq V, a(S) \leq a_0, a(V \setminus S) \leq a_0\}$$

and call this set the cluster weight polytope.

As usual, we will drop G in h_G^S and $P_{CW}(G)$ if the graph is clear from the context. The purpose of studying $P_{CW}(\bar{G})$ is that its polyhedral description immediately yields the epigraph of $\check{\beta}_{\bar{G}}$ via $\text{epi}(\check{\beta}_{\bar{G}}) = P_{CW}(\bar{G}) + \{\lambda(1, 0^T)^T : \lambda \geq 0\}$. This is the content of the next proposition.

PROPOSITION 26. Given a subgraph $\bar{G} = (\bar{V}, \bar{E})$ of G with node weights $a_v \geq 0$ for $v \in V$, an inequality of the form $y_0 + \sum_{e \in \bar{E}} \gamma_e y_e \geq \gamma_0$ is valid for $P_{CW}(\bar{G})$ if and only if $\gamma_0 - \sum_{e \in \bar{E}} \gamma_e y_e$ is an affine minorant of $\check{\beta}_{\bar{G}}$.

Proof. $y_0 + \sum_{e \in \bar{E}} \gamma_e y_e \geq \gamma_0$ is valid for $P_{CW}(\bar{G})$ if and only if

$$y_0 + \sum_{e \in \bar{E}} \gamma_e y_e \geq \gamma_0 \text{ for } \begin{pmatrix} y_0 \\ y \end{pmatrix} \in \{h_{\bar{G}}^S : S \subseteq \bar{V}, a(S) \leq a_0, a(\bar{V} \setminus S) \leq a_0\}$$

if and only if

$$y_0 \geq \gamma_0 - \sum_{e \in \bar{E}} \gamma_e y_e \text{ for } \left\{ \begin{pmatrix} \min\{a(S), a(\bar{V} \setminus S)\} \\ \chi^{\delta_{\bar{G}}(S)} \end{pmatrix} : S \subseteq \bar{V}, \max\{a(S), a(\bar{V} \setminus S)\} \leq a_0 \right\}$$

if and only if $\beta_{\bar{G}}(y) \geq \gamma_0 - \sum_{e \in \bar{E}} \gamma_e y_e$ for $y \in \{0, 1\}^{|\bar{E}|}$ (by (22), recall that $\inf \emptyset = \infty$ by definition) if and only if $\check{\beta}_{\bar{G}}(y) \geq \gamma_0 - \sum_{e \in \bar{E}} \gamma_e y_e$ for $y \in \mathbb{R}^{|\bar{E}|}$ (see (23)). $\square$

Hence, the “lower” facets of P_{CW} are in one-to-one correspondence to the linear components of $\check{\beta}$. For a star $\bar{G} = (\bar{V}, \bar{E})$ we are able to exhibit facets of $P_{CW}(\bar{G})$, which in certain problems enables us to strengthen bisection knapsack walk inequalities of P_B to facet-defining inequalities of P_B (see Example 40 at the end of this section).

Let us first look at a symmetry of P_{CW} for general graphs $G = (V, E)$, a property which we will later use frequently to reduce our efforts in the proofs.

PROPOSITION 27. P_{CW} is symmetric to the hyperplane $\{y \in \mathbb{R}^{|E|} : 2y_0 = a(V)\}$.

Proof. Observe that for any point h^S used in the definition of P_{CW} the point $h^{V \setminus S}$ is contained in P_{CW} , too. Since $\chi^{\delta(S)} = \chi^{\delta(V \setminus S)}$, we have for all those pairs $(h^S, h^{V \setminus S})$

$$\left(\frac{\frac{1}{2}a(V)}{\chi^{\delta(S)}} \right) - h^S = h^{V \setminus S} - \left(\frac{\frac{1}{2}a(V)}{\chi^{\delta(S)}} \right). \quad \square$$

Another useful result for a star $G = (V, E)$ is the following.

LEMMA 28. Let $G = (V, E)$ be a star with center $r \in V$, $a_v \geq 0$ for all $v \in V$, and $a_{v'} = a(V \setminus \{v'\})$ for at least one $v' \in V \setminus \{r\}$. Then $a(S) = a(V \setminus S)$ for all $S \subseteq V$ with $v' \in S$ and $r \in V \setminus S$ if and only if $a_{v'} = a_r$ and $a_v = 0$ for all $v \in V \setminus \{v', r\}$.

Proof. Sufficiency is obvious. We will show necessity: Suppose $a(S) = a(V \setminus S)$ for all $S \subseteq V$ with $v' \in S$ and $r \in V \setminus S$. Then, in particular, this is true for $V \setminus S = \{r\}$, i.e., $a_r = a(V \setminus \{r\}) = a_{v'} + a(V \setminus \{v', r\}) = a(V \setminus \{v'\}) + a(V \setminus \{v', r\}) = a_r + 2a(V \setminus \{v', r\})$. Thus, $a_v = 0$ for all $v \in V \setminus \{v', r\}$ and $a_{v'} = a_r$. $\square$

In the remaining part of the section we will look into P_{CW} for stars $G = (V, E)$ with center node $r \in V$ and the constraint $\sum_{v \in V} a_v x_v \leq a_0$. At first we determine the dimension of the polytope.

PROPOSITION 29. For a star $G = (V, E)$ with center $r \in V$ and $a \geq 0$ with $a(V) \leq a_0$, the polytope P_{CW} has full dimension $|E| + 1$ for $a \neq 0^{|E|}$ and dimension $|E| = |V|$ for $a = 0^{|E|}$.

Proof. Since G is a star and by assumption $a(V) \leq a_0$, the $1 + |E|$ points $h^\emptyset$ and $h^{\{v\}}$ for all $v \in V \setminus \{r\}$ are contained in P_{CW} and affinely independent. Thus the dimension of P_{CW} is at least $|E|$. If $a \neq 0^{|E|}$, then h^V is affinely independent from all points listed previously, and thus P_{CW} is full-dimensional with dimension $|E| + 1$. For $a = 0^{|E|}$ all points lie on the hyperplane $y_0 = 0$. $\square$

For $G = (V, E)$ a star with center $r \in V$ and weights $a_v = 0$ for all $v \in V$ and $a_0 \geq 0$, it can easily be worked out that P_{CW} is completely described by the equality $y_0 = 0$ and the inequalities $0 \leq y_{rv} \leq 1$ for all $v \in V \setminus \{r\}$. So from now on we assume $a_v > 0$ for at least one $v \in V$. Let us first state trivial valid inequalities and facets of P_{CW} .

PROPOSITION 30. For a star $G = (V, E)$ with center $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, and $a(V) \leq a_0$ the trivial inequalities

$$(26) \quad 0 \leq y_{rv} \leq 1 \quad \forall v \in V \setminus \{r\}$$

are facet-inducing for P_{CW} except for one particular case: if there is exactly one $v' \in V \setminus \{r\}$ with $a_{v'} = a_r = \frac{1}{2}a(V)$, then $y_{rv'} \leq 1$ does not induce a facet.

Proof. The validity of the inequalities $y_{rv'} \geq 0$ and $y_{rv'} \leq 1$ for all $v' \in V \setminus \{r\}$ follows from the definition of P_{CW} . In general, to prove that a valid inequality defines a facet of P_{CW} we have to find $\dim(P_{\text{CW}})$ affinely independent points of P_{CW} which fulfill it with equality. From Proposition 29 we know that $\dim(P_{\text{CW}}) = |V|$ if $a \neq 0^{|E|}$. For $y_{rv'} \geq 0$ we choose the $|V|$ points $h^\emptyset$, h^V , and $h^{\{v\}}$ for all $v \in V \setminus \{r, v'\}$. For $y_{rv'} \leq 1$ the accumulation of affinely independent points on the inequality is a bit more involved: If $a_{v'} \neq a(V \setminus \{v'\})$, we can choose the $|V|$ points $h^{\{v'\}}$, $h^{V \setminus \{v'\}}$, and $h^{\{v', v\}}$ for all $v \in V \setminus \{r\}$ with $v \neq v'$. If $a_{v'} = a(V \setminus \{v'\})$, we look at two cases:

1. $a_r \neq a_{v'}$: Then there is a $\tilde{v} \in V \setminus \{r, v'\}$ with $a_{\tilde{v}} > 0$. Furthermore, since $a_{v'} = a(V \setminus \{v'\})$, we have $a_{v'} = \frac{1}{2}a(V)$. Together with $a_{\tilde{v}} > 0$ this implies $a(\{v', \tilde{v}\}) \neq a(V \setminus \{v', \tilde{v}\})$, i.e., $h^{\{v', \tilde{v}\}} \neq h^{V \setminus \{v', \tilde{v}\}}$. Thus we can choose the $|V|$ points $h^{\{v'\}}$, $h^{\{v', v\}}$ for all $v \in V \setminus \{r, v'\}$ and $h^{V \setminus \{v', \tilde{v}\}}$.

2. $a_r = a_{v'}$: The set of points contained in the definition of P_{CW} which fulfill $y_{rv'} = 1$ is $\{h^S, h^{V \setminus S} : S \subseteq V, v' \in S, r \in V \setminus S\}$. Lemma 28 implies for every pair $(h^S, h^{V \setminus S})$ in this set that $a(S) = a(V \setminus S)$. Since $a(S) + a(V \setminus S) = a(V)$, we get $a(S) = \frac{1}{2}a(V)$ for all S with $y = \chi^{\delta(S)}$ and $y_{rv'} = 1$. Thus all vertices of P_{CW} fulfilling $y_{rv'} = 1$ live in the hyperplane $\{y \in \mathbb{R}^{|E|+1} : y_0 = \frac{1}{2}a(V)\}$. Therefore, $y_{rv'} \leq 1$ cannot induce a facet of P_{CW} . $\square$

In the following two propositions we look into nontrivial facets of P_{CW} . Proposition 31 deals with the case $a(V \setminus \{r\}) > a_r$ and Proposition 32 with the case $a(V \setminus \{r\}) \leq a_r$.

PROPOSITION 31. *Given a star $G = (V, E)$ with center $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, $a(V) \leq a_0$, and $a(V \setminus \{r\}) > a_r$, we call a triple $(V_p, \bar{v}, V_n)$ feasible if it fulfills $V = \{r, \bar{v}\} \dot{\cup} V_p \dot{\cup} V_n$ and $a(V_p) \leq \frac{1}{2}a(V) < a(V_p) + a_{\bar{v}}$. For all feasible triples $(V_p, \bar{v}, V_n)$ the inequalities*

$$(27) \quad y_0 + \sum_{v \in V_p} a_v y_{rv} + (a(V) - 2a(V_p) - a_{\bar{v}}) y_{r\bar{v}} - \sum_{v \in V_n} a_v y_{rv} \leq a(V),$$

$$(28) \quad y_0 - \sum_{v \in V_p} a_v y_{rv} - (a(V) - 2a(V_p) - a_{\bar{v}}) y_{r\bar{v}} + \sum_{v \in V_n} a_v y_{rv} \geq 0$$

are facet-inducing for P_{CW} .

Note that it is possible that either V_p or V_n of feasible triples $(V_p, \bar{v}, V_n)$ might be empty, but for $a(V \setminus \{r\}) > a_r$ there always is the special element $\bar{v}$.

Proof of Proposition 31. To reduce our efforts in this proof and the ones to follow, observe that for each feasible triple $(V_p, \bar{v}, V_n)$ the corresponding pair of inequalities (27) and (28) is symmetric to the hyperplane $\{y \in \mathbb{R}^{|E|} : 2y_0 = a(V)\}$. To see this, subtract the equation $2y_0 = a(V)$ from (27) to obtain (28). Thus, by Proposition 27, it suffices to show that (27) is valid and facet-defining. Furthermore, to show the validity of (27) it is sufficient to look only at the “upper” points defining P_{CW} , i.e., if w.l.o.g. $S \subseteq V$ such that $a(S) \geq a(V \setminus S)$, then we only need to check validity of (27) for $h^S = (a(S), \chi^{\delta(S)})^T$.

Consider an arbitrary $S \subseteq V$ such that $a(S) \geq a(V \setminus S)$. Let $V^1 = \{v \in V : rv \in \delta(S)\}$. We discern the following four cases:

1. $\bar{v} \in V^1 = S$: For $\begin{pmatrix} a(S) \\ \chi^{\delta(S)} \end{pmatrix}$ the left-hand side of (27) equals

$$\begin{aligned} a(V^1) + a(V_p \cap V^1) + a(V) - 2a(V_p) - a_{\bar{v}} - a(V_n \cap V^1) \\ = 2a(V_p \cap V^1) + a(V) - 2a(V_p) \\ = a(V) - 2a(V_p \setminus V^1) \leq a(V), \end{aligned}$$

where the first equality uses $a(V^1) = a(V_p \cap V^1) + a_{\bar{v}} + a(V_n \cap V^1)$ and the inequality is due to $a(V_p \setminus V^1) \geq 0$.

2. $\bar{v} \notin V^1 = S$: For $\begin{pmatrix} a(S) \\ \chi^{\delta(S)} \end{pmatrix}$ the left-hand side of (27) equals

$$a(V^1) + a(V_p \cap V^1) - a(V_n \cap V^1) = 2a(V_p \cap V^1) \leq 2a(V_p) \leq a(V),$$

where the equality uses $a(V^1) = a(V_p \cap V^1) + a(V_n \cap V^1)$ and the last inequality is due to $a(V_p) \leq \frac{1}{2}a(V)$ by the definition of V_p .

3. $\bar{v} \in V^1 = V \setminus S$: For $\binom{a(S)}{\chi^{\delta(S)}}$ the left-hand side of (27) equals

$$\begin{aligned} a(V) - a(V^1) + a(V_p \cap V^1) + a(V) - 2a(V_p) - a_{\bar{v}} - a(V_n \cap V^1) \\ = 2a(V) - 2a(V_p) - 2a_{\bar{v}} - 2a(V_n \cap V^1) \\ < 2a(V) - a(V) - 2a(V_n \cap V^1) \leq a(V), \end{aligned}$$

where the first equality uses $a(V^1) = a(V_p \cap V^1) + a_{\bar{v}} + a(V_n \cap V^1)$, the strict inequality is due to $a(V_p) + a_{\bar{v}} > \frac{1}{2}a(V)$ by the definition of V_p and $\bar{v}$, and the inequality holds since $a(V_n \cap V^1) \geq 0$.

4. $\bar{v} \notin V^1 = V \setminus S$: For $\binom{a(S)}{\chi^{\delta(S)}}$ the left-hand side of (27) equals

$$a(V) - a(V^1) + a(V_p \cap V^1) - a(V_n \cap V^1) = a(V) - 2a(V_n \cap V^1) \leq a(V),$$

where the first equality uses $a(V^1) = a(V_p \cap V^1) + a(V_n \cap V^1)$ and the inequality is due $a(V_n \cap V^1) \geq 0$.

In order to show that (27) is also facet-defining, let $V_p = \{v_1^p, \dots, v_{|V_p|}^p\}$ and $V_n = \{v_1^n, \dots, v_{|V_n|}^n\}$. Then the $|V|$ points

$$\begin{aligned} h^V, h^{V \setminus \{v_1^p\}}, \dots, h^{V \setminus \{v_1^p, \dots, v_{|V_p|}^p\}}, h^{\{v_1^p, \dots, v_{|V_p|}^p, \bar{v}\}}, \\ h^{\{v_1^p, \dots, v_{|V_p|}^p, \bar{v}, v_1^n\}}, \dots, h^{\{v_1^p, \dots, v_{|V_p|}^p, \bar{v}, v_1^n, \dots, v_{|V_n|}^n\}} \end{aligned}$$

fulfill inequality (27) with equality and are affinely independent, and thus (27) is a facet-inducing inequality. $\square$

In the case of $a(V \setminus \{r\}) \leq a_r$ the set V_n is empty, there is no $\bar{v}$, and the inequalities (27) and (28) take the following form.

PROPOSITION 32. *For a star $G = (V, E)$ with root $r \in V$ and $a \geq 0$ with $a \neq 0^{|E|}$, $a(V) \leq a_0$, and $a(V \setminus \{r\}) \leq a_r$ the inequalities*

$$(29) \quad y_0 + \sum_{v \in V \setminus \{r\}} a_v y_{e_v} \leq a(V),$$

$$(30) \quad y_0 - \sum_{v \in V \setminus \{r\}} a_v y_{e_v} \geq 0$$

are facet-inducing for P_{CW} .

Proof. We start again by observing the symmetry of inequalities (29) and (30) to the hyperplane $\{y \in \mathbb{R}^{|E|} : 2y_0 = a(V)\}$. To see this, subtract the equation $2y_0 = a(V)$ from inequality (29) to obtain inequality (30). Thus, by Proposition 27, it suffices to prove the validity and facet-induction of (29). Take an $S \subseteq V$ with $a(S) \geq a(V \setminus S)$. Then $h^S = \binom{a(S)}{\chi^{\delta(S)}}$ is one of the points defining P_{CW} . We see that $V \setminus S = \{v \in V : rv \in \delta(S)\}$. Now plug h^S into the left-hand side of (29) to get $a(S) + a(V \setminus S) = a(V)$. The point $h^{V \setminus S} = \binom{a(V \setminus S)}{\chi^{\delta(V \setminus S)}}$ can also not violate (29) since $a(V \setminus S) \leq a(S)$, and thus (29) is valid for P_{CW} .

In order to show that (29) is facet-inducing let $v_1, \dots, v_{|V|-1}$ be an arbitrary ordering of the nodes in $V \setminus \{r\}$. Since $a(S) + a(V \setminus S) = a(V)$ holds, the $\dim(P_{\text{CW}}) = |V|$ points

$$h^V, h^{V \setminus \{v_1\}}, \dots, h^{V \setminus \{v_1, \dots, v_{|V|-1}\}}$$

fulfill inequality (29) with equality and are affinely independent. $\square$

All possible facets of P_{CW} fall into one of the following three classes:

$$(31) \quad y_0 + \sum_{v \in V \setminus \{r\}} \gamma_v y_{rv} \leq \gamma_0,$$

$$(32) \quad \sum_{v \in V \setminus \{r\}} \gamma_v y_{rv} \leq \gamma_0,$$

$$(33) \quad -y_0 + \sum_{v \in V \setminus \{r\}} \gamma_v y_{rv} \leq \gamma_0.$$

In the next two lemmas we will look closer into coefficients of facets of the form (31). The following three propositions state that we have found all facets of P_{CW} of the forms (31), (32), and (33), respectively. Finally, Theorem 38 summarizes the results. The section is accompanied by two small examples on how to apply the inequalities to derive capacity reduced bisection knapsack walk inequalities.

LEMMA 33. *For an arbitrary facet of P_{CW} of the form (31) we have for all $v \in V \setminus \{r\}$*

$$-a_v \leq \gamma_v \leq a_v.$$

Proof. We give the proof for the case $\gamma_{\tilde{v}} > 0$ (the case $\gamma_{\tilde{v}} < 0$ can be proved by analogous arguments). The facet has a root $(\hat{y}_0, \hat{y}^T)^T$ with $\hat{y}_{r\tilde{v}} = 0$, because otherwise all roots $\hat{y}$ would lie on the equation $\hat{y}_{r\tilde{v}} = 1$; thus (31) could not induce a facet. Let $S \subseteq V$ be the corresponding subset satisfying $\hat{y} = \chi^{\delta(S)}$ and $\hat{y}_0 = a(S) \geq a(V \setminus S)$. To bound $\gamma_{\tilde{v}}$ we look at $\bar{y} = \hat{y} + e_{r\tilde{v}}$, i.e., the cut $\delta(S) \cup \{r\tilde{v}\}$. We discern three cases concerning the location of node $\tilde{v}$ and the size of the bigger cluster:

1. $\tilde{v} \in V \setminus S$: Because $a(S) \geq a(V \setminus S)$ we obtain $a(S \cup \{\tilde{v}\}) \geq a(V \setminus (S \cup \{\tilde{v}\}))$. Set $\bar{y}_0 = a(S \cup \{\tilde{v}\})$, i.e., $(\bar{y}_0, \bar{y}^T)^T = h^{S \cup \{\tilde{v}\}} \in P_{CW}$. In order for (31) to be feasible for $(\bar{y}_0, \bar{y}^T)^T$ we need $\gamma_0 \geq \bar{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \bar{y}_{rv}$. As $(\hat{y}_0, \hat{y}^T)^T$ is a root of (31), we have $\gamma_0 = \hat{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \hat{y}_{rv}$. Thus, $\hat{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \hat{y}_{rv} \geq \bar{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \bar{y}_{rv}$, i.e., $\hat{y}_0 \geq \bar{y}_0 + \gamma_{\tilde{v}}$. Therefore, $\gamma_{\tilde{v}} \leq \hat{y}_0 - \bar{y}_0 = -a_{\tilde{v}}$. This contradicts our assumption $\gamma_{\tilde{v}} > 0$; thus the case $\tilde{v} \in V \setminus S$ is not possible.
2. $\tilde{v} \in S$ and $a(S \setminus \{\tilde{v}\}) \geq a((V \setminus S) \cup \{\tilde{v}\})$: Set $\bar{y}_0 = a(S \setminus \{\tilde{v}\})$, i.e., $(\bar{y}_0, \bar{y}^T)^T = h^{S \setminus \{\tilde{v}\}} \in P_{CW}$. As $(\bar{y}_0, \bar{y}^T)^T$ is feasible for (31) we derive, as in the previous case, $\hat{y}_0 \geq \bar{y}_0 + \gamma_{\tilde{v}}$, and hence $\gamma_{\tilde{v}} \leq \hat{y}_0 - \bar{y}_0 = a(S) - a(S \setminus \{\tilde{v}\}) = a_{\tilde{v}}$.
3. $\tilde{v} \in S$ and $a(S \setminus \{\tilde{v}\}) < a((V \setminus S) \cup \{\tilde{v}\})$: This implies $a(S \setminus \{\tilde{v}\}) < \frac{1}{2}a(V)$. Set $\bar{y}_0 = a((V \setminus S) \cup \{\tilde{v}\})$, i.e., $(\bar{y}_0, \bar{y}^T)^T = h^{(V \setminus S) \cup \{\tilde{v}\}} \in P_{CW}$. From the feasibility of (31) we conclude $\hat{y}_0 \geq \bar{y}_0 + \gamma_{\tilde{v}}$. Therefore, $\gamma_{\tilde{v}} \leq \hat{y}_0 - \bar{y}_0 = a(S) - a((V \setminus S) \cup \{\tilde{v}\}) = a_{\tilde{v}} + 2a(S \setminus \{\tilde{v}\}) - a(V) < a_{\tilde{v}}$, where the last inequality uses $a(S \setminus \{\tilde{v}\}) - \frac{1}{2}a(V) < 0$. $\square$

LEMMA 34. *For an arbitrary facet of P_{CW} of the form (31) we have $\gamma_0 = a(V)$ and $\sum_{v \in V \setminus \{r\}} \gamma_v \leq a_r$.*

Proof. In order for (31) to be valid for $h^V = (a(V), (\chi^{\delta(V)})^T)^T \in P_{CW}$ we get $\gamma_0 \geq a(V)$. We discern two cases regarding the weight of the root node r .

$a_r < a(V \setminus \{r\})$: (31) has to be valid for $(a(V \setminus \{r\}), (\chi^{\delta(V \setminus \{r\})})^T)^T = h^{V \setminus \{r\}} \in P_{CW}$, and thus $\sum_{v \in V \setminus \{r\}} \gamma_v \leq \gamma_0 - a(V \setminus \{r\})$.

$a_r \geq a(V \setminus \{r\})$: (31) has to be valid for $(a_r, (\chi^{\delta(\{r\})})^T)^T = h^{\{r\}} \in P_{\text{CW}}$, and thus $\sum_{v \in V \setminus \{r\}} \gamma_v \leq \gamma_0 - a_r \leq \gamma_0 - a(V \setminus \{r\})$.

Thus in any case we have

$$(34) \quad \sum_{v \in V \setminus \{r\}} (a_v + \gamma_v) \leq \gamma_0.$$

Now use $a_v + \gamma_v \geq 0$ (by Lemma 33) and $y_{rv} \in [0, 1]$ for all $(y_0, y^T)^T \in P_{\text{CW}}$ to conclude that

$$(35) \quad \sum_{v \in V \setminus \{r\}} (a_v + \gamma_v) y_{rv} \leq \gamma_0$$

is a valid inequality for P_{CW} . Additionally, $a_r = a(V) - a(V \setminus \{r\})$; thus it is sufficient to show that $\gamma_0 = a(V)$ if (31) induces a facet of P_{CW} , because then (34) implies $\sum_{v \in V \setminus \{r\}} \gamma_v \leq a_r$.

So assume, for contradiction, that $\gamma_0 > a(V)$ with (31) facet-defining. In search for roots of (31) let $S \subseteq V$ be such that $\tilde{y}_0 = a(S) \geq a(V \setminus S)$, put $\tilde{y} = \chi^{\delta(S)}$, and consider the following two cases:

$r \in S$: Then $\tilde{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \tilde{y}_{rv} = a(S) + \sum_{v \in V \setminus S} \gamma_v \leq a(V) < \gamma_0$, where the $\leq$ -inequality is due to $\gamma_v \leq a_v$ by Lemma 33. Therefore, $(\tilde{y}_0, \tilde{y}^T)^T$ cannot lie on the facet.

$r \in V \setminus S$: We show that all such roots also satisfy (35) with equality and so (31) cannot be a facet. Indeed, if it is a root, $(\tilde{y}_0, \tilde{y}^T)^T$ satisfies $\tilde{y}_0 + \sum_{v \in V \setminus \{r\}} \gamma_v \tilde{y}_{rv} = \gamma_0$. Since $\tilde{y}_0 = \sum_{v \in V \setminus \{r\}} a_v \tilde{y}_{rv}$, we obtain $\gamma_0 = \sum_{v \in V \setminus \{r\}} (a_v + \gamma_v) \tilde{y}_{rv}$.

Hence, any facet inducing inequality (31) has $\gamma_0 = a(V)$. $\square$

PROPOSITION 35. *For a star $G = (V, E)$ with root $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, and $a(V) \leq a_0$ all facets of the form (31) for P_{CW} are defined by (27) if $a(V \setminus \{r\}) > a_r$ and by (29) if $a(V \setminus \{r\}) \leq a_r$.*

Proof. We have shown in Lemma 33 that each coefficient γ_v for all $v \in V \setminus \{r\}$ in all facets of P_{CW} of the form (31) fulfills

$$(36) \quad -a_v \leq \gamma_v \leq a_v.$$

Lemma 34 tells us that for each individual facet of P_{CW} of the form (31) the coefficients fulfill

$$(37) \quad \sum_{v \in V \setminus \{r\}} \gamma_v \leq a_r$$

and

$$(38) \quad \gamma_0 = a(V).$$

For any given $y \in [0, 1]^{|E|}$ we will now determine the best γ_0 and γ subject to the constraints (36), (37), and (38), so that the right-hand side of $y_0 \leq \gamma_0 - \sum_{v \in V \setminus \{r\}} \gamma_v y_{rv}$ is as small as possible. If we can always exhibit an optimal solution γ_0^*, γ^* that corresponds to the coefficients of (27) if $a(V \setminus \{r\}) > a_r$ or of (29) if $a(V \setminus \{r\}) \leq a_r$,

then the proof is complete. At first note that (38) directly fixes γ_0 to $a(V)$, which corresponds to the right-hand sides of (27) and (29). Now look at the problem

$$(39) \quad \begin{aligned} \min \quad & a(V) - \sum_{v \in V \setminus \{r\}} y_{rv} \gamma_v \\ \text{s.t.} \quad & \sum_{v \in V \setminus \{r\}} \gamma_v \leq a_r, \\ & -a_v \leq \gamma_v \leq a_v \quad \forall v \in V \setminus \{r\}. \end{aligned}$$

In case $a(V \setminus \{r\}) \leq a_r$, the optimal solution sets $\gamma_v = a_v$ for all $v \in V \setminus \{r\}$ and we have determined inequality (29). So assume $a(V \setminus \{r\}) > a_r$. Using the variable transformation $\tilde{\gamma}_v = \gamma_v + a_v$, problem (39) is equivalent to

$$(40) \quad \begin{aligned} \max \quad & \sum_{v \in V \setminus \{r\}} y_{rv} \tilde{\gamma}_v - \sum_{v \in V \setminus \{r\}} y_{rv} a_v \\ \text{s.t.} \quad & \sum_{v \in V \setminus \{r\}} \tilde{\gamma}_v \leq a(V), \\ & 0 \leq \tilde{\gamma}_v \leq 2a_v \quad \forall v \in V \setminus \{r\}. \end{aligned}$$

Problem (40) is the canonical continuous bounded knapsack problem (see sections 3.2 and 3.3.1 in [16]) with continuous variables γ_v , profits y_{rv} , weights 1, and upper bound $2a_v$ for all items $v \in V \setminus \{r\}$ and knapsack capacity $a(V)$. An optimal solution can be found by sorting the items v with respect to nonincreasing profit-to-weight ratios $y_{rv}/1$ —w.l.o.g., let this ordering be $1, 2, \dots, |V| - 1$ —and by using this ordering to pack the knapsack in the following way: $\tilde{\gamma}_v = 2a_v$ for all $v = 1, \dots, \bar{v} - 1$ with $\bar{v}$ so that $2a(\{1, \dots, \bar{v} - 1\}) \leq a(V)$ and $2a(\{1, \dots, \bar{v} - 1\}) + 2a_{\bar{v}} > a(V)$, $\tilde{\gamma}_{\bar{v}} = a(V) - 2a(\{1, \dots, \bar{v} - 1\})$, and $\tilde{\gamma}_v = 0$ for all $v = \bar{v} + 1, \dots, |V| - 1$. The item $\bar{v}$ is called the critical item. Note that if one $\bar{v}$ can be chosen as the critical item, then so can all $v \neq \bar{v}$ with $y_{rv} = y_{r\bar{v}}$.

Backsubstitution of $\tilde{\gamma}_v = \gamma_v + a_v$ yields the optimal solution of problem (39): $\gamma_v = a_v$ for all $v = 1, \dots, \bar{v} - 1$ with $a(\{1, \dots, \bar{v} - 1\}) \leq \frac{1}{2}a(V)$ and $a(\{1, \dots, \bar{v} - 1\}) + a_{\bar{v}} > \frac{1}{2}a(V)$, $\gamma_{\bar{v}} = a(V) - 2a(\{1, \dots, \bar{v} - 1\}) - a_{\bar{v}}$, and $\gamma_v = -a_v$ for all $v = \bar{v} + 1, \dots, |V| - 1$. Finally we observe that we have determined a feasible triple $(V_p = \{1, \dots, \bar{v} - 1\}, \bar{v}, V_n = \{\bar{v} + 1, \dots, |V| - 1\})$, i.e., we have found an inequality of (27). $\square$

PROPOSITION 36. *For a star $G = (V, E)$ with root $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, and $a(V) \leq a_0$ all facets of the form (33) for P_{CW} are defined by (28) if $a(V \setminus \{r\}) > a_r$ and by (30) if $a(V \setminus \{r\}) \leq a_r$.*

Proof. Use the symmetry of P_{CW} , of pairs (31) and (33) with the same γ_v and γ_0 , of pairs (27) and (28) and of pairs (29) and (30) to the hyperplane $\{y \in \mathbb{R}^{|E|} : 2y_0 = a(V)\}$, and apply Proposition 35. $\square$

PROPOSITION 37. *For a star $G = (V, E)$ with root $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, and $a(V) \leq a_0$ all facets of the form (32) for P_{CW} are defined by (26).*

Proof. It is trivial to show that facets of a polytope with coefficient zero for a fixed variable are also facets of the projection of this polytope if one projects out this variable. Since the hyperplanes defined by inequalities of the form (32) have coefficient zero for variable y_0 , we have to look at the projection of P_{CW} onto the space $\mathbb{R}^{|E|}$ and show that this projection only has facets of the form (26). A point $(a(S), (\chi^{\delta(S)})^T)^T \in \mathbb{R}^{|E|+1}$ used to define P_{CW} is projected to $\chi^{\delta(S)} \in \mathbb{R}^{|E|}$, and since

$a(V) \leq a_0$ the polytope P_{CW} contains the points $(a(S), (\chi^{\delta(S)})^T)^T \in \mathbb{R}^{|E|+1}$ for all $S \subseteq V$; thus its projection contains all possible points $\{0, 1\}^{|E|}$. Furthermore, the projection of any other point of P_{CW} can be written as the convex combination of points $\{0, 1\}^{|E|}$. Thus the projection of P_{CW} is exactly the $|E|$ -dimensional hypercube. To finish the proof we note that the $|E|$ -dimensional hypercube is completely described by the projection of the inequalities (26). $\square$

THEOREM 38. For a star $G = (V, E)$ with root $r \in V$, $a \geq 0$ with $a \neq 0^{|E|}$, and $a(V) \leq a_0$ we have

$$P_{\text{CW}} = \{y \in \mathbb{R}^{|E|+1} : y \text{ fulfills (26), (27), and (28)}\} =: Y \text{ if } a(V \setminus \{r\}) > a_r, \text{ and} \\ P_{\text{CW}} = \{y \in \mathbb{R}^{|E|+1} : y \text{ fulfills (26), (29), and (30)}\} =: Y^r \text{ if } a(V \setminus \{r\}) \leq a_r.$$

Proof. If $a(V \setminus \{r\}) > a_r$, Propositions 30 and 31 show that $Y \supseteq P_{\text{CW}}$, and to show $Y \subseteq P_{\text{CW}}$ we can use Propositions 35, 36, and 37. If $a(V \setminus \{r\}) \leq a_r$, Propositions 30 and 32 show that $Y^r \supseteq P_{\text{CW}}$, and to prove $Y^r \subseteq P_{\text{CW}}$ we can use again Propositions 35, 36, and 37. $\square$

Remark 39. Note that in all assertions of this section we have assumed $a(V) \leq a_0$. This assumption guarantees that every $S \subseteq V$ contributes its point h^S to P_{CW} . If we reduce a_0 below $a(V)$, the facial structure of P_{CW} becomes much more complicated, because suddenly the whole complexity of the knapsack polytope P_K comes into play. So far a complete description of P_{CW} with $a(V) > a_0$ seems out of reach for nontrivial graphs, even if we assume $a_v = 1$ for all $v \in V$.

Example 40. We continue Example 24. For the choice of the subgraphs $\bar{G}_l$ compare Figures 8 and 9.

- (2) The bisection knapsack walk inequality on $V' = \{1, 2, 3\}$ with root node $r = 3$ and $H_v = \emptyset$ for all $v \in V'$ is $1 + (1 - y_{13}) + (1 - y_{23}) \leq 4$. With $\bar{G}_1$ and $\bar{G}_2$ such that $\bar{V}_1 = \{4, 5\}$, $\bar{V}_2 = \{6, 7\}$, $\bar{E}_1 = \{45\}$, and $\bar{E}_2 = \{67\}$ the capacity reduced bisection knapsack walk inequality reads $1 + (1 - y_{13}) + (1 - y_{23}) \leq 4 - y_{45} - y_{67}$ and is a facet of P_B .

FIG. 8. Graph for Example 40 (2). $F = 4$, $\varphi_i = 1$ for all $i \in V$, $\sum_{i \in V} x_i \leq 4$.

FIG. 9. Graph for Example 40 (3). $F = 4$, $\varphi_i = 1$ for all $i \in V$, $\sum_{i \in V} x_i \leq 4$.

- (3) For $V' = \{1, 2, 3, 4\}$, $r = 3$, and $H_v = \emptyset$ for all $v \in V'$ the bisection knapsack walk inequality is $1 + (1 - y_{13}) + (1 - y_{23}) + (1 - y_{34}) \leq 4$. Proposition 31 establishes that for $\bar{G}$ with $\bar{V} = \{5, 6, 7, 8\}$ and $\bar{E} = \{56, 67, 68\}$ one of the best minorizing functions for $\beta_{\bar{G}}$ is $y_{56} + y_{67} - y_{68}$. Thus the resulting capacity

reduced bisection knapsack walk inequality reads $1 + (1 - y_{13}) + (1 - y_{23}) + (1 - y_{34}) \leq 4 - y_{56} - y_{67} + y_{68}$. It is a facet of P_B .

7. Conclusions. We investigated the bisection cut polytope P_B associated with the minimum graph bisection problem (MB). In particular, we exploited the knapsack condition ($f(S) \leq F$ and $f(V \setminus S) \leq F$, $S \subseteq V$) in the formulation of the problem, which makes it NP-hard. As one would expect, inequalities basing on this knapsack constraint define high-dimensional faces of P_B . In the first part of the paper we showed that in case the underlying graph G is a tree the knapsack tree inequalities define facets of P_B . The situation becomes more complicated if one considers a denser graph. We suppose that also in this case there are facet-defining knapsack tree inequalities for P_B . However, so far we have not been able to identify sufficient conditions which must be fulfilled by the tree supporting the inequality. Here there is certainly room for further research. In the second part of the paper we worked out a version of knapsack related inequalities—the bisection knapsack walk inequalities—which exploit the special bisection case. We took a closer look at their strengthening resulting in capacity reduced bisection knapsack walk inequalities. The right-hand sides of these inequalities may be reduced by exploiting weights of nodes that are not endpoints of walks within the respective inequality. The best possible reduction of the right-hand side is achieved by applying facets of the newly introduced cluster weight polytope P_{CW} . As one would expect, the facial structure of P_{CW} is not trivial due to its relation to the knapsack polytope. We gave the full description of P_{CW} for the case that the complement of the walk in G is a star, all nodes of which fit into the knapsack. Even though this simple case was already challenging we encourage the investigation of P_{CW} on more complex graphs than a star and on graphs with an active capacity restriction on the node weight. The practical value of the strengthenings will be investigated in a follow-up paper, which also features extensive results on a comparison of semidefinite versus pure linear branch and cut approaches for bisection problems on large sparse graphs.

LABELED PARTITIONS AND THE q -DERANGEMENT NUMBERS*

WILLIAM Y. C. CHEN[†] AND DEHENG XU[†]

Abstract. Inspired by MacMahon's original proof of his celebrated theorem on the distribution of the major index over permutations, we give a reformulation of his argument in terms of labeled partitions. In this framework, we establish a decomposition theorem for labeled partitions which is analogous to the decomposition of a permutation into derangement points and fixed points. This decomposition implies a reformulation of Wachs's formula concerning the derangement parts and the major index on permutations which was derived in order to present a bijective treatment of Gessel's formula on the q -derangement numbers.

Key words. q -derangement number, major index, bijection, partitions, labeled partitions

DOI. 10.1137/06066326X

1. Introduction. We will follow the terminology and notation on permutations and partitions and q -series in Andrews [2] and Stanley [10]. The set of permutations on $\{1, 2, \dots, n\}$ is denoted by S_n . For any permutation $\pi = \pi_1\pi_2\cdots\pi_n \in S_n$, an index i with $1 \leq i \leq n-1$ is called a *descent* of π if $\pi_i > \pi_{i+1}$. The major index $\text{maj}(\pi)$ of π , introduced by MacMahon [9], is defined as the sum of all descents of π . The following formula is well known:

$$(1.1) \quad \sum_{\pi \in S_n} q^{\text{maj}(\pi)} = [n]! = 1 \cdot (1+q) \cdot (1+q+q^2) \cdots (1+q+\cdots+q^{n-1}).$$

The underlying idea of MacMahon's proof goes as follows. It is easier to consider sequences and partitions than solely permutations for the purpose of studying the major index. MacMahon established (1.1) by proving an equivalent formula,

$$(1.2) \quad \frac{1}{(q)_n} \sum_{\pi \in S_n} q^{\text{maj}(\pi)} = \frac{1}{(1-q)^n},$$

where $(q)_n = (1-q) \cdots (1-q^n)$, and $(q)_n^{-1}$ is the generating function for partitions with n parts, where zero parts are allowed. We will give a reformulation of MacMahon's proof in section 2 by using the notion of standard labeled partitions.

The main objective of this paper is to employ MacMahon's method to deal with the major index of derangements. An integer i with $1 \leq i \leq n$ is said to be a *fixed point* of $\pi \in S_n$ if $\pi_i = i$, and a *derangement point* otherwise. *Derangements* are permutations with no fixed points. Let D_n be the set of all derangements in S_n . The q -derangement numbers are defined by $d_0(q) = 1$ and for $n \geq 1$

$$d_n(q) = \sum_{\pi \in D_n} q^{\text{maj}(\pi)}.$$

[†]Center for Combinatorics, LPMC-TJKLC, Nankai University, Tianjin 300071, People's Republic of China (chen@nankai.edu.cn, xudeheng@eyou.com).

The following elegant formula was first derived by Gessel and published in [6] as a consequence of the quasi-symmetric generating function encoding the descents and the cycle structure of permutations:

$$(1.3) \quad d_n(q) = [n]! \sum_{k=0}^n \frac{(-1)^k}{[k]!} q^{\binom{k}{2}}.$$

A combinatorial proof of (1.3) has been obtained by Wachs [12]. Let us review the combinatorial settings of Wachs. Suppose that the derangement points of π are $p_1, p_2, \dots, p_k$. The reduction of π to its *derangement part*, denoted by $dp(\pi)$, is defined as a permutation on $\{1, 2, \dots, k\}$ induced by the relative order of $\pi_{p_1}, \pi_{p_2}, \dots, \pi_{p_k}$. For example, the derangement points of $\pi = (1, 5, 3, 7, 6, 2, 9, 8, 4)$ are 2, 4, 5, 6, 7, 9, and $\pi_2\pi_4\pi_5\pi_6\pi_7\pi_9 = (5, 7, 6, 2, 9, 4)$. Then $dp(\pi) = (3, 5, 4, 1, 6, 2)$. Clearly $dp(\pi) \in D_k$ if π has k derangement points. On the other hand, we can insert a fixed point j with $1 \leq j \leq k+1$ into $\pi \in S_k$ to obtain a permutation

$$(1.4) \quad \bar{\pi} = \pi'_1 \pi'_2 \cdots \pi'_{j-1} j \pi'_j \cdots \pi'_k \in S_{k+1},$$

where $\pi'_i = \pi_i$ if $\pi_i < j$ and $\pi'_i = \pi_i + 1$ if $\pi_i \geq j$. Such an insertion operation produces one extra fixed point and will be used in the proof of Theorem 2.2. Wachs [12] has established the following relation.

THEOREM 1.1. *Let $0 \leq k \leq n$ and $\sigma \in D_k$. Then we have*

$$(1.5) \quad \sum_{\substack{dp(\pi)=\sigma \\ \pi \in S_n}} q^{\text{maj}(\pi)} = q^{\text{maj}(\sigma)} \begin{bmatrix} n \\ k \end{bmatrix},$$

where $\begin{bmatrix} n \\ k \end{bmatrix} = \frac{[n]!}{[k]![n-k]!}$ is the q -binomial coefficient.

Summing over all derangements $\sigma \in D_k$ and $0 \leq k \leq n$, and applying (1.1), we can deduce from (1.5) that

$$[n]! = \sum_{k=0}^n \begin{bmatrix} n \\ k \end{bmatrix} d_k(q).$$

Thus (1.3) follows from the q -binomial inversion [1, Corollary 3.38].

In order to justify the relation (1.5), Wachs found a bijection on S_n by rearranging a permutation π according to *excedant* (where $\pi_i > i$), fixed point, and *subcedant* (where $\pi_i < i$). She showed that this bijection preserves the major index. Then a result of Garsia and Gessel [4, Theorem 3.1] on shuffles of permutations is applied to establish Theorem 1.1.

Inspired by MacMahon's original proof of (1.1), we present an alternative approach to Wachs's formula (1.5) based on the following reformulation:

$$(1.6) \quad \frac{1}{(q)_n} \sum_{\substack{dp(\pi)=\sigma \\ \pi \in S_n}} q^{\text{maj}(\pi)} = \frac{1}{(q)_k(q)_{n-k}} q^{\text{maj}(\sigma)}.$$

We will use the terminology of labeled partitions and will introduce the notion of standard labeled partitions. In this framework, MacMahon's proof can be easily stated. Moreover, a combinatorial justification of (1.6) reduces to a decomposition theorem which is analogous to the decomposition of a permutation by separating the derangement points and the fixed points.

2. Labeled partitions. Let $\lambda = (\lambda_1, \dots, \lambda_n)$ be a partition, where $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n \geq 0$. We say that λ is a partition with n parts, or of length n , and we write $|\lambda| = \lambda_1 + \dots + \lambda_n$. A *labeled partition* of length n is defined as a pair (λ, π) (or $\binom{\lambda}{\pi}$), where λ is a partition with n parts and π is a permutation $\pi = \pi_1\pi_2 \cdots \pi_n$ on $[n] = \{1, 2, \dots, n\}$. A labeled partition is also represented in the following two-row form as in Andrews [2, p. 43]:

$$\begin{pmatrix} \lambda_1 & \lambda_2 & \cdots & \lambda_n \\ \pi_1 & \pi_2 & \cdots & \pi_n \end{pmatrix}.$$

A labeled partition (λ, π) is said to be *standard* if $\pi_i > \pi_{i+1}$ implies $\lambda_i > \lambda_{i+1}$. For example, the labeled partition in (2.1) is standard.

The following Lemma 2.1 is straightforward to verify, which is MacMahon's original approach for studying the major index with the aid of partitions; see MacMahon [9], Andrews [2, Theorem 3.7], Knuth [8, p. 18] or [7]. This method was further extended by Stanley [11]. For other applications, see [4].

LEMMA 2.1. *Given $\pi \in S_n$, there is a bijection $\psi_\pi: \lambda \mapsto \mu$ between the set of partitions λ with n parts and the set of partitions μ with n parts such that (μ, π) is a standard labeled partition and $|\lambda| + \text{maj}(\pi) = |\mu|$. Formally, we write $\psi(\lambda, \pi) = (\psi_\pi(\lambda), \pi)$.*

The bijection ψ_π (or simply ψ when π is understood from the context) is given as follows:

$$\mu = \psi_\pi(\lambda) = (\lambda_1 + \phi_1, \lambda_2 + \phi_2, \dots, \lambda_n + \phi_n),$$

where ϕ_i is the number of descents in $\pi_i\pi_{i+1} \cdots \pi_n$. One may also view ψ as the operation of adding 1 to $\lambda_1, \dots, \lambda_i$ whenever i is a descent of π . The inverse map ψ^{-1} can be easily described.

Below is a restatement of MacMahon's proof of (1.2) in the terminology of labeled partitions.

Proof of (1.2). Given a sequence $a_1a_2 \cdots a_n$ of nonnegative integers, we associate it with weight $q^{a_1+a_2+\cdots+a_n}$. Let us construct a two-row array:

$$\begin{pmatrix} a_1 & a_2 & \cdots & a_n \\ 1 & 2 & \cdots & n \end{pmatrix}.$$

Observe that a labeled partition (λ, π) is standard if $\lambda_i = \lambda_{i+1}$ implies $\pi_i < \pi_{i+1}$. Therefore, by permuting the columns of the above array, we get a unique standard labeled partition (μ, π) with $|\mu| = a_1 + a_2 + \cdots + a_n$. Applying Lemma 2.1, we obtain a partition λ with $|\lambda| + \text{maj}(\pi) = |\mu|$. Clearly, the above steps are reversible. This completes the proof. $\square$

Let $n = 9$ and $a_1a_2 \dots a_9$ be the first row in the following array:

$$\begin{pmatrix} 3 & 6 & 8 & 3 & 1 & 3 & 6 & 4 & 8 \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \end{pmatrix}.$$

By permuting the columns we get the standard labeled partition,

$$(2.1) \quad \begin{pmatrix} \mu \\ \pi \end{pmatrix} = \begin{pmatrix} 8 & 8 & 6 & 6 & 4 & 3 & 3 & 3 & 1 \\ 3 & \underline{9} & 2 & 7 & \underline{8} & 1 & 4 & \underline{6} & 5 \end{pmatrix},$$

where we have underlined those elements π_i whenever i is a descent of π .

Applying the inverse map ψ^{-1} we obtain

$$\begin{pmatrix} \lambda \\ \pi \end{pmatrix} = \begin{pmatrix} 5 & 5 & 4 & 4 & 2 & 2 & 2 & 2 & 1 \\ 3 & \underline{9} & 2 & 7 & \underline{8} & 1 & 4 & \underline{6} & 5 \end{pmatrix},$$

which is the corresponding labeled partition.

We remark that the idea of standard labeled partitions appeared in [4, p. 292], though it was not used to prove (1.2).

We are now ready to present a decomposition theorem on standard labeled partitions with respect to the fixed points. Let σ be a given derangement in D_k and π a permutation in S_n such that $dp(\pi) = \sigma$. Assume that (μ, π) is a standard labeled partition of length n . Let $i_1 < i_2 < \cdots < i_{n-k}$ be the fixed points and $j_1 < j_2 < \cdots < j_k$ the derangement points of π . We now define the following decomposition of a standard labeled partition:

$$(2.2) \quad \Delta: (\mu, \pi) \mapsto (\beta, \gamma),$$

where $\beta = \mu_{j_1} \mu_{j_2} \cdots \mu_{j_k}$ and $\gamma = \mu_{i_1} \mu_{i_2} \cdots \mu_{i_{n-k}}$ are the partitions corresponding to the derangement points and fixed points, respectively. Evidently, μ consists of the parts from β and γ , or in common notation, $\mu = \beta \cup \gamma$.

THEOREM 2.2. *Let $\sigma \in D_k$. There is a bijection between the set of standard labeled partitions (μ, π) of length n with $dp(\pi) = \sigma$ and the set of pairs of partitions (β, γ) such that β is a partition with k parts, γ is a partition with $n-k$ parts, $\mu = \beta \cup \gamma$, and (β, σ) is a standard labeled partition.*

For example, let

$$\begin{pmatrix} \lambda \\ \pi \end{pmatrix} = \begin{pmatrix} 5 & 4 & 4 & 4 & 4 & 3 & 2 \\ \underline{5} & \underline{2} & 1 & 4 & \underline{7} & 3 & 6 \end{pmatrix}.$$

Applying ψ , we get

$$\begin{pmatrix} \mu \\ \pi \end{pmatrix} = \begin{pmatrix} 8 & \mathbf{6} & \mathbf{5} & \mathbf{5} & 5 & 3 & 2 \\ 5 & \mathbf{2} & \mathbf{1} & \mathbf{4} & 7 & 3 & 6 \end{pmatrix}.$$

The fixed points of π are 2, 4, as signified in boldface. Hence $\sigma = dp(\pi) = (3 \ 1 \ 5 \ 2 \ 4)$. Applying Δ on (μ, π) gives $(\beta, \gamma) = ((8 \ 5 \ 5 \ 3 \ 2), (6 \ 5))$. Finally, applying ψ^{-1} to

$$\begin{pmatrix} \beta \\ \sigma \end{pmatrix} = \begin{pmatrix} 8 & 5 & 5 & 3 & 2 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix},$$

we obtain

$$\begin{pmatrix} \alpha \\ \sigma \end{pmatrix} = \begin{pmatrix} 6 & 4 & 4 & 3 & 2 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix}.$$

We note that the above theorem and Lemma 2.1 lead to a combinatorial interpretation of the relation (1.6). Given a labeled partition (λ, π) , we first use the map ψ to transform it into a standard labeled partition (μ, π) . Let $\sigma = dp(\pi)$. Using the above decomposition for (μ, π) , we obtain a pair of partitions (β, γ) such that (β, σ) is a standard labeled partition and γ is a partition with $n-k$ parts. Moreover, we can find a partition α with k parts such that $\psi_\sigma(\alpha, \sigma) = (\beta, \sigma)$. Thus we are led to the relation

$$(2.3) \quad |\lambda| + \text{maj}(\pi) = |\alpha| + |\gamma| + \text{maj}(\sigma),$$

which yields (1.6).

Proof of Theorem 2.2. We first verify that (β, σ) is standard. Suppose there exists i such that $\sigma_i > \sigma_{i+1}$. Then we need to show that $\beta_i > \beta_{i+1}$. Clearly, σ_i and σ_{i+1} correspond to two elements π_j and π_k ($j < k$) in π such that $\pi_j > \pi_k$, and the points $j+1, j+2, \dots, k-1$, if any, are fixed points of π . In other words, it is necessary to show that $\mu_j > \mu_k$ since $\beta_i = \mu_j$ and $\beta_{i+1} = \mu_k$ by the decomposition. If $j = k-1$, since (μ, π) is standard, we have $\mu_j > \mu_k$. For the case $j < k-1$, we see that either $\pi_j > \pi_{j+1} = j+1$ or $\pi_{k-1} = k-1 > \pi_k$. Otherwise, we have $\pi_j < j+1 \leq k-1 < \pi_k$, a contradiction. Therefore, we have either $\mu_j > \mu_{j+1}$ or $\mu_{k-1} > \mu_k$. This implies that $\mu_j > \mu_k$. So we conclude that (β, σ) is a standard labeled partition.

We now proceed to construct the inverse map φ which corresponds to the procedure to recover π by inserting the fixed points into the derangement σ on $\{1, 2, \dots, k\}$. It turns out that the order of insertions reflects the property of standard labeled partitions.

We begin with $(\mu^0, \pi^0) = (\beta, \sigma)$ and assume that (μ^i, π^i) is obtained from (μ^{i-1}, π^{i-1}) by *inserting* γ_i , where γ_i is the i th part of γ . Let r be the first position such that the insertion of γ_i produces a partition. In other words, if μ^{i-1} already contains some parts equal to γ_i , then we insert γ_i as the first occurrence. This partition is denoted by μ^i . We need to determine the corresponding fixed point of π^i caused by the insertion of γ_i .

Clearly, $\mu_{r-1}^i > \mu_r^i = \gamma_i$. We may assume that $\mu_r^i = \dots = \mu_t^i > \mu_{t+1}^i$ for some $t \geq r$. As in the proof of (1.2), in order to get a standard labeled partition after each insertion of γ_i , we should insert s such that the subsequence

$$\pi_r^{i-1'}, \dots, \pi_{s-1}^{i-1'}, s, \pi_s^{i-1'}, \dots, \pi_{t-1}^{i-1'}$$

of the permutation obtained by inserting s into π^{i-1} is increasing. We see that the position s is uniquely determined. If $r = t$, then we set $s = r$. Otherwise we find the first position s ($r \leq s \leq t$) such that $\pi_{s-1}^{i-1} < s \leq \pi_s^{i-1}$. Strictly speaking, we have adopted the convention that $\pi_{r-1}^{i-1} = -\infty$ and $\pi_t^{i-1} = \infty$. Consequently, we can insert s into π^{i-1} as a fixed point of π^i .

It remains to show that $\pi^{n-k} = \pi$. For notational simplicity, we write π^{n-k} as $\bar{\pi}$. By removing the common fixed points, we may assume that the first fixed point f of π is different from the first fixed point $\bar{f}$ of $\bar{\pi}$. We find that f satisfies the condition $\pi_{f-1} < f \leq \pi_{f+1} - 1$. Furthermore, by the insertion procedure, $\bar{f}$ is the first position we like to locate, and hence we may assume that $\bar{f} < f$. Clearly, $\mu_f = \mu_{\bar{f}}$. Since (μ, π) and $(\mu, \bar{\pi})$ are standard labeled partitions, we have

$$\pi_{\bar{f}} < \pi_{\bar{f}+1} < \dots < \pi_f, \quad \bar{\pi}_{\bar{f}} < \bar{\pi}_{\bar{f}+1} < \dots < \bar{\pi}_f.$$

Now we see that $\pi_f = f$ and $\bar{\pi}_{\bar{f}} = \bar{f}$. But $\pi_{\bar{f}} < \pi_{\bar{f}+1} < \dots < \pi_f$ and $\pi_f = f$, so we can deduce that $\pi_{\bar{f}} \leq \bar{f}$. Since f is the first fixed point of π , we obtain $\sigma_{\bar{f}} = \pi_{\bar{f}} < \bar{f}$. From the construction of $\bar{\pi}$, it follows that $\bar{\pi}_{\bar{f}} \leq \sigma_{\bar{f}} < \bar{f}$, which is impossible given that $\bar{\pi}_{\bar{f}} = \bar{f}$. This completes the proof. $\square$

For example, given $\sigma = (3 \ 1 \ 5 \ 2 \ 4)$, $\beta = (8, 5, 5, 3, 2)$, and $\gamma = (6, 5)$, we may recover (μ, π) through the following steps:

$$\begin{pmatrix} \beta \\ \sigma \end{pmatrix} = \begin{pmatrix} 8 & 5 & 5 & 3 & 2 \\ 3 & 1 & 5 & 2 & 4 \end{pmatrix} \xrightarrow{\gamma_1=6} \begin{pmatrix} 8 & \underline{6} & 5 & 5 & 3 & 2 \\ 4 & \underline{2} & 1 & 6 & 3 & 5 \end{pmatrix} \xrightarrow{\gamma_2=5} \begin{pmatrix} 8 & 6 & 5 & \underline{5} & 5 & 3 & 2 \\ 5 & 2 & 1 & \underline{4} & 7 & 3 & 6 \end{pmatrix} = \begin{pmatrix} \mu \\ \pi \end{pmatrix}.$$

Acknowledgments. The authors would like to thank Henry Y. Gao and Guoce Xin for their valuable suggestions. They are also grateful to the referee for helpful comments leading to an improvement of an earlier version.

EULER–MAHONIAN STATISTICS ON ORDERED SET PARTITIONS*

MASAO ISHIKAWA[†], ANISSE KASRAOUI[‡], AND JIANG ZENG[‡]

Abstract. An ordered partition with k blocks of $[n] := \{1, 2, \dots, n\}$ is a sequence of k disjoint and nonempty subsets, called blocks, whose union is $[n]$. Clearly the number of such ordered partitions is $k!S(n, k)$, where $S(n, k)$ is the Stirling number of the second kind. A statistic on ordered partitions of $[n]$ with k blocks is called an *Euler–Mahonian statistic* if its generating polynomial is $[k]_q!S_q(n, k)$, which is a natural q -analogue of $k!S(n, k)$. Motivated by Steingrímsson’s conjectures dating back to 1997, we consider two different methods to produce Euler–Mahonian statistics on ordered set partitions: (a) we give a bijection between ordered partitions and weighted Motzkin paths by using a variant of Françon–Viennot’s bijection to derive many Euler–Mahonian statistics by expanding the generating function of $[k]_q!S_q(n, k)$ as an explicit continued fraction; (b) we encode ordered partitions by walks in some digraphs and then derive new Euler–Mahonian statistics by computing their generating functions using the transfer-matrix method. In particular, we prove several conjectures of Steingrímsson.

1. Introduction. The systematic study of statistics on permutations and words has its origins in the work of MacMahon, at the turn of the last century. MacMahon [11] considered four different statistics for a permutation π : The number of descents ($\text{des } \pi$), the number of excedances ($\text{exc } \pi$), the number of inversions ($\text{inv } \pi$), and the major index ($\text{maj } \pi$). These are defined as follows: A descent in a permutation $\pi = a_1 a_2 \cdots a_n$ is an i such that $a_i > a_{i+1}$, an excedance is an i such that $a_i > i$, an inversion is a pair (i, j) such that $i < j$ and $a_i > a_j$, and the major index of π is the sum of the descents in π .

In fact, MacMahon studied these statistics in greater generality, namely, over the rearrangement class of an arbitrary word w with repeated letters. The rearrangement class $R(w)$ of a word $w = a_1 a_2 \cdots a_n$ is the set of all words obtained by permutating the letters of w . All of the statistics mentioned above generalize to words, and in each case, except for that of exc , the generalization is trivial.

MacMahon showed, algebraically, that exc is *equidistributed* with des , and that inv is equidistributed with maj , over $R(w)$ for any word w . That is to say,

$$\sum_{z \in R(w)} t^{\text{exc } z} = \sum_{z \in R(w)} t^{\text{des } z} \quad \text{and} \quad \sum_{z \in R(w)} t^{\text{inv } z} = \sum_{z \in R(w)} t^{\text{maj } z}.$$

Any statistic that is equidistributed with des is said to be *Eulerian*, while any statistic equidistributed with inv is said to be *Mahonian*. Foata [5] coined the name *Euler–Mahonian* statistic for a bivariate statistic $(\text{eul } \pi, \text{mah } \pi)$, where eul is Eulerian and mah is Mahonian, and carried out the first study of such pairs.

In 1997 Steingrímsson [18] introduced the notion of *Euler–Mahonian* statistic on ordered partitions. In order to motivate this definition we recall a well-known basic identity relating Eulerian and Stirling numbers along with some basic definitions.

For a permutation $\sigma = \sigma(1)\sigma(2)\dots\sigma(n)$ of $[n] = \{1, 2, \dots, n\}$, the integer $i \in [n-1]$ is called a *descent* (resp., *ascent*) of σ if $\sigma(i) > \sigma(i+1)$ (resp., $\sigma(i) < \sigma(i+1)$). Let $\text{des } \sigma$ be the number of descents of σ and S_n be the set of permutations of $[n]$; then the *Eulerian polynomial* $A_n(x)$ is the generating polynomial of permutations in S_n with respect to the number of descents, i.e.,

$$A_n(x) = \sum_{\sigma \in S_n} x^{1+\text{des } \sigma} = \sum_{k=0}^{n-1} A(n, k) x^{1+k},$$

where the coefficients $A(n, k)$ are called the *Eulerian numbers*. The Eulerian polynomials can also be defined by the following exponential generating function:

$$(1.1) \quad 1 + \sum_{n \geq 1} A_n(x) \frac{z^n}{n!} = \frac{1-x}{1-xe^{(1-x)z}}.$$

A partition $P = B_1/B_2/\dots/B_k$ of $[n]$ is a collection of disjoint and nonempty subsets B_i 's, called *blocks*, whose union is $[n]$, where we write P in the standard way; i.e., the blocks B_i are arranged in increasing order of their minimal elements and separated by $/$. Let $\mathcal{P}_n^k$ be the set of partitions of $[n]$ with k blocks. Now, if σ is a permutation in S_k , the sequence $\pi = B_{\sigma(1)}/B_{\sigma(2)}/\dots/B_{\sigma(k)}$ is called an *ordered partition* of $[n]$ with k blocks. In other words, an ordered partition π of $[n]$ with k blocks can be viewed as a pair (P, σ) , where P is a partition in $\mathcal{P}_n^k$ and σ a permutation in S_k . We shall denote the permutation σ by $\text{perm}(\pi)$. Let $\mathcal{OP}_n^k$ be the set of ordered partitions of $[n]$ into k blocks.

A *preferential arrangement* of $[n]$ is a permutation of $[n]$, of which each ascent is *underlined or not*. A *run* in a permutation σ is an increasing sequence of consecutive terms $\sigma(i) < \sigma(i+1) < \dots < \sigma(j)$ such that $\sigma(i-1) > \sigma(i)$ and $\sigma(j) > \sigma(j+1)$, where $\sigma(0) = n+1$ and $\sigma(n+1) = 0$. Clearly each preferential arrangement can be decomposed uniquely, from left to right, into *runs* or *increasing sequences ending with an underlined ascent*. Hence a preferential arrangement of $[n]$ can be identified with an *ordered set partition* of $[n]$. For example, we have the following correspondence between a preferential arrangement σ and an ordered partition π of [9]:

$$\sigma = \underline{2}931485\underline{6}7 \longleftrightarrow \pi = 2/9/3/148/5\underline{6}/7.$$

Clearly, if k is the number of blocks in the ordered set partition π , then $k-1$ equals the number of descents and underlined ascents of σ . Since the number of ordered partitions of $[n]$ into k blocks is $k!S(n, k)$, where $S(n, k)$ denotes the *Stirling numbers of the second kind*, this correspondence implies immediately the identity:

$$(1.2) \quad k!S(n, k) = \sum_{m=1}^k \binom{n-m}{n-k} A(n, m-1).$$

Indeed, we can construct the corresponding preferential arrangements of $[n]$ by first choosing a permutation of $[n]$ with $m-1$ descents and then underline $k-1-(m-1) = k-m$ ascents.

Let $\mathcal{OP}_n$ be the set of all ordered partitions of $[n]$, and let $\underline{S}_n$ be the set of all preferential arrangements of $[n]$. Clearly the cardinality of $\mathcal{OP}_n$ is given by $|\mathcal{OP}_n| =$

$\sum_{k=0}^n k! S(n, k)$ or $|\mathcal{OP}_n| = \sum_{\sigma \in S_n} 2^{\text{des } \sigma}$, by the correspondence between $\mathcal{OP}_n$ and S_n . We then derive from (1.1) the following exponential generating function:

$$1 + \sum_{n \geq 1} |\mathcal{OP}_n| \frac{z^n}{n!} = \frac{1}{2 - e^z} = 1 + z + 3 \frac{z^2}{2!} + 13 \frac{z^3}{3!} + 75 \frac{z^4}{4!} + \cdots$$

Carlitz [1, 2] was the first to study q -analogues of *Eulerian numbers* and *Stirling numbers of the second kind*, which we recall in the following.

Define the p, q -integer $[n]_{p,q} = \frac{p^n - q^n}{p - q}$, the p, q -factorial $[n]_{p,q}! = [1]_{p,q} [2]_{p,q} \cdots [n]_{p,q}$, and the p, q -binomial coefficient

$$\begin{bmatrix} n \\ k \end{bmatrix}_{p,q} = \begin{cases} \frac{[n]_{p,q}!}{[k]_{p,q}! [n-k]_{p,q}!} & \text{if } 0 \leq k \leq n, \\ 0 & \text{otherwise.} \end{cases}$$

If $p = 1$, we shall write $[n]_q$, $[n]_{q!}$, and $\begin{bmatrix} n \\ k \end{bmatrix}_q$ for $[n]_{1,q}$, $[n]_{1,q!}$, and $\begin{bmatrix} n \\ k \end{bmatrix}_{1,q}$, and usually called q -integer, q -factorial, and q -binomial coefficient, respectively.

The q -Eulerian numbers $A_q(n, k)$ ($n \geq k \geq 0$) are defined by

$$A_q(n, k) = q^k [n - k]_q A_q(n - 1, k - 1) + [k + 1]_q A_q(n - 1, k).$$

The first values of the q -Eulerian numbers $\langle \begin{smallmatrix} n \\ k \end{smallmatrix} \rangle_q$ ($n \geq k \geq 0$) read

$n \setminus k$	0	1	2	3
1	1			
2	1	q		
3	1	$2q + 2q^2$	q^3	
4	1	$3q + 5q^2 + 3q^3$	$3q^3 + 5q^4 + 3q^5$	q^6

The *major index* of σ , noted $\text{maj } \sigma$, is the sum of its descents, i.e., $\text{maj } \sigma = \sum_i i$, where the summation is over all descents i of σ . It is well known that maj is a Mahonian statistic on S_n , i.e.,

$$\sum_{\sigma \in S_n} q^{\text{maj } \sigma} = [n]_{q!}.$$

Carlitz [2] gave the following combinatorial interpretation of q -Eulerian numbers:

$$A_q(n, k) = \sum_{\sigma} q^{\text{maj } \sigma},$$

where the summation is over all permutations of $[n]$ with k descents.

The two natural q -Stirling numbers $S_q(n, k)$ and $\tilde{S}_q(n, k)$ of the second kind are defined by

$$(1.3) \quad S_q(n, k) = q^{k-1} S_q(n - 1, k - 1) + [k]_q S_q(n - 1, k) \quad (n \geq k \geq 0)$$

and

$$(1.4) \quad \tilde{S}_q(n, k) = \tilde{S}_q(n - 1, k - 1) + [k]_q \tilde{S}_q(n - 1, k) \quad (n \geq k \geq 0),$$

where $S_q(n, k) = \tilde{S}_q(n, k) = \delta_{nk}$ if $n = 0$ or $k = 0$, and δ_{nk} is the Kronecker delta.

It is easy to see that $S_q(n, k) = q^{\binom{k}{2}} \widetilde{S}_q(n, k)$. The first values of the q -Stirling numbers $S_q(n, k)$ read

$n \setminus k$	1	2	3	4
1	1			
2	1	q		
3	1	$2q + q^2$	q^3	
4	1	$3q + 3q^2 + q^3$	$3q^3 + 2q^4 + q^5$	q^6

There has been a considerable amount of recent interest in properties and combinatorial interpretations of the q -Eulerian numbers and q -Stirling numbers and related numbers (see, e.g., [1, 2, 3, 10, 12, 13, 14, 15, 16, 18, 20, 21, 22]).

Garsia [8] found a q -analogue of the Frobenius formula relating q -Eulerian numbers and q -Stirling numbers of the second kind:

$$(1.5) \quad \sum_{k=1}^n \frac{[k]! S_q(n, k) x^k}{(x; q)_{k+1}} = \sum_{k=1}^{\infty} [k]^n x^k = \frac{\sum_{\sigma \in S_n} x^{1+\text{des } \sigma} q^{\text{maj } \sigma}}{(x; q)_{n+1}},$$

where $(x; q)_n = (1-x)(1-xq) \cdots (1-xq^{n-1})$. From (1.5) Zeng and Zhang [24] then derived the following q -analogue of (1.2):

$$(1.6) \quad [k]_q! S_q(n, k) = \sum_{m=1}^k q^{k(k-m)} \begin{bmatrix} n-m \\ n-k \end{bmatrix}_q A_q(n, m-1).$$

In his attempt to give a combinatorial proof of (1.6), Steingrímsson [18] introduced the following definition.

DEFINITION 1.1. *A statistic STAT on ordered set partitions is called Euler–Mahonian if for any $n \geq k \geq 1$ its generating function over $\mathcal{OP}_n^k$ is equal to $[k]_q! S_q(n, k)$, i.e.,*

$$\sum_{\pi \in \mathcal{OP}_n^k} q^{\text{STAT } \pi} = [k]_q! S_q(n, k).$$

An Euler–Mahonian statistic on ordered set partitions can be derived from a result of Wachs [12, Theorem 2.1] (see also [18, Theorem 4]). Steingrímsson [18] gave several Euler–Mahonian statistics and conjectured more such statistics.

The aim of this paper is to provide many more such statistics on ordered set partitions by taking two different approaches. In the first approach our starting point is an explicit continued fraction expansion of the generating function $\sum_{n,k} [k]_q! S_q(n, k) u^k z^n$. By embedding the ordered partitions into preferential arrangements we can encode the latter by weighted Motzkin paths, whose generating function is known to have an explicit continued fraction expansion. By identifying these two continued fractions we find many Euler–Mahonian statistics on ordered partitions. In the second approach we shall construct a bijection ψ between ordered partitions and walks in some digraphs (see section 3). This bijection keeps track of several statistics on ordered partitions. Then, by the transfer-matrix method, we evaluate the generating functions of these statistics on ordered partitions. Finally, by identifying the generating functions we derive several Euler–Mahonian statistics. We conclude this paper with some open problems.

2. Definitions and main results. Let $\sigma = \sigma_1\sigma_2\ldots\sigma_n \in S_n$. By convention, we assume that $\sigma_0 = n+1$ and $\sigma_{n+1} = 0$. For $1 \leq i \leq n$, we say that σ_i is a

- *valley* if $\sigma_{i-1} > \sigma_i < \sigma_{i+1}$;
- *underlined valley* if $\sigma_{i-1} > \sigma_i < \sigma_{i+1}$ and σ_i is underlined;
- *peak* if $\sigma_{i-1} < \sigma_i > \sigma_{i+1}$;
- *double ascent* if $\sigma_{i-1} < \sigma_i < \sigma_{i+1}$;
- *underlined double ascent* if $\sigma_{i-1} < \sigma_i < \sigma_{i+1}$ and σ_i is underlined;
- *double descent* if $\sigma_{i-1} > \sigma_i > \sigma_{i+1}$.

We will denote by $\text{DA}(\sigma)$, $\underline{\text{DA}}(\sigma)$, $\text{VA}(\sigma)$, $\underline{\text{VA}}(\sigma)$, $\text{DD}(\sigma)$, $\text{PE}(\sigma)$ the set of double ascents, underlined double ascents, valleys, underlined valleys, double descents, and peaks of σ , respectively. For instance, if $\sigma = \underline{2}931485\underline{6}7$, then

$$\begin{aligned} \text{DA}(\sigma) &= \{4\}, & \underline{\text{DA}}(\sigma) &= \{6\}, & \text{VA}(\sigma) &= \{1, 5\}, \\ \underline{\text{VA}}(\sigma) &= \{2\}, & \text{DD}(\sigma) &= \{3\}, & \text{PE}(\sigma) &= \{7, 8, 9\}. \end{aligned}$$

For $i \in [n]$, define $\text{lsg}_i(\sigma)$ (resp., $\text{rsg}_i(\sigma)$) as the number of runs of σ strictly to the left (resp., right) of i which contain an element smaller than i and an element greater than i . Then we define

$$\text{lsg}(\sigma) = \sum_{i=1}^n \text{lsg}_i(\sigma), \quad \text{rsg}(\sigma) = \sum_{i=1}^n \text{rsg}_i(\sigma).$$

More generally, for a sequence of statistics STAT_i ($i \geq 0$) on a set E , and for F a mapping which associates to any element in E a finite set of integers, we define the statistic $\text{STAT}(F)$ on E by

$$(2.1) \quad \text{STAT}(F)(e) = \sum_{i \in F(e)} \text{STAT}_i(e) \quad \text{for any } e \in E.$$

For instance, the statistic $\text{lsg}(\text{DD} \cup \text{VA})$ is defined for any $\sigma \in S_n$ by

$$\text{lsg}(\text{DD} \cup \text{VA})(\sigma) = \sum_{i \in \text{DD}(\sigma) \cup \text{VA}(\sigma)} \text{lsg}_i(\sigma).$$

Consider the generating polynomial of preferential arrangements:

$$\begin{aligned} \mu_n &= \sum_{\pi \in S_n} \alpha^{\#\text{DD}(\pi)} \beta^{\#\text{DA}(\pi)} \gamma^{\#\underline{\text{DA}}(\pi)} \delta^{\#\text{VA}(\pi)} \xi^{\#\underline{\text{VA}}(\pi)} \eta^{\#\text{PE}(\pi)} \\ &\quad \times a^{\text{lsg}(\text{DD})(\pi)} b^{\text{rsg}(\text{DD})(\pi)} c^{\text{lsg}(\text{DA})(\pi)} d^{\text{rsg}(\text{DA})(\pi)} f^{\text{lsg}(\underline{\text{DA}})(\pi)} g^{\text{rsg}(\underline{\text{DA}})(\pi)} \\ &\quad \times s^{\text{lsg}(\text{VA})(\pi)} t^{\text{rsg}(\text{VA})(\pi)} x^{\text{lsg}(\underline{\text{VA}})(\pi)} y^{\text{rsg}(\underline{\text{VA}})(\pi)} v^{\text{lsg}(\text{PE})(\pi)} w^{\text{rsg}(\text{PE})(\pi)}. \end{aligned}$$

Our first result is an explicit continued fraction expansion for the ordinary generating function of μ_n .

THEOREM 2.1. *We have the following continued fraction expansion:*

$$(2.2) \quad 1 + \sum_{n \geq 1} \mu_n z^n = \frac{1}{1 - b_0 z - \frac{\lambda_1 z^2}{1 - b_1 z - \frac{\lambda_2 z^2}{\ddots}}},$$

where $b_n = \alpha[n+1]_{a,b} + \beta[n]_{c,d} + \gamma[n]_{f,g}$, $\lambda_n = (\delta[n]_{s,t} + \xi[n]_{x,y}) \eta[n]_{v,w}$.

In order to derive Euler–Mahonian statistics on ordered set partitions we need the following lemma.

LEMMA 2.2. *We have*

$$(2.3) \quad \sum_{n,k} [k]_q! S_q(n, k) u^k z^n = \frac{1}{1 - b_0 z - \frac{\lambda_1 z^2}{1 - b_1 z - \frac{\lambda_2 z^2}{\ddots}}},$$

where $b_n = uq^n[n+1]_q + [n]_q(1 + uq^n)$, $\lambda_n = uq^{n-1}[n]_q^2(1 + uq^n)$.

The proofs of Theorem 2.1 and Lemma 2.2 will be given in section 3.

There are several possibilities to specialize the parameters in (2.2) to obtain (2.3). Clearly such a specialization will induce an Euler–Mahonian statistic on ordered set partitions. For example, setting $\alpha = \eta = u$, $\gamma = \xi = uq$, $\beta = \delta = c = s = 1$, $a = f = x = v = q^2$, and $b = d = g = t = y = w = q$ in Theorem 2.1, the right-hand side of (2.2) reduces to that of (2.3). On the other hand, for $\sigma \in \underline{S}_n$, let

$$s(\sigma) = (2 \operatorname{lsg} + \operatorname{rsg} - 2 \operatorname{lsg}(\operatorname{DA}) - 2 \operatorname{lsg}(\operatorname{VA}))(\sigma) + \#\operatorname{VA}(\sigma) + \#\operatorname{DA}(\sigma).$$

Then

$$(2.4) \quad \sum_{\pi \in \underline{S}_n} u^{n - \#\operatorname{DA}(\sigma) - \#\operatorname{VA}(\sigma)} q^{s(\sigma)} = \sum_{k=1}^n [k]_q! S_q(n, k) u^k.$$

As $n - \#\operatorname{DA}(\sigma) - \#\operatorname{VA}(\sigma)$ is the number of blocks of σ identified as an ordered set partition, extracting the coefficients of u^k in (2.4) yields the following result.

THEOREM 2.3. *We have*

$$(2.5) \quad \sum_{\sigma \in \underline{S}_n^k} q^{s(\sigma)} = [k]_q! S_q(n, k),$$

where $\underline{S}_n^k$ is the set of underlined permutations of $[n]$ whose number of descents and underlined ascents equals $k - 1$.

Remark 2.4. By varying the coefficients lsg and rsg in the specialization we have $2^6 = 64$ statistics satisfying (2.5), i.e., $\{a, b\} = \{f, g\} = \{x, y\} = \{v, w\} = \{q, q^2\}$ and $\{c, d\} = \{s, t\} = \{1, q\}$.

It is not difficult to translate all these statistics into the model of ordered set partitions, but we decide to omit their description because they are too involved.

Let $\pi = B_1/B_2/\cdots/B_k$ be an ordered partition in $\mathcal{OP}_n^k$. The *opener* of a block is its least element, while the *closer* is its greatest element. We will denote by $\operatorname{open}(\pi)$ and $\operatorname{clos}(\pi)$ the set of openers and closers, respectively, of π . The letters (integers) of π are divided into four classes:

- *singletons*: elements of the singleton blocks;
- *strict openers*: smallest elements of the nonsingleton blocks;
- *strict closers*: largest elements of the nonsingleton blocks;
- *transients*: all other elements, i.e., nonextremal elements of nonsingleton blocks.

The sets of strict openers, strict closers, singletons, and transients of π will be denoted by $\mathcal{O}(\pi)$, $\mathcal{C}(\pi)$, $\mathcal{S}(\pi)$, and $\mathcal{T}(\pi)$, respectively. Obviously we have

$$\operatorname{open}(\pi) = \mathcal{O}(\pi) \cup \mathcal{S}(\pi), \quad \operatorname{clos}(\pi) = \mathcal{C}(\pi) \cup \mathcal{S}(\pi), \quad \mathcal{S}(\pi) = \operatorname{open}(\pi) \cap \operatorname{clos}(\pi).$$

The 4-tuple $(\mathcal{O}(\pi), \mathcal{C}(\pi), \mathcal{S}(\pi), \mathcal{T}(\pi))$ is called the *type* of π . For instance, if $\pi = 35/246/1/78$, then

$$\mathcal{O}(\pi) = \{2, 3, 7\}, \quad \mathcal{C}(\pi) = \{5, 6, 8\}, \quad \mathcal{S}(\pi) = \{1\}, \quad \text{and} \quad \mathcal{T}(\pi) = \{4\}.$$

We define a *partial order* on blocks B_i 's as follows: $B_i > B_j$ if all the letters of B_i are greater than those of B_j —in other words, if the opener of B_i is greater than the closer of B_j .

DEFINITION 2.5. For a permutation σ of $[n]$, the pair (i, j) is an inversion if $1 \leq i < j \leq n$ and $\sigma(i) > \sigma(j)$. Let $\text{inv } \sigma$ be the number of inversions in σ and

$$\text{cinv } \sigma = \binom{n}{2} - \text{inv } \sigma.$$

By convention, for any ordered set partition π , we put $\text{Inv } \pi = \text{inv}(\text{perm}(\pi))$ and $\text{cInv } \pi = \text{cinv}(\text{perm}(\pi))$.

DEFINITION 2.6. A block inversion in π is a pair (i, j) such that $i < j$ and $B_i > B_j$. We denote by $\text{bInv } \pi$ the number of block inversions in π . We also set $\text{cbInv} = \binom{k}{2} - \text{bInv}$.

Let w_i be the index of the block (counting from left to right) containing i , namely, the integer j such that $i \in B_j$. Following Steingrímsson [18], for $1 \leq i \leq n$ we define ten coordinate statistics on $\pi \in \mathcal{OP}_n^k$:

$$\begin{aligned} \text{ros}_i(\pi) &= \#\{j \in \text{open}(\pi) \mid i > j, w_j > w_i\}, \\ \text{rob}_i(\pi) &= \#\{j \in \text{open}(\pi) \mid i < j, w_j > w_i\}, \\ \text{rcs}_i(\pi) &= \#\{j \in \text{clos}(\pi) \mid i > j, w_j > w_i\}, \\ \text{rcb}_i(\pi) &= \#\{j \in \text{clos}(\pi) \mid i < j, w_j > w_i\}, \\ \text{los}_i(\pi) &= \#\{j \in \text{open}(\pi) \mid i > j, w_j < w_i\}, \\ \text{lob}_i(\pi) &= \#\{j \in \text{open}(\pi) \mid i < j, w_j < w_i\}, \\ \text{lcs}_i(\pi) &= \#\{j \in \text{clos}(\pi) \mid i > j, w_j < w_i\}, \\ \text{lcb}_i(\pi) &= \#\{j \in \text{clos}(\pi) \mid i < j, w_j < w_i\}, \end{aligned}$$

and let $\text{rsb}_i(\pi)$ (resp., $\text{lsb}_i(\pi)$) be the number of blocks B in π to the right (resp., left) of the block containing i such that the opener of B is smaller than i and the closer of B is greater than i . Then define ros , rob , rcs , rcb , lob , los , lcs , lcb , lsb , and rsb as the sum of their coordinate statistics, e.g.,

$$\text{ros} = \sum_i \text{ros}_i.$$

Remark 2.7. Note that ros is the abbreviation of “right, opener, smaller,” while lcb is the abbreviation of “left, closer, bigger,” etc.

Given an ordered set partition π , let π^r be the ordered set partition obtained from π by reversing the order of the blocks. This turns a left (resp., right) opener into a right (resp., left) opener, and likewise for the closers. Moreover, let π^c be the ordered set partition obtained by complementing each of the letters in π , that is, by replacing the letter i by $n + 1 - i$. Then, it is easy to see that $\text{rob}(\pi^c) = \text{rcs}(\pi)$ and $\text{ros}(\pi^c) = \text{rcb}(\pi)$, and likewise for the left and closer statistics. Thus the eight statistics obtained by independently varying left/right, opener/closer, and smaller/bigger fall into only two categories when it comes to their distribution on ordered partitions. One

of these categories consists of rob, lob, rcs, and lcs, and the other contains ros, los, rcb, and lcb. Note that these results are completely false on the unordered set partitions.

For instance, we give the values of the coordinate statistics computed on the ordered partition $\pi = 6\ 8/5/1\ 4\ 7/3\ 9/2$:

$$\begin{array}{rcccccccc} \pi = & 6\ 8 & / & 5 & / & 1\ 4\ 7 & / & 3\ 9 & / & 2 \\ \text{los}_i : & 0\ 0 & / & 0 & / & 0\ 0\ 2 & / & 1\ 3 & / & 1 \\ \text{ros}_i : & 4\ 4 & / & 3 & / & 0\ 2\ 2 & / & 1\ 1 & / & 0 \\ \text{lob}_i : & 0\ 0 & / & 1 & / & 2\ 2\ 0 & / & 2\ 0 & / & 3 \\ \text{rob}_i : & 0\ 0 & / & 0 & / & 2\ 0\ 0 & / & 0\ 0 & / & 0 \\ \text{lcs}_i : & 0\ 0 & / & 0 & / & 0\ 0\ 1 & / & 0\ 3 & / & 0 \\ \text{rcs}_i : & 2\ 3 & / & 1 & / & 0\ 1\ 1 & / & 1\ 1 & / & 0 \\ \text{lcb}_i : & 0\ 0 & / & 1 & / & 2\ 2\ 1 & / & 3\ 0 & / & 4 \\ \text{rcb}_i : & 2\ 1 & / & 2 & / & 2\ 1\ 1 & / & 0\ 0 & / & 0 \\ \text{lsb}_i : & 0\ 0 & / & 0 & / & 0\ 0\ 1 & / & 1\ 0 & / & 1 \\ \text{rsb}_i : & 2\ 1 & / & 2 & / & 0\ 1\ 1 & / & 0\ 0 & / & 0 \end{array}$$

Note that there are four block inversions: $\{6, 8\} > \{5\}$, $\{6, 8\} > \{2\}$, $\{5\} > \{2\}$, and $\{3, 9\} > \{2\}$, and thus $\text{bInv } \pi = 4$. Moreover, $\text{perm}(\pi) = 54132$ and thus $\text{Inv}(\pi) = 8$.

Inspired by the statistic mak on the permutations in [6], Steingrímsson introduced its analogue on $\mathcal{OP}_n^k$ as follows:

$$(2.6) \quad \text{mak} = \text{ros} + \text{lcs},$$

$$(2.7) \quad \text{lmak} = n(k-1) - [\text{los} + \text{rcs}],$$

$$(2.8) \quad \text{mak}' = \text{lob} + \text{rcb},$$

$$(2.9) \quad \text{lmak}' = n(k-1) - [\text{lcb} + \text{rob}].$$

The following result due to Ksavlouf and Zeng [10] permit us to reduce the original conjectures in [18] almost by half. For completeness, we include a more straightforward proof.

PROPOSITION 2.8. *On $\mathcal{OP}_n^k$ the following functional identities hold:*

$$\text{mak} = \text{lmak}' \quad \text{and} \quad \text{mak}' = \text{lmak}.$$

Proof. Let $i \in [n]$. For any $\pi \in \mathcal{OP}_n^k$ the value $(\text{los}_i + \text{lob}_i)\pi$ (resp., $(\text{ros}_i + \text{rob}_i)\pi$) is equal to the number of blocks on the left (resp., right) of the block containing i , so $(\text{los}_i + \text{lob}_i + \text{ros}_i + \text{rob}_i)\pi = k-1$. Similarly, we have $(\text{lcs}_i + \text{lcb}_i + \text{rcs}_i + \text{rcb}_i)\pi = k-1$. Summing over all $i \in [n]$ yields that $\text{los} + \text{lob} + \text{ros} + \text{rob} = \text{lcs} + \text{lcb} + \text{rcs} + \text{rcb} = n(k-1)$. The proposition is then equivalent to $\text{lob} + \text{los} = \text{lcb} + \text{lcs}$, which is obvious. $\square$

Let $\mathcal{OP}^k := \bigcup_{n \geq k} \mathcal{OP}_n^k$ be the set of all ordered set partitions with k blocks. Define also the statistic cinvLSB on $\mathcal{OP}^k$ by

$$(2.10) \quad \text{cinvLSB} := \text{lsb} + \text{cbInv} + \binom{k}{2}.$$

Consider the generating function of ordered partitions with k blocks,

$$(2.11) \quad \phi_k(a; x, y, t, u) := \sum_{\pi \in \mathcal{OP}^k} x^{(\text{mak} + \text{bInv})\pi} y^{\text{cinvLSB } \pi} t^{\text{Inv } \pi} u^{\text{cInv } \pi} a^{|\pi|},$$

and its variant by replacing mak by lmak,

$$(2.12) \quad \varphi_k(a; x, y, t, u) := \sum_{\pi \in \mathcal{OP}^k} x^{(\text{lmak} + \text{bInv})\pi} y^{\text{cinvLSB } \pi} t^{\text{Inv } \pi} u^{\text{cInv } \pi} a^{|\pi|},$$

where $|\pi| = n$ if π is an ordered partition of $[n]$.

One of the main results of this paper is the following theorem, which in particular shows that the above two generating functions are identical.

THEOREM 2.9. *We have*

$$(2.13) \quad \phi_k(a; x, y, t, u) = \frac{a^k (xy)^{\binom{k}{2}} [k]_{tx,uy}!}{\prod_{i=1}^k (1 - a[i]_{x,y})},$$

$$(2.14) \quad \varphi_k(a; x, y, t, u) = \frac{a^k (xy)^{\binom{k}{2}} [k]_{tx,uy}!}{\prod_{i=1}^k (1 - a[i]_{x,y})}.$$

The proof of this theorem will be given in sections 4 and 5. We first show how to derive Euler–Mahonian statistics on ordered set partitions from the above theorem.

By (2.11) and (2.12) we have

$$\begin{aligned} \sum_{\pi \in \mathcal{OP}^k} q^{(\text{mak} + \text{bInv})\pi} a^{|\pi|} &= \phi_k(a; q, 1, 1, 1), \\ \sum_{\pi \in \mathcal{OP}^k} q^{(\text{lmak} + \text{bInv})\pi} a^{|\pi|} &= \varphi_k(a; q, 1, 1, 1), \\ \sum_{\pi \in \mathcal{OP}^k} q^{\text{cinvLSB } \pi} a^{|\pi|} &= \phi_k(a; 1, q, 1, 1) = \varphi_k(a; 1, q, 1, 1). \end{aligned}$$

Theorem 2.9 implies that the right-hand sides of the above three identities are all equal to

$$(2.15) \quad \frac{a^k q^{\binom{k}{2}} [k]_q!}{\prod_{i=1}^k (1 - a[i]_q)} = \sum_{n \geq k} [k]_q! S_q(n, k) a^n,$$

where the last equality follows directly from (1.4). Thus we have proved the following result, which was conjectured by Steingrímsson [18].

THEOREM 2.10. *The following inversion-like statistics are Euler–Mahonian:*

$$\text{mak} + \text{bInv}, \quad \text{lmak} + \text{bInv}, \quad \text{cinvLSB}.$$

In other words, the generating functions of the above statistics over $\mathcal{OP}_n^k$ are all equal to $[k]_q! S_q(n, k)$.

Similarly, we have

$$\begin{aligned} \sum_{\pi \in \mathcal{OP}^k} q^{(\text{mak} + \text{bInv} - \text{inv} + \text{cinv})\pi} a^{|\pi|} &= \phi_k(a; q, 1, 1/q, q), \\ \sum_{\pi \in \mathcal{OP}^k} q^{(\text{lmak} + \text{bInv} - \text{inv} + \text{cinv})\pi} a^{|\pi|} &= \varphi_k(a; q, 1, 1/q, q), \\ \sum_{\pi \in \mathcal{OP}^k} q^{(\text{cinvLSB} + \text{inv} - \text{cinv})\pi} a^{|\pi|} &= \phi_k(a; 1, q, q, 1/q) = \varphi_k(a; 1, q, q, 1/q), \end{aligned}$$

and the three right-hand sides are all equal to (2.15). In other words, we have the following result.

THEOREM 2.11. *The following statistics are Euler–Mahonian:*

$$\text{mak} + \text{bInv} - (\text{inv} - \text{cinv}), \quad \text{lak} + \text{bInv} - (\text{inv} - \text{cinv}), \quad \text{cinvLSB} + (\text{inv} - \text{cinv}).$$

As a further consequence of Theorem 2.9, we can give an alternative proof of the following “hard” combinatorial interpretations for q -Stirling numbers of the second kind. According to Wachs and White [20], a statistic on $\mathcal{P}_n^k$, whose generating function equals the q -Stirling number $S_q(n, k)$, is called “hard” if it is difficult to show that its generating function satisfies the recurrence relation (1.3).

COROLLARY 2.12. *We have*

$$S_q(n, k) = \sum_{\pi \in \mathcal{P}_n^k} q^{\text{mak } \pi} = \sum_{\pi \in \mathcal{P}_n^k} q^{\text{lak } \pi} = \sum_{\pi \in \mathcal{P}_n^k} q^{\text{lsb } \pi + \binom{k}{2}}.$$

Remark 2.13. The first interpretation was proved by Ksavrelof and Zeng [10], while the second is due to Wachs and White [20] and the third interpretation was first proved by Stanton (see [20]).

Proof. An unordered set partition can be identified with an ordered set partition without inversion, i.e., $\mathcal{P}^k = \{\pi \in \mathcal{OP}^k \mid \text{Inv } \pi = 0\}$. Since the statistic bInv vanishes on $\mathcal{P}^k$, we derive from (2.11) and (2.12) that

$$\begin{aligned} \sum_{\pi \in \mathcal{P}^k} q^{\text{mak } \pi} a^{|\pi|} &= \phi_k(a; q, 1, 0, 1), \\ \sum_{\pi \in \mathcal{P}^k} q^{\text{lak } \pi} a^{|\pi|} &= \varphi_k(a; q, 1, 0, 1). \end{aligned}$$

Now, by definition (2.10), the identity $\text{cinvLSB} = \text{lsb} + 2\binom{k}{2}$ holds on $\mathcal{P}^k$. It then follows from (2.11) that

$$\sum_{\pi \in \mathcal{P}^k} q^{\binom{k}{2} + \text{lsb } \pi} a^{|\pi|} = q^{-\binom{k}{2}} \phi_k(a; 1, q, 0, 1).$$

Now, applying Theorem 2.9 we see that the right-hand sides of the above three identities are equal to $\sum_{n \geq k} S_q(n, k) a^n$ in view of (2.15). $\square$

3. Ordered partitions and Motzkin paths.

3.1. Encoding ordered partitions by weighted Motzkin paths. Recall that a Motzkin path of length n is a path $\gamma = (\gamma_0, \gamma_1, \dots, \gamma_n)$ from $\gamma_0 = (0, 0)$ to $\gamma_n = (n, 0)$ in the first quadrant with unit steps $\gamma_i - \gamma_{i-1} = (1, 0)$, $(1, 1)$, or $(1, -1)$, which are called East, Northeast, and Southeast, respectively. For convenience, we will distinguish three kinds of East steps, E , $\overline{E}$, and $\widetilde{E}$, and two kinds of Northeast steps, NE and $\overline{NE}$. The weight of a step at height h is a_h (resp., $\bar{a}_h$, c_h , b'_h , b''_h , and b_h''') if it is NE (resp., $\overline{NE}$, SE , E , $\overline{E}$, and $\widetilde{E}$).

Consider the weighted Motzkin paths with six kinds of steps and weights defined by the following array:

Step	NE	$\overline{NE}$	E	$\overline{E}$	$\widetilde{E}$	SE
Weight	$a_h = h + 1$	$\bar{a}_h = h + 1$	$b_h = h$	$\bar{b}_h = h$	$\widetilde{b}_h = h + 1$	$c_h = h$

A *Meixner diagram* of length n is a pair $h = (\omega, \xi)$, where ω is a Motzkin path of length n and $\xi = (\xi_i)_{1 \leq i \leq n}$ is a sequence of integers such that if the i th step of ω is of height h , then

$$\begin{aligned} 1 \leq \xi_i \leq h+1 & \quad \text{if the step is } NE, \overline{NE}, \text{ or } \widetilde{E}, \\ 2 \leq \xi_i \leq h+1 & \quad \text{if the step is } E, \overline{E}, \text{ or } SE. \end{aligned}$$

We denote by Γ_n the set of *Meixner diagrams* of length n .

There is a classical bijection due to Françon and Viennot [7] (see also [19, Chapter II-38]) between the symmetric group S_n and a set of weighted Motzkin paths of length n , called *Laguerre diagrams*. We shall adapt this classical bijection to give a bijection between $\underline{S}_n$ and Γ_n .

FIG. 1. A *Meixner diagram* of length 9.

Let $h = (\omega, \xi) \in \Gamma_n$. We construct a sequence of words w_i on the alphabet $\{-\} \cup [i]$, $i = 0 \dots n$, satisfying the following conditions:

- (a) for $i \in [n]$, the number of occurrences of $-$ in w_{i-1} is equal to $h_i + 1$, where h_i is the height of the i th step of ω ;
- (b) for each i , $0 \leq i \leq n$, the first letter of the word w_i is the symbol $-$;

and defined by induction as follows:

1. $w_0 = -$;
2. for $i \in [n]$, the word w_i is obtained from w_{i-1} by replacing the ξ_i th occurrences of $-$ (from left to right) in w_{i-1} by i (resp., $-i$, $-\underline{i}$, i , $\underline{i}$, $-i$) if the i th step of ω is SE (resp., NE , $\overline{NE}$, E , $\overline{E}$, $\widetilde{E}$).

It is clear that w_0 satisfies (a) and (b). Now, let $i \in [n]$ and suppose that $w_0, \dots, w_{i-1}$ are defined and that they satisfy the conditions (a) and (b). The definition of a path diagram and condition (a) allow us to construct w_i thanks to condition (2). Step 2 shows also that w_i satisfy conditions (a) and (b). Then the word w_n has only one occurrence of $-$ in the beginning. We then replace it by $n+1$. We can identify such permutations with underlined permutations on $[n]$ by deleting the first letter.

For instance, if h is the Meixner diagram in Figure 1, the step-by-step construction of $\phi(h)$ goes as follows:

$$\begin{aligned} w_0 &= -, & w_1 &= -1-, & w_2 &= -\underline{2}-1-, & w_3 &= -\underline{2}-31-, & w_4 &= -\underline{2}-314-, \\ w_5 &= -\underline{2}-314-5-, & w_6 &= -\underline{2}-314-5\underline{6}-, & w_7 &= -\underline{2}-314-5\underline{6}7, \\ w_8 &= -\underline{2}-31485\underline{6}7, & w_9 &= -\underline{2}931485\underline{6}7. \end{aligned}$$

Hence $\phi(h) = \underline{2}931485\underline{6}7$.

As in [15, 19, 3], we have the following result. The proof is left to the reader.

THEOREM 3.1. *The application ϕ is a bijection between Γ_n and $\underline{S}_n$. Moreover if $h = (\omega, \xi) \in \Gamma_n$ and $\sigma = \phi(h) \in \underline{S}_n$, then for $1 \leq i \leq n$*

- (a) *$i \in \text{VA}(\sigma)$ (resp., $\underline{\text{VA}}(\sigma)$, $\underline{\text{DA}}(\sigma)$, $\underline{\text{DA}}(\sigma)$, $\text{DD}(\sigma)$, $\text{PE}(\sigma)$) if and only if the i th step of ω is NE (resp., $\overline{NE}$, E , $\overline{E}$, $\tilde{E}$, SE);*
 (b) *$\text{rsg}_i(\sigma) = h_i + 1 - \xi_i$ and*

$$\begin{cases} \text{lsg}_i(\sigma) = \xi_i - 1 & \text{if the } i\text{th step is NE, } \overline{NE}, \text{ or } \tilde{E}; \\ \text{lsg}_i(\sigma) = \xi_i - 2 & \text{if the } i\text{th step is E, } \overline{E}, \text{ or SE.} \end{cases}$$

Theorem 2.1 then follows immediately from Theorem 3.1 by applying Flajolet's combinatorial theorem of continued fractions [4].

3.2. A continued fraction expansion. The recurrence (1.3) is equivalent to

$$\sum_{n \geq k} S_q(n, k) z^n = \frac{z^k}{(1-z)(1-[2]_q z) \cdots (1-[k]_q z)}.$$

Let $[b; n]_q! = b(b+q) \cdots (b+q+\cdots+q^{n-1})$. Then

$$(3.1) \quad \sum_{n, k} [b; k]_q! S_q(n, k) u^k z^n = \sum_{k \geq 0} \frac{[b; k]_q! u^k z^k}{(1-z)(1-[2]_q z) \cdots (1-[k]_q z)}.$$

Using the method in [23], we can derive an explicit continued fraction expansion of the last expression.

THEOREM 3.2. *We have*

$$\sum_{n, k} [b; k]_q! S_q(n, k) u^k z^n = \frac{1}{1 - b_0 z - \frac{\lambda_1 z^2}{1 - b_1 z - \frac{\lambda_2 z^2}{\ddots}}},$$

where

$$(3.2) \quad \begin{cases} b_n = uq^n(b+q+\cdots+q^n) + [n]_q(1+uq^n), & n \geq 0, \\ \lambda_n = uq^{n-1}(b+q+\cdots+q^{n-1})[n]_q(1+uq^n), & n \geq 1. \end{cases}$$

Proof. Let $f(b, z) := \sum_{n, k} [b; k]_q! S_q(n, k) u^k z^n$. Then it is easy to see that f satisfies the following functional equation:

$$(3.3) \quad f(b, z) = 1 + \frac{ubz}{1-z} f\left(\frac{b}{q} + 1, \frac{qz}{1-z}\right).$$

Suppose that

$$f(b, z) = \frac{1}{1 - \frac{c_1(b)z}{1 - \frac{c_2(b)z}{\ddots}}}.$$

By contraction from the 1st row we have

$$f(b, z) = 1 + \frac{c_1(b)z}{1 - (c_1(b) + c_2(b))z - \frac{c_2(b)c_3(b)z^2}{\ddots}}.$$

By contraction from the second row we have

$$(3.4) \quad f(b, z) = \frac{1}{1 - c_1(b)z - \frac{c_1(b)c_2(b)z^2}{1 - (c_2(b) + c_3(b))z - \frac{c_3(b)c_4(b)z^2}{\ddots}}}.$$

It follows that

$$\frac{ubz}{1-z} f\left(\frac{b}{q} + 1, \frac{qz}{1-z}\right) = \frac{ubz}{1 - (qc_1(b/q + 1) + 1)z - \frac{c_1(b/q + 1)c_2(b/q + 1)q^2 z^2}{\ddots}}.$$

Hence

$$\begin{aligned} c_1(b) &= ub, \\ c_1(b) + c_2(b) &= qc_1(b/q + 1) + 1 \implies c_2(b) = uq + 1, \\ c_2(b)c_3(b) &= c_1(b/q + 1)c_2(b/q + 1)q^2 \implies c_3(b) = u(b + q)q, \\ c_3(b) + c_4(b) &= 1 + qc_2(b/q + 1) + qc_3(b/q + 1) \implies c_4(b) = (1 + q)(1 + uq^2), \\ c_4(b)c_5(b) &= q^2 c_3(b/q + 1)c_4(b/q + 1) \implies c_5(b) = uq^2(b + q + q^2). \end{aligned}$$

This implies immediately by induction that

$$\begin{aligned} c_{2i+1}(b) &= uq^i(b + q + \cdots + q^i), \quad i \geq 0, \\ c_{2i}(b) &= [i]_q(1 + uq^i), \quad i \geq 1. \end{aligned}$$

Substituting these in (3.4) yields the desired result. $\square$

Note that when $b = 1$ Theorem 3.2 reduces to Lemma 2.2.

4. Ordered set partitions and walks in digraphs.

4.1. Encoding ordered set partitions by walk diagrams. Let $\pi = B_1/B_2/\cdots/B_k$ be an ordered partition of $[n]$ and i an integer in $[n]$. The restriction $B_j \cap [i]$ of a block B_j to $[i]$ is said to be *active* if $B_j \neq [i]$ and $B_j \cap [i] \neq \emptyset$, and *complete* if $B_j \subseteq [i]$. We define the *trace* of the ordered partition π on $[i]$ as an ordered partition $T_i(\pi)$ on $[i]$ with two kinds of blocks, active or complete, i.e.,

$$T_i(\pi) = B_1(\leq i)/B_2(\leq i)/\cdots/B_k(\leq i),$$

where $B_j(\leq i)$ is the complete or active block $B_j \cap [i]$, while empty sets are omitted. The sequence $(T_i(\pi))_{1 \leq i \leq n}$ is called the *trace* of the ordered set partition π .

DEFINITION 4.1. Let $D = (V, E)$ be the digraph on $V = \mathbb{N}^2$ with edge set E defined by

$$E = \{(u, v) \in V^2 \mid u = v = (x, y) \text{ with } y > 0 \text{ or } u - v = (0, 1), (1, 0), (1, -1)\}.$$

For any integer $k \geq 0$, let $V_k = \{(i, j) \in V \mid i + j \leq k\}$ and let D_k be the restriction of the digraph D on V_k .

An illustration of D_k is given in Figure 2.

Clearly there are four types of edges in D . For convenience, an edge (u, v) is called

- *North* if $v = u + (0, 1)$;
- *East* if $v = u + (1, 0)$;

FIG. 2. The digraph D_k .

- *Southeast* if $v = u + (1, -1)$;
- *Null* if $v = u$.

DEFINITION 4.2. A walk of depth k and length n in D is a sequence $\omega = (\omega_0, \omega_1, \dots, \omega_n)$ of vertices in D such that $\omega_0 = (0, 0)$, $\omega_n = (k, 0)$ and (ω_i, ω_{i+1}) is an edge of D for $i = 0, \dots, n-1$. Moreover, the abscissa and ordinate of ω_i are called the abscissa and height of the step (ω_i, ω_{i+1}) , respectively. Let Ω_n^k be the set of walks of depth k and length n and let Ω^k be the set of walks of depth k .

We can visualize a walk ω by drawing a segment from ω_{i-1} to ω_i in the xy plane. For instance, if

$$\omega = ((0, 0), (0, 1), (0, 2), (0, 3), (0, 3), (0, 3), (1, 3), (2, 2), (3, 1), (4, 1), (5, 0)),$$

then the illustration is given in Figure 3.

FIG. 3. A walk in Ω_{10}^5 with two successive Null steps from $(0, 3)$ to $(0, 3)$.

DEFINITION 4.3. A walk diagram of depth k and length n is a pair (ω, ξ) , where $\omega = ((p_i, q_i))_{0 \leq i \leq n}$ is a walk in Ω_n^k and $\xi = (\xi_i)_{1 \leq i \leq n}$ is a sequence of integers such that

- $1 \leq \xi_i \leq q_{i-1}$ if the i th step of ω is Null or Southeast,
- $1 \leq \xi_i \leq p_{i-1} + q_{i-1} + 1$ if the i th step of ω is North or East.

Denote by Δ_n^k the set of walk diagrams of depth k and length n and by $\Delta^k = \bigcup_{n \geq 0} \Delta_n^k$ the set of walk diagrams of depth k . The following is the main result of this section.

THEOREM 4.4. *For each $n \geq k \geq 1$, there is a bijection $\psi : \Delta_n^k \rightarrow \mathcal{OP}_n^k$ such that if $\psi((\omega, \xi)) = \pi$ for $(\omega, \xi) \in \Delta_n^k$, then*

(a) *if the i th step of ω is North (resp., East), then $i \in \mathcal{O}(\pi)$ (resp., $i \in \mathcal{S}(\pi)$) and*

$$\begin{aligned} (\text{lcs} + \text{rcs})_i(\pi) &= p_{i-1}, & \text{los}_i(\pi) &= \xi_i - 1, \\ (\text{lsb} + \text{rsb})_i(\pi) &= q_{i-1}, & \text{ros}_i(\pi) &= p_{i-1} + q_{i-1} + 1 - \xi_i; \end{aligned}$$

(b) *if the i th step of ω is Southeast (resp., Null), then $i \in \mathcal{C}(\pi)$ (resp., $i \in \mathcal{T}(\pi)$) and*

$$\begin{aligned} (\text{lcs} + \text{rcs})_i(\pi) &= p_{i-1}, & \text{lsb}_i(\pi) &= \xi_i - 1, \\ (\text{lsb} + \text{rsb})_i(\pi) &= q_{i-1} - 1, & \text{rsb}_i(\pi) &= q_{i-1} - \xi_i. \end{aligned}$$

Proof. Given a walk diagram $(\omega, \xi) \in \Delta_n^k$, we define the ordered partition $\pi = \psi((\omega, \xi)) \in \mathcal{OP}_n^k$ by constructing successively its traces $T_0 := \emptyset, T_1, \dots, T_n := \pi$. For $1 \leq i \leq n$, assume that $T_{i-1} = B_{i1}/B_{i2}/\dots/B_{i\ell}$ with $\ell = p_{i-1} + q_{i-1}$. Then there are $\ell + 1$ places to insert an active block with i as an opener or a singleton block $\{i\}$: before B_{i1} , between B_{ij} and $B_{i(j+1)}$, where $1 \leq j \leq \ell - 1$, or after $B_{i\ell}$. There are q_{i-1} places to insert i as a transient or closer: in any of the q_{i-1} active blocks. We label these places from left to right. We extend T_{i-1} to T_i as follows:

- if the i th step of ω is North (resp., East), then we create an active block (resp., singleton) with i in T_{i-1} at the ξ_i th place and close it if the step is East;
- if the i th step of ω is Null (resp., Southeast), then we insert i as a transient (resp., closer) in the ξ_i th active block of T_{i-1} .

Consider the walk diagram $h = (\omega, \xi) \in \Omega_{10}^5$, where ω is the walk in Figure 3 and $\xi = (1, 2, 1, 2, 1, 1, 1, 2, 4, 1)$; then the step-by-step construction of $\psi(h)$ goes as follows:

i	ω_i	step_i	ξ_i	T_i
0	(0, 0)			$\emptyset$
1	(0, 1)	North	1	$\{1, \dots\}$
2	(0, 2)	North	2	$\{1, \dots\} - \{2, \dots\}$
3	(0, 3)	North	1	$\{3, \dots\} - \{1, \dots\} - \{2, \dots\}$
4	(0, 3)	Null	2	$\{3, \dots\} - \{1, 4, \dots\} - \{2, \dots\}$
5	(0, 3)	Null	1	$\{3, 5, \dots\} - \{1, 4, \dots\} - \{2, \dots\}$
6	(1, 3)	East	1	$\{6\} - \{3, 5, \dots\} - \{1, 4, \dots\} - \{2, \dots\}$
7	(2, 2)	Southeast	1	$\{6\} - \{3, 5, 7\} - \{1, 4, \dots\} - \{2, \dots\}$
8	(3, 1)	Southeast	2	$\{6\} - \{3, 5, 7\} - \{1, 4, \dots\} - \{2, 8\}$
9	(4, 1)	East	4	$\{6\} - \{3, 5, 7\} - \{1, 4, \dots\} - \{9\} - \{2, 8\}$
10	(5, 0)	Southeast	1	$\{6\} - \{3, 5, 7\} - \{1, 4, 10\} - \{9\} - \{2, 8\}$

Thus $\psi(h) = 6/3 \ 5 \ 7/1 \ 4 \ 10/9/2 \ 8$.

To show that ψ is bijective, we construct its inverse ϕ . Given an ordered partition π in $\mathcal{OP}_n^k$ we denote by $\text{act}_i \pi$ and $\text{com}_i \pi$ the numbers of active and complete blocks in $T_i(\pi)$, respectively. Let $\omega_0(\pi) = (0, 0)$ and $\omega_i(\pi) = (\text{com}_i \pi, \text{act}_i \pi)$ for $1 \leq i \leq n$. If i is a singleton or opener, let ξ_i be the index (from left to right) of the block containing i in $T_i(\pi)$. If i is a transient or closer, let ξ_i be the index (from left to right) of the active block which will contain i in $T_i(\pi)$ among the active blocks in the trace $T_{i-1}(\pi)$. Let $\omega = (\omega_i(\pi))_{0 \leq i \leq n}$ and $\xi = (\xi_i)_{1 \leq i \leq n}$. It is readily seen that (ω, ξ) is a walk diagram in Ω_n^k and ϕ is the inverse of ψ .

It remains to check the other properties.

- (a) If the i th step of ω is North (resp., East), by construction, the element i will be an opener (resp., singleton) of the partitions T_j for $j \geq i$. Since $(\text{lcs} + \text{rcs})_i(\pi)$ (resp., $(\text{lsb} + \text{rsb})_i(\pi)$) is equal to the number of complete (resp., active) blocks in $T_{i-1}(\pi)$, we have

$$(\text{lcs} + \text{rcs})_i(\pi) = p_{i-1} \quad \text{and} \quad (\text{lsb} + \text{rsb})_i(\pi) = q_{i-1}.$$

Since $\text{los}_i \pi$ (resp., $\text{ros}_i \pi$) is the number of blocks in $T_i(\pi)$ on the left (resp., right) of the block containing i , we get $\text{los}_i(\pi) = \xi_i - 1$ and $\text{ros}_i(\pi) = p_{i-1} + q_{i-1} + 1 - \xi_i$.

- (b) If the i th step of ω is Southeast (resp., Null), by construction, the element i is a closer (resp., transient) of the ordered partition T_j for $j \geq i$. As in (a), we have $(\text{lcs} + \text{rcs})_i(\pi) = p_{i-1}$. Note that $\text{lsb}_i(\pi)$ (resp., $\text{rsb}_i(\pi)$) is equal to the number of active blocks in $T_i(\pi)$ on the left (resp., on the right) of the block containing i ; as we insert i in the ξ_i th active block in $T_{i-1}(\pi)$ among q_{i-1} active blocks, we have $\text{lsb}_i(\pi) = \xi_i - 1$ and $\text{rsb}_i(\pi) = q_{i-1} - \xi_i$. Finally we have $(\text{lsb} + \text{rsb})_i(\pi) = (\xi_i - 1) + (q_{i-1} - \xi_i) = q_{i-1} - 1$. $\square$

4.2. Generating functions of walks. Given a walk ω of finite length in D_k , define the valuation of a step (ω_i, ω_{i+1}) of abscissa p and height q by

$$(4.1) \quad v(\omega_i, \omega_{i+1}) = \begin{cases} t_1^p t_7^q [p + q + 1]_{t_5, t_6} & \text{if the step is North or East;} \\ t_2^p [q]_{t_3, t_4} & \text{if the step is Null or Southeast.} \end{cases}$$

The valuation $v(\omega)$ of ω is the product of the weights of all its steps.

Let $\mathbf{t} = (t_1, t_2, t_3, t_4, t_5, t_6, t_7)$. For $k \geq 0$, define

$$(4.2) \quad Q_k(a; \mathbf{t}) := \sum_{w \in \Omega^k} v(w) a^{|w|},$$

where $|w|$ denotes the length of the walk w .

By Theorem 4.4 one can rewrite the generating function $Q_k(a; \mathbf{t})$ of ordered partitions as

$$(4.3) \quad Q_k(a; \mathbf{t}) = \sum_{\pi \in \mathcal{OP}^k} t_1^{(\text{lcs} + \text{rcs})(\mathcal{O} \cup \mathcal{S})\pi} t_2^{(\text{lcs} + \text{rcs})(\mathcal{T} \cup \mathcal{C})\pi} t_3^{\text{rsb}(\mathcal{T} \cup \mathcal{C})\pi} \\ \times t_4^{\text{lsb}(\mathcal{T} \cup \mathcal{C})\pi} t_5^{\text{ros}(\mathcal{O} \cup \mathcal{S})\pi} t_6^{\text{los}(\mathcal{O} \cup \mathcal{S})\pi} t_7^{(\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S})\pi} a^{|\pi|}.$$

It is obvious that the number of vertices of D_k is equal to

$$\widehat{k} := 1 + 2 + \cdots + (k + 1) = \frac{(k + 1)(k + 2)}{2}.$$

We label the vertices of D_k by their ranks in the following total ordering: $(i, j) \leq (i', j')$ if and only if $i + j < i' + j'$ or $(i + j = i' + j'$ and $j \geq j')$. Thus $v_1 = (0, 0)$, $v_2 = (0, 1)$, $v_3 = (1, 0)$, $v_4 = (0, 2)$, $v_5 = (1, 1)$, $v_6 = (2, 0), \dots, v_{\widehat{k}} = (k, 0)$.

The *adjacency matrix* of D_k relative to the valuation $\mathbf{v}$ is the $\widehat{k} \times \widehat{k}$ matrix A_k defined by

$$A_k(i, j) = \begin{cases} \mathbf{v}(v_i, v_j) & \text{if } (v_i, v_j) \text{ is an edge of } D_k; \\ 0 & \text{otherwise.} \end{cases}$$

Applying the transfer-matrix method (see, e.g., [17, Theorem 4.7.2]), we derive

$$(4.4) \quad Q_k(a; \mathbf{t}) = \frac{(-1)^{1+\widehat{k}} \det(I_k - aA_k; \widehat{k}, 1)}{\det(I_k - aA_k)},$$

where $(B; i, j)$ denotes the matrix obtained by removing the i th row and j th column of B and I_k is the $\widehat{k} \times \widehat{k}$ identity matrix.

For instance, when $k = 2$, we have

$$A_2 = \left(\begin{array}{ccc|ccc} 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & t_7 [2]_{t_5, t_6} & t_7 [2]_{t_5, t_6} & 0 \\ 0 & 0 & 0 & 0 & t_1 [2]_{t_5, t_6} & t_1 [2]_{t_5, t_6} \\ \hline 0 & 0 & 0 & [2]_{t_3, t_4} & [2]_{t_3, t_4} & 0 \\ 0 & 0 & 0 & 0 & t_2 & t_2 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{array} \right)$$

and

$$Q_2(a; \mathbf{t}) = -\frac{\det(I_2 - aA_2; 6, 1)}{\det(I_2 - aA_2)} = \frac{a^2 [2]_{t_5, t_6} (at_2 t_7 + t_1 (1 - a[2]_{t_3, t_4}))}{(1 - a)(1 - a[2]_{t_3, t_4})(1 - at_2)}.$$

In order to prove Theorem 2.9 it is sufficient to evaluate the following special cases of $Q_k(a; \mathbf{t})$:

$$(4.5) \quad f_k(a; x, y, t, u) = Q_k(a; x, x, x, y, t, u, y),$$

$$(4.6) \quad g_k(a; x, y, t, u) = Q_k(a; 1, x, 1, xy, t, u, y).$$

Invoking (4.3) and remarking that $\text{Inv} = \text{ros}(\mathcal{O} \cup \mathcal{S})$ and $\text{cInv} = \text{los}(\mathcal{O} \cup \mathcal{S})$, we have the combinatorial interpretations

$$f_k(a; x, y, t, u) = \sum_{\pi \in \mathcal{OP}^k} x^{(\text{lcs} + \text{rcs})\pi + \text{rsb}(\mathcal{T} \cup \mathcal{C})} \pi_y^{((\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}))} \pi_t^{\text{Inv}} \pi_u^{\text{cInv}} \pi_a^{|\pi|},$$

$$g_k(a; x, y, t, u) = \sum_{\pi \in \mathcal{OP}^k} x^{(\text{lcs} + \text{rcs} + \text{lsb})(\mathcal{T} \cup \mathcal{C})} \pi_y^{((\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}))} \pi_t^{\text{Inv}} \pi_u^{\text{cInv}} \pi_a^{|\pi|}.$$

In the next section, we shall prove the following result.

THEOREM 4.5. *For $k \geq 1$, we have*

$$(4.7) \quad f_k(a; x, y, t, u) = \frac{a^k x^{\binom{k}{2}} [k]_{t, u}!}{\prod_{i=1}^k (1 - a[i]_{x, y})},$$

$$(4.8) \quad g_k(a; x, y, t, u) = \frac{a^k [k]_{t, u}!}{\prod_{i=1}^k (1 - ax^{k-i} [i]_{xy})}.$$

The f_k 's and g_k 's are closely related to the ϕ_k 's and φ_k 's, respectively. To explain a relation between these generating functions, we need the following lemma.

LEMMA 4.6. *The following functional identities hold on $\mathcal{OP}_n^k$:*

$$\begin{aligned} \text{mak} + \text{bInv} &= (\text{lcs} + \text{rcs}) + \text{rsb}(\mathcal{T} \cup \mathcal{C}) + \text{Inv}, \\ \text{lmak} + \text{bInv} &= n(k-1) - (\text{lcs} + \text{rcs})(\mathcal{T} \cup \mathcal{C}) - \text{lsb}(\mathcal{T} \cup \mathcal{C}) - \text{cInv}, \\ \text{cinvLSB} &= (\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}) + \text{Inv} + 2 \text{cInv}. \end{aligned}$$

Proof. Since $\text{bInv} = \text{rcs}(\mathcal{O} \cup \mathcal{S})$ and $\text{Inv} = \text{ros}(\mathcal{O} \cup \mathcal{S})$ we can rewrite

$$\begin{aligned} \text{mak} + \text{bInv} &= \text{lcs} + \text{ros} + \text{rcs}(\mathcal{O} \cup \mathcal{S}) \\ &= (\text{lcs} + \text{rcs}) + \text{ros} + (\text{rcs}(\mathcal{O} \cup \mathcal{S}) - \text{rcs}) \\ &= (\text{lcs} + \text{rcs}) + \text{ros} - \text{rcs}(\mathcal{T} \cup \mathcal{C}) \\ &= (\text{lcs} + \text{rcs}) + (\text{ros} - \text{rcs})(\mathcal{T} \cup \mathcal{C}) + \text{ros}(\mathcal{O} \cup \mathcal{S}) \\ &= (\text{lcs} + \text{rcs}) + \text{rsb}(\mathcal{T} \cup \mathcal{C}) + \text{Inv} \end{aligned}$$

and

$$\begin{aligned} \text{cinvLSB} &= k(k-1) + \text{lsb} - \text{bInv} \\ &= 2(\text{Inv} + \text{cInv}) + \text{lsb} - \text{rcs}(\mathcal{O} \cup \mathcal{S}) \\ &= 2(\text{Inv} + \text{cInv}) + (\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) \\ &\quad - (\text{rcs} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}) \\ &= 2(\text{Inv} + \text{cInv}) + (\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) - \text{ros}(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}) \\ &= (\text{lsb} + \text{rsb})(\mathcal{O} \cup \mathcal{S}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}) + \text{Inv} + 2 \text{cInv}. \end{aligned}$$

Invoking (2.7) we have

$$\begin{aligned} n(k-1) - (\text{lmak} + \text{bInv}) &= (\text{los} + \text{rcs}) - \text{rcs}(\mathcal{O} \cup \mathcal{S}) \\ &= \text{los} + \text{rcs}(\mathcal{T} \cup \mathcal{C}) \\ &= \text{los}(\mathcal{O} \cup \mathcal{S}) + \text{rcs}(\mathcal{T} \cup \mathcal{C}) + \text{los}(\mathcal{T} \cup \mathcal{C}) \\ &= \text{cInv} + (\text{lcs} + \text{rcs})(\mathcal{T} \cup \mathcal{C}) + (\text{los} - \text{lcs})(\mathcal{T} \cup \mathcal{C}) \\ &= \text{cInv} + (\text{lcs} + \text{rcs})(\mathcal{T} \cup \mathcal{C}) + \text{lsb}(\mathcal{T} \cup \mathcal{C}). \end{aligned}$$

This completes the proof of Lemma 4.6. $\square$

The following lemma is an immediate consequence of Lemma 4.6.

LEMMA 4.7. *For $k \geq 1$, we have*

$$(4.9) \quad \phi_k(a; x, y, t, u) = f_k(a; x, y, txy, uy^2),$$

$$(4.10) \quad \varphi_k(a; x, y, t, u) = g_k(ax^{k-1}; 1/x, y, ty, uy^2/x).$$

Theorem 2.9 follows immediately from Theorem 4.5 and Lemma 4.7.

5. Determinantal computations. Let A'_k and A''_k be the matrices obtained from A_k by making the substitutions corresponding to (4.5) and (4.6), respectively. Now, for each $k \geq 0$, let

$$M_k = I_k - aA'_k \quad \text{and} \quad N_k = I_k - aA''_k.$$

Then we derive from (4.4), (4.5), and (4.6) that for each $k \geq 1$,

$$(5.1) \quad f_k(a; x, y, t, u) = \frac{(-1)^{1+\widehat{k}} \det(M_k; \widehat{k}, 1)}{\det M_k},$$

$$(5.2) \quad g_k(a; x, y, t, u) = \frac{(-1)^{1+\widehat{k}} \det(N_k; \widehat{k}, 1)}{\det N_k}.$$

It is not difficult to see that M_n and N_n are upper triangular matrices and to obtain then that for each $n \geq 1$

$$(5.3) \quad \det M_n = \prod_{m=1}^n \prod_{i=0}^m (1 - ax^i[m-i]_{x,y}),$$

$$(5.4) \quad \det N_n = \prod_{m=1}^n \prod_{k=0}^{n-m} (1 - ax^k[m]_{xy}).$$

The evaluation of $\det(M_n; \widehat{n}, 1)$ and $\det(N_n; \widehat{n}, 1)$ is highly nontrivial.

THEOREM 5.1. *Let $n \geq 1$ be a positive integer. Then*

$$(5.5) \quad \det(M_n; \widehat{n}, 1) = (-1)^{\binom{n}{2}} a^n x^{\binom{n}{2}} [n]_{t,u}! \prod_{m=1}^{n-1} \prod_{i=1}^m (1 - ax^i[m-i+1]_{x,y}).$$

THEOREM 5.2. *Let $n \geq 1$ be a positive integer. Then*

$$(5.6) \quad \det(N_n; \widehat{n}, 1) = (-1)^{\binom{n}{2}} a^n [n]_{t,u}! \prod_{m=1}^{n-1} \prod_{k=1}^{n-m} (1 - ax^{k-1}[m]_{xy}).$$

Note that in view of (5.1) and (5.2), the above results complete the proof of Theorem 4.5.

5.1. Proof of Theorem 5.1. By definition of the matrix M_n we have

$$M_1 = \left(\begin{array}{c|cc} 1 & -a & -a \\ \hline 0 & 1-a & -a \\ \hline 0 & 0 & 1 \end{array} \right)$$

and

$$M_2 = \left(\begin{array}{ccc|ccc} 1 & -a & -a & 0 & 0 & 0 \\ 0 & 1-a & -a & -ay(t+u) & -ay(t+u) & 0 \\ 0 & 0 & 1 & 0 & -ax(t+u) & -ax(t+u) \\ \hline 0 & 0 & 0 & 1-a(x+y) & -a(x+y) & 0 \\ 0 & 0 & 0 & 0 & 1-ax & -ax \\ 0 & 0 & 0 & 0 & 0 & 1 \end{array} \right).$$

Clearly the matrix M_n is of order $\widehat{n}$ and can be defined recursively by

$$(5.7) \quad M_0 = (1), \quad M_n = \left(\begin{array}{c|c} M_{n-1} & \overline{M}_{n-1} \\ \hline O_{n+1, \widehat{n-1}} & \widehat{M}_{n-1} \end{array} \right),$$

where $n \geq 1$,

$$(5.8) \quad \widehat{M}_{n-1} = (\delta_{ij} - ax^{i-1}[n+1-i]_{x,y}(\delta_{ij} + \delta_{i+1,j}))_{1 \leq i,j \leq n+1}$$

and $\overline{M}_{n-1}$ is the $\widehat{n-1} \times (n+1)$ matrix

$$\overline{M}_{n-1} = \left(\frac{O_{\widehat{n-2}, n+1}}{\check{M}_{n-1}} \right)$$

with the $n \times (n+1)$ matrix

$$(5.9) \quad \check{M}_{n-1} = (-ax^{i-1}y^{n-i}[n]_{t,u}(\delta_{ij} + \delta_{i+1,j}))_{1 \leq i \leq n, 1 \leq j \leq n+1}.$$

Here δ_{ij} stands for the Kronecker delta and $O_{m,n}$ denotes the $m \times n$ zero matrix.

Let

$$K_n = \widehat{n} - 1 = \frac{n(n+3)}{2},$$

and let $P_n = (M_n; \widehat{n}, 1)$, i.e., the $K_n \times K_n$ matrix obtained from M_n by deleting the $\widehat{n}$ th row and the first column. For instance, we have

$$P_1 = \begin{pmatrix} -a & -a \\ 1-a & -a \end{pmatrix}$$

and

$$P_2 = \left(\begin{array}{cc|ccc} -a & -a & 0 & 0 & 0 \\ 1-a & -a & -ay(t+u) & -ay(t+u) & 0 \\ \hline 0 & 1 & 0 & -ax(t+u) & -ax(t+u) \\ 0 & 0 & 1-a(x+y) & -a(x+y) & 0 \\ 0 & 0 & 0 & 1-ax & -ax \end{array} \right).$$

In general we can define P_n as follows:

$$P_n = \left(\frac{P_{n-1} \mid \overline{P}_{n-1}}{X_{n-1} \mid \widehat{P}_{n-1}} \right),$$

where $\overline{P}_{n-1}$ is a $K_{n-1} \times (n+1)$ matrix, X_{n-1} is a $(n+1) \times K_{n-1}$ matrix, and $\widehat{P}_{n-1}$ is an $(n+1) \times (n+1)$ matrix. We shall compute $\det P_n$ by the following well-known formula for any block matrix with an invertible square matrix A :

$$\det \left(\frac{A \mid B}{C \mid D} \right) = \det A \cdot \det (D - CA^{-1}B).$$

Since the entries of $CA^{-1}B$ are also written by minors, we guess these entries and prove it by induction (see Theorem 5.3). Thus, looking at P_2 as the block matrix composed of P_1 , X_1 , $\overline{P}_1$, and $\widehat{P}_1$, we have

$$\overline{P}_1 = \begin{pmatrix} 0 & 0 & 0 \\ -ay(t+u) & -ay(t+u) & 0 \end{pmatrix}$$

and

$$\hat{P}_1 = \begin{pmatrix} 0 & -ax(t+u) & -ax(t+u) \\ 1-a(x+y) & -a(x+y) & 0 \\ 0 & 1-ax & -ax \end{pmatrix}.$$

Since $\bar{P}_n$ is a $K_n \times (n+2)$ matrix, we can write

$$\bar{P}_n = \left(\frac{O_{K_{n-1}, n+2}}{U_n} \right),$$

where U_n is the $(n+1) \times (n+2)$ matrix composed of the last $(n+1)$ rows of $\bar{P}_n$. For $1 \leq k \leq n+2$, let

$$P_n^k = \left(\begin{array}{c|c} P_{n-1} & \bar{P}_{n-1} \\ \hline X_{n-1} & \hat{P}_{n-1}^k \end{array} \right)$$

denote the $K_n \times K_n$ matrix obtained from P_n by replacing the rightmost column with the k th column of $\bar{P}_n$. Here $\hat{P}_{n-1}^k$ is the $(n+1) \times (n+1)$ matrix obtained from $\hat{P}_{n-1}$ by replacing the rightmost column with the k th column of U_n . For example,

$$P_2^2 = \left(\begin{array}{cc|ccc} -a & -a & 0 & 0 & 0 \\ 1-a & -a & -ay(t+u) & -ay(t+u) & 0 \\ \hline 0 & 1 & 0 & -ax(t+u) & 0 \\ 0 & 0 & 1-a(x+y) & -a(x+y) & -ay^2(t^2+tu+t^2) \\ 0 & 0 & 0 & 1-ax & -axy(t^2+tu+t^2) \end{array} \right).$$

THEOREM 5.3. *Let $n \geq 1$ be a positive integer. Then we have*

$$(5.10) \quad \frac{\det P_n}{\det P_{n-1}} = (-1)^{n-1} ax^{n-1} [n]_{t,u} \prod_{i=1}^{n-1} (1 - ax^i [n-i]_{x,y})$$

and

$$(5.11) \quad \frac{\det P_n^k}{\det P_n} = ax^{\frac{(k-1)(k-2)}{2} - \frac{n(n-1)}{2}} y^{\frac{(n+1-k)(n+2-k)}{2}} [n+1]_{t,u} \begin{bmatrix} n+1 \\ k-1 \end{bmatrix}_{x,y}$$

for $1 \leq k \leq n$,

$$(5.12) \quad \frac{\det P_n^{n+1}}{\det P_n} = ay [n+1]_{t,u} [n]_{x,y},$$

and $\det P_n^{n+2} = 0$.

We first prove an elementary identity, which is obvious if it is written in a suitable manner.

LEMMA 5.4. *For $0 \leq m \leq n$,*

$$(5.13) \quad \begin{aligned} & \sum_{k=0}^m (-1)^{m-k} x^{\binom{k}{2}} y^{\binom{n-k}{2}} \begin{bmatrix} n \\ k \end{bmatrix}_{x,y} \prod_{i=0}^{k-1} \{1 - ax^i [n-i]_{x,y}\} \prod_{i=k}^{m-1} \{-ax^i [n-i]_{x,y}\} \\ &= x^{\binom{m}{2}} y^{\binom{n-m}{2}} \begin{bmatrix} n \\ m \end{bmatrix}_{x,y} \prod_{i=1}^m \{1 - ax^i [n-i]_{x,y}\}. \end{aligned}$$

Proof. Note that

$$[n]_{x,y} = y^{n-1} [n]_{x/y}, \quad \begin{bmatrix} n \\ k \end{bmatrix}_{x,y} = y^{kn-k^2} \begin{bmatrix} n \\ k \end{bmatrix}_{x/y}.$$

Since $\binom{n-k}{2} + \binom{k}{2} + kn - k^2 = \binom{n}{2}$, setting $c = ay^{n-1}$ and $q = x/y$, we can rewrite (5.13) as follows:

$$(5.14) \quad \begin{aligned} & \sum_{k=0}^m (-1)^{m-k} q^{\binom{k}{2}} \begin{bmatrix} n \\ k \end{bmatrix}_q \prod_{i=0}^{k-1} \{1 - cq^i [n-i]_q\} \prod_{i=k}^{m-1} \{-cq^i [n-i]_q\} \\ &= q^{\binom{m}{2}} \begin{bmatrix} n \\ m \end{bmatrix}_q \prod_{i=1}^m \{1 - cq^i [n-i]_q\}. \end{aligned}$$

Setting

$$X = 1 + \frac{cq^n}{1-q}, \quad Y = \frac{c}{1-q+cq^n}, \quad Z = \frac{cq^n}{1-q},$$

then $1 - cq^i [n-i]_q = X(1 - Yq^i)$ and $-cq^i [n-i]_q = Z(1 - q^{i-n})$. Hence, in (5.14) making the substitutions

$$\begin{aligned} & \prod_{i=0}^{k-1} \{1 - cq^i [n-i]_q\} = X^k (Y; q)_k, \\ & \prod_{i=1}^m \{1 - cq^i [n-i]_q\} = X^m (Yq; q)_m, \\ & \prod_{i=k}^{m-1} \{-cq^i [n-i]_q\} = (-1)^m Z^{m-k} q^{\binom{m}{2} - mn} \frac{(q^{n-m+1}; q)_m}{(q^{-n}; q)_k} \end{aligned}$$

and writing the q -binomial coefficients as

$$\begin{bmatrix} n \\ k \end{bmatrix}_q = (-1)^k q^{kn-k(k-1)/2} \frac{(q^{-n}; q)_k}{(q; q)_k}, \quad \begin{bmatrix} n \\ m \end{bmatrix}_q = (-1)^m q^{mn-m(m-1)/2} \frac{(q^{-n}; q)_m}{(q; q)_m},$$

we see, after simplifying, that identity (5.14) is equivalent to the special case $Y = c/(1 - q + cq^n)$ of the identity,

$$\sum_{k=0}^m \frac{(Y; q)_k}{(q; q)_k} Y^{m-k} = \frac{(Yq; q)_m}{(q; q)_m},$$

which can be easily verified by induction. $\square$

Proof of Theorem 5.3. We proceed by induction on n . When $n = 1$, by a direct computation we obtain $\det P_1 = a$, $\det P_1^1 = \det P_1^2 = a^2 y [2]_{t,u}$, and $\det P_1^3 = 0$. This shows the theorem is true when $n = 1$. Let n be an integer ≥ 2 . Assume the theorem is true for $n - 1$.

(i) We get

$$\det P_n = \det \left(\begin{array}{c|c} P_{n-1} & \overline{P}_{n-1} \\ \hline X_{n-1} & \widehat{P}_{n-1} \end{array} \right) = \det P_{n-1} \cdot \det \left(\widehat{P}_{n-1} - X_{n-1} P_{n-1}^{-1} \overline{P}_{n-1} \right)$$

and

$$\det P_n^k = \det \left(\begin{array}{c|c} P_{n-1} & \bar{P}_{n-1} \\ \hline X_{n-1} & \hat{P}_{n-1}^k \end{array} \right) = \det P_{n-1} \cdot \det \left(\hat{P}_{n-1}^k - X_{n-1} P_{n-1}^{-1} \bar{P}_{n-1} \right).$$

- (ii) By direct computation we can see that the (i, j) th entry of $X_{n-1} P_{n-1}^{-1} \bar{P}_{n-1}$ ($1 \leq i, j \leq n+1$) is equal to

$$\begin{cases} \frac{\det P_{n-1}^j}{\det P_{n-1}} & \text{if } i = 1, \\ 0 & \text{otherwise.} \end{cases}$$

By the induction hypothesis, the $(1, j)$ th entry of $X_{n-1} P_{n-1}^{-1} \bar{P}_{n-1}$ equals

$$(5.15) \quad \begin{cases} a x^{\binom{j-1}{2} - \binom{n-1}{2}} y^{\binom{n+1-j}{2}} [n]_{t,u} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} & \text{if } 1 \leq j \leq n-1, \\ a y [n-1]_{x,y} [n]_{t,u} & \text{if } j = n, \\ 0 & \text{if } j = n+1. \end{cases}$$

- (iii) Put $W_{n-1}^k = \hat{P}_{n-1}^k - X_{n-1} P_{n-1}^{-1} \bar{P}_{n-1}$ and $W_{n-1} = \hat{P}_{n-1} - X_{n-1} P_{n-1}^{-1} \bar{P}_{n-1}$. Then, by (i), we have $\frac{\det P_n^k}{\det P_{n-1}} = \det W_{n-1}^k$ and $\frac{\det P_n}{\det P_{n-1}} = \det W_{n-1}$. By (5.9) and (5.15), we can see that the $(1, j)$ th entry of W_{n-1}^k is

$$-a x^{\binom{j-1}{2} - \binom{n-1}{2}} y^{\binom{n+1-j}{2}} [n]_{t,u} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y}$$

for $1 \leq j \leq n$, and the $(1, n+1)$ th entry is 0 (the top row does not depend on k). It is also easy to see that the $(1, j)$ th entry of W_{n-1} is

$$-a x^{\binom{j-1}{2} - \binom{n-1}{2}} y^{\binom{n+1-j}{2}} [n]_{t,u} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y}$$

for $1 \leq j \leq n+1$.

- (iv) We claim that

$$\det W_{n-1} = (-1)^{n-1} a x^{n-1} [n]_{t,u} \prod_{i=1}^{n-1} (1 - a x^i [n-i]_{x,y}).$$

In fact, the (i, j) th entry of W_{n-1} is

$$\begin{cases} -a y^{\frac{(n-j)(n-j+1)}{2}} x^{\frac{(j-1)(j-2)}{2} - \frac{(n-1)(n-2)}{2}} [n]_{t,u} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} & \text{if } i = 1 \text{ and } 1 \leq j \leq n+1, \\ 1 - a x^{j-1} [n+1-j]_{x,y} & \text{if } i = j+1 \text{ and } 1 \leq j \leq n, \\ -a x^{j-2} [n+2-j]_{x,y} & \text{if } i = j \text{ and } 2 \leq j \leq n+1, \\ 0 & \text{otherwise.} \end{cases}$$

Thus, if we expand $\det W_{n-1}$ along the top row, then we obtain

$$\begin{aligned} \det W_{n-1} &= -a x^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u} \\ &\quad \times \sum_{j=1}^{n+1} (-1)^{j+1} y^{\frac{(n-j)(n-j+1)}{2}} x^{\frac{(j-1)(j-2)}{2}} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} \det W_{n-1}(1; j). \end{aligned}$$

If we use

$$\det W_{n-1}(1; j) = \prod_{\nu=0}^{j-2} (1 - ax^\nu[n - \nu]_{x,y}) \prod_{\nu=j-1}^{n-1} (-ax^\nu[n - \nu]_{x,y}),$$

then we obtain

$$\begin{aligned} \det W_{n-1} &= -ax^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u} \sum_{j=1}^{n+1} (-1)^{j+1} y^{\frac{(n-j)(n-j+1)}{2}} x^{\frac{(j-1)(j-2)}{2}} \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} \\ &\quad \times \prod_{\nu=0}^{j-2} (1 - ax^\nu[n - \nu]_{x,y}) \prod_{\nu=j-1}^{n-1} (-ax^\nu[n - \nu]_{x,y}) \\ &= (-1)^{n-1} ax^{n-1} [n]_{t,u} \prod_{i=1}^{n-1} (1 - ax^i[n - i]_{x,y}) \end{aligned}$$

by (5.13). Thus, by (i), we conclude that

$$(5.16) \quad \frac{\det P_n}{\det P_{n-1}} = \det W_{n-1} = (-1)^{n-1} ax^{n-1} [n]_{t,u} \prod_{i=1}^{n-1} (1 - ax^i[n - i]_{x,y}).$$

(v) We claim that

$$\frac{\det P_n^k}{\det P_n} = \frac{\det W_{n-1}^k}{\det W_{n-1}} = ax^{\frac{(k-1)(k-2)}{2} - \frac{n(n-1)}{2}} y^{\frac{(n+1-k)(n+2-k)}{2}} [n+1]_{t,u} \begin{bmatrix} n+1 \\ k-1 \end{bmatrix}_{x,y}$$

for $1 \leq k \leq n$. Because the rightmost column of $\hat{P}_{n-1}^k$ is the k th column of U_n , the $(i, n+1)$ th entry of $\hat{P}_{n-1}^k$ is

$$\begin{cases} -ay^n[n+1]_{t,u} & \text{if } i = 2, \\ 0 & \text{otherwise} \end{cases}$$

when $k = 1$,

$$\begin{cases} -ay^{n+2-k}x^{k-2}[n+1]_{t,u} & \text{if } i = k, \\ -ay^{n+1-k}x^{k-1}[n+1]_{t,u} & \text{if } i = k+1, \\ 0 & \text{otherwise} \end{cases}$$

when $2 \leq k \leq n$,

$$\begin{cases} -ayx^{n-1}[n+1]_{t,u} & \text{if } i = n+1, \\ 0 & \text{otherwise} \end{cases}$$

when $k = n+1$, and all zero when $k = n+2$. By the induction hypothesis, the $(1, n+1)$ th entry of $X_{n-1}P_{n-1}^{-1}\bar{P}_{n-1}$ is $\frac{\det P_{n-1}^{n+1}}{\det P_{n-1}} = 0$. Thus the $(n+1)$ th column of $W_{n-1}^k = \hat{P}_{n-1}^k - X_{n-1}P_{n-1}^{-1}\bar{P}_{n-1}$ equals the $(n+1)$ th column of $\hat{P}_{n-1}^k$.

- (a) When $k = 1$, we expand $\det W_{n-1}^1$ along the $(n+1)$ th column; then, by direct computation, we obtain

$$\det W_{n-1}^1 = (-1)^{n+3}(-ay^n[n+1]_{t,u}) \det W_{n-1}(2; n+1).$$

By expanding $\det W_{n-1}^1(2; n+1)$ along the top row we obtain

$$\det W_{n-1}(2; n+1) = \left(-ay^{\frac{n(n-1)}{2}} x^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u}\right) \prod_{\nu=1}^{n-1} (1-ax^\nu[n-\nu]_{x,y}).$$

Thus we conclude that

$$\begin{aligned} \det W_{n-1}^1 &= (-1)^{n-1} a^2 y^{\frac{n(n+1)}{2}} x^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u} \\ &\quad \times [n+1]_{t,u} \prod_{\nu=1}^{n-1} (1-ax^\nu[n-\nu]_{x,y}). \end{aligned} \quad (5.17)$$

By (5.16), this implies

$$\frac{\det W_{n-1}^1}{\det W_{n-1}} = ay^{\frac{n(n+1)}{2}} x^{-\frac{n(n-1)}{2}} [n+1]_{t,u},$$

which is the desired identity.

- (b) When $2 \leq k \leq n$, expanding $\det W_{n-1}^k$ along the $(n+1)$ th column, we obtain

$$\begin{aligned} \det W_{n-1}^k &= (-1)^{k+n+1}(-ay^{n+2-k}x^{k-2}[n+1]_{t,u}) \det W_{n-1}(k; n+1) \\ &\quad + (-1)^{k+n+2}(-ay^{n+1-k}x^{k-1}[n+1]_{t,u}) \det W_{n-1}(k+1; n+1). \end{aligned} \quad (5.18)$$

By expanding along the top row, we obtain

$$\begin{aligned} \det W_{n-1}(k; n+1) &= -ax^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u} \sum_{j=1}^{k-1} (-1)^{j+1} y^{\frac{(n-j)(n-j+1)}{2}} x^{\frac{(j-1)(j-2)}{2}} \\ &\quad \times \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} \det W_{n-1}(1, k; j, n+1), \\ \det W_{n-1}(k+1; n+1) &= -ax^{-\frac{(n-1)(n-2)}{2}} [n]_{t,u} \sum_{j=1}^k (-1)^{j+1} y^{\frac{(n-j)(n-j+1)}{2}} x^{\frac{(j-1)(j-2)}{2}} \\ &\quad \times \begin{bmatrix} n \\ j-1 \end{bmatrix}_{x,y} \det W_{n-1}(1, k+1; j, n+1), \end{aligned}$$

where $W_{n-1}(1, k; j, n+1) = W_{n-1}(k; n+1)(1; j)$ and $W_{n-1}(1, k+1; j, n+1)$

$= W_{n-1}(k+1; n+1)(1; j)$. If we use

$$\begin{aligned} \det W_{n-1}(1, k; j, n+1) &= \prod_{\nu=0}^{j-2} (1 - ax^\nu[n-\nu]_{x,y}) \prod_{\nu=j-1}^{k-3} (-ax^\nu[n-\nu]_{x,y}) \\ &\quad \times \prod_{\nu=k-1}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}), \\ \det W_{n-1}(1, k+1; j, n+1) &= \prod_{\nu=0}^{j-2} (1 - ax^\nu[n-\nu]_{x,y}) \prod_{\nu=j-1}^{k-2} (-ax^\nu[n-\nu]_{x,y}) \\ &\quad \times \prod_{\nu=k}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}), \end{aligned}$$

then, by (5.13), we obtain

$$\begin{aligned} \det W_{n-1}(k; n+1) &= (-1)^{k-1} ax^{\frac{(k-2)(k-3)}{2} - \frac{(n-1)(n-2)}{2}} y^{\frac{(n-k+2)(n-k+1)}{2}} \\ &\quad \times [n]_{t,u} \left[\begin{matrix} n \\ k-2 \end{matrix} \right]_{x,y} \prod_{\nu=1}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}), \\ \det W_{n-1}(k+1; n+1) &= (-1)^k ax^{\frac{(k-1)(k-2)}{2} - \frac{(n-1)(n-2)}{2}} y^{\frac{(n-k)(n-k+1)}{2}} \\ &\quad \times [n]_{t,u} \left[\begin{matrix} n \\ k-1 \end{matrix} \right]_{x,y} \prod_{\nu=1}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}). \end{aligned}$$

Thus, from (5.18), we conclude that

$$\begin{aligned} \det W_{n-1}^k &= (-1)^{n-1} a^2 x^{-\frac{(n-1)(n-2)}{2} + \frac{(k-1)(k-2)}{2}} y^{\frac{(n+1-k)(n+2-k)}{2}} [n]_{t,u} [n+1]_{t,u} \\ &\quad \times \left(y^{n-k+2} \left[\begin{matrix} n \\ k-2 \end{matrix} \right]_{x,y} + x^{k-1} \left[\begin{matrix} n \\ k-1 \end{matrix} \right]_{x,y} \right) \prod_{\nu=1}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}) \\ &= (-1)^{n-1} a^2 x^{-\frac{(n-1)(n-2)}{2} + \frac{(k-1)(k-2)}{2}} y^{\frac{(n+1-k)(n+2-k)}{2}} \\ &\quad \times [n]_{t,u} [n+1]_{t,u} \left[\begin{matrix} n+1 \\ k-1 \end{matrix} \right]_{x,y} \prod_{\nu=1}^{n-1} (1 - ax^\nu[n-\nu]_{x,y}). \end{aligned}$$

Using (5.16), we obtain

$$\frac{\det W_{n-1}^k}{\det W_{n-1}} = ax^{-\frac{n(n-1)}{2} + \frac{(k-1)(k-2)}{2}} y^{\frac{(n+1-k)(n+2-k)}{2}} [n+1]_{t,u} \left[\begin{matrix} n+1 \\ k-1 \end{matrix} \right]_{x,y},$$

which is the desired identity.

- (c) When $k = n+1$, we also expand $\det W_{n-1}^k$ along the $(n+1)$ th column and repeat the same argument. It is not hard to obtain

$$\frac{\det W_{n-1}^{n+1}}{\det W_{n-1}} = ay[n+1]_{t,u} [n]_{x,y}.$$

The details are left to the reader.

- (d) When $k = n+2$, $\det \widehat{P}_{n-1}^k$ vanishes since all the entries of the last column of $\det \widehat{P}_{n-1}^k$ are zero.

This proves the theorem is true for n . By induction we conclude that the theorem is true for all $n \geq 1$. This completes the proof. $\square$

Since $\det(P_1) = a$, Theorem 5.1 (5.5) follows easily from (5.10). $\square$

5.2. Proof of Theorem 5.2. We first introduce two generalizations of q -binomial coefficients. For any sequence of nonzero functions $F = \{F_n\}_{n=1}^\infty$ in finitely many variables $t_1, t_2, \dots$ we define $F_n! = \prod_{k=1}^n F_k$, and for any positive integers n and k ,

$$\begin{bmatrix} n \\ k \end{bmatrix}_F = \begin{cases} \frac{F_n!}{F_k! F_{n-k}!} & \text{if } 0 \leq k \leq n, \\ 0 & \text{otherwise.} \end{cases}$$

Next, for any positive integers n and k , let

$$]n, k[_{x,y} = [n]_{xy} - x^{n-k} [k]_{xy}$$

and

$$]n[_{x,y} \begin{bmatrix} k \\ \end{bmatrix} = \begin{cases} \frac{\prod_{i=0}^{k-1}]n, i[_{x,y}}{[k]_{xy}!} & \text{if } 0 \leq k \leq n, \\ 0 & \text{otherwise.} \end{cases}$$

For instance, we have $]3, 1[_{x,y} = 1 + xy + x^2y^2 - x^2$ and

$$]3[_{x,y} \begin{bmatrix} 2 \\ \end{bmatrix} = \frac{(1 + xy + x^2y^2)(1 + xy + x^2y^2 - x^2)}{(1 + xy)}.$$

Note that $]n, k[_{x,1} = [n - k]_x$ and $]n[_{x,1} \begin{bmatrix} k \\ \end{bmatrix} = \begin{bmatrix} n \\ k \end{bmatrix}_x$.

We prove Theorem 5.2 (5.6) by considering the following matrix $N_n(\lambda, a)$, which reduces to the matrix N_n by setting $\lambda = 1$ and $F_n = [n]_{t,u}$. Let $N_n(\lambda, a)$ be the matrix defined inductively as follows:

$$N_0(\lambda, a) = (\lambda)$$

and

$$(5.19) \quad N_n(\lambda, a) = \left(\begin{array}{c|c} N_{n-1}(\lambda, a) & \overline{N}_{n-1}(\lambda, a) \\ \hline O_{n+1, \widehat{n-1}} & \widehat{N}_{n-1}(\lambda, a) \end{array} \right),$$

where $\widehat{N}_{n-1}(\lambda, a)$ is the $(n+1) \times (n+1)$ matrix defined by

$$(5.20) \quad \widehat{N}_{n-1}(\lambda, a) = (\lambda \delta_{ij} - ax^{i-1} [n+1-i]_{xy} (\delta_{ij} + \delta_{i+1,j}))_{1 \leq i,j \leq n+1}$$

and $\overline{N}_{n-1}(\lambda, a)$ is the $\widehat{n-1} \times (n+1)$ matrix

$$\left(\begin{array}{c} O_{\widehat{n-2}, n+1} \\ \hline \check{N}_{n-1} \end{array} \right)$$

with the $n \times (n+1)$ matrix

$$(5.21) \quad \check{N}_{n-1} = (-ay^{n-i} F_n \cdot (\delta_{ij} + \delta_{i+1,j}))_{1 \leq i \leq n, 1 \leq j \leq n+1}.$$

For instance, we get

$$N_2(\lambda, a) = \begin{pmatrix} \lambda & -aF_1 & -aF_1 & 0 & 0 & 0 \\ 0 & \lambda - a & -a & -ayF_2 & -ayF_2 & 0 \\ 0 & 0 & \lambda & 0 & -aF_2 & -aF_2 \\ 0 & 0 & 0 & \lambda - a(1 + xy) & -a(1 + xy) & 0 \\ 0 & 0 & 0 & 0 & \lambda - ax & -ax \\ 0 & 0 & 0 & 0 & 0 & \lambda \end{pmatrix}.$$

Let $\dot{N}_n(\lambda, a)$ denote the matrix obtained from $N_n(\lambda, a)$ by deleting the $\hat{n}$ th row and the first column. Then the following theorem is sufficient to prove our result. Here our strategy is as follows. We regard $\det N_n(\lambda, a)$ as a polynomial in λ and find all linear factors. Finally we check the leading coefficient on both sides.

THEOREM 5.5. *We have*

$$(5.22) \quad \det \dot{N}_n(\lambda, a) = (-1)^{n(n-1)/2} a^n F_n! \lambda^n \prod_{m=1}^{n-1} \prod_{k=1}^{n-m} (\lambda - ax^{k-1}[m]_{xy}).$$

Then by setting $\lambda = 1$ and $F_n = [n]_{t,u}$ we obtain Theorem 5.2 (5.6). For instance, we have

$$\det \dot{N}_1(\lambda, a) = \det \begin{pmatrix} -aF_1 & -aF_1 \\ \lambda - a & -a \end{pmatrix} = a F_1 \lambda$$

and

$$\begin{aligned} \det \dot{N}_2(\lambda, a) &= \det \begin{pmatrix} -aF_1 & -aF_1 & 0 & 0 & 0 \\ \lambda - a & -a & -ayF_2 & -ayF_2 & 0 \\ 0 & \lambda & 0 & -aF_2 & -aF_2 \\ 0 & 0 & \lambda - a(1 + xy) & -a(1 + xy) & 0 \\ 0 & 0 & 0 & \lambda - ax & -ax \end{pmatrix} \\ &= -a^2 F_1 F_2 \lambda^2 (\lambda - a). \end{aligned}$$

Fix positive integers m and k . Define the row vectors $\mathbf{X}_n^{m,k}$ of degree $\hat{n}$ as follows: For $1 \leq i \leq n+1$ and $1 \leq j \leq i$, the $\left(\frac{i(i-1)}{2} + j\right)$ th entry of $\mathbf{X}_n^{m,k}$ is equal to

$$(5.23) \quad \begin{aligned} X_{i,j}^{m,k} &= (-1)^{i+m+k} x^{-(m+k-1)(i-m-k) + \binom{j-k}{2}} y^{\binom{i-m-k}{2}} \\ &\quad \times \frac{F_{i-m-k}!}{[i-m-k]_{xy}!} \left[\begin{matrix} i-1 \\ m+k-1 \end{matrix} \right]_F \frac{m}{m+k-j} \left[\begin{matrix} m \\ x, y \end{matrix} \right]. \end{aligned}$$

Here we use the convention that $F_n! = [n]_{xy}! = 1$ if $n \leq 0$. For example, if $n = 3$, $m = k = 1$, then

$$\mathbf{X}_3^{1,1} = \left(0, 1, 1, -\frac{F_2}{x}, -\frac{F_2}{x}, 0, \frac{F_2 F_3 y}{x^2 [2]_{xy}!}, \frac{F_2 F_3 y}{x^2 [2]_{xy}!}, 0, 0 \right).$$

LEMMA 5.6. Let n be a positive integer. Let m and k be positive integers such that $0 \leq m \leq n-1$ and $1 \leq k \leq n-m$. Then we have

$$(5.24) \quad \mathbf{X}_n^{m,k} N_n(\lambda, a) = (\lambda - ax^{k-1}[m]_{xy}) \mathbf{X}_n^{m,k}.$$

Before we proceed to the proof of the lemma, we give an example to illustrate (5.24). If $n = 2$ and $m = k = 1$, then we have

$$\begin{aligned} & \left(0, 1, 1, -\frac{F_2}{x}, -\frac{F_2}{x}, 0\right) \begin{pmatrix} \lambda & -F_1 & -F_1 & 0 & 0 & 0 \\ 0 & \lambda - a & -a & -ayF_2 & -ayF_2 & 0 \\ 0 & 0 & \lambda & 0 & -aF_2 & -aF_2 \\ 0 & 0 & 0 & \lambda - a(1+xy) & -a(1+xy) & 0 \\ 0 & 0 & 0 & 0 & \lambda - ax & -ax \\ 0 & 0 & 0 & 0 & 0 & \lambda \end{pmatrix} \\ &= \left(0, \lambda - a, \lambda - a, -\frac{F_2}{x}(\lambda - a), -\frac{F_2}{x}(\lambda - a), 0\right). \end{aligned}$$

Proof of Lemma 5.6. We proceed by induction on n . When $n = 0$ or $n = 1$, our claim is easy to check by direct computation. Assume (5.24) is true up to $n-1$. Then the first $\widehat{n-1}$ entries of $\mathbf{X}_n^{m,k} N_n(\lambda, a)$ agree with those of $(\lambda - x^{k-1}[m]_{xy}) \mathbf{X}_n^{m,k}$ by the induction hypothesis. So we have to check the last $n+1$ entries. In fact we verify the following three cases.

- (i) If $i = n+1$ and $j = 1$, then the $(\frac{n(n+1)}{2} + 1)$ th entry of $\mathbf{X}_n^{m,k} N_n(\lambda, a)$ is equal to

$$(-ay^{n-1} F_n) X_{n,1}^{m,k} + (\lambda - a[n]_{xy}) X_{n+1,1}^{m,k}.$$

Note that the coefficient $\left]_{m+k-1}^m \left[\begin{smallmatrix} n \\ x, y \end{smallmatrix} \right] \right]$ becomes zero by definition unless $k = 1$. Thus, by direct computation, one can easily check that this sum equals

$$\begin{aligned} & (-1)^{n+m+k+1} x^{-(m+k-1)(n-m-k+1) + \binom{1-k}{2}} y^{\binom{n-m-k+1}{2}} \\ & \times \frac{F_{n-m-k+1}!}{[n-m-k+1]_{xy}!} \left[\begin{smallmatrix} n \\ m+k-1 \end{smallmatrix} \right]_F \left]_{m+k-1}^m \left[\begin{smallmatrix} n \\ x, y \end{smallmatrix} \right] \right] (\lambda - ax^{k-1}[m]_{xy}). \end{aligned}$$

- (ii) If $i = n+1$ and $2 \leq j \leq n$, then the $(\frac{n(n+1)}{2} + j)$ th entry of $\mathbf{X}_n^{m,k} N_n(\lambda, a)$ is equal to

$$\begin{aligned} & (-ay^{n-j+1} F_n) X_{n,j-1}^{m,k} + (-ay^{n-j} F_n) X_{n,j}^{m,k} \\ & + (-ax^{j-2}[n-j+2]_{xy}) X_{n+1,j-1}^{m,k} + (\lambda - ax^{j-1}[n-j+1]_{xy}) X_{n+1,j}^{m,k}. \end{aligned}$$

By direct computation, one can easily check that this equals

$$\begin{aligned} & (-1)^{n+m+k+1} x^{-(m+k-1)(n-m-k+1) + \binom{j-k}{2}} y^{\binom{n-m-k+1}{2}} \\ & \times \frac{F_{n-m-k+1}!}{[n-m-k+1]_{xy}!} \left[\begin{smallmatrix} n \\ m+k-1 \end{smallmatrix} \right]_F \left]_{m+k-j}^m \left[\begin{smallmatrix} n \\ x, y \end{smallmatrix} \right] \right] (\lambda - ax^{k-1}[m]_{xy}). \end{aligned}$$

- (iii) If $i = j = n+1$, then the $\frac{(n+1)(n+2)}{2}$ th entry of $\mathbf{X}_n^{m,k} N_n(\lambda, a)$ is equal to

$$(-aF_n) X_{n,n}^{m,k} + (-ax^{n-1}) X_{n+1,n}^{m,k} + \lambda X_{n+1,n+1}^{m,k}.$$

One can easily check that this is always equal to zero.

Thus this completes the proof of our lemma. $\square$

COROLLARY 5.7. *Let n be a positive integer. Then there exists a polynomial $\varphi(\lambda)$ such that*

$$\det \dot{N}_n(\lambda, a) = \varphi(t)\lambda^n \prod_{m=1}^{n-1} \prod_{k=1}^{n-m} (\lambda - ax^{k-1}[m]_{xy}).$$

Proof. Let $\dot{\mathbf{X}}_n^{m,k}$ (resp., $\ddot{\mathbf{X}}_n^{m,k}$) denote the vector of degree $\hat{n} - 1$ obtained from $\mathbf{X}_n^{m,k}$ by deleting the last (resp., first) entry. Note that we have shown, in the proof of Lemma 5.6, that the last entry of $\mathbf{X}_n^{m,k}$ is always zero. Thus, by (5.24), we obtain

$$\dot{\mathbf{X}}_n^{m,k} \dot{N}_n(\lambda, a) = (\lambda - ax^{k-1}[m]_{xy}) \ddot{\mathbf{X}}_n^{m,k}.$$

By substituting $\lambda = ax^{k-1}[m]_{xy}$ into this identity we obtain

$$(5.25) \quad \dot{\mathbf{X}}_n^{m,k} \dot{N}_n(ax^{k-1}[m]_{xy}, a) = \mathbf{0}$$

for $0 \leq m \leq n-1$ and $1 \leq k \leq n-m$. If $1 \leq m \leq n-1$ and $1 \leq k \leq n-m$, then $\dot{\mathbf{X}}_n^{m,k}$ is a nonzero vector so that (5.25) implies $\dot{N}_n(ax^{k-1}[m]_{xy}, a)$ is singular, i.e., $\det \dot{N}_n(ax^{k-1}[m]_{xy}, a) = 0$. Since $\det \dot{N}_n(\lambda, a)$ is a polynomial of λ , $\det \dot{N}_n(\lambda, a)$ is divisible by $\lambda - ax^{k-1}[m]_{xy}$. If $m = 0$, then $\dot{\mathbf{X}}_n^{0,k}$, $1 \leq k \leq n$, are evidently linearly independent and (5.25) implies $\det \dot{N}_n(\lambda, a)$ is divisible by λ^n . Summarizing we immediately obtain the corollary. $\square$

Now we are in position to complete the proof of Theorem 5.5.

Proof of Theorem 5.5. To complete the proof of Theorem 5.5, we need to show that the degree of $\det \dot{N}_n(\lambda, a)$ is $\frac{n(n+1)}{2}$ as a polynomial in λ , and the leading coefficient of $\det \dot{N}_n(\lambda, a)$ is equal to $(-1)^{n(n-1)/2} a^n F_n!$. Let $K_n = \hat{n} - 1$, which is the degree of the matrix $\dot{N}_n(\lambda, a)$. Let $\dot{b}_{ij}$ denote the (i, j) th entry of $\dot{N}_n(\lambda, a)$. By the definition of determinants we have

$$\det \dot{N}_n(\lambda, a) = \sum_{\pi \in S_{K_n}} \text{sgn } \pi \dot{b}_{\pi(1)1} \dot{b}_{\pi(2)2} \cdots \dot{b}_{\pi(K_n)K_n}.$$

We use the two-line notation

$$\pi = \begin{pmatrix} 1 & 2 & \cdots & K_n \\ \pi(1) & \pi(2) & \cdots & \pi(K_n) \end{pmatrix}$$

to express a permutation π of $[K_n]$. For each j , if $\pi(j) = j + 1$, then the entry $\dot{b}_{\pi(j)j}$ is of degree 1 as a polynomial in λ , and otherwise it is a constant. Thus $\det \dot{N}_n(\lambda, a)$ is apparently of at most $K_n - 1 = \frac{(n+1)(n+2)}{2} - 2$ degree as a polynomial in λ . For example, $\dot{N}_3(\lambda, a)$ looks as follows:

$$\begin{pmatrix} \begin{array}{cc|ccc} -aF_1 & -a\mathbf{F}_1 & 0 & 0 & 0 \\ \lambda - a & -a & -ayF_2 & -ayF_2 & 0 \\ 0 & \lambda & 0 & -aF_2 & -a\mathbf{F}_2 \end{array} & \begin{array}{ccc|ccc} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{array} \\ \hline \begin{array}{cc|ccc} 0 & 0 & \lambda - a[2]_{xy} & -a[2]_{xy} & 0 \\ 0 & 0 & 0 & \lambda - a\mathbf{x} & -ax \\ 0 & 0 & 0 & 0 & \lambda \end{array} & \begin{array}{ccc|ccc} -ay^2F_3 & -ay^2F_3 & 0 & 0 & 0 & 0 \\ 0 & -ayF_3 & -ayF_3 & 0 & 0 & 0 \\ 0 & 0 & -aF_3 & -a\mathbf{F}_3 & 0 & 0 \end{array} \\ \hline \begin{array}{cc|ccc} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{array} & \begin{array}{ccc|ccc} \lambda - a[3]_{xy} & -a[3]_{xy} & 0 & 0 & 0 & 0 \\ 0 & \lambda - a\mathbf{x}[2]_{xy} & -ax[2]_{xy} & 0 & 0 & 0 \\ 0 & 0 & \lambda - a\mathbf{x}^2 & -ax^2 & 0 & 0 \end{array} \end{pmatrix}.$$

Our first claim is that $\det \dot{N}_n(\lambda, a)$ is a polynomial of degree $\frac{n(n+1)}{2}$. For each $i = 1, \dots, n$, let Col_i denote the set of columns $j = \frac{i(i+1)}{2}, \frac{i(i+1)}{2} + 1, \dots, \frac{(i+1)(i+2)}{2} - 1$. Note that Col_i includes $i+1$ columns. We claim that $\pi(j) = j+1$ can happen at most i column indices j in each block Col_i . Otherwise $\dot{b}_{\pi(1)1} \dot{b}_{\pi(2)2} \cdots \dot{b}_{\pi(K_n)K_n}$ vanishes. In fact, assume that $\pi(j) = j+1$ for all j in a certain block Col_i . Then this must be the case for the block Col_{i+1} . There is no other choice if we assume $\dot{b}_{\pi(1)1} \dot{b}_{\pi(2)2} \cdots \dot{b}_{\pi(K_n)K_n}$ is nonzero. And this must also be the case for the block Col_{i+2} , and so on. Finally we have to take $\pi(j) = j+1$ for all j in the block Col_n , but this is impossible. Thus we reach a contradiction. We conclude that the degree of $\det \dot{N}_n(\lambda, a)$ is at most $\frac{n(n+1)}{2}$. In fact there is a permutation which realizes this degree, i.e.,

$$\pi = \left(\begin{array}{cc|cc|ccc|cccc} 1 & 2 & 3 & 4 & 5 & \dots & \dots & K_{n-1}+1 & K_{n-1}+2 & \dots & K_n-1 & K_n \\ 2 & 1 & 4 & 5 & 3 & \dots & \dots & K_{n-1}+2 & K_{n-1}+3 & \dots & K_n & K_{n-1}+1 \end{array} \right).$$

It is easy to see that this π is the only permutation with which $\dot{b}_{\pi(1)1} \dot{b}_{\pi(2)2} \cdots \dot{b}_{\pi(K_n)K_n}$ does not vanish and is of degree $\frac{n(n+1)}{2}$. Thus we conclude that the leading coefficient of $\det \dot{N}_n(\lambda, a)$ equals

$$\text{sgn } \pi \cdot (-1)^n a^n F_n!.$$

This immediately implies the resulting identity (5.22). $\square$

Remark 5.8. One may notice that M_n in (5.7) and N_n in (5.19) are in a similar form, but our methods to evaluate them are far from parallel. It seems that the first method does not work with the matrix N_n since we can't guess the entries of $CA^{-1}N$ as we did in (5.11). Meanwhile, the second method does not work with the matrix M_n at this point since even if we generalize M_n to $M_n(\lambda, a)$, we don't know the general form of the eigenvectors of $M_n(\lambda, a)$. The reader can find the general guidance about matrix evaluation in [9]. We may say that the second proof follows this general philosophy.

6. Concluding remarks. We record some open problems in this section. First of all, it is desirable to find a simpler proof of Theorem 2.10. Second, regarding Steingrímsson's original problems in [18], there are still three conjectures remaining open, which we recall as follows. For an ordered partition $\pi = B_1/B_2/\dots/B_k$ in $\mathcal{OP}_n^k$ we say that i is a *block descent* in π if $B_i > B_{i+1}$; the *block major index* of π , denoted $\text{bMaj}(\pi)$, is the sum of the block descents in π . Consider the ordered partition $\pi = 6\ 8/5/1\ 4\ 7/3\ 9/2$, since $\{6, 8\} > \{5\}$ and $\{3, 9\} > \{2\}$, so 1 and 4 are the two block descents in π and $\text{bMaj } \pi = 1 + 4 = 5$. Then Steingrímsson presented the following conjecture in [18].

CONJECTURE 6.1 (Steingrímsson). *The following statistics are Euler–Mahonian:*

$$\text{mak} + \text{bMaj}, \quad \text{lmak} + \text{bMaj}, \quad \text{cmajLSB} := \text{lsb} + \text{cbMaj} + \binom{k}{2},$$

where $\text{cbMaj} = \binom{k}{2} - \text{bMaj}$.

Consider the following two generating functions of ordered partitions with $k \geq 0$ blocks:

$$(6.1) \quad \xi_k(a; x, y) := \sum_{\pi \in \mathcal{OP}^k} x^{(\text{mak} + \text{bMaj})\pi} y^{\text{cmajLSB } \pi} a^{|\pi|},$$

$$(6.2) \quad \eta_k(a; x, y) := \sum_{\pi \in \mathcal{OP}^k} x^{(\text{lmak} + \text{bMaj})\pi} y^{\text{cmajLSB } \pi} a^{|\pi|}.$$

Then we expect the following more general conjecture would hold.

CONJECTURE 6.2. *For $k \geq 0$, the following identities hold.*

$$(6.3) \quad \xi_k(a; x, y) = \eta_k(a; x, y) = \frac{a^k(xy)^{\binom{k}{2}} [k]_{x,y}!}{\prod_{i=1}^k (1 - a[i]_{x,y})}.$$

Note added in proof. A bijective approach to the conjectures of Steingrímsson has been recently discovered by the last two authors. This approach, as well as the proof of Conjectures 6.1 and 6.2, is given in a forthcoming paper (see <http://arxiv.org/abs/0712.1755v1>).

Acknowledgment. The authors would like to thank the referee for his/her careful reading of a previous version of this paper.

LONG LOCAL SEARCHES FOR MAXIMAL BIPARTITE SUBGRAPHS*

HEMANSHU KAUL[†] AND DOUGLAS B. WEST[‡]

Abstract. Given a partition of the vertices of a graph into two sets, a *flip* is a move of a vertex from its own set to the other, under the condition that it has more incident edges to vertices in its own set than in the other. Every sequence of flips eventually produces a bipartite subgraph capturing more than half of the edges in the graph. Each flip gains at least one edge. For an n -vertex loopless multigraph, we show that there is always a sequence of at most $n/2$ flips that cannot be extended, and we construct a graph having a sequence of $\frac{2}{25}(n^2 + n - 31)$ flips.

Key words. large bipartite subgraph, MAX-CUT problem, local switching, hill-climbing algorithm

DOI. 10.1137/060666615

1. Introduction. Finding a bipartite subgraph with the maximum number of edges in a given graph is a classical problem in combinatorial optimization and extremal graph theory. It has been studied in computer science from an algorithmic point of view (as the MAX-CUT problem) and in combinatorics from a more structural point of view. The problem is NP-complete (Karp [11]), so the focus of research has been on heuristics, approximation algorithms, and extremal results (conditions on graph parameters that guarantee large bipartite subgraphs).

For a graph G , let $b(G)$ denote the maximum number of edges in a bipartite subgraph of G . For the graph G in which we study $b(G)$, we always let n and m denote the numbers of vertices and edges. Classical guarantees include $b(G) \geq \frac{m}{2} + \frac{1}{8}(\sqrt{8m+1} - 1)$ (Edwards [5]) and, for connected graphs, $b(G) \geq \frac{m}{2} + \frac{1}{4}(n - 1)$ (conjectured by Erdős [7], and proved by Edwards [6]). Bylka, Idzik, and Tuza [3] strengthened the Edwards–Erdős bound to $b(G) \geq \lceil \frac{m}{2} + \frac{1}{2} \lceil \frac{2t-1}{2t} (n-1) \rceil \rceil$ when G is connected and has no odd cycle of length less than $2t$. Furthermore, this is sharp (using graphs whose blocks are $(2t+1)$ -cycles), and there is a linear-time algorithm to find a bipartite subgraph this big.

Bollobás and Scott [1] gave an algorithm running in time $O(2^{ck^4} + m + n)$ that finds a bipartite subgraph with at least $\frac{m}{2} + \sqrt{\frac{m}{8}} + k$ edges, if one exists, and otherwise provides an optimal partition (they also provide a survey of work in the area, updating the survey [14]). Goemans and Williamson ([9]) gave a randomized .87-approximation algorithm for $b(G)$ based on semidefinite programming. However, Håstad [10] proved that no .942-approximation algorithm exists unless $P=NP$.

An elementary heuristic approach to finding large bipartite subgraphs is to start with an arbitrary vertex partition and then make local improvements. Bylka, Idzik, and Tuza [3] found a local switching algorithm that guarantees a cut as big as the bound of Edwards [5]. A simple type of local improvement is to move a vertex having

more incident edges to vertices in its own set than in the other set; moving it to the other set increases the size of the cut. We call such a change a *flip* of the vertex. Erdős [8] introduced this notion to give a short proof that every graph G has a bipartite subgraph with at least half its edges. When flips are no longer possible, for each vertex at least half of the incident edges appear in the current bipartite subgraph, and hence by summing degrees the subgraph contains at least half the edges of G .

Since the process also must terminate (in at most m flips), this simple process is a .5-approximation algorithm for $b(G)$. Furthermore, it lends itself to parallel computation, since the determination of whether a vertex can flip is independent of that determination for other vertices. Parallelizable local-improvement algorithms based on switching protocols have been studied by Bylka, Idzik, and Tuza [3], by Bylka [2], and by others.

Our purpose in this paper is to study the *length* (number of flips) of a maximal sequence of flips, where *maximal* means that at the end every vertex has at least as many neighbors in the opposite side of the cut as in its own side. At that point, the cut is a local optimum for the MAX-CUT problem.

For the complete graph K_n , every maximal flip sequence has length $\lfloor n/2 \rfloor$. One might think that there is always a linear bound on the length of flip sequences, but Cowen and West [4] showed that this is false. They posed several questions about the lengths of maximal flip sequences in a graph G (we can consider these also for loopless multigraphs).

(1) Let $l(G)$ denote the maximum length of a flip sequence in G starting from the trivial vertex partition $(\emptyset, V(G))$. What is the maximum of $l(G)$ over n -vertex graphs? Over n -vertex graphs with m edges?

(2) Let $s(G)$ denote the minimum length of a maximal flip sequence starting from the trivial vertex partition. What is the maximum of $s(G)$ over n -vertex graphs? Is it true that always $s(G) \leq n/2$, and is there a fast algorithm to produce a flip sequence of length at most $n/2$?

Since every flip increases the number of edges across the cut, $l(G) \leq m$. When n is a perfect square and $m = \frac{1}{2}(n-1)\sqrt{n}$, Cowen and West [4] constructed a graph with a flip sequence of length m , matching the edge bound. It remains open whether $\frac{1}{2}n^{3/2}$ is asymptotically the maximum number of edges in a graph with a flip sequence whose length is the number of edges (increasing the size of the cut by only 1 with each flip).

The construction with length $\frac{1}{2}n^{3/2}$ was at that time the longest known flip sequence in an n -vertex graph. Since each flip increases the size of the cut, $\frac{1}{4}n^2$ is a trivial upper bound. Our main result, Theorem 3, is construction of an n -vertex graph having a flip sequence of length at least $\frac{2}{25}(n^2 + n - 31)$. This graph has roughly $\frac{1}{5}n^2$ edges.

Flips can be found in time proportional to maximum degree, so $l(G)$ times maximum degree is a bound on the worst-case running time of this simple heuristic algorithm. See Korte and Lovász [12], Loeb [13], and Tovey [15] for further discussion of issues related to the complexity of greedy and local-search based algorithms. Our result shows that one cannot guarantee less than $O(n^2)$ for the worst-case number of steps.

It would be interesting to know the coefficient on n^2 in the largest $l(G)$. We believe our construction is near optimal. In Proposition 2, we show that the maximum length of a flip sequence in a graph G with minimum degree d is at most $b(G) - \lfloor d^2/4 \rfloor$.

We also answer most of question (2), proving in Theorem 1 that $s(G) \leq \lfloor n/2 \rfloor$ for every n -vertex loopless multigraph G . The bound is sharp, as every maximal

flip sequence in K_n has length $\lfloor n/2 \rfloor$. It is also sharp for $K_{n/2, n/2}$, where every local optimum splits the vertices in half (including the “worst” local optimum with $n/4$ vertices of each partite set on each side when 4 divides n). Our proof does not provide a fast algorithm to find such a sequence, since it assumes knowledge of an optimal partition (in fact, it reaches some optimal partition in at most $\lfloor n/2 \rfloor$ flips). Thus the complexity of computing $s(G)$ or of finding a flip sequence of length at most $\lfloor n/2 \rfloor$ remains open. Is there a polynomial-time algorithm to find a sequence of $O(n)$ flips that results in a maximal bipartite subgraph? In terms of parallel computation, is there an NC algorithm that will construct a maximal bipartite subgraph?

There remain other open questions about local switching algorithms for MAX-CUT. Bylka, Idzik, and Tuza [3] showed that no algorithm using flips and certain other local switches guarantees a cut as big as the Edwards–Erdős bound [6]. A more general algorithm might come closer to that bound. Fix a positive integer k . Given a current vertex partition, a *local k -switch* selects subsets of size at most k from the two parts and switches them; it is *improving* if the new cut is bigger than the old one. Tuza [14] asked for the largest constant $c(k)$ such that a sequence of improving local k -switches can produce a bipartite subgraph with $\frac{m}{2} + c(k)n - o(n)$ edges.

2. Upper bound on $s(G)$. We use $N(v)$ to denote the neighborhood of a vertex v (in G). For $S \subseteq V(G)$ and $v \in V(G)$, let $d_S(v)$ be the number of edges incident to v whose other endpoints are in S . Recall that $s(G)$ is the minimum length of a maximal flip sequence from the trivial partition.

THEOREM 1. *If G is an n -vertex loopless multigraph, then $s(G) \leq \lfloor n/2 \rfloor$. In particular, given a globally optimal partition, a sequence of at most $\lfloor n/2 \rfloor$ flips can be constructed that produces some globally optimal partition.*

Proof. Let (X, Y) be a globally optimal partition, with $|X| = k \leq n/2$. By starting with $(\emptyset, V(G))$ and flipping to the first part of some or all of the members of the set X , we will obtain a globally optimal partition $(\hat{X}, \hat{Y})$ with $\hat{X} \subseteq X$ and $\hat{Y} \supseteq Y$.

Let X' denote the set of vertices in X having exactly half their neighbors in X and half in Y . Let $G_1, \dots, G_r$ be the components of the induced subgraph $G[X']$. Select $x_i \in V(G_i)$, for $1 \leq i \leq r$. Let $Z = \{x_1, \dots, x_r\}$. Index the rest of X as $x_{r+1}, \dots, x_k$ in such a way that each vertex of $X' - Z$ has an earlier neighbor in X' . In particular, choose a spanning tree of each G_i , root it at x_i , and search the tree from x_i , assigning labels in increasing order as vertices are found.

Now flip the vertices $x_k, \dots, x_{r+1}$ (from the second part to the first) in decreasing order of index. We claim that these flips are all available when desired and that the resulting partition $(\hat{X}, \hat{Y})$ is globally optimal. Since (X, Y) is globally optimal, $d_X(u) \leq d_Y(u)$ whenever $u \in X$, and $d_Y(v) \leq d_X(v)$ whenever $v \in Y$. Furthermore, these inequalities are strict for all vertices of odd degree.

With the given ordering of X , let $X_i = \{x_{k+1-i}, \dots, x_k\}$ for $1 \leq i \leq k-r$, with $X_0 = \emptyset$. Let $Y_i = V(G) - X_i$ for $0 \leq i \leq k-r$. Since $X_{i-1} \subset X$ and $Y \subset Y_{i-1}$, we have $d_{X_{i-1}}(x_i) \leq d_X(x_i) < d_Y(x_i) \leq d_{Y_{i-1}}(x_i)$ when $x_i \notin X'$. For $x_i \in X' - Z$, the indexing gives x_i a neighbor in $X \cap Y_{i-1}$. Thus the inequalities become $d_{X_{i-1}}(x_i) < d_X(x_i) \leq d_Y(x_i) < d_{Y_{i-1}}(x_i)$. The two cases allow us to flip $x_k, \dots, x_{r+1}$ in order.

We have reached a partition $(\hat{X}, \hat{Y})$ with $\hat{X} = X - Z$ and $\hat{Y} = Y \cup Z$. It remains to show that $(\hat{X}, \hat{Y})$ is a global optimum, which also implies that no further flips can be made. Reaching (X, Y) from $(\hat{X}, \hat{Y})$ is accomplished by moving the vertices of Z . Because Z consists of one vertex from each component of $G[X']$, Z is an independent

set. Since also $Z \subseteq X'$, $d_{\hat{X}}(x) = d_{\hat{Y}}(x)$ for each $x \in Z$. Therefore, moving all of Z does not change the size of the cut, and $(\hat{X}, \hat{Y})$ is already optimal. $\square$

If every vertex of G has odd degree, then the first statement of Theorem 1 can be proved more simply. In this case, we do not need to know a globally optimal partition to obtain a maximal flip sequence of length at most $\lfloor n/2 \rfloor$. We can start with any locally optimal partition, which can be found in polynomial time (as discussed in the introduction), and this partition can be reached from the trivial partition simply by flipping each vertex of one part. When G has vertices of even degree, our proof uses a given globally optimal partition to prevent vertices of Y from flipping; finding such a partition is NP-hard.

3. Upper bound on $l(G)$. Henceforth we consider only simple graphs. Recall that $l(G)$ is the maximum length of a flip sequence from the trivial partition of G . Since each flip increases the number of edges across the cut, $l(G) \leq b(G)$, and it is well known that $b(G) \leq n^2/4$. The example constructed by Cowen and West [4] is bipartite, with $l(G) = b(G) = m$. Achieving length $b(G)$ requires gaining only one edge with each flip, so G must have minimum degree 1. Their construction uses about $\sqrt{n}$ vertices of degree 1. It is natural to wonder by how much the upper bound $b(G)$ can be lowered when G has minimum degree d .

The basic idea is that the first few switches must gain many edges, leaving fewer for later flips. It may be that the later flips gain only one edge each. Indeed, this is what happens in our construction, where the minimum degree is linear in n and yet the number of flips is quadratic.

PROPOSITION 2. *If a graph G has minimum degree d , then $l(G) \leq b(G) - \lfloor d^2/4 \rfloor$.*

Proof. In a flip sequence on G from the initial partition with $(X, Y) = (\emptyset, V(G))$, the first move gains at least d edges. The second flip must move another vertex to X . As long as at most $1 + d/2$ vertices have been flipped, no vertex of X can have more neighbors in X than in Y , so no vertex in X can be flipped back to Y .

When $k = \lfloor d/2 \rfloor$, the first k flips thus yield a partition with $|X| = k$; at most $\binom{k}{2}$ edges are induced by X . Hence at this point the cut has at least $kd - 2\binom{k}{2}$ edges. Each subsequent flip after the first k gains at least one edge in the cut until at most $b(G)$ edges have been captured. The total number of flips is thus at most $k + b(G) - (kd - 2\binom{k}{2})$, which simplifies to $b(G) - k(d - k)$. With $k = \lfloor d/2 \rfloor$, the bound follows. $\square$

To see the effect of this bound, suppose that $4 \nmid n$ and $b(G)$ is $n^2/4$, the maximum possible value. This requires G to have the complete bipartite graph $K_{n/2, n/2}$ as a subgraph, and hence G has minimum degree at least $n/2$. Now Proposition 2 yields $l(G) \leq \frac{n^2}{4} - \frac{1}{4} \frac{n^2}{4} = \frac{3}{16} n^2$. More generally, if G is αn -regular, where $0 < \alpha \leq 1$, using $b(G) \leq m$ yields $l(G) \leq m - \frac{1}{4} \alpha^2 n^2 = m(1 - \frac{1}{2} \alpha)$.

For the graph G we construct in Theorem 3, where $l(G) > \frac{2}{25} n^2$, we have $b(G) \approx \frac{4}{25} n^2$, and the minimum degree is about $\frac{2}{5} n$. The resulting upper bound on $l(G)$ from Proposition 2 is about $\frac{3}{25} n^2$, which equals $\frac{3}{2} (\frac{2}{25} n^2)$. This suggests that it will be hard to improve Proposition 2 without knowing something about the structure of G . For example, when G is triangle-free, the gain in the first k flips in the proof of Proposition 2 is at least $kd - 2k^2/4$. This improves the upper bound in Proposition 2 to roughly $b(G) - \frac{3}{8} d^2$, and it improves the upper bound on $l(G)$ for the graph in Theorem 3 to about $\frac{5}{4} (\frac{2}{25} n^2)$.

4. Lower bound construction for $l(G)$. In this section, we construct a graph G and a flip sequence of length about $\frac{2}{25} n^2$ on it. As mentioned earlier, Cowen and

FIG. 1. Graph G in Theorem 3, with $k = 3$.

West [4] achieved a sequence of length $\frac{1}{2}n^{3/2}$ using a graph with that many edges and a sequence that increases the size of the cut by 1 with each flip. We achieve quadratic length by sacrificing equality with m and enlarging the cut rapidly at first in order to permit many more small steps later in which vertices repeatedly move back and forth. With such a sequence we come near the counting bound from Proposition 2.

THEOREM 3. *For every positive integer n , there exists an n -vertex graph G such that $l(G) \geq \frac{2}{25}(n^2 + n - 31)$.*

Proof. We first present an explicit construction for $n \equiv 3 \pmod{5}$, with $l(G) > \frac{2}{25}n^2$. Given a positive integer k , let $n = 5k + 3$. Create vertex subsets $V_1, \dots, V_5$, with $|V_1| = |V_2| = k$ and $|V_3| = |V_4| = |V_5| = k + 1$. Form G by expanding the vertices of a 5-cycle into these sets. That is, given the 5-cycle with vertices $z_1, \dots, z_5$, replace z_i with V_i for each i , with every vertex in V_i adjacent to every vertex in V_{i-1} and V_{i+1} , treating subscripts modulo 5. Label the vertices in the first three sets as follows: $V_1 = \{w_1, \dots, w_k\}$, $V_2 = \{u_1, \dots, u_k\}$, and $V_3 = \{v_1, \dots, v_{k+1}\}$. See Figure 1.

We start with the trivial partition $(V(G), \emptyset)$. During the flip sequence, we use X and Y , respectively, to denote the first and the second set in the current partition, so initially $X = V(G)$. At the end of the flip sequence, we will have $X = V_1 \cup V_2 \cup V_4$ and $Y = V_3 \cup V_5$. As explained after the proof, this in fact is an optimal cut; it has $2k(k+1) + 2(k+1)^2$ edges, including all the edges of G except the k^2 edges between V_1 and V_2 .

Our flip sequence for G begins with a “preprocessing” Phase 0 that gains many edges for each flip. Since G has a large minimum degree, the argument in Proposition 2 implies that the flip sequence must start this way.

Phase 0 consists of two steps. We first flip each vertex of V_1 from X to Y . This is valid because all the neighbors of each vertex of V_1 lie in $X - V_1$ throughout this phase. We next flip each vertex of V_5 from X to Y . This is valid because, after moving V_1 , each vertex of V_5 has $k + 1$ neighbors in X (all of V_4) and k neighbors in Y (all of V_1) throughout the remainder of this phase.

After Phase 0, we have $V_4 \subset X$ and $V_5 \subset Y$, and this remains true for the remainder of the flip sequence. We group the remainder of the flips into Phases 1 through $k + 1$.

Let $V_1(i) = \{w_1, \dots, w_{i-1}\}$ and $V'_1(i) = \{w_i, \dots, w_k\}$. Similarly, let $V_3(i) = \{v_i, \dots, v_{i-1}\}$ and $V'_3(i) = \{v_i, \dots, v_{k+1}\}$. Thus $V_1 = V'_1(1)$ and $V_3 = V'_3(1)$ and $V_1(1) = V_3(1) = \emptyset$. Hence the cut at the end of Phase 0 can be described as $X = V_1(1) \cup V_2 \cup V'_3(1) \cup V_4$ and $Y = V'_1(1) \cup V_3(1) \cup V_5$, which is the description of the starting cut for Phase 1. The four steps of Phase i are shown in Figure 2.

FIG. 2. Steps in Phase i .

Phase i . At the start of Phase i , $X = V_1(i) \cup V_2 \cup V_3'(i) \cup V_4$ and $Y = V_1'(i) \cup V_3(i) \cup V_5$.

Step a_i : Flip all of V_2 from X to Y ; this step is valid because each vertex in V_2 now has $k + 1$ neighbors in X (all of $V_1(i) \cup V_3'(i)$) and k neighbors in Y (all of $V_1'(i) \cup V_3(i)$).

Step b_i : Flip v_i in V_3 from X to Y ; this step is valid because v_i now has $k + 1$ neighbors in X (all of V_4) and k neighbors in Y (all of V_2).

Step c_i : Flip all of V_2 from Y to X ; this step is valid because each vertex in V_2 now has $k + 1$ neighbors in Y (all of $V_3(i + 1) \cup V_1'(i)$) and k neighbors in Y (all of $V_3(i) \cup V_1'(i)$).

Step d_i : If $i \leq k$, then flip w_i in V_1 from Y to X ; otherwise stop. For $i \leq k$, the flip is valid because w_i now has $k + 1$ neighbors in Y (all of V_5) and k neighbors in X (all of V_2).

At the end of Phase $k + 1$, the partition is $X = V_1 \cup V_2 \cup V_4$ and $Y = V_3 \cup V_5$. The flip sequence ends, since each vertex having any neighbors in its own side of the cut has k neighbors in its side and $k + 1$ in the opposite side.

In Phase 0, both V_1 and V_5 were flipped; altogether $2k + 1$ flips. Each subsequent Phase flips V_2 twice and flips one vertex of V_3 and one vertex of V_1 , except that the last phase omits the last flip. Thus the total number of flips is $2k + (k + 1)(2k + 2)$. Since $n = 5k + 3$, we obtain $l(G) \geq \frac{2}{25}(n^2 + 9n - 11)$.

Finally, suppose that $n \not\equiv 3 \pmod{5}$. Let n' be the largest integer congruent to 3 modulo 5 that is at most n . We use an instance of the construction above with n' vertices and leave the remaining vertices isolated. Since $n' \geq n - 4$, we have $l(G) \geq \frac{2}{25}(n'^2 + 9n' - 11) \geq \frac{2}{25}(n^2 + n - 31)$. $\square$

In fact, the final partition in the flip sequence we constructed in the proof of Theorem 3 is globally optimal, as we now show. Let G be any expansion of a 5-cycle replacing the i th vertex with an independent V_i , indexed cyclically. For any partition (X, Y) of $V(G)$ yielding a bipartite subgraph H , let $a_i = |X \cap V_i|$ and $b_i = |Y \cap V_i|$. Each vertex v in V_i has $a_{i-1} + a_{i+1}$ neighbors in X and $b_{i-1} + b_{i+1}$ neighbors in Y . Vertex v has largest degree in H if it is in the set opposite the larger of these two quan-

ties. This applies for all $v \in V_i$ (and for all i), so we achieve the largest bipartite subgraph by putting each V_i onto one side of the cut. Under this restriction, the best we can achieve is to capture all but the smallest of the five complete bipartite subgraphs expanding edges of the cycle, which is what the final partition of Theorem 3 does.

ELEMENTARY INCIDENCE THEOREMS FOR COMPLEX NUMBERS AND QUATERNIONS*

JÓZSEF SOLYMOSI[†] AND KONRAD J. SWANEPOEL[‡]

Abstract. We present some elementary ideas to prove the following Sylvester–Gallai type theorems involving incidences between points and lines in the planes over the complex numbers and quaternions.

1. Let A and B be finite sets of at least two complex numbers each. Then there exists a line ℓ in the complex affine plane such that $|(A \times B) \cap \ell| = 2$.
2. Let S be a finite noncollinear set of points in the complex affine plane. Then there exists a line ℓ such that $2 \leq |S \cap \ell| \leq 5$.
3. Let A and B be finite sets of at least two quaternions each. Then there exists a line ℓ in the quaternionic affine plane such that $2 \leq |(A \times B) \cap \ell| \leq 5$.
4. Let S be a finite noncollinear set of points in the quaternionic affine plane. Then there exists a line ℓ such that $2 \leq |S \cap \ell| \leq 24$.

1. Introduction. The Sylvester–Gallai theorem [12, 11] states that, for any finite noncollinear set of points in the Euclidean plane $\mathbb{R}^2$, there is a line intersecting the set in exactly two points. See [1, section 7.2] for a recent list of references regarding this theorem and its relatives. It is interesting to ask what happens if the underlying field is not the real numbers. In this paper we consider the complex numbers $\mathbb{C}$ and the quaternions $\mathbb{H}$. For more general considerations, see [8]. We consider the plane $\mathbb{K}^2$ over the skew field $\mathbb{K} \in \{\mathbb{R}, \mathbb{C}, \mathbb{H}\}$ to be the two-dimensional left vector space over $\mathbb{K}$. Lines are defined to be the translates of 1-dimensional subspaces. Thus lines are either vertical, i.e., of the form $\{(x, y) \in \mathbb{K}^2 : x = c\}$ for some $c \in \mathbb{K}$, or nonvertical: $\{(x, y) \in \mathbb{K}^2 : y = xm + c\}$ for some $m, c \in \mathbb{K}$. (The equation of a nonvertical line would be the more familiar $y = mx + c$ if we took $\mathbb{K}^2$ to be a right vector space). When $\mathbb{C}^2$ is identified with $\mathbb{R}^4$, lines are special types of 2-dimensional real subspaces, and therefore incidence problems involving them cannot be reduced to the real case. A similar remark holds for the identification of $\mathbb{H}^2$ with $\mathbb{R}^8$.

As observed by Kelly [6], it is a consequence of an inequality of Hirzebruch [5] that any finite noncollinear subset of $\mathbb{C}^2$ always intersects some line in 2 or 3 points (which is best possible, as shown by the nine inflection points of a cubic curve). No elementary proof is known of either the inequality or this consequence (see [1, section 7.3, Problem 7]). However, by adapting Kelly’s proof [2] of the Sylvester–Gallai theorem that uses

the smallest perpendicular distance between points and nonincident lines, it is possible to prove the following somewhat weaker statement.

THEOREM 1. *Let S be a finite noncollinear subset of $\mathbb{C}^2$. Then there exists a line ℓ such that $2 \leq |S \cap \ell| \leq 5$.*

Using the consequence of the inequality of Hirzebruch mentioned above, Kelly [6] showed that, for any finite nonplanar subset of $\mathbb{C}^3$, there exists a line intersecting the set in exactly two points, thus answering a question of Serre [9]. Another proof can be found in [4] that avoids the use of Hirzebruch's inequality. There it is also shown that any finite subset of $\mathbb{H}^4$ not on a hyperplane has a line intersecting the set in exactly two points. The approach in our proof of Theorem 1 also gives the following.

THEOREM 2. *Let S be a finite noncollinear subset of $\mathbb{H}^2$. Then there exists a line ℓ such that $2 \leq |S \cap \ell| \leq 24$.*

Note that although the number 24 is most likely too high, no example is known that shows it has to be larger than 3.

Many applications of incidence bounds to combinatorial number theory use only the special case where the set of points is assumed to be a grid, i.e., a Cartesian product of finite subsets of the ground field (see, for example, [10] and the survey paper of Elekes [3]). For this special case we obtain the following much stronger conclusions.

THEOREM 3. *Let $A, B \subset \mathbb{C}$, with $2 \leq |A|, |B| < \infty$. Then there exists a line ℓ in $\mathbb{C}^2$ such that $|(A \times B) \cap \ell| = 2$.*

THEOREM 4. *Let $A, B \subset \mathbb{H}$, with $2 \leq |A|, |B| < \infty$. Then there exists a line ℓ in $\mathbb{H}^2$ such that $2 \leq |(A \times B) \cap \ell| \leq 5$.*

2. Proofs. We consider $\mathbb{C}^2$ as a complex inner product space in the usual way, i.e., we define the inner product of vectors (a_1, b_1) and (a_2, b_2) in $\mathbb{C}^2$ as $\langle (a_1, b_1), (a_2, b_2) \rangle = a_1 \bar{a}_2 + b_1 \bar{b}_2$, the norm of $(a, b) \in \mathbb{C}^2$ as $\|(a, b)\| = \sqrt{\langle (a, b), (a, b) \rangle}$, and the distance between points (a_1, b_1) and (a_2, b_2) in $\mathbb{C}^2$ as $\|(a_1 - a_2, b_1 - b_2)\|$. Working carefully with inner products one can then determine the shortest distance between a point and a line in $\mathbb{C}^2$, as will be done in the next proof.

Proof of Theorem 1. As in Kelly's proof of the real Sylvester–Gallai theorem, we choose three noncollinear points $p, q, r \in S$ such that the distance between p and the line qr is a minimum. We show that qr contains at most 5 points.

After a unitary transformation and a dilatation (thus preserving the minimum distance) we may assume that $p = (0, 1)$, and that the line qr is the x -axis, i.e., $qr \cap S = \{(z_1, 0), \dots, (z_k, 0)\}$. Thus the distance between p and qr equals 1. Choose any two points $(z_i, 0), (z_j, 0) \in qr \cap S$. Then the distance between $(z_j, 0)$ and the line ℓ through $(0, 1)$ and $(z_i, 0)$ must be at least 1. Considering an arbitrary point $(1 - \lambda)(z_i, 0) + \lambda(0, 1)$ on ℓ , a simple calculation gives the square of its distance to $(z_j, 0)$ to be

$$\begin{aligned} & \|(1 - \lambda)(z_i, 0) + \lambda(0, 1) - (z_j, 0)\|^2 \\ &= \overline{(z_i - z_j)}^2 - (z_i - z_j)\lambda \bar{z}_i - \lambda z_i \overline{(z_i - z_j)} + |\lambda|^2 |z_i|^2 + |\lambda|^2 \\ &= \frac{|z_i - z_j|^2}{1 + |z_i|^2} + \frac{1 + |z_i|^2}{|z_i|^2} \left| \frac{|z_i|^2}{1 + |z_i|^2} (z_i - z_j) - \lambda z_i \right|^2. \end{aligned}$$

The last expression is minimized when

$$\lambda = \frac{(z_i - z_j)\bar{z}_i}{1 + |z_i|^2},$$

which gives that the square of the distance between $(z_j, 0)$ and ℓ is

$$\frac{|z_i - z_j|^2}{1 + |z_i|^2}.$$

Since this quantity is at least 1 for all distinct i and j , we obtain, in particular, that $|z_i - z_j| > |z_i|$ and $|z_i - z_j| > |z_j|$. Identify $\mathbb{C}$ with $\mathbb{R}^2$. Then for each triangle $\triangle 0z_i z_j$ in the Euclidean plane, the side $z_i z_j$ is the unique longest side. This implies that the angle $\angle z_i 0 z_j > 60^\circ$, giving $|qr \cap S| < 6$. $\square$

Proof of Theorem 2. We consider $\mathbb{H}^2$ to be a left vector space, which can be turned into an inner product space in exactly the same way as $\mathbb{C}^2$ where we recall that the conjugate of a quaternion $\alpha = a + bi + cj + dk$ is $\bar{\alpha} = a - bi - cj - dk$. The distance between two points is defined as before, and we may follow the previous proof almost verbatim, since the commutative law is not used anywhere. The only change is that the Euclidean plane has to be replaced by the identification of $\mathbb{H}$ with $\mathbb{R}^4$. We obtain that $|qr \cap S|$ is bounded above by the number of rays from the origin in $\mathbb{R}^4$ such that the angle at the origin between each pair exceeds 60° . This is bounded above by the kissing number of a ball in $\mathbb{R}^4$, which is 24 [7]. $\square$

We in fact obtained in the above proof that the *strict kissing number* is an upper bound, i.e., the largest number of nontouching unit balls in $\mathbb{R}^4$ that all touch a single unit ball. It is conjectured that the kissing arrangement of 24 balls in $\mathbb{R}^4$ is unique [7], which would imply that the strict kissing number is at most 23.

Proof of Theorem 3. Suppose that the conclusion is false. Let a_1 and a_2 be a closest pair in A , and b_1 and b_2 a furthest pair in B . Then there exists a third point $(a_3, b_3) \in A \times B$ such that (a_1, b_1) , (a_2, b_2) , (a_3, b_3) are collinear. Let the equation of the (nonvertical) line in $\mathbb{C}^2$ on which they lie be $y = xm + c$, $m, c \in \mathbb{C}$. Again identify $\mathbb{C}$ with the Euclidean plane $\mathbb{R}^2$. Then the map $\varphi : \mathbb{C} \rightarrow \mathbb{C}$, $z \mapsto zm + c$ is an orientation-preserving similarity transformation, with $\varphi(a_i) = b_i$, $i = 1, 2, 3$. Since a closest pair in $\{a_1, a_2, a_3\}$ is mapped to a furthest pair in $\{b_1, b_2, b_3\}$ and ratios of distances are preserved, $\triangle a_1 a_2 a_3$ and $\triangle b_1 b_2 b_3$ are both equilateral triangles in the plane.

We now interchange b_1 and b_2 , i.e., we consider the line through (a_1, b_2) and (a_2, b_1) with equation $y = xm' + c'$. By assumption there is a third point (a'_3, b'_3) on this line, and exactly as before, the map $\varphi' : \mathbb{C} \rightarrow \mathbb{C}$, $z \mapsto zm' + c'$ preserves orientation and maps the equilateral triangle $\triangle a_1 a_2 a'_3$ to $\triangle b_2 b_1 b'_3$.

Suppose that $a_3 = a'_3$. Then $b_3 \neq b'_3$, since $\triangle b_1 b_2 b_3$ and $\triangle b_2 b_1 b_3$ have opposite orientations. Thus $\triangle b_1 b_2 b_3$ and $\triangle b_1 b_2 b'_3$ are distinct equilateral triangles with a common edge; hence $|b_3 - b'_3| = \sqrt{3}|b_1 - b_2| > |b_1 - b_2|$, which contradicts the choice of b_1 and b_2 .

Therefore $a_3 \neq a'_3$. We have shown that any closest pair of points in A is contained in the vertex sets of two equilateral triangles. This, however, contradicts the finiteness of A . $\square$

Note that we made essential use of the fact that the similarities preserve orientation. Without this, we would only be able to conclude that there is a line ℓ such that $2 \leq |(A \times B) \cap \ell| \leq 3$.

Proof of Theorem 4. We proceed along the same lines as in the previous proof. Let $\{a_1, a_2\}$ be a closest pair in A , and $\{b_1, b_2\}$ a furthest pair in B . Consider the line ℓ through (a_1, b_1) and (a_2, b_2) . Since $a_1 \neq a_2$, ℓ is of the form $y = xm + c$. Then the mapping $\varphi : \mathbb{H} \rightarrow \mathbb{H}$; $x \mapsto xm + c$ maps $A' := \{x \in \mathbb{H} : (x, y) \in \ell \cap (A \times B)\}$ to $B' := \{y \in \mathbb{H} : (x, y) \in \ell \cap (A \times B)\}$. Identifying $\mathbb{H}$ with $\mathbb{R}^4$ we see that φ is a

a similarity transformation of $\mathbb{R}^4$, i.e., a composition of a translation, rotation and dilation. Thus B' is similar to A' . Because the smallest distance in A' is mapped to the largest distance in B' , A' and B' are both equilateral sets in $\mathbb{R}^4$; hence $|\ell \cap (A \times B)| = |A'| = |B'| \leq 5$. $\square$

Acknowledgments. We thank the anonymous referees for their valuable remarks.

SEQUENCES WITH CHANGING DEPENDENCIES*

PAUL BALISTER[†], BÉLA BOLLOBÁS[‡], AND STEFANIE GERKE[§]

Abstract. Consider words over an alphabet with n letters. Fisher [*Amer. Math. Monthly*, 96 (1989), pp. 610–614] calculated the number of distinct words of length ℓ assuming certain pairs of letters commute. In this paper we are interested in a more general setting where the pairs of letters that commute at a certain position of a word depend on the initial segment of the word. In particular, we show that if for each word at each position any letter fails to commute with at most a constant number of other letters, then the number of distinct words of length ℓ is at most $C^{n+\ell}$ for some constant C . We use this result to obtain a lower bound on the number of diagonal flips required in the worst case to transform one n -vertex labeled triangulated planar graph into some other one. This has previously been proved in [D. D. Sleator, R. E. Tarjan, and W. P. Thurston, *SIAM J. Discrete Math.*, 5 (1992), pp. 428–450] by different methods.

Key words. sequences, triangulations, commuting sets

AMS subject classification. 05C30

DOI. 10.1137/060663611

1. Introduction. Let $\mathcal{A} = \{a_1, \dots, a_m\}$ be a finite alphabet consisting of letters $a_1, \dots, a_m$. We denote the set of all words of finite length with letters from $\mathcal{A}$ by $\mathcal{A}^*$. Given a word $w \in \mathcal{A}^*$, we write $[w]_t$ for the prefix of w of length t (that is, $[w]_t$ consists of the first t letters of w). For each word w in $\mathcal{A}^*$ we fix a set $C_w \subseteq \mathcal{A}$. We call the collection $\mathcal{C} = (C_w : w \in \mathcal{A}^*)$ the *commuting family*. Let $\sim_{\mathcal{C}}$ be the smallest equivalence relation such that

$$a_1 \dots a_{t-1} a_t a_{t+1} \dots a_{\ell} \sim_{\mathcal{C}} a_1 \dots a_{t-1} a_{t+1} a_t \dots a_{\ell}$$

whenever $a_{t+1} \in C_{a_1 \dots a_t}$. By enlarging the sets C_w , if necessary, we may assume that for all $a, b \in \mathcal{A}$ and $w \in \mathcal{A}^*$, we have $a \in C_{wb} \Leftrightarrow b \in C_{wa}$. Note that this does not change the equivalence relation. We call two words w and w' equivalent (with respect to $\mathcal{C}$) if $w \sim_{\mathcal{C}} w'$.

Fisher [4] considered the number T_{ℓ} of equivalent classes of words of length ℓ , when C_w depends only on the last letter of w (that is, we specify the pairs of letters that commute). In this case one can construct a dependency graph $G = (V, E)$ where the vertices correspond to the letters of the alphabet and two vertices are adjacent if the corresponding letters commute. Fisher showed that for $\ell > 0$, $T_{\ell} = \sum_{k=1}^{\ell} (-1)^{k+1} c_k T_{\ell-k}$ with $T_0 = 1$, where c_k is the number of complete subgraphs of size k in G . It follows that the generating function $t(x) = \sum_{k=0}^{\infty} T_k x^k$ is closely related to the well-known independence polynomial $Z_G(x) = \sum_{k=0}^{|V|} s_k x^k$, where s_k is the number of independent sets with k vertices. More precisely, $t(x) = 1/Z_{\overline{G}}(-x)$,

where $\overline{G}$ is the complement of G . The notation we use here, Z_G , is the one used in statistical physics, where (a generalization of) the polynomial goes under the name of the “lattice-gas partition function” associated with the graph G . For a review of various combinatorial results concerning the independence polynomial, see Levit and Mandrescu [7].

Clearly, $s_0 = 1$, $s_1 = |V|$ for every graph $G = (V, E)$, and $s_n = 0$ unless G has no edges, in which case it is 1. In particular, Z_G is nonzero in some complex disc

$$D_R = \{z \in \mathbb{C} : |z| \leq R\},$$

where $R > 0$.

Extending a result of Kotecký and Preiss [6], Dobrushin [1] (see also [2]) proved the following fundamental result in statistical physics, widely known as *Dobrushin’s theorem*.

THEOREM 1.1. *Let Z_G be the independence polynomial of a graph $G = (V, E)$. Let r_v , $v \in V$, be constants such that $0 \leq r_v < 1$, and*

$$R \leq r_v \prod_{u: uv \in E} (1 - r_u)$$

for every $v \in V$. Then Z_G is nonzero in the disc $|z| \leq R$.

In fact, if $|z| \leq R$, then

$$(1) \quad |Z_G(z)| \geq Z_G(-R) \geq \prod_{v \in V} (1 - r_v).$$

Twenty years earlier, Lovász had proved a celebrated result in combinatorics with analogous conditions (see [3]). This result, the *Lovász local lemma*, gives necessary conditions for the probability of the intersection of a family of events to be strictly positive, when these events are not far from being independent. Recently, Scott and Sokal [9], [8] showed that these two fundamental results, the Lovász local lemma and Dobrushin’s theorem, are, in fact, equivalent. The proof of this equivalence is not too easy: it is based on the result of Shearer [10] that the conditions in the Lovász local lemma are best possible.

As a consequence of Dobrushin’s theorem, if the degree of every vertex in $G = (V, E)$ is bounded by k , then one can take $R = R(k) > 0$ independently of the size of G . Since $t(x) = 1/Z_{\overline{G}}(-x)$, this implies, for example, that there are at most $C(k)^{\ell+|V|}$ different equivalence classes of words of length ℓ if there are at most k letters that do not commute with any given letter (in other words the dependency graph G has minimum degree at least $|V| - k - 1$).

Sleater, Tarjan, and Thurston [11] used a different setup to count the number of different outcomes of sequences of transformations of graphs. Each transformation is obtained by replacing a subgraph isomorphic to one of a fixed family of graphs by another graph. Whether or not two transformations commute depends on the previous transformations applied. In this sense it is very similar to our approach, but ours appears to be more general as well as simpler.

As an example where the sets C_w depend on the entire word and not only the last letter, we consider words in connection with the class of labeled triangulations on n vertices, that is, maximal planar graphs on the vertex set $\{1, \dots, n\}$. Consider a fixed triangulation that is embedded in the plane. Due to Whitney [14], this embedding is essentially unique. If one removes an edge $\{i, j\}$ of a triangulation, then there is

a face $\{i, k, j, l\}$ of size four, and if the edge $\{k, l\}$ does not already exist, then one can add $\{k, l\}$ instead of $\{i, j\}$ to obtain a new triangulation. Such an operation is called a *flip*. It is well known [13] that each triangulation can be reached from any other triangulation by a finite number of flips. We consider such *flip sequences* from a fixed given embedded triangulation and also *extended flip sequences* where we allow multiple edges but insist that each of the multiple edges has its own face, namely, the face of size four that is obtained by deleting the edge before the flip.

Let $\mathcal{A} = \{a_0, \dots, a_{3n-6}\}$ be the alphabet where for $i = 1, \dots, 3n - 6$ the flip of edge i is represented by the letter a_i and a nonflip is represented by a_0 . After a flip of edge i , the new edge created will still be numbered i . Some flip sequences may lead to the same triangulation. To capture this we define for an extended flip sequence $w = a_i \dots a_j$, the set C_w as the nonflip a_0 , and the set of all edges except for the four edges having a common face with the last edge a_j after the flips of the sequence w have taken place.

Consider the commuting family $\mathcal{C} = (C_w : w \in \mathcal{A}^*)$ and the set $\mathcal{A}^\ell$ of all flip sequences of length ℓ starting with a given embedded triangulation. Note that if two flip sequences in $\mathcal{A}^\ell$ are equivalent, then the two sequences yield the same triangulation. This can be seen by observing that it does not matter at which point an edge is flipped as long as the edges incident to a common face have not been changed, and $\mathcal{C}$ is chosen in such a way that the order of edges incident to a common face can never be changed. Hence the number of equivalence classes is at least the number of triangulations that can be reached with ℓ flips from the given triangulation. We want to find a lower bound on the number of flips ℓ needed to reach all triangulations from a fixed given triangulation. Since Tutte [12] has shown that the number of triangulations is at least $C^n n!$ for any $C < 256/27$ and sufficiently large n , it suffices to find an upper bound on the number of equivalence classes of $\mathcal{A}^\ell$, as we need more equivalence classes than triangulations to reach all triangulations from a given one. We find such an upper bound in Theorem 2.2, where we show that the number of equivalence classes is at most $\tilde{C}^{|\mathcal{A}|+\ell}$ for some constant $\tilde{C}$. Thus to reach all triangulations from a fixed triangulation we have to ensure that the number of flips ℓ satisfies $\tilde{C}^{3n-5+\ell} \geq C^n n!$. It follows that $\Omega(n \log n)$ flips are needed. This lower bound matches asymptotically the upper bound, as it is known (see [11] and [5]) that $O(n \log n)$ flips suffice. The lower bound has also been shown in [11] with a slightly longer, more complicated proof. In particular, in [11] one needs to consider the dual of a triangulation before one can apply their method.

2. Main result. To prove our main result we first show that the number of words over the alphabet $\{1, \dots, m\}$ that never decrease much can be bounded from above.

LEMMA 2.1. *Let $k \in \mathbb{N}$ be a constant. The number of words $a_1 \dots a_\ell$ of length ℓ over the alphabet $\mathcal{A} = \{1, \dots, m\}$ such that $a_{j+1} - a_j \geq -k$ for all $1 \leq j \leq \ell - 1$ is at most*

$$\binom{m + \ell k + \ell}{\ell} \leq ((k + 1)e)^\ell e^{m/(k+1)},$$

where e denotes the base of the natural logarithm.

Proof. We can view the sequence $a_1, \dots, a_\ell$ as the following walk on the integers starting at 0. We consider $a_1, \dots, a_\ell$ in turn. When considering a_i , $b_i = a_i - a_{i-1} + k$ steps of size 1 are taken up (where we set $a_0 = k$) and then one step of size k is taken down; see Figure 1. Note that $b_i \geq 0$ as $a_{j+1} - a_j \geq -k$ for all $1 \leq j \leq \ell - 1$. Given

FIG. 1. Sequence $UUDUUUUUDDUUUU$ corresponds to $(a_1, a_2, a_3) = (2, 5, 3)$, where $k = 2$, $m = 5$.

such a walk we can easily reconstruct the sequence $a_1 \dots a_\ell$, as a_i is just the height of the walk before stepping down for the i th time. Hence it remains to count the number of such walks.

Note that when considering the word $a_1, \dots, a_\ell$ we can step up a total of at most $m + \ell k$ times. By adding additional steps up after the last step down, we may assume without loss of generality that there are exactly $m + \ell k$ steps up and ℓ steps down. Therefore the number of such walks is at most the number of ways we can choose the positions of the ℓ steps down out of the $m + \ell k + \ell$ steps and is thus at most

$$\begin{aligned} \binom{m + \ell k + \ell}{\ell} &\leq \left(\frac{e(m + \ell(k + 1))}{\ell} \right)^\ell \\ &\leq \left((k + 1)e \left(\frac{m}{(k + 1)\ell} + 1 \right) \right)^\ell \leq ((k + 1)e)^\ell e^{m/(k+1)}. \end{aligned}$$

(Here we used the well-known facts that $\binom{a}{b} \leq (ea/b)^b$ and $(1 + x) \leq e^x$.) $\square$

THEOREM 2.2. *Let $k \in \mathbb{N}$ be a constant, let $\mathcal{A}$ be a finite alphabet with m letters, and let $\mathcal{A}^\ell$ be a subset of all words in $\mathcal{A}^*$ of length ℓ . If every member C_w of a commuting family $\mathcal{C}$ has at least $m - k$ elements, then there exists a set $\mathcal{S}$ of size at most $((k + 1)e)^\ell e^{m/(k+1)}$ such that for each word $w \in \mathcal{A}^\ell$ there exists a word $w' \in \mathcal{S}$ with $w \sim_{\mathcal{C}} w'$.*

Proof. We shall define an injection from the set of equivalence classes to the set of sequences $b_1, \dots, b_\ell$ of length ℓ with $b_j \in \{1, \dots, m\}$ and the property that $b_{j+1} - b_j \geq -k$. The result then follows by Lemma 2.1.

Let $\mathcal{A} = \{a_1, \dots, a_m\}$. We start with an arbitrary ordering of the letters, say, $a_1 < a_2 < \dots < a_m$. This ordering might change at each step of the following procedure. We assign the following sequence $b_1, \dots, b_\ell$ to a word $w = a_{i_1}, \dots, a_{i_\ell} \in \mathcal{A}^\ell$: At each step j , $b_j \in \{1, \dots, m\}$ is equal to the position of a_{i_j} in the current ordering. Thus $b_1 = i_1$. Given the ordering when we have considered k letters of w , the next ordering is obtained by moving the letters not in $C_{[w]_k}$ that are below a_{i_k} directly below a_{i_k} so that the relative order is conserved; see Table 1. Observe that letters that are above a_{i_k} in the current ordering are not moved.

Note first that given the set $\mathcal{C}$ and the initial ordering $a_1 < a_2 < \dots < a_m$, a sequence $b_1, \dots, b_\ell$ with $b_i \in \{1, \dots, m\}$ for all $1 \leq i \leq \ell$ represents a unique word in $\mathcal{A}^*$. Thus it remains to show that we can choose a word in each equivalence class in

TABLE 1

The change of the ordering with the word *decaf* which is mapped to $(4, 5, 4, 3, 6)$. We start with the ordering a, b, c, d, e, f and consider the letters of the word *decaf* in turn. After considering d we have to move the letters not in C_d that are below d directly behind d . C_d consists of two elements b, f . Thus we have to move a, c directly behind d to obtain b, a, c, d, e, f . After considering de we have to move all the elements below e that are not in $C_{de} = \{a, d\}$ directly behind e . Thus we have to move b and c to obtain a, d, b, c, e, f . We continue and obtain the word $(4, 5, 4, 3, 6)$.

Commuting sets: $C_d = \{b, f\}$, $C_{de} = \{a, d\}$, $C_{dec} = \{b, d\}$, $C_{deca} = \{e, f\}$					
Order	Initially	After:			
		d	de	dec	$deca$
6	f	f	f	f	f
5	e	e	e	e	e
4	d	d	c	c	c
3	c	c	b	a	a
2	b	a	d	b	b
1	a	b	a	d	d

such a way that each word is mapped to a sequence $b_1, \dots, b_\ell$ with $b_{j+1} - b_j \geq -k$ for all $j \in \{1, \dots, \ell - 1\}$. For each equivalence class we choose the word that is assigned the lexicographically smallest sequence, that is, if $w = a_{i_1} \dots a_{i_\ell}$ is chosen and is mapped to $b_1, \dots, b_\ell$, then every word that is equivalent to w is assigned to a sequence that is bigger than $b_1, \dots, b_\ell$ in the lexicographic order.

We now claim that these chosen words are assigned to sequences $b_1, \dots, b_\ell$ with $b_{j+1} - b_j \geq -k$ for all $1 \leq i \leq \ell$. Assume for contradiction that a chosen word $w = a_{i_1} \dots a_{i_\ell}$ is mapped to a sequence $b_1, \dots, b_\ell$ such that $b_{t+1} - b_t < -k$ for some index $t \in \{1, \dots, \ell - 1\}$. Then by the assumption that $|C_{[w]_t}| \geq m - k$ and the choice of our ordering, $a_{i_{t+1}} \in C_{[w]_t}$. Thus w is equivalent to $w' = a_{i_1} \dots a_{i_{t-1}} a_{i_{t+1}} a_{i_t} a_{i_{t+2}} \dots a_{i_\ell}$. But it is clear that $a_{i_1} \dots a_{i_{t-1}}$ is mapped to the same subsequence in both words. Moreover, after we have considered $a_{i_1} \dots a_{i_{t-1}}$, in the current ordering we have $a_{i_{t+1}} < a_{i_t}$, since $a_{i_{t+1}} \geq a_{i_t}$ at this point would imply that $a_{i_{t+1}} \geq a_{i_t}$ in the ordering after $[w]_t$ has been considered. But this contradicts our assumption. Hence w' is mapped to a sequence that is smaller with respect to the lexicographic ordering, a contradiction to the choice of w . $\square$

As we have discussed in the introduction one can consider the set $\mathcal{A}^\ell$ of all flip sequences of length ℓ from a given triangulation T , and construct sets C_w , $w \in \mathcal{A}^*$ with $|C_w| \leq (3n - 5) - 4$ for all $C_w \in \mathcal{C}$ such that every triangulation T' that can be reached from T with at most ℓ flips is represented by at least one equivalence class. For any $C < 256/27$, there are at least $C^n n!$ triangulations of size n , and by Theorem 2.2 we can reach at most $t(\ell) = (5e)^\ell e^{(3n-5)/5}$ triangulations from T with ℓ flips. Thus we have to choose ℓ such that $t(\ell) \geq C^n n!$ in order to achieve that the number of triangulations that can be reached from T with at most ℓ flips is bigger than the number of all triangulations. But $t(\ell) \geq C^n n!$ is equivalent to $\ell \geq \alpha n \log n$ for some constant $\alpha > 0$. Hence we obtain the following result, a more complicated proof of which can be found in [11].

COROLLARY 2.3. *There are labeled triangulations T and T' on n vertices such that $\Theta(n \log n)$ flips are needed to transform T into T' .*

The alert reader might have observed that we did not need all the properties of the equivalence relation $\sim_{\mathcal{C}}$. Thus we can slightly generalize the definition of a commuting family. We consider sets $\mathcal{B} \subseteq \mathcal{A}^*$ where some of the words in $\mathcal{B}$ are *dominated* by others. More precisely, we are given a set $(C'_w \subseteq \mathcal{A} : w \in \mathcal{A}^*)$ that we call a *generalized*

commuting family, and a word $w_1 \in \mathcal{B}$ dominates a word $w_2 \in \mathcal{B}$ if and only if there exists a sequence of words $w'_1, w'_2, \dots, w'_l \in \mathcal{A}^*$ with $w_1 = w'_1$ and $w_2 = w'_l$ such that for each $j = 1, \dots, l-1$, w'_{j+1} can be obtained from w'_j by exchanging two consecutive letters at positions t_j and $t_j + 1$ and the $t_j + 1$ st letter of w'_{j+1} is contained in $C'_{[w'_j]_{t_j}}$. For example if $\mathcal{B}$ consists of all words of length ℓ and $C'_w = \mathcal{A}$ for all $w \in \mathcal{A}^*$, then every word dominates every other word. If $C'_w = \emptyset$ for all $w \in \mathcal{A}^*$, then no word dominates any other word. Finally, for a set $\mathcal{B}$ with generalized commuting family $\mathcal{C}$, a *basic set* is a subset of $\mathcal{A}^*$ such that each word of $\mathcal{B}$ dominates at least one word of the basic set. Trivial basic sets of $\mathcal{B}$ with commuting family $\mathcal{C}$ are supersets of $\mathcal{B}$. The size of a smallest basic set $\mathcal{B}$ with commuting family $\mathcal{C}$ is denoted by $|\mathcal{B}, \mathcal{C}|$. Now, as in Theorem 2.2 one can prove that $|\mathcal{B}, \mathcal{C}| \leq C(k)^{m+\ell}$ if every element of the generalized commuting family contains at least $m - k$ elements.

SPLIT HYPERGRAPHS*

ÁDÁM TIMÁR†

Abstract. Generalizing the notion of split graphs to uniform hypergraphs, we prove that the class of these hypergraphs can be characterized by a finite list of excluded induced subhypergraphs. We show that a characterization by generalized degree sequences is impossible, unlike in the well-known case of split graphs. We also give an algorithm to decide whether a given uniform hypergraph is a split hypergraph. If it is, the algorithm gives a splitting of it; the running time is $O(N \log N)$. These answer questions of Sloan, Turán, and Peled.

Key words. split hypergraph, split graph, excluded induced subgraph, degree sequence, sparse and dense graph

1. Introduction, split graphs. We call a graph G *split* if there exists a partition $A \cup B$ of its vertex set so that there is no edge between any two points of A and there is an edge between every two points of B . Such a partition $A \cup B$ of $V(G)$ is called a *splitting*.

The following theorem describes split graphs in two different ways.

THEOREM 1.1. *For a graph G the following are equivalent:*

1. G is split.
2. G does not contain C_4 , C_5 , or $K_2 \cup K_2$ as an induced subgraph.
3. There is an m such that $\sum_{i=1}^m d_i - m(m-1) = \sum_{i=m+1}^n d_i$, where $d_1 \geq d_2 \geq \dots \geq d_n$ are the degrees in G .

The equivalence of 1 and 2 is first shown in [5], while the equivalence of 1 and 3 is in [6]. See also [1] or [4] for history and further references.

The generalizations of many graph theoretical questions to hypergraphs have practical significance. Most frequently, posing these problems for hypergraphs makes them rather difficult. For example, testing the existence of a perfect matching can be solved by a well-known polynomial algorithm for graphs. Generalizing it to 3-uniform hypergraphs, we get an NP-complete problem (see [7], [3]).

The class of line graphs can be characterized by a finite list of excluded induced subgraphs—on the other hand, there are infinitely many pairwise nonisomorphic graphs with the property that none of them is the line graph of any 3-uniform hypergraph, but every proper subgraph of any of them is (see [8]). Studying extremal questions for graphs turned out to be very fruitful. The generalization of this theory to hypergraphs comes up against serious difficulties.

Recent research in learning theory has led to a generalization of the notion of split graphs (see [9]). Call a k -uniform hypergraph G a *split hypergraph* if its vertices can be partitioned into two classes so that every k -tuple in one of the classes is an edge and no k -tuple in the other class is an edge in G . We call such a partition a *splitting*.

Note that our definition allows one of the classes to have size smaller than k , in which case the requirement on that class automatically holds.

When G is not a split hypergraph, we say that it is not split or nonsplit. For a hypergraph G , $V(G)$ will denote its vertex set and $E(G)$ its edge set. From now on, n denotes $|V(G)|$ and N is $|V(G)| + |E(G)|$.

The following question arose naturally: Can we state something similar to Theorem 1.1 for the case of split hypergraphs? Peled asked whether the class of k -uniform split hypergraphs can be characterized by a finite list of excluded induced subhypergraphs. We give an affirmative answer to this question in section 2. Section 3 gives examples of minimal nonsplit hypergraphs in the 3-uniform case. We did not strive for completeness of the list. Nevertheless, it may show that the number of excluded induced subhypergraphs increases considerably as we go from graphs to 3-uniform hypergraphs. In section 4 we examine if the connection between degree sequences and the split property of graphs can be generalized. We find a negative answer.

In their paper [9], where they apply split hypergraphs in learning theory, Sloan and Turán gave an algorithm that decides whether a k -uniform hypergraph is split and gives a splitting if possible. The running time of their algorithm is $O(n^{2k})$; they mention that finding a more efficient algorithm is an open question. Feder et al. [2] introduce the notion of a sparse and dense partition of a graph, which is a kind of generalization of a splitting. Their definition can be extended to hypergraphs and the algorithm they present (in Theorem 3.1) can be used to find a splitting (or all splittings) of a uniform hypergraph. The running time of their algorithm in this context is the same as the time requirement of the one given by Sloan and Turán. In section 5 we give an $O(N \log N)$ algorithm for the problem. Our method can also be used to give an algorithm for sparse and dense partitions that in certain cases is faster than the one in [2].

The restriction of an edge to an $X \subset V(G)$ is its intersection with X . Minimality of a graph with respect to a certain property will always mean that no *induced* proper subgraph of it has the property. As usual, $X \Delta Y$ will stand for the symmetric difference between sets X and Y . When $x \in V(G)$, we sometimes simply use x instead of $\{x\}$ in set operations.

2. The existence of a finite characterization. In this section we prove our main theorem. First we state two lemmas. The following lemma holds for hypergraphs with edges of sizes at most k , which is a relaxation of k -uniformity, and is convenient for our inductive proof.

LEMMA 2.1. *Let k and m be positive integers and Γ a hypergraph with edges of size at most k . Then Γ has at most k^m different minimal cover sets of at most m points. Furthermore, there is an algorithm of time requirement $O(|V(\Gamma)| + |E(\Gamma)|)$ that outputs a list of these minimal cover sets.*

Because of the short running time of our algorithm, some more details about the implementation could be added. However, the design of a data structure and the implementation of the algorithm do not match the texture of our paper, so we leave these to the interested reader.

Proof. We prove the first part of the claim by induction on m . The case $m = 1$ is obvious. Suppose that for $m < r$ the statement is true, and let Γ be any hypergraph with edges of size at most k . Let H be an arbitrary edge. Any minimal cover set of Γ with at most m points consists of a point x of H and a minimal cover set of $\Gamma|_{V(\Gamma) \setminus \{x\}}$ with at most $m - 1$ elements. Applying the induction hypothesis to the latter one and noting that x could be chosen in k different ways, we get the statement for $m = r$.

The algorithm will imitate the proof in the previous paragraph. For $i = 1, \dots, m$, pick the first edge e_i that has not been deleted yet, a vertex v_i of e_i , delete the edges that contain v_i , and let $i := i + 1$. The output is $\{v_1, \dots, v_m\}$. Since the number of minimal cover sets is bounded by a constant, we can list all of them by systematically going through all possible ways of picking v_i in the sequence of e_i , and still use only linear time. $\square$

In what follows, for the sake of simplicity, the edges of the k -uniform hypergraph G will be referred to as *type 0 edges*, and the k -tuples not contained in $E(G)$ as *type 1 edges*. (Thus we identify G with a labeling of the edges of a complete k -uniform hypergraph by numbers 0 and 1.)

Consider some minimal nonsplit hypergraph G . Minimality implies that for any $x \in G$ there is a splitting (A_0^x, A_1^x) of $G \setminus x$; i.e., A_0^x induces only edges of type 0, and A_1^x induces only edges of type 1. (A class that contains only edges of type i will sometimes be called a *type i class*.)

LEMMA 2.2. *Fix a splitting (A_0^v, A_1^v) of $G \setminus v$ for every $v \in V(G)$. If $x, y \in V(G)$ are vertices in a minimal nonsplit hypergraph G , then $|A_i^x \cap A_{1-i}^y| < k$ and $|A_i^x \Delta A_i^y| \leq 2k$ for $i = 0, 1$.*

Proof. The first inequality follows by the fact that a k -tuple cannot be contained in the type i class of a splitting (of $G \setminus x$) and a type $1 - i$ class of a splitting (of $G \setminus y$) at the same time. For the second inequality, use the facts

$$A_i^x \setminus A_i^y \subset A_i^x \cap (A_{1-i}^y \cup \{y\}) \quad \text{and} \quad |A_i^x \cap (A_{1-i}^y \cup \{y\})| \leq k$$

by the first inequality. Conclude similarly with x and y interchanged to obtain the bound on the symmetric difference. $\square$

In the proof, we shall consider sets subindexed by 0 or 1. Such a set, of subindex i , will always be a class of edges of type i , or some “preliminary set” in constructing a class only with edges of type i . This notation will provide us with the following convenience in terminology. Given some set $S \subset V(G)$ by a name subindexed by i ($i = 0, 1$), let the *bad edges* of S be the edges of type $1 - i$ on S .

THEOREM 2.3. *If a k -uniform nonsplit hypergraph has more than $4(k+1)k^{4k(k+1)+1}$ vertices, then it has a proper induced subhypergraph that is nonsplit.*

Fix k . We shall give an algorithm. Its brief description is given in the next two paragraphs. The input is $G, x, (A_0^x, A_1^x), \alpha, \beta$, where G is a minimal nonsplit hypergraph, $x \in V(G)$, (A_0^x, A_1^x) is a splitting of $G \setminus x$, $\alpha \in \{1, \dots, 4k\}$, and $\beta \in \{1, \dots, k+1\}$. The algorithm either stops without any output, or outputs a splitting of $G \setminus y$ for some $y \in V(G)$. It has a randomized part to simplify its description.

At the beginning our algorithm adds x to A_0^x , creating some type 1 edges (bad edges) in $B_0 := A_0^x \cup x$. There is another class B_1 , set to be A_1^x at the start. Then we choose a random minimal cover set of size at most $k+1$ for the bad edges and move it over from B_0 to B_1 . In general, at each step at most one of B_0 and B_1 contains any bad edges, depending on the parity of the step. The algorithm always chooses uniformly a random minimal cover set of size at most $k+1$ for these bad edges, and consisting of points that have not been moved between the two classes yet, and any such set is chosen with positive probability. (If there is no such set, then the algorithm fails.) Move this minimal cover set to the other class. When we arrive at the α th step, let the β th element of the minimal cover set be called y . (We may assume that there is some fixed ordering on any subset of the vertices, for example, the one given by the listing of the vertices in the input.) Remove y from the minimal cover set (and hence from both classes in the future) and continue the procedure. We run the algorithm for

at most $4k$ steps. With positive probability, at some step, (B_0, B_1) will be a splitting of $G \setminus y$, and this is the output.

The inputs α and β , together with the choices that the random part of the algorithm makes, determine y . Using Lemma 2.1, we shall give a bound on the number of possible choices and finally get the general upper bound in Theorem 2.3 for the number of vertices in G .

Here is a formal presentation of the algorithm.

ALGORITHM 1.

FUNCTION $\text{BadEdges}(i, B_i)$ returns the list of type $1-i$ (bad) edges of B_i .

FUNCTION $\text{MinCoverSet}(R, L)$ returns a uniformly chosen random minimum cover set of R of size at most $k+1$ that is disjoint from L . If there is no such set, then the algorithm ends and outputs ‘‘Unsuccessful.’’

Start of Algorithm

INPUT: a k -uniform hypergraph G , vertex x of G , a splitting (A_0^x, A_1^x) of $G \setminus x$, numbers $\alpha \in \{1, \dots, 4k\}$ and $\beta \in \{1, \dots, k+1\}$.

$B_0 := A_0^x \cup \{x\}$, $B_1 := A_1^x$, $L := \emptyset$, $i := 0$, $j := 1$, $\ell := \emptyset$

while $j \leq 4k$ **do** {

$R := \text{BadEdges}(i, B_i)$

if $R = \emptyset$ **then** **output** (B_0, B_1) , **end of algorithm**

$\ell := \text{MinCoverSet}(R, L)$

$B_i := B_i \setminus \ell$, $L := L \cup \ell$

if $j = \alpha$ **then** { **if** $|\ell| < \beta$ **then** **output** $(\text{‘‘Unsuccessful’’})$, **end of algorithm**,

else $\ell := \ell \setminus \{y\}$, where y is the β th element of ℓ }

$B_{1-i} := B_{1-i} \cup \ell$

$i := 1 - i$, $j := j + 1$

}

output $(\text{‘‘Unsuccessful’’})$, **end of algorithm**

LEMMA 2.4. Fix G , x , and (A_0^x, A_1^x) in the input. For any $y \in V(G)$, Algorithm 1 outputs a splitting of $G \setminus y$ with positive probability for some values of α, β .

Proof. Fix y and a splitting (A_0^y, A_1^y) of $G \setminus y$. None of the bad edges in $A_0^x \cup \{x\}$ can be contained in A_0^y , so there exists some minimal cover set of these bad edges that is contained in $A_1^y \cup \{y\}$. (Such a minimal cover set is chosen by MinCoverSet with positive probability.) This minimal cover set cannot have more than $k+1$ elements, because then a k -tuple would be present in both A_0^x and A_1^y , contradicting Lemma 2.2. Since the points that we moved are in $A_1^y \cup \{y\}$ by our choice, they get to their final class by the move, so we may assume that they are not moved in later steps of the algorithm. Hence, when the algorithm chooses a minimal cover set of the bad edges of size at most $k+1$ and moves this set from $A_0^x \cup \{x\}$ to A_1^x (call the resulting sets C_0 and C_1 , respectively), we have $|C_0 \Delta A_0^y| < |A_0^x \Delta A_0^y|$, and also $|C_1 \Delta A_1^y| \leq |A_1^x \Delta A_1^y|$. These inequalities are crucial in that we succeed after at most $4k$ repetitions. When y is in ℓ , if α is equal to the actual j and y is the β th element in ℓ , then y is removed from ℓ , and its removal ensures that the remaining graph has a splitting. (This possible removal causes the second inequality above to be not necessarily strict.)

Similarly, denote by D_0 and D_1 the sets B_0 and B_1 , respectively, at some step, and let C_0 and C_1 be B_0 and B_1 , respectively, in the next step. Let ℓ be the set that was moved, as in the algorithm; we may assume by symmetry that it was moved from D_0 to D_1 . So, $C_0 = D_0 \setminus \ell$ and $C_1 = D_1 \cup (\ell \setminus y)$. There were some bad edges in

D_0 because the algorithm did not stop. None of these bad edges can be contained in A_0^y , so there exists some minimal cover set of the bad edges that is contained in A_1^y . We may assume that the elements of this minimal cover set are points that have not been moved at any previous step (i.e., they are not in L), because we are considering the outcome of the algorithm (of positive probability), when the moved vertices must reach the type of class that contains them in (A_0^y, A_1^y) by the move. (The only vertex not in any of A_0^y or A_1^y is y , but it is removed from ℓ if α and β are suitable.) The algorithm chooses such a minimal cover set ℓ with positive probability, and then we have

$$|C_0 \Delta A_0^y| < |D_0 \Delta A_0^y| \text{ and } |C_1 \Delta A_1^y| \leq |D_1 \Delta A_1^y|.$$

We conclude that $|B_0 \Delta A_0^y| + |B_1 \Delta A_1^y|$ decreases in each iteration step by at least 1 with positive probability. At some step, y has to be contained in ℓ , since G itself is not split. If α and β are suitable, then y is removed from ℓ (and the future $B_0 \cup B_1$). Then the algorithm can stop for two reasons. The first is when it outputs “Unsuccessful” because of the random choices made by **MinCoverSet**. However, we have seen that, for a certain sequence of the random choices made by **MinCoverSet** along the iteration steps, there always exists a minimal cover set of the bad edges consisting of points not moved yet, as long as the set of the bad edges is nonempty. On the other hand, when the set of bad edges becomes empty, the actual (B_0, B_1) is a splitting. This happens either when the algorithm has already run for $4k$ steps ($j > 4k$), in which case $|B_0 \Delta A_0^y| + |B_1 \Delta A_1^y|$ has to be 0 (at the first step, $|B_0 \Delta A_0^y| + |B_1 \Delta A_1^y| = |A_0^x \Delta A_0^y| + |A_1^x \Delta A_1^y| \leq 4k$ by Lemma 2.2), and we achieved the splitting (A_0^y, A_1^y) as an output, or when there are no bad edges at some earlier step. In that case the actual (B_0, B_1) does not necessarily coincide with the fixed splitting (A_0^y, A_1^y) , but it is still a splitting of $G \setminus y$. $\square$

Proof of Theorem 2.3. Fix again G , x , and (A_0^x, A_1^x) . According to Lemma 2.4, for every $y \in V(G)$ there is some input α, β such that with positive probability Algorithm 1 gives a splitting of $G \setminus y$. The corresponding sequence of ℓ 's (along the iteration steps of the algorithm) and the α, β determine the output and y . There are at most k^{k+1} choices for ℓ in each step, by Lemma 2.1, and the rest of the algorithm is deterministic. So there are at most $k^{4k(k+1)}$ possible sequences of ℓ 's along the iteration steps of the algorithm. There are $4k(k+1)$ possible inputs α, β . Hence there are at most $k^{4k(k+1)} 4k$ possible y 's, which is our upper bound for the number of vertices in a minimal nonsplit k -uniform hypergraph. $\square$

A straightforward corollary is our main theorem.

THEOREM 2.5. *The family of k -uniform split hypergraphs can be characterized by a finite set of forbidden induced subhypergraphs.*

3. 3-uniform minimal nonsplit hypergraphs. Although Theorem 2.3 gave a very rough upper bound on the size of minimal nonsplit hypergraphs, in this section we illustrate with a few examples that the list of excluded induced subhypergraphs increases considerably compared to the case of graphs.

For $|V(G)| = 6$, G is nonsplit if and only if for any edge its complement is also an edge and if the subhypergraph induced by any four points is neither the empty nor the complete 3-uniform hypergraph. It is clear that these are minimal nonsplit hypergraphs too.

We get examples of minimal nonsplit hypergraphs for the case of $|V(G)| = 7, 8, 9$ in the following manner. Write the vertices along a circle and let the edges be exactly those 3-tuples that consist of three consecutive nodes along the circle. G is not split,

since we could put into the type 0 class at most 3 vertices, but then the rest contains a type 0 edge (and similarly if we put only 2 arbitrary points in the type 0 class). However, dropping any vertex, two suitably chosen points can cut the remaining arc into parts with at most two vertices. In the case of 8 (respectively, 9) vertices, we can erase 1 (respectively, 1, 2, 3, or 4) edges from the hypergraph just described, and similarly, we still get a minimal nonsplit hypergraph. The argument is nearly the same for these new graphs.

We have found minimal 3-uniform nonsplit hypergraphs on vertex sets of 11 and 12 elements, but the details are lengthy. The examples above may show that even in the 3-uniform case there are at least 100 (and probably even many more) minimal excluded subhypergraphs.

4. Degree sequences of hypergraphs. The question arises of whether a characterization like that in part 3 of Theorem 1.1 can be given for split hypergraphs. Since the equivalence of 3 and 1 provides us with an $O(n)$ algorithm to decide whether a graph is split or not, a characterization for split hypergraphs using degree sequences could be promising.

PROPOSITION 4.1. *There are 3-uniform hypergraphs G and G' on the vertex set $\{1, \dots, n\}$ such that G is split and G' is nonsplit; moreover, $d_i = d'_i$ and $\delta_{ij} = \delta'_{ij}$ for any $i, j \in \{1, 2, \dots, n\}$. Here d_i (d'_i) stands for the degree of i in G (G'); δ_{ij} (δ'_{ij}) is the number of edges containing both i and j in G (G').*

Proof. Call a 6-element subset of the vertices of a 3-uniform hypergraph H exchangeable if there is a list $a_1, a_2, a_3, a_{-1}, a_{-2}, a_{-3}$ of these vertices so that $\{a_1, a_2, a_3\}$, $\{a_1, a_{-2}, a_{-3}\}$, $\{a_{-1}, a_2, a_{-3}\}$, $\{a_{-1}, a_{-2}, a_3\}$ are edges of H , and the other 3-tuples not containing a_i and a_{-i} together for some i are not in H . We say that we exchange the exchangeable point set $\{a_1, a_2, a_3, a_{-1}, a_{-2}, a_{-3}\}$ when we erase the four edges described above and add the 3-tuples $\{a_{-1}, a_{-2}, a_{-3}\}$, $\{a_{-1}, a_2, a_3\}$, $\{a_1, a_{-2}, a_3\}$, and $\{a_1, a_2, a_{-3}\}$ to $E(H)$. We may think of the exchangeable 6 vertices as the nodes of an octahedron. Then “exchangeable” means that, if the nodes were labeled appropriately, the four 3-tuples in $E(H)$ are determined by four faces whose pairwise intersection is one point. “Exchanging” means that we replace these 3-tuples in $E(H)$ by the other four faces of the octahedron. One can easily see that these are well defined; the listing of the 6 vertices is essentially unique. On the other hand, the degrees and the number of edges incident to two points do not change after applying an exchange. Thus if we get a nonsplit hypergraph from a split hypergraph after serial exchanging, then the proposition follows.

Now, denote $X = \{1, 2, 3, 4\}$, $Y = \{5, 6, 7, 8\}$. Define G on the vertex set $\{1, \dots, 14\}$ as follows. Every 3-tuple of $X \cup \{9, 10, 11\}$ is red, every 3-tuple of $Y \cup \{12, 13, 14\}$ is blue; if a 3-tuple intersects both X and $\{12, 13, 14\}$, then it is blue; if a 3-tuple intersects both Y and $\{9, 10, 11\}$, then it is red. Moreover, the 3-tuples of $\{9, 10, \dots, 14\}$ that have not been defined yet get colors so that $\{9, 10, \dots, 14\}$ give an exchangeable set of points, as in the first sentence of this proof, with $(a_1, a_2, a_3, a_{-1}, a_{-2}, a_{-3}) = (9, 10, 11, 12, 13, 14)$. The colors of the remaining 3-tuples are arbitrary. G is obviously split with color classes $X \cup \{9, 10, 11\}$ as red and $Y \cup \{12, 13, 14\}$ as blue. Let G' be the hypergraph obtained from G by exchanging $\{9, \dots, 14\}$. In G' , $\{9, 10, 11\}$ has become blue, so at least one of its points must be put into the blue class. But there, this point gives a red edge with any two points of Y . Since at least two points of Y must remain in the blue class, we conclude that G' is indeed nonsplit. $\square$

For an arbitrary k , one can give a k -uniform counterexample with a construction similar to the one above by using the k -dimensional cross-polytope $\{x \in \mathbb{R}^k : \|x\|_1 \leq 1\}$ (the “octahedron” of dimension k).

5. Algorithm for splitting.

THEOREM 5.1. *For an arbitrary, but fixed, k there is an algorithm that decides if a G k -uniform hypergraph is a split hypergraph and gives a splitting when it is. The running time is $O(N \log N)$ (where we defined $N = |V(G)| + |E(G)|$).*

As in the case of Lemma 2.1, we mention that the running time is understood with an appropriately chosen data structure. Let us also point out that the constant in the $O(N \log N)$ bound is exponential in k .

The following lemma is used repeatedly to obtain splittings of larger and larger subhypergraphs of G .

LEMMA 5.2. *Let H be a k -uniform hypergraph, and let (V^1, V^2) be a partition of $V(H)$. Denote by H^1 and H^2 the subhypergraphs of H induced by V^1 and V^2 , respectively. Suppose that (A_0, A_1) is a splitting of H and (A_0^i, A_1^i) is a splitting of H^i ($i = 1, 2$). Then $|A_j \setminus (A_j^1 \cup A_j^2)| \leq 2k - 2$, $j = 0, 1$.*

Proof. If the lemma did not hold, then some k -tuple in A_j would be present in A_{1-j}^1 or A_{1-j}^2 ($j \in \{0, 1\}$), contradicting the fact that both are monochromatic of different types. $\square$

We present an algorithm whose existence proves Theorem 5.1. Call it Algorithm 2. We do not give the pidgin Pascal program this time, because the main structure of the algorithm is very simple, and the more particular elements are similar to Algorithm 1 (except that the random part is replaced by a deterministic choice, as we shall see). Let us start with an overview of the algorithm. We use notation $\langle m \rangle$ for the modulo 2 value of an integer m .

The crucial component of our algorithm is a subroutine called **Tree**. Its input is (H, X_0, X_1) , where H is a k -uniform hypergraph and (X_0, X_1) partitions $V(H)$. **Tree** will create labels for the vertices of a rooted tree T of depth $2k - 2$, where each inner node has k^{2k-2} children. For each vertex, we assume that there is some ordering on its children, so we can talk about the “ m th child” (when $m \leq k^{2k-2}$). Similarly, we assume that for any set of k -tuples of G , there is some fixed ordering on the minimal cover sets of size at most $2k - 2$ of these k -tuples, so we can talk about the “ m th minimal cover set” (when m is small enough). Note that such an ordering of the minimal cover sets can be easily implemented by an algorithm that is linear in the input size, using Lemma 2.1. Finally, fix some ordering on the vertices of T so that vertices at a smaller depth precede vertices at a larger depth.

Say that the root *has depth* 0, its children *have depth* 1, etc. The root r will have label $(X_0^r, X_1^r) := (X_0, X_1)$. If X_0^r contains some edge of type 1 in G , let $s := 0$. Otherwise let $s := 1$.

Suppose that v is a vertex in T , whose parent is u , and v is at depth g . Assume that v is the m th child of u . Let v get label (ℓ_v, X_0^v, X_1^v) , where ℓ_v is the m th minimal cover set of size at most $2k - 2$ of the bad edges in $X_{\langle g+s \rangle}^u$. Let $X_{\langle g+s \rangle}^v := X_{\langle g+s \rangle}^u \setminus \ell_v$ and $X_{\langle 1+g+s \rangle}^v = X_{\langle 1+g+s \rangle}^u \cup \ell_v$. If m is such that there is no m th minimal cover set of size at most $2k - 2$ for the actual bad edges, then delete v and all its offspring from T . If there are no bad edges in $X_{\langle g+s \rangle}^u$, then **Tree** outputs the first such (X_0^u, X_1^u) (in the ordering of the vertices), which is a splitting of the input graph H . If there are bad edges for all the leaves, then **Tree** outputs “No,” indicating H is not split.

Algorithm 2 receives input G , a k -uniform hypergraph. In the preparatory step it partitions $V(G)$ to sets $A_1, \dots, A_{\lceil n/k-1 \rceil}$, where each A_i has $k - 1$ elements, with

the possible exception of $A_{\lceil n/k-1 \rceil}$. Then we call the iteration part of the algorithm with input $((A_1, \emptyset), \dots, (A_{\lceil n/k-1 \rceil}, \emptyset))$.

In each cycle of the iteration part of Algorithm 2 there is an incoming list $((X_0^1, X_1^1), (X_0^2, X_1^2), \dots, (X_0^m, X_1^m))$, where (X_0^i, X_1^i) is a splitting of $G|_{X_0^i \cup X_1^i}$, and the $(X_0^i \cup X_1^i)_{i=1}^m$ give a partition of $V(G)$. Now form pairs $(Y_0^i, Y_1^i) := (X_0^{2i-1} \cup X_0^{2i}, X_1^{2i-1} \cup X_1^{2i})$ as $i = 1, \dots, \lfloor m/2 \rfloor$; if m is odd, then define $(Y_0^{\lceil m/2 \rceil}, Y_1^{\lceil m/2 \rceil}) := (X_0^m, X_1^m)$. Now, call **Tree** for each $i \in \{1, \dots, \lceil m/2 \rceil\}$, with input (Y_0^i, Y_1^i) . If any of these returns “No,” then Algorithm 2 ends and outputs “ G has no splitting.” Otherwise, if **Tree** returns (A_0^i, A_1^i) at the i th call, then the input for the next iteration step is $((A_0^1, A_1^1), (A_0^2, A_1^2), \dots, (A_0^{\lceil m/2 \rceil}, A_1^{\lceil m/2 \rceil}))$. The last cycle of the iteration is when $m = 2$, that is, when we call **Tree** only once. Suppose then that it returns the pair (A_0^1, A_1^1) . In this case Algorithm 2 outputs this pair, which is a splitting of G .

LEMMA 5.3. Algorithm 2 provides a splitting of G , if there is any, and answers “ G has no splitting” if G is nonsplit.

Proof. We shall prove that **Tree** indeed decides if there is a splitting of the hypergraph that it receives while Algorithm 2 is running, and outputs a splitting if there is one. (Note that the hypergraphs that **Tree** receives in Algorithm 2 have a very specific form.) Then it is clear that the iteration steps give splittings for families of bigger and bigger graphs and finally for G , if G is split. So, as in Lemma 5.2, let H be a k -uniform hypergraph, and let (V^1, V^2) be a partition of $V(H)$. Denote by H^1 and H^2 the subhypergraphs of H induced by V^1 and V^2 , respectively. Suppose that (A_0^i, A_1^i) is a splitting of H^i ($i = 1, 2$). We need to show that if the input is $(H, A_0^1 \cup A_0^2, A_1^1 \cup A_1^2)$, then **Tree** finds a splitting of H , if there is any, and answers “No” if H is not split. Note that the inputs that **Tree** can get in Algorithm 2 indeed have this special form.

Suppose that H has a splitting; fix one such (A_0, A_1) . The process of finding a splitting of H corresponds to a walk on T , starting from the root and moving towards a child in each step. Each step of the walk corresponds to finding a minimal cover set for the bad edges in the class actually being examined and putting this set into the other class (starting with the two classes from the input of **Tree**). By the same argument as in Lemma 2.4 (now using the analogue Lemma 5.2 of Lemma 2.2), we shall conclude that if there is a splitting, we get it in $\leq 2k - 2$ steps, or equivalently, at the latest when arriving at a leaf of T .

To be more detailed, suppose that $(A_0^1 \cup A_0^2, A_1^1 \cup A_1^2) =: (B_0, B_1)$ is not yet a splitting (otherwise we are done; the algorithm outputs the splitting after making the label for the root). Then there are type 1 edges in B_0 , or there are type 0 edges in B_1 (call any of these a *bad edge*). We may assume by symmetry that B_0 has bad edges. Then some minimal cover set of these bad edges is contained in A_1 , and the root has a child v such that ℓ_v is this minimal cover set. The iteration part of Algorithm 2 moves over ℓ_v from B_0 to B_1 , hence creating X_0^v and X_1^v . We have $|X_0^v \Delta A_0| + |X_1^v \Delta A_1| < |B_0 \Delta A_0| + |B_1 \Delta A_1|$, similarly to the displayed line in the proof of Lemma 2.4. Note that after the first step of the walk on T only one of X_0^v and X_1^v can have bad edges.

Proceed similarly as follows: When the walk in T is in u and the bad edges are in X_i^u ($i \in \{0, 1\}$), there is a minimal cover set for these bad edges that is contained in A_{1-i} , and such that it is disjoint from $\bigcup \ell_w$, where w ranges through the ancestors of u . (This latter assumption can be made because in each step we moved points that got to their “final class” in (A_0, A_1) by this move.) Some child v of u is such that this

minimal cover set is ℓ_v , and for the arising (X_0^v, X_1^v) we again have

$$|X_0^v \Delta A_0| + |X_1^v \Delta A_1| < |X_0^u \Delta A_0| + |X_1^u \Delta A_1|.$$

Since for the root r we have $|X_0^r \Delta A_0| + |X_1^r \Delta A_1| \leq 2k - 2$ by Lemma 5.2, in at most $2k - 2$ steps we necessarily arrive to a vertex where the two cases contain no bad edges. At this step **Tree** outputs the two classes, which is a splitting of H .

If H is not split, then it is clear that there are bad edges in some class for any partition of the vertex set, so **Tree** will eventually output “No.” $\square$

LEMMA 5.4. *The algorithm runs in $O(N \log N)$ time.*

Proof. First, **Tree** runs in linear time, because the size of the underlying tree is a constant (determined by k), and the labels consisting of minimal cover sets can be constructed in a number of steps that is linear in the input of **Tree**, using the method in Lemma 2.1.

In each iteration step, each element of $V(G) \cup E(G)$ is present in at most one of the subhypergraphs that some **Tree** subroutine receives, and then in each iteration cycle there is a linear number of extra steps when the iteration cycle creates what it returns from the outputs of the **Tree** subroutines. This is $O(N)$, and there are $O(\log N)$ iteration steps, so we get the claim. $\square$

DETECTING A THETA OR A PRISM*

MARIA CHUDNOVSKY[†] AND ROHAN KAPADIA[‡]

Abstract. A theta in a graph is an induced subgraph consisting of two nonadjacent vertices joined by three disjoint paths. A prism in a graph is an induced subgraph consisting of two disjoint triangles joined by three disjoint paths. This paper gives a polynomial-time algorithm to test whether a graph has an induced subgraph that is either a prism or a theta.

Key words. induced subgraph, detection algorithm, theta, prism

AMS subject classification. 05C85

DOI. 10.1137/060672613

1. Introduction. The vertex set of a graph G is denoted by $V(G)$ and the edge set by $E(G)$. All graphs in this paper are simple. A *cycle* is a connected subgraph in which all vertices have degree two. A *path* P in G is an induced connected subgraph of G such that either P is a 1-vertex graph, or two vertices of P have degree one and all others have degree two. (Please note that we are using a nonstandard definition.) The *ends* of a path are the two vertices with degree one in the path. If $X \subseteq V(G)$, the subgraph with vertex set X and edge set all edges of G with both ends in X is denoted $G[X]$ and called the subgraph *induced* on X .

A *prism* is a graph consisting of two disjoint triangles $\{a_1, a_2, a_3\}$ and $\{b_1, b_2, b_3\}$ together with three paths P_1 , P_2 , and P_3 such that the union of every two of P_1 , P_2 , and P_3 is an induced cycle. A *theta* is a graph consisting of two nonadjacent vertices s and t , and three paths P , Q , and R with ends s and t , such that the union of every two of P , Q , and R is an induced cycle. The vertices s, t are called the *ends* of the theta. Finally, a *pyramid* is a graph consisting of a triangle $\{b_1, b_2, b_3\}$, a vertex $a \notin \{b_1, b_2, b_3\}$, and, for $i = 1, 2, 3$, a path P_i between a and b_i , such that a is adjacent to at most one of b_1, b_2, b_3 and the union of every two of P_1, P_2 , and P_3 is an induced cycle. An induced subgraph H of G is a *prism*, *theta*, or *pyramid* in G if H is a prism, theta, or pyramid, respectively. We say that a graph G *contains* a prism, a theta, or a pyramid if some induced subgraph of G is a prism, a theta, or a pyramid, respectively. A *hole* in a graph is an induced cycle of length at least four. A hole is *odd* if it has an odd number of vertices, and is even otherwise. Given a graph G , the *complement* $\overline{G}$ of G is the graph with the same vertex set as G , and such that two vertices are adjacent in $\overline{G}$ if and only if they are nonadjacent in G . A graph G is called *Berge* if neither G nor $\overline{G}$ contains an odd hole.

In [1] a polynomial-time algorithm is presented to test whether a graph contains a pyramid. The main result of [1] is a polynomial-time algorithm to test if a graph is Berge. Since every pyramid contains an odd hole, no Berge graph contains a pyramid, and testing for pyramids is the first step in testing for Berge-ness. Similarly to

pyramids, every theta and every prism contains an even hole, and therefore a graph with no even holes contains no theta or prism. In [4] Maffray and Trotignon prove that the problem of deciding if a graph contains a prism is NP-complete, and in [2] Chudnovsky and Seymour show that testing if a graph contains a theta can be done in polynomial time. However, the complexity of deciding if a graph contains a prism or a theta remains open (and this is the analogue of the pyramid problem for graphs with no even holes). Our main result here is a polynomial-time algorithm that, given a graph G , decides if G contains either a prism or a theta. The algorithm is described in section 5, and its running time is $O(|V(G)|^{35})$.

Before continuing with the outline of this algorithm, we need a few more definitions. The *interior* of a path P is the set of vertices that have degree two in P , and it is denoted by P^* . If u and v are two vertices in a path P , then u - P - v denotes the subpath of P whose ends are u and v , and if u and v are consecutive, then we may denote u - P - v by just u - v . For a subgraph X of G we say that $v \in V(G) \setminus V(X)$ has a neighbor in X if there exists a vertex in $V(X)$ adjacent to v .

For $A \subseteq V(G)$, a vertex is called *A-complete* if it is adjacent to every vertex in A . Two subsets $A, B \subseteq V(G)$ are *anticomplete* to each other if no vertex of A is adjacent to any vertex of B . For any two vertices a and b , let $N(a)$ be the set of neighbors of a in G , and let $N(a, b)$ be the set of all $\{a, b\}$ -complete vertices in G .

Let K be a prism. Label the triangles of K $\{a_1, a_2, a_3\}$ and $\{b_1, b_2, b_3\}$, and for $i = 1, 2, 3$ let P_i be the path from a_i to b_i . For $i = 1, 2, 3$ let m_i be the vertex in P_i such that for the paths a_i - P_i - m_i , denoted by S_i , and m_i - P_i - b_i , denoted by T_i , we have $|E(T_i)| \leq |E(S_i)| \leq |E(T_i)| + 1$. A *K-major* vertex, or just a *major* vertex when there is no danger of confusion, is a vertex not in $V(K)$ whose neighbors in K are not a subset of the vertex set of a 3-vertex path contained in K .

Finally, a subgraph H is *smaller* than a subgraph H' if $|V(H)| < |V(H')|$. An induced subgraph X of G that is either a theta or a prism is called *smallest* if no other theta or prism in G is smaller than X .

The idea of the algorithm is as follows. Let G be the graph input to the algorithm and suppose there is a prism K in G . A shortest path Q with the same ends as S_1 is called a *shortcut* across K . If the subgraph induced by $V(K) \cup Q^* \setminus S_1^*$ is also a prism, then Q is *good*, and if not, then Q is *bad*. Shortest paths with the same ends as one of T_1, S_2, T_2, S_3 , and T_3 are also called shortcuts across K . Shortcuts will be defined in the same way for thetas. A theta or prism is *clean* if all shortcuts across it are good. The algorithm uses a procedure called *cleaning*, first introduced by Conforti and Rao in [3]. The idea of cleaning is to identify a *cleaner*, which is a subset $X \subseteq V(G)$ such that if G contains a prism or a theta, then the graph G' induced by G on $V(G) \setminus X$ contains a clean prism or a clean theta.

In G' , it becomes easy to detect the clean theta or prism. For example, if G' contains a clean prism K , then for any shortcut Q across the path S_1 of K , the subgraph induced on $V(K) \cup Q^* \setminus S_1^*$ is also a prism, because Q is a good shortcut. The same is true for any other shortcut across K . So the algorithm checks all 9-tuples of vertices $a_1, a_2, a_3, m_1, m_2, m_3, b_1, b_2, b_3$; for each of the pairs $a_1m_1, a_2m_2, a_3m_3, m_1b_1, m_2b_2, m_3b_3$, it finds a shortest path joining the pair, then tests whether the subgraph induced by the union of these paths is a prism. If there is a clean smallest prism in G' , then it can be shown that a prism is found when considering one of the 9-tuples. A similar procedure works to find clean smallest thetas.

There are three stages of cleaning required. The first two cleaning algorithms output a list of polynomially many subsets of $V(G)$, one of which is a cleaner if G

contains a smallest prism or theta. The first outputs a cleaner when G contains a smallest theta and is given in section 2. The second outputs a cleaner when G contains a smallest prism K and is given in section 3. However, the second algorithm requires that the input graph G contain no K -major vertices. For this reason, we need the third cleaning algorithm, which outputs a list of subsets of which one contains all K -major vertices and is disjoint from $V(K)$. This algorithm is given in section 4. Finally, the algorithms for detecting clean prisms and thetas are described in section 5.

2. Theta shortcuts. Let K be a theta in G with ends a and b and paths P_1, P_2 , and P_3 between them. For $1 \leq i \leq 3$, let s_i be the neighbor of a in P_i , and let t_i be the neighbor of b in P_i . Also, for $1 \leq i \leq 3$ define $m_i \in P_i^*$ and subpaths S_i and T_i of P_i such that $S_i = s_i P_i m_i$, $T_i = m_i P_i t_i$, and $|V(T_i)| \leq |V(S_i)| \leq |V(T_i)| + 1$. We call P_1, P_2 , and P_3 the *paths* of K and call S_1, T_1, S_2, T_2, S_3 , and T_3 the *half-paths* of K . The *frame* of the theta K is the 11-tuple

$$\{a, b, s_1, s_2, s_3, m_1, m_2, m_3, t_1, t_2, t_3\},$$

and we say that K has a *tidy frame* if

- a and b have no neighbors in $V(G) \setminus V(K)$, and
- for $i = 1, 2, 3$, if m_i is adjacent to a and b , then m_i has no neighbors in $V(G) \setminus V(K)$.

If S is one of the half-paths of K , then a *shortcut* across S is a shortest path in G with the same ends as S . A shortcut across K is a shortcut across any half-path of K . A shortcut S' across S is *good* if no interior vertex of S' has neighbors in $V(K) \setminus V(S)$ and *bad* otherwise.

THEOREM 2.1. *Let K be a smallest theta in G . Assume K has a tidy frame. Then there is a vertex $c \in P_2^* \cup P_3^*$ such that c has a neighbor in the interior of every bad shortcut across S_1 or T_1 .*

Proof. Let C be the cycle induced by G on $V(P_2) \cup V(P_3)$. Let Q be a bad shortcut across S_1 . Suppose there is no edge between $V(Q)$ and $V(C)$ except s_1-a . Since Q is a bad shortcut, it follows that some vertex of Q has a neighbor in $V(T_1) \setminus \{m_1\}$, and then the graph induced by G on $V(C) \cup V(Q) \cup V(T_1)$ contains a theta smaller than K , a contradiction. Since m_1 has no neighbors in C and a is the only neighbor of s_1 in C , this proves that some vertex in Q^* has a neighbor in C . Let $q \in Q^*$ be the vertex with neighbors in C such that no other vertex in $q-Q-m_1$ has neighbors in C .

CLAIM 2.1. *The vertex q has exactly two neighbors in C , and they are adjacent to each other.*

If $m_1 = t_1$, then any shortcut between m_1 and s_1 has empty interior, and therefore is a good shortcut. Consequently, we may assume $m_1 \neq t_1$.

Suppose q has two neighbors in C that are not adjacent to each other. Let u and v be the neighbors of q in C such that a path between u and v in C contains b and no other neighbor of q . Then u and v are not adjacent to each other. Let C_u be the path of C from u to b such that $v \notin V(C_u)$ and let C_v be the path of C from v to b such that $u \notin V(C_v)$. The paths $q-u-C_u-b$, $q-v-C_v-b$ and a path between q and b with interior in $V(q-Q-m_1-T_1-b)$ form a theta, K' . Since $V(K') \subseteq (V(K) \setminus V(S_1)) \cup (V(Q) \setminus \{s_1\})$, and $|V(Q)| \leq |V(S_1)|$, we have $|V(K')| < |V(K)|$, contradicting the fact that no theta in G is smaller than K . Therefore all neighbors of q in C are pairwise adjacent.

Suppose q has exactly one neighbor in C ; call it u . If u is not adjacent to b , then the two paths between u and b in C and a path with interior in $V(u-q-Q-m_1-T_1-b)$ form a theta, K' . Since $V(K') \subseteq (V(K) \setminus V(S_1)) \cup (V(Q) \setminus \{s_1\})$, K' is smaller than K , a contradiction. Therefore u is adjacent to b . Assume u is not adjacent to a . Since

$m_1 \neq t_1$, the two paths between u and a in C and a path P' between u and a with interior in $V(u-q-Q-m_1-S_1-s_1-a)$ form a theta, K' . If q is nonadjacent to s_1 , then $|V(q-Q-m_1)| < |V(T_1)|$, and therefore $|V(K')| < |V(K)|$; and if q is adjacent to s_1 , then $V(P') = \{q, s_1, a\}$, and so $V(K') = V(C) \cup \{s_1\}$ and, again, $|V(K')| < |V(K)|$; in both cases, a contradiction. Therefore u is adjacent to a . Since u is adjacent to both a and b , it is one of m_2 or m_3 , contradicting the fact that K has a tidy frame. Therefore, q has two neighbors in C , and they are adjacent. This proves Claim 2.1.

Let R be a bad shortcut across T_1 . Suppose there is no edge between $V(R)$ and $V(C)$ except t_1-b . Since R is a bad shortcut, it follows that some vertex of R has a neighbor in $V(S_1) \setminus \{m_1\}$, and then the graph induced by G on $V(C) \cup V(R) \cup V(S_1)$ contains a theta smaller than K , a contradiction. Since m_1 has no neighbors in C , and b is the only neighbor of t_1 in C , this proves that some vertex in R^* has a neighbor in C . Let $r \in R^*$ be the vertex with neighbors in C such that no other vertex in $r-R-m_1$ has neighbors in C .

CLAIM 2.2. *The vertex r has exactly two neighbors in C , and they are adjacent to each other.*

This proof is very similar to that of Claim 2.1. If $m_1 = s_1$, then $m_1 = t_1$, and there are no shortcuts between m_1 and t_1 . Therefore we may assume $m_1 \neq s_1$.

Suppose r has two neighbors in C that are not adjacent to each other. Let u and v be the neighbors of r in C such that a path between u and v in C contains a and no other neighbor of r . Then u and v are not adjacent to each other. Let C_u be the path of C from u to a such that $v \notin V(C_u)$, and let C_v be the path of C from v to a such that $u \notin V(C_v)$. The paths $r-u-C_u-a$, $r-v-C_v-a$ and a path between r and a with interior contained in $V(r-R-m_1-S_1-a)$ form a theta, K' . Since $V(K') \subseteq (V(K) \setminus V(T_1)) \cup (V(R) \setminus \{t_1\})$, and $|V(R)| \leq |V(T_1)|$, we have $|V(K')| < |V(K)|$, contradicting the fact that no theta in G is smaller than K . Therefore all neighbors of r in C are pairwise adjacent.

Suppose r has exactly one neighbor in C ; call it u . If u is not adjacent to a , then the two paths between u and a in C and a path with interior in $V(u-r-R-m_1-S_1-a)$ form a theta, K' . Since $V(K') \subseteq (V(K) \setminus V(T_1)) \cup (V(R) \setminus \{t_1\})$, K' is smaller than K , a contradiction. Therefore u is adjacent to a . Assume u is not adjacent to b . Since $m_1 \neq s_1$, the two paths between u and b in C and a path with interior in $V(u-r-R-m_1-T_1-t_1-b)$ form a theta, K' . Since $r-R-m_1$ contains fewer vertices than R and $|V(R)| \leq |V(S_1)|$, we have $|V(K')| < |V(K)|$, a contradiction. Therefore u is adjacent to b . Since u is adjacent to both a and b , it is one of m_2 or m_3 , contradicting the fact that K has a tidy frame. Therefore, r has two neighbors in C , and they are adjacent. This proves Claim 2.2.

Let Q' be another bad shortcut across S_1 , and let $q' \in Q'^*$ be the vertex with neighbors in C such that no other vertex in $q'-Q'-m_1$ has neighbors in C . Denote by x_q and y_q the neighbors of q in C , and denote by x'_q and y'_q the neighbors of q' in C .

Let R' be another bad shortcut across T_1 , and let $r' \in R'^*$ be the vertex with neighbors in C such that no other vertex in $r'-R'-m_1$ has neighbors in C . Denote by x_r and y_r the neighbors of r in C , and denote by x'_r and y'_r the neighbors of r' in C .

CLAIM 2.3. *No two of the subsets $\{x_q, y_q\}$, $\{x'_q, y'_q\}$, $\{x_r, y_r\}$, and $\{x'_r, y'_r\}$ are disjoint.*

Assume that $\{x_q, y_q\}$ is disjoint from $\{x'_q, y'_q\}$. Since K has a tidy frame, $\{a, b\} \cap \{x_q, x'_q, y_q, y'_q\} = \emptyset$. Let Q'' be the path between q and q' with interior in $V(q-Q-m_1) \cup V(q'-Q'-m_1)$. The triangles $\{q, x_q, y_q\}$ and $\{q', x'_q, y'_q\}$, the two paths between them in

C , and the path Q'' form a prism, K' . Since

$$|V(Q'')| \leq 2|V(S_1)| - 3 < |V(S_1)| + |V(T_1)| - 1,$$

and $V(K') \subseteq V(C) \cup V(Q'')$, we deduce that K' is smaller than K , a contradiction. Therefore, $\{x_q, y_q\} \cap \{x'_q, y'_q\} \neq \emptyset$.

Assume that $\{x_r, y_r\}$ is disjoint from $\{x'_r, y'_r\}$. Since K has a tidy frame, $\{a, b\} \cap \{x_r, x'_r, y_r, y'_r\} = \emptyset$. Let R'' be the path between r and r' with interior in $V(r-R-m_1) \cup V(r'-R'-m_1)$. The triangles $\{r, x_r, y_r\}$ and $\{r', x'_r, y'_r\}$, the two paths between them in C and the path R'' form a prism, K' . Since

$$|V(R'')| \leq 2|V(T_1)| - 3 < |V(S_1)| + |V(T_1)| - 2,$$

and $V(K') \subseteq V(C) \cup V(R'')$, we deduce that K' is smaller than K , a contradiction. Therefore, $\{x_r, y_r\} \cap \{x'_r, y'_r\} \neq \emptyset$.

Suppose $\{x_q, y_q\}$ is disjoint from $\{x_r, y_r\}$. Then the triangles $\{q, x_q, y_q\}$ and $\{r, x_r, y_r\}$, the two paths in C between $\{x_q, y_q\}$ and $\{x_r, y_r\}$, and the path between q and r with interior in $V(q-Q-m_1-R-r)$ form a prism, K' . Since $V(K') \subseteq V(C) \cup V(Q) \cup V(R) \setminus \{s_1, t_1\}$, the prism K' is smaller than K , a contradiction. Therefore $\{x_q, y_q\} \cap \{x_r, y_r\} \neq \emptyset$. By symmetry, we also have that $\{x_q, y_q\} \cap \{x'_r, y'_r\} \neq \emptyset$, $\{x'_q, y'_q\} \cap \{x_r, y_r\} \neq \emptyset$, and $\{x'_q, y'_q\} \cap \{x'_r, y'_r\} \neq \emptyset$. This proves Claim 2.3.

Let U, W , and Z each be a bad shortcut across either S_1 or T_1 . Since the choices of Q, Q', R , and R' were arbitrary, it follows from Claims 2.1, 2.2, and 2.3 that there exist $u \in U^*$, $w \in W^*$, and $z \in Z^*$ such that u has two adjacent neighbors $x_u, y_u \in V(C)$, w has two adjacent neighbors $x_w, y_w \in V(C)$, z has two adjacent neighbors $x_z, y_z \in V(C)$, and no two of $\{x_u, y_u\}$, $\{x_w, y_w\}$, and $\{x_z, y_z\}$ are disjoint.

Assume that $\{x_w, y_w\} \cap \{x_z, y_z\} = \{x_w\}$ and $\{x_w, y_w\} \cap \{x_u, y_u\} = \{y_w\}$. Then, since x_w and y_w are adjacent and x_z and y_z are adjacent, $\{x_z, y_z\}$ contains x_w and the vertex adjacent to x_w in $V(C) \setminus \{y_w\}$. Similarly, since x_u and y_u are adjacent, $\{x_u, y_u\}$ contains y_w and the vertex adjacent to y_w in $V(C) \setminus \{x_w\}$. Since x_w and y_w have no common neighbors in C , we have that $\{x_z, y_z\} \cap \{x_u, y_u\} = \emptyset$, a contradiction. Therefore, by symmetry between x_w and y_w we may assume that $x_w \in \{x_z, y_z\}$ and $x_w \in \{x_u, y_u\}$. Therefore every bad shortcut across S_1 or T_1 contains an interior vertex adjacent to x_w ; taking $c = x_w$ proves Theorem 2.1. $\square$

THEOREM 2.2. *There is an algorithm with the following specifications:*

- **Input:** A graph G .
- **Output:** A sequence of subsets $X_1, \dots, X_r$ of $V(G)$ with $r \leq |V(G)|^3$, such that for every smallest theta K in G with a tidy frame and $i \in \{1, 2, 3\}$, one of $X_1, \dots, X_r$ is disjoint from $V(K)$ and contains a vertex of every bad shortcut across the half-paths S_i and T_i of K .
- **Running Time:** $O(|V(G)|^4)$.

Proof. The algorithm is as follows. Enumerate all triples of vertices (c, u, v) for which u and v are adjacent to c . For each such triple, compute the subset $N(c) \setminus \{u, v\}$. Let $X_1, \dots, X_r$ be the subsets generated. We output the list $\emptyset, X_1, \dots, X_r$. That concludes the description of the algorithm; we now prove that it works correctly. The number of subsets generated is at most $|V(G)|^3$ and the running time is $O(|V(G)|^4)$ because it takes linear time to compute $N(c)$. It remains to check that the sequence $X_1, \dots, X_r$ has the properties claimed. Let K be a smallest theta in G and assume it has a tidy frame. By Theorem 2.1, for every $i = 1, 2, 3$ there is a vertex $c' \in V(K)$ such that every bad shortcut across S_i or T_i contains an interior vertex adjacent to c' . The vertex c' has exactly two neighbors in K ; call them u' and v' . One of the triples

enumerated by the algorithm will be (c', u', v') . The subset $N(c') \setminus \{u', v'\}$ includes all neighbors of c' , except its two neighbors that are in K , and is therefore disjoint from $V(K)$. This proves Theorem 2.2. $\square$

3. Prism shortcuts. Let K be a prism in G . Label the triangles of K $\{a_1, a_2, a_3\}$ and $\{b_1, b_2, b_3\}$ and the paths P_1 , P_2 , and P_3 such that for $i = 1, 2, 3$ the path P_i has ends a_i and b_i . For $i = 1, 2, 3$ choose $m_i \in P_i^*$ and subpaths S_i and T_i such that $S_i = a_i - P_i - m_i$, $T_i = m_i - P_i - b_i$, $|V(S_i)| \leq |V(T_i)| + 1$, and $|V(T_i)| \leq |V(S_i)| + 1$. We call P_1 , P_2 , and P_3 the *paths* of K and S_1 , T_1 , S_2 , T_2 , S_3 , and T_3 the *half-paths* of K . The 9-tuple

$$\{a_1, a_2, a_3, m_1, m_2, m_3, b_1, b_2, b_3\}$$

is the *frame* of K . A prism K has a *tidy frame* if for $i = 1, 2, 3$ the following hold:

- Neither a_i nor b_i has neighbors in $V(G) \setminus V(K)$, and
- if m_i is adjacent to a_i and b_i , then m_i has no neighbors in $V(G) \setminus V(K)$.

The prism K in G is *almost clean* if it has a tidy frame and G contains no K -major vertices.

If S is one of the half-paths of K , then a *shortcut* across S is a shortest path in G with the same ends as S . A shortcut across K is a shortcut across some half-path of K . A shortcut Q across S is *good* if no interior vertex of Q has neighbors in $V(K) \setminus V(S)$, and *bad* otherwise.

Let C be the cycle induced by G on $V(P_2) \cup V(P_3)$.

THEOREM 3.1. *Let K be a smallest prism. For every bad shortcut Q across S_1 , some vertex of Q^* has a neighbor in C .*

Proof. Suppose no vertex of Q^* has a neighbor in C . Then, since Q is bad, some vertex of Q^* has a neighbor in $V(T_1) \setminus \{m_1\}$. Therefore, there exists a path P'_1 from a_1 to b_1 with $P'_1 \subset V(Q) \cup V(T_1) \setminus \{m_1\}$. So there is a prism contained in $V(C) \cup V(P'_1)$ that is smaller than K , which is a contradiction because K is a smallest prism. This proves Theorem 3.1. $\square$

In view of Theorem 3.1, for a bad shortcut Q across S_1 or T_1 , define $\beta_Q \in Q^*$ to be the vertex with neighbors in $V(C)$ such that no other vertex in $\beta_Q - Q - m_1$ has neighbors in $V(C)$.

THEOREM 3.2. *Let K be an almost clean smallest prism. For a bad shortcut Q across S_1 , either $|N(\beta_Q) \cap V(K)| = |N(\beta_Q) \cap V(C)| = 1$ or $N(\beta_Q) \cap V(K)$ is the vertex set of a three-vertex path of C .*

Proof. Since K is almost clean, β_Q is not a K -major vertex, and therefore $N(\beta_Q) \cap V(K) \subseteq N(\beta_Q) \cap V(C)$. Assume β_Q has exactly two neighbors in C , u , and v . If u and v are not adjacent, then $u - \beta_Q - v$ and the two paths in C between u and v form a theta that has fewer vertices than K , a contradiction. So u and v are adjacent. Denote $\beta_Q - Q - m_1$ by U . Since K is almost clean, $\{u, v\} \cap \{b_1, b_2, b_3\} = \emptyset$, so there is a prism K' containing the triangles $\{b_1, b_2, b_3\}$ and $\{\beta_Q, u, v\}$ with $V(K') \subseteq V(C) \cup V(T_1) \cup V(U)$ (the three paths of K' are two paths of C and the path contained in $V(U) \cup V(T_1)$). Since $|V(U)| < |V(S_1)|$ (because $a_1 \notin V(U)$), K' is smaller than K , a contradiction. Therefore, β_Q has either a unique neighbor in C or at least three neighbors in C . Since K is almost clean, β_Q is not K -major, so if it has at least three neighbors in C , then it has exactly three neighbors in C , which are the vertex set of a 3-vertex path of C . This proves Theorem 3.2. $\square$

THEOREM 3.3. *Let K be a smallest prism in G . Assume K is almost clean. Then there exist two edges e_1 and e_2 , one in $E(P_2)$ and the other in $E(P_3)$, such that either*

- there exists a bad shortcut T across S_1 with $|N(\beta_T) \cap V(C)| = 1$ and for every bad shortcut Q across S_1 , if $|N(\beta_Q) \cap V(C)| = 1$, then β_Q is adjacent to an end of e_1 and if $|N(\beta_Q) \cap V(C)| > 1$, then β_Q is adjacent to both ends of e_1 , or
- for every bad shortcut Q , $|N(\beta_Q) \cap V(C)| = 3$ and β_Q is adjacent either to both ends of e_1 or to both ends of e_2 .

Proof. We start with a few observations about bad shortcuts across S_1 .

CLAIM 3.1. *There exists an edge $e_1 \in E(C)$ such that for every bad shortcut Q across S_1 , if $|N(\beta_Q) \cap V(C)| = 1$, then β_Q is adjacent to an end of e_1 .*

We may assume that there exist two distinct bad shortcuts Q and Q' across S_1 such that β_Q has a unique neighbor x in C , $\beta_{Q'}$ has a unique neighbor y in C , and $x \neq y$. Let U be the path β_Q - Q - m_1 , let U' be the path $\beta_{Q'}$ - Q' - m_1 , and let W be a path between β_Q and $\beta_{Q'}$ with interior in $V(U) \cup V(U')$. If x and y are nonadjacent, then the two paths between them in C and the path x - β_Q - W - $\beta_{Q'}$ - y form a theta, K' . Since $|V(W)| \leq 2|V(S_1)| - 3$ and $|V(P_1)| \geq 2|V(S_1)| - 2$, K' is smaller than K , a contradiction. Therefore, x is adjacent to y .

Let Q'' be any other bad shortcut across S_1 such that $\beta_{Q''}$ has a unique neighbor z in C . By the previous argument, applied to the pairs Q, Q'' and Q', Q'' , it follows that z is equal or adjacent to x and equal or adjacent to y . Then either $z \in \{x, y\}$ or z is adjacent to both x and y . But since x and y are adjacent vertices of C , they have no common neighbor in C , so $z \in \{x, y\}$. Therefore, there exists an edge $e_1 = x$ - y such that whenever $\beta_{Q''}$ has a unique neighbor in C , $\beta_{Q''}$ is adjacent to an end of e_1 . This proves Claim 3.1.

CLAIM 3.2. *There exist edges $e_1 \in E(P_2)$ and $e_2 \in E(P_3)$ such that for every bad shortcut Q across S_1 , if $|N(\beta_Q) \cap V(C)| = 3$, then β_Q is either adjacent to both ends of e_1 or to both ends of e_2 .*

Let Q be a bad shortcut across S_1 such that $\beta_{Q'}$ has three neighbors in C . By Theorem 3.2, $N(\beta_Q) \cap V(C)$ is the vertex set of a 3-vertex path of C . Since K is almost clean, $N(\beta_Q) \cap V(C)$ is contained in either P_2^* or P_3^* .

Therefore, in order to prove Claim 3.2, it is enough to show that there exist edges $e_1 \in E(P_2)$ and $e_2 \in E(P_3)$ such that for every bad shortcut Q across S_1 , if $|N(\beta_Q) \cap V(P_2)| = 3$, then β_Q is adjacent to both ends of e_1 , and if $|N(\beta_Q) \cap V(P_3)| = 3$, then β_Q is adjacent to both ends of e_2 .

Let Q and Q' be bad shortcuts across S_1 . Suppose that each of β_Q and $\beta_{Q'}$ has three neighbors in P_2 . Then each of $N(\beta_Q) \cap V(C)$ and $N(\beta_{Q'}) \cap V(C)$ is the vertex set of a 3-vertex path of P_2 .

We claim that $|N(\beta_Q) \cap V(C) \cap N(\beta_{Q'})| \geq 2$. Assume that $|N(\beta_Q) \cap V(C) \cap N(\beta_{Q'})| < 2$. If β_Q and $\beta_{Q'}$ are adjacent to each other, then there is a path P'_2 between a_2 and b_2 whose interior is contained in $P_2^* \cup \{\beta_Q, \beta_{Q'}\}$ and is anticomplete to $V(K) \setminus P_2^*$. Then $(V(K) \setminus P_2^*) \cup P_2'^*$ contains a prism smaller than K , a contradiction. So we may assume that β_Q and $\beta_{Q'}$ are not adjacent to each other. Then there are two paths A and B between β_Q and $\beta_{Q'}$ whose interiors are anticomplete to each other and are contained in $V(C)$. The paths A , B and a path between β_Q and $\beta_{Q'}$ with interior in $V(Q) \cup V(Q')$ form a theta, K' . Since $|V(Q) \cup V(Q')| \leq 2|V(S_1)| - 3 < |V(S_1)| + |V(T_1)| - 1 = |V(P_1)|$, the theta K' is smaller than the prism K , a contradiction. This proves the claim.

Label the neighbors of β_Q in C as x, y , and z and the neighbors of $\beta_{Q'}$ in C as x', y' , and z' such that x - y - z and x' - y' - z' are paths of C . Let Q'' be another bad shortcut across S_1 such that $\beta_{Q''}$ has three neighbors $x'', y'',$ and z'' in P_2

and $x''-y''-z''$ is a path of P_2 . Then we have that $|\{x'', y'', z''\} \cap \{x, y, z\}| \geq 2$ and $|\{x'', y'', z''\} \cap \{x', y', z'\}| \geq 2$. Since $x-y-z$ is a path, either $\{x, y\} \subset \{x', y', z'\}$ or $\{y, z\} \subset \{x', y', z'\}$, and similarly, either $\{x, y\} \subset \{x'', y'', z''\}$ or $\{y, z\} \subset \{x'', y'', z''\}$. Assume that $\{x, y, z\} \cap \{x', y', z'\} = \{x, y\}$ and $\{x, y, z\} \cap \{x'', y'', z''\} = \{y, z\}$. Then since $x-y-z$ is a path and $x'-y'-z'$ is a path, $\{x', y', z'\}$ contains $\{x, y\}$ and the vertex adjacent to x in $V(P_2) \setminus \{y\}$. Similarly, since $x''-y''-z''$ is a path, $\{x'', y'', z''\}$ contains $\{y, z\}$ and the vertex adjacent to z in $V(P_2) \setminus \{y\}$. Since x and z are not adjacent and x and z have no common neighbors in $V(P_2) \setminus \{y\}$, it follows that $\{x', y', z'\} \cap \{x'', y'', z''\} = \{y\}$, a contradiction. Therefore, by symmetry between $\{x, y\}$ and $\{y, z\}$ we may assume that $\{x, y\} \subset \{x', y', z'\}$ and $\{x, y\} \subset \{x'', y'', z''\}$. This proves that for every bad shortcut R across S_1 , if $|N(\beta_R) \cap V(P_2)| = 3$, then β_R is adjacent to both ends of $e_1 = x-y$.

From the symmetry, there exists an edge $e_2 \in E(P_3)$ such that for every bad shortcut R across S_1 , if $|N(\beta_R) \cap V(P_3)| = 3$, then β_R is adjacent to both ends of e_2 . This proves Claim 3.2.

CLAIM 3.3. *If Q and Q' are bad shortcuts across S_1 with $|N(\beta_Q) \cap V(C)| = 1$ and $|N(\beta_{Q'}) \cap V(C)| = 3$, then the neighbor of β_Q in C is adjacent to $\beta_{Q'}$.*

Denote by x the neighbor of β_Q in C . By Theorem 3.2, the neighbors of $\beta_{Q'}$ in C are the vertex set of a 3-vertex path of C , say $c_1-c_2-c_3$.

Assume that $x \notin \{c_1, c_2, c_3\}$. Then the subgraph induced by G on $(V(C) \setminus \{c_2\}) \cup V(Q) \cup V(Q')$ contains a theta, K' (the three paths of K' are two paths between $\beta_{Q'}$ and x with interior in C and the path with interior in $V(\beta_{Q'}-Q'-m_1-Q-\beta_Q-x)$). Since $V(K') \subseteq V(C) \cup Q^* \cup Q'^* \cup \{m_1\}$ and $|Q^*| + |Q'^*| + 1 \leq 2|V(S_1)| - 3 < |V(S_1)| + |V(T_1)| - 1$, the theta K' is smaller than K , a contradiction. Therefore, $x \in \{c_1, c_2, c_3\}$. This proves Claim 3.3.

If for every bad shortcut Q , $|N(\beta_Q) \cap V(C)| = 3$, then the second outcome of the theorem holds by Claim 3.2. So we may assume that there exists a bad shortcut Q with $N(\beta_Q) \cap V(C) = \{x\}$. Suppose there exists a bad shortcut Q' with $|N(\beta_{Q'}) \cap V(C)| = \{y\}$ such that $x \neq y$. Then by Claims 3.1 and 3.3 the first outcome of the theorem holds with e_1 being the edge as in Claim 3.1. So we may assume that for every bad shortcut Q' with $|N(\beta_{Q'}) \cap V(C)| = 1$, $\beta_{Q'}$ is adjacent to x . Let c_1-x-c_2 be the 3-vertex path in C with x as its interior vertex. If there exist bad shortcuts Q' and Q'' with $|N(\beta_{Q'}) \cap V(C)| = 3$ and $|N(\beta_{Q''}) \cap V(C)| = 3$ such that $\beta_{Q'}$ is not adjacent to c_1 and $\beta_{Q''}$ is not adjacent to c_2 , then $N(\beta_{Q'}) \cap V(C) \cap N(\beta_{Q''}) = \{x\}$, contradicting Claim 3.2. Thus one of c_1 and c_2 , say c_1 , is complete to $\{\beta_{Q'}, \beta_{Q''}\}$, and the theorem holds with $e_1 = c_1-x$. This completes the proof of Theorem 3.3. $\square$

THEOREM 3.4. *Let K be a smallest prism in G . Assume K is almost clean. Then there exist two edges e_1 and e_2 , one in $E(P_2)$ and the other in $E(P_3)$, such that either*

- *there exists a bad shortcut T across S_1 or T_1 with $|N(\beta_T) \cap V(C)| = 1$, and for every bad shortcut Q across S_1 or T_1 , if $|N(\beta_Q) \cap V(C)| = 1$, then β_Q is adjacent to an end of e_1 , and if $|N(\beta_Q) \cap V(C)| > 1$, then β_Q is adjacent to both ends of e_1 , or*
- *for every bad shortcut Q across S_1 or T_1 , $|N(\beta_Q) \cap V(C)| = 3$ and β_Q is adjacent either to both ends of e_1 or to both ends of e_2 .*

Proof. We start with a few observations about bad shortcuts across S_1 and T_1 .

CLAIM 3.4. *Let Q be a bad shortcut across S_1 with $|N(\beta_Q) \cap V(C)| = 1$ and R a bad shortcut across T_1 with $|N(\beta_R) \cap V(C)| = 1$. Then the neighbor of β_Q in C and the neighbor of β_R in C are either equal or adjacent to each other.*

Let $\{x_q\} = N(\beta_Q) \cap V(C)$ and $\{x_r\} = N(\beta_R) \cap V(C)$. Assume that x_q and x_r are distinct and nonadjacent. There are two paths between them, A and B , each of length at least two and contained in C . There is a path P between x_q and x_r with interior in $V(\beta_Q-Q-m_1-R-\beta_R)$. The three paths A , B , and P form a theta, K' . Since $|V(P)| \leq |Q^* \cup \{m_1\} \cup R^*| < |V(P_1)|$, the theta K' is smaller than the prism K , a contradiction. This proves Claim 3.4.

CLAIM 3.5. *Let Q be a bad shortcut across S_1 with $|N(\beta_Q) \cap V(C)| = 3$ and $N(\beta_Q) \cap V(C) \subseteq P_2^*$. Let R be a bad shortcut across T_1 with $|N(\beta_R) \cap V(C)| = 3$ and $N(\beta_R) \cap V(C) \subseteq P_2^*$. Then there is an edge in $E(P_2)$ whose ends are $\{\beta_Q, \beta_R\}$ -complete.*

Assume that $|N(\beta_Q) \cap V(C) \cap N(\beta_R)| < 2$. By Theorem 3.2, each of $N(\beta_Q) \cap V(K)$ and $N(\beta_R) \cap V(K)$ is the vertex set of a 3-vertex path of C . If β_Q is adjacent to β_R , then there is a path A between a_2 and b_2 with interior in $P_2^* \cup \{\beta_Q, \beta_R\}$ such that $\{\beta_Q, \beta_R\} \subset V(A)$. Since $|N(\beta_Q) \cap V(C)| = |N(\beta_R) \cap V(C)| = 3$, it follows that $|N(\beta_Q) \cup N(\beta_R) \cap V(C)| \geq 5$. So $|V(P_2) \setminus V(A)| \geq 3$ and $|V(A) \setminus V(P_2)| = 2$, which implies that $|V(A)| < |V(P_2)|$. It follows from Theorem 3.2 that A^* is anticomplete to P_1^* and P_3^* , and so the induced subgraph with vertex set $(V(K) \setminus V(P_2)) \cup V(A)$ is a prism smaller than K , a contradiction. This proves that β_Q is not adjacent to β_R . It follows that there are two paths B and B' between β_Q and β_R whose interiors are anticomplete to each other and are contained in $V(C)$. There is also a path P between them with interior contained in $V(\beta_Q-Q-m_1-R-\beta_R)$. Since β_Q is not adjacent to β_R , P has length at least two. Since $|V(P)| \leq |Q^* \cup \{m_1\} \cup R^*| < |V(P_1)|$, the paths B , B' , and P form a theta smaller than K , a contradiction. This proves that $|N(\beta_Q) \cap V(C) \cap N(\beta_R)| \geq 2$. Since each of $N(\beta_Q) \cap V(C)$ and $N(\beta_R) \cap V(C)$ is the vertex set of a 3-vertex subpath of P_2 , Claim 3.5 follows.

CLAIM 3.6. *Let Q be a bad shortcut across S_1 with $|N(\beta_Q) \cap V(C)| = 1$ and R a bad shortcut across T_1 with $|N(\beta_R) \cap V(C)| = 3$. Then the neighbor of β_Q in C is adjacent to β_R .*

Let $\{x_q\} = N(\beta_Q) \cap V(C)$. Assume that $x_q \notin N(\beta_R)$. There are two paths A and B between x_q and β_R whose interiors are anticomplete to each other and are contained in $V(C)$. There is a path P between x_q and β_R with interior in $V(\beta_Q-Q-m_1-R-\beta_R)$. Since $|V(P)| \leq |Q^* \cup \{m_1\} \cup R^*| + 1 < |V(P_1)|$, the paths A , B , and P form a theta smaller than K , a contradiction. This proves Claim 3.6.

CLAIM 3.7. *Suppose that there exist $p \in V(P_2)$ and $s \in V(P_3)$ such that for every bad shortcut Q across S_1 or T_1 , β_Q is adjacent to p or s . Then the theorem holds.*

Since there are no K -major vertices in G , for every bad shortcut Q across S_1 or T_1 with $N(\beta_Q) \cap V(C) \subseteq P_2^*$, $N(\beta_Q) \cap V(C)$ is contained in the vertex set of the 5-vertex path $c_1-c_2-p-c_3-c_4$ contained in C . Suppose there exist two bad shortcuts P and P' across either S_1 or T_1 with $N(\beta_P) \cap V(C) = \{c_1, c_2, p\}$ and $N(\beta_{P'}) \cap V(C) = \{p, c_3, c_4\}$. Then $N(\beta_P) \cap V(C) \cap N(\beta_{P'}) = \{p\}$. If both P and P' are shortcuts across S_1 or both are shortcuts across T_1 , then this contradicts both outcomes of Theorem 3.3. If one of P and P' is a shortcut across S_1 and the other is a shortcut across T_1 , then this contradicts Claim 3.5. Therefore, there exists a 4-vertex path A of C with $p \in A^*$ such that for every bad shortcut P across S_1 or T_1 , if $N(\beta_P) \cap V(C) \subseteq P_2^*$, then $N(\beta_P) \cap V(C) \subset V(A)$. Let e_1 be the edge with both ends in A^* . It follows that for every bad shortcut P across S_1 or T_1 with $N(\beta_P) \cap V(C) \subseteq P_2^*$, if $|N(\beta_P) \cap V(C)| = 1$, then β_P is adjacent to the end p of e_1 , and if $|N(\beta_P) \cap V(C)| > 1$, then β_P is adjacent to both ends of e_1 . By symmetry between P_2 and P_3 , it also follows that there is an edge $e_2 \in E(P_3)$ such that for every bad shortcut P across S_1 or T_1 with

$N(\beta_P) \cap V(C) \subseteq P_3^*$, if $|N(\beta_P) \cap V(C)| = 1$, then β_P is adjacent to an end of e_2 , and if $|N(\beta_P) \cap V(C)| > 1$, then β_P is adjacent to both ends of e_2 . So if for all bad shortcuts Q across S_1 and T_1 , $|N(\beta_Q) \cap V(C)| > 1$, then the second outcome of the theorem holds. If not, then by Claims 3.4 and 3.6, either for all bad shortcuts Q across S_1 and T_1 , $N(\beta_Q) \cap V(C) \subseteq P_2^*$, or for all bad shortcuts Q across S_1 and T_1 , $N(\beta_Q) \cap V(C) \subseteq P_3^*$. In both cases, (with e_2 in place of e_1 in the second case), the first outcome of the theorem holds. This proves Claim 3.7.

First assume that there exist a bad shortcut Q across S_1 with $|N(\beta_Q) \cap V(C)| = 1$ and a bad shortcut R across T_1 with $|N(\beta_R) \cap V(C)| = 1$. The first outcome of Theorem 3.3 holds for both S_1 and T_1 . Let $\{x_q\} = N(\beta_Q) \cap V(C)$ and $\{x_r\} = N(\beta_R) \cap V(C)$. Assume that $x_q \neq x_r$. By Claim 3.4, x_q is adjacent to x_r . Let Q' be any other bad shortcut across S_1 and let R' be any other bad shortcut across T_1 . It follows from Claim 3.4 that if $|N(\beta_{Q'}) \cap V(C)| = 1$, then $\beta_{Q'}$ is adjacent to x_q or x_r ; it also follows that if $|N(\beta_{R'}) \cap V(C)| = 1$, then $\beta_{R'}$ is adjacent to x_r or x_q . Also, Theorem 3.3 implies that if $|N(\beta_{Q'}) \cap V(C)| > 1$, then $\beta_{Q'}$ is adjacent to x_q , and if $|N(\beta_{R'}) \cap V(C)| > 1$, then $\beta_{R'}$ is adjacent to x_r . By Claim 3.6, if $|N(\beta_{Q'}) \cap V(C)| > 1$, then $\beta_{Q'}$ is adjacent to x_r , and if $|N(\beta_{R'}) \cap V(C)| > 1$, then $\beta_{R'}$ is adjacent to x_q . Therefore, the first outcome of the theorem holds with e_1 being x_q-x_r . Now we may assume that for every bad shortcut Q across S_1 with $|N(\beta_Q) \cap V(C)| = 1$ and R across T_1 with $|N(\beta_R) \cap V(C)| = 1$, if $\{x_q\} = N(\beta_Q) \cap V(C)$ and $\{x_r\} = N(\beta_R) \cap V(C)$, then $x_q = x_r$. By the first outcome of Theorem 3.3, for any bad shortcut Q' across S_1 with $|N(\beta_{Q'}) \cap V(C)| > 1$, $\beta_{Q'}$ is adjacent to x_q , and for any bad shortcut R' across T_1 with $|N(\beta_{R'}) \cap V(C)| > 1$, $\beta_{R'}$ is adjacent to x_r , which equals x_q . By Claim 3.7 with $p = x_q$, the first outcome of the theorem holds.

Next assume that there exists a bad shortcut Q across S_1 with $|N(\beta_Q) \cap V(C)| = 1$. Then we may assume because of the previous paragraph that for every bad shortcut R across T_1 , $|N(\beta_R) \cap V(C)| > 1$. The first outcome of Theorem 3.3 holds for shortcuts across S_1 , and the second outcome of Theorem 3.3 holds for shortcuts across T_1 . Let $\{x_q\} = N(\beta_Q) \cap V(C)$. Suppose there is a bad shortcut Q' across S_1 with $N(\beta_{Q'}) \cap V(C) = \{x_{q'}\}$ such that $x_{q'} \neq x_q$. By the first outcome of Theorem 3.3, x_q is adjacent to $x_{q'}$, and for every bad shortcut Q'' across S_1 , if $|N(\beta_{Q''}) \cap V(C)| = 1$, then $\beta_{Q''}$ is adjacent to either x_q or to $x_{q'}$, and if $|N(\beta_{Q''}) \cap V(C)| > 1$, then $\beta_{Q''}$ is adjacent to both x_q and $x_{q'}$. By Claim 3.6, for every bad shortcut R' across T_1 , both x_q and $x_{q'}$ are adjacent to $\beta_{R'}$. Then the first outcome of the theorem holds with e_1 being the edge $x_q-x_{q'}$. So for every bad shortcut Q' across S_1 with $|N(\beta_{Q'}) \cap V(C)| = 1$ we may assume that $\beta_{Q'}$ is adjacent to x_q . By the first outcome of Theorem 3.3, for any bad shortcut Q' across S_1 with $|N(\beta_{Q'}) \cap V(C)| > 1$, $\beta_{Q'}$ is adjacent to x_q . By Claim 3.6, for any bad shortcut R' across T_1 , $\beta_{R'}$ is adjacent to x_q . Therefore, by Claim 3.7 with $p = x_q$, the first outcome of the theorem holds.

If there exists a bad shortcut R across T_1 with $|N(\beta_R) \cap V(C)| = 1$, then by symmetry, the argument of the previous paragraph applies. So we may finally assume that for every shortcut P across either S_1 or T_1 , $|N(\beta_P) \cap V(C)| > 1$. Then the second outcome of Theorem 3.3 holds for both S_1 and T_1 . Let Q be a bad shortcut across S_1 with $N(Q) \cap V(C) \subseteq P_2^*$. Let c_1-p-c_2 be a subpath of P_2 such that $N(Q) \cap V(C) = \{c_1, p, c_2\}$. By the second outcome of Theorem 3.3, for any bad shortcut Q' across S_1 with $N(\beta_{Q'}) \cap V(C) \subseteq P_2^*$, $\beta_{Q'}$ is adjacent to p . Also, by Claim 3.5, for any bad shortcut R across T_1 with $N(\beta_R) \cap V(C) \subseteq P_2^*$, β_R is adjacent to p . By symmetry between P_2 and P_3 , there is also a vertex $s \in P_3^*$ such that for every bad shortcut R across S_1 or T_1 with $N(\beta_R) \cap V(C) \subseteq P_3^*$, β_R is adjacent to s . Therefore, by Claim 3.7, the second case of the theorem holds. This proves Theorem 3.4. $\square$

THEOREM 3.5. *There is an algorithm with the following specifications:*

- **Input:** A graph G .
- **Output:** A sequence of subsets $X_1, \dots, X_r$ of $V(G)$ with $r \leq 2|V(G)|^4$, such that for every almost clean smallest prism K in G and $i \in \{1, 2, 3\}$, one of $X_1, \dots, X_r$ is disjoint from $V(K)$ and contains a vertex of every bad shortcut across the half-paths S_i and T_i of K .
- **Running Time:** $O(|V(G)|^5)$.

Proof. The algorithm is as follows. Enumerate all quadruples of distinct vertices (u_1, u_2, u_3, u_4) . For each, define the subset

$$Y = (N(u_2) \cup N(u_3)) \setminus \{u_1, u_2, u_3, u_4\}$$

and the subset

$$Z = N(u_1, u_2) \cup N(u_3, u_4).$$

Let $Y_1, \dots, Y_s$ and $Z_1, \dots, Z_s$ be the subsets generated. Output $\emptyset, Y_1, \dots, Y_s, Z_1, \dots, Z_s$.

That concludes the description of the algorithm; we now prove that it works correctly. It takes time $O(|V(G)|^5)$ to find the sets $Y_1, \dots, Y_s$ and $Z_1, \dots, Z_s$, and the number of subsets in the output is $\leq 2|V(G)|^4$. It remains to check that the output sequence has the properties claimed. Let K be an almost clean smallest prism in G with half-paths S_1, T_1, S_2, T_2, S_3 , and T_3 . We may assume by symmetry that $i = 1$. Apply Theorem 3.4 to S_1 and T_1 .

If the first outcome of Theorem 3.4 holds, then there is an edge in $P_2^* \cup P_3^*$, say u_2-u_3 , such that every bad shortcut across S_1 or T_1 contains an interior vertex adjacent to either u_2 or u_3 . Choose u_1 to be the neighbor of u_2 in $V(K) \setminus \{u_3\}$ and u_4 to be the neighbor of u_3 in $V(K) \setminus \{u_2\}$. Then the subset $(N(u_2) \cup N(u_3)) \setminus \{u_1, u_2, u_3, u_4\}$ is disjoint from $V(K)$ and contains an interior vertex of every bad shortcut across S_1 or T_1 .

If the second outcome of Theorem 3.4 holds, then there are two edges in $P_2^* \cup P_3^*$, say u_1-u_2 and u_3-u_4 , such that the set $N(u_1, u_2) \cup N(u_3, u_4)$ contains an interior vertex of every bad shortcut across S_1 or T_1 . Since u_1 and u_2 are adjacent, they have no common neighbors in $V(K)$, and since u_3 and u_4 are adjacent, they have no common neighbors in $V(K)$, so $N(u_1, u_2) \cup N(u_3, u_4)$ is disjoint from $V(K)$. This proves Theorem 3.5. $\square$

4. Major vertices. In this section, let K be a smallest prism in a graph G , and assume that K has a tidy frame. Let the vertices of P_1 be $f_1, f_2, \dots, f_n$, numbered in order with $f_1 = a_1$ and $f_n = b_1$. Let the vertices of P_2 be $h_1, h_2, \dots, h_m$, numbered in order with $h_1 = a_2$ and $h_m = b_2$, and let the vertices of P_3 be $g_1, g_2, \dots, g_p$, numbered in order with $g_1 = a_3$ and $g_p = b_3$.

Recall that a K -major vertex is a vertex in $V(G) \setminus V(K)$ whose neighbors in K are not contained in a 3-vertex path in K . Since K has a tidy frame, every K -major vertex is anticomplete to $\{a_1, a_2, a_3, b_1, b_2, b_3\}$. For a K -major vertex x , if x has neighbors in P_1 , let j_x be minimal such that x is adjacent to f_{j_x} and let k_x be maximal such that x is adjacent to f_{k_x} . Similarly, let s_x be minimal and t_x maximal such that x is adjacent to h_{s_x} and h_{t_x} , and let c_x be minimal and d_x maximal such that x is adjacent to g_{c_x} and g_{d_x} .

We start with a few easy but useful lemmas.

THEOREM 4.1. *A K -major vertex has at least three neighbors in K .*

Proof. Let x be a major vertex with $N(x) \cap V(K) = \{u, v\}$. We may assume by symmetry that $\{u, v\} \subset V(P_2) \cup V(P_3)$. Since x is major, u and v are not adjacent, so the subgraph induced by G on $V(P_2) \cup V(P_3) \cup \{x\}$ is a theta smaller than K , a contradiction. $\square$

THEOREM 4.2. *There is no K -major vertex with exactly two neighbors in P_2 and no neighbors in P_3 .*

Proof. Let x be a K -major vertex with $N(x) \cap V(P_2) = \{h_{s_x}, h_{t_x}\}$ and $N(x) \cap V(P_3) = \emptyset$. By Theorem 4.1, x has at least one neighbor in P_1 . If $s_x + 1 < t_x$, then the subgraph induced by G on $V(P_2) \cup V(P_3) \cup \{x\}$ is a theta smaller than K , a contradiction. So we may assume that $s_x + 1 = t_x$. Now the triangles $\{h_{s_x}, h_{t_x}, x\}$ and $\{a_1, a_2, a_3\}$ and the paths $h_{s_x}-P_2-a_2$, $h_{t_x}-P_2-b_2-b_3-P_3-a_3$, and $x-f_{j_x}-P_1-a_1$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x\} \setminus \{f_{j_x+1}, b_1\}$, the prism K' is smaller than K unless $f_{j_x+1} = b_1$. Also, the triangles $\{x, h_{s_x}, h_{t_x}\}$ and $\{b_1, b_2, b_3\}$ and the paths $h_{s_x}-P_2-a_2-a_3-P_3-b_3$, $h_{t_x}-P_2-b_2$, and $x-f_{k_x}-P_1-b_1$ form a prism, K'' . Since $V(K'') \subseteq V(K) \cup \{x\} \setminus \{f_{k_x-1}, a_1\}$, the prism K'' is smaller than K unless $f_{k_x-1} = a_1$. Therefore, since K is a smallest prism, $f_{j_x+1} = b_1$ and $f_{k_x-1} = a_1$. It follows that $j_x = k_x$ and f_{j_x} is adjacent to both a_1 and b_1 , so $f_{j_x} = m_1$, contradicting the fact that K has a tidy frame. $\square$

THEOREM 4.3. *Let x and y be vertices, each with at least two nonadjacent neighbors in a path $P = v_1 \cdots v_n$. If there do not exist paths A and B between x and y with $A^* \subset V(P)$ and $B^* \subset V(P)$ such that A^* and B^* are anticomplete to each other, then for some $1 \leq i \leq n$, $N(x) \cap V(P) \subset \{v_1, \dots, v_{i+1}\}$ and $N(y) \cap V(P) \subset \{v_i, \dots, v_n\}$.*

Proof. Let v_s and v_t be the neighbors of x in P with s minimum and t maximum. Let v_p and v_r be the neighbors of y in P with p minimum and r maximum. Since x and y each have two nonadjacent neighbors in P , $s + 1 < t$ and $p + 1 < r$. If $p < s$ and $r > t$, then there are paths A and B between x and y with $A^* \subseteq \{v_p, \dots, v_s\}$ and $B^* \subseteq \{v_t, \dots, v_r\}$, and A^* and B^* are anticomplete to each other, a contradiction. So either $p \geq s$ or $r \leq t$. By symmetry, we may assume that $p \geq s$. If $r \leq t$, then there are paths A and B between x and y with $A^* \subseteq \{v_s, \dots, v_p\}$ and $B^* \subseteq \{v_r, \dots, v_t\}$, and A^* and B^* are anticomplete to each other, a contradiction. Therefore, $r > t$. If $p < t - 1$, then there are paths A and B between x and y with $A^* \subseteq \{v_s, \dots, v_p\}$ and $B^* \subseteq \{v_t, \dots, v_r\}$, and A^* and B^* are anticomplete to each other, a contradiction. So $p \geq t - 1$, and the theorem holds with $i = t - 1$. This proves Theorem 4.3. $\square$

THEOREM 4.4. *Every K -major vertex has neighbors in at least two of P_1 , P_2 , and P_3 .*

Proof. Let v be a K -major vertex with $N(v) \cap V(K) \subseteq V(P_1)$. Since v is major, $j_v + 2 < k_v$. The subgraph induced by G on $V(K) \cup \{v\} \setminus \{f_{j_v+1}, \dots, f_{k_v-1}\}$ is a prism that is smaller than K . Therefore, $N(v) \cap V(K) \not\subseteq V(P_1)$. By symmetry between P_1 , P_2 , and P_3 , it follows that $N(v) \cap V(K) \not\subseteq V(P_2)$ and $N(v) \cap V(K) \not\subseteq V(P_3)$. This proves Theorem 4.4. $\square$

THEOREM 4.5. *Let x and y be K -major vertices that are not adjacent to each other. Then for some i, j with $1 \leq i < j \leq 3$, $N(x) \cap V(K) \subseteq V(P_i) \cup V(P_j)$ and $N(y) \cap V(K) \subseteq V(P_i) \cup V(P_j)$.*

Proof. We first prove that each of x and y has neighbors in exactly two of P_1 , P_2 , and P_3 .

CLAIM 4.1. *None of x and y has neighbors in all of P_1 , P_2 , P_3 .*

Assume that x and y both have neighbors in all three of P_1 , P_2 , and P_3 . Then there are three paths between x and y , each with interior in P_i^* for $i \in \{1, 2, 3\}$. These paths form a theta whose vertex set is contained in $(V(K) \setminus \{a_1, a_2, a_3, b_1, b_2, b_3\}) \cup \{x, y\}$

and is thus smaller than K , a contradiction. Therefore, at least one of x and y does not have neighbors in all three paths P_1 , P_2 , and P_3 .

We may assume by symmetry that $N(y) \cap V(P_1) = \emptyset$. Also, we may assume that x has neighbors in all of P_1 , P_2 , and P_3 , because otherwise Claim 4.1 holds. By Theorem 4.4, y has neighbors in both P_2 and P_3 . By Theorem 4.1, it has at least two neighbors in one of these paths, say P_2 . Then by Theorem 4.2, it has two nonadjacent neighbors in P_2 .

Since x and y both have neighbors in P_3 , there is a path R between them with interior in P_3^* . Let P be the path $h_{s_y}-P_2-a_2-a_1-P_1-b_1-b_2-P_2-h_{t_y}$. Assume that x has two nonadjacent neighbors in P . Then by Theorem 4.3, there are two paths R' and R'' between x and y whose interiors are anticomplete to each other and contained in $V(P)$. Since $V(P)$ is anticomplete to P_3^* , the paths $x-R-y$, $x-R'-y$, and $x-R''-y$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_3, b_3, h_{s_y+1}\}$, K' is smaller than K , a contradiction. Therefore, x does not have two nonadjacent neighbors in P . Since P_1 is a subpath of P , this implies that x does not have two nonadjacent neighbors in P_1 , so $j_x \geq k_x - 1$. Also, since $N(x) \cap P_1^* \neq \emptyset$, it follows that $N(x) \cap (V(P) \setminus V(P_1)) = \emptyset$. Thus $s_x > s_y$ and $t_x < t_y$.

If $s_x < t_y - 1$, then the paths $x-R-y$, $x-f_{k_x}-P_1-b_1-b_2-P_2-h_{t_y}-y$ and a path between x and y with interior in $\{h_{s_y}, \dots, h_{s_x}\}$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{t_y-1}, a_3, b_3\}$, K' is smaller than K , a contradiction. Therefore, $s_x \geq t_y - 1$. Since $s_x \leq t_x$ and $t_x < t_y$, this proves that $s_x = t_y - 1 = t_x$. If $t_x > s_y + 1$, then the paths $x-R-y$, $x-f_{j_x}-P_1-a_1-a_2-P_2-h_{s_y}-y$ and a path between x and y with interior in $\{h_{t_x}, h_{t_y}\}$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{s_y+1}, a_3, b_3\}$, K' is smaller than K , a contradiction. Therefore, $t_x \leq s_y + 1$. Since $t_x = s_x > s_y$, this proves that $s_x = t_x = s_y + 1$. Therefore, $s_y + 2 = t_y$ and $N(x) \cap V(P_2) = \{h_{s_y+1}\}$.

If y is not adjacent to h_{s_y+1} , then $|N(y) \cap V(P_2)| = 2$ and $N(y) \cap V(P_1) = \emptyset$, contradicting Theorem 4.2. Therefore, y is adjacent to h_{s_y+1} . If $j_x = k_x$, then the subgraph induced by G on $V(P_1) \cup V(P_2) \cup \{x\}$ is a theta smaller than K , a contradiction. Therefore, $j_x < k_x$, and since $j_x \geq k_x - 1$, it follows that $j_x = k_x - 1$. If $c_y < c_x$, then the triangles $\{h_{s_y}, h_{s_y+1}, y\}$ and $\{a_1, a_2, a_3\}$ and the paths $h_{s_y}-P_2-a_2$, $h_{s_y+1}-x-f_{j_x}-P_1-a_1$, and $y-g_{c_y}-P_3-a_3$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{b_1, b_2, b_3\}$, K' is smaller than K , a contradiction. Therefore $c_y \geq c_x$. If $c_x < c_y$, then the triangles $\{x, f_{j_x}, f_{k_x}\}$ and $\{a_1, a_2, a_3\}$ and the paths $x-g_{c_x}-P_3-a_3$, $f_{j_x}-P_1-a_1$, and $f_{k_x}-P_1-b_1-b_2-P_2-h_{t_y}-y-h_{s_y}-P_2-a_2$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{s_y+1}, b_3, g_{c_y}\}$, K' is smaller than K , a contradiction. Therefore $c_x = c_y$. By the symmetry of the prism K , it follows by the same argument that $d_x = d_y$.

If $c_x = d_x$, then the induced subgraph with vertex set $V(P_2) \cup V(P_3) \cup \{x\}$ is a theta smaller than K , a contradiction. So $c_x < d_x$, which means that $c_y < d_y$. If $c_y < d_y - 1$, then the paths $x-g_{c_y}-y$, $x-g_{d_y}-y$, and $x-h_{s_y+1}-y$ form a theta smaller than K , a contradiction. Therefore, $c_y = d_y - 1$. But then $|N(y) \cap V(P_3)| = 2$ and $N(y) \cap V(P_1) = \emptyset$, which contradicts Theorem 4.2. This proves Claim 4.1.

By Theorem 4.4 and Claim 4.1, each of x and y has neighbors in precisely two of the paths P_1 , P_2 , and P_3 . Assume that $N(x) \cap V(K)$ and $N(y) \cap V(K)$ are not both contained in the union of the same two of $V(P_1)$, $V(P_2)$, and $V(P_3)$. By symmetry, we may assume that $N(x) \cap V(P_3) = \emptyset$ and that $N(y) \cap V(P_1) = \emptyset$.

Assume that $j_x < k_x - 1$ and $c_y < d_y - 1$; this means that x has two nonadjacent neighbors in P_1 and y has two nonadjacent neighbors in P_3 . Since both x and y have neighbors in P_2 , there exists a path R between x and y with interior in P_2^* . Then the three paths $x-f_{j_x}-P_1-a_1-a_3-P_3-g_{c_y}-y$, $x-f_{k_x}-P_1-b_1-b_3-P_3-g_{d_y}-y$, and $x-R-y$ form a

theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_2, b_2, f_{j_x+1}\}$, K' is smaller than K , a contradiction. This implies that either x does not have two nonadjacent neighbors in P_1 or y does not have two nonadjacent neighbors in P_3 . By symmetry we may assume that x does not have two nonadjacent neighbors in P_1 , so $j_x \geq k_x - 1$. By Theorem 4.2, $N(x) \cap V(P_1)$ does not consist of two adjacent vertices. Therefore, $|N(x) \cap V(P_1)| = 1$, and $j_x = k_x$.

Since x is K -major, by Theorem 4.1, $|N(x) \cap V(P_2)| \geq 2$, and by Theorem 4.2, $N(x) \cap V(P_2)$ does not consist of two adjacent vertices. Therefore, x has two nonadjacent neighbors in P_2 , and $s_x < t_x - 1$.

First assume that $|N(y) \cap V(P_2)| = 1$. Then $s_y = t_y$, and by Theorems 4.2 and 4.1, y has two nonadjacent neighbors in P_3 , so $c_y < d_y - 1$. If $s_y < t_x - 1$, then the paths $y-g_{d_y}-P_3-b_3-b_2-P_2-h_{t_x}-x$, $y-g_{c_y}-P_3-a_3-a_1-P_1-f_{j_x}-x$ and a path between x and y with interior in $V(h_{s_y}-P_2-h_{s_x})$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{t_x-1}, a_2, b_1\}$, K' is smaller than K , a contradiction. Therefore, $s_y \geq t_x - 1$. From the symmetry, $s_y \leq s_x + 1$. So we have that $t_x - 1 \leq s_y \leq s_x + 1$ and $s_x < t_x - 1$, from which it follows that $s_x + 1 = s_y = t_x - 1$. If x is not adjacent to h_{s_x+1} , then $|N(x) \cap V(P_2)| = 2$ and $N(x) \cap V(P_3) = \emptyset$, contradicting Theorem 4.2. Therefore, x is adjacent to h_{s_x+1} . The triangles $\{h_{s_x}, h_{s_x+1}, x\}$ and $\{a_1, a_2, a_3\}$ and the paths $h_{s_x}-P_2-a_2$, $h_{s_x+1}-y-g_{c_y}-P_3-a_3$, and $x-f_{j_x}-P_1-a_1$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{b_1, b_2, b_3\}$, K' is smaller than K , a contradiction. This proves that $|N(y) \cap V(P_2)| > 1$.

By Theorem 4.2, y has more than two neighbors in P_2 , and $s_y < t_y - 1$. Let Q be the path $x-f_{j_x}-P_1-a_1-a_3-P_3-g_{c_y}-y$. If there are two paths A and B between x and y whose interiors are anticomplete to each other and contained in P_2^* , then the paths Q , A , and B form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{b_1, b_2, b_3\}$, K' is smaller than K , a contradiction. Therefore, there are no two paths between x and y whose interiors are anticomplete to each other and contained in P_2^* . Then by Theorem 4.3, either $N(y) \cap V(P_2) \subseteq \{h_1, \dots, h_{s_x+1}\}$ or $N(y) \cap V(P_2) \subseteq \{h_{t_x-1}, \dots, h_m\}$. By symmetry, we may assume that $N(y) \cap V(P_2) \subseteq \{h_1, \dots, h_{s_x+1}\}$, which means that $t_y \leq s_x + 1$.

If $t_y \leq s_x$, then the paths $y-h_{s_y}-P_2-a_2-a_1-P_1-f_{j_x}-x$, $y-g_{d_y}-P_3-b_3-b_2-P_2-h_{t_x}-x$ and a path between x and y with interior in $V(h_{t_y}-P_2-h_{s_x})$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_3, b_1, h_{s_x+1}\}$, K' is smaller than K , a contradiction. Therefore, $t_y > s_x$, and since $t_y \leq s_x + 1$, it follows that $t_y = s_x + 1$ and y is adjacent to h_{s_x+1} .

Assume that $s_y < s_x - 1$ and $t_x > t_y + 1$. Then the paths $x-f_{j_x}-P_1-a_1-a_2-P_2-h_{s_y}-y$, $x-h_{t_x}-P_2-b_2-b_3-P_3-g_{d_y}-y$ and a path between x and y with interior in $\{h_{s_x}, h_{s_x+1}\}$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_3, h_{s_x-1}, h_{t_x-1}\}$, K' is smaller than K , a contradiction. Therefore, either $s_y \geq s_x - 1$ or $t_x \leq t_y + 1$.

First assume that $s_y \geq s_x - 1$. Then since $s_x = t_y - 1$ and $s_y < t_y - 1$, this implies that $s_y = s_x - 1$. If y is adjacent to h_{s_x} , then the triangles $\{h_{s_x-1}, h_{s_x}, y\}$ and $\{a_1, a_2, a_3\}$ and the paths $h_{s_x-1}-P_2-a_2$, $h_{s_x}-x-f_{j_x}-P_1-a_1$, and $y-g_{c_y}-P_3-a_3$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{b_1, b_2, b_3\}$, K' is smaller than K , a contradiction. Therefore, y is not adjacent to h_{s_x} . Then since $t_y = s_y + 2$, this means that $|N(y) \cap V(P_2)| = 2$, which contradicts Theorem 4.2. This proves that $s_y < s_x - 1$, so we may now assume that $t_x \leq t_y + 1$. Since $t_y = s_x + 1$ and $t_x > s_x + 1$, this implies that $t_x = s_x + 2$. If x is adjacent to h_{s_x+1} , then the triangles $\{h_{s_x+1}, h_{t_x}, x\}$ and $\{b_1, b_2, b_3\}$ and the paths $h_{s_x+1}-y-g_{d_y}-P_3-b_3$, $h_{t_x}-P_2-b_2$, and $x-f_{k_x}-P_1-b_1$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_1, a_2, a_3\}$, K' is smaller than K , a contradiction. Therefore, x is not adjacent to h_{s_x+1} . Then since $t_x = s_x + 2$, this means that $|N(x) \cap V(P_2)| = 2$,

which contradicts Theorem 4.2. This proves Theorem 4.5. $\square$

THEOREM 4.6. *Two K -major vertices that are not adjacent have a common neighbor in K .*

Proof. Let x and y be K -major vertices that are not adjacent to each other. Assume that $N(x) \cap V(K) \cap N(y) = \emptyset$. From Theorem 4.5 we may assume that $(N(x) \cup N(y)) \cap V(K) \subset P_1^* \cup P_2^*$. By Theorem 4.4, each of P_1^* and P_2^* contains a neighbor of x and a neighbor of y . Let C be the cycle induced by G on $V(P_1) \cup V(P_2)$. A *gap* is a minimal path in C containing a neighbor of x and a neighbor of y . Every edge of C is in at most one gap, and any vertex common to two distinct gaps is an end of both. Since x and y have no common neighbor in C , there is an even number of gaps. For a gap P , let P^+ be the path between x and y whose interior is $V(P)$. Let $R_1, \dots, R_k$ be the gaps of C numbered in their order on C , such that the vertex set of the path of C sharing one end with R_i and the other end with R_{i+1} , and with interior disjoint from all the gaps, is anticomplete to y if i is odd and anticomplete to x if i is even. Call a gap a *small gap* if it consists of one edge and shares both of its ends with other gaps.

CLAIM 4.2. *There are at most six gaps.*

Suppose there are at least eight gaps. Assume that for some i , R_i is not a small gap. Then the paths R_{i+1}^+, R_{i+4}^+ , and R_{i+7}^+ form a theta, K' . It is smaller than K because each of R_i , $R_{i+2} \cup R_{i+3}$, and $R_{i+5} \cup R_{i+6}$ contains at least one vertex not in $V(K')$. Therefore, every gap is small. Then every edge of C is in a gap and every gap consists of one edge, so $V(C) \subseteq N(x) \cup N(y)$. But this contradicts the fact that x and y have no neighbors in $\{a_1, a_2, b_1, b_2\} \subseteq C$. This proves Claim 4.2.

CLAIM 4.3. *There are at most four gaps.*

Suppose there are six gaps. Assume that no gap is small. The paths R_1^+, R_3^+ , and R_5^+ form a theta. It is smaller than K because R_2, R_4 , and R_6 each contains at least one vertex not in the theta since each is not a small gap. So there is a small gap; by symmetry let it be R_1 . Assume next that none of R_2, R_4 , or R_6 is a small gap. Then the paths R_1^+, R_3^+ , and R_5^+ form a theta smaller than K . Therefore one of R_2, R_4 , or R_6 is small.

First assume that R_2 is a small gap. Then $R_1 \cup R_2$ is a 3-vertex path whose vertices are contained in $N(x) \cup N(y)$, and so it is a subpath of either P_1 or P_2 in K , because x and y have no neighbors in $\{a_1, a_2, b_1, b_2\}$. By symmetry assume it is a subpath of P_1 . Both x and y have a neighbor in P_2 , so there is a path Q between them with interior in P_2 . Let u be the vertex that is an end of both R_1 and R_2 . The three paths $u-R_1^+-y$, $u-R_2^+-y$, and $u-x-Q-y$ form a theta, K' . Since $V(K')$ is disjoint from $\{a_1, a_2, a_3, b_1, b_2, b_3\}$, it follows that the theta K' is smaller than K , a contradiction. This proves that R_2 is not a small gap. From the symmetry, we deduce that R_6 is not a small gap either.

Therefore R_4 is a small gap. From the argument in the previous paragraph with R_4 playing the role of R_1 , we deduce that neither R_3 nor R_5 is a small gap. Since R_1 is a small gap and R_5 is not, we deduce that $V(R_1) \cap V(R_6) \neq \emptyset$, and that $V(R_6)$ is anticomplete to $V(R_4)$. Let $V(R_1) \cap V(R_6) = \{v\}$. The paths $x-R_4^+-y-v$, $R_6^+ \setminus y$, and $R_1^+ \setminus y$ form a theta smaller than K , a contradiction.

This proves Claim 4.3.

CLAIM 4.4. *There are at most two gaps.*

Assume there are four gaps. Let $Q_1, \dots, Q_4$ be subpaths of C such that none of their interiors meet any gap, and such that for $1 \leq i \leq 3$, one end of Q_i is an end of R_i and the other is an end of R_{i+1} , while the ends of Q_4 are ends of R_1 and R_4 . The

neighbors of x in C are contained in $V(Q_1) \cup V(Q_3)$ and the neighbors of y in C are contained in $V(Q_2) \cup V(Q_4)$.

Assume that Q_1 and Q_3 both have length at most one. Then since x has neighbors in both P_1 and P_2 but no neighbors in $\{a_1, a_2, b_1, b_2\}$, one of Q_1 and Q_3 is a subpath of P_1 and the other is a subpath of P_2 . But then x has at most two neighbors in each of P_1 and P_2 , contradicting Theorems 4.1 or 4.2. This shows that at least one of Q_1 and Q_3 has length at least two. By symmetry, we may assume that Q_1 does. Therefore $V(R_1)$ is anticomplete to $V(R_2)$.

By the same argument applied to Q_2 and Q_4 , we deduce that at least one of Q_2 and Q_4 has length at least two. From the symmetry, we may assume that Q_2 has length at least two, and therefore $V(R_2)$ is anticomplete to $V(R_3)$. Since the paths R_1^+ , R_2^+ , and R_3^+ do not form a theta smaller than K , it follows that $|V(Q_3)| = |V(Q_4)| = 1$ and R_4 is a small gap. Let $V(Q_3) = \{q_3\}$ and $V(Q_4) = \{q_4\}$. Since $V(R_2)$ is anticomplete to both $V(R_1)$ and $V(R_3)$, the paths $x-q_3-q_4$, $R_1^+ \setminus y$, and $x-R_2^+-y-q_4$ form a theta smaller than K , a contradiction. This proves Claim 4.4.

Since x and y each have a neighbor in C , there are at least two gaps; so from Claim 4.4 there are two gaps. Since x and y each have neighbors in both P_1 and P_2 , there is a gap contained in P_1 and a gap contained in P_2 . The subgraph $C \setminus (R_1 \cup R_2)$ is the disjoint union of two paths, Q_1 and Q_2 , such that Q_1 contains no neighbors of x and Q_2 contains no neighbors of y . By Theorems 4.1 and 4.2, each of x and y has two nonadjacent neighbors in one of P_1 and P_2 , so each of x and y has a neighbor in C that is anticomplete to $V(R_1) \cup V(R_2)$. Therefore, there is a path S between x and y whose interior is anticomplete to $V(R_1) \cup V(R_2)$ and is contained in $V(K) \setminus (V(R_1) \cup V(R_2))$. The paths S , R_1^+ , and R_2^+ form a theta smaller than K , a contradiction. This proves Theorem 4.6. $\square$

A *broom* is a vertex $v \in V(G)$ such that, for some $\{i_1, i_2, i_3\} = \{1, 2, 3\}$,

- $N(v) \cap V(P_{i_1}) = \emptyset$,
- $|N(v) \cap V(P_{i_2})| = 1$, and
- $N(v) \cap V(P_{i_3})$ is the vertex set of a 3-vertex path.

THEOREM 4.7. *If x and y are two K -major vertices that are not adjacent to each other, then one of them is a broom, and for some i, j such that $1 \leq i < j \leq 3$, $N(x) \cap V(P_i) \cap N(y) \neq \emptyset$ and $N(x) \cap V(P_j) \cap N(y) \neq \emptyset$.*

Proof. By Theorem 4.5, we may assume that $N(x) \cap V(K) \subseteq P_1^* \cup P_2^*$ and $N(y) \cap V(K) \subseteq P_1^* \cup P_2^*$. By Theorem 4.4, x and y each have a neighbor both in P_1^* and in P_2^* . Also, by Theorem 4.6, x and y have a common neighbor in K , and by the symmetry between P_1 and P_2 we may assume that $f_r \in P_1^*$ is a neighbor of both x and y .

Let A be the path induced by G on $V(P_1) \cup V(P_2) \setminus \{f_{r-1}, f_r, f_{r+1}\}$.

CLAIM 4.5. *x and y do not both have a neighbor in $V(A) \cap V(P_1)$.*

Suppose both x and y have a neighbor in $V(A) \cap V(P_1)$. Then there is a path, S , between x and y with interior in $(V(A) \cap V(P_1)) \cup V(P_3)$. Since x and y each have a neighbor in P_2^* , there is a path R between them with interior in P_2^* . The paths S , $x-f_r-y$, and R form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{f_{r-1}, f_{r+1}, a_2, b_2\}$, K' is smaller than K , a contradiction. This proves Claim 4.5.

CLAIM 4.6. *If exactly one of x and y has a neighbor in $V(A) \cap V(P_1)$, then the theorem holds.*

Assume that exactly one of x and y has neighbors in $V(A) \cap V(P_1)$. By symmetry between x and y we may assume that $N(x) \cap V(A) \cap V(P_1) \neq \emptyset$ and $N(y) \cap V(A) \cap V(P_1) = \emptyset$. By Theorems 4.1 and 4.2, y has two nonadjacent neighbors in at least one of P_1 and P_2 . Since y has no neighbors in $V(A) \cap V(P_1)$, this means that it either has

two nonadjacent neighbors in P_2 , so $t_y > s_y + 1$, or it is adjacent to both f_{r-1} and f_{r+1} .

First assume that $t_y > s_y + 1$. Since $N(x) \cap V(A) \cap V(P_1) \neq \emptyset$ and $N(x) \cap V(P_2) \neq \emptyset$, each of x and y has two nonadjacent neighbors in A . If there are two paths S and R between x and y whose interiors are anticomplete to each other and are contained in $V(A)$, then the paths $x-f_{r-1}-y$, S , and R form a theta smaller than K , a contradiction. Therefore, by Theorem 4.3 we may assume that $N(x) \cap V(A) \subseteq V(a_1-P_1-f_{r-2}) \cup V(a_2-P_2-h_{s_y+1})$, which means that $t_x \leq s_y + 1$. Since $N(x) \cap V(A) \cap V(P_1) \neq \emptyset$, $j_x < r - 1$. If $s_x < t_y - 1$, then the paths $x-f_{r-1}-y$, $x-f_{j_x}-P_1-a_1-a_3-P_3-b_3-b_2-P_2-h_{t_y}-y$ and a path between x and y with interior in $V(h_{s_x}-P_2-h_{s_y})$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_2, b_1, f_{r-1}\}$, K' is smaller than K , a contradiction. Therefore, $s_x \geq t_y - 1$, and since $t_x \leq s_y + 1$ and $t_y > s_y + 1$, it follows that $s_y + 1 = t_y - 1$ and $N(x) \cap V(P_2) = \{h_{s_y+1}\}$. By Theorem 4.2, $|N(y) \cap V(P_2)| \neq 2$, so y is adjacent to h_{s_y+1} . Also by Theorem 4.2, $|N(y) \cap V(P_1)| \neq 2$, so y is either complete or anticomplete to $\{f_{r-1}, f_{r+1}\}$.

Suppose that y is $\{f_{r-1}, f_{r+1}\}$ -complete. If x is not adjacent to f_{r+1} , then the triangles $\{f_r, f_{r+1}, y\}$ and $\{b_1, b_2, b_3\}$ and the paths $f_r-x-f_{j_x}-P_1-a_1-a_3-P_3-b_3$, $f_{r+1}-P_1-b_1$, and $y-h_{t_y}-P_2-b_2$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{s_y}, h_{s_y+1}, f_{r-1}\}$, K' is smaller than K , a contradiction. So x is adjacent to f_{r+1} , and the paths $x-f_{r+1}-y$, $x-h_{s_y+1}-y$ and a path between x and y with interior in $V(f_{j_x}-P_1-f_{r-1})$ form a theta smaller than K , a contradiction. Therefore, y is anticomplete to $\{f_{r-1}, f_{r+1}\}$, and so y is a broom and the theorem holds.

Since we have shown that the theorem holds when $t_y > s_y + 1$, we may now assume that $t_y \leq s_y + 1$ and that y is $\{f_{r-1}, f_{r+1}\}$ -complete. By Theorem 4.2, $|N(y) \cap V(P_2)| \neq 2$, so $t_y = s_y$. Since $N(x) \cap V(A) \cap V(P_1) \neq \emptyset$, either $j_x < r - 1$ or $k_x > r + 1$. By symmetry we may assume that $j_x < r - 1$.

Suppose that $|N(x) \cap V(P_2)| = 1$. If x is adjacent to f_{r+1} , then the path $x-f_{r+1}-y$, a path between x and y with interior in $V(f_{j_x}-P_1-f_{r-1})$, and a path between x and y with interior in P_2^* form a theta smaller than K , a contradiction. Therefore, x is not adjacent to f_{r+1} . If $s_x < s_y$, then the triangles $\{f_r, f_{r+1}, y\}$ and $\{b_1, b_2, b_3\}$ and the paths $f_r-x-f_{j_x}-P_1-a_1-a_3-P_3-b_3$, $f_{r+1}-P_1-b_1$, and $y-h_{s_y}-P_2-b_2$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{f_{r-1}, a_2, h_{s_x}\}$, K' is smaller than K , a contradiction. If $s_x > s_y$, then the triangles $\{f_r, f_{r+1}, y\}$ and $\{a_1, a_2, a_3\}$ and the paths $f_r-x-f_{j_x}-P_1-a_1$, $f_{r+1}-P_1-b_1-b_3-P_3-a_3$, and $y-h_{s_y}-P_2-a_2$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{f_{r-1}, b_2, h_{s_x}\}$, K' is smaller than K , a contradiction. This proves that $s_x = s_y$, and y is a broom, so the theorem holds. So we may assume that $|N(x) \cap V(P_2)| > 1$, and it follows from Theorem 4.2 that $s_x < t_x - 1$.

Let Q be the path between x and y with interior in $V(f_{j_x}-P_1-f_{r-1})$. If $t_x \leq s_y$, then the paths Q , $x-h_{t_x}-P_2-h_{s_y}-y$, and $x-h_{s_x}-P_2-a_2-a_3-P_3-b_3-b_1-P_1-f_{r+1}-y$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{f_r, a_1, b_2\}$, K' is smaller than K , a contradiction. Therefore, $t_x > s_y$. If $s_x \geq s_y$, then the paths Q , $x-h_{s_x}-P_1-h_{s_y}-y$, and $x-h_{t_x}-P_2-b_2-b_1-P_1-f_{r+1}-y$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_1, a_2, a_3\}$, K' is smaller than K , a contradiction. Therefore, $s_x < s_y$. If x is not adjacent to h_{s_y} , then the path $h_{s_y}-y-f_r-x$, a path between h_{s_y} and x with interior in $V(h_{s_y}-P_2-h_{s_x})$, and a path between h_{s_y} and x with interior in $V(h_{s_y}-P_2-h_{t_x})$ form a theta smaller than K , a contradiction. Thus x is adjacent to h_{s_y} , and y is a broom, so the theorem holds. This proves Claim 4.6.

CLAIM 4.7. *If neither x nor y has a neighbor in $V(A) \cap V(P_1)$, then the theorem holds.*

Suppose that neither x nor y has a neighbor in $V(A) \cap V(P_1)$. By Theorem 4.2, each of x and y is either complete or anticomplete to $\{f_{r-1}, f_{r+1}\}$. If both x and y are $\{f_{r-1}, f_{r+1}\}$ -complete, then the paths $x-f_{r-1}-y$, $x-f_{r+1}-y$ and a path between x and y with interior in P_2^* form a theta smaller than K , a contradiction. This means that at most one of x and y is $\{f_{r-1}, f_{r+1}\}$ -complete.

Assume that exactly one of x and y is $\{f_{r-1}, f_{r+1}\}$ -complete. By symmetry, we may assume that x is, and that y is anticomplete to $\{f_{r-1}, f_{r+1}\}$. By Theorems 4.1 and 4.2, $|N(y) \cap V(P_2)| \geq 3$, so $s_y + 1 < t_y$.

Suppose that $|N(x) \cap V(P_2)| > 1$; then by Theorem 4.2, $|N(x) \cap V(P_2)| \geq 3$ so $s_x + 1 < t_x$. If there are two paths S and R between x and y whose interiors are anticomplete to each other and contained in P_2^* , then S , R , and $x-f_r-y$ form a theta smaller than K , a contradiction. So from Theorem 4.3, we may assume that $t_x \leq s_y + 1$. From this it follows that $s_x < s_y$. Then the triangles $\{f_r, f_{r+1}, x\}$ and $\{b_1, b_2, b_3\}$ and the paths $f_r-y-h_{t_y}-P_2-b_2$, $f_{r+1}-P_1-b_1$, and $x-h_{s_x}-P_2-a_2-a_3-P_3-b_3$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_1, h_{s_y}, f_{r-1}\}$, K' is smaller than K , a contradiction. This proves that $|N(x) \cap V(P_2)| = 1$.

If $s_x < s_y$, then the triangles $\{f_{r-1}, f_r, x\}$ and $\{a_1, a_2, a_3\}$ and the paths $f_{r-1}-P_1-a_1$, $f_r-y-h_{t_y}-P_2-b_2-b_3-P_3-a_3$, and $x-h_{s_x}-P_2-a_2$ form a prism, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{h_{s_y}, b_1, f_{r+1}\}$, K' is smaller than K , a contradiction. Therefore $s_x \geq s_y$, and from the symmetry $s_x \leq t_y$.

If y is not adjacent to h_{s_x} , then $s_y < s_x$ and $t_y > s_x$. The path $y-f_r-x-h_{s_x}$ and two paths between y and h_{s_x} with interiors in $V(h_{s_y}-P_2-h_{s_x})$ and $V(h_{t_y}-P_2-h_{s_x})$ form a theta smaller than K , a contradiction. So y is adjacent to h_{s_x} . Since x is a broom, the theorem holds.

Since we have shown that the theorem holds when one of x and y is $\{f_{r-1}, f_{r+1}\}$ -complete, we may now assume that $\{x, y\}$ is anticomplete to $\{f_{r-1}, f_{r+1}\}$. Now $N(x) \cap V(P_1) = N(y) \cap V(P_1) = \{f_r\}$, so by Theorems 4.1 and 4.2, x and y each have two nonadjacent neighbors in P_2 . If there are two paths S and R between x and y whose interiors are anticomplete to each other and contained in P_2^* , then the paths S , R , and $x-f_r-y$ form a theta smaller than K , a contradiction. Therefore, by Theorem 4.3, we may assume that $t_x \leq s_y + 1$.

If $t_x \leq s_y$, then the paths $x-f_r-y$, $x-h_{t_x}-P_2-h_{s_y}-y$, and $x-h_{s_x}-P_2-a_2-a_3-P_3-b_3-b_2-P_2-h_{t_y}-y$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_1, b_1, h_{s_y+1}\}$, K' is smaller than K , a contradiction. Therefore $t_x > s_y$ so $t_x = s_y + 1$.

If $s_x < s_y - 1$ and $t_y > t_x + 1$, then the paths $x-f_r-y$, $x-h_{s_x}-P_2-a_2-a_3-P_3-b_3-b_2-P_2-h_{t_y}-y$ and a path between x and y with interior in $\{h_{s_y}, h_{t_x}\}$ form a theta, K' . Since $V(K') \subseteq V(K) \cup \{x, y\} \setminus \{a_1, b_1, h_{s_y-1}\}$, K' is smaller than K , a contradiction. Therefore, either $s_x \geq s_y - 1$ or $t_y \leq t_x + 1$. From the symmetry we may assume that $s_x \geq s_y - 1$. Then since $s_x < t_x - 1$ and $t_x = s_y + 1$, it follows that $s_x = s_y - 1$. If x is not adjacent to h_{s_y} , then $|N(x) \cap V(P_2)| = 2$, contradicting Theorem 4.2. So x is adjacent to h_{s_y} . Then x is a broom and the theorem holds. This proves Claim 4.7.

Now Theorem 4.7 follows from Claims 4.5, 4.6, and 4.7. $\square$

Let M be the subgraph of G induced on the set of K -major vertices. The following algorithm constructs a superset of $V(M)$ that is disjoint from $V(K)$ and is used for cleaning.

THEOREM 4.8. *There is an algorithm with the following specifications:*

- **Input:** A graph G .
- **Output:** A sequence of subsets $X_1, \dots, X_r$ of $V(G)$, with $r \leq 2|V(G)|^6$, such that for every smallest prism K in G , if K has a tidy frame, then one of $X_1, \dots, X_r$ is disjoint from $V(K)$ and contains all K -major vertices.
- **Running Time:** $O(|V(G)|^7)$.

Proof. The algorithm is as follows. For each triple of vertices (a, b, c) compute the set U of vertices complete to $N(a, b) \cup \{c\}$. List all subsets $W \subseteq V(G)$ of at most three vertices. For each pair of (a, b, c) and W , compute the subset

$$N(a, b) \cup \{c\} \cup U \setminus W.$$

Label the subsets generated $Y_1, \dots, Y_s$, and label the list of subsets $N(a, b)$ by $N_1, \dots, N_p$. Enumerate all quintuples of vertices (u, w, z_1, z_2, z_3) . For each, compute the subset

$$Z(u, w, z_1, z_2, z_3) = \{u\} \cup (N(u) \setminus \{w, z_1, z_2, z_3\}) \cup N(w, z_1) \cup N(w, z_2) \cup N(w, z_3).$$

Label the subsets generated $Z_1, \dots, Z_t$. Output the subsets

$$\emptyset, N_1, \dots, N_p, Y_1, \dots, Y_s, Z_1, \dots, Z_t.$$

This completes the description of the algorithm.

Since $p \leq |V(G)|^2$, $s \leq |V(G)|^6$, and $t \leq |V(G)|^5$, the number of subsets in the output sequence is $r \leq 2|V(G)|^6$. For each triple (a, b, c) , the subset U can be computed in quadratic time and the subsets W can be enumerated in cubic time. Computing $N(a, b) \cup \{c\} \cup U \setminus W$ takes linear time, so the time taken to generate the sequence $N_1, \dots, N_p, Y_1, \dots, Y_s$ is $O(|V(G)|^7)$. Since each of the $|V(G)|^5$ subsets Z can be computed in linear time, their computation does not affect the total running time.

Let K be a smallest prism in G , and assume K has a tidy frame. Let M be the subgraph induced by G on the set of K -major vertices. Suppose M is the complete graph. We may assume that there exists a set $\{a, b\} \subseteq V(K)$ that is not a subset of the vertex set of a 3-vertex subpath of K , because if no such choice is possible, then $V(M) = \emptyset$, which is in the output. We may also assume that, subject to these conditions, $\{a, b\}$ is chosen with $|N(a, b)|$ maximum. Then $N(a, b) \subseteq V(M)$. If $N(a, b) = V(M)$, then $V(M)$ is in the output sequence. Otherwise there is a vertex $c \in V(M) \setminus N(a, b)$. Then since $N(a, b) \cup \{c\} \subseteq V(M)$ and M is a complete graph, the set U of vertices complete to $N(a, b) \cup \{c\}$ contains $V(M) \setminus (N(a, b) \cup \{c\})$; so

$$V(M) \subseteq N(a, b) \cup \{c\} \cup U.$$

If $U \cap V(K)$ is not a subset of the vertex set of a 3-vertex path of K , then there are two vertices $a', b' \in U \cap V(K)$ such that $\{a', b'\}$ is not a subset of the vertex set of a 3-vertex path of K . Since $N(a, b) \cup \{c\} \subseteq N(a', b')$, this contradicts the choice of a and b . So $|U \cap V(K)| \leq 3$ and we can choose $W = U \cap V(K)$. Then the subset $N(a, b) \cup \{c\} \cup U \setminus W$ contains $V(M)$, and since $(N(a, b) \cup \{c\}) \cap V(K) = \emptyset$, $N(a, b) \cup \{c\} \cup U \setminus W$ is disjoint from $V(K)$. The subset in the output corresponding to this choice of (a, b, c) and W contains $V(M)$ and is disjoint from $V(K)$.

Therefore, we may assume that M is not a complete graph. Then there exist two vertices in $V(M)$ that are not adjacent to each other. By Theorem 4.7, one of these is a broom. So we may choose u to be a broom such that z_1, z_2, z_3 , and w are its neighbors in K and z_1 - z_2 - z_3 is a path of K . By Theorem 4.7, any nonneighbor of u in $V(M)$ is contained in the subset $N(w, z_1) \cup N(w, z_2) \cup N(w, z_3)$. Therefore the subset $Z(u, w, z_1, z_2, z_3)$ contains $V(M)$. Since w is in the interior of a different path of the prism K from that containing $\{z_1, z_2, z_3\}$, the subset $N(w, z_1) \cup N(w, z_2) \cup N(w, z_3)$ is disjoint from $V(K)$. Since $N(u) \cap V(K) = \{w, z_1, z_2, z_3\}$, $Z(u, w, z_1, z_2, z_3)$ is disjoint from $V(K)$. This proves Theorem 4.8. $\square$

5. The complete algorithm.

THEOREM 5.1. *There is an algorithm with the following specifications:*

- **Input:** A graph G .
- **Output:** Either
 - a theta in G , or
 - a determination that there is no smallest theta in G .
- **Running Time:** $O(|V(G)|^{22})$.

Proof. Here is the algorithm. Enumerate all 11-tuples $(a, b, s_1, s_2, s_3, m_1, m_2, m_3, t_1, t_2, t_3)$ of vertices of G such that

- a, b, s_1, s_2 , and s_3 are all distinct;
- a, b, t_1, t_2 , and t_3 are all distinct;
- a is not adjacent to b ; and
- a is complete to $\{s_1, s_2, s_3\}$ and b is complete to $\{t_1, t_2, t_3\}$.

We can find all such 11-tuples in time $O(|V(G)|^{11})$. For each 11-tuple do the following.

Remove $N(a) \setminus \{s_1, s_2, s_3\}$ and $N(b) \setminus \{t_1, t_2, t_3\}$ from $V(G)$, and for $i = 1, 2, 3$, if m_i is adjacent to a and b , then remove $N(m_i) \setminus \{a, b\}$ from $V(G)$. This can be done in linear time, and after this step every smallest theta in G with the 11-tuple as its frame has a tidy frame. Run the algorithm of Theorem 2.2, which takes $O(|V(G)|^4)$ time. Let $X_1, \dots, X_t$ be the subsets in the output; $t \leq |V(G)|^3$. For every triple of subsets $(X_{i_1}, X_{i_2}, X_{i_3})$ from this list, do the following.

Let G_1 be the graph induced by G on $V(G) \setminus X_{i_1}$. Find shortest paths S'_1 between s_1 and m_1 and T'_1 between m_1 and t_1 in G_1 . Next, let G_2 be the graph induced by G_1 on $V(G_1) \setminus X_{i_2}$. Find shortest paths S'_2 between s_2 and m_2 and T'_2 between m_2 and t_2 in G_2 . Finally, let G_3 be the graph induced by G_2 on $V(G_2) \setminus X_{i_3}$. Find shortest paths S'_3 between s_3 and m_3 and T'_3 between m_3 and t_3 in G_3 . Finding these paths takes quadratic time. Finally, test whether the following are true in the graph G :

- For $1 \leq i \leq 3$, $V(S'_i) \setminus \{m_i\}$ and $V(T'_i) \setminus \{m_i\}$ are disjoint and anticomplete to each other, and
- for $1 \leq i, j \leq 3$ with $i \neq j$, $V(S'_i) \cup V(T'_i)$ and $V(S'_j) \cup V(T'_j)$ are disjoint and anticomplete to each other.

If these conditions are satisfied, output that $\{a, b\}$ and the three paths $a-s_1-S'_1-m_1-T'_1-t_1-b$, $a-s_2-S'_2-m_2-T'_2-t_2-b$, and $a-s_3-S'_3-m_3-T'_3-t_3-b$ form a theta and stop. Testing these conditions takes quadratic time. So the time it takes to examine one 11-tuple is $O(|V(G)|^{11})$.

After examining all 11-tuples, output that G contains no smallest theta. The total running time is $O(|V(G)|^{22})$. Now we need to prove that this algorithm is correct. Suppose there is a smallest theta K in G ; let its half-paths be S_1, T_1, S_2, T_2, S_3 , and T_3 . Some 11-tuple chosen is the frame of K , and after the first step of the algorithm, K and every smallest theta in G with the same frame as K have a tidy frame.

By Theorem 2.2, we may choose X_{i_1} such that the graph G_1 contains K and there are no bad shortcuts across S_1 or T_1 in G_1 . Therefore, the subgraph induced by G_1 on $V(K) \setminus (V(S_1) \cup V(T_1)) \cup V(S'_1) \cup V(T'_1)$ is a theta, K_1 , in G_1 . Since S'_1 and T'_1 are shortest paths, $|V(K_1)| \leq |V(K)|$, so K_1 is also a smallest theta in G_1 . Since K_1 is not smaller than K in G it follows that $V(S'_1) \setminus \{m_1\}$ and $V(T'_1) \setminus \{m_1\}$ are anticomplete to each other. We observe that K_1 has the same frame as K , so it has a tidy frame.

Therefore, by Theorem 2.2, for some subset X_{i_2} the graph G_2 contains K_1 , and all shortcuts across S_2 or T_2 in G_2 are good shortcuts across K_1 . Then the subgraph induced by G_2 on $V(K_1) \setminus (V(S_2) \cup V(T_2)) \cup V(S'_2) \cup V(T'_2)$ is a theta, K_2 , in G_2 . Since

S'_2 and T'_2 are shortest paths, $|V(K_2)| \leq |V(K_1)|$, so K_2 is also a smallest theta in G_2 . Since K_2 is not smaller than K_1 in G it follows that $V(S'_2) \setminus \{m_2\}$ and $V(T'_2) \setminus \{m_2\}$ are anticomplete to each other. We observe that K_2 has the same frame as K , so it has a tidy frame.

Finally, by Theorem 2.2 again, for some subset X_{i_3} the graph G_3 contains K_2 , and all shortcuts across S_3 or T_3 in G_3 are good shortcuts across K_2 . Then the subgraph induced by G_3 on $V(K_2) \setminus (V(S_3) \cup V(T_3)) \cup V(S'_3) \cup V(T'_3)$ is a theta, K_3 , in G_3 . Since K_3 is not smaller than K_2 in G it follows that $V(S'_3) \setminus \{m_3\}$ and $V(T'_3) \setminus \{m_3\}$ are anticomplete to each other. We observe that K_3 is the theta that is output by the algorithm when it considers $X_{i_1}, X_{i_2}, X_{i_3}$. This proves that the output of the algorithm is a theta.

Conversely, if the algorithm outputs that there is a theta, then the properties of the 11-tuple and the conditions on the paths that the algorithm checks ensure that this output is actually a theta. $\square$

THEOREM 5.2. *There is an algorithm with the following specifications:*

- **Input:** A graph G .
- **Output:** Either
 - a prism in G , or
 - a determination that there is no smallest prism in G .
- **Running Time:** $O(|V(G)|^{35})$.

Proof. Here is the algorithm. Enumerate all 15-tuples of vertices of G ,

$$(a_1, a_2, a_3, m_1, m_2, m_3, b_1, b_2, b_3, a'_1, a'_2, a'_3, b'_1, b'_2, b'_3),$$

such that

- $a_1, a_2, a_3, b_1, b_2, b_3$ are distinct,
- $a_1, a_2, a_3, a'_1, a'_2, a'_3$ are distinct,
- $b_1, b_2, b_3, b'_1, b'_2, b'_3$ are distinct,
- G induces a triangle on each of $\{a_1, a_2, a_3\}$ and $\{b_1, b_2, b_3\}$, and
- for $i = 1, 2, 3$, a'_i is adjacent to a_i and b'_i is adjacent to b_i .

For each 15-tuple, do the following.

For $i = 1, 2, 3$ remove the subsets $N(a_i) \setminus \{a'_i, a_1, a_2, a_3\}$ and $N(b_i) \setminus \{b'_i, b_1, b_2, b_3\}$ from $V(G)$, and if $m_i = a'_i = b'_i$, then remove $N(m_i) \setminus \{a_i, b_i\}$ from $V(G)$. Now any smallest prism K that has $\{a_1, a_2, a_3, m_1, m_2, m_3, b_1, b_2, b_3\}$ as its frame and contains $\{a'_1, a'_2, a'_3, b'_1, b'_2, b'_3\}$ has a tidy frame.

Run the algorithm of Theorem 4.8 on G . This outputs $O(|V(G)|^6)$ subsets. For each subset Y output, do the following. Let G' be the graph induced by G on $V(G) \setminus Y$. Run the algorithm of Theorem 3.5, which takes $O(|V(G)|^5)$ time and outputs $O(|V(G)|^4)$ subsets. Let $X_1, \dots, X_t$ be the subsets in the output. For every triple of subsets $(X_{i_1}, X_{i_2}, X_{i_3})$ from this list, do the following.

Let G_1 be the graph induced by G' on $V(G') \setminus X_{i_1}$. Find shortest paths S'_1 between a_1 and m_1 and T'_1 between m_1 and b_1 in G_1 . Remove from $V(G_1)$ the set U_1 consisting of all vertices in $V(G_1) \setminus (S'^*_1 \cup T'^*_1 \cup \{a_1, b_1, m_1\})$ that have a neighbor in $S'^*_1 \cup T'^*_1$. Next, let G_2 be the graph induced by G_1 on $V(G_1) \setminus X_{i_2}$. Find shortest paths S'_2 between a_2 and m_2 and T'_2 between m_2 and b_2 in G_2 . Remove from G_2 the set U_2 consisting of all vertices in $V(G_2) \setminus (S'^*_2 \cup T'^*_2 \cup \{a_2, b_2, m_2\})$ that have a neighbor in $S'^*_2 \cup T'^*_2$. Finally, let G_3 be the graph induced by G_2 on $V(G_2) \setminus X_{i_3}$. Find shortest paths S'_3 between a_3 and m_3 and between m_3 and b_3 in G_3 . Finding these paths and removing these subsets take quadratic time.

Finally, for $1 \leq i < j \leq 3$ test whether $V(S'_i) \cup V(T'_i) \cup V(S'_j) \cup V(T'_j)$ is the vertex set of an induced cycle in the graph G . If so, then output that the triangles $\{a_1, a_2, a_3\}$

and $\{b_1, b_2, b_3\}$ and the paths $a_1-S'_1-m_1-T'_1-b_1$, $a_2-S'_2-m_2-T'_2-b_2$, and $a_3-S'_3-m_3-T'_3-b_3$ form a prism and stop. Testing this takes quadratic time. So the time it takes to examine one 15-tuple is $O(|V(G)|^{20})$.

After examining all 15-tuples, output that G contains no smallest prism. The total running time is $O(|V(G)|^{35})$.

Now we need to prove that this algorithm is correct. Suppose there is a smallest prism K in G ; let its half-paths be S_1, T_1, S_2, T_2, S_3 , and T_3 . For some 15-tuple chosen, $\{a_1, a_2, a_3, m_1, m_2, m_3, b_1, b_2, b_3\}$ is the frame of K , and $\{a'_1, a'_2, a'_3, b'_1, b'_2, b'_3\} \subseteq V(K)$. Therefore, after the first step of the algorithm runs for this 15-tuple, K has a tidy frame.

CLAIM 5.1. *Let J be an almost clean smallest prism in a graph H and let S' be a good shortcut across a half-path S of J . Let $U \subset V(H)$ be the set of vertices not in $V(S')$ that have a neighbor in S'^* . Then the subgraph J' induced by H on $(V(J) \setminus V(S)) \cup V(S')$ is an almost clean smallest prism in the graph induced by H on $V(H) \setminus U$.*

Since S' is a good shortcut, the subgraph J' induced by H on $(V(J) \setminus V(S)) \cup V(S')$ is a prism. Since a good shortcut is a shortest path, $|V(J')| \leq |V(J)|$, so J' is a smallest prism in H . We observe that since J' has the same frame as J , it has a tidy frame. Assume that there is a J' -major vertex $v \in V(H) \setminus U$. Then since $v \notin U$, $N(v) \cap S'^* = \emptyset$. Since v is J' -major, this means that $N(v) \cap (V(J') \setminus S'^*)$ is not a subset of the vertex set of a 3-vertex path in J' . Since $N(v) \cap (V(J') \setminus S'^*) = N(v) \cap (V(J) \setminus S^*)$, v is J -major, contradicting the fact that J is almost clean in H . Therefore, all J' -major vertices are contained in U . We observe also that U is disjoint from $V(J')$ because J' is a prism, so J' is an almost clean prism in the graph induced by H on $V(H) \setminus U$. This proves Claim 5.1.

By Theorem 4.8, we can choose Y such that G' contains no K -major vertices. Then K is almost clean in G' , so by Theorem 3.5, we can choose X_{i_1} such that the graph G_1 contains K and there are no bad shortcuts across S_1 or T_1 in G_1 . Let K_1 be the subgraph induced by G_1 on $V(K) \setminus (V(S_1) \cup V(T_1)) \cup V(S'_1) \cup V(T'_1)$. Since K_1 is not smaller than K in G , S'_1 is anticomplete to T'_1 . It now follows from Claim 5.1 applied twice (once for each half-path S_1 and T_1) that, after removing the set U_1 from $V(G_1)$, K_1 is an almost clean smallest prism in G_1 .

Therefore, by Theorem 3.5, we can choose X_{i_2} such that the graph G_2 contains K_1 and there are no bad shortcuts across S_2 or T_2 in G_2 . Let K_2 be the subgraph induced by G_2 on $V(K_1) \setminus (V(S_2) \cup V(T_2)) \cup V(S'_2) \cup V(T'_2)$. Since K_2 is not smaller than K_1 in G , S'_2 is anticomplete to T'_2 . Again it follows from Claim 5.1 applied twice (once for each half-path S_2 and T_2) that, after removing the set U_2 from $V(G_2)$, K_2 is an almost clean smallest prism in G_2 .

Finally, by Theorem 3.5, we can choose X_{i_3} such that the graph G_3 contains K_2 and there are no bad shortcuts across S_3 or T_3 in G_3 . Then it follows that the subgraph K_3 induced by G_3 on $V(K_2) \setminus (V(S_3) \cup V(T_3)) \cup V(S'_3) \cup V(T'_3)$ is a prism. Since K_3 is not smaller than K_2 in G , S'_3 is anticomplete to T'_3 . We observe that since G_3 is an induced subgraph of G , a prism in G_3 is a prism in G , and that K_3 is the prism output by the algorithm when it considers $X_{i_1}, X_{i_2}, X_{i_3}$. This proves that the algorithm outputs a prism.

Conversely, if the algorithm outputs that there is a prism, then the properties of the 15-tuple and the conditions on the paths that the algorithm checks ensure that this output is actually a prism. $\square$

Finally, we can put together the algorithms of Theorems 5.1 and 5.2 to construct

the complete algorithm.

THEOREM 5.3. *There is an algorithm with the following specifications:*

- **Input:** *A graph G .*
- **Output:** *Either*
 - *a theta or a prism in G , or*
 - *a determination that there is no theta or prism in G .*
- **Running Time:** $O(|V(G)|^{35})$.

Proof. First run the algorithm of Theorem 5.1. If it outputs a theta, then output this theta and stop. Otherwise run the algorithm of Theorem 5.2. If it outputs a prism, then output this prism and stop. Otherwise, output that there is no theta or prism in G .

The running time of this algorithm is the maximum of those of Theorems 5.1 and 5.2, which is $O(|V(G)|^{35})$. If this algorithm outputs either a theta or a prism, then it follows from Theorems 5.1 and 5.2 that it is correct. Conversely, if G contains a theta or a prism, then it contains a smallest theta or a smallest prism. Therefore, one of the algorithms of Theorem 5.1 or of Theorem 5.2 will output a theta or a prism, which will then be output by this algorithm. This proves Theorem 5.3. $\square$

AXIS-ALIGNED SUBDIVISIONS WITH LOW STABBING NUMBERS*

CSABA D. TÓTH†

Abstract. It is shown that for every subdivision of the d -dimensional Euclidean space, $d \geq 2$, into n axis-aligned boxes, there is an axis-parallel line that stabs at least $\Omega(\log^{1/(d-1)} n)$ boxes, and this bound is best possible. In general, it is also shown that for every integer k , $0 < k < d$, there is an axis-aligned k -flat that stabs at least $\Omega(\log^{1/\lfloor (d-1)/k \rfloor} n)$ boxes of the subdivision.

Key words. stabbing number, transversal, subdivision, Euclidean space

1. Introduction. An affine subspace in the d -dimensional Euclidean space $\mathbb{R}^d$ *stabs* a set $b \subset \mathbb{R}^d$ if it intersects the relative interior of b but does not contain b . The *stabbing number* (resp., *k-stabbing number*) of a family of objects in $\mathbb{R}^d$ is the maximum number of objects stabbed by a line (resp., k -dimensional affine subspace or *k-flat*). Geometric data structures of low stabbing numbers (e.g., spanning trees, triangulations, and R -trees) have versatile applications in computational geometry. They were used in efficient algorithms for simplex range searching [12], ray shooting [1], collision detection [1, 18], and dynamic point location [7]. They are also related to geometric tomography [10] and the shadow problem [4]. Data structures are often based on subdivisions of the Euclidean space (e.g., triangulations, Kd-trees, binary space partitions).

Following earlier results of Chazelle, Edelsbrunner, and Guibas [11], we address combinatorial problems about the stabbing number of subdivisions of the space. It was shown in [11] that for every subdivision of the plane into n convex cells, there is a line that stabs $\Omega(\log n / \log \log n)$ cells, and this bound is best possible, which means that the plane can be subdivided into n convex cells such that every line stabs $O(\log n / \log \log n)$ cells. This result was recently generalized to every dimension [24]: for every subdivision of $\mathbb{R}^d$ into n convex cells, with $d \geq 2$ fixed, there is a line that stabs $\Omega((\log n / \log \log n)^{1/(d-1)})$ cells, and this bound is best possible.

In this paper, we prove tight bounds on analogous problems in every dimension for the case that both the cells and the stabbing lines are axis aligned. For a subdivision B of $\mathbb{R}^d$ into axis-aligned boxes, we denote by $s_{d,k}(B)$ the *axis-aligned k-stabbing number* of B , which is the maximum number of boxes stabbed by an *axis-aligned k-flat*. In particular, the axis-aligned 1-stabbing number is also called the *axis-parallel stabbing number* of B . Denoting by $|B|$ the size (i.e., number of cells) of a subdivision B , we are interested in the minimum stabbing number over all axis-aligned subdivisions of size n . For an integer $n \in \mathbb{N}$, let

$$s_{d,k}(n) = \min\{s_{d,k}(B) : |B| = n \text{ and } B \text{ is an axis-aligned subdivision of } \mathbb{R}^d\}.$$

Contribution. A tight bound $s_{2,1}(n) = \Theta(\log n)$ easily follows from the Erdős–Szekeres theorem [15] and a result of de Berg and van Kreveld [8]. In section 2, we further extend this proof technique to arbitrary dimensions.

THEOREM 1. *For every $d, k \in \mathbb{N}$, $d/2 \leq k < d$, we have $s_{d,k}(n) = \Theta(\log n)$.*

In sections 3 and 4 we prove the main result of this paper, which is an asymptotically tight bound on the axis-parallel stabbing number of axis-aligned subdivisions in higher dimensions.

THEOREM 2. *For every $d \in \mathbb{N}$, we have*

$$s_{d,1}(n) = \Theta\left(\log^{1/(d-1)} n\right).$$

In other words, if d is fixed and every axis-parallel line stabs at most i boxes of a d -dimensional axis-aligned subdivision B , then the size of the subdivision is bounded by $|B| = \exp(O(i^{d-1}))$, and this bound is best possible. We prove the lower bound $s_{d,1}(n) = \Omega(\log^{1/(d-1)} n)$ in section 3 by generalizing the methods presented in section 2. The upper bound $s_{d,1}(n) = O(\log^{1/(d-1)} n)$ follows from an intricate construction that we describe in section 4. The lower bound also generalizes to k -stabbing numbers for every $k \in \mathbb{N}$, $0 < k < d$, and gives

$$s_{d,k}(n) = \Omega\left(\log^{1/\lfloor (d-1)/k \rfloor} n\right).$$

We conjecture this bound to be tight apart from a constant factor for every $d, k \in \mathbb{N}$, $0 < k < d$. The conjecture is confirmed in the cases that $k = 1$ (Theorem 2) and $k \geq d/2$ (Theorem 1), but it remains open for $1 < k < d/2$.

We develop nontrivial techniques to prove our upper and lower bounds. Theorem 1 indicates that Theorem 2 does not follow from a straightforward induction on the dimension. By Theorem 1, there is an axis-aligned subdivision B_n of size n in $\mathbb{R}^3$ such that any axis-aligned plane intersects only $O(\log n)$ boxes, and there exists an axis-aligned subdivision of size $O(\log n)$ in the plane such that every axis-parallel line stabs only $O(\log \log n)$ boxes. By Theorem 2, however, there is an axis-parallel line that stabs $\Omega(\sqrt{\log n})$ boxes of B_n . Our proof of Theorem 2 does use induction on the dimension and projections along the coordinate axes, but in a nontrivial way.

1.1. Related work. In a pivotal result, Chazelle and Welzl [12, 25] proved that for every fixed $d \in \mathbb{N}$, any n points in $\mathbb{R}^d$ can be connected by a straight line spanning tree such that every hyperplane stabs $O(n^{1-1/d})$ edges of the tree, and this bound is best possible. Matoušek [21] showed that for any r , $1 \leq r^d \leq n$, a set of n points in $\mathbb{R}^d$ can be partitioned into r^d subsets, each of size $\Theta(n/r^d)$, such that every hyperplane stabs the convex hull of $O(r^{d-1})$ subsets. If the points are uniformly distributed in a cube in $\mathbb{R}^d$, then a subdivision into r^d congruent cubes gives such a partition of the point set; Matoušek's partition, however, does not typically correspond to a subdivision of the space.

Researchers have also considered *subdivisions* with low stabbing numbers. Agarwal, Aronov, and Suri [2] proved that n points in $\mathbb{R}^2$ and in $\mathbb{R}^3$ can be triangulated (with Steiner points) such that every line stabs $O(\sqrt{n} \cdot \log n)$ simplices. They also presented point sets in general position where the stabbing number of any triangulation is $\Omega(\sqrt{n})$. The stabbing number of a *Delaunay* triangulation of n points in $\mathbb{R}^d$, however, may be $\Theta(n^{\lceil d/2 \rceil})$ in the worst case [23]. Bose and Devroye [9] showed recently that the expected stabbing number of the Delaunay triangulation of n points chosen uniformly at random from a compact convex set in the plane is $\Theta(\sqrt{n})$ with high probability.

Hershberger and Suri [19] studied stabbing numbers restricted to the interior of a simple polygon. They showed that every simple polygon with n vertices has a triangulation (with Steiner points) of size $O(n)$ such that any segment lying entirely in the polygon stabs $O(\log n)$ triangles. De Berg and van Kreveld [8] proved that every simple rectilinear polygon with n vertices can be subdivided into $O(n)$ rectangles such that any axis-parallel line segment lying entirely in the polygon stabs $O(\log n)$ rectangles. Both bounds are best possible. These results no longer hold if we drop the condition that the stabbing segment lies entirely in the polygon: a line may cross $\Theta(n)$ triangles in any triangulation of a comb polygon with n vertices (Figure 1(a)), and a horizontal line may cross $\Theta(n)$ rectangles in any rectangle decomposition of a rectilinear comb polygon with n vertices (Figure 1(b)).

FIG. 1. (a) A comb polygon; (b) a rectilinear comb polygon; (c) a convex subdivision of a box where the axis-parallel stabbing number is 4; and (d) a staircase polygon with 5 reflex vertices.

Instead of the stabbing number of triangulations in $\mathbb{R}^d$, one can consider the stabbing number of lower-dimensional but noncrossing simplices on a given vertex set. Pach [22] asked: What is the minimum k -stabbing number of e distinct r -simplices with disjoint relative interiors and having n distinct vertices in $\mathbb{R}^d$, for $1 \leq r < k \leq d$? Some initial bounds were obtained by Dey and Pach [13].

Axis-aligned box configurations with low axis-aligned stabbing numbers were studied in various contexts. Agarwal et al. [3] constructed an axis-aligned rectangle hierarchy for an input of n disjoint boxes in the plane such that the 0-stabbing number of the rectangles is $O(\log^2 n)$; that is, any point lies in $O(\log^2 n)$ rectangles. De Berg et al. [7] studied similar questions for an input of *overlapping* objects in the plane. Gaur, Ibaraki, and Krishnamurti [17] gave a d -approximation algorithm for computing the minimum number of axis-aligned hyperplanes that jointly stab all input rectangles in $\mathbb{R}^d$.

In this paper, we give worst-case optimal combinatorial bounds for the axis-parallel stabbing numbers in every dimension. Note that it is easy to compute the axis-aligned k -stabbing number of any given d -dimensional axis-aligned subdivision of size n in $O(n^{d-k})$ time if $d, k \in \mathbb{N}$, $0 < k < d$, are constants. It is enough to construct the orthogonal projection of the subdivision into $(n-k)$ -flats in all $\binom{d}{k}$ directions and find the maximal multiplicity of a cell in $\mathbb{R}^{d-k}$. Each projection consists of up to $O(n^{d-k})$ cells. However, the computational complexity of this problem is not known if d and k are part of the input.

Fekete, Lübbecke, and Meijer [16] have recently proved that it is NP-complete to compute the minimum (axis-parallel) stabbing number of perfect matchings or triangulations for a given point set in the plane. Aronov and Fortune [6] and Aronov et al. [5] considered the average stabbing number of triangulations of polygonal scenes.

1.2. Further directions. In this paper, we prove lower and upper bounds on $s_{d,k}(n)$, the minimum axis-aligned k -stabbing number of axis-aligned subdivisions of

size n . One could consider, instead, the axis-aligned k -stabbing number of subdivisions of $\mathbb{R}^d$ into *convex* cells. For every $d \geq 2$ and $n \in \mathbb{N}$, it is easy to construct subdivisions of $\mathbb{R}^d$ into n full-dimensional convex cells with an axis-aligned k -stabbing number at most $d+2$. For example, consider a thin cylinder whose axis is the line $x_1 = x_2 = \dots = x_d$ and whose base is a regular d -gon; partition the cylinder into $n-d$ long cells and divide the complement of the cylinder into d unbounded convex cells (Figure 1(c)).

All our bounds on $s_{d,k}(n)$ also hold for the k -stabbing number (with k -flats of arbitrary orientations) of axis-aligned subdivisions, but we do not know whether they are tight or not for $d \geq 3$. For $d = 2$, Chazelle, Edelsbrunner, and Guibas [11] gave an $\Omega(\log n)$ bound on the stabbing number of axis-aligned subdivisions of size n in the plane and showed that this bound is best possible. A tight bound of $\Omega((\log n / \log \log n)^{1/(d-1)})$ was derived [11, 24] for the stabbing number of convex subdivisions in $\mathbb{R}^d$ for every $d \geq 2$. No nontrivial bound is known, however, for the k -stabbing number of convex subdivisions for $1 < k < d$.

1.3. Definitions. Every logarithm in this paper is of base 2, and we define the exponential function as $\exp(x) = 2^x$. For two real numbers $a, c \in \mathbb{R}$, let (a, c) and $[a, c]$ denote the open and closed intervals, respectively, between a and c . An *axis-aligned box* (for short, *box*) in $\mathbb{R}^d$ is the cross product of d (possibly infinite) closed intervals: $b = \prod_{i=1}^d [a_i, c_i]$, where $a_i \in \{-\infty\} \cup \mathbb{R}$ and $c_i \in \mathbb{R} \cup \{\infty\}$ for $i = 1, 2, \dots, d$. The interval $[a_i, c_i]$ is the i th *extent* of b .

An axis-aligned subdivision B in $\mathbb{R}^d$ is a set of interior disjoint boxes whose union is $\mathbb{R}^d$. We denote by $|B|$ the size of B . For a polyhedron P , let $B|P := \{b \cap P : b \in B, \text{int}(b \cap P) \neq \emptyset\}$ denote the restriction of B to P . For every $k \in \mathbb{N}$, $0 \leq k < d$, we say that a k -flat f *stabs* a d -dimensional box b if f intersects the interior of b . In our upper bound constructions, we define subdivisions restricted to a (bounding) box. Any axis-aligned subdivision of a box can, of course, be extended to fill the entire space with the same axis-aligned stabbing numbers.

2. k -stabbing numbers for $d/2 \leq k < d$. In this section, we study the axis-aligned k -stabbing numbers of axis-aligned subdivisions in the case that k is at least half of the dimension d . The tight bound $s_{2,1}(n) = \Theta(\log n)$ follows from an easy combination of previous results, which we present in subsection 2.1. Then in subsection 2.2, we generalize these arguments and establish Theorem 1.

2.1. Axis-aligned subdivisions in the plane. De Berg and van Kreveld [8] proved that the axis-parallel stabbing number of every axis-aligned subdivision of a staircase polygon with $n-1$ reflex vertices (see Figure 1(d)) is $\Omega(\log n)$; vice versa, every staircase polygon with $n-1$ reflex vertices can be subdivided into n rectangles so that the axis-parallel stabbing number of the subdivision is $O(\log n)$. (Note, however, that there are staircase polygons with $n-1$ reflex vertices, where a line of slope 1 stabs at least n cells of any convex subdivision.) We also evoke a result of Erdős and Szekeres [15].

THEOREM 3 (Erdős and Szekeres). *Every sequence of n reals, $n \in \mathbb{N}$, has a monotone subsequence of size $\lceil \sqrt{n} \rceil$.*

To show $s_{2,1}(n) = \Omega(\log n)$, consider an axis-aligned subdivision B of the plane into n boxes. Choose a *reference point* in the interior of every box such that all coordinates of all reference points are pairwise distinct. Let $\hat{B}$ be a subdivision of size $4n$ obtained from B by splitting every box of B into four boxes along the two axis-parallel lines passing through the reference point in the interior of that box. Order the reference points according to their x -coordinates. By Theorem 4, there

is a subsequence R of size $\lceil \sqrt{n} \rceil$ with strictly monotonically increasing or decreasing y -coordinates. We may assume without loss of generality that both coordinates are strictly monotonically increasing in R . Let π be an infinite monotonically increasing axis-aligned polyline that visits every point in R such that its lower-right vertices are the reference points in R . Denote by F the area below π , which is a staircase polygon whose reflex vertices are the reference points in R . The subdivision $\hat{B}|F$ is a subdivision of F into less than $4n$ boxes. By [8], an axis-parallel line stabs $\Omega(\log n)$ rectangles of $\hat{B}|F$. This line must stab at least $\Omega(\log n)$ boxes of B , as well.

To prove $s_{2,1}(n) = O(\log n)$, we subdivide the plane into n rectangles. For every $n \geq 3$, subdivide the plane into two polygonal regions by a monotonically increasing axis-aligned polyline with $n-2$ vertices. The two polygonal regions on the two sides of the polyline have $\lfloor (n-2)/2 \rfloor$ and $\lceil (n-2)/2 \rceil$ reflex vertices, respectively. By [8], they can be subdivided into $\lfloor n/2 \rfloor$ and $\lceil n/2 \rceil$ boxes, respectively, with each subdivision having a stabbing number of at most $O(\log n)$. Let B be the union of the two subdivisions: it is a subdivision of the plane into n boxes with stabbing number $O(\log n)$, as required.

2.2. Proof of Theorem 1. De Bruijn (see Kruskal [20]) generalized the Erdős–Szekeres theorem (his result follows from Dilworth’s theorem [14], as well).

THEOREM 4 (De Bruijn). *Every n -element sequence of d -dimensional vectors has a subsequence of size $\lceil n^{2^{1-d}} \rceil$ which is monotone in each coordinate. This bound is tight in the worst case.*

The argument of de Berg and van Kreveld also generalizes to k -flats in $\mathbb{R}^d$ if $k \geq d/2$.

LEMMA 5. *For every fixed $d, k \in \mathbb{N}$, $d/2 \leq k < d$, we have $s_{d,k} = \Omega(\log n)$.*

Proof. Consider a subdivision of $\mathbb{R}^d$ into n axis-aligned boxes. Choose a sufficiently small axis-aligned *reference cube* in the interior of each box of B such that all extents of all reference cubes are pairwise nonoverlapping and disjoint from any coordinates of the vertices of the boxes in B . Pick a *reference point* in the interior of each reference cube. By Theorem 4, there is a coordinatewise strictly monotone sequence $R = (r_i : i = 1, 2, \dots, \lceil n^{2^{1-d}} \rceil)$ of reference points. For $1 \leq i \leq j \leq m$, let $u(i, j)$ denote the box spanned by the reference cubes containing r_i and r_j .

Let m be the power of 2 such that $m \leq \lceil n^{2^{1-d}} \rceil < 2m$. Build a binary hierarchy of height $\log m$ on the reference cubes $u(i, i)$, $i = 1, 2, \dots, m$. For $j = 0, 1, \dots, \log m$, let level j of the hierarchy consist of the set $U_j = \{u(i2^j + 1, i2^j + 2^j) : i = 0, 1, \dots, m2^{-j} - 1\}$ of pairwise disjoint boxes. That is, the reference cubes containing a single reference point $r_1, \dots, r_m$ form the 0th level $U_0 = \{u(i, i) : i = 1, 2, \dots, m\}$, and every box $u \in U_{j+1}$ at level $j+1$ is spanned by exactly two boxes of U_j . The root level, level $\log m$, consists of a single box $u(1, m)$, which we denote by $u_{\max}$. See Figure 2(a). Choose two axis-aligned k -flats X and Y such that they span the entire space $\mathbb{R}^d$. This is possible, since $k \geq d/2$. For any box u , let $x(u)$ (resp., $y(u)$) denote the maximum number of boxes of $B|u$ stabbed by a k -flat parallel to X (resp., Y) and incident to a reference point in $R \cap u$. We prove by induction on j that

$$(1) \quad x(u) + y(u) \geq j + 1 \quad \text{for every } u \in U_j, \quad j = 0, 1, \dots, \log m.$$

This immediately implies that $s_{d,k}(B) = \Omega(\log n)$, since

$$s_{d,k}(B) \geq \max(x(u_{\max}), y(u_{\max})) \geq \frac{x(u_{\max}) + y(u_{\max})}{2} \geq \frac{1 + \log m}{2} = \Omega(\log n).$$

We proceed by induction on j . Since $u(i, i)$ lies in the interior of a box of B , for every $i = 1, 2, \dots, m$, we have $x(i, i) = y(i, i) = 1$. This proves inequality (1) in the

FIG. 2. (a) A sequence of eight reference points with strictly increasing coordinates (the corresponding subdivision is not shown in the figure); boxes of U_1 , U_2 , and U_3 are also shown. (b) Our upper bound construction. (c) An axis-aligned subdivision where the size of every monotone sequence of reference points is at most $\sqrt{n}$.

base case $j = 0$. For the induction step, suppose that $x(u') + y(u') \geq j' + 1$ holds for every $u' \in U_{j'}$, $0 \leq j' \leq j$. We prove for every box $u = u(i2^{j+1} + 1, i2^{j+1} + 2^{j+1}) \in U_{j+1}$ that $x(u) + y(u) \geq j + 2$. Box u contains two disjoint boxes, $u_1 = u(2i \cdot 2^j + 1, 2i \cdot 2^j + 2^j) \in U_j$ and $u_2 = u((2i + 1) \cdot 2^j + 1, (2i + 2) \cdot 2^j) \in U_j$. Let h_1 and v_1 be k -flats parallel to X and Y which attain $x(u_1)$ and $y(u_1)$, respectively. Similarly, let h_2 and v_2 be k -flats parallel to X and Y attaining $x(u_2)$ and $y(u_2)$. By induction, we have $x(u_1) + y(u_1) \geq j + 1$ and $x(u_2) + y(u_2) \geq j + 1$. If the total number of boxes of $B|u$ stabbed by h_1 and v_1 is at least $j + 2$, then $x(u) + y(u) \geq j + 2$ and the induction step is complete. Otherwise h_1 and v_1 each stab exactly $x(u_1)$ and $y(u_1)$ boxes of the subdivision $B|u$. Therefore, h_1 stabs the same boxes of the subdivisions $B|u_1$ and $B|u$. In other words, every box of $B|u$ stabbed by h_1 intersects $u_1 \subset u$. This implies that every box of $B|u$ stabbed by h_1 is disjoint from u_2 . Indeed, every box that intersects both u_1 and u_2 must contain both reference points $r_{2i \cdot 2^j + 2^j} \in u_1$ and $r_{(2i+1) \cdot 2^j + 1} \in u_2$. Since the reference points lie in distinct boxes of B , no box of B can intersect both u_1 and u_2 .

Note that h_1 and v_2 intersect in the interior of u (that is, there is a point $p \in h_1 \cap v_2 \cap \text{int}(u)$), and so the k -flat v_2 stabs at least one more box in $B|u$ than in $B|u_2$ (namely, the box containing p). Hence, v_2 stabs $y(u_2) + 1$ boxes of $B|u$, and the total number of boxes of $B|u$ stabbed by h_2 and v_2 is at least $x(u_2) + y(u_2) + 1 \geq j + 2$. We have $x(u) + y(u) \geq j + 2$, as required. $\square$

The upper bound $s_{d,k}(n) = O(\log n)$, $0 < k < d$, follows from a simple construction obtained by successively subdividing every box lying along a skew line (e.g., a diagonal).

LEMMA 6. For every $k, d \in \mathbb{N}$, $1 \leq k \leq d$, we have $s_{d,k}(n) = O(\log n)$.

Proof. Consider an axis-aligned cube C in $\mathbb{R}^d$, and let e be one of its diagonals. We construct inductively a sequence of axis-aligned subdivisions of C . We start with the trivial subdivision $B_0 = \{C\}$. If B_i is defined, we construct B_{i+1} as follows. For every box $b \in B_i$ whose interior intersects the diagonal e , choose a point $p_b \in \text{int}(b) \cap e$ and split b into 2^d boxes along the d axis-aligned hyperplanes incident to p_b (Figure 2(b)).

It is easy to see by induction that the diagonal e intersects the interior of 2^i boxes of B_i . In one induction step, each of these boxes is split into 2^d pieces, so $|B_{i+1}| - |B_i| = (2^d - 1)2^i$. This recursion gives $|B_i| = (2^d - 1)(2^i - 1) + 1$. On the other hand, every axis-aligned k -flat, $0 \leq k \leq d - 1$, stabs at most $i(2^k - 1) + 1$ boxes of B_i . For every $k, d \in \mathbb{N}$, $1 \leq k \leq d$, this gives $s_{d,k}(B_i) = O(i) = O(\log |B_i|)$. $\square$

3. Lower bound on the axis-parallel stabbing number. In this section, we prove that $s_{d,k}(n) = \Omega(\log^{1/\lfloor (d-1)/k \rfloor} n)$ for every $k, d \in \mathbb{N}$, $0 < k < d$. In particular, for $k = 1$ and every $d \in \mathbb{N}$, we have $s_{d,1}(n) = \Omega(\log^{1/(d-1)} n)$. For $k < d \leq 2k$, this is equivalent to Lemma 5. We proceed by induction on d using an argument analogous to the proof of Lemma 5.

Consider a subdivision B of $\mathbb{R}^d$ into n axis-aligned boxes. Similar to the proof of Lemma 5, choose sufficiently small axis-aligned *reference cubes* in the interior of each box of B such that all extents of all reference cubes are pairwise nonoverlapping and disjoint from any coordinates of the vertices of the boxes in B . Pick a *reference point* in the interior of the reference cube. Let $R = (r_i : i = 1, 2, \dots, \lceil n^{2^{1-d}} \rceil)$ be a coordinate-wise strictly monotone sequence of reference points, which exists by Theorem 4. Let m be the power of 2 such that $m \leq \lceil n^{2^{1-d}} \rceil < 2m$. For $1 \leq i \leq j \leq m$, let $u(i, j)$ denote the box spanned by the reference cubes containing r_i and r_j . Build the same binary hierarchy $U_0, U_1, \dots, U_{\log m}$ spanned by reference cubes as in the previous section.

For a box b and $0 < k < d$, let $x_k(b)$ denote the maximum number of boxes of $B|b$ stabbed by a k -flat parallel to the first k coordinate axes and incident to a reference point in $R \cap b$. In particular, let $x_k(i, j) = x_k(u(i, j))$ for $1 \leq i \leq j \leq m$. Let $V_k(b)$ denote the $(d - k)$ -flat orthogonal to the first k coordinate axes and incident to the first reference point in $R \cap b$ (for example, $V_{d-1}(b(i, j))$ is the hyperplane orthogonal to the x_1 -axis and incident to r_i for all j). We prove an inequality, which is analogous in some sense to inequality (1).

LEMMA 7. *If every $(n - k)$ -flat orthogonal to the first k coordinate axes stabs fewer than 2^α boxes of B for some integer α , then*

$$(2) \quad x_k(u) \geq \lfloor \ell / \alpha \rfloor + 1 \quad \text{for every } u \in U_\ell, \ell = 0, 1, \dots, \log m.$$

Before we prove Lemma 7, we show that it immediately implies the lower bound of Theorem 2.

LEMMA 8. *For every fixed $d, k \in \mathbb{N}$, $0 < k < d$, we have*

$$s_{d,k}(n) = \Omega\left(\log^{1/\lfloor (d-1)/k \rfloor} n\right).$$

Proof. For every $k \in \mathbb{N}$, we proceed by induction on d . The cases that $k < d \leq 2k$ are established in Lemma 5. Assume that $d > 2k$ and $s_{d',k} = \Omega(\log^{1/\lfloor (d'-1)/k \rfloor} n)$ for every $d' \in \mathbb{N}$, $k < d' < d$. We show that $s_{d,k}(n) = \Omega(\log^{1/\lfloor (d-1)/k \rfloor} n)$.

Consider an axis-aligned subdivision B of size n in $\mathbb{R}^d$. If an axis-aligned $(d - k)$ -flat W stabs $w \geq \exp(\log^{1-1/\lfloor (d-1)/k \rfloor} n) = \exp(\log^{\lfloor (d-k-1)/k \rfloor / \lfloor (d-1)/k \rfloor} n)$ boxes of B , then we apply the induction hypothesis for the subdivision induced by B in W : there is an axis-aligned k -flat in W that stabs at least $s_{d-k,k}(w) = \Omega(\log^{1/\lfloor (d-k-1)/k \rfloor} w) \geq \Omega(\log^{1/\lfloor (d-1)/k \rfloor} n)$ boxes of B .

If every axis-aligned $(d - k)$ -flat stabs fewer than $\exp(\log^{1-1/\lfloor (d-1)/k \rfloor} n)$ boxes of B , then apply Lemma 7 with $\alpha = \lfloor \log^{1-1/\lfloor (d-1)/k \rfloor} n \rfloor$ for the box $u(1, m)$. Hence,

$$x_k(u(1, m)) > \left\lceil \frac{\log m}{\lfloor \log^{1-1/\lfloor (d-1)/k \rfloor} n \rfloor} \right\rceil = \Omega\left(\frac{\log n}{\log^{1-1/\lfloor (d-1)/k \rfloor} n}\right) = \Omega\left(\log^{1/\lfloor (d-1)/k \rfloor} n\right).$$

Thus a k -flat parallel to the first k coordinate axes stabs at least $\Omega(\log^{1/\lfloor (d-1)/k \rfloor} n)$ boxes of B . $\square$

Proof of Lemma 7. We proceed by induction on ℓ . Since $u(i, i)$ lies in the interior of a box of B , we have $x_k(i, i) = 1$ for every $i = 1, 2, \dots, m$. This establishes inequality (2) in the base case $\ell = 0$. Note that $x_k(u)$ is an integer for every box u , so it is enough to prove (2) for $\ell = \alpha j$, $j \in \mathbb{N}$; otherwise $\lfloor (\ell - 1)/\alpha \rfloor = \lfloor \ell/\alpha \rfloor$. For the induction step, suppose that $x_k(u') \geq j' + 1$ holds for every $u' \in U_{\alpha j'}$, $0 \leq j' \leq j$. For every box $u = u(i2^{(j+1)\alpha} + 1, i2^{(j+1)\alpha} + 2^{(j+1)\alpha}) \in U_{(j+1)\alpha}$, we prove that $x_k(u) \geq j + 2$. Box u contains 2^α disjoint boxes of level $j\alpha$, namely, it contains the boxes $u_s = u(i2^{(j+1)\alpha} + s2^{\alpha j} + 1, i2^{(j+1)\alpha} + (s+1)2^{\alpha j}) \in U_{j\alpha}$ for $s = 0, 1, \dots, 2^\alpha - 1$.

For $s = 0, 1, \dots, 2^\alpha - 1$, let h_s denote a k -flat that is parallel to the first k coordinate axes and attains $x_k(u_s)$. By induction, we have $x_k(u_s) \geq j + 1$ for every s . If the total number of boxes of $B|u$ stabbed by h_s is at least $j + 2$ for any s , then we have $x_k(u) \geq j + 2$ and the induction step is complete. Otherwise h_s stabs exactly $j + 1$ boxes of the subdivision $B|u$ for every s . This means that every h_s stabs the same boxes of the subdivisions $B|u_s$ and $B|u$. In other words, every box of $B|u$ stabbed by h_s must intersect u_s . Let $b_s \in B$ be the box of B containing the intersection point $h_s \cap V(u_s)$ for $s = 0, 1, \dots, 2^\alpha - 1$. We have shown that box b_s intersects u_s .

However, every box that intersects both u_s and u_t , $0 \leq s < t \leq 2^\alpha - 1$, must contain both reference points $r_{i2^{(j+1)\alpha} + (s+1)2^{\alpha j}} \in u_s$ and $r_{i2^{(j+1)\alpha} + t2^{\alpha j} + 1} \in u_t$. Since distinct reference points lie in the interiors of distinct boxes of B , no box of B can intersect both u_s and u_t for $0 \leq s < t \leq 2^\alpha - 1$. Hence, the boxes b_s , $s = 0, 1, \dots, 2^\alpha - 1$, are distinct. We have shown that $V_k(u)$ stabs at least 2^α boxes of the subdivision $B|u$. This contradicts our assumption that every $(d - k)$ -flat orthogonal to the first k coordinate axes stabs fewer than 2^α boxes of B . We conclude that $x_k(u) \geq j + 2$. $\square$

4. Upper bound constructions. Every box in our constructions has integral vertices (all coordinates are integers). The bounding box of our constructions in $\mathbb{R}^d$ will be $[0, n]^d$, that is, the d -dimensional cube of edge length $n \in \mathbb{N}$. In this section, we construct an axis-aligned subdivision $D_d(n)$ of $[0, n]^d$ that contains at least n unit boxes and has axis-parallel stabbing number $s_{d,1}(D_d(n)) = O(\log^{1/(d-1)} n)$.

FIG. 3. The subdivision $\mathcal{C}_i$ of a cube for $\ell = 0, 1, 2$.

4.1. Preliminaries. It is convenient to describe our constructions in terms of a hierarchy of cube subdivisions. For a given $n \in \mathbb{N}$, let $\ell = \lceil \log n \rceil$ and consider the cube $E_{d,\ell} = [0, 2^\ell]^d$, which contains $[0, n]^d$. We define a hierarchy of subdivisions of $E_{d,\ell}$. Each level of the hierarchy is a subdivision $\mathcal{C}_i$, $i = 0, 1, \dots, \ell$, defined as follows. Let $\mathcal{C}_0 = \{E_{d,\ell}\}$, and for every $i = 1, 2, \dots, \ell$, we obtain $\mathcal{C}_i$ by partitioning each cube of $\mathcal{C}_{i-1}$ into 2^d congruent cubes (Figure 3). In particular, $\mathcal{C}_\ell$ is the subdivision of $E_{d,\ell}$ into unit cubes. The cubes in $\mathcal{C} = \bigcup_{i=0}^\ell \mathcal{C}_i$ are organized in a 2^d -ary tree: the parent

of a cube $u \in \mathcal{C}_i$, $1 \leq i \leq \ell$, is the unique cube $\hat{u} \in \mathcal{C}_{i-1}$ that contains u . Let e be the diagonal of $E_{d,\ell}$ incident to the origin. The cubes of $\mathcal{C}$ stabbed by e are called *diagonal cubes* (note that if e stabs a cube $u \in \mathcal{C}$, then $e \cup u$ is a diagonal of u). The 2^ℓ unit cubes stabbed by e are called *diagonal unit cubes*.

We define another subdivision of $[0, n]^d$, which we call $Q_d(n)$. If $n = 2^\ell$, $\ell \in \mathbb{N}$, then let $Q_d(2^\ell)$ be a subdivision of $E_{d,\ell}$ that contains all diagonal unit cubes of $\mathcal{C}$ and all maximal nondiagonal cubes of $\mathcal{C}$ (that is, every cube $u \in \mathcal{C}_i$, $1 \leq i \leq \ell$, such that its interior is disjoint from e , but its parent cube $\hat{u} \in \mathcal{C}_{i-1}$ is a diagonal cube). Figure 2(b) depicts $Q_2(64)$ in the plane. If n is not a power of 2, then let $Q_d(n) = \{[0, n]^d \cap u : u \in Q_d(\exp(\lceil \log n \rceil))\}$, which consist of the boxes of $Q_d(\exp(\lceil \log n \rceil))$ clipped in $[0, n]^d$.

Shadows. Our constructions of axis-aligned subdivisions rely heavily on the concept of *shadows*.

DEFINITION 9. Consider two axis-aligned boxes b and E in $\mathbb{R}^d$ such that $b \subset E$ and $b = \prod_{i=1}^d [a_i, c_i]$. For every sign vector $\mathbf{v} \in \{-, 0, +\}^d$, we define the $\mathbf{v}$ -shadow of b with respect to E as the set of points $p = (p_1, p_2, \dots, p_d) \in E$ such that (1) $a_i \leq p_i \leq c_i$ if $v_i = 0$; (2) $p_i \leq a_i$ if $v_i = -$; and (3) $c_i \leq p_i$ if $v_i = +$. (See Figure 4.)

We also introduce some terminology for certain frequently used shadows. For a vector $\mathbf{v}$, we denote by $|\mathbf{v}|$ the number of nonzero coordinates (the support of $\mathbf{v}$). For an integer s , $0 \leq s \leq d$, we say that a box is an s -shadow of b if it is a $\mathbf{v}$ -shadow of b for some $\mathbf{v}$ with $|\mathbf{v}| = s$. If $|\mathbf{v}| = 1$ and the j th coordinate of $\mathbf{v}$ is $v_j = \sigma \in \{-, +\}$, then we may also say that the $\mathbf{v}$ -shadow is the x_j^σ -shadow.

FIG. 4. (a) A box b in a cube E in $\mathbb{R}^3$. (b) The $(0, 0, -)$ -shadow of b , which can also be called the x_3^- -shadow. (c) The $(+, 0, -)$ -shadow of b .

It is clear that the $\mathbf{0}$ -shadow of the box b is itself. Since there are $2^s \binom{d}{s}$ distinct sign vectors $\mathbf{v} \in \{-, 0, +\}^d$ with $|\mathbf{v}| = s$, every box $b \subset E$ has $2^s \binom{d}{s}$ distinct s -shadows. Note, however, that some of the shadows might have empty interiors when the boundaries of E and b intersect. A key property of shadows is that the k -shadows, $k < d/2$, of any two boxes whose extents are disjoint in all d dimensions are also disjoint. The next proposition formulates this property.

PROPOSITION 10. Assume that we are given two axis-aligned boxes $b_1 \subset E$ and $b_2 \subset E$ whose extents have disjoint interiors in every dimension. We are also given two vectors $\mathbf{v}_1, \mathbf{v}_2 \in \{-, 0, +\}^d$ with $|\mathbf{v}_1| + |\mathbf{v}_2| < d$. Then the $\mathbf{v}_1$ -shadow of b_1 and the $\mathbf{v}_2$ -shadow of b_2 have disjoint interiors.

Proof. Assume, to the contrary, that a point $p \in E$ lies in the interior of both the $\mathbf{v}_1$ -shadow of b_1 and the $\mathbf{v}_2$ -shadow of b_2 . Then $d - |\mathbf{v}_1|$ coordinates of p lie in the interiors of the corresponding extents of b_1 , and $d - |\mathbf{v}_2|$ coordinates of p lie in the

interiors of the corresponding extents of b_2 . Since $|\mathbf{v}_1| + |\mathbf{v}_1| < d$, there is an index $1 \leq i \leq d$ such that the i th coordinate of p lies in the interior of the i th extent of both u_1 and u_2 . This contradicts our assumption, completing the proof. $\square$

Bricks. A $\mathbf{v}$ -shadow of a diagonal cube $u \subset E_{d,\ell}$ for a vector $\mathbf{v} \in \{-, 0, +\}^d$, $0 < |\mathbf{v}| < d$, is called a *brick* of $E_{d,\ell}$. In particular, if the j th coordinate of $\mathbf{v}$ is $v_j = \sigma \in \{-, +\}$, then the $\mathbf{v}$ -shadow of u is called an x_j^σ -*brick*. Every diagonal cube has $3^d - 2$ distinct bricks (some of which may have empty interiors). Bricks are crucial for our argument: it turns out that every box in our construction is either a diagonal unit cube or lies in some brick of $E_{d,\ell}$.

Side buffers. We define $2d$ subsets of the cube $E_{d,\ell}$, $d \geq 3$, called *side buffers*, one for each $((d-1)$ -dimensional) side of $E_{d,\ell}$. For every $j \in \{1, 2, \dots, d\}$ and $\sigma \in \{-, +\}$, let the side buffer F_j^σ be the union of the x_j^σ -shadows of all diagonal cubes of $\mathcal{C}$ of all possible sizes. (See Figure 5.) By Proposition 10, the $2d$ side buffers of $E_{d,\ell}$ have pairwise disjoint interiors if $d \geq 3$.

We introduce a shorthand notation to refer to each of the $2d$ sides of a d -dimensional box. We say that the x_j^σ -*side* of a box $\prod_{i=1}^d [a_i, c_i]$ is the side contained in the hyperplane $x_j = a_j$ if $\sigma = -$, and in the hyperplane $x_j = c_j$ if $\sigma = +$. In particular, let f_j^σ denote the x_j^σ -side of $E_{d,\ell}$. We say that the x_j^σ -*neighbor* of a cube $u \in \mathcal{C}_i$ is the cube of $\mathcal{C}_i$ adjacent to the x_j^σ -side of u .

FIG. 5. The side buffer F_3^- of the cube $E_{3,\ell}$ for $\ell = 1, 2$, and 3 .

In $\mathbb{R}^3$, the diagonal unit cubes and the side buffers tile the entire cube $E_{3,\ell}$ for every $\ell \in \mathbb{N}$. For $d \geq 4$, however, they do not completely fill $E_{d,\ell}$. We show next that the remaining space in $E_{d,\ell}$, $d \geq 4$, can be subdivided into axis-aligned boxes, at most two of which are stabbed by any axis-parallel line.

LEMMA 11. Denote by $\hat{E}_{d,\ell}$ the complement of all diagonal unit cubes and the $2d$ side buffers of $E_{d,\ell}$. There is an axis-aligned subdivision $S_{d,\ell} \subset Q_d(2^\ell)$ of $\hat{E}_{d,\ell}$ whose axis-parallel stabbing number is at most 2.

Proof. A cube $u \in Q_d(2^\ell)$ can be of three possible types: it can be (i) a diagonal unit cube, (ii) contained in a side buffer, or (iii) interior disjoint from all diagonal unit cubes and side buffers. Cube u is a diagonal unit cube if and only if the diagonal e intersects the interior of u . Cube u is contained in a side buffer if and only if e intersects the interior of any 1-shadow of u (which must contain a diagonal cube in this case). Let $S_{d,\ell}$ be the set of cubes in $Q_d(2^\ell)$ of type (iii). Clearly, it is a subdivision of $\hat{E}_{d,\ell}$. It remains to show that its axis-parallel stabbing number is at most 2.

Suppose that an axis-parallel line L stabs a cube $u \in S_{d,\ell}$, where $u \in \mathcal{C}_i$ for some $i \in \{1, 2, \dots, \ell\}$. Consider its parent box $\hat{u} \in \mathcal{C}_{i-1}$, $u \subset \hat{u}$. The cube $\hat{u}$ must be a diagonal cube (by the definition of $Q_d(2^\ell)$). If we subdivide $\hat{u}$ into 2^d congruent subcubes, then one of the subcubes is u , but the diagonal e does not stab u (since u is not a diagonal box) or any of its d neighbors within $\hat{u}$ (since u is not contained

in any of the side buffers). So each of the d neighbors of u within $\hat{u}$ is contained in either a side buffer or it is another element of $S_{d,\ell}$. Hence, L stabs at most two boxes of $S_{d,\ell}$ within $\hat{u}$. Outside of $\hat{u}$, however, L cannot stab any boxes of $S_{d,\ell}$ because e stabs $\hat{u}$, and so each 1-shadow of $\hat{u}$ is contained in one of the side buffers. $\square$
