

BROOKS-TYPE THEOREMS FOR PAIR-LIST COLORINGS AND LIST HOMOMORPHISMS*

TOMÁS FEDER[†], PAVOL HELL[‡], AND JING HUANG[§]

Abstract. Brooks proved that every connected graph other than a clique or odd cycle can be colored with Δ colors. Erdős, Rubin, and Taylor (and, independently, Vizing) generalized the theorem of Brooks to list colorings, describing all uncolorable connected graphs in which no vertex has a list smaller than its degree. Other authors have extended this to list T -colorings and their generalizations. We further extend it to model pair-list colorings. In addition to including all of the previous situations, pair-list colorings also generalize list homomorphisms (also known as list H -colorings). In the general context of pair-list colorings, we prove a Brooks-type theorem which extends many (but not all) of the existing results. Our result applies to both graphs and digraphs, with or without loops. We discuss several applications of the result, including a polynomial test for the existence of balanced list homomorphisms and retractions.

1. Background. The theorem of Brooks [5] states that a connected graph G can be colored by $\Delta(G)$ (the maximum degree) colors, except for cliques and odd cycles, which can be colored by $\Delta(G) + 1$ colors. The theorem of Erdős, Rubin, and Taylor (and, independently, Vizing) [6, 21] generalizes this result to list colorings. In a list coloring problem, each vertex v of G is equipped with a list $L(v)$ of allowed colors that can be used as a color of v , while at the same time seeking a proper coloring in the usual sense (adjacent vertices are to obtain distinct colors). Instead of a condition relating the number of colors to the maximum degree $\Delta(G)$, it is now natural to assume a condition relating the number of colors available at a vertex v to its degree $\deg_G(v)$. We say that G with lists L is *balanced* if each vertex v has $|L(v)| = \deg_G(v)$. Erdős, Rubin, and Taylor described all balanced problems that do not admit list colorings (cf. Corollary 8). Further extension of this idea to list T -colorings and their generalizations was explored in [13, 22]. Let T be a set of nonnegative integers (usually including 0). A T -coloring of G is a mapping $f : V(G) \rightarrow \mathbb{N}$ such that $|f(u) - f(v)| \notin T$ whenever uv is an edge of G . (Note that when $T = \{0\}$, a T -coloring is just a usual coloring.) Given a graph G with lists $L(v) \subseteq \mathbb{N}$, a list T -coloring of G is a T -coloring f of G with all $f(v) \in L(v)$.

List colorings and list T -colorings are naturally generalized to list homomorphisms, also known as list H -colorings. Let H be a fixed graph (or digraph), and let G be a graph (respectively, digraph) together with lists $L(v) \subseteq V(H)$, $v \in V(G)$. A *list H -coloring* of G , with respect to lists L , is a homomorphism (edge-preserving mapping of the vertices) f of G to H such that all $f(v) \in L(v)$. The *list H -coloring*

problem asks whether or not a graph G with lists L admits a list H -coloring. The problem was investigated, and its complexity classified, in [7, 8, 9]; cf. also [17]. When all lists are equal to $V(H)$, the list H -coloring problem is known as the H -coloring problem [15]. We explicitly note that when H is a complete graph (without loops), then list H -colorings become just list colorings. On the other hand, when H is the graph with vertex set $\mathbf{N}$ and with edges ij such that $|i - j| \notin T$, then H -colorings become exactly T -colorings, and list H -colorings become exactly list T -colorings. (Note that if $0 \in T$, then the graph H has no loops.)

In [13], a more general model for list T -colorings was introduced. An instance of the *generalized list T -coloring problem* is a graph G in which each edge uv has its own constraints on the difference of colors of its endpoints, i.e., its own set $T(u, v)$ of integers, requiring that $|f(u) - f(v)| \notin T(u, v)$. The authors gave a result for these colorings which generalizes all of the earlier Brooks-type results [13].

In the same spirit, we introduce the following *pair-list coloring problem*. Let G be a graph and C a set of colors. For each edge $uv \in E(G)$, let the *forbidden set* $T(u, v)$ be a subset of $C \times C$. For consistency, we shall assume that $T(u, v) = \{(a, b) : (b, a) \in T(v, u)\}$. We shall extend the definition of $T(u, v)$ to all ordered pairs of distinct vertices, where $T(u, v) = \emptyset$ if uv is not an edge. Since edges $uv \in E(G)$ having $T(u, v) = \emptyset$ don't restrict our search for a coloring (see below), in what follows we will always assume that $T(u, v) \neq \emptyset$ if (and only if) $uv \in E(G)$. Given a graph G with forbidden sets $T(u, v)$, a *pair-list coloring* is a mapping $f : V(G) \rightarrow C$ such that $uv \in E(G)$ implies $f(u)f(v) \notin T(u, v)$. The *pair-list coloring problem* asks whether or not a given instance G, T has a pair-list coloring.

We shall also assume that each vertex v is equipped with a *list* $L(v) \subseteq C$ in the usual sense; additionally, each pair-list coloring f must have all $f(v) \in L(v)$. If these lists are not specifically given, we may set $L(v)$ equal to the set of all colors not explicitly forbidden for v by the sets $T(v, w), w \in V(G)$. Note that this is not a more general model, as the lists can be eliminated by adjusting the forbidden sets. (We can remove a list $L(v)$ and add to each $T(v, w)$ all pairs (a, b) with $a \notin L(v)$ without changing the problem.) In the rest of the paper, we shall consider an instance of the problem to be a graph G , with lists $L(v), v \in V(G)$, and forbidden sets $T(v, w), v, w \in V(G)$, such that $T(v, w) \neq \emptyset$ if and only if vw is an edge of G . We shall often refer to an instance G, L, T only by its graph G ; for example, we may say the instance is *connected* if the graph G is connected.

This concept is a common extension of (generalized) list T -colorings and list H -colorings of graphs (and digraphs). When $C = \mathbf{N}$ and each set $T(u, v)$ is described by listing the forbidden set D of differences, i.e., $T(u, v) = \{(a, b) : |a - b| \in D\}$, the pair-list coloring problem becomes the list T -coloring problem from [1, 22] (if the set D is fixed) or the generalized list T -coloring problem (if D depends on the edge uv).

Now to explain the connection of pair-list colorings to list H -colorings, let H be a graph. When the forbidden set for each edge $uv \in E(G)$ is defined as $T(u, v) = \{(a, b) : a \in L(u), b \in L(v), ab \notin E(H)\}$, the pair-list coloring problem becomes the list H -coloring problem. The same transformation works also when H is a digraph. In that case, the instance G is also a digraph; however, the directions of its arcs can be ignored by adjusting the forbidden sets so that only homomorphisms preserving the arc directions are allowed by the forbidden sets. (Note that the consistency assumption that $T(u, v) = \{(a, b) : (b, a) \in T(v, u)\}$ does not prevent us from modeling digraphs in this way.) At this point it is convenient to introduce a product graph $G \times T$ with the vertex set $V(G) \times C$, in which $(u, a)(v, b)$ is an edge whenever $(a, b) \in T(u, v)$. In fact, we may restrict our attention to vertices (v, a) with $a \in L(v)$. This product

FIG. 1. Versions of coloring problems.

conveniently captures the structure of forbidden color pairs. We depict its edges by dashed lines to emphasize that these are the *forbidden* pairs. Thus a pair list coloring f of G corresponds to a set of vertices $(v, f(v)), v \in V(G)$, one from each set $\{v\} \times L(v)$, which does not include an edge of $G \times T$.

The inclusion relations among the various versions of these coloring problems are illustrated in Figure 1.

Our main result is a Brooks-like characterization of balanced instances which do not admit a pair-list coloring. It implies the theorems of Brooks and Erdős, Rubin, and Taylor, but only a weaker version of the results in [13, 22]. On the other hand, our result also applies to (generalized) list T -colorings in which $0 \notin T$, providing some answers to the questions raised in [13] concerning this case. It seems possible to extend our context to forbidden triples, and higher order tuples, to generalize also the hypergraph Brooks theorems of [18], but we will keep our focus on forbidden pairs.

We shall consider both graphs and digraphs, and allow loops, unless specifically excluded. Graphs and digraphs without loops are called *irreflexive*. Graphs and digraphs in which every vertex has a loop are called *reflexive*. An *oriented graph* is a digraph without opposite arcs uv, vu . Graphs and digraphs have different definitions, and various concepts such as degree are applied differently to them; however, if convenient, we may view graphs as symmetric digraphs (digraphs in which $uv \in E(G)$ if and only if $vu \in E(G)$), as the homomorphism properties under this definition are the same [17]. In this context, it is important that a loop contributes one to the degree of a vertex in the case of graphs, and to both the indegree and the outdegree of a vertex in the case of digraphs.

2. The general result. In this section we deal with the problem in full generality. Note that loops in G have no effect on the problem, and we shall assume that the graph G is irreflexive. Consider an instance of the pair-list coloring problem, i.e., a graph G with lists L and forbidden sets T . Let $N(v)$ denote the set of neighbors of the vertex v in G . We say that v is *pair-balanced* if it satisfies the following two assumptions:

- (i) For each $u \in N(v)$ and each assignment $f(x) \in L(x)$, $x \in N(v) - u$, there

exists a color $a \in L(v)$ with all $(a, f(x)) \notin T(v, x)$. (We say that the assignment f can be *compatibly extended* to v .)

- (ii) If an assignment $f(x) \in L(x)$ for all $x \in N(v)$ cannot be compatibly extended to v , then for each color $a \in L(v)$ there exists a unique $u \in N(v)$ with $(f(u), a) \in T(u, v)$.

Recall the product $G \times T$ defined in the introduction. The T -weight of an ordered pair (u, v) of vertices of G is the maximum number of neighbors of any one (v, b) among all $(u, a), a \in L(u)$, in $G \times T$. Note that if $uv \notin E(G)$, the weight of both pairs $(u, v), (v, u)$ is 0, and that in general the weight of (u, v) is not the same as that of (v, u) . The T -weight of (u, v) represents the maximum number of possible colors for u that can be forbidden by one color of v . The T -degree of u , denoted by $\deg_T(u)$, is the sum over all $v, v \neq u$ of the T -weights of ordered pairs (u, v) . It is easy to see that the following fact holds.

PROPOSITION 1. *A vertex v with $|L(v)| \geq \deg_T(v)$ is pair-balanced.*

A graph G with lists L and forbidden sets T is *pair-balanced* if all its vertices are pair-balanced; it is *pair-overbalanced* if all vertices are pair-balanced, and for at least one vertex v , assumption (ii) can be replaced by the following stronger assumption:

- (ii') Every assignment $f(x) \in L(x), x \in N(v)$, can be compatibly extended to v .

The easy part of Brooks' theorem states that any graph with maximum degree Δ admits a coloring with $\Delta + 1$ colors. The counterpart of this result in our context is as follows.

THEOREM 2. *Every connected pair-overbalanced instance of the pair-list problem has a solution.*

Proof. If (ii') holds for vertex v , we can color G greedily in the order of decreasing distance to v . When coloring a vertex u other than the special vertex v we can use (i); such a vertex u has at least one uncolored neighbor closer to u ; when coloring the special vertex v we can use (ii'). $\square$

There are pair-balanced instances of the pair-list problem which do not have a solution. A connected instance G, L, T of the pair-list problem is a *Gallai configuration* if

1. each block B of G is a clique or a cycle;
2. each list $L(v), v \in V$, can be partitioned into nonempty subsets $L_B(v)$, over all blocks B of G with $v \in B$, so that
3. if block B is a clique with $q + 1$ vertices, then each list $L_B(v)$ can be further partitioned into q nonempty subsets $L_B^1(v), \dots, L_B^q(v)$ such that for $u, v \in B$ with $u \neq v$ we have

$$T(u, v) = \{(a, b) : a \in L_B^i(u), b \in L_B^i(v), i = 1, 2, \dots, q\};$$

4. if block B is a cycle, then each list $L_B(v)$ can be further partitioned into two nonempty subsets $L_B^1(v), L_B^2(v)$ so that for one edge uv of the cycle B we have

$$T(u, v) = \{(a, b) : a \in L_B^i(u), b \in L_B^i(v), i = 1, 2\},$$

and for all other edges uv of B we have

$$T(u, v) = \{(a, b) : a \in L_B^i(u), b \in L_B^{3-i}(v), i = 1, 2\};$$

5. if B, B' are distinct blocks, and $u \in B, v \in B \cap B'$ are distinct vertices, then for any $a \in L_B(u), b \in L_{B'}(v)$ we have $(a, b) \notin T(u, v)$.

These conditions imply a particularly simple structure of the product $G \times T$, illustrated in Figure 2: the vertices (v, a) , $a \in L(v)$, are always grouped close together; as mentioned earlier, the edges of $G \times T$ are dashed. In both illustrations in Figure 2, all parts $L_B^i(v)$ are singletons; if a part has more vertices, the adjacencies are just repeated. As mentioned earlier, a pair-list coloring needs to choose one vertex from each group and not include a dashed edge; clearly this is impossible in both these cases.

FIG. 2. The product $G \times T$ for a four-cycle and a four-clique block G .

Our main result states that Gallai configurations are the only pair-balanced instances which do not admit a pair-list coloring.

THEOREM 3. *Let G be a connected instance of the pair-list problem. Then the following statements are equivalent:*

- *The instance is pair-balanced but has no solution.*
- *The instance is a Gallai configuration.*

Proof. We first prove that a Gallai configuration is pair-balanced and has no solution. For a vertex which belongs to a unique block of a Gallai configuration, it is easy to verify assumptions (i) and (ii) by considering the above descriptions of the various types of blocks; for a vertex v which is a cutpoint, i.e., belongs to several blocks, we use condition 4 to focus on individual blocks containing v . To show that a Gallai configuration admits no solution, consider the block-cutpoint tree of G : starting with a leaf block B , it is easy to check (in each of the types of blocks described above) that no solution exists using only colors from $L_B(v)$, $v \in B$. (Compare with Figure 2.) Thus the unique cutpoint u of G contained in B must be assigned a color not from $L_B(u)$, in any solution. Since condition 5 ensures that any other color it may be assigned is compatible with other choices made within B , we may remove the entire block B , and delete from $L(u)$ the colors of $L_B(u)$, and proceed recursively. A contradiction is reached when only one block remains, since no assignment within the block is possible.

To prove the converse, we shall use the following three simple lemmas.

LEMMA 4. *Let G, L, T be a pair-balanced instance which has no pair-list coloring. Let u be a vertex of G such that $G - u$ is connected. Then for every neighbor v of u and each $a \in L(u)$ there exists some $b \in L(v)$ with $(a, b) \in T(u, v)$.*

Proof. Suppose v is a vertex of G such that $(a, b) \notin T(u, v)$ for all $b \in L(v)$. Then a pair-list coloring of G exists. We first color u by color a ; since $G - u$ is connected, we can color $G - u$ greedily in the order of decreasing distance to v , taking into account the color of u . When coloring v , we can disregard u by our assumption. $\square$

LEMMA 5. *Let G, L, T be a pair-balanced instance which has no pair-list coloring. Let u, v be two vertices of G such that $G - u - v$ is connected. Then for every vertex w adjacent to both u and v and all $a \in L(u), b \in L(v), c \in L(w)$ with $(a, c) \in T(u, w)$ and $(b, c) \in T(v, w)$, we must also have $(a, b) \in T(u, v)$.*

Proof. If $(a, b) \notin T(u, v)$, then there again is a pair-list coloring of G : color u by a and v by b , and then proceed as in Lemma 4, coloring $G - u - v$ greedily in the order of decreasing distance to w . At the end, w can be colored by (ii), since its neighbors u, v forbid the same color c . $\square$

LEMMA 6. *Let G, L, T be a pair-balanced instance which has no pair-list coloring. Let v be a vertex of G with precisely two neighbors, u and w , and assume that $G - v - w$ is connected. Then for all $a \in L(u), b, b' \in L(v)$, and $c \in L(w)$ with $(b, c) \notin T(v, w), (b', c) \notin T(v, w)$, and $(a, b) \notin T(u, v)$, we must also have $(a, b') \notin T(u, v)$.*

Proof. If $(a, b') \in T(u, v)$, then a pair-list coloring of G can be found as follows. Color w by c and v by b' , and then proceed as in Lemma 4, coloring $G - v - w$ greedily in the order of decreasing distance to u , using (i), until reaching the vertex u . If u cannot be colored, then by assumption (ii) the color a is forbidden only by the color b' on v . Recoloring v by b doesn't create a problem for w and solves the problem for u ; since the degree of v is two, this is a pair-list coloring. $\square$

We now continue proving the theorem; thus assume that we have a connected pair-balanced instance G, L, T which has no solution.

Assume first that G is a block, that is, has no cutpoint. If G has only two vertices, then it is an edge uv with $T(u, v) = L(u) \times L(v)$; this is a Gallai configuration of type 3 with $q = 1$. Thus we assume that G has at least three vertices. Assume further that G has no vertices of degree two. In this case, we first note that there must exist a vertex v such that $G - v$ is also a block. (Indeed, according to a theorem of Kaugars, every critical block other than an edge contains a vertex of degree two; cf. [2, p. 49].) We now show that v is adjacent to every vertex of $G - v$. Otherwise, there would be two vertices u, w in $G - v$ such that v is adjacent to w , w is adjacent to u , but v is not adjacent to u . Then there exist $b \in L(v)$ and $c \in L(w)$ so that $(b, c) \in T(v, w)$, since vw is an edge of G . By Lemma 4, there also exists a color $a \in L(u)$ such that $(a, c) \in T(u, w)$. Since uv is not an edge of G , $(a, b) \notin T(u, v)$, contrary to Lemma 5. This contradiction shows that v is adjacent to all other vertices of G . Since $G - v$ is a block, $G - v'$ must be a block for every other vertex v' in G , and so the preceding argument applies to v' as well; i.e., G is a clique.

We have shown that if G is a block without vertices of degree two, then G is a clique. We now prove that if G is a clique, then it is a Gallai configuration of type 3, i.e., that the lists $L(v)$ can be partitioned as claimed. Consider any three vertices u, v, w of G and $a \in L(u), b \in L(v), c \in L(w)$: if $(a, b) \in T(u, v)$ and $(b, c) \in T(v, w)$, then by Lemma 5 we also have $(a, c) \in T(u, w)$. For $a \in L(u)$, we let $S(v)$ be the set of elements $b \in L(v)$ such that $(a, b) \in T(u, v)$, and we let $S(w)$ be the set of elements $c \in L(w)$ such that $(a, c) \in T(u, w)$. Then $(b, c) \in T(v, w)$ if $b \in S(v), c \in S(w)$, and by symmetry $(b, c) \notin T(v, w)$ if $b \in S(v)$ and $c \in L(w) - S(w)$, or if $b \in L(v) - S(v)$ and $c \in S(w)$. Thus the lists $L(v)$ can each be partitioned into some number q of nonempty subsets $L^1(v), \dots, L^q(v)$ such that $(a, b) \in T(u, v)$ for $a \in L^i(u), b \in L^j(v)$ if and only if $i = j$. Since the graph has no pair-list coloring, it must have at least $q + 1$ vertices. On the other hand, G cannot have more than $q + 1$ vertices, since there is no pair-list coloring, yet all vertices are pair-balanced. Thus G has exactly $q + 1$ vertices, as claimed.

Now we claim that if G (a block pair-balanced instance without a solution) has a vertex v of degree two, then it is a Gallai configuration of type 4. This is clear if G is a three-cycle, by the above argument for cliques. (Note that in this case the partitions of lists in cases 3 and 4 can be relabeled to coincide.) Otherwise, let v be a vertex of degree two, with neighbors u, w in G . We construct a new instance G', L', T'

as follows: the graph G' is obtained from $G - v$ by adding the edge uw if it was not present (it will turn out below that it was not present); the lists L' are the lists L restricted to the vertices of G' , and the forbidden sets T' are the same as T , except for $T'(u, w)$ which is obtained from $T(u, w)$ by adding the set $T^*(u, w)$ consisting of all pairs (a, b) such that $a \in L(u)$, $b \in L(w)$ and each $c \in L(v)$ has $(a, c) \in T(u, v)$ or $(b, c) \in T(w, v)$. It is easy to observe that the instance G', L', T' has no solution, since the definition of $T'(u, w)$ would allow it to be extended to a solution of G, L, T . It is also clear that G' is a block. Moreover, it can be argued that G', L', T' is also pair-balanced. (For instance, it follows from assumption (i) that for every $c \in L(w)$ there exists a $b \in L(v)$ such that $(b, c) \notin T(v, w)$; therefore if $(a, c) \in T^*(u, w)$, then $(a, b) \in T(u, v)$. Thus when proving that u is pair-balanced in G' , we can use b instead of c and appeal to the fact that u is pair-balanced in G .)

Suppose first that G' does not contain a vertex of degree two, and so is a clique (with at least three vertices). Suppose also that some $b, b' \in L(v)$ admit a $c \in L(w)$ with $(b, c) \notin T(v, w)$, $(b', c) \notin T(v, w)$. Then, by Lemma 6, for any $a \in L(u)$, we have $(a, b) \notin T(u, v)$ if and only if $(a, b') \notin T(u, v)$. There exists an $a \in L(u)$ with $(a, b) \notin T(u, v)$ by assumption (i), and thus also $(a, b') \notin T(u, v)$. By a symmetric argument, for any $c \in L(w)$ we have $(b, c) \notin T(v, w)$ if and only if $(b', c) \notin T(v, w)$. It follows from this that there exists a $p \geq 2$ such that each of the lists $L(x)$, $x = u, v, w$, can be partitioned into nonempty disjoint subsets $L^1(x), \dots, L^p(x)$ such that for $a \in L^i(u)$, $b \in L^j(v)$, $c \in L^\ell(w)$ we have $(a, b) \in T(u, v)$ if and only if $i \neq j$, $(b, c) \in T(v, w)$ if and only if $j \neq \ell$, and hence $(a, c) \in T^*(u, w)$ if and only if $i \neq \ell$. This means that the subgraph of $G' \times T'$ induced by $\{u\} \times L(u) \cup \{w\} \times L(w)$ has at least all edges (a, c) , where $a \in L^i(u)$, $c \in L^\ell(w)$, $i \neq \ell$ (maybe more if uw was an edge of G), and hence is connected unless $p = 2$. On the other hand, since G' is a clique, $G' \times T$ has the form dictated by condition 3, in which the subgraph induced by $\{u\} \times L(u) \cup \{w\} \times L(w)$ has $q \geq 2$ components. Thus $p = 2$, and condition 3 implies that also $q = 2$, whence G' is a three-cycle. We now argue that G could not have had an edge uw ; indeed, if $T'(u, w)$ contained more pairs than $T^*(u, w)$, then the subgraph of $G' \times T'$ induced by $\{u\} \times L(u) \cup \{w\} \times L(w)$ would again be connected, contradicting the form of $G' \times T'$ from condition 3, as above. On the other hand, if $T'(u, w) = T(u, w) \cup T^*(u, w) = T^*(u, w)$, then condition (i) would imply that G' admits a pair-list coloring, which is not the case. It is now clear that G is a four-cycle, with the lists partitioned as described in condition 4.

If $G' = G_1$ does contain a vertex of degree two, we construct graphs $G_2, G_3, \dots$, where G_i is obtained from G_{i-1} by deleting a vertex of degree two and inserting an edge joining its two neighbors. (It follows as above that the two neighbors are not adjacent in G_{i-1} , unless G_{i-1} is a three-cycle.) In any event, we finally obtain a graph G_t which is a three-cycle and a Gallai configuration of type 4. Working backwards as above, we see that G_{t-1} is a four-cycle and a Gallai configuration of type 4; in fact, all G_i 's are cycles and Gallai configurations, including $G_1 = G'$, and finally G . This completes the proof in the case when G is a block.

Finally, if G is not a block, then G has a leaf block B with cutpoint $w \in B$. In B , we may assign colors $f(v) \in L(v)$ to $v \neq w$ in the order of decreasing distance from w by our assumption (i). If it is not possible to assign a color $f(w)$, then we let $L_B(w)$ be the set of colors for w forbidden by assigned colors to neighbors v of w in B , and we let $L'(w)$ be the set of colors for w forbidden by assigned colors to neighbors u of w in $G - (B - w)$. By assumption (ii), the sets $L_B(w)$ and $L'(w)$ are disjoint. Both the subproblem on B with $L(w)$ replaced by $L_B(w)$ and the subproblem on $G - (B - w)$

with $L(w)$ replaced by $L'(w)$ satisfy our assumptions (i) and (ii), and the problem on G admits an assignment if and only if either of these two subproblems on B and $G - (B - w)$ has an assignment. Proceeding inductively to decompose the subproblem on $G - (B - w)$, either the problem on G has an assignment, or it decomposes into subproblems for the various blocks B_i , with corresponding decompositions of the lists $L(v)$, so that the original problem has a solution if and only if at least one subproblem for a block B_i has a solution. This proves all the claims, except for the last one, for arbitrary G . For the last claim, if v and w are adjacent in G , with $v \in B$ and $w \in B \cap B'$ for distinct blocks B and B' , and there exist $b \in L_B(v)$ and $c \in L_{B'}(w)$ such that $(b, c) \in T(v, w)$, we proceed as follows. Consider B with lists $L_B(x)$, set $f(v) = b$, and assign $f(x) \in L_B(x)$ for $x \neq w$ in B in order of decreasing distance from w . For each block B'' containing w other than B , assign $f(x) \in L_{B''}(x)$ for $x \neq w$ from B'' in order of decreasing distance from w . The resulting assignments for blocks B'' other than B forbid at least all of $L_{B''}(w)$ for w , and the assignment for block B forbids at least all of $L_B(w)$ as well as $f(w) = c$ for w . Thus there is no possible color for w . Yet $f(w) = c$ is forbidden both by $f(v) = b$ in B and by some $f(u)$ in B' , since $c \in L_{B'}(w)$ and all of $L_{B'}(w)$ is forbidden by neighbors of w in B' . This contradicts assumption (ii). Therefore, there are no $b \in L_B(v)$ and $c \in L_{B'}(w)$ such that $(b, c) \in T(v, w)$. This completes the proof. $\square$

Since checking the block structure of an instance, and seeking the partitions of the simple kind described above, can be accomplished in polynomial time, this represents a polynomial time algorithm for solving the pair-list problem for pair-balanced instances.

3. Balanced list H -coloring problems. Recall that in the list H -coloring problem we have a fixed graph (or digraph) H , and an instance consists of a graph (respectively, digraph) G together with lists $L(v) \subseteq V(H), v \in V(G)$. A solution is a list H -coloring f of G , i.e., a homomorphism of G to H in which all $f(v) \in L(v)$. While we will allow loops in H , it will be simpler to assume that G is irreflexive. (Note that if G is not irreflexive, we can make it so by eliminating a loop at vertex v and at the same time deleting from $L(v)$ any vertices of H which do not have a loop.)

Our Theorem 3 can be applied to list H -colorings by taking each forbidden set $T(u, v)$ to be the set $L(u) \times L(v) - E(H)$. Thus there are many different applications possible. We shall single out just two very simple contexts to illustrate the applications, one for graphs and one for digraphs. In both cases we focus on instances with $\deg_G(v) = |L(v)|$, in analogy with [6]. We shall call such instances *balanced*. (For digraphs, $\deg_G(v)$ is to be interpreted as the total degree of v in G , i.e., the sum of in- and out-degrees of v in G .) A balanced instance G, L is called *overbalanced* if it contains a vertex with degree (respectively, total degree) $\deg_G(v)$, which satisfies $\deg_G(v) > |L(v)|$. The *balanced list H -coloring problem* for a graph H is the restriction of the list H -coloring problem to balanced graphs G with lists L . The *balanced list H -coloring problem* for a digraph H is the restriction of the list H -coloring problem to balanced *oriented* graphs G with lists L . (Recall that an oriented graph is a digraph without a pair of opposite arcs.) We note that our notion of balanced vertices is not the same as that of [13].

In this situation we naturally focus on graphs (respectively, digraphs) H that are *nearly complete*, in the sense that at each vertex v they have $vw \in E(H)$ for all $w \in V(H)$ except possibly one vertex w , which could be equal to v (respectively, $vw \in E(H)$ for all $w \in V(H)$ except possibly one w , and $uv \in E(H)$ for all $u \in V(H)$ except possibly one u , where $u = v = w$ is possible). Thus in a nearly complete

graph, each vertex has at most one edge missing, and that edge could be the loop, and in a nearly complete digraph, each vertex has at most one in-edge and at most one out-edge missing, and if it has the loop missing, it counts as both the missing in-edge and the missing out-edge. The *complement* of H has edges and loops precisely where H does not have edges and loops. (Normally complements are defined without reference to loops.) Note that the usual irreflexive complete graph is nearly complete in this sense, as it is missing the loop at each vertex. Some other nearly complete graphs and digraphs are depicted in Figure 3. Recall that when we model the list H -coloring problem as a pair-list coloring problem, the forbidden sets $T(u, v)$ for $uv \in E(G)$ are those pairs (a, b) , $a \in L(u)$, $b \in L(v)$ which have $ab \notin E(H)$.

FIG. 3. Some examples of nearly complete graphs and digraphs.

Recall the definition of the T -degree of a vertex v . Since the T -weight of any pair (u, v) with $uv \in E(G)$ (or, in the case of digraphs, $uv \in E(G)$ or $vu \in E(G)$) is at most 1, the T -degree of v is at most $\deg_G(v)$. Therefore Proposition 1 ensures that a balanced graph (or oriented graph) G with lists L is pair-balanced, and hence Theorems 2 and 3 apply to guarantee that connected overbalanced instances always have a solution (list H -coloring) and to describe all connected unsolvable balanced instances as Gallai configurations. It remains to consider which of the Gallai configurations are actually possible. It is immediately obvious that all parts $L_B^i(v)$ must have a single element, since otherwise there would exist two distinct pairs $(a, b), (a', b) \in T(v, w)$.

First, we focus on the balanced list H -coloring problem for nearly complete graphs H . Note that in this situation colors $a, b \in V(H)$ either satisfy $(a, b) \notin T(u, v)$ for all edges $uv \in E(H)$ or satisfy $(a, b) \in T(u, v)$ for all edges $uv \in E(H)$. Consider a block B of a Gallai configuration, which is a clique of $q + 1 \geq 3$ vertices, each with a list of q colors. Suppose u, v, w are distinct vertices with $L_B^i(u) = \{a\}, L_B^i(v) = \{b\}, L_B^i(w) = \{c\}$. Then $(a, b) \in T(u, v), (a, c) \in T(u, w)$, i.e., $ab, ac \notin E(H)$, whence $b = c$ since H is nearly complete. The same argument shows that all sets $L_B(v), v \in B$, are the same set, L_B , of q vertices of H . Consider a block B which is a cycle $v_1, v_2, \dots, v_k$, and suppose the list of each v_i consists of $a_i \in L_B^1(v_i)$ and $b_i \in L_B^2(v_i)$, where $(a_i, a_{i+1}) \in T(v_i, v_{i+1})$ and $(b_i, b_{i+1}) \in T(v_i, v_{i+1})$ for $i = 1, 2, \dots, k-1$, and $(a_k, b_1) \in T(v_k, v_1), (b_k, a_1) \in T(v_k, v_1)$. We again apply the fact that H is nearly complete to

deduce that $a_1 = a_3 = a_5 = \dots$, $b_1 = b_3 = b_5 = \dots$, $a_2 = a_4 = \dots$, $b_2 = b_4 = \dots$. If k is even, $a_k = a_2$, $b_k = b_2$ and so both (a_1, a_2) and (a_1, b_2) are in $T(v_1, v_2)$, which is impossible in a Gallai configuration. Hence k is odd, and therefore all lists consist of the same pair of vertices in H . Thus, for nearly complete graphs H , a block of size at least three has the lists of all its vertices equal to the same set L_B , and all cycle blocks are odd. The vertices of H that appear in these blocks must be missing only their loops. On the other hand, the blocks that have two vertices could have equal lists, corresponding to missing loops in H , or they could have different lists, corresponding to missing nonloop edges in H . Summarizing this additional information, we have the following result for graphs H (with loops allowed).

COROLLARY 7. *Suppose H is a nearly complete graph, whose complement has isolated loops a_i , $i = 1, 2, \dots, k$, and isolated edges $b_i c_i$, $i = 1, 2, \dots, \ell$.*

If G is a balanced connected irreflexive graph with lists L , then either G has a list H -coloring, or it is a Gallai configuration in which

- *each block B that is a clique with $q+1 \geq 3$ vertices has all lists $L_B(v)$, $v \in B$, equal to the same set of q vertices a_i ;*
- *each block B that is a cycle has odd length and all the lists $L_B(v)$, $v \in B$, are equal to the same pair of vertices a_i, a_j ;*
- *each block B that is an edge $uv \in E(B)$ (clique with two vertices) has either $L_B(u) = L_B(v) = \{a_i\}$ for some $i = 1, 2, \dots, k$, or has $L_B(u) = \{b_j\}$, $L_B(v) = \{c_j\}$ for some $j = 1, 2, \dots, \ell$.*

Note that vertices of H that have no missing incident edges play no role in the result.

We single out two important special cases of the corollary. When H is irreflexive, we have $\ell = 0$, i.e., H is an irreflexive complete graph, and we obtain the following theorem of Erdős, Rubin, and Taylor [6]; also see Vizing [21] (for other proofs see [4, 13, 18]).

COROLLARY 8. *If G is a connected balanced irreflexive graph with lists $L(v)$, $v \in V(G)$, then either G admits a list coloring, or it is a Gallai configuration in which each block is either a clique with $q+1$ vertices, all with the same list of size q , or an odd cycle with all vertices having the same list of size two.*

The only difference from the above is that the third item on cliques of size $q+1$ also applies to $q+1 = 2$; i.e., the last item is not needed. ($L_B(u)$ and $L_B(v)$ are equal.) A Gallai configuration for this case is illustrated in Figure 4.

FIG. 4. A Gallai configuration for the irreflexive complete graph H .

When H is reflexive, we have $k = 0$, and we obtain the following new result.

COROLLARY 9. *Suppose H is a reflexive graph whose complement has isolated edges $b_i c_i$, $i = 1, 2, \dots, \ell$.*

If G is a balanced connected irreflexive graph with lists $L(v) \subseteq V(H)$, $v \in V(G)$, then either G admits a list H -coloring, or it is a Gallai configuration that is a tree,

in which each edge block $B = uv$ has $L_B(u), L_B(v)$ equal to $\{b_j\}, \{c_j\}$ for some j .

We illustrate a Gallai configuration for this case in Figure 5. The graph H is the reflexive four-cycle from Figure 3. Each edge uv of the tree is a block of the Gallai configuration and has $L_B(u), L_B(v)$ chosen as either b_1, c_1 or b_2, c_2 , in some order, labeled on the edge with lowercase letters. The lists of the leaves are marked, and all other vertices have the full lists $\{b_1, b_2, c_1, c_2\}$. It is instructive to see that there is no list H -coloring.

FIG. 5. A Gallai configuration for the reflexive four-cycle H .

We now briefly turn to the balanced list H -coloring problem for nearly complete digraphs H . In this situation colors $a, b \in V(H)$ may have $(a, b) \notin T(u, v)$ if uv is an edge, but not if vu is an edge, of H . However, it is still the case that (a, b) is either in $T(u, v)$ for all edges $uv \in E(H)$ or not in $T(u, v)$ for all edges $uv \in E(H)$. The instance of the balanced H -coloring problem consists of an oriented graph G with lists $L(v), v \in V(H)$, and total degrees $\deg_G(v) = |L(v)|$ for all $v \in V(H)$. Recall that to model this by a pair-list coloring problem, we remove the orientations of the edges of G and set, for each edge $uv \in E(H)$, the forbidden set $T(u, v)$ to consist of those pairs $(a, b), a \in L(u), b \in L(v)$ for which $ab \notin E(H)$. Thus the orientations of the edges of G can be ignored because they are encoded in the pair lists.

Consider a block B of a Gallai configuration containing two edges uv, uw with $v \neq w$. Since H is nearly complete, it follows as above that the lists $L_B(v)$ and $L_B(w)$ must be the same. This is easily seen to imply that, for a block B which is a clique with $q + 1 \geq 4$ vertices, each vertex has the same list q colors, and each color is a vertex of H that has no loop. A block B that is a clique with three vertices either has each vertex v with the same lists $L_B(v)$ consisting of two vertices of H without loops, or is a directed three-cycle with distinct lists corresponding to two distinct directed three-cycles in the complement of H . Consider a block B that is a cycle of G ; it may be a directed k -cycle with k even, with lists that correspond to a directed $2k$ -cycle in H ; or it may be a directed k -cycle with k odd, with lists that correspond to two disjoint k -cycles in H . The cycle B could also be oriented in more complex ways, implying certain equalities of lists; once two consecutive vertices of the cycle B are to have the same lists, all vertices of B must have the same lists. It is not hard to see that this can occur only when k is odd. Instead of stating all these necessary and sufficient conditions in such great detail, we only summarize a few necessary conditions.

COROLLARY 10. *Suppose H is a nearly complete digraph, whose complement $\overline{H}$ consists of disjoint directed cycles $D_1, D_2, \dots, D_k$ (some of which may have length one).*

If G is a balanced connected irreflexive oriented graph with lists L that does not

admit a list H -coloring, then it is a Gallai configuration in which

- each block B that is a clique with $q+1 \geq 4$ vertices has all lists $L_B(v), v \in B$, equal to the same set of q vertices lying in cycles of length one in $\overline{H}$;
- each block B that is a clique with three vertices either has all lists $L_B(v), v \in B$, equal to the same set of two vertices lying in cycles of length one in $\overline{H}$, or is a directed three-cycle of G , and its vertices have lists formed from two three-cycles of $\overline{H}$;
- each block B that is an oriented cycle has equal lists $L_B(u) = L_B(v)$ on vertices u, v that admit a $w \in B$ with $uw, vw \in E(B)$ or with $wu, wv \in E(B)$.

Thus if H is a nearly complete graph or digraph, we have solved the balanced list H -coloring problem in polynomial time.

4. Extension problems. In a future paper [11], we shall apply our results to extension problems. Let H be a fixed graph or digraph. Given a graph (respectively, oriented graph) G and a partial assignment f of some vertices of G to vertices of H , a homomorphism F of G to H is an *extension* of f if $F(v) = f(v)$ for all vertices for which $f(v)$ is defined. The *H -extension problem* asks whether or not an instance G, f has an extension. This problem is also known as the *precoloring extension problem*, the *one-or-all list H -coloring problem*, or the *H -retraction problem* [17]. Classifying the complexity of H -extension problems appears to be much harder than for list H -coloring problems [9, 12].

It is easy to see that the H -extension problem is a restriction of the list H -coloring problem to instances G, L in which each $L(v)$ either is equal to $V(H)$ or consists of a single color (vertex of H). If, moreover, the degrees of G are at most $|V(H)|$, we have basically a balanced instance, since a vertex v with $\deg_G(v) = k$ and $L(v) = \{a\}$ can be replaced by k vertices of degree one, with the same list, without changing the problem. Let us say that a graph is *k -bounded* if its maximum degree is at most k . Thus if H is a nearly complete graph or digraph with k vertices, then the H -extension problem for k -bounded graphs (respectively, oriented graphs) can be solved in polynomial time.

In [11], we shall also prove the following fact.

THEOREM 11. *Let H be a graph (with loops allowed) such that any two vertices a, b have a common neighbor c in H . Then the H -extension problem for 3-bounded irreflexive graphs can be solved in polynomial time.*

If H is a reflexive graph of diameter at most two, then it satisfies the condition. In particular, this implies that the reflexive five-cycle H has a polynomial time solvable H -extension problem for 3-bounded graphs. For the reflexive four-cycle H (which is a nearly complete graph; see Figure 3), Corollary 9 implies that the H -extension problem is polynomial time solvable for any 4-bounded graph. Finally, for the reflexive three-cycle H , any mapping of any graph G to H is a homomorphism, so the H -extension problem is trivial for all graphs. We shall prove in [11] that for all other reflexive cycles H , the H -extension problem is NP-complete, even for 3-bounded graphs; we shall also show that for the reflexive five-cycle H the H -extension problem is NP-complete. Summarizing this information, we conclude that for the reflexive k -cycle H , the H -extension problem in general is polynomial only when $k = 3$ (unless $P = NP$), but it also becomes polynomial when $k = 4$ for 4-bounded graphs and additionally when $k = 5$ for 3-bounded graphs. Similarly, it will turn out that for the irreflexive k -cycle H , the H -extension problem in general is polynomial only when $k = 4$ or $k = 6$ (unless $P = NP$), but also becomes polynomial when $k = 3$ for 3-bounded graphs [11]. This kind of sensitivity to degree constraints is unusual for

list H -coloring problems in general; in [10] we have proved that the complexity classification of list H -coloring problems (as NP-complete or polynomial time solvable) does not change when the instances are restricted to k -bounded graphs for any $k \geq 3$.

Consider now instances in which the graph G is allowed to have loops. For reflexive graphs H of diameter at most two, our polynomial time algorithm will still apply. The condition in Theorem 11 is also satisfied if H is an irreflexive graph of diameter at most two, all of whose edges belong to triangles, and the algorithm also applies to graphs G with loops allowed. For general graphs H (with loops allowed), we shall also require, in addition to having, for any two vertices a, b , a common neighbor c , that each vertex $a \in V(H)$ have a neighbor in H that has a loop. Then the H -extension problem for 3-bounded graphs G with loops allowed also has a polynomial time algorithm [11]. In all cases, the algorithms proceed by exploring some Gallai-type configurations that may or may not turn out to be uncolorable [11].

Acknowledgment. We are grateful to an anonymous referee whose uncompromising standards led to an improved presentation of several arguments.

FACES OF GENERALIZED CLUSTER COMPLEXES AND NONCROSSING PARTITIONS*

ELENI TZANAKI†

Abstract. Let Φ be a finite root system with corresponding reflection group W , and let m be a nonnegative integer. We consider the generalized cluster complex $\Delta^m(\Phi)$ defined by Fomin and Reading and the poset $NC_{(m)}(W)$ of m -divisible noncrossing partitions defined by Armstrong. We give a characterization of the faces of $\Delta^m(\Phi)$ in terms of $NC_{(m)}(W)$, generalizing that of Brady and Watt given in the case $m = 1$. Making use of this, we give a case free proof of a conjecture of Chapoton and Armstrong, which relates a certain refined face count of $\Delta^m(\Phi)$ with the Möbius function of $NC_{(m)}(W)$.

1. Introduction. Let Φ be a finite root system of rank n with associated reflection group W . Let Φ^+ be a positive system for Φ with corresponding simple system Π . Motivated by their theory of cluster algebras [16], Fomin and Zelevinsky introduced the cluster complex $\Delta(\Phi)$ in [15]. This is a pure $(n-1)$ -dimensional simplicial complex on the vertex set $\Phi^+ \cup (-\Pi)$ which is homeomorphic to a sphere [15]. Later, Fomin and Reading [14] introduced the generalized cluster complex $\Delta^m(\Phi)$, where m is any nonnegative integer (see also [20]). This is a simplicial complex on the vertex set of *colored almost positive roots* $\Phi_{\geq -1}^m$, that is, the set consisting of m (colored) copies of each positive root and one copy of each negative simple root. In the case $m = 1$, the generalized cluster complex $\Delta^m(\Phi)$ reduces to $\Delta(\Phi)$. The complex $\Delta^m(\Phi)$ has remarkable properties and surprising connections with other combinatorial objects such as m -divisible noncrossing partitions $NC_{(m)}(W)$ [1, 17, 18] and Catalan hyperplane arrangements [2, 3, 7]. For instance, it is proved in [14, Proposition 8.4] that, if Φ is irreducible, the number of facets of $\Delta^m(\Phi)$ is equal to the generalized Catalan number $N_m(\Phi) = \prod_{i=1}^n \frac{e_i + mh + 1}{e_i + 1}$ defined in [2]. Moreover, the entries of the f and h vectors of $\Delta^m(\Phi)$, as well as those of the natural subcomplex $\Delta_+^m(\Phi)$ called its *positive part*, have many interesting combinatorial interpretations [3, 7].

In his thesis [1] Armstrong defined the poset $NC_{(m)}(\gamma)$, where γ is a Coxeter element of W . There, he proved that the isomorphism type of the poset $NC_{(m)}(\gamma)$ is independent of the Coxeter element γ . We denote this poset by $NC_{(m)}(W)$ when the choice of γ is irrelevant and call it the poset of *m -divisible noncrossing partitions*. The poset $NC_{(m)}(W)$ is a graded meet-semilattice, and it reduces to the lattice of noncrossing partitions NC_W [9, 11] associated to W in the case $m = 1$. If W is irreducible, the number of elements of $NC_{(m)}(W)$ is equal to $N_m(\Phi)$ and the h -polynomial of $\Delta^m(\Phi)$ is equal to the rank-generating polynomial of $NC_{(m)}(W)$ [1, 14].

It was shown in [12, section 8] that the cluster complex $\Delta(\Phi)$ arises naturally in the context of the lattice NC_W . Our first main result is to extend this connection

*Received by the editors July 21, 2006; accepted for publication (in revised form) August 27, 2007; published electronically February 6, 2008. The present research will be part of the author's Ph.D. thesis at the University of Crete.

by means of a new characterization of the faces of $\Delta^m(\Phi)$ in terms of m -divisible noncrossing partitions. More precisely, let Φ be an irreducible root system, and let $\Pi = \Pi_+ \cup \Pi_-$ be a partition of the set of simple roots Π into two disjoint sets such that the roots within each are pairwise orthogonal. Let γ be a bipartite Coxeter element with respect to this partition of Π (see (5) in section 2). Consider a face σ of $\Delta^m(\Phi)$, and let σ^i be the subset of σ consisting of positive roots of color i and $\sigma_\pm = \sigma \cap (-\Pi_\pm)$. If $\tau \subseteq \Phi_{\geq -1}^m$ such that either $\tau \subseteq (-\Pi)$ or τ consists of positive roots of the same color, we denote by w_τ the product of reflections through the roots in τ taken in a certain order (see (7) in section 2). We make the convention that $w_\emptyset = \mathbf{1}$, where $\mathbf{1}$ is the identity in W . The faces of $\Delta^m(\Phi)$ can be characterized by the following criterion.

THEOREM 1.1. *For $m \geq 2$, the set $\sigma \subseteq \Phi_{\geq -1}^m$ is a face of $\Delta^m(\Phi)$ if and only if the sequence $(w_{\sigma_+} w_{\sigma^m}, w_{\sigma^{m-1}}, \dots, w_{\sigma^2}, w_{\sigma^1} w_{\sigma_-})$ is an element of $NC_{(m)}(\gamma)$ of rank $|\sigma|$.*

As will be made clear by the restatement of Theorem 1.1 in section 3 (see Theorem 3.1), the above criterion generalizes the characterization of Brady and Watt [12, section 8] in the case $m = 1$. Moreover, making use of this criterion one may discover many interesting properties of $\Delta^m(\Phi)$, for instance, that $\Delta^m(\Phi)$ is shellable and $(m+1)$ -Cohen–Macaulay. This is discussed in the article [8].

Our second main result is the proof of a conjecture that relates the cluster complex $\Delta^m(\Phi)$ with the poset $NC_{(m)}(W)$. Chapoton [13] conjectured a surprising enumerative relation between a refined face count of $\Delta(\Phi)$ and the Möbius function of NC_W . This conjecture, which was proved by Athanasiadis [4], can be stated in the $m \geq 1$ case as follows [1] (see also [17, 18]). The F -triangle for $\Delta^m(\Phi)$ is defined by the generating function

$$(1) \quad F_\Phi^{(m)}(x, y) = \sum_{k=0}^n \sum_{l=0}^n f_{k,l}(\Phi, m) x^k y^l,$$

where $f_{k,l}(\Phi, m)$ is the number of faces of $\Delta^m(\Phi)$ consisting of k colored positive roots and l negative simple roots. The M -triangle for $NC_{(m)}(W)$ is defined similarly as

$$(2) \quad M_W^{(m)}(x, y) = \sum_{\substack{a \leq b \\ \text{in } NC_{(m)}(W)}} \mu(a, b) x^{rk(b) - rk(a)} y^{rk(a)},$$

where $\leq$ denotes the order relation in the poset $NC_{(m)}(W)$, μ stands for its Möbius function, and $rk(a)$ is the rank of $a \in NC_{(m)}(W)$.

The following relation was formulated by Chapoton [13, Conjecture 1] as a conjecture in the case $m = 1$ and was restated by Armstrong for any $m \geq 1$.

THEOREM 1.2. *Let Φ be a finite root system of rank n with corresponding reflection group W , and let m be a nonnegative integer. The F -triangle for $\Delta^m(\Phi)$ and the M -triangle for $NC_{(m)}(W)$ are related by the equality*

$$(3) \quad (1-y)^n F_\Phi^{(m)}\left(\frac{x+y}{1-y}, \frac{y}{1-y}\right) = M_W^{(m)}(-x, -y/x).$$

Theorem 1.2 has been proved in part by Krattenthaler [17], in a case-by-case fashion, for all finite root systems when $m = 1$ and for those that do not contain a copy of D_k for any $k \geq 4$ in the case $m \geq 2$. It was also observed by Krattenthaler that the relation (3) implies the following interesting reciprocity [18, Theorem 8]:

$$y^n M_W^{(-m)}(xy, 1/y) = M_W^{(m)}(x, y),$$

for which there is no intrinsic explanation yet.

This paper is organized as follows. After providing the necessary background, we proceed with the proof of Theorem 1.1 in section 3. In section 4 we find an EL-labeling of the poset $NC_{(m)}(\gamma)$, in which the decreasing chains are in bijection with facets of $\Delta_+^m(\Phi)$. Given the above results, we conclude with the proof of Theorem 1.2 in section 5, generalizing that of Athanasiadis [4] for the case $m = 1$.

2. Preliminaries. In this section we introduce our main objects of study and state a few lemmas and theorems necessary in later sections.

The lattice NC_W and the reflection length order on W . Let W be a finite Coxeter group of rank n , and let T be the set of all reflections in W . The group W is generated by T , and one can define a length function l_T on W so that $l_T(w)$ is the smallest k such that w can be written as a product of k reflections in T . The set W can be partially ordered by letting

$$u \leq v \quad \text{if and only if} \quad l_T(u) + l_T(u^{-1}v) = l_T(v),$$

in other words, if there exists a shortest factorization of u into reflections in T which is a prefix of such a shortest factorization of v . Note that l_T is not the usual Coxeter length function associated to a simple system for W . The order $\leq$ is called *reflection length order* or *absolute order* and turns W into a graded poset having the identity of W as its unique minimal element and rank function l_T . If $\Phi = A_{n-1}$, so that W can be realized as the symmetric group of permutations of the set $\{1, 2, \dots, n\}$, then $l_T(w) = n - c(w)$, where $c(w)$ is the number of cycles of w . Moreover, $u \leq w$ if and only if each cycle of u can be obtained from some cycle of w by deleting elements.

Note that all Coxeter elements are maximal in this partial order of W . The group W acting by conjugation gives automorphisms of this partial order, since the set of reflections is stable under conjugation. We define the *noncrossing partition lattice* NC_W to be an interval between the identity 1 and any Coxeter element γ . Since all Coxeter elements are conjugate, the isomorphism type of NC_W is independent of γ . The poset NC_W is a self-dual lattice of rank n [12]. If we have chosen some particular Coxeter element γ , then we denote the noncrossing partition lattice by $NC_W(\gamma)$. Should there be no element of confusion, we just write $NC(\gamma)$, suppressing W in the notation.

For later reference we summarize a few definitions and general facts.

DEFINITION 2.1 (see [1, Definition 3.1.1]). *The m -tuple $(w_1, \dots, w_m) \in W^m$ is a minimal factorization of $w \in W$ if $w = w_1 w_2 \dots w_m$ and $l_T(w) = \sum_{i=1}^m l_T(w_i)$.*

LEMMA 2.2.

- (i) *Conjugate elements have the same length.*
- (ii) [1, Lemma 3.1.2] *If $(w_1, w_2, \dots, w_k)$ is a minimal factorization of $w \in W$, then so is the k -tuple*

$$(w_i, w_i^{-1} w_1 w_i, \dots, w_i^{-1} w_{i-1} w_i, w_{i+1}, \dots, w_k)$$

for every $1 \leq i \leq k$. In other words, for every w_i there is a minimal factorization of w with w_i in the first place.

- (iii) *If $(w_1, w_2, \dots, w_k)$ is a minimal factorization of w , then $w_{i_1} w_{i_2} \dots w_{i_\ell} \leq w$ and $l_T(w_{i_1} \dots w_{i_\ell}) = \sum_{j=1}^\ell l_T(w_{i_j})$ for every $1 \leq i_1 < i_2 < \dots < i_\ell \leq k$.*

Proof. Part (i) follows from the fact that all reflections in W are conjugate, and then part (ii) is immediate. To prove (iii) it suffices to apply (ii) repeatedly for every w_{i_j} , $1 \leq j \leq \ell$, to get a minimal factorization of w starting with $w_{i_1} w_{i_2} \dots w_{i_\ell}$. $\square$

LEMMA 2.3 (see [4, Lemma 2.1]). *Let a, b, w be elements of W .*

- (i) *$a \leq aw \leq b$ if and only if $w \leq a^{-1}b \leq b$.*
- (ii) *$a \leq aw \leq b$ if and only if $a \leq bw^{-1} \leq b$.*
- (iii) *$a \leq b$ if and only if $a^{-1}b \leq b$, and, in that case, the interval $[a, b]$ is isomorphic to $[1, a^{-1}b]$.*

LEMMA 2.4.

- (i) [6, Lemma 2.1(iv)] *If $a, b \leq c \leq w$ for some $w \in W$ and $ab \leq w$, then $ab \leq c$.*
- (ii) [12, Relation (3)] *If $a \leq b \leq c$, then $a^{-1}b \leq a^{-1}c$ and $ba^{-1} \leq ca^{-1}$.*
- (iii) [12, Relation (7)] *For distinct reflections t_1, t_2 and $w \in W$ we have $t_1 t_2 \leq w \Leftrightarrow t_2 \leq t_1 w \Leftrightarrow t_1 \leq w t_2$.*

The following simple observation is immediate from the definition of the partial order $\leq$ of W and Lemma 2.2(i).

LEMMA 2.5. *For $u, v, w \in W$ we have $u \leq v$ if and only if $wuw^{-1} \leq wvw^{-1}$.*

Posets and EL-labelings. Let $(P, \leq)$ be a finite graded poset. We say that y covers x and write $x \rightarrow y$ if $x < y$ and $x < z \leq y$ holds only for $z = y$. Let $\mathcal{E}(P)$ be the set of covering relations in P and consider Λ a totally ordered set. An *edge labeling* of P with label set Λ is a map $\lambda : \mathcal{E}(P) \rightarrow \Lambda$. If $C : x_0 \rightarrow x_1 \rightarrow \cdots \rightarrow x_r$ is an unrefinable chain, we let $\lambda(C) = (\lambda(x_0 \rightarrow x_1), \lambda(x_1 \rightarrow x_2), \dots, \lambda(x_{r-1} \rightarrow x_r))$ be the label of C with respect to λ , and we call C *rising or decreasing* with respect to λ if the entries of $\lambda(C)$ strictly increase or weakly decrease, respectively, in the total order of Λ . Since P is graded, all maximal chains C in every interval $I = [x, y]$ have the same length, equal to $rk(y) - rk(x)$. The edge labeling allows us to order the maximal chains in I by ordering the labels $\lambda(C)$ lexicographically. That is, C is lexicographically smaller than C' if $\lambda(C)$ precedes $\lambda(C')$ in the lexicographic order induced by the total order of Λ .

DEFINITION 2.6 (see [10]). *An edge labeling λ of P is called EL-labeling if for every nonsingleton interval $[x, y]$ in P ,*

- (i) *there is a unique rising maximal chain in $[x, y]$ and*
- (ii) *this chain is lexicographically smallest among all maximal chains in $[x, y]$ with respect to λ .*

If, in addition, P has a unique minimal and maximal element, then we say that P is EL-shellable.

If $P_1, \dots, P_m$ are posets, then their direct product $P = P_1 \times \cdots \times P_m$ is the poset on the set $\{(x_1, \dots, x_m) : x_i \in P_i\}$ such that $(x_1, \dots, x_m) \leq (x'_1, \dots, x'_m)$ in P if $x_i \leq x'_i$ in P_i for every $1 \leq i \leq m$. Moreover $(x'_1, \dots, x'_m)$ covers $(x_1, \dots, x_m)$ in P if there is some $1 \leq i_0 \leq m$ such that $x_i = x'_i$ for all $1 \leq i \neq i_0 \leq m$ and x'_{i_0} covers x_{i_0} in P_{i_0} . The following lemma is a reformulation of [10, Theorem 4.3].

LEMMA 2.7 (see [10]). *If $P_1, P_2, \dots, P_m$ are graded posets that admit an EL-labeling, then $P = P_1 \times P_2 \times \cdots \times P_m$ admits an EL-labeling as well.*

The EL-labeling that P inherits from $P_1, \dots, P_m$ is the following. Assume that Λ_i is the totally ordered set of the EL-labels of P_i . If $\lambda_i \in \Lambda_i$, we totally order the m -tuples $(\emptyset, \dots, \emptyset, \lambda_i, \emptyset, \dots, \emptyset)$ with λ_i in the i th entry by letting

$$(4) \quad (\emptyset, \dots, \emptyset, \lambda_i, \emptyset, \dots, \emptyset) \leq (\emptyset, \dots, \emptyset, \lambda_j, \emptyset, \dots, \emptyset) \text{ if and only if} \\ i = j \text{ and } \lambda_i \leq \lambda_j \text{ in the total order of } \Lambda_i \\ \text{or } i > j.$$

If $x = (x_1, \dots, x_m)$ is covered by $x' = (x'_1, \dots, x'_m)$ in the poset P , then there is some $1 \leq i_0 \leq m$ such that $x_i = x'_i$ for all $1 \leq i \neq i_0 \leq m$ and $x_{i_0} \rightarrow x'_{i_0}$ in P_{i_0} .

If $\lambda_{i_0} = \lambda(x_{i_0} \rightarrow x'_{i_0})$ is the edge label from the EL-labeling of P_{i_0} , then we label the edge $x \rightarrow x'$ in P by the m -tuple $(\emptyset, \dots, \emptyset, \lambda_{i_0}, \emptyset, \dots, \emptyset)$ with λ_{i_0} in the i_0 th entry. The edge labels of P we obtain this way, totally ordered as in (4), form an EL-labeling of $P_1 \times P_2 \times \dots \times P_m$.

The EL-labeling of $NC(\gamma)$. Let Φ be an irreducible root system of rank n with positive part Φ^+ , and let $\Pi = \{\sigma_1, \sigma_2, \dots, \sigma_n\}$ be a choice of simple system for Φ such that $\Pi_+ = \{\sigma_1, \sigma_2, \dots, \sigma_r\}$ and $\Pi_- = \{\sigma_{r+1}, \dots, \sigma_n\}$ are orthonormal sets. For each $\alpha \in \Phi$ we denote by r_α the reflection in the hyperplane in $\mathbb{R}^n$ orthogonal to α . A *bipartite Coxeter element* of the root system Φ is a Coxeter element of type $\gamma = \gamma_+ \gamma_-$, where

$$(5) \quad \gamma_\pm = \prod_{\alpha \in \Pi_\pm} r_\alpha.$$

Thus, in the present case, the bipartite Coxeter element is $\gamma = r_{\sigma_1} \dots r_{\sigma_n}$.

Let $N = nh/2$ be the number of positive roots of Φ^+ . For $1 \leq i \leq 2N$ we define $\rho_i = r_{\sigma_1} r_{\sigma_2} \dots r_{\sigma_{i-1}}(\sigma_i)$, where the simple roots σ_i are indexed cyclically modulo n and we make the convention that $\rho_{-i} = \rho_{2N-i}$ for $i \geq 0$. The following formula, which is easily verified, appears in [12, section 3]:

$$(6) \quad \rho_i = \begin{cases} \sigma_i & \text{for } i = 1, \dots, r, \\ -\gamma(\sigma_i) & \text{for } i = r+1, \dots, n, \\ \gamma(\rho_{i-n}) & \text{for } i > n. \end{cases}$$

Then we have

$$\begin{aligned} \{\rho_1, \dots, \rho_N\} &= \Phi^+, \\ \{\rho_{N+i} : 1 \leq i \leq r\} &= -\Pi_+, \\ \{\rho_{-i} : 0 \leq i < n-r\} &= \{-\rho_{N-i} : 0 \leq i < n-r\} = -\Pi_-. \end{aligned}$$

Let $\Phi_{\geq -1} = \Phi^+ \cup (-\Pi)$ be the set of *almost positive roots*. We totally order the roots in $\Phi_{\geq -1}$ as follows:

$$(7) \quad \underbrace{\rho_{-n+r+1} \prec \dots \prec \rho_0}_{-\Pi_-} \prec \underbrace{\rho_1 \prec \dots \prec \rho_N}_{\Phi^+} \prec \underbrace{\rho_{N+1} \prec \dots \prec \rho_{N+r}}_{-\Pi_+}.$$

This order induces a total order, which we again denote by $\prec$, on the set T of reflections in W as follows:

$$(8) \quad r_{\rho_1} \prec r_{\rho_2} \prec \dots \prec r_{\rho_N}.$$

Let $u, v \in NC(\gamma)$ such that v covers u . Clearly $v = ut$, where t is a reflection in W . The *natural edge labeling* of the edge $u \rightarrow v$ is the reflection $t = u^{-1}v$.

THEOREM 2.8 (see [5, Theorem 4.2]). *If the set T of reflections in W is totally ordered by (8) and $\gamma = r_{\sigma_1} r_{\sigma_2} \dots r_{\sigma_n}$, then the natural edge labeling of $NC(\gamma)$ with label set T is an EL-labeling.*

The poset $NC_{(m)}(W)$. Here we recall some general facts for the poset $NC_{(m)}(W)$ of m -divisible noncrossing partitions. We refer the reader to [1] for more details.

DEFINITION 2.9 (see [1, Definition 3.2.2]). *Let W be a reflection group, and fix a Coxeter element γ . We denote by $NC_{(m)}(\gamma)$ the set of m -tuples $(w_1, \dots, w_m) \in (NC(\gamma))^m$ for which*

- (i) $w = w_1 \dots w_m \leq \gamma$ and
- (ii) $l_T(w) = \sum_{i=1}^m l_T(w_i)$.

Recall that a subset I of a poset $(P, \leq)$ is an *order ideal* if $x, y \in P$, $x \in I$, and $y \leq x$ implies $y \in I$. The set $NC_{(m)}(\gamma)$ is a subposet of $(NC(\gamma))^m$. Moreover it is an order ideal of $(NC(\gamma))^m$ whose maximal elements are the m -tuples $(w_1, \dots, w_m)$ where $w_1 \dots w_m$ is a minimal factorization of γ [1, Lemma 3.4.3]. Thus, the set $NC_{(m)}(\gamma)$ inherits the partial order as well as the rank function of $(NC(\gamma))^m$. More specifically, for $(u_1, \dots, u_m), (w_1, \dots, w_m) \in NC_{(m)}(\gamma)$ we have

$$(u_1, u_2, \dots, u_m) \leq (w_1, w_2, \dots, w_m) \text{ if } u_i \leq w_i \text{ for all } 1 \leq i \leq m$$

and

$$rk((w_1, \dots, w_m)) = \sum_{i=1}^m l_T(w_i).$$

By the fact that all Coxeter elements are conjugate and Lemma 2.5, we deduce that the isomorphism type of $NC_{(m)}(\gamma)$ is independent of the choice of γ . Therefore, if we are not interested in the particular choice of γ , we write $NC_{(m)}(W)$, and we call this the poset of *m -divisible noncrossing partitions*. The poset $NC_{(m)}(W)$ is a ranked meet-semilattice [1, Lemma 3.4.4] with unique minimal element the m -tuple $(1, \dots, 1)$.

The cluster complex $\Delta(\Phi)$. Let Φ be an irreducible root system, and let $\Phi_{\geq -1} = \Phi^+ \cup (-\Pi)$ be the set of almost positive roots. We define the map $\mathcal{R}$ on $\Phi_{\geq -1}$ as follows:

$$(9) \quad \mathcal{R}(\alpha) = \begin{cases} \gamma^{-1}(\alpha) & \text{if } \alpha \notin \Pi_+ \cup (-\Pi_-), \\ -\alpha & \text{if } \alpha \in \Pi_+ \cup (-\Pi_-). \end{cases}$$

THEOREM 2.10 (see [15]). *There is a unique symmetric binary relation on $\Phi_{\geq -1}$ called compatibility such that*

- (i) α and β are compatible if and only if $\mathcal{R}(\alpha)$ and $\mathcal{R}(\beta)$ are compatible, and
- (ii) a negative simple root $-\sigma_i$ is compatible with a positive root β if and only if the simple root expansion of β does not involve σ_i .

The cluster complex $\Delta(\Phi)$ is defined as the simplicial complex on the vertex set $\Phi_{\geq -1}$ such that a set $\sigma \subseteq \Phi_{\geq -1}$ is a face of $\Delta(\Phi)$ if every pair of roots in σ is compatible. The maximal faces of $\Delta(\Phi)$ are called *clusters*. The simplicial complex $\Delta(\Phi)$ is pure, $(n-1)$ -dimensional, and homeomorphic to a sphere [15].

The generalized cluster complex $\Delta^m(\Phi)$. The *generalized cluster complex* $\Delta^m(\Phi)$, introduced in [14], is a simplicial complex on the vertex set $\Phi_{\geq -1}^m$ of *colored almost positive roots*. More specifically, $\Phi_{\geq -1}^m$ is the union of the set $\Phi_{>0}^m$ of m (colored) copies $\alpha^1, \dots, \alpha^m$ of each positive root $\alpha \in \Phi^+$ with the set of negative simple roots. We make the convention that each negative simple root is colored by 1. Thus,

$$\Phi_{\geq -1}^m = \Phi_{>0}^m \cup (-\Pi)^1 = \{\alpha^k : \alpha \in \Phi^+, k \in \{1, \dots, m\}\} \cup \{\alpha^1 : \alpha \in -\Pi\}.$$

The generalized cluster complex $\Delta^m(\Phi)$ is a simplicial complex on the vertex set $\Phi_{\geq -1}^m$. The faces of $\Delta^m(\Phi)$ are the sets $\sigma \subseteq \Phi_{\geq -1}^m$ whose elements are pairwise m -compatible in the sense we are going to describe just below. For every $\alpha \in \Phi_{\geq -1}^m$ we define the *degree* $d(\alpha)$ of α to be the smallest d such that $\mathcal{R}^d(\alpha)$ is a negative simple root. Clearly, $d(\alpha) = 0$ if α is a negative simple root.

DEFINITION 2.11 (see [14, Definition 3.1]). *Two colored roots $\alpha^k, \beta^l \in \Phi_{\geq -1}^m$ are called m -compatible if and only if one of the following conditions is satisfied:*

- $k > l$, $d(\alpha) \leq d(\beta)$, and the roots $\mathcal{R}(\alpha)$ and β are compatible in the original noncolored sense (Theorem 2.10),
- $k < l$, $d(\alpha) \geq d(\beta)$, and the roots α and $\mathcal{R}(\beta)$ are compatible,
- $k > l$, $d(\alpha) > d(\beta)$, and the roots α and β are compatible,
- $k < l$, $d(\alpha) < d(\beta)$, and the roots α and β are compatible, and
- $k = l$ and the roots α and β are compatible.

It is immediate from the definition that m -compatibility is a symmetric relation. There is another equivalent way to define this relation, by introducing the m -analogue of the map $\mathcal{R}$, as follows.

DEFINITION 2.12 (see [14, Definition 3.3]). *For $\alpha^k \in \Phi_{\geq -1}^m$, we set*

$$(10) \quad \mathcal{R}_m(\alpha^k) = \begin{cases} \alpha^{k+1} & \text{if } \alpha \in \Phi_{>0}^m \text{ and } k < m, \\ (\mathcal{R}(\alpha))^1 & \text{otherwise.} \end{cases}$$

THEOREM 2.13 (see [14, Theorem 3.4]). *The m -compatibility relation on $\Phi_{\geq -1}^m$ has the following properties:*

- (i) α^k is m -compatible with β^l if and only if $\mathcal{R}_m(\alpha^k)$ is m -compatible with $\mathcal{R}_m(\beta^l)$;
- (ii) $(-\sigma_i)^1$ is m -compatible with β^l if and only if the simple root expansion of β does not involve σ_i .

Furthermore, the above conditions uniquely determine this relation.

We denote by $\Delta_+^m(\Phi)$ the *positive part* of $\Delta^m(\Phi)$, which is the induced subcomplex of $\Delta^m(\Phi)$ on the vertex set $\Phi_{>0}^m$ of positive colored roots. If Φ is reducible with irreducible components $\Phi_1, \dots, \Phi_\ell$, then $\Phi_{\geq -1}^m = \bigcup_{i=1}^\ell (\Phi_i^m)_{\geq -1}$. We declare two roots in $\Phi_{\geq -1}^m$ m -compatible if they either belong to different components or belong to the same component and are m -compatible within it. Thus, the complex $\Delta^m(\Phi)$ is the simplicial join of the complexes $\Delta^m(\Phi_i)$.

3. Proof of Theorem 1.1. Throughout this section we assume that Φ is an irreducible root system and γ a bipartite Coxeter element. We will prove the following restatement of Theorem 1.1 which can be deduced immediately from Definition 2.9.

THEOREM 3.1. *The set $\sigma \subseteq \Phi_{\geq -1}^m$ is a face of $\Delta^m(\Phi)$ if and only if*

- (i) $w_{\sigma^+} w_{\sigma^m} w_{\sigma^{m-1}} \dots w_{\sigma^1} w_{\sigma^-} \leq \gamma$ and
- (ii) $l_T(w_{\sigma^+} w_{\sigma^m} w_{\sigma^{m-1}} \dots w_{\sigma^1} w_{\sigma^-}) = |\sigma|$.

The above criterion reduces to that of Brady and Watt [12, section 8] in the case $m = 1$. Before proving Theorem 3.1 we need to establish a few more facts.

Let $\mu : \mathbb{R}^n \rightarrow \mathbb{R}^n$ be the map introduced in [12], with

$$\mu(x) = 2(I - \gamma)^{-1}(x)$$

for all $x \in \mathbb{R}^n$. In what follows, we denote by $\alpha \cdot \beta$ the inner product of $\alpha, \beta \in \mathbb{R}^n$.

LEMMA 3.2.

- (i) [12, section 8] *Let $\alpha, \beta \in \Phi_{\geq -1}$, with $\alpha \prec \beta$. The roots α, β are compatible if and only if $\mathbf{1} \neq r_\beta r_\alpha \leq \gamma$.*

(ii) For $\alpha, \beta \in \Phi_{\geq -1}$ we have $\mu(\alpha) \cdot \beta = 0$ if and only if $\mathbf{1} \neq r_\alpha r_\beta \leq \gamma$.

Proof of (ii). Part (ii) is a slight modification of [6, Lemma 2.2], which states that if the roots $\alpha, \beta \in \Phi_{\geq -1}$ are nonparallel, then $\mu(\alpha) \cdot \beta = 0 \Leftrightarrow r_\alpha r_\beta \leq \gamma$. From [12, Corollary 3.3(b)] we have that $\mu(\alpha) \cdot \alpha = 1$ for all $\alpha \in \Phi_{\geq -1}$. Thus, if $\mu(\alpha) \cdot \beta = 0$, then $\alpha \neq \pm\beta$, or, equivalently, the roots α, β are nonparallel and therefore $\mathbf{1} \neq r_\alpha r_\beta \leq \gamma$. Conversely, if $\mathbf{1} \neq r_\alpha r_\beta \leq \gamma$, then $\alpha \neq \pm\beta$; that is, the roots α, β are nonparallel, and therefore $\mu(\alpha) \cdot \beta = 0$ by [6, Lemma 2.2]. $\square$

LEMMA 3.3 (see [12, Theorem 3.7]). For the total order (7) of roots in $\Phi_{\geq -1}$ we have $\mu(\rho_j) \cdot \rho_{i-n} = -\mu(\rho_i) \cdot \rho_j$ for all i, j .

LEMMA 3.4. If ρ_i is a positive root, then $\rho_{i-n} = \gamma^{-1}(\rho_i)$.

Proof. If $n+1 \leq i \leq N$, the result is clear by (6). If $1 \leq i \leq n$, then recall that $\rho_{i-n} = \rho_{2N+i-n} = \rho_{nh+i-n}$, where N is the number of positive roots. By the relation $\rho_i = \gamma(\rho_{i-n})$ holding for $i > n$ and the fact that $\gamma^h = \mathbf{1}$, we have

$$\rho_{n(h-1)+i} = \gamma(\rho_{n(h-2)+i}) = \gamma^2(\rho_{n(h-3)+i}) = \cdots = \gamma^{h-1}(\rho_i) = \gamma^{-1}(\rho_i),$$

which completes our proof. $\square$

LEMMA 3.5. Let $w \in W$ and $t_1, t_2, \dots, t_k$ be distinct reflections in W such that $t_i t_j \leq w$ for every $i < j$. Then $t_1 t_2 \dots t_k \leq w$ and $l_T(t_1 t_2 \dots t_k) = k$.

Proof. We will proceed by induction, the case $k = 2$ being trivial. We assume that the statement holds for k , and we prove it for $k+1$. To this end we consider $t_1, \dots, t_k, t_{k+1}$ distinct reflections in W such that $t_i t_j \leq w$ for every $i < j$. We have $t_1 \dots t_k \leq w$ and $t_2 \dots t_{k+1} \leq w$ by the inductive assumption. Since $t_1 \leq t_1 t_2 \dots t_k \leq w$, then $t_2 \dots t_k \leq t_1 w$ by Lemma 2.4(ii). Moreover, since $t_1 t_{k+1} \leq w$, then $t_{k+1} \leq t_1 w$ by part (iii) of the same lemma. By setting $a = t_2 \dots t_k$, $b = t_{k+1}$, $c = t_1 w$, and applying Lemma 2.4(i), we get $t_2 \dots t_{k+1} \leq t_1 w$. Thus $t_1 t_2 \dots t_{k+1} \leq w$ by Lemma 2.4(ii).

To prove the statement for the length, note that since $t_2 \dots t_{k+1} \leq t_1 w$, then $l_T(t_1 w) = l_T(t_2 \dots t_{k+1}) + l_T(t_{k+1} \dots t_2 t_1 w)$. Equivalently, $l_T(w) - 1 = k + l_T(w) - l_T(t_1 \dots t_{k+1})$ by the inductive assumption and the fact that $t_1 \dots t_{k+1} \leq w$. Thus $l_T(t_1 \dots t_{k+1}) = k + 1$, which completes our proof. $\square$

In view of (6) and the remarks following it, the total order (7) of the set of almost positive roots $\Phi_{\geq -1}$ can be reformulated as follows:

$$(11) \quad \begin{aligned} & -\Pi_- \prec \underbrace{\Pi_+ \prec \gamma(-\Pi_-)}_{d=1} \prec \underbrace{\gamma(\Pi_+) \prec \gamma^2(-\Pi_-)}_{d=2} \prec \gamma^2(\Pi_+) \prec \cdots \prec \\ & \prec \gamma^{-1}(-\Pi_+) \prec \Pi_- \prec -\Pi_+. \end{aligned}$$

LEMMA 3.6.

- (i) If $\alpha, \beta \in \Phi^+$ and $d(\alpha) < d(\beta)$, then $\alpha \prec \beta$.
- (ii) If $\alpha \in \Phi^+$, $\beta \in \Phi^+ \setminus \Pi_+$, and $d(\beta) \leq d(\alpha)$, then $\mathcal{R}(\beta) \prec \alpha$.

Proof. Part (i) follows from the fact that for the set of positive roots the degree d increases according to the total order $\prec$, as one may check from (11). To prove (ii), we have that since $\beta \in \Phi^+ \setminus \Pi_+$, then $\mathcal{R}(\beta) = \gamma^{-1}(\beta)$ by (9) so that $d(\mathcal{R}(\beta)) = d(\beta) - 1$. Thus $d(\mathcal{R}(\beta)) < d(\alpha)$, and therefore $\mathcal{R}(\beta) \prec \alpha$ by (i). $\square$

To prove Theorem 3.1 we use a criterion which determines when two colored almost positive roots in $\Phi_{\geq -1}^m$ are m -compatible. More precisely, we totally order the roots in $\Phi_{\geq -1}^m$ as follows:

$$(12) \quad (-\Pi_-)^1 \prec (\Phi^+)^1 \prec \cdots \prec (\Phi^+)^{m-1} \prec (\Phi^+)^m \prec (-\Pi_+)^1,$$

where the roots in each of the sets $(-\Pi_-)^1$, $(-\Pi_+)^1$, and $(\Phi^m)^k$, $1 \leq k \leq m$, are ordered as in (7). The following criterion generalizes Lemma 3.2(i). We make the convention that $r_{\alpha^i} = r_\alpha$ for every colored root $\alpha^i \in \Phi_{\geq -1}^m$.

PROPOSITION 3.7. *Let $\alpha^i, \beta^j \in \Phi_{\geq -1}^m$, with $\alpha^i \prec \beta^j$ in the total order (12). The roots α^i, β^j are m -compatible if and only if $\mathbf{1} \neq r_{\beta^j} r_{\alpha^i} \leq \gamma$.*

Proof. Let $\alpha^i, \beta^j \in \Phi_{\geq -1}^m$, with $\alpha^i \prec \beta^j$ in the total order (12). We distinguish cases:

(i) $i = j$. Notice that if $i = j$, then $\alpha^i \prec \beta^j$ in the total order (12) if and only if $\alpha \prec \beta$ in the total order (7). Moreover, recall by Definition 2.11 that roots of the same color are m -compatible if and only if they are compatible in the noncolored sense. Our claim then follows from Lemma 3.2(i).

(ii) $\beta^j \in \Phi_{>0}^m$, $i = 1$, and $\alpha^1 \in (-\Pi_-)^1$. Recall that the roots $\alpha^1 \in (-\Pi_-)^1$ and $\beta^j \in \Phi_{\geq -1}^m$ are m -compatible if and only if the roots $\alpha \in -\Pi, \beta \in \Phi^+$ are compatible in the noncolored sense (Theorems 2.10(ii) and 2.13(ii)). Moreover, the roots in $-\Pi_-$ precede all roots in Φ^+ in the total order (7). Thus $\alpha \in -\Pi_-$ and $\beta \in \Phi^+$ are compatible if and only if $\mathbf{1} \neq r_\beta r_\alpha \leq \gamma$ by Lemma 3.2(i).

(ii)' $\alpha^i \in \Phi_{>0}^m$, $j = 1$, and $\beta^1 \in (-\Pi_+)^1$. This case is symmetric to case (ii), bearing in mind that the roots in $-\Pi_+$ succeed all roots in Φ^+ .

(iii) $\alpha^i, \beta^j \in \Phi_{>0}^m$ and $i < j$. We first suppose that $d(\alpha) < d(\beta)$ so that $\alpha \prec \beta$ by Lemma 3.6(i). In this case, the roots α^i, β^j are m -compatible if and only if the noncolored roots α, β are compatible. By Lemma 3.2(i) we have that the roots α, β are compatible if and only if $\mathbf{1} \neq r_\beta r_\alpha \leq \gamma$, which proves our claim. Next, we suppose that $d(\alpha) \geq d(\beta)$ so that the roots α^i, β^j are m -compatible if and only if the roots $\alpha, \mathcal{R}(\beta)$ are compatible. We distinguish two cases:

Case 1: $\alpha \in \Phi^+$ and $\beta \in \Pi_+$. From (9) we have that $\mathcal{R}(\beta) = -\beta \in -\Pi_+$, and, since the roots in Φ^+ precede those in $-\Pi_+$, we have that $\alpha \prec \mathcal{R}(\beta)$. By Lemma 3.2(i), the roots $\alpha, \mathcal{R}(\beta)$ are compatible if and only if $\mathbf{1} \neq r_{\mathcal{R}(\beta)} r_\alpha \leq \gamma$. Since $r_{\mathcal{R}(\beta)} = r_{-\beta} = r_\beta$, then the roots $\alpha, \mathcal{R}(\beta)$ are compatible if and only if $\mathbf{1} \neq r_\beta r_\alpha \leq \gamma$, which is what we are after.

Case 2: $\alpha \in \Phi^+$ and $\beta \in \Phi^+ \setminus \Pi_+$. Since $d(\beta) \leq d(\alpha)$, then $\mathcal{R}(\beta) \prec \alpha$ by Lemma 3.6(ii). By Lemma 3.2(i) we have that the roots $\alpha, \mathcal{R}(\beta)$ are compatible if and only if $\mathbf{1} \neq r_\alpha r_{\mathcal{R}(\beta)} \leq \gamma$. We set $\alpha = \rho_i$, $\beta = \rho_j$, with $i \geq 0$ and $j \geq r+1$, and we notice that $\mathcal{R}(\rho_j) = \gamma^{-1}(\rho_j) = \rho_{j-n}$ by the definition of $\mathcal{R}$ and Lemma 3.4. We have $\mathbf{1} \neq r_\alpha r_{\mathcal{R}(\beta)} \leq \gamma \Leftrightarrow \mathbf{1} \neq r_{\rho_i} r_{\rho_{j-n}} \leq \gamma \Leftrightarrow \mathbf{1} \neq r_{\rho_i} r_{\rho_{j-n}} \leq \gamma \Leftrightarrow \mu(\rho_i) \cdot \rho_{j-n} = 0 \Leftrightarrow \mu(\rho_j) \cdot \rho_i = 0 \Leftrightarrow \mathbf{1} \neq r_{\rho_j} r_{\rho_i} \leq \gamma \Leftrightarrow \mathbf{1} \neq r_\beta r_\alpha \leq \gamma$ by Lemmas 3.2(ii) and 3.3. Therefore, the roots $\alpha, \mathcal{R}(\beta)$ are compatible if and only if $\mathbf{1} \neq r_\beta r_\alpha \leq \gamma$, and this completes our proof. $\square$

Proof of Theorem 3.1. Let $\sigma \subseteq \Phi_{\geq -1}^m$. Recall that the set σ is a face of $\Delta^m(\Phi)$ if and only if any two roots $\alpha^i, \beta^j \in \sigma$ are m -compatible. We totally order the elements of the set σ in decreasing order with respect to (12). That is, we partition the set σ into the sets $\sigma_+, \sigma^m, \dots, \sigma^1, \sigma_-$, and we totally order them as follows:

$$(13) \quad \sigma_+, \sigma^m, \sigma^{m-1}, \dots, \sigma^1, \sigma_-,$$

where the roots in each of the sets σ_+, σ_- , and σ^k , $1 \leq k \leq m$, are in decreasing order with respect to (7). The criterion of Proposition 3.7 implies that the roots in σ are m -compatible if and only if for any two roots $\alpha^i, \beta^j \in \sigma$, with $\alpha^i \prec \beta^j$, we have $r_{\beta^j} r_{\alpha^i} \leq \gamma$. This, in view of Lemma 3.5 and the total ordering (13) of the roots in σ , implies that σ is a face of $\Delta^m(\Phi)$ if and only if $w_{\sigma_+} w_{\sigma^m} w_{\sigma^{m-1}} \dots w_{\sigma^1} w_{\sigma_-} \leq \gamma$ and $l_T(w_{\sigma_+} w_{\sigma^m} w_{\sigma^{m-1}} \dots w_{\sigma^1} w_{\sigma_-}) = |\sigma|$, which completes our proof.

Remark 3.8. Note that the total order (7) of the set of almost positive roots $\Phi_{\geq -1}$ can be expressed in terms of the map $\mathcal{R}$ as follows:

$$(14) \quad \begin{aligned} -\Pi_- < \Pi_+ < \mathcal{R}^{-1}(-\Pi_-) < \mathcal{R}^{-1}(\Pi_+) < \mathcal{R}^{-2}(-\Pi_-) < \mathcal{R}^{-2}(-\Pi_+) < \dots \\ < \mathcal{R}(-\Pi_+) < \Pi_- < -\Pi_+. \end{aligned}$$

However, this property does not generalize when $m > 1$. That is, the total order (12) of the set of colored almost positive roots $\Phi_{\geq -1}^m$ is not the one suggested by $\mathcal{R}_m$.

4. The EL-labeling and decreasing chains in $NC_{(m)}(\gamma)$. In this section we describe the EL-labeling that $NC_{(m)}(\gamma)$ inherits from $NC(\gamma)$ and explain the relation of decreasing chains with respect to this EL-labeling to facets of $\Delta_+^m(\Phi)$. The idea for the EL-labeling was suggested by Armstrong (see [1, section 3.7]).

Since $NC(\gamma)$ admits an EL-labeling, so does $(NC(\gamma))^m$, by Proposition 2.7. Moreover, recall that $NC_{(m)}(\gamma)$ is an order ideal in $(NC(\gamma))^m$ so that we can restrict the EL-labeling of the latter to the former. The labeling that $NC_{(m)}(\gamma)$ inherits from $(NC(\gamma))^m$ is the following. If $(w_1, \dots, w_m) \rightarrow (w'_1, \dots, w'_m)$ in $NC_{(m)}(\gamma)$, then there exists some $1 \leq i_0 \leq m$ such that $w_i = w'_i$ for all $1 \leq i \neq i_0 \leq m$ and $w_{i_0} \leq w'_{i_0} = w_{i_0} t_{i_0}$ for some reflection t_{i_0} in W . We label the edge $(w_1, \dots, w_m) \rightarrow (w'_1, \dots, w'_m)$ by $(\mathbf{1}, \dots, \mathbf{1}, t_{i_0}, \mathbf{1}, \dots, \mathbf{1})$, with t_{i_0} in the i_0 th entry, and we call this the *natural edge labeling* of $NC_{(m)}(\gamma)$. Let Λ be the set of m -tuples $(\mathbf{1}, \dots, r_\alpha, \dots, \mathbf{1})$, where r_α is the reflection corresponding to the root α . Following (4), we totally order the elements of Λ by letting

$$(15) \quad (\mathbf{1}, \dots, r_\alpha, \dots, \mathbf{1}) \preceq (\mathbf{1}, \dots, r_{\alpha'}, \dots, \mathbf{1})$$

with the reflection on the i th and i' th entries, respectively, if and only if

$$i = i' \quad \text{and} \quad \alpha \preceq \alpha' \quad \text{or} \\ i > i'.$$

The preceding discussion leads us to the following result. We should point out that the following proposition is part of a stronger result [1, Theorem 3.7.2], namely, that the poset $NC_{(m)}(\gamma) \cup \{\hat{1}\}$ of m -divisible noncrossing partitions with a maximal element adjoined is EL-shellable.

PROPOSITION 4.1. *If Λ is totally ordered as in (15), then the natural edge labeling of $NC_{(m)}(\gamma)$ is an EL-labeling.*

Let $[\hat{0}, w]$ be an interval in $NC_{(m)}(\gamma)$. Our next goal is to relate the maximal decreasing chains of $[\hat{0}, w]$ to facets of certain subcomplexes of $\Delta_+^m(\Phi)$. For a fixed $w = (w_1, \dots, w_m) \in NC_{(m)}(\gamma)$ we define $\Delta_+^m(w)$ as the induced subcomplex of $\Delta_+^m(\Phi)$ on the vertex set of colored positive roots $\alpha^i \in \Phi_{>0}^m$, with $r_{\alpha^i} \leq w_{m-i+1}$. By Lemmas 3.2(i) and 3.5 and the fact that m -compatible roots of the same color are compatible, we deduce that $\Delta_+^m(w)$ is the simplicial complex whose faces are the sets $\sigma \subseteq \Phi_{>0}^m$ with $(w_{\sigma^m}, \dots, w_{\sigma^1}) \leq (w_1, \dots, w_m)$. Equivalently, the faces of $\Delta_+^m(w)$ are the sets $\sigma \subseteq \Phi_{>0}^m$ with $w_{\sigma^i} \leq w_{m-i+1}$ for all $1 \leq i \leq m$. The complex $\Delta_+^m(w)$ is the simplicial join of $\Delta_+(w_i)$, $1 \leq i \leq m$, and therefore it is pure of dimension $rk(w) - 1$.

Now consider $w = (w_1, \dots, w_m) \in NC_{(m)}(\gamma)$ with $rk(w) = k$, and write $\hat{0} = (\mathbf{1}, \dots, \mathbf{1})$. If C is a maximal decreasing chain in $[\hat{0}, w]$, then we can decompose it into m unrefinable parts C_i as follows. We define C_i to be the unrefinable subchain of C whose edge labels have a reflection on the i th entry. Clearly, in view of the total

order (15), C is the chain formed by arranging the subchains C_i one following the other, starting with C_1 and terminating with C_m . Next, consider the subsets of Φ^+ defined by

$$\begin{aligned} \sigma(C_i) &= \{\alpha \in \Phi^+ : (\mathbf{1}, \dots, r_\alpha, \dots, \mathbf{1}) \text{ is an edge label on } C_i\} \\ &= \{\alpha \in \Phi^+ : (\mathbf{1}, \dots, r_\alpha, \dots, \mathbf{1}) \text{ is an edge label on } C \\ &\quad \text{with } r_\alpha \text{ on the } i\text{th coordinate}\} \end{aligned}$$

for $1 \leq i \leq m$. Let $w_{\sigma(C_i)}$ be the product of reflections corresponding to the roots in $\sigma(C_i)$ in decreasing order with respect to (7). By (15), this is the order in which these reflections appear on the edge labels of C . Thus $w_{\sigma(C_i)} = w_i$, and therefore $(w_{\sigma(C_1)}, \dots, w_{\sigma(C_m)}) \in NC_{(m)}(\gamma)$. By Theorem 1.1, if we color the roots in each $\sigma(C_i)$ by $m - i + 1$, we obtain a face of $\Delta_+^m(\Phi)$ and in particular a facet of $\Delta_+^m(w)$.

Conversely, let σ be a facet of $\Delta_+^m(w)$, so that $w_{\sigma^{m-i+1}} = w_i$ for all $1 \leq i \leq m$. Consider the set

$$\Lambda_\sigma := \{(\mathbf{1}, \dots, r_{\alpha^i}, \dots, \mathbf{1}) : \alpha^i \in \sigma^i \text{ and } r_{\alpha^i} \text{ on the } (m - i + 1)\text{th entry}, 1 \leq i \leq m\},$$

and order its elements in decreasing order with respect to (15). Now we construct by induction a decreasing chain C_σ in the interval $[\hat{0}, w]$ of $NC_{(m)}(\gamma)$ as follows. The first element of C is $(\mathbf{1}, \dots, \mathbf{1})$. Suppose that we have found the first $k + 1$ elements of C_σ by using the first k (in the total order (15)) elements of Λ_σ . If the $(k + 1)$ th element of C_σ is $(u_1, \dots, u_m)$ and the $(k + 1)$ th element of Λ_σ is $(\mathbf{1}, \dots, r_{\alpha_j}, \dots, \mathbf{1})$, with r_{α_j} on the j th coordinate, then the $(k + 2)$ th element of the chain C_σ is $(u_1, \dots, u_{j-1}, r_{\alpha_j} u_j, u_{j+1}, \dots, u_m)$.

We summarize the above facts in the following proposition.

PROPOSITION 4.2. *Let $w = (w_1, \dots, w_m) \in NC_{(m)}(\gamma)$, and let C be a maximal decreasing chain in $[\hat{0}, w]$. The map which sends C to $\bigcup_{i=1}^m \sigma(C_i)^{m-i+1}$ is a bijection from the set of maximal decreasing chains of $[\hat{0}, w]$ to the set of facets of $\Delta_+^m(w)$.*

In the case $m = 1$ the next corollary reduces to the remark following Corollary 4.3 in [5].

COROLLARY 4.3. *The set of maximal decreasing chains in $NC_{(m)}(\gamma)$ bijects to the set of facets of $\Delta_+^m(\Phi)$.*

Proof. The set of maximal decreasing chains in $NC_{(m)}(\gamma)$ is the disjoint union of the sets of such chains within each $[\hat{0}, w]$ with $rk(w) = n$. Moreover, the set of facets of $\Delta_+^m(\Phi)$ is the disjoint union of the set of facets of each $\Delta_+^m(w)$, where $rk(w) = n$. Our claim then follows from Proposition 4.2. $\square$

The reader is invited to verify Corollary 4.3 in the following example.

Example 4.4. Consider the root system A_2 , and identify the corresponding reflection group W_{A_2} with the group of permutations on the set $\{1, 2, 3\}$. Let $\sigma_1, \sigma_2, \alpha$ be the standard choice of positive roots, where σ_1, σ_2 are simple roots and $\alpha = \sigma_1 + \sigma_2$. More precisely, the reflection in the hyperplane of $\mathbb{R}^3$ orthogonal to each of σ_1, σ_2 , and α acts on $\mathbb{R}^3$ by transposing coordinates, so that $r_{\alpha_1} = (12)$, $r_{\alpha_2} = (23)$, and $r_\alpha = (13)$. We set $\Pi_+ = \{\sigma_1\}$, $\Pi_- = \{\sigma_2\}$ so that $\sigma_1 \prec \alpha \prec \sigma_2$. The bipartite Coxeter element in this case is $\gamma = (123)$. Figure 1 illustrates the natural edge labeling of $NC_{(2)}(\gamma)$. The set of maximal decreasing chains in $NC_{(2)}(\gamma)$ bijects to the set of

FIG. 1. The EL-labeling of $NC_2((123))$ for $\Phi = A_2$. The decreasing chains are marked with dashed lines.

positive clusters as shown in the following table.

Edge labels of decreasing chains	Positive clusters
$(1, (23)) \rightarrow (1, (13))$	σ_2^1, α^1
$(1, (13)) \rightarrow (1, (12))$	α^1, σ_1^1
$((23), 1) \rightarrow (1, (13))$	σ_2^2, α^1
$((23), 1) \rightarrow ((13), 1)$	σ_2^2, α^2
$((12), 1) \rightarrow (1, (23))$	σ_1^2, σ_2^1
$((13), 1) \rightarrow ((12), 1)$	α^2, σ_1^1
$((13), 1) \rightarrow (1, (12))$	α^2, σ_1^1

LEMMA 4.5. For $w = (w_1, \dots, w_m) \in NC_{(m)}(\gamma)$ the number $(-1)^{rk(w)} \mu(\hat{0}, w)$ is equal to the number of facets of $\Delta_+^m(w)$.

Proof. A standard fact on Möbius functions of EL-shellable posets is that the Möbius function on every interval $[a, b]$ is equal to $(-1)^{rk(b) - rk(a)}$ times the number of maximal decreasing chains in $[a, b]$ [19, section 3.13]. Applying this in our case with $a = \hat{0}$ and $b = w$, we deduce that $(-1)^{rk(w)} \mu(\hat{0}, w)$ is equal to the number of maximal decreasing chains in $[\hat{0}, w]$ which, in view of Proposition 4.2, is equal to the number of facets of $\Delta_+^m(w)$. $\square$

5. Proof of Theorem 1.2. As pointed out in [17, Proposition F(i)], for any finite root systems Φ and Φ' we have

$$F_{\Phi \times \Phi'}^{(m)}(x, y) = F_{\Phi}^{(m)}(x, y) \cdot F_{\Phi'}^{(m)}(x, y).$$

Moreover, by the multiplicativity of the Möbius function, the above relation holds for the M -triangle as well. Therefore, it suffices to prove Theorem 1.2 in the case where Φ is irreducible.

The h -polynomial of an abstract $(n - 1)$ -dimensional simplicial complex Δ is defined as

$$h(\Delta, y) = \sum_{i=0}^n f_i(\Delta) y^i (1 - y)^{n-i},$$

where $f_i(\Delta)$ is the number of faces of Δ of dimension $i - 1$. The link of a face σ of Δ is the abstract simplicial complex $\text{lk}_\Delta(\sigma) = \{\tau \setminus \sigma : \sigma \subseteq \tau \in \Delta\}$. One can check by comparing the table in [1, Figure 3.4] and [14, Theorem 10.2] that for any irreducible root system Φ the h -polynomial of $\Delta^m(\Phi)$ coincides with the rank-generating polynomial of $NC_{(m)}(\gamma)$, and thus

$$h(\Delta^m(\Phi), y) = \sum_{w \in NC_{(m)}(\gamma)} y^{rk(w)}.$$

The following lemma will be used as in [4]. For $\alpha \in \Pi$ we denote by Φ_α the standard parabolic root subsystem obtained by intersecting Φ with the linear span of $\Pi \setminus \{\alpha\}$.

LEMMA 5.1. *Let Φ be irreducible, $\alpha \in \Pi$, and $\sigma \subseteq \Phi_{>-1}^m$.*

(i) *For $\sigma \in \Delta^m(\Phi)$ we have $-\alpha \in \sigma$ if and only if $\sigma \setminus \{-\alpha\} \in \Delta^m(\Phi_\alpha)$.*

(ii) *For any $\beta^\ell \in \Phi_{>0}^m$ there exists i such that $\mathcal{R}_m^i(\beta^\ell) \in (-\Pi)$.*

(iii) *$\sigma \in \Delta^m(\Phi)$ if and only if $\mathcal{R}_m(\sigma) \in \Delta^m(\Phi)$.*

Proof. Part (i) can be verified from [14, Theorem 3.7]. Part (ii) follows from Definition 2.12 and the fact that for every $\beta \in \Phi^+$ there exists some j such that $\mathcal{R}^j(\beta) \in (-\Pi)$ [15, section 3]. Finally, part (iii) is clear from Theorem 2.13(i). $\square$

We continue with some technical lemmas required in the proof of Theorem 1.2.

LEMMA 5.2. *If σ is a face of $\Delta = \Delta^m(\Phi)$ and $w_\sigma = w_{\sigma_+} w_{\sigma^m} w_{\sigma^{m-1}} \dots w_{\sigma^1} w_{\sigma_-}$, then*

$$h(\text{lk}_\Delta(\sigma), y) = \sum_{\alpha \in NC_{(m)}(\gamma w_\sigma^{-1})} y^{rk(\alpha)}.$$

Proof. The proof is analogous to the proof of [4, Lemma 2.6], replacing $\mathcal{R}$ by $\mathcal{R}_m$ and using Lemma 5.1. $\square$

LEMMA 5.3. *If $(a_1, \dots, a_m) \leq (b_1, \dots, b_m)$ in $NC_{(m)}(\gamma)$, then $(a_1^{-1}b_1, \dots, a_m^{-1}b_m) \in NC_{(m)}(\gamma)$ and the intervals $I = [(a_1, \dots, a_m), (b_1, \dots, b_m)]$ and $I' = [(\mathbf{1}, \dots, \mathbf{1}), (a_1^{-1}b_1, \dots, a_m^{-1}b_m)]$ are isomorphic.*

Proof. Let $(a_1, \dots, a_m) \leq (b_1, \dots, b_m)$ in $NC_{(m)}(\gamma)$ so that $a_i \leq b_i$ for all $1 \leq i \leq m$. It follows from Lemma 2.3(iii) that since $a_i \leq b_i$, then $a_i^{-1}b_i \leq b_i$. Hence $(a_1, a_1^{-1}b_1, \dots, a_m, a_m^{-1}b_m)$ is a minimal factorization of $b_1 \dots b_m$, and in view of Lemma 2.2(iii) we have that $(a_1^{-1}b_1, \dots, a_m^{-1}b_m) \in NC_{(m)}(\gamma)$. This proves the first part of our statement.

Next, we define the map $\varphi : I \rightarrow I'$ with $\varphi((w_1, \dots, w_m)) = (a_1^{-1}w_1, \dots, a_m^{-1}w_m)$. To prove that the intervals I and I' are isomorphic, we claim that φ is an order-preserving bijection and that its inverse φ^{-1} is order-preserving as well. We first have to check that φ and φ^{-1} are well-defined. Indeed, if $(w_1, \dots, w_m) \in I$, then $(a_1, a_1^{-1}w_1, \dots, a_m, a_m^{-1}w_m)$ is a minimal factorization of $w_1 \dots w_m$, and therefore $(a_1^{-1}w_1, \dots, a_m^{-1}w_m) \in NC_{(m)}(\gamma)$ by Lemma 2.2(iii). Conversely, let $(w_1, \dots, w_m) \in I'$ so that $w_i \leq a_i^{-1}b_i \leq b_i$ for $1 \leq i \leq m$. In view of Lemma 2.3(i) we have $a_i \leq a_i w_i \leq b_i$, and therefore $(a_1 w_1, w_1^{-1} a_1^{-1} b_1, \dots, a_m w_m, w_m^{-1} a_m^{-1} b_m)$ is a minimal factorization of $b_1 \dots b_m$. Thus $(a_1 w_1, \dots, a_m w_m) \in NC_{(m)}(\gamma)$ as in the previous situation. It is immediate to see that φ is a bijection. Moreover, by the fact that $a_i \leq w_i \leq b_i$ if and only if $a_i^{-1}w_i \leq a_i^{-1}b_i$ (Lemma 2.3(i)), we deduce that both φ and φ^{-1} are order-preserving. This completes our proof. $\square$

LEMMA 5.4. *Let $(w_1, \dots, w_m) \in NC_{(m)}(\gamma)$. There is a rank-preserving bijection between the sets $A = \{(a_1, \dots, a_m) : (a_1, \dots, a_m) \leq (a_1 w_1, \dots, a_m w_m) \text{ in } NC_{(m)}(\gamma)\}$ and $NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})$.*

Proof. Let $a'_i = w_1 \dots w_{i-1} a_i w_{i-1}^{-1} \dots w_1^{-1}$ for $1 \leq i \leq m$, and consider the map $\phi(a_1, \dots, a_m) = (a'_1, \dots, a'_m)$. We will prove that ϕ is a rank-preserving bijection between the sets A and $NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})$. Clearly, the map ϕ as well as its inverse $\phi^{-1}(a'_1, \dots, a'_m) = (a_1, \dots, a_m)$, with $a_i = w_{i-1}^{-1} \dots w_1^{-1} a'_i w_1 \dots w_{i-1}$, are injective. Moreover, since a_i, a'_i are conjugate, then $l_T(a_i) = l_T(a'_i)$, and therefore ϕ is rank-preserving. So it suffices to prove that ϕ is well-defined. To this end let $(a_1, \dots, a_m) \in A$, and note that $a'_1 \dots a'_m = (a_1 w_1 \dots a_m w_m) w_m^{-1} \dots w_1^{-1}$. Since $a_i \leq a_i w_i$, then $l_T(a_i w_i) = l_T(a_i) + l_T(w_i)$, and therefore $(a_1, w_1, \dots, a_m, w_m)$ is a minimal factorization of $a_1 w_1 \dots a_m w_m$. Thus, by Lemma 2.2(iii) we have

$$w_1 \dots w_m \leq a_1 w_1 \dots a_m w_m \leq \gamma,$$

with $l_T(w_1 \dots w_m) = \sum_{i=1}^m l_T(w_i)$. In view of Lemma 2.4(ii) this implies that

$$(a_1 w_1 \dots a_m w_m) w_m^{-1} \dots w_1^{-1} \leq \gamma w_m^{-1} \dots w_1^{-1},$$

with $l_T((a_1 w_1 \dots a_m w_m) w_m^{-1} \dots w_1^{-1}) = \sum_{i=1}^m l_T(a_i)$. Equivalently, $a'_1 \dots a'_m \leq \gamma w_m^{-1} \dots w_1^{-1}$ and $l_T(a'_1 \dots a'_m) = \sum_{i=1}^m l_T(a_i) = \sum_{i=1}^m l_T(a'_i)$, which shows that indeed $(a'_1, \dots, a'_m) \in NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})$.

For the converse, let $(a'_1, \dots, a'_m) \in NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})$, and notice that $a_1 w_1 \dots a_m w_m = a'_1 \dots a'_m w_1 \dots w_m$. Since $a'_1 \dots a'_m \leq \gamma w_m^{-1} \dots w_1^{-1} \leq \gamma$, then by Lemma 2.3(ii) we have $a'_1 \dots a'_m w_1 \dots w_m \leq \gamma$, with $l_T(a'_1 \dots a'_m w_1 \dots w_m) = \sum_{i=1}^m l_T(a'_i) + \sum_{i=1}^m l_T(w_i)$. This forces $(a_1 w_1, \dots, a_m w_m) \in NC_{(m)}(\gamma)$. We next prove that $(a_1, \dots, a_m) \leq (a_1 w_1, \dots, a_m w_m)$. We have $a'_i \leq \gamma w_m^{-1} \dots w_1^{-1}$ or, equivalently, $w_1 \dots w_{i-1} a_i w_{i-1}^{-1} \dots w_1^{-1} \leq \gamma w_m^{-1} \dots w_1^{-1}$. In view of Lemma 2.5 this implies that $a_i \leq w_{i-1}^{-1} \dots w_1^{-1} \gamma w_m^{-1} \dots w_i^{-1}$. By Lemma 3.8 and elementary calculations one may check that $w_{i-1}^{-1} \dots w_1^{-1} \gamma w_m^{-1} \dots w_i^{-1} \leq w_{i-1}^{-1} \dots w_1^{-1} \gamma w_i^{-1} \leq \gamma w_i^{-1}$. Thus $a_i \leq \gamma w_i^{-1} \leq \gamma$, and therefore $a_i \leq a_i w_i \leq \gamma$ by Lemma 2.3(ii). This completes our proof. $\square$

Proof of Theorem 1.2. To simplify notation let us write Δ^m , Δ_+^m , $F(x, y)$, and $M(x, y)$ instead of $\Delta^m(\Phi)$, $\Delta_+^m(\Phi)$, $F_\Phi^{(m)}(x, y)$, and $M_W^{(m)}(x, y)$, respectively. We use the relation

$$(16) \quad (1-y)^n F\left(\frac{x+y}{1-y}, \frac{y}{1-y}\right) = \sum_{\sigma \in \Delta_+^m} x^{|\sigma|} h(\text{lk}_{\Delta^m}(\sigma), y),$$

which appears in the course of the proof of [4, Theorem 1.1] and can be generalized straightforwardly in the case where $m \geq 1$. We have

$$M(-x, -y/x) = \sum_{\substack{a \leq b \\ a, b \in NC_{(m)}(\gamma)}} \mu(a, b) (-x)^{rk(b) - rk(a)} y^{rk(a)}.$$

Let $\hat{0} = (\mathbf{1}, \dots, \mathbf{1})$, $w = (w_1, \dots, w_m) = (a_1^{-1} b_1, \dots, a_m^{-1} b_m)$, and note that $rk(w) = rk(b) - rk(a)$. In view of Lemmas 5.3 and 5.4 the last sum becomes

$$\sum_{w \in NC_{(m)}(\gamma)} \mu(\hat{0}, w) (-x)^{rk(w)} \sum_{a' \in NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})} y^{rk(a')},$$

which by Lemma 4.5 is equal to

$$\sum_{w \in NC_{(m)}(\gamma)} \sum_{\substack{\sigma \in \Delta_+^m(w) \\ |\sigma| = rk(w)}} x^{rk(w)} \sum_{a' \in NC_{(m)}(\gamma w_m^{-1} \dots w_1^{-1})} y^{rk(a')}.$$

If σ is a facet of $\Delta_+^m(w)$, then $w_\sigma = w_{\sigma^m} \dots w_{\sigma^1} = w_1 \dots w_m$, and thus the last expression is equal to

$$\sum_{w \in NC_{(m)}(\gamma)} \sum_{\substack{\sigma \in \Delta_+^m(w) \\ |\sigma| = rk(w)}} x^{|\sigma|} \sum_{a' \in NC_{(m)}(\gamma w_\sigma^{-1})} y^{rk(a')}$$

or, in view of Lemma 5.2,

$$\sum_{w \in NC_{(m)}(\gamma)} \sum_{\substack{\sigma \in \Delta_+^m(w) \\ |\sigma| = rk(w)}} x^{|\sigma|} h(\text{lk}_{\Delta^m}(\sigma), y).$$

Observe that the sets of facets of the subcomplexes $\Delta_+^m(w)$ for $w \in NC_{(m)}(\gamma)$ form a partition of Δ_+^m , so that the last sum is

$$\sum_{\sigma \in \Delta_+^m} x^{|\sigma|} h(\text{lk}_{\Delta^m}(\sigma), y),$$

which, in view of (16), is equal to

$$(1 - y)^n F\left(\frac{x + y}{1 - y}, \frac{y}{1 - y}\right),$$

and this completes our proof. $\square$

SWITCHING OPERATIONS FOR HADAMARD MATRICES*

WILLIAM P. ORRICK†

Abstract. We define several operations that switch substructures of Hadamard matrices, thereby producing new, generally inequivalent, Hadamard matrices. These operations have application to the enumeration and classification of Hadamard matrices. To illustrate their power, we use them to greatly improve the lower bounds on the number of equivalence classes of Hadamard matrices in orders 32 and 36 to 3,578,006 and 18,292,717.

Key words. Hadamard equivalence, Hadamard matrix, integer equivalence, Smith normal form, Hadamard code

AMS subject classifications. Primary, 05B20; Secondary, 11C20, 15A36, 94B05

DOI. 10.1137/050641727

1. Introduction. Two matrices, A and B , with entries in the set $\{-1, 1\}$ are *Hadamard equivalent* if B can be obtained from A by some sequence of

- row negations,
- column negations,
- row permutations, and
- column permutations.

Hadamard equivalence is so named because of its connection with Hadamard matrices, defined as square matrices with elements equal to ± 1 whose rows are mutually orthogonal. The listed moves all preserve the property of being a Hadamard matrix.

In this paper, we describe some additional moves, called *switching operations*, that preserve the property of being a Hadamard matrix. These operations, when applied over and over again to a seed matrix, generally produce many inequivalent Hadamard matrices.

Furthermore, adjoining the new operations to the list above gives new notions of equivalence. These weaker notions of equivalence may be useful in the classification of Hadamard matrices since they partition the set of Hadamard matrices into a much smaller number of equivalence classes than does Hadamard equivalence, but at the same time provide an effective method for enumerating the elements of these newly defined equivalence classes.

Extensive calculation indicates that the number of Hadamard equivalence classes that can be constructed using the new operations is enormous. This is a big step forward since, although complete enumerations up to order 28 suggest that the number of equivalence classes grows rapidly in higher order, until now there has been no general method for producing the vast numbers of equivalence classes that we expect to exist. The many known Hadamard matrix construction techniques typically apply only in scattered orders, or tend to produce Hadamard matrices with special features such as large automorphism groups, large Hadamard submatrices, or self-duality.

†Department of Mathematics, Indiana University, Bloomington, IN 47405 (worrick@indiana.edu).

The most prolific method for constructing Hadamard matrices has been to use two Hadamard matrices A and B , both of size n , to build Hadamard matrices of size $2n$,

$$(1.1) \quad H = \begin{bmatrix} A & PB \\ A & -PB \end{bmatrix} \quad \text{and} \quad \tilde{H} = \begin{bmatrix} A & A \\ BP & -BP \end{bmatrix},$$

where P is any permutation matrix. Both A and B can be taken from any equivalence class. In order 32, Lin, Wallis, and Lie [25] produced at least 66099 inequivalent matrices from the five equivalence classes in order 16. Since the resulting matrices contain Hadamard submatrices of order 16, however, they cannot be considered generic. In contrast, the new operations produce at least 3.57 million equivalence classes, most of which do not contain Hadamard submatrices of order 16.

Lam, Lam, and Tonchev [22, 23] have exercised great ingenuity in deriving lower bounds on the number of Hadamard matrices of size $2n$ of the form (1.1) and have produced spectacularly large bounds in orders 40 and higher. If the lessons learned from order 32 are any guide, the true numbers of Hadamard equivalence classes in these orders are far greater still.

Our results are even more striking in orders congruent to 4 (mod 8) since the construction (1.1) does not apply. The previously known equivalence classes in order 36 numbered in the hundreds. By the new methods, at least 18.29 million classes can be produced.

The seed matrices used to obtain all these new equivalence classes were derived from the Hadamard matrix literature up to 2005. After this work was substantially complete, Bouyukliev, Fack, and Winne announced the classifications of 2-(31, 15, 7) and 2-(35, 17, 8) designs with automorphisms of odd prime order. From these designs, they found tens of thousands of new Hadamard equivalence classes in orders 32 and 36 [4, 5]. Most of these matrices have not yet been analyzed by our method. Compared with the analysis of the dozens of previously known Hadamard equivalence classes in order 32 (excluding the matrices from construction (1.1)), and the hundreds of previously known H-classes in order 36, analyzing these new matrices is a major undertaking and will require considerable optimization of our methods. Therefore, with one important exception, we have not used the matrices of Bouyukliev, Fack, and Winne in our enumeration, although we make a few remarks on our preliminary analysis in the next paragraph. The exception is a matrix of order 36 in Smith class 16 (defined in section 4.3), no previous example of which appears to have been known. This was used as a seed matrix to produce a new family containing at least five million Hadamard equivalence classes.

In orders 4, 8, 12, 16, 20, 24, 28 the numbers of Hadamard equivalence classes are known to be 1, 1, 1, 5, 3, 60, 487 [11, 12, 13, 18, 19]. We define a weaker notion of equivalence, which we call *Q-equivalence*, by adjoining the new operations to the operations that define Hadamard equivalence. The numbers of Q-equivalence classes are 1, 1, 1, 1, 1, 2, 2. In order 32, we find that the 3.57 million known Hadamard equivalence classes are grouped into 11 Q-equivalence classes, and that in order 36, the 18.29 million known equivalence classes are grouped into 21 Q-equivalence classes. As mentioned above, these numbers do not include Hadamard equivalence classes or Q-equivalence classes derived from the recently discovered matrices of Bouyukliev, Fack, and Winne. An analysis of their matrices should provide a good test of the ideas of this paper regarding using Q-equivalence in classifying Hadamard matrices. Preliminary analysis of a sampling of the new matrices does not turn up any new large Q-classes

but does indicate the presence of a large number of new small Q-classes (perhaps in the hundreds or more). We intend to make a complete enumeration of these and a full analysis of all the new matrices. The results will be presented in a follow-up to the present paper.

2. Overview of switching. Suppose that an $n \times n$ Hadamard matrix can be put in the form

$$(2.1) \quad \begin{bmatrix} \mathbf{1} & \cdots & \mathbf{1} & - & \cdots & - & - & \cdots & - & 1 & \cdots & 1 \\ \mathbf{1} & \cdots & \mathbf{1} & - & \cdots & - & 1 & \cdots & 1 & - & \cdots & - \\ \mathbf{1} & \cdots & \mathbf{1} & 1 & \cdots & 1 & - & \cdots & - & - & \cdots & - \\ \mathbf{1} & \cdots & \mathbf{1} & 1 & \cdots & 1 & 1 & \cdots & 1 & 1 & \cdots & 1 \\ & a_5 & & b_5 & & c_5 & & d_5 & & & & \\ & \vdots & & \vdots & & \vdots & & \vdots & & & & \\ & a_n & & b_n & & c_n & & d_n & & & & \end{bmatrix},$$

where a_i , b_i , c_i , and d_i are $\{-1, 1\}$ -vectors of length $n/4$. The columns of the matrix have been grouped into four sets of $n/4$ columns each. A new, generally inequivalent, Hadamard matrix can be obtained by negating the $4 \times \frac{n}{4}$ block of 1's in the upper left corner (shown in boldface). We call this operation *switching a closed quadruple*.

Suppose instead that we can put the matrix in the form

$$(2.2) \quad \begin{bmatrix} 1 & - & - & - & \mathbf{1} & \cdots & \mathbf{1} & 1 & \cdots & 1 & 1 & \cdots & 1 & - & \cdots & - \\ - & 1 & - & - & \mathbf{1} & \cdots & \mathbf{1} & - & \cdots & - & - & \cdots & - & - & \cdots & - \\ - & - & 1 & - & \mathbf{1} & \cdots & \mathbf{1} & - & \cdots & - & 1 & \cdots & 1 & 1 & \cdots & 1 \\ - & - & - & 1 & \mathbf{1} & \cdots & \mathbf{1} & 1 & \cdots & 1 & - & \cdots & - & 1 & \cdots & 1 \\ \mathbf{1} & \mathbf{1} & \mathbf{1} & \mathbf{1} & & & & & & & & & & & & \\ \vdots & \vdots & \vdots & \vdots & A_{11} & & A_{12} & & A_{13} & & A_{14} & & & & & \\ \mathbf{1} & \mathbf{1} & \mathbf{1} & \mathbf{1} & & & & & & & & & & & & \\ - & 1 & 1 & - & & & & & & & & & & & & \\ \vdots & \vdots & \vdots & \vdots & A_{21} & & A_{22} & & A_{23} & & A_{24} & & & & & \\ - & 1 & 1 & - & & & & & & & & & & & & \\ - & 1 & - & 1 & & & & & & & & & & & & \\ \vdots & \vdots & \vdots & \vdots & A_{31} & & A_{32} & & A_{33} & & A_{34} & & & & & \\ - & 1 & - & 1 & & & & & & & & & & & & \\ 1 & 1 & - & - & & & & & & & & & & & & \\ \vdots & \vdots & \vdots & \vdots & A_{41} & & A_{42} & & A_{43} & & A_{44} & & & & & \\ 1 & 1 & - & - & & & & & & & & & & & & \end{bmatrix},$$

where the A_{ij} are square matrices of size $(n-4)/4$. A new, often inequivalent, matrix can be obtained by negating the all 1 block of size $4 \times \frac{n-4}{4}$ contained in the first four rows, and the all 1 block of size $\frac{n-4}{4} \times 4$ contained in the first four columns (both shown in boldface). We call this operation *switching a Hall set*.

Justification for these claims and further elaboration are given in the subsequent sections.

3. Closed quadruples and Hall sets.

3.1. 3-normalization. Let H be a Hadamard matrix of size n . Denote its rows by h_i and its elements by h_{ij} . Define the Hadamard product of two vectors to be

$$(a_1, \dots, a_n) \circ (b_1, \dots, b_n) := (a_1 b_1, \dots, a_n b_n).$$

Let j_k be the all 1 vector of length k .

DEFINITION 3.1. A Hadamard matrix of size n is 3-normalized on rows (i, j, k) if, in every column ℓ , the set $\{h_{i\ell}, h_{j\ell}, h_{k\ell}\}$ contains an even number of -1 's, or equivalently, if $h_i \circ h_j \circ h_k = j_n$.

3-normalization is a normalization of the columns. A 3-normalized matrix remains 3-normalized if any two of the rows i, j, k , or any single row other than i, j, k , is negated. Note that 3-normalization was introduced in [31]. The definition given here is slightly weaker in that it makes no stipulation that the row sums be positive and does not impose any particular ordering on the columns. In the next paragraph we restate some needed results from [31].

The field structure (C_1, C_2, C_3, C_4) of a 3-normalized Hadamard matrix of size n is the partition of the set of columns c into four classes, C_i , accordingly as

$$(h_{jc}, h_{kc}, h_{\ell c}) = (1, 1, 1), (-1, -1, 1), (-1, 1, -1), \text{ or } (1, -1, -1).$$

The four classes are called *fields* and are all of length $n/4$. In a row $r \notin \{j, k, \ell\}$ the sum of the elements in a field is the same for each of the four fields in the row. This follows from orthogonality of row r with rows j, k, ℓ . Since the sum of the entries in a field is even if $n/4$ is even, and odd if $n/4$ is odd, the row sum of row $r \notin \{j, k, \ell\}$ must be congruent to $n \pmod{8}$.

A quadruple of rows (i, j, k, ℓ) of a Hadamard matrix H of size n is said to be of *type* r , $0 \leq r \leq n/8$, if exactly $4r$ of the entries in $h_i \circ h_j \circ h_k \circ h_\ell$ equal -1 or exactly $4r$ entries equal $+1$. This notion was introduced by Kimura [19].

DEFINITION 3.2. A quadruple of rows (i, j, k, ℓ) of a Hadamard matrix H of size n is closed if $h_i \circ h_j \circ h_k \circ h_\ell = \pm j_n$.

A closed quadruple is a quadruple of type 0. Thus if H is 3-normalized on three rows of a closed quadruple, then the fourth will consist entirely of 1's or entirely of -1 's. The field structure is independent of which three rows of the closed quadruple are chosen.

Quadruples of type 1 will also play an important role in what follows. They were used extensively by Hall in the classification of Hadamard matrices of order 20 [12] and by Kimura in the classification for order 28 [20, 19]. If H is 3-normalized on three rows of a type-1 quadruple, then the fourth row will contain one odd-sign entry in each of the fields induced by the 3-normalization. Kimura and Ohmori referred to such quadruples as *Hall sets* [21].

PROPOSITION 3.3. If a Hadamard matrix of size n has a closed quadruple, then $n = 4$ or $n \equiv 0 \pmod{8}$.

Proof. Let (i, j, k, ℓ) be the closed quadruple. 3-normalize the matrix on rows i, j, k so that $h_\ell = \pm j_n$. Orthogonality implies that all rows except for h_ℓ have row sum 0. All row sums of rows other than i, j, k must be congruent to $n \pmod{8}$. If $n > 4$, this can happen only when $n \equiv 0 \pmod{8}$. $\square$

3.2. Obtaining new Hadamard matrices by switching closed quadruples.

DEFINITION 3.4. Let H be a Hadamard matrix of size n which has a closed quadruple, Q . Let (C_1, C_2, C_3, C_4) be the partition of columns induced by 3-normalization on Q . Switching the closed quadruple Q means negating all the elements h_{rc} , where $r \in Q$ and $c \in C_i$ for some $i \in \{1, 2, 3, 4\}$.

PROPOSITION 3.5. The matrix produced by switching a closed quadruple Q in a Hadamard matrix H is a Hadamard matrix.

Proof. Any matrix containing a closed quadruple is Hadamard equivalent to one of the form (2.1). It is evident that switching preserves orthogonality of the columns in that matrix. Since column orthogonality is preserved under the operations needed to put H in the form (2.1), the conclusion holds generally. $\square$

It appears that when $n > 8$, switching always produces a Hadamard matrix that is inequivalent to the original Hadamard matrix.

Note that the equivalence class of the Hadamard matrix produced by switching Q is independent of which of the four fields C_i we choose to negate. To see this, note that negating the closed quadruple elements in C_2 is equivalent to first negating the closed quadruple elements in C_1 , then negating all four rows of the closed quadruple, and finally performing a certain permutation of the rows of Q . The same holds for C_3 and C_4 .

3.3. More general row switching operations. It was observed by Denniston [7] in connection with symmetric $(25, 9, 3)$ designs that, starting from a design, a new inequivalent design can be obtained by switching a substructure known as an oval. Denniston's switching operation can be thought of as an operation that permutes certain elements of the incidence matrix of the design. In fact, if 0's are replaced with -1 's in the incidence matrix of a $(25, 9, 3)$ design, ovals satisfy our definition of a closed quadruple, and our switching operation is equivalent to Denniston's.

We can formulate more general switching operations acting on more general structures, which we will refer to generically as "designs." Consider a set, $\mathcal{M}$, of matrices of a fixed size which represent the designs in question. If $R \in \mathcal{M}$, we suppose that the elements of R are taken from some set $\mathcal{S}$, that the rows satisfy some set of properties $\mathcal{P}$, and furthermore, that R satisfies

$$R^T R = M,$$

where M is some fixed matrix. For example, if $\mathcal{M}$ represents $(25, 9, 3)$ designs, then $\mathcal{S} = \{0, 1\}$, the set $\mathcal{P}$ contains the property that every row of $R \in \mathcal{M}$ has exactly nine 1's, and $M = 6I + 3J$, where J is the 25×25 all 1 matrix. If $\mathcal{M}$ represents Hadamard matrices of size n , then $\mathcal{S} = \{-1, 1\}$, the set $\mathcal{P}$ is empty, and $M = nI$. Many other types of matrices and designs, including certain D-optimal designs, can also be defined within this framework.

Let $R \in \mathcal{M}$ and partition the incidence matrix into two submatrices, A and X ,

$$R = \begin{bmatrix} A \\ X \end{bmatrix}.$$

Now suppose that B is a matrix of the same dimensions as A , with elements taken from the same set $\mathcal{S}$, satisfying the same properties $\mathcal{P}$, and that $B^T B = A^T A$. Then the matrix obtained from R by replacing A with B is also a matrix of the original type.

Suppose, for example, that R is an $n \times n$ Hadamard matrix with an $m \times n$ submatrix A whose columns are all identical to columns of a particular $m \times m$ Hadamard matrix H_m or to negations of such columns. Let H'_m be another $m \times m$ Hadamard matrix. Denote column j of H_m by v_j and column j of H'_m by v'_j . Define $[a, b]$ to be the set of integers i satisfying $a \leq i \leq b$. For $j = 1, \dots, n$, let column j of A be $\sigma(j)v_{a(j)}$, where $\sigma : [1, n] \rightarrow \{-1, 1\}$ and $a : [1, n] \rightarrow [1, m]$. Let B be the matrix with the same dimensions as A whose columns are $\sigma(j)v'_{a(j)}$ for $j = 1, \dots, n$. Then B will satisfy $B^T B = A^T A$, and so we may use it to obtain a new Hadamard matrix of order n .

Note that if $m = 1$ and we let $H_1 = [1]$ and $H'_1 = [-1]$, then the above operation amounts to negation of a row. Likewise, if $m = 2$ and $H_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$ while $H'_2 = \begin{bmatrix} 1 & -1 \\ 1 & 1 \end{bmatrix}$, then the above operation amounts to swapping two rows.

Switching closed quadruples is an instance of the $m = 4$ case. Let A be a $4 \times n$ matrix whose columns, or their negations, are columns of H_4 , a 4×4 Hadamard matrix. Orthogonality of the rows of A implies that A is a closed quadruple. Now negating one column of H_4 and using the resulting matrix to construct B has the effect of switching the closed quadruple formed by the rows of A . Thus in some sense switching closed quadruples is a natural extension of the operations of row negation and row permutation.

3.4. Closed quadruples and Hadamard submatrices. There is an additional sense in which switching closed quadruples is a natural extension of the operation of row permutation. Consider the matrix H of size $2n$ defined in (1.1). One may negate or permute the columns of A or B without changing the equivalence class of H . One may also negate a row of PB (or of A) without changing the equivalence class of H . The reason is that negating row j of PB amounts to swapping rows j and $n + j$ of H .

On the other hand, changing the permutation P , for example, by performing the additional row swap (i, j) , usually does change the equivalence class of H . The additional swap will affect four rows of H , namely, $i, j, i + n, j + n$. These four rows form a closed quadruple. One of the four fields of this quadruple is the set of columns of H in which rows i and j of PB differ. We make the switch that negates the entries in rows $i, j, i + n$, and $j + n$ that lie within this field. The result is identical to the result of swapping rows i and j of PB . Therefore, in this context, switching a closed quadruple amounts to swapping a pair of rows in one of the two matrices from which H was constructed.

3.5. Properties of Hall sets. Hall sets play the role for matrices of order $n \equiv 4 \pmod{8}$ that closed quadruples play for matrices of order $n \equiv 0 \pmod{8}$.

Hall sets can be found both in Hadamard matrices of order $n \equiv 0 \pmod{8}$ and in those of order $n \equiv 4 \pmod{8}$. Four columns are singled out in the definition of a Hall set, namely, the columns whose sign in the Hadamard product differs from the sign of all the other columns. When $n \equiv 4 \pmod{8}$ these form a Hall set in the columns, as shown by Kimura and Ohmori [21]. For convenience of the reader, we reprove this here. We include the corresponding result for $n \equiv 0 \pmod{8}$ for good measure. Define the *Hall columns* to be the four distinguished columns. There is one Hall column in each field.

PROPOSITION 3.6. *Let H be a Hadamard matrix of order n . If $n \equiv 0 \pmod{8}$, then the Hall columns form a closed quadruple. If $n \equiv 4 \pmod{8}$, then the Hall columns form a Hall set.*

Proof. We assume without loss of generality that H is 3-normalized on three rows of the Hall set. Consider a row not contained in the Hall set. Let x_i denote the element of that row in the Hall column of field i . Let a_i denote the sum of the remaining elements of field i . Then orthogonality with the Hall set rows implies

$$(3.1) \quad x_1 + a_1 = x_2 + a_2 = x_3 + a_3 = x_4 + a_4,$$

$$(3.2) \quad a_1 + a_2 + a_3 + a_4 = x_1 + x_2 + x_3 + x_4,$$

which implies that the row sum, which must be congruent to $n \pmod{8}$, equals $2(x_1 + x_2 + x_3 + x_4)$. Hence the product $x_1 x_2 x_3 x_4$ is positive for $n \equiv 0 \pmod{8}$ and negative for $n \equiv 4 \pmod{8}$. In each row of the Hall set, the product of the four elements in Hall columns is always positive, so the result follows. $\square$

Remark. When $n \equiv 0 \pmod{8}$ the existence of a Hall set implies the existence of a closed quadruple in the columns, but the converse is not true. The existence of a closed quadruple does not imply the existence of a corresponding Hall set.¹

Henceforth we will consider the $n \equiv 4 \pmod{8}$ case, and when we speak of a Hall set, we will mean both the four rows of the set and the four corresponding Hall columns.

By permuting the Hall rows and columns to the top- and leftmost positions and normalizing appropriately, we obtain the form

$$(3.3) \quad H = \begin{bmatrix} H_4 & F_1 & F_2 & F_3 & F_4 \\ G_1 & A_{11} & A_{12} & A_{13} & A_{14} \\ G_2 & A_{21} & A_{22} & A_{23} & A_{24} \\ G_3 & A_{31} & A_{32} & A_{33} & A_{34} \\ G_4 & A_{41} & A_{42} & A_{43} & A_{44} \end{bmatrix},$$

where

$$(3.4) \quad H_4 = \begin{bmatrix} 1 & - & - & - \\ - & 1 & - & - \\ - & - & 1 & - \\ - & - & - & 1 \end{bmatrix}, \quad F_1 = \begin{bmatrix} 1 & \dots & 1 \\ 1 & \dots & 1 \\ 1 & \dots & 1 \\ 1 & \dots & 1 \end{bmatrix}, \quad F_2 = \begin{bmatrix} 1 & \dots & 1 \\ - & \dots & - \\ - & \dots & - \\ 1 & \dots & 1 \end{bmatrix},$$

$$F_3 = \begin{bmatrix} 1 & \dots & 1 \\ - & \dots & - \\ 1 & \dots & 1 \\ - & \dots & - \end{bmatrix}, \quad F_4 = \begin{bmatrix} - & \dots & - \\ - & \dots & - \\ 1 & \dots & 1 \\ 1 & \dots & 1 \end{bmatrix},$$

$G_1 = F_1^T$, $G_j = -F_j^T$ for $j \in \{2, 3, 4\}$, and A_{ij} are submatrices whose row and column sums equal 2 when $i = j$ and 0 when $i \neq j$.

DEFINITION 3.7. By switching a Hall set in the matrix H defined in (3.3) we mean the operation of replacing F_i by its negation and G_i by its negation for one of the choices $i = 1, 2, 3, 4$.

The four possible negations of the definition produce equivalent matrices. The proof of this is similar to the proof of the analogous property of closed quadruples

¹Sylvester matrices exhibit this in extreme form. One can show by induction on k that the Sylvester matrix of size 2^k has $\frac{1}{4}\binom{2^k}{3}$ closed quadruples and that any of its other row quadruples is of type 2^{k-3} (which means its Hadamard product has as many entries $+1$ as -1). Therefore, if $k \geq 4$, the Sylvester matrix has many closed quadruples but no Hall sets. Since Sylvester matrices are self-dual, the same is true of column quadruples.

given in the discussion following Proposition 3.5. Switching is well defined even when the Hall rows and columns do not appear in positions 1–4 or when the normalization is different from the one in (3.3). We need only apply a signed permutation to put the matrix into the form (3.3), switch as in the definition, and then apply the inverse signed permutation.

PROPOSITION 3.8. *The matrix produced by switching a Hall set in a Hadamard matrix is a Hadamard matrix.*

Proof. We will assume the form (3.3) since the conclusion is unaffected by the permutations and negations needed to convert the matrix to that form. When $i \neq j$, the rows of F_j are orthogonal to the rows of A_{ij} as the latter have row sum 0. Therefore, negating F_j does not alter the orthogonality of rows 1–4 of H with the rows of H contained in the block $[G_i \ A_{i1} \ A_{i2} \ A_{i3} \ A_{i4}]$. Row k ($k = 1, 2, 3, 4$) of F_j has inner product ± 2 with any of the rows of A_{jj} , while row k of H_4 has inner product ∓ 2 with any of the rows of G_j . Negating both F_j and G_j produces sign changes in these inner products that produce opposite contributions to any of the inner products of rows 1–4 of H with the rows of H contained in the block $[G_j \ A_{j1} \ A_{j2} \ A_{j3} \ A_{j4}]$. $\square$

Examples are known in which switching a Hall set in a Hadamard matrix H produces a matrix equivalent to H . In general, however, one obtains an inequivalent matrix.

4. Invariants. First, we prove that the number of closed quadruples in a Hadamard matrix of size $16k + 8$ is invariant under switching closed quadruples. Second, we show that the binary, doubly even, self-dual code associated to the transpose of a Hadamard matrix of size $16k + 8$ is unchanged by switching a closed quadruple of that matrix. Finally, we show that the integer equivalence class is preserved under switching of Hall sets.

4.1. A closed quadruple switching invariant for $n \equiv 8 \pmod{16}$. We will need to understand the ways that closed row quadruples may overlap within a Hadamard matrix.

PROPOSITION 4.1. *Suppose (i, j, k, ℓ) and (i', j', k', ℓ') are distinct closed quadruples with nonempty intersection. Then the number of rows common to the two quadruples is 2 if $n \equiv 8 \pmod{16}$ and 1 or 2 if $n \equiv 0 \pmod{16}$.*

Proof. The number of common rows cannot be 3 since the fourth row of a closed quadruple is determined, up to sign, by the other three, and the two quadruples are assumed distinct. Therefore the number of common rows must be either 1 or 2.

We will show that if the number of common rows is 1, then $n \equiv 0 \pmod{16}$.

Assume the number of common rows to be 1 and let $n = 8r$. Take the two quadruples to be $(1, 2, 3, 4)$ and $(1, 5, 6, 7)$, and 3-normalize the matrix on rows 2, 3, 4. Normalize row 1 to have positive entries. By suitable column permutations, the structure of the first five rows can be brought to the form

$$\begin{array}{cccccccc} 1. & 1_r & 1_r & 1_r & 1_r & 1_r & 1_r & 1_r \\ 2. & 1_r & 1_r & -1_r & -1_r & -1_r & -1_r & 1_r \\ 3. & 1_r & 1_r & -1_r & -1_r & 1_r & 1_r & -1_r \\ 4. & 1_r & 1_r & 1_r & 1_r & -1_r & -1_r & -1_r \\ 5. & 1_r & -1_r & 1_r & -1_r & 1_r & -1_r & 1_r \end{array}$$

The form of row 5 is a consequence of the fact that the sum of elements in each of the four fields must be zero. Since $(1, 5, 6, 7)$ is closed, the Hadamard product of rows 6 and 7 equals either row 5 or its negation. By normalizing row 7 appropriately we

may assume the former. Consider the two subfields that compose the first field in the above structure. They will be further subdivided as

$$\begin{array}{llllll} 5. & 1_a & 1_{r-a} & -1_b & -1_{r-b} & \dots \\ 6. & 1_a & -1_{r-a} & 1_b & -1_{r-b} & \dots \\ 7. & 1_a & -1_{r-a} & -1_b & 1_{r-b} & \dots \end{array}$$

The subfields composing the remaining three fields will be subdivided similarly. Because there are r 1's per field in rows 6 and 7, just as in row 5, we have the constraints $a + b = r$ and $a + (r - b) = r$. Therefore $a = b = r - a = r - b = r/2$, and hence r is even. Consequently $n \equiv 0 \pmod{16}$. $\square$

Note that all of the degrees of overlap between closed quadruples allowed by the proposition occur in practice.

PROPOSITION 4.2. *Let $n \equiv 8 \pmod{16}$. Let H be a Hadamard matrix of size n which has a closed row quadruple Q . Switching Q does not change the number of closed row quadruples in H .*

Proof. In the matrix obtained from H by switching Q , the rows of Q still form a closed quadruple. Also, any quadruple, whether closed or not, that does not involve any rows of Q is unaffected by switching. The only way the number of closed quadruples could change is if a closed quadruple were created or destroyed by switching Q . Such a closed quadruple would have to overlap Q (either before or after switching) and would therefore share exactly two of Q 's rows. However, the Hadamard product of any pair of rows in Q is not altered by negation of any of the fields of Q . Hence the Hadamard product of the four rows of a putative overlapping quadruple would be unchanged by such a negation. Therefore, any closed quadruple overlapping Q in two rows remains closed after switching Q . Likewise, any quadruple overlapping Q in two rows which is not closed initially will not be closed after switching Q . $\square$

It is worth pointing out that switching a closed *column* quadruple does change the number of closed row quadruples in general. Furthermore, switching closed row quadruples generally does change the number of closed row quadruples when $n \equiv 0 \pmod{16}$. For example, when $n = 16$, the five equivalence classes of Hadamard matrices have 140, 76, 44, 28, and 28 closed row quadruples. Each of these five classes can be obtained starting from any of the others and performing a series of switches of closed row quadruples.

4.2. Invariant codes. Codes can be associated with Hadamard matrices and are useful in their classification. For our purposes, codes can be thought of as collections of vectors over some finite field. The vectors in a code are called *codewords*, and the *weight* of a codeword is the number of its entries that are nonzero. The *support* of a codeword is the set of positions in which it has a nonzero entry.

One way to associate a *linear* code with a Hadamard matrix of size n is to normalize the columns of the matrix so that all entries in the first row equal 1, then to change all -1 entries to 0, and finally to take the linear span of the rows of the resulting matrix over some finite field $\mathbb{F}_p$, where p is a prime. One could equally well normalize on a row other than the first and the resulting code would be the same. The *dimension* of such a linear code is its dimension as a subspace of $\mathbb{F}_p^n$. If $\mathcal{C}$ is such a linear code, then its *dual code*, $\mathcal{C}^\perp$, is the subspace of $\mathbb{F}_p^n$ consisting of all vectors orthogonal to all codewords in $\mathcal{C}$. Basic linear algebra implies that the dimensions of a code and its dual satisfy $\dim(\mathcal{C}) + \dim(\mathcal{C}^\perp) = n$. If $\mathcal{C} \subseteq \mathcal{C}^\perp$, then $\mathcal{C}$ is said to be *self-orthogonal*. If $\mathcal{C} = \mathcal{C}^\perp$, then $\mathcal{C}$ is said to be *self-dual*.

We will consider only binary codes ($p = 2$) in this paper, but it should be noted

that codes over $\mathbb{F}_p$, p an odd prime, are closely connected with integer equivalence, which is discussed in the next section. The 2-rank of a Hadamard matrix is the same as the dimension of its associated binary code. Two binary codes are *isomorphic* if one can be converted to the other by a permutation of coordinate positions. The following result is proved (in greater generality) in many places. (For example, see [24, section 2.3].)

THEOREM 4.3. *Let H be a Hadamard matrix of size n . Let $\mathcal{C}$ be a binary code associated to H as described above. Then*

- (1) *if $n \equiv 4 \pmod{8}$, then $\mathcal{C} = \{1_n\}^\perp$ which implies $\dim(\mathcal{C}) = n - 1$;*
- (2) *if $n \equiv 0 \pmod{8}$, then $\mathcal{C}$ is self-orthogonal which implies $\dim(\mathcal{C}) \leq n/2$;*
- (3) *if $n \equiv 8 \pmod{16}$, then $\mathcal{C}$ is self-dual which implies $\dim(\mathcal{C}) = n/2$.*

Since all Hadamard matrices of a size congruent to 4 (mod 8) have the same binary code, the binary code does not help with classification (although codes over other fields may). For the present, we focus on binary codes associated with matrices of size $n \equiv 0 \pmod{8}$. It is not hard to show that such codes are *doubly even*; that is, all of their codewords have weight divisible by 4. For an illustration that various 2-ranks allowed by Theorem 4.3 do occur in practice, we consider some results discussed by Assmus and Key in [3, 2]. They note that the five inequivalent Hadamard matrices of size 16 have binary codes of dimensions 5, 6, 7, 8, and 8. Only the last two are self-dual, and they turn out not to be isomorphic. Contrast this with size 24, where the 60 nonequivalent Hadamard matrices must *all* have self-dual codes of dimension 12. Assmus and Key proved that these 60 classes of matrices are associated with six different doubly even, self-dual binary codes.

Key pointed out [17] that when H is a Hadamard matrix of size 24, the number of closed quadruples coincides with the number of codewords of weight 4 in the binary code associated with the *columns* of H . (We might also call this the code associated with H^T .) We elaborate a bit on her observation, which reflects a general phenomenon for matrices of size $n \equiv 8 \pmod{16}$.

PROPOSITION 4.4. *Let H be a Hadamard matrix of size $n \equiv 0 \pmod{8}$. Let $\mathcal{C}$ be the linear binary code constructed from the columns of H . That is, $\mathcal{C}$ is the linear span over $\mathbb{F}_2$ of the columns of a matrix A formed by normalizing H so that one of its columns consists entirely of 1's and then changing -1 's to 0's. Let $\{i, j, k, \ell\}$ be the support of a weight 4 codeword in $\mathcal{C}$. Then rows i, j, k , and ℓ of H form a closed quadruple.*

Proof. Since $\mathcal{C}$ is self-orthogonal, the weight 4 codeword with support $\{i, j, k, \ell\}$ is orthogonal to every column of A . This means that every column of A has an even number of 1's in positions i, j, k , and ℓ , which implies the result. $\square$

This result has a partial converse with self-duality of $\mathcal{C}$ being the needed additional assumption.

PROPOSITION 4.5. *Let H, A , and $\mathcal{C}$ be defined as in Proposition 4.4 and suppose in addition that $\mathcal{C}$ is self-dual. Let i, j, k , and ℓ label the rows of a closed quadruple in H . Then $\{i, j, k, \ell\}$ is the support of a weight 4 codeword in $\mathcal{C}$.*

Proof. Since one column of A consists entirely of 1's, and since i, j, k , and ℓ label a closed quadruple, every column of A has an even number of 1's among the positions i, j, k , and ℓ . Let $\mathbf{c}$ be the vector in $\mathbb{F}_2^n$ with support $\{i, j, k, \ell\}$. Then $\mathbf{c}$ is orthogonal to every column of A and therefore to every codeword in $\mathcal{C}$. Hence $\mathbf{c} \in \mathcal{C}^\perp$. Since $\mathcal{C}$ is self-dual, we also have $\mathbf{c} \in \mathcal{C}$. $\square$

We have established a one-to-one correspondence between the closed quadruples of a Hadamard matrix H of size $n \equiv 0 \pmod{8}$ and weight 4 codewords in the binary code associated to the columns of H , provided that code is self-dual. This correspon-

dence therefore holds for all Hadamard matrices of size congruent to 8 (mod 16).

We finally investigate the effect of switching a closed quadruple of H on the binary code associated to the columns of H . In this connection, we note that the closed quadruple switching operation was defined and used in the coding theory context by Phelps, Rifà, and Villanueva [32]. They were concerned with Hadamard matrices of size 2^t whose codes can range in dimension from $t + 1$ to 2^{t-1} . Starting with a code of minimal dimension, corresponding to the Sylvester matrix, they produced codes, and the corresponding matrices, of the next two higher dimensions by switching. For further details, see Lemmas 4.2 and 4.3 of [32]. Note that closed quadruples correspond to subcodes of dimension 3.

Our focus in this paper will be on codes at the opposite end of the range of possible dimensions, that is, on the self-dual codes. We have the following inclusion of codes.

PROPOSITION 4.6. *Let H , A , and $\mathcal{C}$ be defined as in Proposition 4.4 and suppose in addition that $\mathcal{C}$ is self-dual. Let H' be a Hadamard matrix obtained from H by switching a closed quadruple, and let $\mathcal{C}'$ be the code associated to the columns of H' . Then $\mathcal{C}' \subseteq \mathcal{C}$. Furthermore, if $\mathcal{C}' \neq \mathcal{C}$, then $\mathcal{C}$ is spanned by $\mathcal{C}'$ and a particular weight 4 vector.*

Proof. We may assume that H has been normalized so that all entries in its first column equal 1. The matrix A is then obtained from H simply by replacing -1 's with 0 's. The code $\mathcal{C}$ is the span of the columns of A .

Let (i, j, k, ℓ) be a closed quadruple of H . Proposition 4.5 asserts that $\mathcal{C}$ contains a codeword $\mathbf{c}$ with support $\{i, j, k, \ell\}$. Let $\{C_1, C_2, C_3, C_4\}$ be the partition into fields of the set of columns of H induced by the closed quadruple (i, j, k, ℓ) . Switching means negating all matrix elements in rows i, j, k, ℓ and in the columns of one of the C_m , $m = 1, 2, 3$, or 4 . Should column 1 be one of the affected columns, the normalization of the resulting matrix, H' , will no longer be such that column 1 contains 1 's only. To restore the normalization, we simply negate rows i, j, k, ℓ . The net result will be that all columns *but* those of C_m are affected by the switching.

At any rate, the matrix A' , obtained from H' by changing -1 's to 0 's, will differ from A only in that the elements in rows i, j, k, ℓ and in a certain subset of the columns will have been changed to their complements ($0 \rightarrow 1, 1 \rightarrow 0$). This change can be effected by adding the vector $\mathbf{c}$ to the appropriate columns of A . Therefore, $\mathcal{C}'$, which is the span of the columns of A' , is spanned by a set of linear combinations of codewords in $\mathcal{C}$. Hence $\mathcal{C}' \subseteq \mathcal{C}$. Finally, $\mathcal{C}$ is clearly the span of $\mathcal{C}' \cup \{\mathbf{c}\}$. $\square$

We note that the code $\mathcal{C}'$ obtained in the above proof depends on which of the four fields, C_m , was used in the switching. Nevertheless, the isomorphism class of the code will be independent of this choice.

As an illustration of the use of Proposition 4.6 consider the codes associated with the five equivalence classes of 16×16 Hadamard matrices. Matrices in either of the two classes associated with self-dual codes have 28 closed quadruples. Switching any of these 28 quadruples produces a matrix in the class corresponding to the code of dimension 7. We therefore conclude that the code of dimension 7 is a subspace of both of the codes of dimension 8, and that each of the latter can be obtained by augmenting the code of dimension 7 with a weight 4 vector whose support corresponds to a suitable closed quadruple.

A corollary of Proposition 4.6 is immediate.

COROLLARY 4.7. *Let H' be obtained from a Hadamard matrix H by switching a closed quadruple. If the linear binary codes associated to the columns of H and H'*

are both self-dual, then they are equal. In particular, if H is of size $n \equiv 8 \pmod{16}$, then the linear binary codes associated to the columns of H and H' are equal.

Corollary 4.7 will be important when we discuss classification of Hadamard matrices of size 24. Since in the setting of Corollary 4.7 there is a one-to-one correspondence between closed quadruples and weight 4 codewords, the corollary also provides an alternative proof of Proposition 4.2.

4.3. A Hall set switching invariant. An important notion used in the classification of Hadamard matrices is that of integer equivalence.

DEFINITION 4.8. *Two integer matrices A and B are integer equivalent if A can be converted to B by some sequence of the following row and column operations:*

- *permutation of rows (columns);*
- *negation of rows (columns);*
- *addition of an integer multiple of a row (column) to another row (column).*

Associated to the integer equivalence class of a matrix A of size n is a set of integers $s_1, \dots, s_n$ called *invariant factors* satisfying that

1. the matrix $\text{diag}(s_1, \dots, s_n)$ is integer equivalent to A .
2. there exists r such that $1 \leq r \leq n$ and $s_i | s_{i+1}$ for $1 \leq i \leq r-1$ and $s_{r+1} = \dots = s_n = 0$.
3. the product $s_1 s_2 \dots s_i$ equals the GCD of the $i \times i$ minors of A .

The matrix $\text{diag}(s_1, \dots, s_n)$ is called the *Smith normal form* of A . Two integer equivalent matrices have the same Smith normal form.

A number of properties of the Smith normal form of a Hadamard matrix have been proved [38, 30]:

1. $s_1 = 1$; $s_2 = \dots = s_{\alpha+1} = 2$, for some $\alpha \geq \lfloor \log_2 n \rfloor + 1$;
2. $s_i s_{n+1-i} = n$.

In order 36, for example, we have [6]

- $s_1 = 1$;
- $s_i = 2$ for the next α values of i ($2 \leq i \leq \alpha + 1$);
- $s_i = 6$ for the next $34 - 2\alpha$ values of i ;
- $s_i = 18$ for the next α values of i ;
- $s_{36} = 36$,

where $6 \leq \alpha \leq 17$. The single parameter α determines the integer equivalence class of a Hadamard matrix H in order 36, and we say that H is in *Smith class* α .

That the Smith class is invariant under switching Hall sets is implied by the following.

PROPOSITION 4.9. *If B is obtained from A by switching a Hall set, then B is integer equivalent to A .*

Proof. Switching a Hall set can be achieved by a sequence of integer row and column operations. Let the order of the matrix in (3.3) be $4k + 4$. Adding each of rows 1 through 4 to each of the k rows 5 through $k + 4$, and then adding each of columns 1 through 4 to each of columns 5 through $k + 4$ has the effect of negating F_1 and G_1 . $\square$

5. Equivalence relations. Hadamard equivalence, usually just called “equivalence,” was defined in the introduction. We will call Hadamard equivalence classes *H-classes*. By adjoining additional operations to the list of operations given there, we can define new equivalence relations. We already did this in the previous section when we defined integer equivalence, whose equivalence classes are the Smith classes. The considerations of the previous section also allow us to define *equivalence with respect to the associated binary linear code*, or *code equivalence* for short: Two

Hadamard matrices are code equivalent if their binary linear codes, as defined in the statement of Proposition 4.4, are isomorphic. In this section, we define further notions of equivalence.

DEFINITION 5.1. *If $n \equiv 0 \pmod{8}$, then two Hadamard matrices A and B of size n are Q-equivalent if B can be obtained from A by some sequence of the operations*

- *row or column negation;*
- *row or column permutation;*
- *switching a closed quadruple of rows;*
- *switching a closed quadruple of columns.*

If the last operation is disallowed, then A and B are said to be QR-equivalent; if the third operation is disallowed, then A and B are said to be QC-equivalent. When $n \equiv 4 \pmod{8}$, Q-equivalence is defined by replacing the last two operations with

- *switching a Hall set.*

Associated with these equivalence relations are equivalence classes, called Q-classes, QR-classes, and QC-classes.

Hadamard equivalence is stronger than Q-equivalence and therefore has a more refined equivalence class structure. In other words, there are at least as many H-classes as there are Q-classes, and each H-class is contained entirely within a particular Q-class. QR-equivalence (or QC-equivalence) is intermediate in strength between H-equivalence and Q-equivalence and will therefore have an intermediate number of equivalence classes. When $n \equiv 8 \pmod{16}$, Corollary 4.7 implies that QR-equivalence is a refinement of code equivalence: two Hadamard matrices in the same QR class have isomorphic codes; the converse does not necessarily hold, as will be seen in the case $n = 24$, which is discussed in the next section.

By Proposition 4.9, Q-equivalence is stronger than integer equivalence when $n \equiv 4 \pmod{8}$, which implies that there are at least as many Q-classes as there are Smith classes in those orders.

An equivalence class, of any type, may or may not be *self-dual*. The *dual* of a set of matrices is the set containing their transposes. A set that equals its own dual is self-dual. Many, but not all, Q-classes turn out to be self-dual. In other words, many matrices are Q-equivalent to their transposes. From the row-column symmetry in the definition of Q-equivalence it follows that if a Q-class contains at least one self-dual matrix, then that Q-class is self-dual.

We will see examples of these phenomena in the next section.

6. Application to the enumeration of inequivalent Hadamard matrices.

We remind the reader that Hadamard matrices have been completely classified up to order 28. There are five H-classes in order 16 [11], three in order 20 [12], 60 in order 24 [13, 18], and 487 in order 28 [19]. Using the available lists of H-classes, which can be obtained from a number of sources [33, 34, 36], we will be able to determine the structure of the Q-classes in these orders. The classification of H-classes in orders 32 and higher appears to be very difficult. We will content ourselves with identifying the Q-classes of all Hadamard matrices in orders 32 and 36 that were known before the recent work of Bouyukliev, Fack, and Winne (see the introduction) and completely enumerating those Q-classes that are small enough for this to be feasible.

Our procedure requires that we maintain a database of inequivalent matrices. As new matrices are generated, they are put in a canonical form and compared with known matrices to prevent duplication in the database. To put the matrices in canonical form, we followed the suggestion of Brendan McKay [26], converting $n \times n$ matrices to graphs on $4n$ vertices and then using the graph isomorphism program *nauty* that

he developed [27]. The canonical form of the graph computed by *nauty* was then converted back into a matrix. As suggested in the *nauty* User's Guide [28], we used the vertex invariant *cellquads* at level 2, which improves the efficiency in processing this type of graph.

To generate lists of inequivalent Hadamard matrices of order n we carried out the following procedure, which requires a seed Hadamard matrix of order n as input:

1. Initialize **hadList** to null list.
2. Compute canonical form of seed matrix using *nauty*. Append it to **hadList**.
3. Compute canonical form of transpose of seed matrix. If it differs from canonical form of seed matrix, append it to **hadList**.
4. Initialize **ctr** to 1.
5. Let H be matrix number **ctr** on **hadList**. If $n \equiv 4 \pmod{8}$ and this matrix is in the H-class of the transpose of the previous one, skip to step 7.
6. For each closed row quadruple ($n \equiv 0 \pmod{8}$) or Hall set ($n \equiv 4 \pmod{8}$) in H ,
 - (a) switch the quadruple (Hall set) and compute the canonical form of the resulting matrix to obtain H' .
 - (b) if H' differs from all matrices on **hadList**, append it to **hadList**. Then if the canonical form of the transpose of H' differs from H' , append it to **hadList** as well.
7. Increment **ctr**. If **hadList** is not exhausted, return to step 5.

Note that this procedure generates the Q-class of the seed matrix unless the Q-class happens to be non-self-dual, in which case it generates the union of the Q-class and its dual. This is due to the use of the transposition operation in step 6(b). Non-self-dual Q-classes always turn out to be small, and when the situation arises, we partition the union into two Q-classes by hand. (We could use column quadruple switching in the $n \equiv 0 \pmod{8}$ case and dispense with transposition in both cases, thereby avoiding this issue, but we found it convenient to use transposition to keep track of duality.) We can also modify the procedure by simply eliminating the transposition step, in which case the procedure generates the QR-class of the seed matrix in the $n \equiv 0 \pmod{8}$ case.

Here are the results on the Q-classes and QR-classes for orders 16 and 24:

- $n = 16$: The five H-classes are all Q-equivalent. More strikingly, they are all QR-equivalent.
- $n = 24$: Of the 60 H-classes, 59 are Q-equivalent. The H-class missing from the main Q-class is that of the Paley matrix which has no closed quadruples and is self-dual. It forms a Q-class all by itself.

As stated in section 4.2, Assmus and Key classified the 60 H-classes according to the doubly even binary codes associated to the columns of the matrices. (See Table 1 in [3] or Table 7.1 in [2], but beware that, in both tables, matrix 42_D^{32} , listed with the code D , should be listed with the code C , and that 32_D^{42} in line 3 should be changed to 32_C^{42} .) We use QR-equivalence to refine this classification.

Assmus and Key found that six codes, labeled A , C , D , E , F , and G , occur. They are distinguished by the number of codewords of weight 4 and therefore, according to Propositions 4.4 and 4.5, by the number of closed row quadruples in the associated matrices. We now see Corollary 4.7, on the invariance of codes under switching, in action. For example, the matrices associated with the code D all have 12 closed row quadruples. Switching any of these

TABLE 1
The six codes associated with the 60 Hadamard matrices of order 24.

Code	# weight 4 codewords	Size of code class	Sizes of QR-classes
A	30	8	8
C	18	17	17
D	12	15	5, 10
E	66	8	8
F	6	10	5, 5
G	0	2	1, 1

quadruples produces another matrix with code D . Depending on which of these matrices one starts with, switching row quadruples produces a QR-class of size 5 or of size 10. These two QR-classes together account for all 15 H-classes associated with the code D . Results for all the codes appear in Table 1.

Note that the matrices associated with the $[24, 12]$ extended Golay code G do not contain closed row quadruples. One class of such matrices must be that of the Paley Hadamard matrix, as we have already stated that it has no closed quadruples. There is a second class of matrices with no closed row quadruples. The matrices in this class, however, do each have 66 closed column quadruples, since their duals turn out to be in the class of the code E .

The results on Q-classes in orders 20 and 28 are

- $n = 20$: The 3 H-classes are Q-equivalent.
- $n = 28$: Of the 487 H-classes, 486 of them (the ones containing Hall sets [20]) are Q-equivalent. The Paley matrix (generated from quadratic residues in $\text{GF}(3^3)$) contains no Hall set, and therefore its H-class forms a Q-class by itself.

Before presenting our results in orders 32 and 36, we ask what might the results so far lead us to expect in higher order? It is striking that except for a small number of exceptions (the H-classes of the Paley matrices in orders 24 and 28), all Hadamard matrices of given order are Q-equivalent. Could this be a general phenomenon?

In order 36, a difficulty arises. By Proposition 4.9 the Smith class is invariant under the defining operations of Q-equivalence. We will see that at least six different Smith classes occur, and so there must be at least six Q-classes, each possibly containing many H-classes. The reason the multiplicity of Smith classes was not an issue in order 28 is that $7 = 28/4$ is an odd square-free number. By a result in [39] this implies that all Hadamard matrices in order 28 lie in a single Smith class. From the foregoing discussion, the best we can hope for, for general $n \equiv 4 \pmod{8}$, is that within each Smith class there will be a single dominant Q-class, and that the total number of Q-classes will still be small.

The results we have obtained so far appear to support the idea of a single dominant Q-class in order 32, and of a single dominant Q-class within each Smith class in order 36. The total number of Q-classes also appears to be very small relative to the number of H-classes. We found only a few tens of Q-classes in our analysis of the matrices known prior to the work of Bouyukliev, Fack, and Winne, but a preliminary analysis of their matrices suggests that the number will rise into the hundreds, if not higher. Our method was to collect as many Hadamard matrices as possible from the literature or using known construction techniques, and then to apply our algorithm to each of these

matrices in order to obtain its Q-class. In fortunate cases our program terminated in a reasonable time, giving us a complete enumeration of the elements of the Q-class of the given seed matrix. In less fortunate cases—and if our speculations are correct, this is expected to be the usual situation—the Q-class was too big to enumerate completely. Instead, we compared partially constructed Q-classes with each other and looked for overlaps. By so doing, we managed to identify unambiguously the Q-class of every Hadamard matrix in orders 32 and 36 known to us prior to the work of Bouyukliev, Fack, and Winne, to enumerate the smaller of these Q-classes, and to obtain lower bounds on the sizes of the larger Q-classes.

6.1. Order 32.

PROPOSITION 6.1. *All Hadamard matrices of either of the forms*

$$H = \begin{bmatrix} A & B \\ A & -B \end{bmatrix}, \quad \tilde{H} = \begin{bmatrix} A & A \\ B & -B \end{bmatrix},$$

where A and B are any Hadamard matrices of order 16, are Q-equivalent.

Proof. From the discussion in section 3.4 it follows that, from the matrix $\begin{bmatrix} A & B \\ A & -B \end{bmatrix}$, with A and B fixed, we may obtain any matrix of the form $\begin{bmatrix} A & PB \\ A & -PB \end{bmatrix}$ by switching closed row quadruples.

To show that all matrices of the form H are Q-equivalent we need only show that we can change the H-class of A or of B to any of the five classes in order 16 by switching closed quadruples. Since all Hadamard matrices of order 16 are QR- and QC-equivalent, we can achieve this by switching closed column quadruples in the A columns of H only or in the B columns of H only. (Closed column quadruples of A or of B extend to closed column quadruples of H , and switching transforms the top and bottom halves of a column the same way.)

Analogous arguments, with rows and columns interchanged, show that all matrices of the form $\tilde{H}$ are Q-equivalent. To show that matrices of the form H and of the form $\tilde{H}$ are Q-equivalent to each other, simply note that both sets contain the Sylvester Hadamard matrix. $\square$

Thus the 66099 H-classes identified in [25] are Q-equivalent. We call the Q-class of these matrices the *Sylvester Q-class*. We now turn to other known Hadamard matrices in order 32:

- the Paley matrix,
- 13 matrices from generalized Legendre (GL) pairs [9],
- four matrices listed in [1] and their transposes,
- the maximal excess matrix in [8],
- four matrices from Construction II in [25],
- two Williamson matrices,
- eight Goethals–Seidel matrices constructed from circulant blocks,
- 18 Goethals–Seidel matrices constructed from negacyclic blocks,
- 10 matrices constructed from two circulants,
- 17 matrices constructed from two negacyclic matrices,
- a matrix from the appendix of [23] and its transpose.

Some of these matrices were provided by Hadi Kharaghani. Discarding duplicates (which occur due to accidental equivalences) and matrices that happen to have one of the forms in Proposition 6.1, we are left with a list of 59 matrices. Of these, 49 are in the Sylvester Q-class. Using these matrices, and some matrices from Proposition 6.1 as seeds, we have managed to generate 3,577,996 H-classes in the Sylvester Q-class by using our program and then piecing together the results. This is certainly a gross

underestimate of the actual number.

The ten exceptional matrices among the 59 all lack closed quadruples both in rows and in columns, and therefore form Q-classes by themselves. Of the ten exceptional matrices, six are constructed from GL pairs, and four are constructed from two negacyclic blocks. The matrices from GL pairs are listed on the Web page [33] as P12–P19 (with transposes of nonself-dual matrices omitted). The exceptional GL pair matrices are P13, P15 and its transpose, P17, and P19 and its transpose. Matrix P17 is Hadamard equivalent to the Paley matrix. Of the matrices constructed from two negacyclic blocks, the exceptional ones come in two dual pairs.

The Sylvester Q-class and the 10 singleton Q-classes give a total of 11 known Q-classes in order 32, containing at least 3,578,006 Hadamard equivalence classes.

6.2. Order 36. As noted above, in order 36 we must consider each Smith class separately. Although Smith classes $\alpha = 6, 7, \dots, 17$ are allowed, the only Smith classes known to be nonempty are $\alpha = 11, 12, 13, 14, 15, 16, 17$.

A complete summary of the seed matrices we compiled in order 36 follows:

- Ted Spence’s 180 matrices related to regular 2-graphs (S1–S180) [35, 29, 36];
- the 24 matrices of Goethals–Seidel type classified by Spence and Turyn (GS1–GS24) [36];
- the 11 matrices with automorphism of size 17 classified by Tonchev (T1–T11) [37];
- the Bush-type Hadamard matrix found by Janko (B1) [14];
- a regular Hadamard matrix found by Seberry and listed on her Web page (R1) [33] (she actually lists four, but two are duplicates, and two are of Goethals–Seidel type);
- four Williamson Hadamard matrices (W1–W4) (there is a fifth, but it is equivalent to one of Tonchev’s);
- the (35, 17, 8)-difference set construction (D1);
- seven matrices of the type defined by Whiteman (a Goethals–Seidel array bordered by a Hall set) (Wh1–Wh7) [40];
- two block negacyclic Bush-type Hadamard matrices, the first given in the paper of Janko and Kharaghani (NB1, NB2) [15];
- a matrix in Smith class 11, found in the course of a (fruitless) search for block circulant Bush-type matrices (O1);
- a skew Bush-type Hadamard matrix found by Jørgensen and its transpose (J1, J2) [16];
- a matrix listed in the appendix of [23] (LLT1);
- the first matrix known (to us) in Smith class 16, found by Bouyukliev, Fack, and Winne [4] (BFW1).

Reference [6] was helpful in assembling the above list, but the reader should note that the 80 matrices from Steiner triple systems, which are a subset of Spence’s 180 matrices, are in Smith class 13, not 12 as stated there. We have not made a serious effort to credit the original author of every matrix on our list, as we were more concerned with compiling as complete a list as possible from readily obtainable sources. We should note, however, that many of these matrices derive from the important work of Goethals and Seidel [10], including the 80 matrices from Steiner triple systems mentioned above, and 11 matrices derived from Latin squares of order 6, which are also a subset of Spence’s list.

The structure we have uncovered in Smith class 13 is interesting, so we describe it in detail. Hadamard matrices in this class include 179 of Spence’s 180 matrices.

TABLE 2

Sizes of known Q-classes in order 36 for the six known Smith classes, α . A representative matrix is listed for each Q-class.

α	Q-classes
11	1 (S137), 1 (O1)
12	1 (D1)
13	1 (S179), 1 (S180), 1 (NB1), 6 (S172), 3425 (S1)
14	954,254 (B1)
15	5 (W3), 5 (W4), ≥ 5 , 520, 880 (GS1)
16	≥ 5 , 814, 129 (BFW1)
17	1 (GS11), 1 (GS12), 1 (T1), 1 (T2), 1 (T5), 1 (T6), 1 (T7), $\geq 6,000,000$ (GS4)

(His matrix 137 is in Smith class 11.) Two other matrices in Smith class 13 were previously known: the regular Hadamard matrix constructed by Seberry, and the block negacyclic Bush-type Hadamard matrix constructed by Janko and Kharaghani. Seberry's matrix and 172 of Spence's fall into the same Q-class which we found has size 3425. Two of Spence's matrices (179 and 180) and the Bush-type matrix form singleton Q-classes. They have no Hall sets. The remaining five of Spence's matrices lie in a Q-class of size 6.

Spence's matrix 137, which is in Smith class 11 and is one of the matrices derived from a Latin square of order 6, is intriguing. It has nine Hall sets, but switching any of these produces a matrix H-equivalent to the original.

Only two matrices on our list are in Smith class 14, B1 and LLT1. They are Q-equivalent. A major success of our program has been the complete enumeration of their Q-class, which has 954,254 elements. In each of Smith classes 15, 16, and 17 there is one known Q-class of size above 5 million, while all other known Q-classes are of size no greater than 5. The three large Q-classes have not yet been completely enumerated. At present, there is no evidence for more than one large Q-class in any Smith class.

The 236 matrices we compiled represent seven different Smith classes and lie in 21 different Q-classes. Some details are given in Table 2. The union of the known Q-classes contains at least 18,292,717 Hadamard equivalence classes of order 36.

Acknowledgments. I thank Bruce Solomon for numerous interesting discussions and for careful comments on the manuscript. I thank Hadi Kharaghani for extensive correspondence and for providing many unpublished Hadamard matrices in orders 32 and 36. I thank Jennifer Key for recomputing a table that appears in [3, 2], and for pointing out the connection between closed quadruples and codewords of weight 4. I am indebted to Robin Chapman who pointed out an error in the proof of Proposition 3.8 in an earlier version of the manuscript and who suggested the simple proof of Proposition 3.5. Iliya Bouyukliev, Veerle Fack, and Joost Winne kindly provided me with a list of the matrices they obtained in their work on classification of 2-(35, 17, 8)-designs. Jayoung Nam made numerous helpful suggestions about presentation. I thank the editor, Kevin Phelps, and the anonymous referees for suggestions that improved the paper. This project relied on the High Performance Computing facilities of Indiana University, in particular the IBM RS/6000 SP system.

ALGORITHMS FOR SQUARE-3PC($\cdot, \cdot$)-FREE BERGE GRAPHS*

FRÉDÉRIC MAFFRAY[†], NICOLAS TROTIGNON[‡], AND KRISTINA VUŠKOVIĆ[§]

Abstract. We consider the class of graphs containing no odd hole, no odd antihole, and no configuration consisting of three paths between two nodes such that any two of the paths induce a hole, and at least two of the paths are of length 2. This class generalizes claw-free Berge graphs and square-free Berge graphs. We give a combinatorial algorithm of complexity $O(n^7)$ to find a clique of maximum weight in such a graph. We also consider several subgraph-detection problems related to this class.

Key words. recognition algorithm, maximum weight clique algorithm, combinatorial algorithms, perfect graphs, star decomposition

1. Introduction. A graph G is *perfect* if every induced subgraph G' of G satisfies $\chi(G') = \omega(G')$, where χ denotes the chromatic number and ω denotes the size of a maximum clique. We say that a graph G *contains* a graph H if H is isomorphic to an induced subgraph of G . A graph G is *H-free* if it does not contain H . A *hole* is a chordless cycle of length at least 4. A *square* is a hole of length 4. A graph is said to be *Berge* if it does not contain an odd hole or the complement of an odd hole.

Berge conjectured in 1960 that a graph is Berge if and only if it is perfect. This was proved by Chudnovsky et al. in 2002 [8]. Later, Chudnovsky et al. [7] gave a polynomial time algorithm that recognizes Berge graphs. In the 1980s, Grötschel, Lovász, and Schrijver [16], [17] gave a polynomial time algorithm that for any perfect graph computes an optimal coloring and a clique of maximum size. This algorithm uses the ellipsoid method and a polynomial time separation algorithm for a certain class of positive semidefinite matrices related to Lovász's upper bound on the Shannon capacity of a graph [20]. The question remains whether these optimization problems can be solved by purely combinatorial polynomial time algorithms, and thus avoiding the numerical instability of the ellipsoid method. The aim of this paper is to give such an algorithm for finding a clique of maximum weight in a subclass of perfect graphs that generalizes claw-free perfect graphs and square-free perfect graphs.

3-path-configurations ($\cdot, \cdot$)'s: A $3PC(x, y)$ is a graph induced by three chordless paths that have the same endnodes x and y and such that the union of any two of them induces a hole. We say that a graph G contains a $3PC(\cdot, \cdot)$ if it contains a $3PC(x, y)$ for some $x, y \in V(G)$. It is easy to see that in a $3PC(x, y)$, each of the three paths must have length at least 2. In the literature, $3PC(\cdot, \cdot)$'s are also known as *thetas* in [9]. A *square-3PC($\cdot, \cdot$)* is a $3PC(\cdot, \cdot)$ that has at least two paths of length 2.

In this paper we give a combinatorial algorithm, with time complexity $O(n^7)$, that computes a maximum weight clique in every square-3PC($\cdot, \cdot$)-free Berge graph. We will show that every square-3PC($\cdot, \cdot$)-free Berge graph has a node whose neighborhood has no long hole (where a *long hole* is a hole of length greater than 4). This yields a linear-size decomposition tree into square-3PC($\cdot, \cdot$)-free Berge graphs that have no long hole, and then these graphs are further decomposed into cobipartite graphs, resulting in a decomposition tree of total size $O(n^4)$.

Recall that there is an $O(n^9)$ recognition algorithm for the class of Berge graphs [7]. Detecting square-3PC($\cdot, \cdot$)-s in a graph G can be done easily: it suffices to check, for every square a_1, a_2, a_3, a_4, a_1 , whether a_1 and a_3 are in the same connected component of $G \setminus ((N(a_2) \cup N(a_4)) \setminus \{a_1, a_3\})$. This takes time $O(n^6)$. In section 4, we deal with the complexity of several subgraph-detection problems related to this class.

A *claw* is a graph on nodes u, a, b, c with three edges ua, ub, uc . It is easy to see that every 3PC($\cdot, \cdot$) contains a claw. So 3PC($\cdot, \cdot$)-free graphs generalize claw-free graphs. 3PC($\cdot, \cdot$)-free Berge graphs were first studied by Aossey and Vušković [2], [3] in the context of proving the strong perfect graph conjecture for this class. The conjecture was proved by decomposing 3PC($\cdot, \cdot$)-free Berge graphs into claw-free graphs using star cutsets, homogeneous pairs, and 6-joins (a new edge cutset introduced in [3]).

Clearly, square-3PC($\cdot, \cdot$) graphs generalize square-free graphs. In [12] square-free Berge graphs are decomposed by 2-joins and star cutsets into bipartite graphs and line graphs of bipartite graphs (hence proving the strong perfect graph conjecture for this class).

Square-3PC($\cdot, \cdot$)-free Berge graphs contain both claw-free Berge graphs and square-free Berge graphs, and it is likely that one might be able to obtain a similar decomposition theorem that uses star cutsets and some of the other mentioned cutsets. Of course all Berge graphs have been decomposed in [8] (thus proving the strong perfect graph conjecture) into basic classes by skew cutsets, 2-joins, and their complements; see also [6].

Our initial idea was to try to use the above mentioned types of decomposition theorems to develop an algorithm for finding a maximum weight clique in a square-3PC($\cdot, \cdot$)-free Berge graph. Interestingly, we did end up developing a *decomposition-based algorithm* for finding a maximum weight clique, but it does not use any of the types of decomposition theorems mentioned above.

Finding a maximum weight clique in a claw-free Berge graph is not difficult. Indeed, in such a graph G the neighborhood of every node induces a cobipartite graph (first observed in [18]; see also [19]), so the problem reduces to n instances of the maximum weight stable set problem in a bipartite graph, which can be reduced to a maximum flow problem and can be done in time $O(n^3)$; see [19].

For a graph G let k denote the number of maximal cliques in G , n the number of nodes in G , and m the number of edges of G . Farber [14], and independently Alekseev [1], showed that there are $O(n^2)$ maximal cliques in any square-free graph. Tsukiyama et al. [27] gave an $O(nmk)$ algorithm for generating all maximal cliques of a graph, and Chiba and Nishizeki [5] improved this complexity to $O(\sqrt{m+n}mk)$. So one can generate all the maximal cliques of a square-free graph in time $O(\sqrt{m+n}mn^2)$.

For square-free Berge graphs, one can obtain a slightly better algorithm by using the following characterization obtained by Parfenoff, Roussel, and Rusu [24]: *Every square-free Berge graph has a node whose neighborhood is triangulated.*

We conclude this section by defining two more types of 3PC's and wheels.

3PC(Δ, Δ)'s. Let $x_1, x_2, x_3, y_1, y_2, y_3$ be six distinct nodes of G such that $\{x_1, x_2, x_3\}$ and $\{y_1, y_2, y_3\}$ both induce triangles. A $3PC(x_1x_2x_3, y_1y_2y_3)$ is a graph induced by three chordless paths $P_1 = x_1 \cdots y_1$, $P_2 = x_2 \cdots y_2$, and $P_3 = x_3 \cdots y_3$ such that any two of them induce a hole. We say that a graph G contains a $3PC(\Delta, \Delta)$ if it contains a $3PC(x_1x_2x_3, y_1y_2y_3)$ for some $x_1, x_2, x_3, y_1, y_2, y_3 \in V(G)$. Such graphs are also known as prisms in [8] and stretchers in [13].

3PC($\Delta, \cdot$)'s. Let x_1, x_2, x_3, y be four distinct nodes of G such that $\{x_1, x_2, x_3\}$ induces a triangle. We call $3PC(x_1x_2x_3, y)$ any graph induced by three chordless paths $P_1 = x_1 \cdots y$, $P_2 = x_2 \cdots y$, and $P_3 = x_3 \cdots y$ such that the union of any two of them induces a hole. Note that at least two of the three paths must have length at least 2. We say that a graph G contains a $3PC(\Delta, \cdot)$ if it contains a $3PC(x_1x_2x_3, y)$ for some $x_1, x_2, x_3, y \in V(G)$. Such graphs are called pyramids in [8].

Wheels. A *wheel* (H, x) is a graph induced by a hole H and a node $x \notin V(H)$ that has at least three neighbors in H . Node x is the *center* of the wheel. A subpath of H of length at least 1, whose endnodes are adjacent to x and where no intermediate node is adjacent to x , is called a *sector* of (H, x) . A *short sector* is a sector of length 1, and a *long sector* is a sector of length greater than 1. A wheel is *odd* if it contains an odd number of short sectors.

It is easy to see that every odd wheel and every $3PC(\Delta, \cdot)$ contains an odd hole, so Berge graphs cannot contain these two structures. These facts will be used repeatedly in the proofs.

2. Finding a maximum weight clique in a square-3PC($\cdot, \cdot$)-free Berge graph. We assume that we are given a graph G with a weight $f(x)$ associated with every node x . The problem is to find a clique of G of maximum weight, where the weight of a subset of nodes is the sum of the weights of its elements. The maximum weight of a clique is denoted by $\omega_f(G)$. The next theorem will help us solve this problem.

For $x \in V(G)$, $N(x)$ denotes the set of nodes of G that are adjacent to x , and $N[x] = N(x) \cup \{x\}$. For $A \subseteq V(G)$, $G[A]$ denotes the subgraph of G induced by the node set A . $G \setminus A$ denotes the subgraph of G obtained by removing the node set A , i.e., $G \setminus A = G[V(G) \setminus A]$.

THEOREM 2.1. *Let G be a square-3PC($\cdot, \cdot$)-free Berge graph. Let x be a node of G such that $N(x)$ contains a long hole H , and let C be any connected component of $G \setminus N[x]$. Then some node of H has no neighbor in C .*

The proof of this theorem is long and technical, and we leave it for section 3. Here we give a corollary of Theorem 2.1 and show how to use it in an algorithm for the maximum clique problem.

Let $\mathcal{F}$ be a class of graphs. We say that a graph G is $\mathcal{F}$ -free if G does not contain any of the graphs from $\mathcal{F}$.

A class $\mathcal{F}$ of graphs satisfies *property (*)* w.r.t. a graph G if the following holds: For every node x of G such that $G \setminus N[x] \neq \emptyset$, and for every connected component C of $G \setminus N[x]$, if $F \in \mathcal{F}$ is contained in $N(x)$, then there exists a node of F that has no neighbor in C .

In a graph G , for any node x , let $C_1, \dots, C_k$ be the components of $G \setminus N[x]$, with $|C_1| \geq |C_2| \geq \dots \geq |C_k|$, and let the numerical vector $(|C_1|, \dots, |C_k|)$ be associated with x . The nodes of G can thus be ordered according to the lexicographical ordering of the numerical vectors associated with them. Say that a node x is *lex-maximal* if the associated numerical vector is lexicographically maximal over all nodes of G .

THEOREM 2.2. *Let $\mathcal{F}$ be a class of graphs such that for every $F \in \mathcal{F}$, no node of F is adjacent to all the other nodes of F . If $\mathcal{F}$ satisfies property (*) w.r.t. a graph G and x is a lex-maximal node of G , then $N(x)$ is $\mathcal{F}$ -free.*

Proof. Let $\mathcal{F}$ be a class of graphs such that for every $F \in \mathcal{F}$, no node of F is adjacent to all the other nodes of F . Assume that $\mathcal{F}$ satisfies property (*) w.r.t. G .

Let x be a lex-maximal node of G and suppose that $N(x)$ is not $\mathcal{F}$ -free. Then G is not a clique, and hence, since x is lex-maximal, $G \setminus N[x] \neq \emptyset$.

Let $C_1, \dots, C_k$ be the connected components of $G \setminus N[x]$, with $|C_1| \geq |C_2| \geq \dots \geq |C_k|$. Let $N = N(x)$, and for $i = 1, \dots, k$, let $N_i = N(x) \cap N(C_i)$.

CLAIM 2.1. *$N_1 \subseteq N_2 \subseteq \dots \subseteq N_k$, and for every $i = 1, \dots, k$, every node of $(N \setminus N_i) \cup (C_{i+1} \cup \dots \cup C_k)$ is adjacent to every node of N_i .*

Proof of Claim 2.1. We argue by induction. First we show that every node of $(N \setminus N_1) \cup (C_2 \cup \dots \cup C_k)$ is adjacent to every node of N_1 . Assume the contrary and let $y \in (N \setminus N_1) \cup (C_2 \cup \dots \cup C_k)$ be such that it is not adjacent to $z \in N_1$. Clearly y has no neighbor in C_1 , but z does. So $G \setminus N[y]$ contains a connected component that contains $C_1 \cup z$, contradicting the choice of x .

Now let $i > 1$ and assume that $N_1 \subseteq \dots \subseteq N_{i-1}$ and that every node of $(N \setminus N_{i-1}) \cup (C_i \cup \dots \cup C_k)$ is adjacent to every node of N_{i-1} . Since every node of C_i is adjacent to every node of N_{i-1} , it follows that $N_{i-1} \subseteq N_i$. Suppose that there exists a node $y \in (N \setminus N_i) \cup (C_{i+1} \cup \dots \cup C_k)$ that is not adjacent to a node $z \in N_i$. Then $z \in N_i \setminus N_{i-1}$, and z has a neighbor in C_i . Also y is adjacent to all nodes in N_{i-1} and no node of $C_1 \cup \dots \cup C_i$. So there exist connected components of $G \setminus N[y]$, $C_1^y, \dots, C_i^y$ such that $C_1 = C_1^y, \dots, C_{i-1} = C_{i-1}^y$ and $C_i \cup z$ is contained in C_i^y . This contradicts the choice of x . This completes the proof of Claim 2.1.

Since $G[N]$ is not $\mathcal{F}$ -free, it contains $F \in \mathcal{F}$. By property (*), a node y of F has no neighbor in C_k . By Claim 2.1, y is adjacent to every node of N_k , and no node of $N \setminus N_k$ has a neighbor in $C = C_1 \cup \dots \cup C_k$. So (since every node of F has a nonneighbor in F) F must contain another node $z \in N \setminus N_k$, nonadjacent to y . But then $C_1, \dots, C_k$ are connected components of $G \setminus N[y]$ and z is contained in $(G \setminus N[y]) \setminus C$, so y contradicts the choice of x . $\square$

THEOREM 2.3. *Let G be a square-3PC($\cdot, \cdot$)-free Berge graph. Let x be a lex-maximal node in G . Then the neighborhood of x in G contains no long hole.*

Proof. Let G be a square-3PC($\cdot, \cdot$)-free Berge graph and let x be a lex-maximal node of G . Let $\mathcal{F}$ be the set of all long holes of G . By Theorem 2.1, $\mathcal{F}$ satisfies property (*) w.r.t. G . So by Theorem 2.2, $N(x)$ is $\mathcal{F}$ -free, i.e., long-hole-free. $\square$

Let $\mathcal{F}$ be the class of square-3PC($\cdot, \cdot$)-free Berge graphs which contain no long hole. Suppose that we have an algorithm A that computes a clique of maximum weight for every graph in $\mathcal{F}$ in time $O(n^t)$. Then we can compute a clique of maximum weight for every square-3PC($\cdot, \cdot$)-free Berge graph G as follows. By Theorem 2.3, G has a node x whose neighborhood contains no long hole. Let G_0 be the subgraph of G induced by $N(x)$. So G_0 is in $\mathcal{F}$. Clearly, since every clique of G either contains x or does not, we have $\omega_f(G) = \max\{f(x) + \omega_f(G_0), \omega_f(G \setminus \{x\})\}$. Thus, in order to compute $\omega_f(G)$, we need only compute $\omega_f(G_0)$ and $\omega_f(G \setminus \{x\})$. The former can be done by algorithm A , and the latter can be done recursively. Note that computing the numerical vector associated with a node takes time $O(n^2)$, and so we can find a lex-maximal node in time $O(n^3)$. So we can find in time $O(n^4)$ an ordering $x_1, \dots, x_n$ of the nodes of G such that, for each $i = 1, \dots, n$, node x_i is lex-maximal in the subgraph induced by $x_i, \dots, x_n$. Thus we can compute $\omega_f(G)$ for every square-3PC($\cdot, \cdot$)-free Berge graph G in time $O(n^4 + n^{t+1})$. Now we describe such an algorithm A . For this purpose we

will use the following definition.

Full star decomposition. For $x \in V(G)$ such that x is not adjacent to every node of $G \setminus \{x\}$, let $C_1, \dots, C_m$ be the connected components of $G \setminus N[x]$. Note that $N[x]$ need not be a cutset, i.e., possibly $m = 1$. The blocks of the *full star decomposition* at x are the graphs $G_0, G_1, \dots, G_m$ defined as follows: G_0 is the subgraph of G induced by $N(x)$ and, for $i = 1, \dots, m$, G_i is the subgraph of G induced by $C_i \cup N_i$, where N_i is the set of nodes of $N(x)$ which have a neighbor in C_i .

Remark 2.4. From the construction of the blocks of full star decomposition of G it follows easily that $\omega_f(G) = \max\{f(x) + \omega_f(G_0), \omega_f(G_1), \dots, \omega_f(G_m)\}$.

This remark shows that the problem of finding a maximum weight clique in G can be reduced to finding a maximum weight clique in some subgraphs of G . Our algorithm for finding a maximum weight clique in a square-3PC($\cdot, \cdot$)-free Berge graph G with no long hole consists of the following two stages:

- Stage 1: A decomposition tree T is constructed, where each leaf node is cobipartite (i.e., complement of a bipartite graph), and for each nonleaf node F , the children of F in T represent the blocks of a full star decomposition of F .
- Stage 2: A maximum weight clique is computed for each of the leaf nodes, and then the algorithm backtracks along T to find a maximum weight clique for G using Remark 2.4.

Finding a maximum weight clique in a cobipartite graph is equivalent to finding a maximum weight stable set in a bipartite graph, and it is well known that this problem can be reduced to a maximum flow in a directed network associated with the bipartite graph; see [19]. From that it is easy to deduce an algorithm (henceforth the “cobipartite maximum weight clique algorithm”) that computes a maximum weight clique in a cobipartite graph G in time $O(n^3)$. So if the size of the decomposition tree is polynomial, then Stage 2 of the algorithm can be performed in polynomial time. The key difficulty is to construct T in polynomial time. To perform Stage 1, we decompose using a full star centered at a node contained in an independent set of size 3. Note that when a Berge graph does not contain any independent set of size 3, then it is cobipartite. The following lemma implies that the decomposition tree so constructed has polynomial size.

LEMMA 2.5. *Let G be a square-3PC($\cdot, \cdot$)-free Berge graph that contains no long hole, and let $G_0, G_1, \dots, G_m$ be the blocks of a full star decomposition at some node x of G . Then the following hold:*

- (1) *No independent set of G of size 2 is contained in both G_i and G_j for any $1 \leq i \neq j \leq m$.*
- (2) *No independent set of G of size 3 is contained in both G_0 and G_i for any $1 \leq i \leq m$.*

Proof. Note that in a long-hole-free graph every 3PC($\cdot, \cdot$) is a square-3PC($\cdot, \cdot$). To prove (1), suppose that $\{a, b\}$ is an independent set of G contained in both G_i and G_j with $1 \leq i \neq j \leq m$. Then $\{a, b\} \subseteq N(x)$, and both a and b have neighbors in both C_i and C_j . But then there exists a chordless a, b -path P_i (resp., P_j) whose intermediate nodes are in C_i (resp., C_j), and hence $P_i \cup P_j \cup x$ induces a 3PC(a, b), which is a contradiction.

To prove (2), suppose that there exists an independent set $\{a, b, c\}$ which is contained in both G_0 and G_1 . Then $\{a, b, c\} \subseteq N(x)$ and every node of $\{a, b, c\}$ has a neighbor in C_1 . Let u, v, t be neighbors of a, b, c , respectively, in C_1 . Then there is a path P in C_1 from u to v . W.l.o.g., u, v, P are chosen so that P is minimal. Then

$P \cup \{x, a, b\}$ induces a hole, and since this hole cannot be long, $u = v$. If $t = u$, then $\{x, a, b, c, u\}$ induces a $3PC(x, u)$. So $t \neq u$. Let Q be a shortest path from t to u in C_1 . W.l.o.g., no node of $Q \setminus \{t\}$ is adjacent to c . Since the graph induced by $Q \cup \{x, a, c\}$ cannot contain a long hole, a is adjacent to t . By symmetry, b is also adjacent to t , and hence $\{x, a, b, c, t\}$ induces a $3PC(x, t)$. $\square$

ALGORITHM 2.6.

INPUT: A square- $3PC(\cdot, \cdot)$ -free Berge graph G with no long hole, and a weight function f on $V(G)$.

OUTPUT: A maximum weight clique of G .

METHOD: Step 1. Let $\mathcal{L} = \{G\}$, $\mathcal{L}' = \emptyset$, and let T be a tree that consist of a single node G .

Step 2. If $\mathcal{L} = \emptyset$, then go to Step 3. Otherwise, remove a graph F from $\mathcal{L}$. If F does not contain an independent set of size 3, then place F in $\mathcal{L}'$ and return to Step 2. Otherwise, let $\{x, y, z\}$ be an independent set of F . Decompose F using the full star decomposition centered at x . Place the blocks of the decomposition in $\mathcal{L}$, add the blocks of the decomposition to T as children of F , and return to Step 2.

Step 3. For every $F \in \mathcal{L}'$, find a maximum weight clique of F using the cobipartite maximum weight clique algorithm. Note that the leaves of T are precisely the graphs in $\mathcal{L}'$. Using Remark 2.4, backtrack along T to a maximum weight clique of G .

COMPLEXITY: $O(n^6)$.

Proof. By the definition of Step 2, the graphs in $\mathcal{L}'$ (that represent the leaves of T) do not contain any independent set of size 3. Since G is Berge, these graphs are cobipartite. So Step 3 correctly finds a maximum weight clique.

Now we determine the complexity of the algorithm. Consider the tree T obtained at the end of Step 2. We show that the number of nonleaf nodes in T is $O(n^3)$. Let F be a nonleaf node of T . Let $\{x, y, z\}$ be an independent set of F from Step 2 such that F is decomposed by the full star centered at x . We view $\{x, y, z\}$ as the label of F . By Lemma 2.5 and the fact that x is not contained in any of the blocks of decomposition of F , no two nonleaf nodes of T have the same label. So the number of nonleaf nodes of T is at most n^3 .

We now show that the number of leaf nodes of T is also $O(n^3)$. For a node F of T , define a measure $\tau(F)$ as follows: If F is a nonleaf node of T , then let $\tau(F)$ be the number of independent sets of size 3 in F ; if F is a leaf node and F has at least three siblings in the decomposition tree, then $\tau(F) = 1$; otherwise, $\tau(F) = 0$. Let F be a nonleaf node of T . Suppose that F is decomposed by a full star centered at x . Let $C_1, \dots, C_m$ be the connected components of $F \setminus N[x]$, and let $F_0, \dots, F_m$ be the blocks of decomposition. We claim that the following inequality holds:

$$(1) \quad \tau(F) \geq \tau(F_0) + \tau(F_1) + \dots + \tau(F_m).$$

Indeed, by Lemma 2.5, no independent set of F of size 3 is contained in more than one block of the decomposition. So if $m < 3$, then (1) clearly holds. Suppose that $m \geq 3$. To show (1), it is enough to show that the number of independent sets of F of size 3 that are not contained in any of the blocks is $\geq m + 1$. For $i = 1, \dots, m$, let c_i be a node of C_i . The number of sets that contain x and two nodes from $\{c_1, \dots, c_m\}$ is $\binom{m}{2}$. The number of sets that contain three nodes from $\{c_1, \dots, c_m\}$ is $\binom{m}{3}$. Note that all these sets of size 3 are independent sets of F that are not contained in any of the blocks of the decomposition. So the number of independent sets of size 3 of

F that are not contained in any of the blocks is at least $\binom{m}{2} + \binom{m}{3}$. Since $m \geq 3$, $\binom{m}{2} + \binom{m}{3} \geq m + 1$. Therefore, (1) holds.

By repeated applications of (1) we get the inequality $\tau(G) \geq \sum \{\tau(F) \mid F \text{ leaf of } T\}$. So the number of leaves F of T such that $\tau(F) = 1$ is $O(n^3)$. By the definition of τ , the number of leaves F of T such that $\tau(F) = 0$ is at most 3 times the number of internal nodes of T . Hence, the number of leaves F of T such that $\tau(F) = 0$ is $O(n^3)$. Therefore the number of leaves of T is $O(n^3)$.

So the size of T is $O(n^3)$. When the algorithm examines a nonleaf node of T , it looks for an independent set of size 3. Since F is Berge, it suffices to check whether its complement $\bar{F}$ is bipartite, which can be done in time $O(n^2)$ with standard breadth-first search (and this method will produce an independent set of size 3 whenever $\bar{F}$ is not bipartite). So the complexity of constructing T is $O(n^5)$, and the total complexity of Step 3 is $O(n^6)$. Therefore, the overall complexity of the algorithm is $O(n^6)$. $\square$

This implies that we can compute $\omega_f(G)$ for every square-3PC($\cdot, \cdot$)-free Berge graph G in time $\mathcal{O}(n^7)$. In fact this algorithm can be turned into a robust algorithm (in Spinrad's sense [25]). We would not need to know that the input graph G to the algorithm is a square-3PC($\cdot, \cdot$)-free Berge graph. The algorithm would then either correctly compute $\omega_f(G)$ (in all cases when G is a square-3PC($\cdot, \cdot$)-free Berge graph, and in some cases when it is not) or it would identify G as not being a square-3PC($\cdot, \cdot$)-free Berge graph. As in the algorithm we have just given, we would start by looking for a lex-maximal vertex x . We would then check whether $N(x)$ is long-hole-free. If it is not, we would terminate the algorithm, outputting that G is not a square-3PC($\cdot, \cdot$)-free Berge graph (by Theorem 2.3). In the second part of the algorithm, where we decompose graphs with no long hole, at each decomposition we would verify that (1) and (2) of Lemma 2.5 hold (which can easily be done). If one of those conditions fails, we would again terminate the algorithm, outputting that G is not a square-3PC($\cdot, \cdot$)-free Berge graph. Otherwise, we would end up with an $\mathcal{O}(n^3)$ decomposition tree as before. We would now just have to check whether the leaves are cobipartite. If they are not, we would again terminate, outputting that G is not a square-3PC($\cdot, \cdot$)-free Berge graph.

3. Proof of Theorem 2.1. To prove Theorem 2.1 we prove the following stronger result. We *sign* a graph by assigning 0, 1 weights to its edges in such a way that, for every triangle in the graph, the sum of the weights of its edges is odd. A graph G is *even-signable* if there is a signing of its edges so that for every hole in G , the sum of the weights of its edges is even. Clearly, every odd-hole-free graph is even-signable (assign weight 1 to all its edges). The following theorem is an easy consequence of a theorem of Truemper [26].

THEOREM 3.1 (Conforti et al. [10], [11]). *A graph is even-signable if and only if it does not contain an odd wheel or a 3PC($\Delta, \cdot$).*

The fact that even-signable graphs do not contain odd wheels and 3PC($\Delta, \cdot$)'s will be used throughout the proof of the next theorem.

Remark. Even though Theorem 3.2 below implies that every square-3PC($\cdot, \cdot$) even-signable graph has a node whose neighborhood is long-hole-free, finding a largest clique in a claw-free odd-hole-free graph (and hence in a square-3PC($\cdot, \cdot$)-free even-signable graph) is NP-hard. Indeed, it is proved in [22] that it is NP-hard to find a largest independent set in a graph with no cycle of length 3, 4, or 5, and so it is NP-hard to find a largest clique in a graph with no stable set of size 3 and no hole of length 5.

THEOREM 3.2. *Let G be a square-3PC($\cdot, \cdot$)-free even-signable graph. Let x be a node of G such that $N(x)$ contains a long hole H , and let C be any connected component of $G \setminus N[x]$. Then some node of H has no neighbor in C .*

Proof. Assume that every node of H has a neighbor in C . We will show that this leads to a contradiction. Let n be the length of H , and let $H = h_1 h_2 \cdots h_n h_1$. Note that since (H, x) cannot be an odd wheel, H must be of even length, so $n \geq 6$. For any node u , we denote by $N_H(u)$ the set $N(u) \cap V(H)$.

CLAIM 3.1. *Every node u of C that has a neighbor in H is one of the following five types:*

- *Type 1, $i = 1, 2, 3$: u has exactly i neighbors in H , and they are consecutive along H .*
- *Type 4: u has exactly four neighbors $h_i, h_{i+1}, h_j, h_{j+1}$ in H (that appear in this order when traversing H clockwise), where i, j have different parities.*
- *Type 5: u has exactly two neighbors h_i and h_j in H , i and j are of the same parity, and the two subpaths of H from h_i to h_j are of length greater than 2.*

Proof. Let $s = |N_H(u)|$. Note that if u has three pairwise nonadjacent neighbors a, b, c in H , then $\{x, u, a, b, c\}$ induces a square-3PC(x, u), a contradiction. Therefore $N_H(u)$ is covered by at most two cliques of H and $s \leq 4$. If $s = 1$, then u is of Type 1. Suppose $s = 2$ and u is not of Type 2. Let h_i and h_j be the two neighbors of u in H . Let H' be a subpath of H whose 1 endnode is h_i and the other is h_j . If i and j are not of the same parity, then H' is of odd length greater than 1 and $H' \cup \{u, x\}$ induces an odd wheel with center x . If H' is of length 2, then $H \cup u$ induces a square-3PC(h_i, h_j). So u must be of Type 5. If $s = 3$ and u is not of Type 3, then (H, u) is an odd wheel. Suppose $s = 4$ and u is not of Type 4. Then u has four neighbors $h_i, h_{i+1}, h_j, h_{j+1}$ in H , where i, j have the same parity. Let H' be a subpath of H from h_{i+1} to h_j . H' cannot be of length 1, since then (H, u) is an odd wheel. So H' is of odd length greater than 1, and hence $H' \cup \{u, x\}$ induces an odd wheel with center x . This proves the claim. $\square$

CLAIM 3.2. *Let $P = p_1 \cdots p_k$ be a chordless path in C such that $k \geq 2$, nodes p_1 and p_k both have neighbors in H , and no node of $P \setminus \{p_1, p_k\}$ has a neighbor in H . If $N_H(p_1) \not\subseteq N_H(p_k)$ and $N_H(p_k) \not\subseteq N_H(p_1)$, then one of the following holds:*

- (i) $N_H(p_1) = \{a\}$, $N_H(p_k) = \{b\}$, and either ab is an edge or the two subpaths of $H \setminus \{a, b\}$ are both of even length.
- (ii) $N_H(p_1) = \{a, b\}$, $N_H(p_k) = \{c, d\}$, ab and cd are edges, and the subpaths of $H \setminus \{a, b, c, d\}$ are of even length.
- (iii) For some $i \in \{1, \dots, n\}$, $N_H(p_1) = \{h_i, h_{i+1}, h_{i+2}\}$, indices taken modulo n , $N_H(p_k) \cap \{h_i, h_{i+1}, h_{i+2}\} = h_i$, and p_k is of Type 3 or 5.
- (iv) Nodes p_1 and p_k are both of Type 5 and have a common neighbor in H .

Proof. Consider the following property S_3 : There are three pairwise nonadjacent nodes h_r, h_s, h_t of H such that p_1 is adjacent to h_r and h_s (and thus not to h_t) and p_k is adjacent to h_t and not to h_r, h_s . Note that S_3 does not hold, for otherwise $P \cup \{h_r, h_s, h_t, x\}$ induces a square-3PC(p_1, x). By Claim 3.1, p_1 and p_k are of Type 1, 2, 3, 4, or 5. This leads, up to symmetry, to the following case analysis.

First suppose that p_1 is of Type 4, with $N_H(p_1) = \{h_1, h_2, h_t, h_{t+1}\}$ with t even, $4 \leq t \leq n - 2$. If p_k is of Type 1, 2, or 5, then S_3 holds. If p_k is of Type 3, then either S_3 holds or $N_H(p_k) = \{h_1, h_2, h_3\}$, and in this case either $k = 2$ and $\{p_1, p_2, h_1, h_3, h_{t+1}, x\}$ induces a 3PC($h_1 p_1 p_2, x$), or $k > 2$ and $(H \setminus \{h_2\}) \cup \{p_1, p_k\}$ induces an odd wheel with center p_1 . If p_k is of Type 4, then either S_3 holds; or $N_H(p_k) = \{h_1, h_2, h_s, h_{s+1}\}$ with s even and $4 \leq s \leq t - 2 < t \leq n - 2$, and in this

case either $k = 2$ and $\{p_1, p_2, h_1, h_{s+1}, h_{t+1}, x\}$ induces a $3PC(h_1 p_1 p_2, x)$, or $k > 2$ and $\{h_{s+1}, \dots, h_n, h_1, p_1, p_k\}$ induces an odd wheel with center p_1 ; or $N_H(p_k) = \{h_2, h_3, h_{t+1}, h_{t+2}\}$, and in this case either $k = 2$ and $\{x, h_1, h_2, h_3, p_1, p_2\}$ induces an odd wheel with center h_2 , or $k > 2$ and $\{x, h_2, h_{t+1}, p_1, p_k\}$ induces a square- $3PC(h_2, h_{t+1})$.

Now suppose that p_1 is of Type 3, with $N_H(p_1) = \{h_1, h_2, h_3\}$. If p_k is of Type 1, 2 or 3, then either property S_3 holds, or we have outcome (iii), or p_k is adjacent to h_4 and $N_H(p_k) \subseteq \{h_2, h_3, h_4\}$, and in this case $(H \setminus \{h_2, h_3\}) \cup P \cup x$ induces an odd wheel with center x . If p_k is of Type 5, then either S_3 holds, or we have outcome (iii).

Now suppose that p_1 is of Type 5, with $N_H(p_1) = \{h_1, h_t\}$ and t odd, $5 \leq t \leq n-3$. If p_k is of Type 1 or 2, then either S_3 holds, or p_k is adjacent to h_2 and $N_H(p_k) \subseteq \{h_1, h_2\}$, and in this case $P \cup \{x, h_2, \dots, h_t\}$ induces an odd wheel with center x . If p_k is of Type 5, then either S_3 holds, or we have outcome (iv), or $N_H(p_k) = \{h_2, h_s\}$ with $s = t \pm 1$, and in this case $P \cup \{x, h_1, h_2, h_t\}$ induces a $3PC(x h_1 h_2, p_1)$.

Finally, if p_1, p_k are both of Type 1, say $N_H(p_1) = h_i$ and $N_H(p_k) = h_j$ with $i < j$, then either we have outcome (i) or $P \cup \{h_i, \dots, h_j, x\}$ induces an odd wheel with center x . If one of p_1, p_k is of Type 1 and the other is of Type 2, then $H \cup P$ induces a $3PC(\Delta, \cdot)$. If p_1, p_k are both of Type 2, then either we have outcome (ii) or there is a subpath $H' = h_i \dots h_j$ of H such that $N(p_1) \cap H' = \{h_i\}$, $N(p_k) \cap H' = \{h_j\}$, and H' is of odd length, and then $P \cup H' \cup \{x\}$ induces an odd wheel with center x . This proves the claim. $\square$

CLAIM 3.3. *C does not contain a path $P = p_1 \dots p_k$ such that either $k = 1$ and p_1 is of Type 4 or $k \geq 2$ and $H \cup P$ induces a $3PC(\Delta, \Delta)$.*

Proof. Suppose that there is such a path. W.l.o.g., we have either $k = 1$ and $N_H(p_1) = \{h_1, h_2, h_t, h_{t+1}\}$, or $k \geq 2$, $N_H(p_1) = \{h_1, h_2\}$, and $N_H(p_k) = \{h_t, h_{t+1}\}$. Then by Claims 3.1 and 3.2, t is even. In particular, $h_2 h_t$ and $h_{t+1} h_1$ are not edges. Since every node of H has a neighbor in C , there exists a chordless path $Q = q_1 \dots q_l$ in C such that q_1 is adjacent to a node of $H \setminus \{h_1, h_2, h_t, h_{t+1}\}$ and q_l is adjacent to a node of P . We may assume that such paths P and Q are chosen so that $|V(P) \cup V(Q)|$ is minimized. Thus no node of $Q \setminus \{q_l\}$ has a neighbor in P , and the only nodes of H that can have a neighbor in $Q \setminus \{q_1\}$ are h_1, h_2, h_t, h_{t+1} .

First suppose that $k = 1$. W.l.o.g., q_1 has a neighbor h_i in $h_3 \dots h_{t-1}$. Some node q_j of Q must be adjacent to one of h_1, h_{t+1} , else $Q \cup \{p_1, h_1, h_{t+1}, h_i, x\}$ induces a square- $3PC(x, p_1)$. Let j be the smallest such index; say q_j is adjacent to h_1 . Then q_j is not adjacent to h_{t+1} , else $\{q_1, \dots, q_j, x, h_1, h_i, h_{t+1}\}$ induces a square- $3PC(x, q_j)$. By the choice of j , node q_1 is not adjacent to h_{t+1} . Then $j < l$, else $\{q_1, \dots, q_j, p_1, h_1, h_i, h_{t+1}, x\}$ induces a $3PC(h_1 p_1 q_j, x)$. Then q_1 has a neighbor in $h_{t+2} \dots h_n$, else $\{p_1, q_1, \dots, q_j\} \cup H \setminus \{h_2, \dots, h_{i-1}\}$ contains a $3PC(h_t h_{t+1} p_1, h_1)$. It follows that q_1 is either of Type 4, or of Type 5 not adjacent to any of h_1, h_2, h_t, h_{t+1} . By Claim 3.2 applied to $Q \cup \{p_1\}$, some node q_s of $Q \setminus \{q_1\}$ has a neighbor in H , and we choose the smallest such s . By Claim 3.2 applied to $q_1 \dots q_s$, we have $N_H(q_s) \subseteq N_H(q_1)$, which is possible only if q_1 is of Type 4 with a neighbor in $\{h_1, h_2, h_t, h_{t+1}\}$; so, up to symmetry, $N_H(q_1) = \{h_n, h_1, h_i, h_{i+1}\}$, $2 < i < t$. Let R be the shortest path from q_1 to h_{t+1} in the subgraph induced by $Q \cup \{p_1, h_{t+1}\}$. If $n > t + 2$, then $R \cup \{h_{t+2}, \dots, h_n, x\}$ induces an odd wheel with center x , while if $n = t + 2$, then $R \cup \{h_n, x, h_i\}$ induces a $3PC(x h_{t+1} h_{t+2}, q_1)$, which is a contradiction. Therefore we must have $k \geq 2$, and p_1 and p_k are of Type 2.

Now we show that either p_1 or p_k is the only neighbor of q_l in P . Suppose the contrary. Let a, b be, respectively, the smallest and largest integers such that q_l is

adjacent to nodes p_a and p_b of P . So either $a \neq b$ or $1 < a = b < k$. Let j be the largest integer such that q_j has a neighbor in H . We can apply Claim 3.2 to paths $P_a = p_1 \cdots p_a q_l \cdots q_j$ and $P_b = p_k \cdots p_b q_l \cdots q_j$. Since $N_H(q_j)$ cannot be a subset of both $N_H(p_1)$ and $N_H(p_k)$, this implies that either $N_H(q_j) = \{h_1, h_2, h_t, h_{t+1}\}$ or $N_H(q_j) = \{h_i, h_{i+1}\}$ for some i . In the first case, $\{q_1, \dots, q_j\}$ contradicts the minimality of $P \cup Q$. So we have the second case. If $i = 1$, then $\{p_b, \dots, p_k\} \cup Q$ contradicts the minimality of $P \cup Q$. If $i = t$, we have a similar contradiction. If $i \notin \{1, t\}$, then the parity condition of Claim 3.2(ii) is violated by one of P_a, P_b . Therefore, and up to symmetry, we may assume that p_k is the only neighbor of q_l in P .

Put $p_k = q_{l+1}$. Let r be the largest index such that a node q_r of Q has a neighbor in $H \setminus \{h_t, h_{t+1}\}$. Along the path $q_{r+1} \cdots q_{l+1}$, let s be the smallest index such that q_s has a neighbor in H . By the choice of q_r , we have $N_H(q_s) \subseteq \{h_t, h_{t+1}\}$, and q_s is of Type 1 or 2. W.l.o.g., q_s is adjacent to h_t . By Claim 3.2 applied to path $q_r \cdots q_s$, we have either case (a) nodes q_r, q_s are both of Type 1, or (b) nodes q_r, q_s are both of Type 2, or (c) $N_H(q_s) \subseteq N_H(q_r)$. More precisely, we have the following.

In case (a), we have $N_H(q_s) = \{h_t\}$ and $N_H(q_r) = \{h_i\}$ for some even $i \neq t$. Suppose $t + 2 \leq i \leq n$. So $r = 1$. If $s = l$, then $P \cup Q \cup \{x, h_2, h_t, h_i\}$ induces a 3PC($p_k q_l h_t, x$). If $s < l$, then $P \cup \{q_1, \dots, q_s\} \cup \{h_t, \dots, h_n, h_1\}$ induces a 3PC($p_k h_t h_{t+1}, h_i$). Thus $2 \leq i \leq t - 2$.

In case (b), we have $N_H(q_s) = \{h_t, h_{t+1}\}$ and $N_H(q_r) = \{h_i, h_{i+1}\}$ for some odd i . If $i = 1$, then $r > 1$, and $\{q_1, q_2, \dots, q_s\}$ contradicts the minimality of $P \cup Q$. Thus we may assume w.l.o.g. that $3 \leq i \leq t - 1$.

In case (c), we have either case (c1) node q_r is of Type 2 or 3 adjacent to h_{t-1} and h_t , or (c2) node q_r is of Type 4 with $N_H(q_r) = \{h_i, h_{i+1}, h_t, h_{t+1}\}$ for some odd i with $3 \leq i \leq t - 3$, or (c3) node q_r is of Type 4 and not adjacent to one of h_t, h_{t+1} , or (c4) node q_r is of Type 5 adjacent to h_t and h_i for some even $i \neq t - 2, t, t + 2$. In case (c3), $\{q_r, \dots, q_l, p_k\}$ contradicts the minimality of $P \cup Q$. In case (c4), suppose $t + 2 \leq i \leq n$. If $r = l$, then $P \cup \{q_r, x, h_2, h_t, h_i\}$ induces a 3PC($p_k q_l h_t, x$), while if $r < l$, then $P \cup \{q_r\} \cup \{h_t, \dots, h_n, h_1\}$ induces a 3PC($p_k h_t h_{t+1}, h_i$). Thus $2 \leq i \leq t - 2$. So we have case (a), (b), (c1), (c2), or (c4), and in either case there is an index i , with $2 \leq i \leq t - 1$, such that q_r is adjacent to h_i and $N_H(q_r) \subseteq \{h_i, \dots, h_{t+1}\}$. Now, if h_{t+1} has no neighbor in $q_r \cdots q_l$, then $P \cup (H \setminus \{h_{i+1}, \dots, h_t\}) \cup \{q_r, \dots, q_l\}$ induces a 3PC($h_1 h_2 p_1, p_k$). If h_{t+1} has a neighbor in $q_r \cdots q_{l-1}$, then $P \cup (H \setminus \{h_{i+1}, \dots, h_t\}) \cup \{q_r, \dots, q_{l-1}\}$ contains a 3PC($h_1 h_2 p_1, h_{t+1}$). So q_l is the unique neighbor of h_{t+1} in $q_r \cdots q_l$. If $i = 2$, then $P \cup \{q_r, \dots, q_l, x, h_2, h_{t+1}\}$ induces a 3PC($h_{t+1} p_k q_l, h_2$). If $i > 2$, then $P \cup \{q_r, \dots, q_l, x, h_1, h_i, h_{t+1}\}$ induces a 3PC($h_{t+1} p_k q_l, x$). This proves the claim. $\square$

For $i = 1, \dots, n$, let H_i be the set of Type 3 nodes of C adjacent to h_i, h_{i+1}, h_{i+2} (indices taken modulo n). Note that H_i induces a clique, for if $a, b \in H_i$ are not adjacent, then $\{a, b, x, h_i, h_{i+2}\}$ induces a square-3PC(h_i, h_{i+2}).

CLAIM 3.4. *Let h_s, h_t be nonadjacent nodes of H and $P = y \cdots z$ be a chordless path in C such that y is the only neighbor of h_s in P and z is the only neighbor of h_t in P . If both h_{s-1}, h_{s+1} have a neighbor in P , then $N_H(y) = \{h_{s-1}, h_s, h_{s+1}\}$.*

Proof. We may assume up to symmetry that $s = 2$ and $t \neq 4$. Let H' be the hole induced by $P \cup \{x, h_2, h_t\}$. Since (H', h_3) cannot be an odd wheel, $(H' \setminus \{x\}) \cup \{h_3\}$ must contain an odd number of triangles. Let R be any long sector of (H', h_1) . If $R \cup \{h_3\}$ contains an odd number of triangles and R contains at least three neighbors of h_3 , then $R \cup \{h_1, h_3\}$ induces an odd wheel with center h_3 . If R contains only two

adjacent neighbors a, b of h_3 , then R cannot contain x and h_t ; and then, if R does not contain h_2 , then $R \cup \{h_1, h_3, x\}$ induces a $3PC(h_3ab, h_1)$, while if R contains h_2 , then $\{a, b\} = \{h_2, y\}$, and $R \cup \{h_1, h_3, x\}$ induces an odd wheel with center h_2 . Thus $R \cup \{h_3\}$ contains an even number of triangles for every long sector R of (H', h_1) . It follows that some edge of $H' \setminus \{x\}$ is a short sector of both (H', h_1) and (H', h_3) , and thus some node of P is adjacent to h_1 and h_3 ; by Claims 3.1 and 3.3, such a node is of Type 3 adjacent to h_1, h_2, h_3 and so it can only be y . This proves the claim. $\square$

CLAIM 3.5. *Let u be a node of C that has a neighbor in $h_4 \cdots h_n$. Let $P = p_1 \cdots p_k$ be a path of C such that $p_k = u$, $p_1 \in H_1$, and no node of $P \setminus \{p_1\}$ belongs to H_1 . Then exactly one node of h_1, h_3 has a neighbor in $P \setminus \{p_1\}$, say h_1 . Node h_1 must in fact have a neighbor in $P \setminus \{p_1, p_2\}$, and so $k \geq 3$. Furthermore, if $Q = q_1 \cdots q_l$ is any other path of C such that $q_l = u$, $q_1 \in H_1$, and no node of $Q \setminus \{q_1\}$ belongs to H_1 , then h_1 has a neighbor in $Q \setminus \{q_1\}$.*

Proof. Let h_i be any neighbor of u in $h_4 \cdots h_n$, and let j be the smallest index such that h_i is adjacent to p_j . Suppose that neither h_1 nor h_3 has a neighbor in $p_2 \cdots p_j$. If $i \notin \{4, n\}$, then $\{p_1, \dots, p_j, h_1, h_3, h_i, x\}$ induces a square-3PC(p_1, x). Otherwise, w.l.o.g. $i = 4$, and hence the same node set induces a $3PC(h_3h_4x, p_1)$. Therefore h_1 or h_3 must have a neighbor in $P \setminus \{p_1\}$.

Suppose that both h_1 and h_3 have a neighbor in $P \setminus \{p_1\}$. If they both have a neighbor in $P \setminus \{p_1, p_2\}$, then there is a shortest subpath P' of $P \setminus \{p_1, p_2\}$ whose one endnode is adjacent to h_1 and the other to h_3 , and hence $P' \cup \{p_1, x, h_1, h_3\}$ induces a square-3PC(h_1, h_3). So we may assume w.l.o.g. that p_2 is the unique neighbor of h_1 in $P \setminus \{p_1\}$. Let p_t be the node of P with lowest index adjacent to h_3 . If $t = 2$, then Claim 3.1 implies $p_2 \in H_1$, a contradiction. So $t > 2$, and hence $\{p_1, \dots, p_t, h_1, h_3, x\}$ induces a $3PC(p_1p_2h_1, h_3)$. Therefore, both h_1 and h_3 cannot have a neighbor in $P \setminus \{p_1\}$.

Assume w.l.o.g. that h_1 has a neighbor in $P \setminus \{p_1\}$. Suppose that p_2 is the unique neighbor of h_1 in $P \setminus \{p_1\}$. If a node h_t , $4 < t < n$, has a neighbor in P , then $P \cup \{h_1, h_3, h_t, x\}$ contains a $3PC(h_1p_1p_2, x)$. So no node of $h_5 \cdots h_{n-1}$ has a neighbor in P . If h_n has no neighbor in $p_1 \cdots p_j$, then $i = 4$, and hence $\{p_1, \dots, p_j, x\} \cup (H \setminus \{h_2, h_3\})$ induces an odd wheel with center x . So h_n has a neighbor in $p_1 \cdots p_j$. Let p_t be such a neighbor with smallest index. If $t < j$ or $t = j$ and p_j is not adjacent to h_4 , then $\{p_1, \dots, p_t, x\} \cup (H \setminus \{h_1, h_2\})$ induces an odd wheel with center x . So $t = j$, and p_j is adjacent to h_4 . Hence $\{p_1, \dots, p_j, h_3, h_4, h_n, x\}$ induces a $3PC(h_3h_4x, p_j)$. Therefore, h_1 has a neighbor in $P \setminus \{p_1, p_2\}$.

Now suppose that h_1 does not have a neighbor in $Q \setminus \{q_1\}$. Then h_3 must have a neighbor in $Q \setminus \{q_1, q_2\}$, and hence $(P \setminus \{p_1, p_2\}) \cup (Q \setminus \{q_1, q_2\}) \cup \{h_1, h_3\}$ contains a chordless path R from h_1 to h_3 . If p_1 does not have a neighbor in $Q \setminus \{q_1, q_2\}$, then $R \cup \{p_1, x\}$ induces a square-3PC(h_1, h_3). So p_1 has a neighbor in $Q \setminus \{q_1, q_2\}$. Let Q' be the shortest path from p_1 to u whose vertices are contained in $(Q \setminus \{q_1, q_2\}) \cup \{p_1\}$. Now apply the same argument to P and Q' . This proves the claim. $\square$

Suppose that $H_1 \neq \emptyset$. Let u be any node of C that has a neighbor in $h_4 \cdots h_n$. Then there exists a path $P = p_1 \cdots p_k$ in C such that $p_k = u$, $p_1 \in H_1$, and no node of $P \setminus \{p_1\}$ belongs to H_1 . By Claim 3.5, exactly one of h_1, h_3 has a neighbor in $P \setminus \{p_1\}$. If h_1 does, then we say that u is *labeled 1* w.r.t. H_1 , and otherwise u is *labeled 3* w.r.t. H_1 . Note that by Claim 3.5 this label is unique.

CLAIM 3.6. *If $H_1 \neq \emptyset$, every node of C adjacent to h_4 must be labeled 3 w.r.t. H_1 , and every node of C adjacent to h_n must be labeled 1 w.r.t. H_1 .*

Proof. Suppose, up to symmetry, that some node u of C adjacent to h_4 is labeled

1 w.r.t. H_1 . Let $P = p_1 \cdots p_k$ be a path of C such that $p_1 \in H_1$, $p_k = u$, and no node of $P \setminus \{p_1\}$ belongs to H_1 . Then h_3 has no neighbor in $P \setminus \{p_1\}$. Let p_j be the node of P with lowest index adjacent to h_4 . By Claim 3.5, we have $j \geq 3$ and h_1 has a neighbor in $p_3 \cdots p_j$. But then $\{p_1, p_3, \dots, p_j, h_1, h_3, h_4, x\}$ contains a $3PC(h_3 h_4 x, h_1)$. This proves the claim. $\square$

CLAIM 3.7. *No node of C is of Type 3.*

Proof. Assume the contrary. W.l.o.g. $H_1 \neq \emptyset$.

Suppose that $H_3 = \emptyset$. Let $P = p_1 \cdots p_k$ be a shortest path in C from a node p_1 of H_1 to a node p_k adjacent to h_4 . So no node of $P \setminus \{p_1\}$ belongs to H_1 , and no node of $P \setminus \{p_k\}$ is adjacent to h_4 . By Claims 3.5 and 3.6, we have $k \geq 3$, node h_3 has a neighbor in $P \setminus \{p_1, p_2\}$, node h_1 has no neighbor in $P \setminus \{p_1\}$, and so, by Claim 3.6 again, h_n has no neighbor in P . Then h_5 has no neighbor in P , else by Claim 3.4, applied to h_4 and P , we should have $p_k \in H_3$. Some node of $h_6, \dots, h_{n-1}$ must have a neighbor in P , else $P \cup (H \setminus \{h_2, h_3\}) \cup \{x\}$ induces an odd wheel with center x . Let h_i be such a node with smallest index. If i is odd, then $P \cup \{h_4, \dots, h_i, x\}$ contains an odd wheel with center x . So i is even. If h_i has a neighbor in $P \setminus \{p_k\}$, then $(P \setminus \{p_k\}) \cup \{h_3, \dots, h_i, x\}$ contains an odd wheel with center x . So p_k is the only neighbor of h_i in P . By Claims 3.1 and 3.3, node h_3 cannot be adjacent to p_k . But then $P \cup \{h_3, h_4, h_i, x\}$ contains a $3PC(xh_3h_4, p_k)$, a contradiction. So $H_3 \neq \emptyset$.

Repeating this argument, we obtain that $H_i \neq \emptyset$ for each odd i .

Let $y \cdots z$ be any shortest path in C from a node y of H_1 to a node z of H_3 . By Claim 3.6, z is labeled 3 w.r.t. H_1 , and y is labeled 3 w.r.t. H_3 . So there exists a largest odd integer i such that C contains a chordless path $P = p_1 \cdots p_k$ from a node p_1 of H_1 to a node p_k of H_i , with no intermediate nodes in $H_1 \cup H_i$, such that p_k is labeled 3 w.r.t. H_1 and p_1 is labeled i w.r.t. H_i . In particular, by Claim 3.5, we have $k \geq 3$, node h_i has a neighbor in $P \setminus \{p_k, p_{k-1}\}$, and h_{i+2} has no neighbor in $P \setminus \{p_k\}$. Also since p_k is labeled 3 w.r.t. H_1 , and since by Claim 3.6 all nodes of H_{n-1} are labeled 1 w.r.t. H_1 , it follows that $i < n - 1$. Since $H_{i+2} \neq \emptyset$, there exists a shortest path $Q = q_1 \cdots q_l$ in C such that $q_1 \in H_{i+2}$ and q_l has a neighbor in P . Node q_1 is not adjacent to p_k , for otherwise $\{x, h_{i+1}, h_{i+2}, h_{i+3}, p_k, q_1\}$ induces an odd wheel.

Suppose that q_l is not adjacent to p_k . If q_l has a neighbor in $P \setminus \{p_k, p_{k-1}\}$, then $(P \setminus \{p_{k-1}\}) \cup Q \cup \{h_i, h_{i+2}, x\}$ contains a square- $3PC(h_i, h_{i+2})$. So $N(q_l) \cap P = \{p_{k-1}\}$. Let $Q' = q'_1 \cdots q'_t$ be the path induced by $(P \setminus \{p_k\}) \cup Q$, where $q'_1 = q_1$ and $q'_t = p_1$. Suppose that q_1 is labeled 1 w.r.t. H_1 . By Claim 3.5 applied to Q' , this is possible only if p_k is the only neighbor of h_3 in P , so $i = 3$, and h_1 has a neighbor in Q . Then $k = 3$, for otherwise $Q \cup \{x, h_1, h_3, p_1, p_{k-1}, p_k\}$ contains a square- $3PC(h_1, h_3)$. But then $\{x, h_3, h_6\} \cup P \cup Q$ contains a square- $3PC(h_3, p_2)$. So q_1 is labeled 3 w.r.t. H_1 . If p_1 is labeled $i + 2$ w.r.t. H_{i+2} , the maximality of i is contradicted. Hence p_1 is labeled $i + 4$ w.r.t. H_{i+2} , and by Claim 3.5, we have $t \geq 3$, node h_{i+4} has a neighbor in $Q' \setminus \{q'_1, q'_2\}$, and h_{i+2} has no neighbor in $Q' \setminus \{q'_1\}$. If $l > 1$, then $(Q' \setminus \{q'_2\}) \cup \{p_k, h_{i+2}, h_{i+4}, x\}$ contains a square- $3PC(h_{i+2}, h_{i+4})$. So $l = 1$. But then $P \cup \{q_1, h_2, h_{i+2}, x\}$ contains a square- $3PC(p_{k-1}, h_{i+2})$. Therefore, q_l must be adjacent to p_k . Thus $l \geq 2$.

Let p_j be the node of P with smallest index adjacent to q_l . Let $Q' = q'_1 \cdots q'_t$ be the path induced by $Q \cup \{p_1, \dots, p_j\}$, where $q'_1 = q_1$ and $q'_t = p_1$. Note that h_1 cannot have a neighbor in Q , since otherwise $(P \setminus \{p_2\}) \cup Q \cup \{h_1, h_3, x\}$ contains a square- $3PC(h_1, h_3)$. So node q'_1 must be labeled 3 w.r.t. H_1 . Node q'_t must be labeled $i + 4$ w.r.t. H_{i+2} , else the maximality of i is contradicted. So, by Claim 3.5, we have $t \geq 3$, node h_{i+4} has a neighbor in $Q' \setminus \{q'_1, q'_2\}$, and h_{i+2} has no neighbor in $Q' \setminus \{q'_1\}$.

But then $P \cup (Q \setminus \{q_2\}) \cup \{h_{i+2}, h_{i+4}, x\}$ contains a square-3PC(h_{i+2}, h_{i+4}). This proves the claim. $\square$

By Claims 3.1, 3.3, and 3.7, the nodes of C that have a neighbor in H are of Type 1, 2, or 5. Let C' be a minimal connected induced subgraph of C such that for some $s, t \in \{1, \dots, n\}$ node h_t is not adjacent to h_s or h_{s+1} , and each of h_s, h_{s+1}, h_t has a neighbor in C' . W.l.o.g. $s = 1$. Let $P = p_1 \cdots p_k$ be a shortest path in C' such that h_1 is adjacent to p_1 and h_2 to p_k .

Suppose that $k = 1$. So p_1 is of Type 2. Let $Q = q_1 \cdots q_l$ be a path in C' such that q_1 has a neighbor in $H \setminus \{h_n, h_1, h_2, h_3\}$ and q_l is adjacent to p_1 . Thus $C' = Q \cup \{p_1\}$, and no node of $Q \setminus \{q_1\}$ has a neighbor in $H \setminus \{h_n, h_1, h_2, h_3\}$. If both h_1, h_2 have a neighbor in Q , then Q contradicts the minimality of C' . So we may assume that h_1 has no neighbor in Q . Then h_n has no neighbor in $Q \cup \{p_1\}$, for otherwise a subpath of $Q \cup \{p_1\}$ violates Claim 3.2 or 3.3. If h_2 too has no neighbor in Q , then similarly h_3 has no neighbor in $Q \cup \{p_1\}$, and then by Claim 3.2, $H \cup Q \cup p_1$ induces a 3PC(Δ, Δ), contradicting Claim 3.3. So h_2 has a neighbor in Q . Let h_t be the node of $H \setminus \{h_n, h_1, h_2, h_3\}$ with highest index adjacent to q_1 . Then $Q \cup \{h_t, \dots, h_n, h_1, h_2\}$ and $Q \cup \{h_1, h_2, h_t, x\}$ induce two wheels with center h_2 , one of which is odd, a contradiction. So $k > 1$.

Let $Q = q_0 \cdots q_l$ be a shortest path such that $q_0 \in H \setminus \{h_n, h_1, h_2, h_3\}$, $Q \setminus \{q_0\} \subseteq C'$, and q_l has a neighbor in P (possibly $l = 0$). So if $l > 0$, no node of $P \cup Q \setminus \{q_0, q_1\}$ has a neighbor in $H \setminus \{h_n, h_1, h_2, h_3\}$. Note that $C' = P \cup Q \setminus \{q_0\}$.

Suppose that h_1 has a neighbor in Q . So $l > 0$. Let h_t be the node of $h_4 \cdots h_{n-1}$ with smallest index adjacent to q_1 . Then, by the minimality of C' , $N(q_l) \cap P = \{p_1\}$ and h_2 has no neighbor in Q . If h_3 has no neighbor in $P \cup Q$, then $P \cup (Q \setminus \{q_0\}) \cup \{h_1, h_2, \dots, h_t\}$ or $P \cup (Q \setminus \{q_0\}) \cup \{x, h_1, h_2, h_t\}$ induces an odd wheel with center h_1 . So h_3 has a neighbor in $P \cup Q$. Then Claim 3.4, applied to h_2 and $P \cup Q$, implies that p_k is of Type 3, a contradiction. Therefore h_1 cannot have a neighbor in Q , and similarly neither can h_2 .

If q_l has exactly one neighbor p_a in P , then $P \cup Q \cup \{h_1, h_2, x\}$ induces a 3PC($h_1 h_2 x, p_a$). If q_l has two nonconsecutive neighbors in P , then the same node set contains a 3PC($h_1 h_2 x, q_l$). So $N(q_l) \cap P = \{p_a, p_{a+1}\}$. Node h_3 must have a neighbor in P , else $P \cup Q \cup \{h_1, h_2, \dots, q_0\}$ contains a 3PC($q_l p_a p_{a+1}, h_2$). By Claim 3.1, h_3 cannot be adjacent to p_1 . Now h_2, h_3, q_0 all have a neighbor in $C' \setminus \{p_1\}$, which is connected, and so the minimality of C' implies $q_0 = h_4$. Then $N(h_3) \cap P = \{p_k\}$, else h_1, h_3, h_4 all have a neighbor in $C' \setminus \{p_k\}$, contradicting the minimality of C' . But then $P \cup \{h_1, h_2, h_3, x\}$ induces an odd wheel with center h_2 . This completes the proof of the theorem. $\square$

4. On the complexity of several detection problems.

4.1. Detecting a 3PC($\cdot, \cdot$) or a 3PC($\Delta, \cdot$). Chudnovsky and Seymour gave an $O(n^{11})$ to decide if a graph contains a 3PC($\cdot, \cdot$) [9] and an $O(n^9)$ algorithm to decide if a graph contains a 3PC($\Delta, \cdot$) [7]. Here we give an $O(n^7)$ algorithm that decides whether a given graph has either a 3PC($\cdot, \cdot$) or a 3PC($\Delta, \cdot$). Say that a 3PC($\Delta, \cdot$) is *long* if its three paths have length at least 2. Otherwise, exactly one of its paths has length 1, and we say it is *short*. Here is a sufficient condition for a graph to have a 3PC($\cdot, \cdot$) or a long 3PC($\Delta, \cdot$).

LEMMA 4.1. *Let G be a graph with four nodes u, a, b, c and a set $W \subseteq V(G) \setminus \{u, a, b, c\}$ such that*

- $\{u, a, b, c\}$ induces a claw centered at u ;
- W induces a connected subgraph of G ;

- u has no neighbor in W ;
- Every node in $\{a, b, c\}$ has exactly one neighbor in W .

Then, G contains a $3PC(\cdot, \cdot)$ or a long $3PC(\Delta, \cdot)$.

Proof. Let a', b', c' be the neighbors of a, b, c in W . If $a' = b' = c'$, then $\{u, a, b, c, a'\}$ induces a $3PC(u, a')$. Now we may assume $a' \neq b'$. Then $G[W]$ contains a path with ends a' and b' , and we let P be a shortest such path. Let $Q = c', \dots, v$ be a path in $G[W]$ such that v has a neighbor in P and no node of $Q \setminus v$ has a neighbor in P . Such a Q exists because W is connected (possibly $c' = v$). Let d (resp., e) be the neighbor of v in P closest to a' (resp., to b'). Let T be the graph induced by $P \cup Q \cup \{u, a, b, c\}$. If $d = e$, then T is a $3PC(d, u)$. If d, e are distinct and adjacent, then T is a long $3PC(vde, u)$. If d, e are distinct and nonadjacent, then T contains a $3PC(v, u)$. $\square$

Now we can give an $O(n^6)$ algorithm for the detection of nonsquare- $3PC(\cdot, \cdot)$'s or long $3PC(\Delta, \cdot)$'s that is very similar to an $O(n^5)$ algorithm by Maffray and Trotignon [21] that detects $3PC(\Delta, \Delta)$'s or $3PC(\Delta, \cdot)$'s.

ALGORITHM.

INPUT: A graph G .

OUTPUT: The positive answer “ G contains a nonsquare- $3PC(\cdot, \cdot)$ or a long $3PC(\Delta, \cdot)$ ” if it does; else the negative answer “ G contains no nonsquare- $3PC(\cdot, \cdot)$ and no long $3PC(\Delta, \cdot)$.”

METHOD: For every claw $\{u, b_1, b_2, b_3\}$ centered at u do:

Step 1. Compute the set X_1 of those nodes of $V(G)$ that are adjacent to b_1 and not adjacent to u, b_2 , or b_3 , and the similar sets X_2, X_3 , and compute the set X of those nodes of $V(G)$ that are not adjacent to any of u, b_1, b_2, b_3 . Compute the connected components of X in G . For each component H of X , and for $i = 1, 2, 3$, if some node of H has a neighbor in X_i then mark H with label i .

Step 2. For every component H of X that has received label $i \in \{1, 2, 3\}$, and for every node x of X_i that has a neighbor in H , assign to x the other labels of H (if any). For each $i = 1, 2, 3$ and for every node x of X_i that has a neighbor in X_j with $j \in \{1, 2, 3\}$ and $j \neq i$, assign label j to x .

Step 3. If some node of $X_1 \cup X_2 \cup X_3$ gets two different labels, return the positive answer and stop.

If the positive answer has not been returned at Step 3, return the negative answer.

COMPLEXITY: $O(n^6)$.

Proof of correctness. Suppose that G contains a nonsquare- $3PC(\cdot, \cdot)$ or a long $3PC(\Delta, \cdot)$, say K . Let u, b_1, b_2, b_3 be the four nodes of a u -centered claw of K , and for $i = 1, 2, 3$ let c_i be the neighbor of b_i in $K \setminus \{u, b_1, b_2, b_3\}$. Let us observe what the algorithm will do when it examines the 4-tuple $\{u, b_1, b_2, b_3\}$. The algorithm will place the three nodes c_1, c_2, c_3 in the sets X_1, X_2, X_3 , respectively.

First suppose that K is neither a $3PC(\cdot, \cdot)$ with one of the paths of length 2 nor a $3PC(\Delta, \cdot)$ with all three paths of length 2. Then $K \setminus \{u, b_1, b_2, b_3, c_1, c_2, c_3\}$ is contained in a connected component H of X , and all three nodes c_1, c_2, c_3 have a neighbor in H , i.e., H gets assigned all three labels 1, 2, and 3. So c_1 gets labels 2 and 3, and hence Step 3 returns the positive answer. If K is a $3PC(\Delta, \cdot)$ with all three paths of length 2, then K is a $3PC(c_1 c_2 c_3, u)$, so by Step 2 c_1 gets labels 2 and 3, and hence Step 3 returns the positive answer. Finally, assume that K is a $3PC(\cdot, \cdot)$ with one of the paths of length 2. W.l.o.g. K is a $3PC(u, c_1)$. Let H_2 (resp., H_3) be the

connected component of $K \setminus \{u, b_1, b_2, b_3, c_1, c_2, c_3\}$ in which both c_1 and c_2 (resp., c_1 and c_3) have a neighbor. Since c_1 has a neighbor in both H_2 and H_3 , in Step 2 c_1 gets labels 2 and 3, and hence Step 3 returns the positive answer.

Conversely, suppose that the algorithm returns the positive answer when it is examining a u -centered claw $\{x, b_1, b_2, b_3\}$. So (up to symmetry) some node $c_1 \in X_1$ gets labels 2 and 3 at Step 2. This means that for $j = 2, 3$, there exists a path R_j from c_1 to a node of X_j such that the interior nodes of R_j (if any) lie in X . We can apply Lemma 4.1 to the claw $\{u, b_1, b_2, b_3\}$ and the set $W = V(R_2) \cup V(R_3)$, which implies that this subgraph (and thus G itself) contains a long 3PC($\Delta, \cdot$) or a 3PC($\cdot, \cdot$) (that is nonsquare because the c_i 's are pairwise distinct). This completes the proof of correctness.

Finding all 4-tuples takes time $O(n^4)$. For each 4-tuple, computing the sets X_1, X_2, X_3, X takes time $O(n^2)$. Finding the components of X takes time $O(n^2)$. Marking the components at the end of Step 1 can be done as follows: For each edge uv of G , if u is in a component H of X and v is in some X_i then mark H with label i . This takes time $O(n^2)$. Marking the nodes of $X_1 \cup X_2 \cup X_3$ at Step 2 can be done similarly. Thus the overall complexity is $O(n^6)$. $\square$

Detecting square-3PC($\cdot, \cdot$)'s is easy to do in time $O(n^6)$, as noted in the introduction. So, in order to detect 3PC($\cdot, \cdot$)'s or 3PC($\Delta, \cdot$)'s, we are left with the problem of deciding whether a graph has a short 3PC($\Delta, \cdot$). This is an NP-complete problem (proved in the next section) but we can solve it assuming that the graph has no 3PC($\cdot, \cdot$) and no long 3PC($\Delta, \cdot$). This could be done in time $O(n^9)$ using the algorithm of Chudnovsky et al. [7] that detects a 3PC($\Delta, \cdot$). We propose here something faster and simpler but based on the same ideas.

If K is a short 3PC(bde, u) such that u sees b , a is the neighbor of u along the path of K from u to d , and c is the neighbor of u along the path of K from u to e , then we say that (u, a, b, c, d, e) is a *frame* of K .

LEMMA 4.2. *Let G be a graph with no 3PC($\cdot, \cdot$) and no long 3PC($\Delta, \cdot$). Let K be a smallest short 3PC($\Delta, \cdot$) of G with frame (u, a, b, c, d, e) . Let P be the path of $K \setminus \{u\}$ between a and d . Let R be a shortest path of G between a and d such that the interior nodes of R are not adjacent to b, c, e . Then the graph induced by $(K \setminus P) \cup R$ induces a smallest short 3PC($\Delta, \cdot$) of G .*

Proof. Note that G has no 3PC($\Delta, \cdot$) smaller than K , because it has no long 3PC($\Delta, \cdot$) at all, and because K is a smallest short 3PC($\Delta, \cdot$). Let us denote by $r_1 = a, \dots, r_k = d$ the nodes of R . Let r_s be the neighbor of u in R with greatest index. Note that r_s exists because r_1 is a neighbor of u .

We claim that the graph induced by $(K \setminus P) \cup \{r_s, \dots, r_k\}$ induces a short 3PC($\Delta, \cdot$). Indeed, let Q be the path of $K \setminus \{u\}$ with endnodes c and e . Let us denote by $q_1 = c, \dots, q_l = e$ the nodes of Q . If no node of $r_s \dots r_{k-1}$ has neighbors in Q , then the claim holds. So, we may assume that there is a node r_t in $r_s \dots r_{k-1}$ that has a neighbor in the interior of Q , and we choose t maximum. Note that $t > 1$. Let i be the smallest index and j be the greatest index such that q_i, q_j are neighbors of r_t . If $t = s$, then $\{r_t, \dots, r_k, q_j, \dots, q_l, u, b\}$ induces a 3PC(bde, r_t) that is smaller than K , a contradiction. So $t > s$. If $i = j$, then $Q \cup \{r_t, \dots, r_k, u, b\}$ induces a 3PC(bde, q_j) that is smaller than K , a contradiction. If $j > i + 1$, then $\{r_t, \dots, r_k, q_1, \dots, q_i, q_j, \dots, q_l, u, b\}$ induces a 3PC(bde, r_t) that is smaller than K , a contradiction. So $j = i + 1$. There is a shortest path S with endnodes r_t and a in the graph induced by $P \cup \{r_t \dots, r_k\}$. If $d \notin V(S)$, then $Q \cup S \cup \{u, b\}$ induces a long 3PC($r_t q_i q_j, u$), a contradiction. If $d \in V(S)$, then $S \cup \{q_1, \dots, q_i, b, u\}$ induces a

$3PC(d, u)$, a contradiction. This proves the claim.

We proved that $K' = (K \setminus P) \cup \{r_s, \dots, r_k\}$ induces a $3PC(\Delta, \cdot)$. If $s > 1$, then K' is a $3PC(\Delta, \cdot)$ smaller than K , a contradiction. So $s = 1$, proving the lemma. $\square$

Now we can give an algorithm for the detection of short $3PC(\Delta, \cdot)$'s in graphs with no $3PC(\cdot, \cdot)$ and no long $3PC(\Delta, \cdot)$.

ALGORITHM.

INPUT: A graph G with no $3PC(\cdot, \cdot)$ and no long $3PC(\Delta, \cdot)$.

OUTPUT: The positive answer “ G contains a short $3PC(\Delta, \cdot)$ ” if it does; else the negative answer “ G contains no short $3PC(\Delta, \cdot)$.”

METHOD: For every 5-tuple (a, b, c, d, e) of nodes do:

Step 1. Compute in $V(G) \setminus (N(b) \cup N(c) \cup N(e))$ a shortest path P from a to d (if any). Compute in $V(G) \setminus (N(b) \cup N(a) \cup N(d))$ a shortest path Q from c to e (if any). If at least one of the paths does not exist, go to the next 5-tuple.

Step 2. Check if the edge-set of $G[V(P) \cup V(Q) \cup \{a, b, c, d, e\}]$ is exactly $E(P) \cup E(Q) \cup \{bd, be, de\}$. If it is not, go to the next 5-tuple.

Step 3. For every node u of G , check if ua , ub , and uc are the only edges from u to $V(P) \cup V(Q) \cup \{a, b, c, d, e\}$. If it is the case, return the positive answer and stop. Else, go to the next 5-tuple.

If, after checking every 5-tuple, the positive answer has not been returned, return the negative answer.

COMPLEXITY: $O(n^7)$.

Proof. If the algorithm gives the positive answer, let us consider the 5-tuple (a, b, c, d, e) , the paths P, Q , and the node u that make the algorithm stop. It is clear by the method that $V(P) \cup V(Q) \cup \{a, b, c, d, e\}$ induces a short $3PC(\Delta, \cdot)$. Conversely, if G has a short $3PC(\Delta, \cdot)$ K with frame (u, a, b, c, d, e) , then let us examine what the algorithm will do when checking the 5-tuple (a, b, c, d, e) . By two applications of Lemma 4.2, we see that the two paths computed by the algorithm can take the place of the corresponding paths of K to give another short $3PC(\Delta, \cdot)$ K' (possibly not K) with apex u . So, since u exists, the algorithm will find a node that has the same neighborhood as u (in K') and give the positive answer. This proves the correctness of the algorithm. Checking every 5-tuple takes $O(n^5)$, computing shortest paths takes $O(n^2)$, checking every possible edge at Step 2 takes $O(n)^2$, checking every u at Step 3 takes $O(n)$, and checking every neighbor of u takes $O(n)$. So the overall complexity is $O(n^7)$. $\square$

By the algorithms above, we obtain the following.

THEOREM 4.3. *There is an $O(n^7)$ -time algorithm that decides whether a graph has a $3PC(\cdot, \cdot)$ or a $3PC(\Delta, \cdot)$.*

4.2. NP-completeness results. Let us denote by “problem II” the decision problem whose input is a graph G , whose two nonadjacent nodes a, b of G are of degree 2, and whose question is the following: “Does G have a hole that contains both a, b ?” Bienstock [4] proved that this problem is NP-complete. Adapting Bienstock’s proof, Maffray and Trotignon [21] remarked that the problem remains NP-complete for triangle-free graphs. Here is an easy consequence.

THEOREM 4.4. *The problem of deciding whether a graph has an odd wheel is NP-complete. The problem of deciding whether a graph has a short $3PC(\Delta, \cdot)$ is NP-complete.*

Proof. Suppose there is a polynomial time algorithm $\mathcal{A}$ for the detection of short $3PC(\Delta, \cdot)$'s or an algorithm $\mathcal{A}'$ for the detection of odd wheels. Let G, a, b be an

instance of problem Π . Let b', b'' be the neighbors of b in G . Build a graph H by adding to G nodes c_1, c_2, c_3, c_4, c_5 and edges $c_1a, c_1c_2, c_1c_3, c_2c_3, c_2c_4, c_4b', c_3c_5, c_5b''$. Since G has no triangle, every short $3PC(\Delta, \cdot)$ in H has apex a . So there is a short $3PC(\Delta, \cdot)$ in H if and only if there is a hole passing through a and b in G . Similarly, there is an odd wheel in H if and only if there is a hole passing through a and b in G . Thus, algorithm $\mathcal{A}$ (or $\mathcal{A}'$) yields a polynomial time algorithm that solves the NP-complete problem Π . $\square$

When $k \geq 2$, a $kPC(\Delta, \cdot)$ is a graph induced by k chordless paths $P_1, \dots, P_k$, such that each path P_i is from a node x to a node $y_i \neq x$, the nodes $y_1, \dots, y_k$ are distinct and pairwise adjacent, and the union of any two paths P_i, P_j induces a hole. Note that this latter condition implies that at most one of the paths $P_1, \dots, P_k$ can have length 1.

When $k \geq 2$, a $kPC(\cdot, \cdot)$ is a graph induced by k chordless paths $P_1, \dots, P_k$, such that they all have the same endnodes, and the union of any two paths P_i, P_j induces a hole.

For any integer $n \geq 1$, let $K_{1,n}$ denote the graph on $n + 1$ nodes with n edges and a node of degree n . Adapting the proof of Bienstock, we prove that problem Π remains NP-complete for $K_{1,4}$ -free graphs. Before presenting the proof of this result, we point out that problem Π is polynomial for $K_{1,3}$ -free graphs. To see this, consider an instance (G, a, b) of problem Π , where G is $K_{1,3}$ -free. Consider the graph G' obtained from G by adding a node c of degree 2 adjacent to a and b . It is easy to see that G contains a hole going through a and b if and only if G' contains a $3PC(\cdot, \cdot)$. Since this last problem is polynomial [9], problem Π is polynomial when restricted to $K_{1,3}$ -free graphs.

THEOREM 4.5. *Problem Π is NP-complete for $K_{1,4}$ -free graphs.*

Proof. Let us give a polynomial reduction from the problem 3-SATISFIABILITY of Boolean functions to problem Π restricted to $K_{1,4}$ -free graphs. Recall that a Boolean function with n variables is a mapping f from $\{0, 1\}^n$ to $\{0, 1\}$. A Boolean vector $\xi \in \{0, 1\}^n$ is a *truth assignment* for f if $f(\xi) = 1$. For any Boolean variable z on $\{0, 1\}$, we write $\bar{z} := 1 - z$, and each of $z, \bar{z}$ is called a *literal*. An instance of 3-SATISFIABILITY is a Boolean function f given as a product of clauses, each clause being the Boolean sum $\vee$ of three literals; the question is whether f admits a truth assignment. The NP-completeness of 3-SATISFIABILITY is a fundamental result in complexity theory; see [15].

Let f be an instance of 3-SATISFIABILITY consisting of m clauses $C_1, \dots, C_m$ on n variables $z_1, \dots, z_n$. Let us build a graph G_f with two specialized nodes a, b such that there will be a hole containing a and b in G if and only if there exists a truth assignment for f .

For each variable z_i ($i = 1, \dots, n$), make a graph $G(z_i)$ with four nodes a_i, b_i, a'_i, b'_i , and $4(3(m + 1))$ nodes $t_{i,j}, f_{i,j}, t'_{i,j}, f'_{i,j}$, with $j \in \{0, \dots, 3m + 2\}$. Add edges so that the four sets $\{a_i, t_{i,0}, t_{i,1}, \dots, t_{i,3m+2}, b_i\}$, $\{a_i, f_{i,0}, f_{i,1}, \dots, f_{i,3m+2}, b_i\}$, $\{a'_i, t'_{i,0}, t'_{i,1}, \dots, t'_{i,3m+2}, b'_i\}$, $\{a'_i, f'_{i,0}, f'_{i,1}, \dots, f'_{i,3m+2}, b'_i\}$ all induce paths (and the nodes appear in this order along these paths). For $k = 0, \dots, m$, add every possible edge between $\{t_{i,3k}, t_{i,3k+1}\}$ and $\{f_{i,3k}, f_{i,3k+1}\}$, between $\{f_{i,3k}, f_{i,3k+1}\}$ and $\{t'_{i,3k}, t'_{i,3k+1}\}$, between $\{t'_{i,3k}, t'_{i,3k+1}\}$ and $\{f'_{i,3k}, f'_{i,3k+1}\}$, and between $\{f'_{i,3k}, f'_{i,3k+1}\}$ and $\{t_{i,3k}, t_{i,3k+1}\}$. See Figure 1.

For each clause C_j ($j = 1, \dots, m$), with $C_j = y_j^1 \vee y_j^2 \vee y_j^3$, where each y_j^p ($p = 1, 2, 3$) is a literal from $\{z_1, \dots, z_n, \bar{z}_1, \dots, \bar{z}_n\}$, make a graph $G(C_j)$ with fourteen nodes $c_j, d_j, u_j^1, v_j^1, w_j^1, x_j^1, u_j^2, v_j^2, w_j^2, x_j^2, u_j^3, v_j^3, w_j^3, x_j^3$. Add edges so that the

FIG. 1. Graph $G(z_i)$.FIG. 2. Graph $G(C_j)$.

three sets $\{c_j, u_j^1, v_j^1, w_j^1, x_j^1, d_j\}$, $\{c_j, u_j^2, v_j^2, w_j^2, x_j^2, d_j\}$, $\{c_j, u_j^3, v_j^3, w_j^3, x_j^3, d_j\}$ all induce paths (and the nodes appear in this order along these paths). Add six more edges so that $\{u_j^1, u_j^2, u_j^3\}$, $\{x_j^1, x_j^2, x_j^3\}$ induce two triangles. See Figure 2.

The graph G_f is obtained from the disjoint union of the $G(z_i)$'s and the $G(C_j)$'s as follows. For $i = 1, \dots, n-1$, add edges $b_i a_{i+1}$ and $b'_i a'_{i+1}$. Add an edge $b'_n c_1$. For $j = 1, \dots, m-1$, add an edge $d_j c_{j+1}$. Introduce the two special nodes a, b and add edges aa_1, aa'_1 and bd_m, bb_n . See Figure 4. For $p = 1, 2, 3$, if $y_j^p = z_i$, then add four edges $v_j^p f_{i,3j-1}, v_j^p f'_{i,3j-1}, w_j^p f_{i,3j-1}, w_j^p f'_{i,3j-1}$, while if $y_j^p = \bar{z}_i$, then add four edges $v_j^p t_{i,3j-1}, v_j^p t'_{i,3j-1}, w_j^p t_{i,3j-1}, w_j^p t'_{i,3j-1}$. See Figure 3. Clearly the size of G_f is polynomial (actually quadratic) in the size $n+m$ of f . Moreover, it is a routine matter to check that G_f contains no $K_{1,4}$, and that a, b are nonadjacent and both have degree 2.

Suppose that f admits a truth assignment $\xi \in \{0, 1\}^n$. We can build a hole in G by selecting nodes as follows. Select a, b . For $i = 1, \dots, n$, select a_i, b_i, a'_i, b'_i . If $\xi_i = 1$, select $t_{i,j}, t'_{i,j}$ where $j \in \{0, \dots, 3m+2\}$. If $\xi_i = 0$, select $f_{i,j}, f'_{i,j}$ where $j \in \{0, \dots, 3m+2\}$. For $j = 1, \dots, m$, since ξ is a truth assignment for f , at least one of the three literals of C_j is equal to 1, say $y_j^p = 1$ for some $p \in \{1, 2, 3\}$. Then select c_j, d_j and $u_j^p, v_j^p, w_j^p, x_j^p$. Now it is a routine matter to check that the selected nodes induce a cycle Z that contains a, b , and that Z is chordless, so it is a hole. The main point is that there is no chord in Z between some subgraph $G(C_j)$ and some subgraph $G(z_i)$, for that would be either an edge $t_{i,3j-1} v_j^p$ (or similarly $t'_{i,3j-1} v_j^p$,

FIG. 3. The four edges added to G_f in the case $y_j^1 = z_i$.FIG. 4. Graph G_f .

$t_{i,3j-1}w_j^p, t'_{i,3j-1}w_j^p$) with $y_j^p = z_i$ and $\xi_i = 1$, or, symmetrically, an edge $f_{i,3j-1}v_j^p$ (or similarly $f'_{i,3j-1}v_j^p, f_{i,3j-1}w_j^p, f'_{i,3j-1}w_j^p$) with $y_j^p = \bar{z}_i$ and $\xi_i = 0$, and in either case this would contradict the way the nodes of Z were selected.

Conversely, suppose that G_f admits a hole Z that contains a, b . Clearly Z contains a_1, a'_1 since these are the only neighbors of a in G_f .

CLAIM 4.1. *For $i = 1, \dots, n$, Z contains exactly $6m + 10$ nodes of $G(z_i)$: four of these are a_i, a'_i, b_i, b'_i , and the others are either the $t_{i,q}, t'_{i,q}$'s or the $f_{i,q}, f'_{i,q}$'s, where $q \in \{0, \dots, 3m + 2\}$.*

Proof. First we prove the claim for $i = 1$. Since a, a_1 are in Z and a_1 has only three neighbors $a, t_{1,0}, f_{1,0}$, exactly one of $t_{1,0}, f_{1,0}$ is in Z . Likewise exactly one of $t'_{1,0}, f'_{1,0}$ is in Z . If $t_{1,0}, f'_{1,0}$ are in Z , then the nodes $a, a_1, a'_1, t_{1,0}, f'_{1,0}$ are all in Z and they induce a hole that does not contain b , a contradiction. Likewise we do not have both $t'_{1,0}, f_{1,0}$ in Z . Therefore, up to symmetry we may assume that $t_{1,0}, t'_{1,0}$ are in Z and $f_{1,0}, f'_{1,0}$ are not. This implies $t_{1,1}, t'_{1,1} \in Z$.

Suppose that for some $j \in \{1, \dots, m + 1\}$ and $k \in \{0, 1, 2\}$ one of $t_{1,3(j-1)+k}, t'_{1,3(j-1)+k}$ is not in Z . Let $3(j-1) + k$ be minimum with that property and assume up to a symmetry that $t_{1,3(j-1)+k}$ is not in Z . If $k = 0$ or $k = 1$, then Z contains up to a symmetry $f_{1,3(j-1)+k}$ that is adjacent to $t'_{1,3(j-1)+k}$, so Z cannot contain a, b , a contradiction. So, $k = 2$, $t_{1,3(j-1)+k}$ is in Z and one of v_j^p, w_j^p , $p \in \{1, 2, 3\}$, say v_j^1 up to a symmetry, must be in Z . But then, by the definition of G_f , v_j^1 is adjacent to $t'_{1,3(j-1)+2}$. So, Z has node set $\{a, t_{1,0}, t'_{1,0}, \dots, t_{1,3(j-1)+2}, t'_{1,3(j-1)+2}, v_j^1\}$ and b is not in Z , a contradiction. So, for $q = 0, \dots, 3m + 2$, we have $t_{1,j}, t'_{1,j} \in Z$ and $b_1, b'_1 \in Z$.

Now, for $j = 0, \dots, m$, none of $f_{i,3j}, f_{i,3j+1}$ can be in Z . So, $f_{i,3j+2}$ cannot be in Z because only one of its neighbor can be in Z . In particular, $a_2 \in Z$ and similarly $a'_2 \in Z$.

This proves our claim for $i = 1$. The proof of the claim for $i = 2$ is essentially the same as for $i = 1$, and by induction the claim holds up to $i = n$. $\square$

CLAIM 4.2. *For $j = 1, \dots, m$, Z contains c_j, d_j and exactly one of $\{u_j^1, v_j^1, w_j^1, x_j^1\}, \{u_j^2, v_j^2, w_j^2, x_j^2\}, \{u_j^3, v_j^3, w_j^3, x_j^3\}$.*

Proof. First we prove this claim for $j = 1$. By Claim 4.1, b'_n is in Z and exactly one of $t'_{n,3m+2}, f'_{n,3m+2}$ is in Z , so (since b'_n has degree 3 in G_f) c_1 is in Z . Consequently exactly one of u_1^1, u_1^2, u_1^3 is in Z , say u_1^1 . The neighbor of u_1^1 in $Z \setminus c_1$ cannot be a node among u_1^2, u_1^3 , for this would imply that Z contains a triangle. Hence $v_1^1 \in Z$. The neighbor of v_1^1 in $Z \setminus u_1^1$ cannot be in some $G(z_i)$ ($1 \leq i \leq n$), for in that case that neighbor would be either $t_{i,2}$ (or $f_{i,2}$) and thus, by Claim 4.1, node $t'_{i,2}$ (or $f'_{i,2}$) would be a third neighbor of v_1^1 in Z , a contradiction. Thus the other neighbor of v_1^1 in Z is w_1^1 . Similarly, we prove that w_1^1, x_1^1, d_1 are in Z , and so the claim holds for $j = 1$. Since d_1 has degree 4 in G_f and exactly one of x_1^1, x_1^2, x_1^3 is in Z , it follows that the fourth neighbor c_2 of d_1 is in Z . Now the proof of the claim for $j = 2$ is the same as for $j = 1$, and by induction the claim holds up to $j = m$. $\square$

We can now make a Boolean vector ξ as follows. For $i = 1, \dots, n$, if Z contains $t_{i,0}, t'_{i,0}$, then set $\xi_i = 1$; if Z contains $f_{i,0}, f'_{i,0}$, then set $\xi_i = 0$. By Claim 4.1 this is consistent. Consider any clause C_j ($1 \leq j \leq m$). By Claim 4.2 and up to symmetry we may assume that v_j^1 is in Z . If $y_j^1 = z_i$ for some $i \in \{1, \dots, n\}$, then the construction of G_f implies that $f_{i,3j-1}, f'_{i,3j-1}$ are not in Z , so $t_{i,3j-1}, t'_{i,3j-1}$ are in Z , so $\xi_i = 1$, so clause C_j is satisfied by x_i . If $y_j^1 = \bar{z}_i$ for some $i \in \{1, \dots, n\}$, then the construction of G_f implies that $t_{i,3j-1}, t'_{i,3j-1}$ are not in Z , so $f_{i,3j-1}, f'_{i,3j-1}$ are in Z , so $\xi_i = 0$, and so clause C_j is satisfied by $\bar{z}_i$. Thus ξ is a truth assignment for f . This completes the proof of the lemma. $\square$

THEOREM 4.6. *For each integer $k \geq 4$, the problem of deciding whether a graph contains a $kPC(\cdot, \cdot)$ is NP-complete, and the problem of deciding whether a graph contains a $kPC(\Delta, \cdot)$ is NP-complete.*

Proof. Let $k \geq 4$ be an integer. We give a reduction from problem Π to the problems whose NP-completeness is claimed. So let (G, a, b) be any instance of problem Π , where G is a $K_{1,4}$ -free graph and a, b are nonadjacent nodes of G of degree 2. Let us call a', a'' the two neighbors of a and b', b'' the two neighbors of b in G .

Reduction to the detection of a $kPC(\cdot, \cdot)$. Starting from G , build a graph G' as follows: Add nodes $y_1, \dots, y_{k-2}$. Add edges $ay_1, \dots, ay_{k-2}, by_1, \dots, by_{k-2}$. We see that G' contains a $kPC(\cdot, \cdot)$ if and only if G contains a hole that contains a and b . So every instance of Π can be reduced polynomially to an instance of the detection of a $kPC(\cdot, \cdot)$, which proves that this problem is NP-complete.

Reduction to the detection of a $kPC(\Delta, \cdot)$. Starting from G , build the same graph G' as above. Subdivide every edge ay_i , $i \in 1, \dots, k-2$, by adding a node z_i of degree 2. Subdivide edge aa' by adding a node a''' of degree 2. Add every possible edge between the nodes of $\{b', b'', y_1, \dots, y_{k-2}\}$. We see that G' contains a $kPC(\Delta, \cdot)$ if and only if G contains a hole that contains a and b . So every instance of Π can be reduced polynomially to an instance of the detection of a $kPC(\Delta, \cdot)$, which proves that this problem is NP-complete. $\square$

A NEW ALGORITHM FOR ON-LINE COLORING BIPARTITE GRAPHS*

HAJO J. BROERSMA[†], AGOSTINO CAPPONI[‡], AND DANIEL PAULUSMA[†]

Abstract. We first show that for any bipartite graph H with at most five vertices there exists an on-line competitive algorithm for the class of H -free bipartite graphs. We then analyze the performance of an on-line algorithm for coloring bipartite graphs on various subfamilies. The algorithm yields new upper bounds for the on-line chromatic number of bipartite graphs. We prove that the algorithm is on-line competitive for P_7 -free bipartite graphs, i.e., that do not contain an induced path on seven vertices. The number of colors used by the on-line algorithm for P_6 -free and P_7 -free bipartite graphs is, respectively, bounded by roughly twice and roughly eight times the on-line chromatic number. In contrast, it is known that there exists no competitive on-line algorithm to color P_6 -free (or P_7 -free) bipartite graphs, i.e., for which the number of colors is bounded by any function depending only on the chromatic number.

Key words. on-line coloring, bipartite graph, (on-line) competitive

1. Introduction. In static optimization problems one is often faced with the challenge of determining efficient algorithms that solve a particular problem (nearly) optimally for any given instance of the problem. This task is usually facilitated if the structure of the instances is pretty straightforward. As an example, it is a trivial exercise to determine an algorithm for finding a 2-coloring of a given bipartite graph.

In the area of dynamic optimization the situation gets more complicated. There, one often lacks the knowledge of the complete instances of the problems. As an illustration, compare the previous problem with the slightly changed situation in which the bipartite graph is presented on-line, i.e., vertex by vertex, and the algorithm has to assign a color irrevocably to a vertex as it comes in, i.e., only based on the knowledge of the subgraph that has been revealed so far. This slight change of the problem formulation makes it a lot more difficult: whereas the static problem was trivial, no algorithm for the dynamic problem can guarantee an optimal solution for every instance. In [12] it has been shown that the worst-case performance ratio between on-line and off-line coloring of a known input graph on n vertices is at least $2n/(\log_2 n)^2$. It is even questionable whether one can expect to determine an on-line algorithm that does reasonably well, in the sense that the number of colors used is bounded in some other reasonable way, e.g., as a function of some invariant of the input instances.

In this paper we will focus on particular questions of this type related to coloring bipartite graphs. These types of questions in a more general setting are at the heart of the areas of on-line algorithms and of approximation algorithms.

We first give a short historical excursion starting with a benchmark paper from Gyárfás and Lehel [9]. They introduced the concept of on-line coloring as a general approach. This was motivated by their translation of a rectangle packing problem related to dynamical storage allocation appearing in [4] into an on-line coloring problem. The latter problem was to decide whether the on-line coloring algorithm known as *First-Fit* (*FF*) has a constant worst-case performance ratio on the family of interval graphs. We note that since [9] many papers on on-line (coloring) problems have appeared. We refer to [14] for a survey on on-line coloring and to [2] for more background on the general area of on-line algorithms.

In order to have some measure of the performance of on-line algorithms, the notion of competitive algorithms has been introduced in [20] and specifically for coloring in [9]. Intuitively, an on-line coloring algorithm is said to be competitive for a family of graphs $\mathcal{G}$ if, for any graph $G \in \mathcal{G}$, the number of colors used by the algorithm on G is bounded from above by a function depending only on the chromatic number of G . The chromatic number of G is the smallest number of colors that is necessary to properly color the vertices of G (off-line), i.e., such that adjacent vertices receive different colors. In [13] it is shown that *FF* is competitive for interval graphs, with a bounding function that is linear in the chromatic number, and in [6] competitiveness of *FF* for geometric intersection graphs has been proven. In [5] it is shown that *FF* is competitive for graphs with a bounded independence number, including co-planar graphs.

It is well known that *FF* is not competitive for P_6 -free bipartite graphs, i.e., bipartite graphs that do not contain an induced path on six vertices: if the vertices of a complete bipartite graph $K_{m,m}$ minus a perfect matching $\{u_1, v_1\}, \{u_2, v_2\}, \dots, \{u_m, v_m\}$ are presented in the ordering $u_1, v_1, u_2, v_2, \dots, u_m, v_m$, then *FF* uses m colors. In fact, there are many families of graphs for which it has been proven that no competitive algorithms exist: two examples given in [9] are the family of trees and the family of P_6 -free bipartite graphs. These negative results have led to the definition of a weaker form of competitiveness in [7], namely on-line competitiveness, although results of this type have been obtained before the term was formally introduced.

We can explain the notion of on-line competitiveness as follows. It is perhaps more natural to compare the number of colors that is needed to color a graph G by an on-line algorithm to the on-line chromatic number instead of the chromatic number. We will define the on-line chromatic number formally in section 3. Intuitively, it is the number of colors used by the best performing on-line algorithm for G , i.e., that gives the smallest number of colors in the worst-case ordering of the presented vertices of G . An on-line coloring algorithm is said to be on-line competitive if the number of colors is bounded from above by a function only depending on the on-line chromatic number of G . The main open problem is whether on-line competitive coloring algorithms exist for all graphs. A subproblem is to establish such algorithms for certain classes of graphs for which competitive algorithms do not exist. Solving this subproblem can be particularly useful if somebody must design an on-line coloring algorithm in the case that the input graphs are only known to be in a specified class of graphs. This also motivated our choice for considering special graph classes.

It is shown in [10] that *FF* is on-line competitive for trees; it is even optimal for trees, in the sense that if *FF* uses k colors, then the on-line chromatic number of the tree is also k . In [7] it is shown that *FF* is on-line competitive with an exponential bounding function for graphs with girth of at least five.

In the context of algorithmic graph theory it has become rather fashionable to

consider forbidden subgraph conditions. For instance, many NP-hard problems turn out to be solvable in polynomial time when restricted to H -free graphs for particular choices of H . Therefore, these graph classes are well studied throughout a range of NP-hard problems. In the context of coloring, e.g., 3-colorability is polynomially solvable for P_6 -free graphs, while 4-colorability remains NP-hard for P_{12} -free graphs, and 5-colorability remains NP-hard for P_8 -free graphs. We refer the reader to the survey paper [19] for more details. Note also that well-studied graph classes like chordal graphs (or, more generally, perfect graphs) and line graphs (or, more generally, claw-free graphs) can be characterized by forbidden subgraph conditions.

2. Results of this paper. One of the main open problems concerning on-line competitive coloring algorithms [7] is to decide whether for every k there exists an on-line competitive coloring algorithm for the family of graphs with on-line chromatic number k . Perhaps surprisingly, this is even open for bipartite graphs for $k = 4$, whereas it has been solved for general graphs for $k \leq 3$: in both [8] and [17] it is proven that for the family of graphs with on-line chromatic number 3 at most four colors are needed. The open problem on bipartite graphs seems to be very hard and emphasizes how much on-line coloring differs from off-line coloring.

Our results are motivated by a number of open problems, but most strongly by the above open problem for bipartite graphs. We solve the problem for several subclasses of bipartite graphs which are defined by forbidding a certain fixed bipartite graph H as an induced subgraph. For a relatively small graph H this is an easy exercise, but for larger graphs this gets difficult, in correspondence with the fact that the class of H -free graphs contains the class of H' -free graphs if H' is a subgraph of H . By combining known results and dealing with a few cases ourselves, we show that for every bipartite graph H with at most five vertices there exists an on-line competitive coloring algorithm for the class of H -free bipartite graphs. Since for P_4 -free and P_5 -free graphs there even exists a competitive algorithm [9, 11], and since P_6 -free bipartite graphs do not admit a competitive algorithm [9], our natural starting point from there is the latter class. In [3] we proved that there exists an on-line competitive algorithm for the class of P_6 -free bipartite graphs; its bounding function is *linear* in the on-line chromatic number, namely roughly twice the on-line chromatic number. In fact, this gives a 2-approximation algorithm for on-line coloring P_6 -free bipartite graphs. In this paper we prove a similar result for the larger class of P_7 -free bipartite graphs with a bounding function that is roughly eight times the on-line chromatic number. Note that the on-line chromatic number for both these graph classes can be arbitrarily high, so these classes are definitely no subclasses of the class of bipartite graphs with on-line chromatic number 4. In this sense, our results have a broader appeal than just solving the aforementioned problem with $k = 4$ for the restricted classes of P_6 -free and P_7 -free bipartite graphs. It might be possible that our algorithm or variations on it can be used to prove similar results for larger subclasses of bipartite graphs, although we have not been able to do so yet. We also note that our algorithm uses at most four colors (so it is competitive) for the class of P_5 -free bipartite graphs.

The rest of the paper is organized as follows. Section 3 contains the basic notation and definitions. In section 4 we start our exposition by proving the result on H -free bipartite graphs with $|V(H)| \leq 5$. Next we introduce the key algorithm of this paper called *BicolorMax*. We prove in section 6 that it is on-line competitive for P_7 -free bipartite graphs. In section 7 we deduce new upper bounds for the on-line chromatic number of bipartite graphs. We give some final remarks in section 8 and conclusions in section 9.

3. Preliminaries. Throughout we consider simple graphs $G = (V(G), E(G))$, where $V(G)$ is a set of vertices and $E(G)$ is a set of unordered pairs of vertices, called edges. For graph terminology not defined below we refer to [1].

A graph is called *bipartite* if its vertex set can be partitioned into two disjoint sets so that all edges are incident with vertices from both sets. If H is a *subgraph* of G , i.e., if H is a graph and $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$, then we write $H \subseteq G$. If $S \subseteq V(G)$, then $G[S]$ denotes the subgraph of G with vertex set S and edge set $\{\{x, y\} \mid x \in S, y \in S\}$. A graph is an *induced subgraph* of G if it is isomorphic to $G[S]$ for some nonempty $S \subseteq V(G)$. A graph is *H-free* if it does not contain the graph H as an induced subgraph. We call two vertex-disjoint graphs *remote* if there are no edges joining them. A maximal connected subgraph of a graph G is called a *component* of G . For any two vertices x, y of a connected graph G we denote by P_{xy} a path between x and y in G . We define the *distance* $d(x, y, G)$ between x and y in G as the number of edges of a shortest path between x and y . We use K_n , C_n , and P_n to denote, respectively, the complete graph, the cycle, and the path on n vertices, and we use $K_{m,n}$ to denote the complete bipartite graph with m vertices in one bipartition class and n vertices in the other. A *coloring* of a graph G is a function $c : V(G) \rightarrow \{1, 2, \dots\}$ such that $c(v) \neq c(w)$ whenever $\{v, w\} \in E(G)$. The smallest number of colors in a coloring of G is the *chromatic number* of G and denoted by $\chi(G)$. Clearly, a graph G is bipartite if and only if $\chi(G) \leq 2$.

We assume that the reader is familiar with the basic concept of an on-line coloring algorithm. For details we refer to [14]. Intuitively, an on-line coloring algorithm properly colors the vertices of a graph one by one, consistently using a fixed strategy, depending only on the subgraph induced by the revealed vertices and the colors that have been assigned to them by the algorithm, according to an externally determined ordering of the presented vertices.

A popular informative way of looking at on-line coloring is as a two-person game. In the two-person game, the *Drawer* reveals the vertices of G one by one together with their adjacencies to vertices already revealed. The *Painter* irrevocably assigns an admissible color to the currently revealed vertex, based on a strategy involving the graph induced by the already revealed vertices and their colors, and the adjacencies of the currently revealed vertex. The aim of Drawer is to reveal the vertices in an order that forces Painter to use many colors. The aim of Painter is to invent a strategy that uses as few colors as possible. The order in which Drawer reveals the vertices of G is an ordering of the vertices of $V(G)$. Any strategy Painter chooses can be extended to some on-line coloring algorithm in the above sense that assigns Painter's coloring to G . The reverse is also true: a coloring prescribed by an on-line coloring algorithm can be simulated by a two-person game with a Drawer and Painter as described above.

We denote the (finite) set of all on-line coloring algorithms for a graph G by $AOL(G)$. Let $\Pi(G)$ denote the set of all permutations of the vertices of G . If $A \in AOL(G)$ and $\pi \in \Pi(G)$, then we denote by $\chi_A(G, \pi)$ the number of colors used by A when the vertices of G are presented according to π . The largest number of colors used by the on-line algorithm A for G is called the *A-chromatic number* of G and denoted by $\chi_A(G)$. Hence

$$\chi_A(G) = \max_{\pi \in \Pi(G)} \chi_A(G, \pi).$$

The smallest number of colors used by an on-line algorithm for G is the *on-line chromatic number* of G and denoted by $\chi_{OL}(G)$ [9]. Hence

$$\chi_{OL}(G) = \min_{A \in AOL(G)} \chi_A(G).$$

Let $\mathcal{G}$ denote a (possibly infinite) family of graphs. If $A \in AOL(G)$ for every $G \in \mathcal{G}$, then we say that A is an on-line coloring algorithm for $\mathcal{G}$ and write $A \in AOL(\mathcal{G})$. An algorithm $A \in AOL(\mathcal{G})$ is said to be *competitive* for $\mathcal{G}$ if there exists a function f such that $\chi_A(G) \leq f(\chi(G))$ for every $G \in \mathcal{G}$; it is *on-line competitive* if $\chi_A(G) \leq f(\chi_{OL}(G))$ for every $G \in \mathcal{G}$.

4. Small forbidden subgraphs. As stated before, it has been shown that there does not exist a competitive on-line coloring algorithm for P_6 -free bipartite graphs, but there exists a competitive on-line coloring algorithm for P_5 -free bipartite graphs. In fact, combining results from [7, 11, 15, 16], and analyzing a few cases ourselves, we can show that there exists an on-line coloring algorithm that is on-line competitive for the class of H -free bipartite graphs for any fixed bipartite graph H on at most five vertices. We are not able to show such a result for any fixed graph H that is not bipartite. Since a bipartite graph does not contain a nonbipartite subgraph, this would come down to proving that there exists an on-line coloring algorithm that is on-line competitive for the class of bipartite graphs. This, however, is still a major open problem.

Before stating and proving our proposition below, let us first note that we are not aiming at obtaining nice performance ratios in our proof of this proposition. As we are primarily interested in the existence result, here we took the freedom to use rather unsophisticated methods for reaching our goal.

PROPOSITION 4.1. *Let H be a bipartite graph on at most five vertices. Then there exists an on-line coloring algorithm that is on-line competitive for the class of H -free bipartite graphs.*

Proof. We may restrict ourselves to bipartite graphs on exactly five vertices, noting that an F -free bipartite graph with F bipartite on at most four vertices is also H -free for some bipartite graph H on five vertices. We use $H + H'$ to denote the disjoint union of two graphs H and H' , and pH to denote the disjoint union of $p \geq 2$ copies of H . Before we make a case distinction we first make the following easy observation:

- (1) Let F be a graph and A an on-line coloring algorithm that is on-line competitive for the class of F -free bipartite graphs. Then there exists an on-line coloring algorithm A' that is on-line competitive for the class of $F + K_1$ -free bipartite graphs.

This claim can be seen as follows. Initially we use algorithm A to color the vertices of an $F + K_1$ -free bipartite graph G . If G does not contain an induced F , then we do not need any extra colors. Suppose G contains an induced subgraph G' that is isomorphic to F . We assume that G' is the first occurrence of F if G is revealed to A . Let v be the last vertex of G' presented to A . We color v with a new color c^* . Since G is $F + K_1$ -free, any vertex w that is presented after v must have a neighbor in G' . Let $Q_1, \dots, Q_p$ be the components of G' . We note that these components are bipartite, since G is bipartite. For each component Q_i ($i = 1, \dots, p$) we define a set of two new colors $\{c_i, d_i\}$, each of which corresponds to one of the classes in the bipartition of Q_i . Now suppose Q_h is the component that has the smallest index h of all the components of G' , which w is adjacent to. Then we color w with c_h or d_h , depending on which bipartite class of Q_h vertex w belongs to. This way we can finish the coloring of G with at most $2p + 1$ extra colors.

We now distinguish a number of cases depending on the value of $|E(H)| = m$.

Case I. $m = 0$. Then $H = 5K_1$. Since G is bipartite, we obtain $\chi_{FF} \leq \Delta(G) + 1 \leq 5$.

Case II. $m = 1$. Then $H = K_2 + 3K_1$. It is trivial to see that FF is on-line competitive for the class of K_2 -free graphs, i.e., graphs with only isolated vertices. After applying (1) three times we get the desired result.

Case III. $m = 2$. Then $H = P_3 + 2K_1$ or $2K_2 + K_1$. For the first subcase we can proceed similarly as in Case II. For the second subcase we use the following result from [11]:

(2) If G is a P_5 -free graph without triangles, then $\chi_{FF}(G) \leq 3$.

Noting that $2K_2$ -free bipartite graphs are both P_5 -free and triangle-free, and combining (1) and (2), yields the result.

Case IV. $m = 3$. Then $H = P_4 + K_1$, $K_{1,3} + K_1$, or $P_3 + K_2$. Noting that P_4 -free bipartite graphs are both P_5 -free and triangle-free, and combining (1) and (2), yields the desired result for the first subcase. For the second subcase we first observe that $\chi_{FF}(G) \leq \Delta(G) + 1 \leq 3$ for any $K_{1,3}$ -free bipartite graph G and then we apply (1) to get the result. Since a $P_3 + K_2$ -free bipartite graph is a P_7 -free bipartite graph, we can of course immediately apply Theorem 6.8 (which will be presented later) for the third subcase. It is also not difficult to give a direct proof that our algorithm *BicolorMax* (which will be presented in the next section) is on-line competitive for this class of graphs.

Case V. $m = 4$. Then $H = K_{1,4}$, $C_4 + K_1$, P_5 , or the unique graph with degree sequence 3,2,1,1,1 which we denote by $K_{1,3}^+$. For the first subcase we easily get that $\chi_{FF}(G) \leq \Delta(G) + 1 \leq 4$. The *girth* of a graph G is the number of edges of a smallest cycle in G . For the second subcase we combine (1) with the following result from [7]:

(3) If G has a girth of at least five, then $\chi_{FF}(G) \leq \binom{2^{\chi_{OL}(G)}}{2}$.

For the third subcase we use (2). The *radius* of a graph G is defined as the minimum of $\max_v d(u, v, G)$ over all vertices u in G . Since $K_{1,3}^+$ has a radius of 2, we can use the following result from [16]:

(4) For every tree T with a radius of 2, there is an on-line coloring algorithm A that is on-line competitive for the class of T -free graphs.

Case VI. $m = 5$. Then $H = K_{2,3} - e$ for an edge e of $K_{2,3}$. We need a separate proof for this case and first prove the following claim.

Claim. Let G be bipartite and H -free and let C be a component of G such that C_4 is an induced subgraph of C . Then $C = K_{s,t}$ for some integers $s, t \geq 2$.

We prove this claim as follows. If $C = C_4 = K_{2,2}$, then the claim trivially holds. If not, let $C_4 = uvwxu$, and let $N(p)$ denote the neighbors of vertex p in C . If $N(u) \not\subseteq N(w)$, then G contains H as an induced subgraph. So, by symmetry, $N(u) = N(w)$, and similarly $N(v) = N(x)$. Let $y \in N(u) \cap N(w)$. Then $uvwxyu$ is an induced C_4 , so as before $N(y) = N(v) = N(x)$. Hence all neighbors of u and w are adjacent to all neighbors of v and x and vice versa. By repeating the arguments for all induced C_4 's, we obtain that $C = K_{s,t}$ for some $s, t \geq 2$.

A component in a bipartite graph that does not contain an induced C_4 has a girth of at least six. Since $\chi_{FF}(K_{s,t}) = 2$, the above claim together with (3) then implies that $\chi_{FF}(G) \leq \max\{\binom{2^{\chi_{OL}(G)}}{2}, 2\}$.

Case VII. $m = 6$. Then $H = K_{2,3}$. Kierstead and Penrice [15] showed that FF is on-line competitive for the class of H -free graphs. $\square$

We conclude that the first open question with respect to the (non)existence of on-line competitive coloring algorithms for H -free bipartite graphs concerns bipartite graphs H on six vertices, in particular $H = P_6$, which has radius 3. In the next section we present an on-line algorithm for coloring general bipartite graphs. We will show that it is on-line competitive for (P_6 -free and) P_7 -free bipartite graphs.

5. The algorithm BicolorMax. Let G be a bipartite graph on n vertices denoted by $1, 2, \dots, n$. Let $A = \{a_1, a_2, \dots, a_p\}$ and $B = \{b_1, b_2, \dots, b_p\}$ be two disjoint ordered sets of colors. For a fixed positive integer $k \leq p$, let $A(k) = \{a_1, a_2, \dots, a_k\}$ and $B(k) = \{b_1, b_2, \dots, b_k\}$.

We first give the general idea of our on-line algorithm called *BicolorMax*. Suppose that G is presented to the algorithm. At some stage a new uncolored vertex v of G is revealed, together with its adjacencies to the set S of already colored vertices of G . If v is not adjacent to any previously revealed vertex of G , then v receives color a_1 . Otherwise, the choice of the color for v is based on the present colors in the bipartition classes of the component containing v of the subgraph of G induced by v and the vertices of S with colors in $A(k) \cup B(k)$ for some suitable $k \geq 1$. To make this choice explicit we first need to introduce some additional terminology.

If $F \subseteq V(G)$, then the *hue* of F , denoted by $H(F)$, is the set of all colors used on vertices in F . Let $\pi \in \Pi(G)$ for a bipartite graph G , and assume that $v = \pi(j)$. Let G_j^k denote the subgraph of $G[\{\pi(1), \dots, \pi(j)\}]$ induced by $v = \pi(j)$ and all the vertices in $\{\pi(1), \dots, \pi(j-1)\}$ that have been assigned colors from $A(k) \cup B(k)$. We denote by C_j^k the component of G_j^k containing v , and we write $C_j^k := (I_1, I_2)$ to indicate the bipartition of its vertex set. Note that (I_1, I_2) is the unique bipartition of C_j^k (up to renaming), because C_j^k is connected. We say that color a_k is *mixed* on $C_j^k = (I_1, I_2)$ if there exist at least two vertices, $v \in I_1$ and $w \in I_2$, that have been colored with a_k . We then call (v, w) a *k-mixed pair*.

We are now ready to explain the choice of the color of a new vertex. The key idea is to prevent the mixing of colors as much as possible. Recall that in the worst case FF uses m colors for a complete bipartite graph $K_{m,m}$ minus a perfect matching, because the worst-case ordering forces FF to assign the same color to each pair of the perfect matching; hence, all m colors are used on both bipartite classes. In order to reduce the total number of colors we somehow need to avoid this as much as possible by changing the coloring strategy with respect to mixing colors.

The algorithm *BicolorMax* has been designed with this intuitive idea in mind. It is defined inductively. Vertex $\pi(1)$ is colored with a_1 . Suppose that vertices $\pi(1), \dots, \pi(j-1)$ have already been colored. Let $v = \pi(j)$ be the next vertex presented to the algorithm. The algorithm first computes the highest value of k such that a_k is mixed on C_j^k . We denote this value by m . In order to stop the mixing of colors, the algorithm colors v with a_{m+1} or with b_{m+1} . By definition of m , the color a_{m+1} is not mixed on C_j^{m+1} . The choice will fall on a_{m+1} if v is in the same bipartition class as a vertex with color a_{m+1} or if a_{m+1} has not been used before on C_j^{m+1} . Otherwise v receives color b_{m+1} . This way the mixing of color a_{m+1} within a component is prevented. We note that a_{m+1} might get mixed later on: if at a certain stage two components that both contain a vertex with color a_{m+1} are joined by a new vertex, then a_{m+1} becomes mixed if at least two vertices with color a_{m+1} belong to different bipartition classes.

Before we give a formal description of our algorithm we would like to make the following remark. The algorithm FF uses at most three colors on any path P_n . However, *BicolorMax* does not try to use the colors a_k or b_k for any $k < m$ if a_m is mixed on C_j^m . Hence, it is easy to see that *BicolorMax* is not on-line competitive for the family of paths. In section 8 we return to this observation and show how we can combine FF and *BicolorMax* to obtain an on-line competitive algorithm for families of graphs for which FF is on-line competitive as well.

```

BicolorMax( $G[\{\pi(1), \dots, \pi(j-1)\}], v$ )

 $m := \max(\{0\} \cup \{k : a_k \text{ is mixed on } C_j^k\})$ .
if  $a_{m+1} \notin H(V(C_j^{m+1}))$ 
     $C_j^{m+1} := (I_1, I_2)$  such that  $v \in I_1$ 
else
     $C_j^{m+1} := (I_1, I_2)$  such that  $a_{m+1} \in H(I_1)$ .
if  $v \in I_1$ 
    assign color  $a_{m+1}$  to  $v$ 
else
    assign color  $b_{m+1}$  to  $v$ .
```

It is immediately clear that *BicolorMax* is not able to color a nonbipartite graph G . For instance, take $G = K_3$. Then $C_3^1 = C_3^2 = K_3$ cannot be partitioned into two independent sets I_1 and I_2 . For bipartite graphs, *BicolorMax* does assign a coloring for each vertex permutation.

OBSERVATION 5.1. *BicolorMax is an on-line coloring algorithm for bipartite graphs.*

Proof. Let $\pi \in \Pi(G)$ for a bipartite graph G . Let $v = \pi(j)$ be the j th vertex presented to *BicolorMax*. Let $m := \max(\{0\} \cup \{k : a_k \text{ is mixed on } C_j^k\})$.

Suppose $a_{m+1} \notin H(V(C_j^{m+1}))$. This means that v is not adjacent to a previously presented vertex with color a_{m+1} . Hence, *BicolorMax* may color v with color a_{m+1} in a proper vertex coloring.

Suppose $a_{m+1} \in H(V(C_j^{m+1}))$. By maximality of m , we find that a_{m+1} is not mixed on C_j^{m+1} . Then, a_{m+1} is only assigned to vertices in one bipartite class of C_j^{m+1} , and we can indeed define $C_j^{m+1} = (I_1, I_2)$ with $a_{m+1} \in H(I_1)$ and $a_{m+1} \notin H(I_2)$. If v is in I_1 , then *BicolorMax* colors v with a_{m+1} . Since $a_{m+1} \notin H(I_2)$, vertex v is not adjacent to any previously presented vertex with color a_{m+1} . If v is in I_2 , then *BicolorMax* colors v with b_{m+1} . Suppose v is adjacent to a vertex $u = \pi(i)$ for some $i \leq j-1$ with color b_{m+1} . By definition of the algorithm, $C_i^{m+1} = (I'_1, I'_2)$ with $a_{m+1} \in H(I'_1)$ and $u \in I'_2$. Since $C_i^{m+1} \subseteq C_j^{m+1}$, we find that $I'_1 \subseteq I_1$ and $I'_2 \subseteq I_2$. This leads to a contradiction because the vertices u and v cannot be adjacent if they are both in I_2 . $\square$

To illustrate how the choice of the color of $v = \pi(j)$ depends on the components of G_j^k we apply the algorithm to the following example.

Example. Let G be a $K_{4,4}$ without a perfect matching, i.e., with $V(G) = \{1, 2, 3, 4, 5, 6, 7, 8\}$, bipartition in $\{1, 3, 5, 7\}$ and $\{2, 4, 6, 8\}$, and only edges $\{1, 2\}$, $\{3, 4\}$, $\{5, 6\}$, and $\{7, 8\}$ omitted. If the vertices are revealed in the order of increasing numbers, the algorithm assigns colors $a_1, a_1, b_1, b_1, a_2, b_2, a_2, b_2$, respectively. The color b_2 is assigned to vertex 8 for the following three reasons. First, a_1 is mixed on C_8^1 , i.e., the subgraph of G induced by $\{1, 2, 3, 4, 8\}$. Second, a_2 is not mixed on $C_8^2 = G$. Third, a_2 has already been assigned to a vertex in $\{1, 3, 5, 7\}$, i.e., the bipartition class of C_8^2 not containing the vertex 8.

Suppose that G is extended and a new vertex 9 is revealed to the algorithm after presenting vertices $1, \dots, 8$. Suppose 9 is only adjacent to 7. Then a_1 is not mixed on $C_9^1 = (\{9\}, \emptyset)$ and a_2 is not mixed on $C_9^2 = G$. Hence, *BicolorMax* colors 9 with a_1 . It is left to the reader to check that 9 is assigned color b_1 if 9 is adjacent to 1 and 7, color b_2 if 9 is adjacent to 1, 3, and 7, and color a_2 if 9 is adjacent to 2, 4, and 6.

For a $K_{n,n}$ without a perfect matching with $n \geq 5$, the algorithm will continue assigning a_2 and b_2 if the vertices are presented in an order alternating between the two classes of the bipartition, as in the previous example for $n = 4$. In contrast, recall that *FF* uses n colors in this case.

Remark. In [18], the authors leave it as an “easy exercise” to construct an on-line coloring algorithm A such that $\chi_A(G) = O(\log_2 n)$ on the class of bipartite graphs (where G is a bipartite graph on n vertices). There are several choices for A to solve this exercise. One of these choices is the algorithm *BicolorMax* that we presented previously and that will be analyzed in this paper. We are not aware of any publications that contain this algorithm *BicolorMax* (except for [3], of course). Clearly, our main purpose in this paper is to show that *BicolorMax* works particularly well in the sense of on-line competitiveness for P_7 -free bipartite graphs. As can be concluded from the next section this is not an easy exercise.

One might be inclined to think that *BicolorMax* coincides with other on-line algorithms that have been proposed to solve the “easy exercise” from [18], e.g., the algorithm from the survey paper of Kierstead (see [14, Theorem 2, p. 286]) that is also known under the acronym *BFF* (Bipartite First-Fit). The formulation of *BFF* is very simple: when vertex v_i is presented, there is a unique partition (I_1, I_2) of the component to which v_i belongs such that $v_i \in I_1$. The algorithm *BFF* assigns to v_i the smallest color (in some ordering of the colors) that has not already been assigned to a vertex of I_2 . We do something more advanced, as can be seen from the above example. In this example, as we have argued, if the vertices 1 to 8 are presented in the order of increasing numbers, the algorithm *BicolorMax* assigns colors $a_1, a_1, b_1, b_1, a_2, b_2, a_2, b_2$, respectively. It can be checked that *BFF* also assigns these colors in the same order. Now suppose a new vertex 9 is presented which is only adjacent to vertex 7. Then *BicolorMax* assigns color a_1 to 9, as explained in the example, whereas *BFF* assigns color b_2 to 9.

Although at first sight *BicolorMax* looks very similar to *BFF*, the subtle difference in the choice of colors to avoid mixing colors enables us to prove the on-line competitiveness of our algorithm for P_7 -free bipartite graphs. Our earlier attempts to use a simpler strategy, like in *BFF*, for such a competitiveness proof failed even for the more restricted class of P_6 -free bipartite graphs. In fact, finding a suitable variant for our competitiveness proof turned out to be rather tricky.

6. P_7 -free bipartite graphs. In this section we prove our main theorem showing that *BicolorMax* is a linear on-line competitive algorithm for the class of P_7 -free bipartite graphs. The proof is modelled along the following lines. We will define a class of tree-like bipartite graphs, show that the on-line competitive factor of any on-line coloring algorithm for these graphs is high, and show that whenever *BicolorMax* uses many colors on a P_7 -free bipartite input graph G , then G contains a large member of the class of tree-like graphs as an induced subgraph. More specifically, denote by $\chi_{BM}(G)$ the maximum number of colors used by *BicolorMax* for coloring a graph G .

By a series of lemmas and propositions we prove that $\chi_{BM}(G) \leq 8\chi_{OL}(G) + 8$ for any P_7 -free bipartite graph G . In the next two lemmas we first show that *BicolorMax* controls the mixing of color pairs. We note that these lemmas are valid for any bipartite graph.

LEMMA 6.1. *Let G be a bipartite graph. Let *BicolorMax* color vertex $v = \pi(j)$ with a_m or b_m , $m \geq 2$. Let (x, y) be a k -mixed pair in C_j^k with $k \leq m - 1$. Then any path between x and y in C_j^k must pass through v .*

Proof. Let $x = \pi(r)$, and let $y = \pi(s)$ for some $r, s \leq j - 1$. We assume without loss of generality that y has been presented to *BicolorMax* after x , i.e., $s > r$. Suppose x belongs to C_s^k , implying that $a_k \in H(V(C_s^k))$. Since y is colored with a_k , color a_k is not mixed on C_s^k . Since (x, y) is a k -mixed pair, x (together with all the other vertices in C_s^k that have color a_k) and y are in different bipartite classes. So *BicolorMax* would have colored y with color b_k . Hence, x does not belong to C_s^k .

Suppose there exists an index i with $s < i < j$ such that x and y belong to C_i^k . This means that a_k is mixed on C_i^k . Then *BicolorMax* would never use a color a_h or b_h with $h \leq k$ to color $\pi(i)$. We conclude that every path between x and y in C_j^k must pass through v . $\square$

LEMMA 6.2. *Let G be a bipartite graph. Let *BicolorMax* color vertex $v = \pi(j)$ with a_m or b_m , $m \geq 2$. For some $k \leq m - 1$ let x and y be two vertices in C_j^k colored with a_k and b_k , respectively, such that $d(x, y, C_j^k)$ is even. Then any path between x and y in C_j^k must pass through v .*

Proof. Let $x = \pi(r)$, and let $y = \pi(s)$ for some $r, s \leq j - 1$. Suppose x belongs to C_s^k implying that y appeared after x . Since y is colored with b_k , color a_k is not mixed on C_s^k . Because G is bipartite and the distance $d(x, y, C_j^k)$ is even, the distance between x (or any other vertex in C_s^k with color a_k) and y in C_s^k is also even. Then *BicolorMax* would have colored y with color a_k . Hence, x does not belong to C_s^k .

Suppose y belongs to C_r^k . Since x is colored with a_k , color a_k is not mixed on C_r^k . Then the distance between x and any vertex in C_r^k with color a_k is even. Since y has received color b_k , by definition of *BicolorMax*, there exists at least one vertex z in C_r^k with color a_k , which is in a different bipartite class than y . Since the distance between x and y in C_j^k , and consequently in C_r^k , is even, this implies that the distance between x and z in C_r^k is odd. This is a contradiction. Hence, y does not belong to C_r^k .

In the remaining case there exists an index i with $\max(\{r, s\}) < i < j$ such that x and y belong to C_i^k . Since y is colored with b_k , by definition of *BicolorMax*, the component C_s^k , which is a subgraph of C_i^k , must contain a vertex w with color a_k and with odd distance to y . Since the distance between x and y is even, the distance between w and x is odd, and we find that a_k is mixed on C_i^k . Then *BicolorMax* would never use a color a_h or b_h with $h \leq k$ to color $\pi(i)$. We conclude that every path between x and y in C_j^k must pass through v . $\square$

In the following lemma we show that *BicolorMax* ensures that vertices of higher colors are very “close” to at least some vertices of lower colors.

LEMMA 6.3. *Let G be a P_7 -free bipartite graph. Let *BicolorMax* color vertex $v = \pi(j)$ with a_m or b_m , $m \geq 3$. There exists an $(m - 1)$ -mixed pair (z^*, z) in C_j^{m-1} with $d(v, z^*, C_j^{m-1}) = 1$ and $d(v, z, C_j^{m-1}) = 2$.*

Proof. By definition of *BicolorMax*, color a_{m-1} is mixed on C_j^{m-1} . So C_j^{m-1} contains at least one $(m - 1)$ -mixed pair (z, z') . We assume without loss of generality that the distance between z and v is even and the distance between z' and v is odd. Since (z, z') is an $(m - 1)$ -mixed pair, by Lemma 6.1, a shortest path $P_{zz'}$ from z to z' in C_j^{m-1} must be formed by joining shortest paths P_{zv} from z to v and $P_{vz'}$ from v to z' . First, we show that $d(v, z, C_j^{m-1}) = 2$.

Suppose $d(v, z, C_j^{m-1}) \geq 4$. Then $d(v, z', C_j^{m-1}) = 1$; i.e., z' and v are adjacent. Otherwise, since z' has odd distance to v , the path $P_{zz'}$ contains an induced P_7 . Let $z' = \pi(s)$ for some $s < j$. Since *BicolorMax* has used color $a_{m-1} \neq a_1$ (due to our assumption that $m \geq 3$) on vertex z' , the component C_s^{m-2} contains an $(m - 2)$ -mixed

FIG. 6.1. The trees T_1, T_2, T_3, T_4 .

pair. This means that z' has a neighbor $w \neq v$ in $C_s^{m-2} \subseteq C_j^{m-1}$. Bipartiteness of G and Lemma 6.1 imply that w is not adjacent to any vertex in P_{zv} . This implies that G contains an induced P_7 , which is a contradiction. Hence, $d(v, z, C_j^{m-1}) = 2$.

We now show that $d(v, z', C_j^{m-1}) \leq 3$. Suppose $d(v, z', C_j^{m-1}) \geq 5$. Then $P_{zz'}$ would contain an induced P_7 . Hence, $d(v, z', C_j^{m-1}) = 1$ or $d(v, z', C_j^{m-1}) = 3$. In the first case we are done. In the second case, i.e., if $d(v, z', C_j^{m-1}) = 3$, we will show that there exists a vertex z^* on $P_{z'v}$ with color a_{m-1} that is adjacent to v .

Let y and z^* be vertices of G such that $P_{z'v} = z'y z^* v$. Note that the distance between z^* and z' is even. Then, due to Lemma 6.2, vertex z^* has not been colored with b_{m-1} . We will show that z^* has not been colored with any color from $A(m-2) \cup B(m-2)$ either. First, note that any neighbor of z' in C_j^{m-1} is adjacent to z^* . Otherwise, we could extend the path $P_{zz'}$ on six vertices with one extra vertex, and C_j^{m-1} would contain an induced P_7 .

Let $r < j$ be chosen such that $z^* = \pi(r)$. Recall that $z' = \pi(s)$. We first consider the case $s > r$, i.e., vertex z' has appeared after z^* . Since z^* is adjacent to every neighbor of z' in $C_s^{m-2} \subseteq C_j^{m-1}$ and a_{m-2} is mixed on C_s^{m-2} , Lemma 6.1 prevents z^* from being in C_s^{m-2} . Otherwise, C_s^{m-2} would contain a path (using z^*) between two vertices u_1 and u_2 of an $(m-2)$ -mixed pair (u_1, u_2) in C_s^{m-2} not going through z' . We already noted that z^* has not received color b_{m-1} . Then, since z^* is in C_j^{m-1} , vertex z^* must have been colored with a_{m-1} .

Now assume $s < r$, i.e., vertex z^* has appeared after z' . Every neighbor of z' in C_r^{m-2} is adjacent to z^* . Hence, a_{m-2} is mixed not only on C_s^{m-2} but also on C_r^{m-2} . Since b_{m-1} was not allowed and z^* is in C_j^{m-1} , *BicolorMax* must have colored z^* with a_{m-1} . $\square$

We inductively define a class of trees (see Figures 6.1 and 6.2). Each tree T_k of the class has a root vertex $r(T_k)$, and the following hold:

- T_1 is a tree consisting of an edge, one of whose end vertices is the root vertex $r(T_1)$.
- T_2 is a path on three vertices, one of whose end vertices is the root vertex $r(T_2)$.
- T_k , $k \geq 3$, consists of a root vertex $r(T_k)$ that is adjacent to the root vertices of mutually disjoint copies of $T_1, T_2, \dots, T_{k-1}$ (one copy of each of these trees). These copies are then called the *child trees* of T_k .

We denote a copy of a tree T_k with root vertex $v = r(T_k)$ by $T_k(v)$. The child trees of

FIG. 6.2. The tree T_5 .

$T_k(v)$ are denoted by $T_1^v, T_2^v, \dots, T_{k-1}^v$. The following lemma turns out to be useful.

LEMMA 6.4. *Let G be a P_7 -free bipartite graph. If $BicolorMax$ uses color a_k or b_k on vertex $v = \pi(j)$ with $k \geq 2$, then C_j^{k-1} contains the tree $T_{k-1}(v)$ as a (not necessarily induced) subgraph in such a way that the following hold:*

- (i) *If there exists an edge in G between any two vertices x, y in $T_{k-1}(v)$ with $d(v, x, T_{k-1}(v)) \leq d(v, y, T_{k-1}(v))$, then x lies on the path from y to v in $T_{k-1}(v)$.*
- (ii) *The root of child tree T_i^v is colored with a_{i+1} or b_{i+1} for all $1 \leq i \leq k-2$.*

Proof. The proof proceeds by induction on k . Let $k = 2$; i.e., $BicolorMax$ uses color a_2 or b_2 on vertex v . Then C_j^1 contains a 1-mixed pair. This implies that v has a neighbor in C_j^1 , and the conditions of the lemma are trivially satisfied.

Let $k = 3$; i.e., $BicolorMax$ uses color a_3 or b_3 on vertex v . By Lemma 6.3, vertex v has a neighbor z^* in C_j^2 with color a_2 . Let $z^* = \pi(q)$ for some $q < j$. Then C_q^1 contains a 1-mixed pair. This implies that z^* has a neighbor not equal to v in C_j^2 . We conclude that the conditions of the lemma are satisfied.

Let $k \geq 4$. Since $BicolorMax$ uses color a_k or b_k on vertex v , there exists a $(k-1)$ -mixed pair (x, y) in C_j^{k-1} . By Lemma 6.3, we may without loss of generality assume that $d(v, x, C_j^{k-1}) = 2$ and $d(v, y, C_j^{k-1}) = 1$. Assume $x = \pi(h)$ for some $h < j$ and $y = \pi(i)$ for some $i < j$. By the induction hypothesis, C_h^{k-2} contains the tree $T_{k-2}(x)$, and C_i^{k-2} contains the tree $T_{k-2}(y)$. Since (x, y) is a $(k-1)$ -mixed pair in C_j^{k-1} , every path from x to y in C_j^{k-1} must go through v due to Lemma 6.1. This implies that every path in C_j^{k-1} from a vertex in $C_h^{k-2} \subseteq C_j^{k-1}$ to a vertex in $C_i^{k-2} \subseteq C_j^{k-1}$ must go through v . Then we have also found that every path in C_j^{k-1} from a vertex in $T_{k-2}(x) \subseteq C_h^{k-2}$ to a vertex in $T_{k-2}(y) \subseteq C_i^{k-2}$ must go through v . We distinguish two cases: either C_h^{k-2} contains a common neighbor of v and x , or C_h^{k-2} does not contain any common neighbors of v and x .

Case 1. Component C_h^{k-2} contains a common neighbor w of x and v . Again we need to distinguish two cases: either w is in $T_{k-2}(x)$, or w is not in $T_{k-2}(x)$.

Case 1a. Vertex w is in $T_{k-2}(x)$. Then w is in a child tree T_p^x of $T_{k-2}(x)$ for some $1 \leq p \leq k-3$. If $k = 4$, then $T_{k-2}(x) = T_2(x)$, and w must be the root of T_1^x . By the induction hypothesis w is colored with a_2 or b_2 . Recall that every path in C_j^3 from a vertex in $T_2(x)$ to a vertex in $T_2(y)$ goes through v , and that y is colored with

$a_{k-1} = a_3$. This implies that v is the root of a copy of T_3 satisfying (i) and (ii).

Suppose $k \geq 5$. Then $T_{k-2}(x)$ has a child tree T_q^x with root u for some $q \neq p$. Note that for all $k \geq 2$ any child tree of a tree T_k consists of at least two vertices. Let u' be a neighbor of u in T_q^x . Let y' be a neighbor of y in $T_{k-2}(y)$. Note that u', u, x, w, v, y, y' are seven different vertices of G . This implies that $P_{u'y'} = u'uxwvyy'$ is a path on seven vertices in C_j^{k-1} . Recall that every path from a vertex of $T_{k-2}(x)$ to a vertex of $T_{k-2}(y)$ goes through v . Then there are no edges between $\{u', u, x, w\}$ and $\{y, y'\}$. By the induction hypothesis, T_p^x and T_q^x are remote. This implies that w is adjacent neither to u nor to u' . Then there must be an edge between u and v ; otherwise $P_{u'y'}$ is an induced P_7 in G . Hence, we have found that v is adjacent to the root of all child trees of $T_{k-2}(x)$ that are not equal to T_p^x . However, the root of T_p^x must also be joined to v by an edge. This can be shown by using exactly the same arguments (in which vertex u takes over the role of vertex w).

From the above we conclude that v is adjacent to the roots of all child trees of $T_{k-2}(x)$. These trees together with tree $T_{k-2}(y)$ form the child trees of $T_{k-1}(v)$. Due to the fact that any path from a vertex in $T_{k-2}(x)$ to a vertex in $T_{k-2}(y)$ goes through v and our induction hypothesis, the child trees of $T_{k-1}(v)$ satisfy (i). Recall that the root vertex y of $T_{k-2}^v = T_{k-2}(y)$ is colored with a_{k-1} . The root vertices of the other child trees of $T_{k-1}(v)$ are colored with the desired colors due to the induction hypothesis. Hence, condition (ii) of the lemma is also satisfied.

Case 1b. Vertex w is not in $T_{k-2}(x)$. Since $k \geq 4$, there exists a vertex s with color a_{k-2} in C_h^{k-2} with $d(x, s, C_h^{k-2}) = 2$ due to Lemma 6.1. Since $d(x, w, C_h^{k-2}) = 1$, vertex s is not equal to vertex w . Again, let y' be a neighbor of y in $T_{k-2}(y)$. We first show that we may without loss of generality assume that w is adjacent to s .

Suppose w is not adjacent to s . Since $d(x, s, C_h^{k-2}) = 2$, vertices s and x have a common neighbor t in C_h^{k-2} . Note that s, t, x, w, v, y, y' are seven different vertices of G . This implies that $P_{sy'} = stxwvyy'$ is a path on seven vertices in C_j^{k-1} . Recall that every path from a vertex in C_h^{k-2} to a vertex in $T_{k-2}(y)$ goes through v . Then there are no edges between $\{s, t, x, w\}$ and $\{y, y'\}$. This together with $\{w, s\} \notin E(G)$ implies that v must be adjacent to t ; otherwise $P_{sy'}$ is an induced P_7 in G . Then, we can pick vertex t instead of vertex w . So from now on we assume that w is a common neighbor of s and x in C_h^{k-2} .

Let r be the root of child tree T_{k-3}^x of $T_{k-2}(x)$. Let r' be a neighbor of r in T_{k-3}^x . Note that r', r, x, w, v, y, y' are seven different vertices of G . This implies that $P_{r'y'} = r'rxwvyy'$ is a path on seven vertices in C_j^{k-1} . By the induction hypothesis, r is colored with a_{k-2} or b_{k-2} .

Suppose r is colored with a_{k-2} . Since $d(r, s, C_h^{k-2})$ is odd and s is colored with a_{k-2} , the pair (r, s) is a $(k-2)$ -mixed pair in C_h^{k-2} . Lemma 6.1 implies that every path from s in C_h^{k-2} , and hence every path from w in C_h^{k-2} , to a vertex in $T_{k-3}^x \subseteq C_h^{k-2}$ goes through x . Then there are no edges between $\{r, r'\}$ and w . Furthermore, recall that every path in C_j^{k-1} from a vertex in C_h^{k-2} to a vertex in $T_{k-2}(y) \subseteq C_i^{k-2}$ goes through v . Then there are no edges between $\{r', r, x, w\}$ and $\{y, y'\}$ either. Since $P_{r'y'}$ may not be an induced P_7 , these observations imply that there must be an edge between v and r . Hence, using vertex r instead of w brings us back to Case 1a.

Suppose r is colored with b_{k-2} . By Lemma 6.3, C_h^{k-2} contains a vertex $\hat{s}$ that has received color a_{k-2} and is adjacent to x . Let $\hat{s} = \pi(\ell)$ for some $\ell < j$. By our induction hypothesis, vertex $\hat{s}$ is the root of a tree $T_{k-3}(\hat{s})$ in C_ℓ^{k-3} .

Suppose every path in C_h^{k-2} from $\hat{s}$ to a vertex in any child tree T_p^x for $1 \leq p \leq k-4$ goes through x . Then in $T_{k-2}(x)$ we can replace the child tree $T_{k-3}(r)$ by the

child tree $T_{k-3}(\hat{s})$. Then we can repeat the argument above (replace r by $\hat{s}$, which is colored by a_{k-2}) in order to find that v is adjacent to $\hat{s}$, and we return to Case 1a.

Suppose C_h^{k-2} contains a path from $\hat{s}$ to a child tree T_m^x for some $1 \leq m \leq k-4$ that does not go through x . Let z be the root of T_m^x , and let z' be a neighbor of z in T_m^x . Note that z', z, x, w, v, y, y' are seven different vertices of G . This implies that $P_{z'y'} = z'zxwvyy'$ is a path on seven vertices in C_j^{k-1} . Recall that w is a neighbor of s . We then find that z' and w are not adjacent. Otherwise, C_h^{k-2} would contain a path between s and $\hat{s}$, which are the vertices of a $(k-2)$ -mixed pair, not going through x (a contradiction due to Lemma 6.1). Then as before, in order not to have an induced P_7 , vertex v must be adjacent to z . We return to Case 1a.

Case 2. Component C_h^{k-2} does not contain a common neighbor of x and v . Since x has distance 2 from v in C_j^{k-1} , there exists a common neighbor v' of v and x in C_j^{k-1} . We first prove that v' has received color b_{k-1} .

Since $k \geq 4$, Lemma 6.3 implies that C_h^{k-2} contains a vertex s with color a_{k-2} at distance $d(x, s, C_h^{k-2}) = 2$ from x , and C_h^{k-2} contains a vertex t with color a_{k-2} that is a neighbor of x . Since $d(x, s, C_h^{k-2}) = 2$, vertices s and x have a common neighbor s' in C_h^{k-2} . Since $k \geq 4$, vertex t has a neighbor t' in C_h^{k-2} that is not equal to x . Let y' be a neighbor of y in $T_{k-2}(y)$. Note that $s, s', t, t', x, v', v, y, y'$ are nine different vertices in G . This implies that both $P_{sy'} = ss'xv'vy'y'$ and $P_{t'y'} = t'txv'vy'y'$ are paths on seven vertices in C_j^{k-1} . Any path in C_j^{k-1} from a vertex in $T_{k-2}(y)$ to a vertex in C_h^{k-2} or to v' goes through v . Otherwise there exists a path in C_j^{k-1} from y to x that does not use v , which is not possible due to Lemma 6.1. Hence, there are no edges between $\{s, s', x, v'\}$ and $\{y, y'\}$, and there are no edges between $\{t, t', x, v'\}$ and $\{y, y'\}$ either. Since we assumed that C_h^{k-2} does not contain any common neighbor of v and x , there are no edges between v and $\{s', t'\}$. Then v' must be adjacent to both s and t' ; otherwise, G contains an induced P_7 . Since v' is in C_j^{k-1} and adjacent to vertex x with color a_{k-1} , the color of v' is in $A(k-2) \cup B(k-1)$.

Suppose v' has not received color b_{k-1} but some color from $A(k-2) \cup B(k-2)$. Then v' must have appeared after x , due to our assumption that v' is not in C_h^{k-2} . However, in that case, v' has also appeared after s and t . Then (s, t) is a $(k-2)$ -mixed pair of $C_{\pi^{-1}(v')}^{k-2}$ implying that *BicolorMax* would never color v' with a color from $A(k-2) \cup B(k-2)$. Hence, v' must have received color b_{k-1} .

Recall that $y = \pi(i)$ is assigned color a_{k-1} . Then, by Lemma 6.3, component C_i^{k-2} contains a $(k-2)$ -mixed pair (z^*, z) such that $d(y, z^*, C_i^{k-2}) = 1$ and $d(y, z, C_i^{k-2}) = 2$. We first show that v is adjacent to z and every neighbor of z^* in C_i^{k-2} .

Since $d(y, z, C_i^{k-2}) = 2$, component C_i^{k-2} contains a common neighbor z' of y and z . Let x' be a neighbor of x in C_h^{k-2} . Since v' with color b_{k-1} and neighbor v with color a_{k-1} are neither in C_h^{k-2} nor in C_i^{k-2} , we find that z, z', y, v, v', x, x' are seven different vertices. This implies that $P_{zx'} = zz'yvv'xx'$ is a path on seven vertices in C_j^{k-1} . By Lemma 6.1, any path from y to x in C_j^{k-1} must go through v . This implies that there are no edges between vertices from $\{z, z', y\}$ and $\{v', x, x'\}$. Since we assume that v and x do not have a common neighbor in C_h^{k-2} , vertices x' and v are not adjacent. Then v must be adjacent to z . By the same arguments we find that v is adjacent to every neighbor of z^* in C_i^{k-2} .

Let $z^* = \pi(\ell^*)$ for some $\ell^* < j$. By our induction hypothesis, $C_{\ell^*}^{k-3}$ contains the tree $T_{k-3}(z^*)$ satisfying conditions (i) and (ii) of the lemma. Since v is adjacent to every neighbor of z^* in $C_i^{k-2} \supseteq C_{\ell^*}^{k-3}$, vertex v is adjacent to the roots of all child trees $T_{k-4}^{z^*}, T_{k-5}^{z^*}, \dots, T_1^{z^*}$.

FIG. 6.3. The graphs F_1, F_2, F_3, F_4 .

We are also going to use our induction hypothesis with respect to vertex z , which has been assigned color a_{k-2} . Let $z = \pi(\ell)$ for some $\ell < j$. Then C_ℓ^{k-3} contains the tree $T_{k-3}(z)$ satisfying conditions (i) and (ii) of the lemma. Recall that z is adjacent to v . So v is adjacent to the root of a copy of a tree T_{k-3} . Due to Lemma 6.1, the trees $T_{k-3}(z)$ and $T_{k-3}(z^*)$ do not have a vertex in common.

Finally, we consider vertex v' with color b_{k-1} . Let $v' = \pi(\ell')$ for some $\ell' < j$. Again by our induction hypothesis, $C_{\ell'}^{k-2}$ contains the tree $T_{k-2}(v')$ satisfying conditions (i) and (ii) of the lemma. Recall that v is adjacent to v' . So v is adjacent to a copy of T_{k-2} that does not have any vertex in common with the trees $T_{k-3}(z)$ and $T_{k-3}(z^*)$ due to Lemma 6.1.

We conclude that C_j^{k-1} contains the tree $T_{k-1}(v)$ as a subgraph such that condition (ii) has been satisfied and that condition (i) will be satisfied as well if we can show the following statement: there are no edges between $T_{k-3}^v = T_{k-3}(z)$ and a child tree $T_i^v = T_i^{z^*}$ for all $1 \leq i \leq k-4$, and there are no edges between $T_{k-2}^v = T_{k-2}(v')$ and a child tree T_i^v for all $1 \leq i \leq k-3$. This claim can be seen as follows. If there is an edge between T_{k-2}^v and a child tree T_i^v for $1 \leq i \leq k-3$, then C_j^{k-1} contains a path from x to y that does not go through v . Since (x, y) is a $(k-1)$ -mixed pair in C_j^{k-1} , this is not possible due to Lemma 6.1. If there is an edge between T_{k-3}^v and a child tree T_i^v for $1 \leq i \leq k-4$, then C_i^{k-2} contains a path from z to z^* that does not go through y . Since (z^*, z) is a $(k-2)$ -mixed pair in C_i^{k-2} , this is not possible, again due to Lemma 6.1. $\square$

We also inductively define a class of P_6 -free bipartite graphs F_i (see Figures 6.3 and 6.4). Its purpose and its relation to the class of trees T_i will be made clear later on. Each graph F_i of the class has a root vertex $r(F_i)$, and the following hold:

- F_1 is a graph consisting of a single root vertex.
- F_2 is a graph consisting of an edge, one of whose end vertices is the root vertex.
- F_k , $k \geq 3$, consists of a root vertex $r(F_k)$ that is adjacent to the root vertices of disjoint copies of $F_1, F_2, \dots, F_{k-1}$ (one copy of each of these graphs). These copies are then called the *child graphs* of F_k . For all $1 \leq j \leq k-1$, we join vertex $r(F_k)$ also to every vertex in F_j that has distance 2 to $r(F_j)$. This implies that every vertex of F_k is at distance at most 2 from $r(F_k)$. Hence, the maximum distance between two vertices in F_k is at most 4, and F_k is P_6 -free.

A graph F_k has the following useful properties (see also Figure 6.4).

LEMMA 6.5. *Any graph F_k with $k \geq 4$ contains copies F_t^1 and F_t^2 of F_t for all*

FIG. 6.4. The graph F_5 which contains copies $F_2^1, F_2^2, F_3^1, F_3^2$.

$2 \leq t \leq k-2$ such that the following hold:

- (i) For all $1 \leq i, j \leq 2$ and all $2 \leq s < t \leq k-2$, the graphs F_s^i and F_t^j are remote.
- (ii) For all $2 \leq t \leq k-2$, the vertices of the graph F_t^1 in the bipartite class containing the root vertex of F_t^1 are adjacent to $r(F_k)$.
- (iii) For all $2 \leq t \leq k-2$, the vertices of the graph F_t^2 in the bipartite class not containing the root vertex of F_t^2 are adjacent to $r(F_k)$.

Proof. One easily checks that child graph F_{t+1} of graph F_k contains the desired copies F_t^1 and F_t^2 for $2 \leq t \leq k-2$. $\square$

The following proposition is a key ingredient for the proof of our main result. It also implies that there exists no competitive on-line coloring algorithm for the family of P_6 -free bipartite graphs (cf. [9], where this has been proven using a different subfamily of P_6 -free bipartite graphs).

PROPOSITION 6.6. For any $k \geq 1$, $\chi_{OL}(F_{2k}) \geq k$.

Proof. By induction on k . The case $k = 1$ is trivial. Let $k \geq 2$. Consider F_{2k} and an on-line algorithm A for coloring F_{2k} . The first time the i th color is used by A we identify it as color i . We choose an ordering on $V(F_{2k})$ such that the vertices of remote copies of $F_2, F_4, \dots, F_{2k-2}$ are presented until color i is used on F_{2i} ($i = 1, \dots, k-1$); i.e., as soon as color 1 is used on F_2 we start presenting vertices of F_4 , as soon as color 2 is used on F_4 we start presenting vertices of F_6 and so on, until color $k-1$ is used on F_{2k-2} . By the adjacency relations from the definition of F_{2k} and the properties of Lemma 6.5, the ordering of the presented vertices of $F_2, F_4, \dots, F_{2k-2}$ can be chosen in such a way that $r(F_{2k})$ is adjacent to the (not necessarily root) vertices that received colors $1, \dots, k-1$. Hence, a new color k is forced upon A . $\square$

Below we denote a copy of a graph F_k with root vertex v by $F_k(v)$. The child graphs of $F_k(v)$ are denoted by $F_1^v, F_2^v, \dots, F_{k-1}^v$.

LEMMA 6.7. Let G be a P_7 -free bipartite graph. If *BicolorMax* uses color a_k or b_k with $k \geq 3$ on vertex $v = \pi(j)$, then C_j^{k-1} contains the graph $F_{\lfloor \frac{k-1}{2} \rfloor}(v)$ as an induced subgraph.

Proof. Due to Lemma 6.4 the component C_j^{k-1} contains the tree $T_{k-1}(v)$ as a subgraph in such a way that the following hold:

- (i) If there exists an edge in G between any two vertices x, y in $T_{k-1}(v)$ with $d(v, x, T_{k-1}(v)) \leq d(v, y, T_{k-1}(v))$, then x lies on the path from y to v in

$T_{k-1}(v)$.

(ii) The root of child tree T_i^v is colored with a_{i+1} or b_{i+1} for all $1 \leq i \leq k-2$.

By induction on k we will show that the subgraph of G induced by $V(T_{k-1}(v))$ contains the graph $F_{\lfloor \frac{k-1}{2} \rfloor}(v)$ as an induced subgraph. The case $k = 3$ is trivial. Let $k \geq 4$.

Claim. The following is true for at least $k-3$ child trees T_i^v : vertex v is adjacent to every vertex in T_i^v that has distance 2 to $r(T_i^v)$.

We prove this claim by contradiction. Suppose there exist two child trees of $T_{k-1}(v)$ not satisfying the claim. Let T_h^v be a child tree of $T_{k-1}(v)$ for some $1 \leq h \leq k-2$ that contains a vertex x with $d(x, r(T_h^v), T_h^v) = 2$ and with $\{x, v\} \notin E(G)$. Let T_j^v be a child tree of $T_{k-1}(v)$ for some $1 \leq j \neq h \leq k-2$ that contains a vertex y with $d(y, r(T_j^v), T_j^v) = 2$ and with $\{y, v\} \notin E(G)$. Let y' be the common neighbor of y and $r(T_j^v)$ in T_j^v . Let x' be the common neighbor of x and $r(T_h^v)$ in T_h^v . Since $T_{k-1}(v)$ satisfies (i), G contains an induced $P_7 = xx'r(T_h^v)vr(T_j^v)y'y$, which is a contradiction. Hence, the above claim has been proven.

By the induction hypothesis and condition (ii), for $2 \leq i \leq k-2$, the subgraph induced by $V(T_i^v)$ contains the graph $F_{\lfloor \frac{i}{2} \rfloor}(r(T_i^v))$ as an induced subgraph. This, together with the above claim and the fact that $T_{k-1}(v)$ satisfies condition (i), implies that C_j^{k-1} contains the graph $F_{\lfloor \frac{k-1}{2} \rfloor}(v)$ as an induced subgraph. $\square$

THEOREM 6.8. *If G is a P_7 -free bipartite graph, then $\chi_{BM}(G) \leq 8\chi_{OL}(G) + 8$.*

Proof. Let k be the highest index such that *BicolorMax* uses color a_{4k+1} on a vertex in G . Note that it is possible that *BicolorMax* uses colors $a_{4k+2}, a_{4k+3}, a_{4k+4}$ or $b_{4k+2}, b_{4k+3}, b_{4k+4}$ to color G . Hence, every color used on a vertex of G is from $A(4k+4) \cup B(4k+4)$. Since *BicolorMax* uses b_i only if a_i has been used before, then $\chi_{B<}(G) \leq 2(4k+4) = 8k+8$. For $k = 0$ the statement obviously holds. Suppose $k \geq 1$. Due to Lemma 6.7, G contains a copy of F_{2k} as an induced subgraph. Proposition 6.6 implies that $\chi_{OL}(G) \geq \chi_{OL}(F_{2k}) \geq k$. $\square$

7. New upper bounds on χ_{OL} for bipartite graphs. As we noted in section 5, in [18], the authors leave it as an “easy exercise” to construct an on-line coloring algorithm A such that $\chi_A(G) = O(\log_2 n)$ on the class of bipartite graphs (where G is a bipartite graph on n vertices). There are several choices for A to solve this exercise. One of these choices is the algorithm *BicolorMax* that we presented and analyzed in this paper.

As a byproduct, using the derived properties of *BicolorMax*, below we give an upper bound on $\chi_A(G)$ for a bipartite graph G in terms of the independence number $\alpha(G)$ and in terms of the number of remote induced P_5 's in G . It is not possible to prove an upper bound in terms of induced subgraphs isomorphic to P_6 , since it has been proven in [9] (and also follows from Proposition 6.6) that no competitive algorithm exists for the family of P_6 -free bipartite graphs.

THEOREM 7.1. *Let G be a bipartite graph in which each component has at most s remote induced subgraphs isomorphic to P_5 . If $s = 0$, then $\chi_{BM}(G) \leq 4$. If $s > 0$, then $\chi_{BM}(G) \leq 2\log_2(s) + 6$.*

Proof. We prove the theorem by showing that a component C of G contains at least 2^{k-3} remote induced subgraphs isomorphic to P_5 if *BicolorMax* uses color a_k on C with $k \geq 3$. We use induction on k .

Let $k = 3$. It is easy to check that a component of G contains an induced P_5 if *BicolorMax* uses color a_3 on a vertex of that component. Let $k \geq 4$. Suppose $v = \pi(j)$ is colored by a_k or b_k . Then there exists a $(k-1)$ -mixed pair (x, y) in C_j^{k-1} . By Lemma 6.1, x and y belong to two different components in $G_j^{k-1} - v$, both

containing 2^{k-4} remote induced subgraphs isomorphic to P_5 . $\square$

Our next result gives an upper bound on the number of colors used by *BicolorMax* on a bipartite graph G in terms of its independence number $\alpha(G)$ (i.e., the largest number of vertices of G that are mutually nonadjacent in G).

THEOREM 7.2. *Let G be a bipartite graph with independence number α . Then*

$$\chi_{BM}(G) \leq \begin{cases} \alpha + 1 & \text{if } 1 \leq \alpha \leq 3, \\ 4 & \text{if } \alpha = 4, \\ 2p & \text{if } 5 \cdot 2^{p-3} \leq \alpha \leq 5 \cdot 2^{p-2} - 1 \text{ for some } p \geq 3. \end{cases}$$

Proof. Let k be the highest index such that *BicolorMax* uses color a_k on a vertex v in G . If $\alpha = 1$, then $k = 1$; hence, $\chi_{BM}(G) \leq 2$. If $\alpha = 2$, then $k \leq 2$ but color b_2 is never used; hence, $\chi_{BM}(G) \leq 3$. Now assume that $\alpha \geq 3$.

Let $v = \pi(j)$. We write $C_j^{k-1} = (I_1^k, I_2^k)$ for the bipartition with $v \in I_1^k$. Clearly, $|I_1^2| \geq 2$ and $|I_2^2| \geq 2$. We will use induction to show that $|I_1^k| \geq 5 \cdot 2^{k-3}$ and $|I_2^k| \geq 5 \cdot 2^{k-3} - 1$ for $k \geq 3$.

For a fixed $k \geq 3$, by definition of *BicolorMax*, there exists a $(k-1)$ -mixed pair (x, y) in C_j^{k-1} with $x \in I_1^k$ and $y \in I_2^k$. By Lemma 6.1, x and y belong to two different components $D = (J_1, J_2)$ and $D' = (J'_1, J'_2)$ in $G_j^{k-1} - v$, say $x \in J_1 \subseteq I_1^k$ and $y \in J'_1 \subseteq I_2^k$. For $k = 3$, we get $|I_1^3| \geq |J_1| + |J'_2| + 1 = 2 + 2 + 1 = 5$ and $|I_2^3| \geq |J_2| + |J'_1| \geq 2 + 2 = 4$.

Now let $k \geq 4$. Then $|I_1^k| \geq |J_1| + |J'_2| + 1 = 5 \cdot 2^{k-4} + 5 \cdot 2^{k-4} - 1 + 1 = 5 \cdot 2^{k-3}$ and $|I_2^k| \geq |J_2| + |J'_1| \geq 5 \cdot 2^{k-4} - 1 + 5 \cdot 2^{k-4} = 5 \cdot 2^{k-3} - 1$. We conclude that $|I_1^k| \geq 5 \cdot 2^{k-3}$ and $|I_2^k| \geq 5 \cdot 2^{k-3} - 1$ for $k \geq 3$.

Assume $3 \leq \alpha \leq 4$. If $k = 3$, then $\alpha \geq |I_1^3| \geq 5$. Hence $k \leq 2$. Then $\chi_{BM} \leq 2k \leq 4$.

Finally assume $5 \cdot 2^{p-3} \leq \alpha \leq 5 \cdot 2^{p-2} - 1$ for some $p \geq 3$. If $k \geq p + 1$, then $\alpha \geq |I_1^k| \geq 5 \cdot 2^{p-2}$. Hence $k \leq p$. Then $\chi_{BM} \leq 2p$. This completes the proof of Theorem 7.2. $\square$

The bounds of Theorem 7.2 improve a bound in [5] for bipartite graphs: the main result of [5] applied to bipartite graphs shows that for any bipartite graph G any greedy on-line coloring algorithm uses at most $\alpha(G) + 1$ colors.

8. Final remarks. As we noted in section 5, *BicolorMax* is not on-line competitive for the family of paths. This is in contrast to *FF*, which uses at most three colors on any path P_n . Below we show in a more general way how to combine two on-line competitive algorithms satisfying certain conditions.

For this purpose we need the following terminology. We call a family of graphs $\mathcal{G}$ *decidable* if there exists a (finite) procedure to decide whether or not a graph G belongs to $\mathcal{G}$. Note that the family of H -free graphs is decidable for any fixed graph H . Also the family of paths is decidable. We call an on-line coloring algorithm A for a graph G *component-independent* if the color assigned by A to every revealed vertex $v = \pi(j)$ depends only on the component of $G[\{\pi(1), \dots, \pi(j)\}]$ that vertex v belongs to. For instance, *FF* and *BicolorMax* are component-independent. For two families of graphs $\mathcal{F}$ and $\mathcal{G}$ we define $\mathcal{F} + \mathcal{G} = \{L \mid L \in \mathcal{F} \cup \mathcal{G}, \text{ or } L = F + G \text{ with } F \in \mathcal{F} \text{ and } G \in \mathcal{G}\}$.

THEOREM 8.1. *Let $\mathcal{F}$ be a decidable family of graphs for which an on-line competitive coloring algorithm A_1 exists, and let $\mathcal{G}$ be a decidable family of graphs for which an on-line competitive component-independent coloring algorithm A_2 exists. Then there exists an on-line coloring algorithm A_3 that is on-line competitive for $\mathcal{F} + \mathcal{G}$.*

Proof. We assume A_1 and A_2 use disjoint color sets $\{c_1, c_2, \dots\}$ and $\{d_1, d_2, \dots\}$, respectively. Let $\pi \in \Pi(L)$ for some graph $L \in \mathcal{F} + \mathcal{G}$.

We inductively define A_3 as follows. The vertex $\pi(1)$ is colored with d_1 . Suppose that vertices $\pi(1), \dots, \pi(j-1)$ have already been colored and let $v = \pi(j)$ be the next vertex of L presented to A_3 . For $i = 1, 2$, we let $L_j(A_i)$ be the subgraph of L that consists of v and all vertices in $\{\pi(1), \dots, \pi(j-1)\}$ colored by A_i . We let $C_j(A_2)$ be the component of $L_j(A_2)$ that contains v . If $C_j(A_2)$ is an induced subgraph of some graph in $\mathcal{G}$, then color v with the color that A_2 would have used on v after the other vertices of $C_j(A_2)$ had been presented to A_2 in the suborder defined by π . Otherwise, $L_j(A_1)$ is a subgraph of a graph in $\mathcal{F}$, and we color v with the color that A_1 would have used on v after the other vertices of $L_j(A_1)$ had been presented to A_1 in the suborder defined by π . It is easy to see that A_3 is on-line competitive on $\mathcal{F} + \mathcal{G}$. $\square$

9. Conclusions and future work. We have presented an on-line coloring algorithm *BicolorMax* for bipartite graphs. We have shown that the number of colors used by this algorithm on a bipartite graph G is bounded from above by the number of remote induced subgraphs of G isomorphic to P_5 , and we gave a similar upper bound in terms of the independence number of G . As a consequence we improved known upper bounds for the on-line chromatic number of bipartite graphs given in [5, 18]. We showed in [3] that for any P_6 -free bipartite graph G , *BicolorMax* uses at most twice as many colors as any optimal on-line coloring algorithm for G . Here we showed that for any P_7 -free bipartite graph G , *BicolorMax* uses at most eight times as many colors as any optimal on-line coloring algorithm for G .

In a future continuation of this work, we would like to face the problem of deciding whether for any $n \geq 8$ a linear on-line competitive algorithm can be defined for the class of P_n -free bipartite graphs. We also consider analyzing *BicolorMax* and related algorithms for other classes of H -free bipartite graphs, in particular for bipartite graphs H with six vertices. A seemingly difficult and interesting open case is the (non)existence of an on-line competitive algorithm for the class of C_6 -free bipartite graphs.

Acknowledgments. We thank the anonymous referees for their useful comments on an earlier version of this paper.

AVERAGE DISTANCE AND EDGE-CONNECTIVITY I*

PETER DANKELMANN[†], SIMON MUKWEMBI[†], AND HENDA C. SWART[†]

Abstract. The average distance $\mu(G)$ of a connected graph G of order n is the average of the distances between all pairs of vertices of G . We prove that if G is a λ -edge-connected graph of order n , then the bounds $\mu(G) \leq 2n/15 + 9$ if $\lambda = 5, 6$, $\mu(G) \leq n/9 + 10$ if $\lambda = 7$, and $\mu(G) \leq n/(\lambda + 1) + 5$ if $\lambda \geq 8$ hold. Our bounds are shown to be best possible, and our results solve a problem of Plesník [*J. Graph Theory*, 8 (1984), pp. 1–24].

Key words. distance, average distance, edge-connectivity

1. Introduction. Let $G = (V, E)$ be a connected graph of order n . The *average distance* $\mu(G)$ of G is defined as $\mu(G) = \binom{n}{2}^{-1} \sum_{\{x,y\} \subset V} d_G(x, y)$, where $d_G(x, y)$ denotes the distance between the vertices x and y in G . The average distance has been investigated by several authors and under various names; for instance, Kouider and Winkler [8], Favaron, Kouider, and Mahéo [6], Doyle and Graver [4] depict average distance as the *mean distance*; Wuchty and Stadler [16] use the term *average path length*; Bermond, Liu, and Syska [1] use the term *mean eccentricity*; whilst Plesník [12], Soltés [14] work with the total distance of a graph and call it the *transmission*. The transmission differs from the average distance by only a factor of $n(n-1)$. The study of average distance seems to have been started by the chemist Wiener [15] in 1947, when he introduced the Wiener index $W(G)$ of a graph G which differs from the average distance by a factor of $\binom{n}{2}$, i.e., $W(G) = \binom{n}{2} \mu(G)$. The applications of the Wiener index in physical chemistry are legion (see, for example, [7, 10, 13] for references); it has been used in the characterization of many different types of chemical species, including alkanes, alkenes, and arenes. The Wiener index is also a tool for designing quantitative structure-property relations in organic chemistry.

Several upper and lower bounds on the average distance in terms of other graph parameters are known. The *edge-connectivity* $\lambda(G)$ of G is the minimum number of edges whose deletion from G results in a disconnected or trivial graph. We say G is *k-edge-connected* if $\lambda(G) \geq k$. It has been proved (see, for example, [9, 4, 5]) that the average distance of a connected graph with n vertices is at most $(n+1)/3$ and that this bound is attained only by the path of order n . Plesník [12] showed that this bound can be improved for a 2-edge-connected (2-vertex-connected) graph G of order n to $\mu(G) \leq \lfloor \frac{n^2}{4} \rfloor / (n-1)$ and that this bound is achieved if and only if G is a cycle. He posed the problem of finding upper bounds on the average distance of a graph of given order and edge-connectivity. The goal of this paper is to find asymptotically sharp upper bounds on $\mu(G)$ for a graph G of given order and edge-connectivity λ . For $\lambda \geq 8$, we obtain bounds as an immediate consequence of known bounds on

the average distance in terms of order and minimum degree. For small values of λ , $\lambda \in \{3, \dots, 7\}$, the problem requires a more intricate analysis. In this paper we give asymptotically sharp bounds on μ for $\lambda \in \{5, 6, 7\}$. The cases $\lambda \in \{3, 4\}$ will be considered in a subsequent paper [3].

We use the following notation. Let $G = (V, E)$ be a connected simple graph. For a subset $S \subseteq V$, $G[S]$ denotes the subgraph induced by S in G , and $\text{diam}(S)$ is the maximum value of $d_G(x, y)$, $x, y \in S$. Let $v \in V$. The *eccentricity* $ex_G(v)$ of v is the maximum value of $d_G(v, x)$, $x \in V$. The *distance* $\sigma_G(v)$ of v is the sum $\sum_{x \in V} d_G(v, x)$, whereas the *distance* $\sigma(G)$ of G is $\sum_{u \in V} \sigma_G(u) = \sum_{(x, y) \in V \times V} d_G(x, y)$. Thus $\mu(G) = \sigma(G)/n(n-1)$, where n is the order of G . For subsets $M_1, M_2 \subseteq V$, the distance $\sigma_{M_1}(v)$ of v with respect to M_1 is the sum $\sum_{x \in M_1} d_G(v, x)$, and the distance $\sigma_{M_1}(M_2)$ of M_2 with respect to M_1 is $\sum_{x \in M_2} \sigma_{M_1}(x)$. $E(M_1, M_2)$ denotes the set of edges $\{ab \in E \mid a \in M_1, b \in M_2\}$. $N_G(v) = N(v)$ denotes the set of all vertices adjacent to v in G , and its cardinality is the degree of v in G and is denoted by $\deg_G(v)$. We denote the closed neighbourhood of v by $N[v]$, i.e., $N[v] = N(v) \cup \{v\}$. For a positive integer i , the i th *distance layer* $N_i(v)$ of v is the set of vertices at distance i from v , i.e., $N_i(v) = \{x \in V \mid d_G(v, x) = i\}$. We denote the cardinality of $N_i(v)$ by $k_i(v)$, and if the vertex v is understood we omit the argument v and simply write N_i, k_i . We denote the set $\bigcup_{0 \leq j \leq i} N_j(v)$ by $N_{\leq i}(v)$ and the set $\bigcup_{j \geq i} N_j(v)$ by $N_{\geq i}(v)$.

A *disconnecting (separating) set* of G is a set of edges (vertices) of G whose removal increases the number of components of G . A *vertex cutset* of G is a separating set, S say, such that no proper subset of S is a separating set of G . A vertex v of G is a *cutvertex* if $\{v\}$ is a separating set of G . A maximal subgraph of G with no cutvertex is called a *block*, and an *end block* of G is a block of G that contains exactly one cutvertex of G . For vertex disjoint graphs $G_1, G_2, \dots, G_k$, the *sequential join* $G_1 + G_2 + \dots + G_k$ is the graph obtained from the union of $G_1, \dots, G_k$ by joining every vertex of G_i to every vertex of G_{i+1} for $i = 1, 2, \dots, k-1$.

2. Results on 8-edge-connected graphs. Dankelmann and Entringer [2] proved that if G is a connected graph of order n and minimum degree δ , then $\mu(G) \leq n/(\delta+1) + 5$. An application of the well-known inequality $\lambda \leq \delta$ to this bound yields part (a) of the following proposition.

PROPOSITION 1. *Let G be a λ -edge-connected graph of order n .*

(a) *Then $\mu(G) \leq \frac{n}{\lambda+1} + 5$.*

(b) *The bound in (a), apart from the additive constant, is best possible for $\lambda \geq 8$.*

Proof. (b) Assume that $\lambda \geq 8$. We show that the bound is sharp apart from the exact value of the additive constant. Given integers n, λ , and k with $n = \frac{1}{3}(\lambda+1)(k+2)$, $k \equiv 1 \pmod{3}$, $k \geq 7$, let

$$G_{n,\lambda} = G_1 + G_2 + G_3 + \dots + G_k,$$

where $G_1 = K_1 = G_k$, $G_2 = K_\lambda = G_{k-1}$, and for $3 \leq i \leq k-2$, G_i

$$= \begin{cases} K_{\frac{\lambda+1}{3}} & \text{if } \lambda \equiv 2 \pmod{3}, \\ K_{\frac{\lambda}{3}} \text{ for } i \equiv 0, 2 \pmod{3} \text{ and } K_{\frac{\lambda}{3}+1} \text{ for } i \equiv 1 \pmod{3} & \text{if } \lambda \equiv 0 \pmod{3}, \\ K_{\frac{\lambda+2}{3}} \text{ for } i \equiv 0, 2 \pmod{3} \text{ and } K_{\frac{\lambda-1}{3}} \text{ for } i \equiv 1 \pmod{3} & \text{if } \lambda \equiv 1 \pmod{3}. \end{cases}$$

Clearly, since $\lambda \geq 8$, $G_{n,\lambda}$ is λ -edge-connected. It is easy to show that, for constant λ and large n , $\mu(G_{n,\lambda}) \geq \frac{n}{\lambda+1} + O(1)$. $\square$

3. Results on 5-edge-connected graphs.

LEMMA 2. *Let G be a 5-edge-connected graph with n vertices, and let v be any vertex of G . Then $\sigma_G(v) \leq \frac{1}{5}(n^2 - 4n + 14)$. Moreover, $\sigma(G) \leq \frac{n}{5}(n^2 - 4n + 14)$.*

Proof. Let e be the eccentricity of v , and note that

$$(1) \quad \sigma_G(v) = 1k_1 + 2k_2 + \cdots + ek_e.$$

The lemma can easily be verified for $e \leq 4$. Assume that $e \geq 5$. Since G is 5-edge-connected, $k_i k_{i+1} \geq |E(N_i, N_{i+1})| \geq \lambda(G) \geq 5$. From $k_i k_{i+1} \geq 5$ we deduce that $k_i + k_{i+1} \geq 5$. Hence it is easy to see that

$$(*) \quad k_i k_{i+1} \geq 5, k_i + k_{i+1} \geq 5 \text{ for } i = 0, 1, \dots, e-1, k_{e-1} + k_e \geq 6, \sum_{i=0}^e k_i = n.$$

Let $(a_0, a_1, \dots, a_e)$ be a sequence that maximizes (1) subject to (*). We first show that we can assume that $a_i > 1$ for $i = 2, \dots, e-1$. If $a_2 = 1$, then since $e \geq 5$ and $a_3 \geq 5$, the sequence $(b_0, b_1, \dots, b_e)$ given by $b_2 = 2$, $b_3 = a_3 - 2$, $b_4 = a_4 + 1$, and $b_i = a_i$ otherwise, also maximizes (1) subject to (*). Hence we can assume that $a_2 > 1$. Now we show that $a_i > 1$ for $i = 3, \dots, e-1$. If this were false, let s , $3 \leq s \leq e-1$, be the smallest integer for which $a_s = 1$. Let $(b_0, b_1, \dots, b_e)$ be the sequence given by (i) $b_i = 3$ if $i = s-1$, (ii) $b_i = 2$ if $i = s$, (iii) $b_i = a_{s-1} + a_{s+1} - 4$ if $i = s+1$, and (vi) $b_i = a_i$ otherwise. By (*), $a_{s-1}, a_{s+1} \geq 5$. This, in conjunction with $b_{s-2} = a_{s-2} \geq 2$, yields that the sequence (b_i) satisfies (*), and, moreover, $\sum_{i=0}^e i a_i = \sum_{i=0}^e i b_i + 7 - 2a_{s-1} < \sum_{i=0}^e i b_i$, contradicting our choice of the sequence (a_i) . Therefore, we can assume that $a_i \geq 2$ for all $i = 2, 3, \dots, e-1$.

Hence we maximize (1) subject to the conditions

$$k_1 \geq 5, k_i \geq 2, k_i + k_{i+1} \geq 5, \text{ for } i = 1, 2, \dots, e-1, k_{e-1} + k_e \geq 6, \sum_{i=0}^e k_i = n.$$

Clearly for fixed e , (1) is maximized, subject to these conditions, for

$$(k_0, k_1, \dots, k_{e-1}) = \begin{cases} (1, 5, 2, 3, 2, 3, \dots, 2, 3) & \text{if } e \text{ is even,} \\ (1, 5, 2, 3, 2, 3, \dots, 2, 3, 2) & \text{if } e \text{ is odd,} \end{cases}$$

and $k_e = n - \sum_{i=0}^{e-1} k_i$. Then

$$\begin{aligned} \sigma_G(v) &= 1k_1 + 2k_2 + 3k_3 + 4k_4 + 5k_5 + \cdots + ek_e \\ &\leq \begin{cases} 1 \cdot 5 + [2 \cdot 2 + 3 \cdot 3] + \cdots + [(e-2) \cdot 2 \\ \quad + (e-1) \cdot 3] + e(n - \frac{5}{2}e - 1) & \text{if } e \text{ is even,} \\ 1 \cdot 5 + [2 \cdot 2 + 3 \cdot 3] + \cdots + [(e-3) \cdot 2 \\ \quad + (e-2) \cdot 3] + (e-1) \cdot 2 + e(n - \frac{5}{2}e - \frac{1}{2}) & \text{if } e \text{ is odd} \end{cases} \\ (2) \quad &\leq en - \frac{5}{4}e^2 - 2e + \frac{9}{4}. \end{aligned}$$

By (*),

$$n = \sum_{i=0}^e k_i \geq \begin{cases} \frac{5e+8}{2} & \text{if } e \text{ is even,} \\ \frac{5e+9}{2} & \text{if } e \text{ is odd.} \end{cases}$$

(Note that for even e we use $k_2 + k_3 + k_4 \geq 7$.) Hence $e \leq \frac{2n-8}{5}$. A simple differentiation shows that (2) is maximized, subject to the constraint $e \leq \frac{2n-8}{5}$, for $e = \frac{2n-8}{5}$, and we obtain $\sigma_G(v) \leq \left(\frac{2n-8}{5}\right)n - \frac{5}{4}\left(\frac{2n-8}{5}\right)^2 - 2\left(\frac{2n-8}{5}\right) + \frac{9}{4} \leq \frac{1}{5}(n^2 - 4n + 14)$, as desired.

Summing $\sigma_G(v)$ for all v , the bound in the second part of the lemma follows from the first part. $\square$

PROPOSITION 3. *Let G be a 5-edge-connected block and v a vertex of G . If $k_l + k_{l+1} + k_{l+2} \leq 11$ for some l , $1 \leq l \leq \text{ex}_G(v) - 3$, then $\text{diam}(N_{l+1}) \leq 2$ and $2 \leq k_{l+1} \leq 7$.*

Proof. Suppose to the contrary that for some $a, b \in N_{l+1}$, $d(a, b) > 2$. Then $N[a] \cap N[b] = \emptyset$. Thus, since $N[a], N[b] \subseteq N_l \cup N_{l+1} \cup N_{l+2}$ and $\delta(G) = \delta \geq 5$, we have $k_l + k_{l+1} + k_{l+2} \geq |N[a]| + |N[b]| \geq (\delta + 1) + (\delta + 1) \geq 12$, a contradiction. Therefore, for all $a, b \in N_{l+1}$, $d(a, b) \leq 2$ as desired.

Since G is a block, $k_l, k_{l+1}, k_{l+2} \geq 2$. Therefore, $2 \leq k_{l+1} \leq 11 - (k_l + k_{l+2}) \leq 11 - 4 = 7$. $\square$

DEFINITION 4. *Let G be a 5-edge-connected graph and v a vertex of G . We say that (N_l, N_{l+1}, N_{l+2}) , where $22 \leq l \leq \text{ex}_G(v) - 24$, is a forbidden separating triple of v if $k_l + k_{l+1} + k_{l+2} \leq 11$.*

Clearly, if a vertex v with $\text{ex}_G(v) \geq 46$ has no forbidden separating triple, then for all $i \in \{22, \dots, \text{ex}_G(v) - 24\}$ we have that $k_i + k_{i+1} + k_{i+2} \geq 12$. This will allow us to show that the distance of a vertex v with no forbidden separating triple is small and bounded by a term of the form $\frac{n^2}{8} + O(n)$.

LEMMA 5. *Let G be a 5-edge-connected graph with n vertices, and let v be a vertex of G with $\text{ex}_G(v) \geq 46$. If v has no forbidden separating triple, then*

$$\sigma_G(v) \leq \frac{1}{8}n^2 + \frac{33}{4}n + \frac{1361}{8}.$$

Proof. Denote the eccentricity of v by e , where e is fixed. We first show that

$$(3) \quad \sigma_G(v) \leq en - 2e^2 + 33e + 34.$$

As above,

$$(4) \quad \sigma_G(v) = 1k_1 + 2k_2 + 3k_3 + \dots + ek_e.$$

Since G is a 5-edge-connected graph and v has no forbidden separating triple, the sequence (k_i) satisfies the conditions: $k_1 \geq 5$; $k_{e-1} + k_e \geq 6$; $k_i \geq 1$ for $i = 0, 1, \dots, e$; $k_i + k_{i+1} \geq 5$ for $i = 0, 1, \dots, 20$, $i = e - 21, \dots, e - 1$; $k_i + k_{i+1} + k_{i+2} \geq 12$ for $i = 22, 23, \dots, e - 24$ and $\sum_{i=0}^e k_i = n$. If $e \equiv 0 \pmod{3}$, then clearly (4) is maximized, subject to these conditions, for $(k_0, k_1, \dots, k_{21}) = (1, 5, 1, 4, \dots, 1, 4)$, $(k_{22}, k_{23}, \dots, k_{e-22}) = (1, 1, 10, 1, 1, 10, \dots, 1, 1, 10, 1, 1)$, $(k_{e-21}, k_{e-20}, \dots, k_{e-1}) = (1, 4, 1, 4, \dots, 1, 4, 1)$, and k_e as large as possible. Then

$$\begin{aligned} \sigma_G(v) &= 1k_1 + 2k_2 + 3k_3 + \dots + ek_e \\ &\leq 5 + [2 \cdot 1 + 3 \cdot 4] + \dots + [20 \cdot 1 + 21 \cdot 4] + [22 \cdot 1 + 23 \cdot 1 + 24 \cdot 10] \\ &\quad + \dots + [(e - 26) \cdot 1 + (e - 25) \cdot 1 + (e - 24) \cdot 10] + (e - 23) \cdot 1 \\ &\quad + (e - 22) \cdot 1 + [(e - 21) \cdot 1 + (e - 20) \cdot 4] + \dots \\ &\quad + [(e - 3) \cdot 1 + (e - 2) \cdot 4] + (e - 1) \cdot 1 + e(n - 4e + 71) \\ &= en - 2e^2 + 33e + 34. \end{aligned}$$

By a similar argument, for $e \equiv 1 \pmod 3$ and for $e \equiv 2 \pmod 3$, we have $\sigma_G(v) \leq en - 2e^2 + 33e + 34$.

Note that by the conditions satisfied by the sequence (k_i) , we have

$$n = \sum_{i=0}^e k_i \geq \begin{cases} 4e - 66 & \text{if } e \equiv 0 \pmod 3, \\ 4e - 63 & \text{if } e \equiv 2 \pmod 3, \\ 4e - 60 & \text{if } e \equiv 1 \pmod 3. \end{cases}$$

Hence $e \leq \frac{n+66}{4}$. A simple differentiation shows that (3) is maximized, subject to the constraint $e \leq \frac{n+66}{4}$, for $e = \frac{n+33}{4}$, and we obtain

$$\begin{aligned} \sigma_G(v) &\leq \left(\frac{n+33}{4}\right)n - 2\left(\frac{n+33}{4}\right)^2 + 33\left(\frac{n+33}{4}\right) + 34 \\ &= \frac{1}{8}n^2 + \frac{33}{4}n + \frac{1361}{8}, \end{aligned}$$

as desired. $\square$

We first establish an upper bound on distance for blocks.

THEOREM 6. *Let G be a 5-edge-connected block of order n . Then*

$$\sigma(G) \leq n(n-1) \left(\frac{2}{15}n + 9 \right).$$

Proof. Let v be a vertex of G of largest distance, and let e be its eccentricity.

For $e \leq 45$, the result is obtained as follows. If, on one hand, $n \leq 116$, then the second part of Lemma 2 yields the desired bound by a simple calculation. If, on the other hand, $n \geq 117$, then we have

$$\begin{aligned} \sigma_G(v) &\leq 5 + [2(2) + 3(3)] + \cdots + [42(2) + 43(3)] + 44(2) \\ &\quad + 45(n - 6 - 5 \cdot 21 - 2) \\ &= 45n - 2619. \end{aligned}$$

Since $45n - 2619 \leq (n-1)(\frac{2}{15}n + 9)$ for $n \geq 117$, it follows that $\sigma(G) \leq n\sigma_G(v) \leq n(45n - 2619) \leq n(n-1)(\frac{2}{15}n + 9)$ for all n . Thus the result holds.

So assume that $e \geq 46$ and hence $n \geq 119$. If v has no forbidden separating triple, then summing $\sigma_G(v)$ for all v , we obtain the result by Lemma 5.

If v has a forbidden separating triple, we prove the theorem by induction on the order n of G . For $n \leq 143$, the result follows by the second part of Lemma 2. So assume that $n \geq 144$ and that the result holds for any 5-edge-connected block with less than n vertices. Since v has a forbidden separating triple, let N_α , $23 \leq \alpha \leq e-23$, be chosen in accordance with Proposition 3, that is, $\text{diam}(N_\alpha) \leq 2$ and $2 \leq k_\alpha \leq 7$. Let K_5 be a copy of the complete graph with five vertices such that $V(G) \cap V(K_5) = \emptyset$. Denote the vertex set of K_5 by $A = \{a_1, \dots, a_5\}$. We form a new graph H from $G \cup K_5$ by attaching K_5 to N_α , that is, by joining every vertex in N_α to every vertex in K_5 .

Let $G_1 = H[N_{\leq \alpha} \cup A]$ and $G_2 = H[N_{\geq \alpha} \cup A]$. Since $\text{diam}(N_\alpha) \leq 2$, no distances in G have been reduced; hence $d_G(x, y) = d_H(x, y)$ for all $x, y \in V(G)$. The proof of the following claim is elementary.

Claim 1. Let $X = \sum_{i=1}^5 \sigma_{G_1}(a_i)$ and $Y = \sum_{i=1}^5 \sigma_{G_2}(a_i)$. Then

$$\begin{aligned} \sigma(G) &= \sigma(G_1) + \sigma(G_2) - 2(X + Y) + 2\sigma_A(A) \\ &\quad + 2 \sum_{x \in N_{< \alpha}} \sum_{y \in N_{> \alpha}} d_H(x, y) - \sum_{(x, y) \in N_\alpha \times N_\alpha} d_H(x, y). \end{aligned}$$

Note that G_1 and G_2 have $N_\alpha \cup A$ in common. Hence, letting $|V(G_i)| = n_i$, $i = 1, 2$, we obtain

$$(5) \quad n_1 + n_2 - k_\alpha - 10 = n.$$

Note also that $n_1 \geq |N_{\leq \alpha}| + |A| \geq (k_0 + k_1) + \dots + (k_{20} + k_{21}) + k_{22} + k_\alpha + 5 \geq 63 + k_\alpha$. Analogously, $n_2 \geq |N_{\geq \alpha}| + |A| \geq 63 + k_\alpha$. It follows from (5) that

$$63 + k_\alpha \leq n_1, \quad n_2 \leq n - 53.$$

We bound $\sigma(G_1)$ and $\sigma(G_2)$ using induction. It is easy to verify the following claim.

Claim 2. G_1 and G_2 are 5-edge-connected blocks.

We now find bounds on the terms in Claim 1. First, note that

$$(6) \quad \sigma_A(A) \leq \sigma(K_5) = 20 \quad \text{and} \quad \sum_{(x,y) \in N_\alpha \times N_\alpha} d_H(x, y) \geq k_\alpha(k_\alpha - 1).$$

Now, let a be a fixed vertex in N_α . Then

$$\begin{aligned} 2 \sum_{x \in N_{< \alpha}, y \in N_{> \alpha}} d_H(x, y) &\leq 2 \sum_{x \in N_{< \alpha}} \sum_{y \in N_{> \alpha}} [d_H(x, a) + d_H(a, y)] \\ &= 2 \sum_{x \in N_{< \alpha}} [|N_{> \alpha}| d_H(x, a) + \sigma_{G_2}(a) - \sigma_{N_\alpha \cup A}(a)] \\ &= 2[|N_{> \alpha}|(\sigma_{G_1}(a) - \sigma_{N_\alpha \cup A}(a)) \\ &\quad + |N_{< \alpha}|(\sigma_{G_2}(a) - \sigma_{N_\alpha \cup A}(a))]. \end{aligned}$$

Note that $\sigma_{N_\alpha \cup A}(a) \geq |(N_\alpha \cup A) - \{a\}| = k_\alpha + 4$. Thus,

$$\begin{aligned} (7) \quad 2 \sum_{x \in N_{< \alpha}, y \in N_{> \alpha}} d_H(x, y) &\leq 2[(n_2 - k_\alpha - 5)(\sigma_{G_1}(a) - k_\alpha - 4) + (n_1 - k_\alpha - 5)(\sigma_{G_2}(a) - k_\alpha - 4)]. \end{aligned}$$

We find lower bounds on X and Y . Note that for $i = 1, 2, \dots, 5$,

$$\begin{aligned} \sigma_{G_1}(a) &= \sum_{x \in V(G_1)} d(a, x) \leq \sum_{x \in V(G_1)} [d(a, a_i) + d(a_i, x)] \\ &= \sum_{x \in V(G_1)} [1 + d(a_i, x)] = n_1 + \sigma_{G_1}(a_i). \end{aligned}$$

Therefore, $\sigma_{G_1}(a_i) \geq \sigma_{G_1}(a) - n_1$ and

$$(8) \quad X \geq 5\sigma_{G_1}(a) - 5n_1.$$

Analogously,

$$(9) \quad Y \geq 5\sigma_{G_2}(a) - 5n_2.$$

Using induction, we have $\sigma(G_i) \leq n_i(n_i - 1) \left(\frac{2}{15}n_i + 9\right)$, whereas by Lemma 2 we have $\sigma_{G_i}(a) \leq \frac{1}{5}(n_i^2 - 4n_i + 14)$ for $i = 1, 2$.

This, together with (5), Claim 1, and (6)–(9), yields

$$\begin{aligned} \sigma(G) \leq n(n-1) \left(\frac{2}{15}n + 9 \right) &+ \left\{ (n_1 + n_2) \left(\frac{28}{3}k_\alpha + \frac{2414}{15} - \frac{2}{5}k_\alpha^2 \right) \right. \\ &\left. - n_1n_2 \left(\frac{194}{15} - \frac{4}{5}k_\alpha \right) + \frac{2}{15}k_\alpha^3 - \frac{28}{15}k_\alpha^2 - \frac{1808}{15}k_\alpha - \frac{2506}{3} \right\}. \end{aligned}$$

Denote the term in curly brackets of the right-hand side of the last inequality by $f(n_1, n_2)$. It is sufficient to show that, subject to $63 + k_\alpha \leq n_1, n_2$, we have $f(n_1, n_2) \leq 0$. Clearly, $(n_1 - (63 + k_\alpha))(n_2 - (63 + k_\alpha)) \geq 0$; hence $n_1n_2 \geq (63 + k_\alpha)(n_1 + n_2) - (63 + k_\alpha)^2$. This, in conjunction with (5), yields $f(n_1, n_2) \leq n(\frac{2}{5}k_\alpha^2 + \frac{234}{5}k_\alpha - \frac{9808}{15}) - \frac{4}{15}k_\alpha^3 - \frac{584}{15}k_\alpha^2 - 1852k_\alpha + \frac{219792}{5}$, and thus from $2 \leq k_\alpha \leq 7$ we obtain $f(n_1, n_2) \leq \frac{601448}{15} - \frac{920}{3}n \leq 0$ for all $n \geq 131$, as desired. $\square$

We now show that the upper bound on the distance proved above for 5-edge-connected blocks holds for all 5-edge-connected graphs.

THEOREM 7. *Let G be a 5-edge-connected graph of order n . Then*

$$\mu(G) \leq \frac{2}{15}n + 9.$$

Apart from the additive constant, this inequality is best possible.

Proof. We prove this result by induction on the number of blocks in G . If G is a block, then the result follows by Theorem 6. So assume that G has at least two blocks. We prove the equivalent statement

$$\sigma(G) \leq n(n-1) \left(\frac{2}{15}n + 9 \right).$$

Let G_1 be an end block, G_2 be the union of the other blocks, and u be the unique common vertex of G_1 and G_2 . For $i = 1, 2$, let $n_i = |V(G_i)|$. Then the relation $n_1 + n_2 - 1 = n$ holds. By definition,

$$\begin{aligned} \sigma(G) &= \sum_{(x,y) \in V(G) \times V(G)} d(x, y) \\ &= \sigma(G_1) + 2 \sum_{x \in V(G_1) - \{u\}} \sum_{y \in V(G_2) - \{u\}} d(x, y) + \sigma(G_2) \\ (10) \quad &= \sigma(G_1) + 2[(n_2 - 1)\sigma_{G_1}(u) + (n_1 - 1)\sigma_{G_2}(u)] + \sigma(G_2). \end{aligned}$$

Clearly, G_1 and G_2 are 5-edge-connected. Thus, by induction, $\sigma(G_i) \leq n_i(n_i - 1)(\frac{2}{15}n_i + 9)$ for $i = 1, 2$. By Lemma 2, we have $\sigma_{G_i}(u) \leq \frac{1}{5}(n_i^2 - 4n_i + 14)$ for $i = 1, 2$. This, in conjunction with (10) and $n_1 + n_2 - 1 = n$, yields $\sigma(G) \leq n(n-1)(\frac{2}{15}n + 9) + \{\frac{368}{15}(n_1 + n_2) - \frac{302}{15}n_1n_2 - \frac{434}{15}\}$. Denote the term in curly brackets of the right-hand side of the last inequality by $f(n_1, n_2)$. We show that $f(n_1, n_2) \leq 0$ for all $n_1, n_2 \geq 6$. Clearly, $(n_1 - 6)(n_2 - 6) \geq 0$; hence $n_1n_2 \geq 6(n_1 + n_2) - 36$. This, in conjunction with $n_1 + n_2 - 1 = n$, yields $f(n_1, n_2) \leq \frac{2998}{5} - \frac{1444}{15}n \leq 0$ for all $n \geq 7$. Note that if $n = 6$, then $G = K_6$, and the result holds.

We now show that, apart from the additive constant, the bound is best possible. Given integers n, k with $n = \frac{1}{2}(5k + 9)$, $k \geq 5$ odd, let

$$G_n = G_1 + G_2 + \cdots + G_k,$$

where $G_1 = K_5 = G_k$ and for $2 \leq i \leq k-1$,

$$G_i = \begin{cases} K_2 & \text{if } i \text{ is even,} \\ K_3 & \text{if } i \text{ is odd.} \end{cases}$$

Clearly, G_n is 6-edge-connected (and thus 5-edge-connected) of order n . Straight-forward calculations show that

$$\mu(G_n) \geq \frac{2}{n(n-1)} \left(\frac{1}{15}(n^3 - 15n^2 + 20n + 57) \right) = \frac{2}{15}n - \frac{28}{15} + \frac{2(6n+57)}{15n(n-1)},$$

as desired. $\square$

Since every 6-edge-connected graph is also 5-edge-connected and since the graph G_n defined above is 6-edge-connected, the following theorem becomes immediate.

THEOREM 8. *Let G be a 6-edge-connected graph of order n . Then*

$$\mu(G) \leq \frac{2}{15}n + 9.$$

Apart from the additive constant, this inequality is best possible.

4. Results on 7-edge-connected graphs. We now focus our attention on 7-edge-connected graphs.

LEMMA 9. *Let G be a 7-edge-connected graph with n vertices, and let v be an arbitrary vertex of G . Then $\sigma_G(v) \leq \frac{1}{6}(n^2 - 6n + 27)$. Moreover, $\sigma(G) \leq \frac{n}{6}(n^2 - 6n + 27)$.*

Proof. Let e be the eccentricity of v . Then

$$(11) \quad \sigma_G(v) = 1k_1 + 2k_2 + \cdots + ek_e.$$

The lemma can easily be verified for $e \leq 4$. Assume that $e \geq 5$. Since G is 7-edge-connected and as in the proof of Lemma 2, we have

$$(*) \quad k_1, k_i k_{i+1} \geq 7, k_i + k_{i+1} \geq 6 \text{ for } i = 1, \dots, e-1, k_{e-1} + k_e \geq 8, n = \sum_{i=0}^e k_i.$$

Let $(a_0, a_1, \dots, a_e)$ be a sequence that maximizes (11) subject to (*). We first show that $a_i > 1$ for $i = 2, \dots, e-1$. If this were not true, let s , $2 \leq s \leq e-1$, be the smallest integer for which $a_s = 1$. First assume that $s \geq 3$. Let $(b_0, b_1, \dots, b_e)$ be the sequence defined by (i) $b_i = 4$ if $i = s-1$, (ii) $b_i = 2$ if $i = s$, (iii) $b_i = a_{s-1} + a_{s+1} - 5$ if $i = s+1$, and (vi) $b_i = a_i$ otherwise. Then from $a_{s-2} \geq 2$, $a_{s-1}, a_{s+1} \geq 7$, we have that the sequence (b_i) satisfies (*) and $\sum_{i=0}^e ia_i = \sum_{i=0}^e ib_i - (2a_{s-1} - 9) < \sum_{i=0}^e ib_i$, contradicting our choice of the sequence (a_i) . If $s = 2$, then let $(b_0, b_1, \dots, b_e)$ be defined by $b_2 = 2$, $b_3 = 4$, $b_4 = a_3 + a_4 - 5$, and $b_i = a_i$ otherwise. Since $a_3 \geq 7$ and $e \geq 5$, the sequence (b_i) satisfies (*) and $\sum_{i=0}^e ia_i = \sum_{i=0}^e ib_i - (a_3 - 6) < \sum_{i=0}^e ib_i$, again contradicting our choice of the sequence (a_i) . Therefore, $a_i \geq 2$ for all $i = 2, \dots, e-1$. Hence we maximize (11) subject to the conditions

$$k_1 \geq 7, k_i \geq 2, k_i + k_{i+1} \geq 6 \text{ for } i = 1, 2, \dots, e-1, k_{e-1} + k_e \geq 8, \sum_{i=0}^e k_i = n.$$

Clearly for fixed e , (11) is maximized, subject to these constraints, for

$$(k_0, k_1, \dots, k_{e-1}) = \begin{cases} (1, 7, 2, 4, 2, 4, \dots, 2, 4) & \text{if } e \text{ is even,} \\ (1, 7, 2, 4, 2, 4, \dots, 2, 4, 2) & \text{if } e \text{ is odd.} \end{cases}$$

As in the proof of Lemma 2, we obtain $\sigma_G(v) \leq \frac{1}{6}(n^2 - 6n + 27)$, as desired. The second part also follows similarly. $\square$

The proposition below is an analogue to Proposition 3. Its proof is similar, so we omit it.

PROPOSITION 10. *Let G be a 7-edge-connected block and v a vertex of G . If for some l , $1 \leq l \leq \text{ex}_G(v) - 3$, we have $k_l + k_{l+1} + k_{l+2} \leq 15$, then $\text{diam}(N_{l+1}) \leq 2$ and $2 \leq k_{l+1} \leq 11$.*

DEFINITION 11. *Let G be a 7-edge-connected graph and v a vertex of G . We say that (N_l, N_{l+1}, N_{l+2}) , where $22 \leq l \leq \text{ex}_G(v) - 24$, is a forbidden separating triple of v if $k_l + k_{l+1} + k_{l+2} \leq 15$.*

The bound on the distance of a vertex of G with no forbidden separating triple is given below. Its proof is analogous to the proof of Lemma 5.

LEMMA 12. *Let G be a 7-edge-connected graph of order n and v a vertex of G with $\text{ex}_G \geq 46$. If v has no forbidden separating triple, then*

$$\sigma_G(v) \leq \frac{3}{32}n^2 + \frac{153}{16}n + \frac{9275}{32}.$$

THEOREM 13. *Let G be a 7-edge-connected block of order n . Then*

$$\mu(G) \leq \frac{1}{9}n + 10.$$

Proof. Let v be a vertex of G of largest distance and let e be its eccentricity.

If $e \leq 45$, then the result is obtained as follows. If, on one hand, $n \leq 142$, then, by the second part of Lemma 9, $\sigma(G) \leq \frac{1}{6}n(n^2 - 6n + 27) \leq n(n-1)(\frac{1}{9}n + 10)$ for all $n \leq 142$ and the theorem holds. If, on the other hand, $n \geq 143$, then, as in the proof of Lemma 9, we have

$$\begin{aligned} \sigma_G(v) &\leq 7 + [2(2) + 3(4)] + \cdots + [42(2) + 43(4)] + 44(2) + 45(n - 136) \\ &= 45n - 3169. \end{aligned}$$

Since $45n - 3169 \leq (n-1)(\frac{1}{9}n + 10)$ for $n \geq 143$, it follows that $\sigma(G) \leq n\sigma_G(v) \leq n(n-1)(\frac{1}{9}n + 10)$ for all n . Thus the theorem holds for $e \leq 45$.

So assume that $e \geq 46$ and hence $n \geq 144$. If v has no forbidden separating triple, then summing $\sigma_G(v)$ for all v , we obtain the result by Lemma 12. If v has a forbidden separating triple, then we proceed with our proof as follows. We prove the equivalent statement

$$\sigma(G) \leq n(n-1) \left(\frac{1}{9}n + 10 \right)$$

by induction on the order n of G . For $n \leq 194$, the result follows by the second part of Lemma 9. So assume that $n \geq 195$ and that the result holds for any 7-edge-connected block with fewer than n vertices. Since v has a forbidden separating triple, let N_α , $23 \leq \alpha \leq e - 23$, be chosen in accordance with Proposition 10, that is, $\text{diam}(N_\alpha) \leq 2$ and $2 \leq k_\alpha \leq 11$. Let K_7 be a copy of the complete graph with seven vertices such that $V(G) \cap V(K_7) = \emptyset$. Denote the vertex set of K_7 by $A = \{a_1, \dots, a_7\}$. We form a new graph H from $G \cup K_7$ by attaching K_7 to N_α , that is, by joining each vertex in N_α to every vertex in K_7 .

Let $G_1 = H[N_{\leq \alpha} \cup A]$ and $G_2 = H[N_{\geq \alpha} \cup A]$. Since $\text{diam}(N_\alpha) \leq 2$, no distances in G have been reduced; hence $d_G(x, y) = d_H(x, y)$ for all $x, y \in V(G)$. The claim below is easy to establish.

Claim 3. Let $X = \sum_{i=1}^7 \sigma_{G_1}(a_i)$ and $Y = \sum_{i=1}^7 \sigma_{G_2}(a_i)$. Then

$$\begin{aligned} \sigma(G) &= \sigma(G_1) + \sigma(G_2) - 2(X + Y) + 2\sigma_A(A) \\ &\quad + 2 \sum_{x \in N_{<\alpha}} \sum_{y \in N_{>\alpha}} d_H(x, y) - \sum_{(x,y) \in N_\alpha \times N_\alpha} d_H(x, y). \end{aligned}$$

By bounding the terms on the right-hand side of the equation in Claim 3 in a manner similar to that done in Theorem 6, we obtain $\sigma(G) \leq n(n-1)(\frac{1}{9}n + 10)$, as desired. $\square$

THEOREM 14. *Let G be a 7-edge-connected graph of order n . Then*

$$\mu(G) \leq \frac{1}{9}n + 10.$$

Apart from the additive constant, this inequality is best possible.

Proof. The proof of this result is treated similarly to the proof of Theorem 7. To show that the bound is best possible apart from the exact value of the additive constant, let n and k be integers satisfying $n = 3k + 4$, $k \geq 6$, and let $G_{n,7} = G_1 + G_2 + \cdots + G_k$, where $G_1 = K_1 = G_k$, $G_2 = K_7 = G_{k-1}$, and $G_i = K_3$ for $i = 3, \dots, k-2$. Clearly, $G_{n,7}$ is 7-edge-connected and $\mu(G_{n,7}) = \frac{1}{9}n + \frac{1}{9} + \frac{2(736-97n)}{9n(n-1)}$, as desired. $\square$

TREE-RELATED WIDTHS OF GRAPHS AND HYPERGRAPHS*

ISOLDE ADLER[†]

Abstract. A *hypergraph pair* is a pair (G, H) where G and H are hypergraphs on the same set of vertices. We extend the definitions of *hypertree-width* [G. Gottlob, N. Leone, and F. Scarcello, *J. Comput. System Sci.*, 64 (2002), pp. 579–627] and *generalized hypertree-width* [G. Gottlob, N. Leone, and F. Scarcello, *J. Comput. System Sci.*, 66 (2003), pp. 775–808] from hypergraphs to hypergraph pairs. We show that for constant k the problem of deciding whether a hypergraph pair has generalized hypertree-width $\leq k$, is equivalent to the *hypergraph sandwich problem* (HSP) [A. Lustig and O. Shmueli, *J. Algorithms*, 30 (1999), pp. 400–422]. It was recently proved in [G. Gottlob, Z. Miklós, and Th. Schwentick, *Proceedings of the Symposium on Principles of Database Systems (PODS07)*] that the HSP is NP-complete. For constant k there is a polynomial time algorithm that decides whether a given hypergraph pair has hypertree-width $\leq k$. (For hypertree-width of hypergraphs, this was shown in [G. Gottlob, N. Leone, and F. Scarcello, *J. Comput. System Sci.*, 64 (2002), pp. 579–627].) It follows that the HSP is solvable in polynomial time for inputs (G, H) satisfying: $\text{ghw}(G, H) \leq 1$ if and only if $\text{hw}(G, H) \leq 1$. Besides this practical interest, hypergraph pairs serve as a tool for giving a common proof for the game theoretic characterizations of tree-width [P. D. Seymour and R. Thomas, *J. Combin. Theory Ser. B*, 58 (1993), pp. 22–33] and hypertree-width [G. Gottlob, N. Leone, and F. Scarcello, *J. Comput. System Sci.*, 66 (2003), pp. 775–808]. Furthermore, they enable us to show a *compactness property* of generalized hypertree-width for a large class of hypergraphs, the hypergraphs with *finite character*. Finally, we present two examples showing that neither hypertree-width of hypergraph pairs nor hypertree-width of hypergraphs has the *compactness property*.

Key words. hypergraphs, hypertree-width, hypergraph sandwich problem, tree-width, infinite hypergraphs

1. Introduction. The well-studied notion of tree-width of a graph (or a hypergraph) is important for various reasons, one of which is that problems that are NP-complete¹ in general become polynomially solvable when restricted to graphs of bounded tree-width (see [5]). Similarly, restriction to hypergraphs with bounded hypertree-width (hw) or bounded generalized hypertree-width (ghw) yields large classes of polynomially solvable instances of problems that are NP-complete in general (see [7]). There are classes of hypergraphs with bounded (generalized) hypertree-width, whose tree-width is unbounded, and where the tree-width of the incidence graphs is also unbounded (see [3, Example 2]).

This paper is organized as follows: section 2 contains the basic definitions, some observations, and an example of a hypergraph pair with hypertree-width 2 and generalized hypertree-width 1.

In section 3, we reformulate the hypergraph sandwich problem (HSP) in terms of generalized hypertree-width of a hypergraph pair. Gottlob, Miklós, and Schwentick [9] recently proved that the HSP is NP-complete. Therefore it is of interest to find tractable restrictions of the HSP. For constant k there is a polynomial time algorithm that decides whether a given hypergraph pair has hypertree-width $\leq k$. (For

¹See [6] for definitions.

hypertree-width of *hypergraphs*, this was shown in [7].) It follows that the HSP is solvable in polynomial time for inputs (G, H) satisfying: $\text{ghw}(G, H) \leq 1$ if and only if $\text{hw}(G, H) \leq 1$.

Section 4 gives a characterization of the hypertree-width of a (possibly infinite) hypergraph pair (G, H) by the number of marshals necessary to catch the robber in the monotone robber and marshals game played on (G, H) . As a corollary, we obtain the game theoretic characterizations of the well-studied notion of tree-width (tw) [14] and of hypertree-width of hypergraphs [8]. We use the game theoretic characterization in section 6 for constructing examples with special properties.

In section 5 we define the notion of *finite character*, and we show that for hypergraph pairs with finite character generalized hypertree-width is *compact*, i.e.,: a hypergraph pair (G, H) with finite character has generalized hypertree-width $\leq k$ if and only if every finite induced subhypergraph pair (G_0, H_0) of (G, H) has generalized hypertree-width $\leq k$. As special cases we obtain compactness of tree-width of graphs² and compactness of generalized hypertree-width of hypergraphs with finite character.

Finally, section 6 contains two examples, one showing that hypertree-width of hypergraph pairs is not compact, and the other showing that hypertree-width of hypergraphs is not compact. Both examples have hyperedges of size at most 3, which implies that they have finite character.

2. Preliminaries.

2.1. Graphs, hypergraphs, and hypergraph pairs. A *graph* is a pair $G = (V(G), E(G))$ where $V(G)$ is a nonempty set of *vertices*, and $E(G) \subseteq \mathcal{P}_{=2}(V(G))$ is the set of *edges* of G . Thus the edges of G are two-element subsets of $V(G)$. A *clique* is a complete graph. A *forest* is a graph without cycles, and a *tree* is a connected forest. A *directed tree* is a rooted tree where all the edges are directed away from the root.

A *hypergraph* is a pair $H = (V(H), E(H))$, consisting of a nonempty set $V(H)$ of *vertices*, and a set $E(H) \subseteq \mathcal{P}_{<\omega}(V(H))$ of finite subsets of $V(H)$, the *hyperedges* of H . Let $X \subseteq V(H)$. Then $H[X] := (X, \{e \cap X \mid e \in E(H)\})$ is the *subhypergraph of H induced by X* . H_0 is an *induced subhypergraph of H* if $H_0 = H[X]$ for some $X \subseteq V(H)$. For a hypergraph H the *underlying graph of H* is the graph $\underline{H} = (V(H), \{\{v, w\} \mid \text{there exists an } e \in E(H) \text{ such that } \{v, w\} \subseteq e\})$.

A *hypergraph pair* is a pair (G, H) , where G and H are hypergraphs and $V(G) = V(H)$. A hypergraph pair (G_0, H_0) is an *induced subhypergraph pair of (G, H)* , if G_0 is an induced subhypergraph of G and H_0 is an induced subhypergraph of H .

In this paper all graphs are connected and all hypergraphs H satisfy $\bigcup E(H) = V(H)$. Furthermore we only consider hypergraph pairs (G, H) , where G is connected (i.e., $\underline{G}$ is connected).

2.2. Decompositions and acyclicity. Let H be a hypergraph. A *tree-decomposition of H* is a tuple (T, B) , consisting of a directed tree T and a family $B := (B_t)_{t \in V(T)}$ of finite subsets of $V(T)$, the *pieces of T* , satisfying

1. For each edge $e \in E(H)$ there exists $t \in V(T)$, such that $e \subseteq B_t$. (t covers e .)
2. For each $v \in V(H)$ the set $\{t \in V(T) \mid v \in B_t\}$ is connected in T .

²This was first proved by Thomas in [15]. See [16] for a shorter proof.

The *width* of a tree-decomposition of H is

$$w(T, B) := \sup \{ |B_t| - 1 \mid t \in V(T) \} \in \mathbb{N} \cup \{\infty\}.$$

The *tree-width* of H is

$$\text{tw}(H) := \min \{ w(T, B) \mid (T, B) \text{ is a tree-decomposition of } H \} \in \mathbb{N} \cup \{\infty\}.$$

Condition 2 will be referred to as the “connectedness condition.” Since $V(H) \neq \emptyset$ and $\bigcup E(H) = V(H)$, condition 1 implies that a tree-decomposition (T, B) of H always satisfies $w(T, B) \geq 0$. It is not until the definition of a hypertree decomposition that we need T to be a *directed* tree. Nevertheless, it is convenient to require T to be directed.

REMARK 1. Let $C \subseteq \underline{H}$ be a finite clique, and let (T, B) be a tree-decomposition of H . Then there exists a node $t \in V(T)$ with $V(C) \subseteq B_t$.

For a directed tree T and $t \in V(T)$, the maximal subtree of T with root t is denoted by T_t . For a tree-decomposition (T, B) we set $B_{T_t} := \bigcup_{s \in V(T_t)} B_s$.

Proof. Let (T, B) be a tree-decomposition of H . Starting with the root r of T we find a path leading us to a node $t \in V(T)$ with $V(C) \subseteq B_t$ as follows:

- Set $p_0 := r$. If $V(C) \subseteq B_r$ we are finished. Otherwise, connectedness shows that for each $v \in V(C) \setminus B_r$ there exists a unique successor s_v of r such that $v \in B_{T_{s_v}}$.
- If $u \in V(C) \setminus B_r$ and $u \neq v$, then the edge $\{u, v\}$ must be covered by some $s' \in V(T)$.
- Connectedness implies that $s' \in V(T_{s_v})$ and hence $s_u = s_v$. We set $p_1 := s_v$. By connectedness, $(B_r \cap V(C)) \subseteq (B_{p_1} \cap V(C))$.

Suppose the path $p_0, p_1, \dots, p_n$ is already defined. If $V(C) \subseteq B_{p_n}$, then we are finished. Otherwise, by the same arguments as above, there exists a unique successor s of p_n with $V(C) \setminus B_{p_n} \subseteq B_{T_s}$. We set $p_{n+1} := s$. By connectedness, $(B_{p_n} \cap V(C)) \subseteq (B_s \cap V(C))$.

Since $|V(C)| < \omega$, after finitely many steps the path ends at a node p_m with $V(C) \subseteq B_{p_m}$. $\square$

Since every hyperedge of a hypergraph H induces a clique in $\underline{H}$, with Remark 1 it is easy to see that every hypergraph H satisfies $\text{tw}(H) = \text{tw}(\underline{H})$. Hence the tree-width of H only depends on $\underline{H}$.

Let (G, H) be a hypergraph pair. A *hypertree decomposition* of (G, H) is a triple (T, B, C) , where

1. (T, B) is a tree-decomposition of G , and $C := (C_t)_{t \in V(T)}$ is a family of subsets of $E(H)$, such that:
2. Each $t \in V(T)$ satisfies $B_t \subseteq \bigcup C_t$.
3. Each $t \in V(T)$ satisfies $(\bigcup C_t) \cap B_{T_t} \subseteq B_t$.

The *width* of a hypertree decomposition of (G, H) is

$$w(T, B, C) := \sup \{ |C_t| \mid t \in V(T) \} \in \mathbb{N} \cup \{\infty\}.$$

The *hypertree-width* of (G, H) is

$$\text{hw}(G, H) := \min \{ w(T, B, C) \mid (T, B, C) \text{ is a hypertree decomposition of } (G, H) \}.$$

By dropping condition 3 from the definition of hypertree decomposition of (G, H) , we obtain a *generalized hypertree decomposition* $(T, B, C,)$ of (G, H) and the *generalized hypertree-width* of (G, H) , $\text{ghw}(G, H)$.

 FIG. 2.1. A hypergraph pair (G, H) .

 FIG. 2.2. A width 2 hypertree decomposition of (G, H) from Figure 2.1.

Note that by definition, $\text{ghw}(G, H) \leq \text{hw}(G, H)$. Furthermore, every hypergraph pair (G, H) satisfies $\text{hw}(G, H) = \text{hw}(\underline{G}, H)$ and $\text{ghw}(G, H) = \text{ghw}(\underline{G}, H)$.

Figure 2.1 shows a hypergraph pair (G, H) with

$$V(G) = V(H) = \{1, 2, 3, 4, 5, 6\},$$

$$E(G) = \{\{1, 2\}, \{2, 3\}, \{3, 4\}, \{4, 5\}, \{5, 6\}\}, \text{ and}$$

$$E(H) = \{\{1, 2\}, \{2, 3\}, \{1, 3, 4, 6\}, \{4, 5\}, \{5, 6\}\}.$$

For convenience, the hyperedges containing exactly two vertices are shown as graph edges. Figure 2.2 shows a width 2 hypertree decomposition of (G, H) . Figure 2.3 shows a width 1 generalized hypertree decomposition of (G, H) . Each tree node t is depicted with B_t on the left-hand side and C_t on the right-hand side. Actually, these decompositions are optimal in the sense that $\text{hw}(G, H) = 2$ and $\text{ghw}(G, H) = 1$. This is left to the reader as an exercise.

For a hypergraph H , define the *hypertree-width* of H by $\text{hw}(H) := \text{hw}(H, H)$ and the *generalized hypertree-width* of H by $\text{ghw}(H) := \text{ghw}(H, H)$. In this way we get exactly the definitions from [8] of (generalized) hypertree-width of a hypergraph. In particular, $\text{hw}(H) \leq k$ implies $\text{ghw}(H) \leq k$. In general the converse does not hold.³

It is easy to see that we also obtain tree-width as a special case.

REMARK 2. Let (G, H) be a hypergraph pair with $H = \{\{v\} \mid v \in V(G)\}$, then

$$\text{hw}(G, H) = \text{tw}(G) + 1.$$

A tree-decomposition (T, B) of H is *small*, if all $s, t \in V(T)$ with $s \neq t$ satisfy $B_s \not\subseteq B_t$.

REMARK 3. If a finite hypergraph pair (G, H) has a generalized hypertree decomposition of width $k \in \mathbb{N}$, then (G, H) also has a generalized hypertree decomposition (T, B, C) of width k , such that (T, B) is small.

³A counterexample can be found in [1].

FIG. 2.3. A width 1 generalized hypertree decomposition of (G, H) from Figure 2.1.

Proof. Let (T', B', C') be a generalized hypertree decomposition of width k for the finite hypergraph pair (G, H) . We may assume that T is finite. If $\{s, t\} \in E(T)$ with $B_s \subseteq B_t$, remove s , B_s , and C_s from (T, B, C) and connect each neighbor $t' \neq t$ of s by an edge to t . It is easy to see that thus we obtain a new generalized hypertree decomposition (T'', B'', C'') of width k for (G, H) . Since T is finite, we can repeat this procedure finitely often until we obtain a generalized hypertree decomposition (T, B, C) of width k for (G, H) s.t. (T, B) is small. $\square$

Note that this is not true for infinite hypergraph pairs: Let $H = (\omega, \mathcal{P}_{<\omega}(\omega))$. Then $\text{ghw}(\underline{H}, H) = 1$ (take a one way infinite path with an increasing sequence of pieces $B_t = \bigcup C_t$), but $(\underline{H}, H)$ has no small generalized hypertree decomposition of width 1: Let (T, B, C) be a generalized hypertree decomposition of $(\underline{H}, H)$. Since all B_t are finite, for each B_t there is an edge $e \in E(H)$ s.t. $B_t \subsetneq e$ and e is covered by some $t' \in V(T)$.

A hypergraph H is *acyclic* if its hyperedges can be arranged as nodes of a tree T so that for every vertex $v \in V(H)$, the subtree of T defined by the nodes containing v is connected (cf. [13]).

LEMMA 4. *Let H be a finite hypergraph. The following statements are equivalent:*

- (i) $\text{ghw}(H) \leq 1$.
- (ii) $\text{hw}(H) \leq 1$.
- (iii) H is *acyclic*.

The equivalence of (ii) and (iii) was already observed in [7].

Proof of Lemma 4. It is easy to see that (iii) implies (ii), and that (ii) implies (i).

(i) $\Rightarrow$ (iii): Let (T, B, C) be a generalized hypertree decomposition for H of width at most 1. By Remark 3 we may assume that (T, B) is small. Then $B_t = \bigcup C_t$ for all $t \in T$. (Otherwise $B_t \subsetneq \bigcup C_t$ and $C_t = \{e\}$ for some $e \in E$. But there must be a node $s \in T$ such that $e \subseteq B_s$. Hence $B_t \subsetneq B_s$, in contradiction to (T, B) being small.) We may assume that $t = B_t$ for every $t \in T$. Now we can extend T to a tree T' with $V(T') = E(H)$ and such that each $e \in E(H) \setminus V(T)$ is attached to some $t \in T$ with $e \in t = B_t$. $\square$

3. The hypergraph sandwich problem. In this section, all graphs and hypergraphs are finite. We relate generalized hypertree-width of hypergraph pairs to the HSP.

For an integer $k \geq 0$ the problem k -GHW is defined as follows: Given a finite hypergraph H , decide whether $\text{ghw}(H) \leq k$. In [9], Gottlob, Miklós, and Schwentick proved that k -GHW is NP-complete. In [7] it was shown that k -HW, the correspond-

ing problem of deciding whether $\text{hw}(H) \leq k$, is in P (for fixed k). Hence, by Lemma 4, 1-GHW is in P.

Let $k\text{-GHW}^{\text{pair}}$ ($k\text{-HW}^{\text{pair}}$) be the extension of $k\text{-GHW}$ ($k\text{-HW}$) to hypergraph pairs: Given a finite hypergraph pair (G, H) , decide whether $\text{ghw}(G, H) \leq k$ ($\text{hw}(G, H) \leq k$). For fixed k , the problem $k\text{-HW}^{\text{pair}}$ is also solvable in polynomial time: The proof of $k\text{-HW} \in \text{P}$ from [7] generalizes to hypergraph pairs. We will give a different proof in the next section (Corollary 16). Both algorithms can easily be modified in such a way that if $\text{hw}(G, H) \leq k$, then they return a hypertree decomposition of width at most k .

For a hypergraph H and $k \in \mathbb{N}$, we define the hypergraph

$$H^{\leq k} = (V(H), \{e_1 \cup \dots \cup e_i \mid i \leq k, e_j \in E(H) \text{ for all } j = 1, \dots, i\}).$$

Note that for fixed k and input H , we can compute $H^{\leq k}$ in polynomial time.

LEMMA 5. *Let (G, H) be a hypergraph pair. Then:*

- (i) $\text{ghw}(G, H) \leq k$ if and only if $\text{ghw}(G, H^{\leq k}) \leq 1$.
- (ii) $\text{hw}(G, H) \leq k$ if and only if $\text{hw}(G, H^{\leq k}) \leq 1$.

Proof. Let (T, B, C) be a (generalized) hypertree decomposition of width $\leq k$ for (G, H) . For every $t \in V(T)$ replace the hyperedges in C_t by their union. Conversely, if (T, B, C) is a (generalized) hypertree decomposition of width ≤ 1 for $(G, H^{\leq k})$, replace each edge $e_1 \cup \dots \cup e_i$, in C_t by the edges $e_1, \dots, e_i$ ($i \leq k$). $\square$

Let (G, H) be a hypergraph pair. We write $G \leq H$, if for every hyperedge $e_1 \in E(G)$ there exists a hyperedge $e_2 \in E(H)$ such that $e_1 \subseteq e_2$. For example, $\underline{H} \leq H$ for every hypergraph H .

The *hypergraph sandwich problem* is the following problem [13]: Given a hypergraph pair (G, H) , decide whether an acyclic hypergraph A exists such that $G \leq A \leq H$. (So, A is “sandwiched” between G and H .) Clearly, the HSP is in NP. It was proved in [9] that it is actually NP-complete.

LEMMA 6. *Let (G, H) be a hypergraph pair. The following are equivalent:*

- (i) *There is an acyclic hypergraph A such that $G \leq A \leq H$.*
- (ii) $\text{ghw}(G, H) \leq 1$.

Proof. Let A be acyclic with $G \leq A \leq H$. By the obvious part of Lemma 4 (which holds even in the infinite case), A has a generalized hypertree decomposition (T, B, C) of width ≤ 1 . For every $t \in V(T)$ we set $C'_t := \{e'\}$, where $C_t = \{e\}$ and $e \subseteq e' \in E(H)$. Thus we obtain a generalized hypertree decomposition (T, B, C') of (G, H) of width ≤ 1 .

Conversely, let (T, B, C) be a generalized hypertree decomposition of (G, H) of width ≤ 1 . We may assume that $B_t \neq \emptyset$ for all $t \in V(T)$. Define a hypergraph A with $V(A) = V(G)$ and $E(A) = \{B_t \mid t \in V(T)\}$. It is easy to see that A is acyclic. Since every edge $e \in E(G)$ is covered by some B_t we have $G \leq A$. On the other hand, by condition 2 of the definition of a hypertree decomposition of (G, H) , all $t \in V(T)$ satisfy $B_t \subseteq \bigcup C_t = e'$ for some $e' \in E(H)$. Hence $A \leq H$. $\square$

Gottlob, Scarcello, and Leone pinpointed in [8] that there is a polynomial time reduction from $k\text{-GHW}$ to the HSP. We actually have the following theorem.

THEOREM 7. *The following problems are NP-complete:*

- (i) HSP,
- (ii) $1\text{-GHW}^{\text{pair}}$, and
- (iii) $k\text{-GHW}^{\text{pair}}$.

Proof. (i) is proved in [9]. By Lemma 6, (i) and (ii) are polynomial time equivalent. (ii) and (iii) are also polynomial time equivalent: (ii) $\Rightarrow$ (iii) is easy with Lemma 5. $\square$

Instead of solving the HSP with input (G, H) , or, equivalently, $1\text{-GHW}^{\text{pair}}$, we can solve $1\text{-HW}^{\text{pair}}$ with input (G, H) in polynomial time. If $\text{hw}(G, H) \leq 1$, then we get a hypertree decomposition for (G, H) of width at most 1. As in Lemma 6, the hypertree decomposition gives rise to a solution for the HSP. Thus the HSP is solvable in polynomial time for inputs (G, H) satisfying $\text{ghw}(G, H) \leq 1$ if and only if $\text{hw}(G, H) \leq 1$.

Unfortunately, if $\text{hw}(G, H) > 1$, we know nothing about the HSP: By [2, Theorem 3.3.18], for each positive integer k there is a hypergraph pair (G_k, H_k) with $\text{ghw}(G_k, H_k) = 1$ and $\text{hw}(G_k, H_k) = k$.

4. Game theoretic characterizations. This section contains a generalization of the robber and marshals game of [8] to (possibly infinite) hypergraph pairs. The main result of this section (Theorem 9) is that even for infinite hypergraph pairs (G, H) , the minimum number of marshals necessary to catch the robber on (G, H) equals $\text{hw}(G, H)$. This generalizes both the game theoretic characterization of tree-width [14] and the game theoretic characterization of hypertree-width [8].

4.1. Games. Let (G, H) be a hypergraph pair, and let $k \geq 0$ be an integer. The *monotone robber and marshals game on (G, H)* , $\text{mon-mars}((G, H), k)$, is played by two players: The *marshal player* plays k marshals on H , and the *robber player* plays the robber on G . A *position* of $\text{mon-mars}((G, H), k)$ is a pair (X, r) , where $X \in \mathcal{P}_{\leq k}(E(H))$ and $r \in V(G) \setminus \bigcup X$. At the beginning of the game, the marshal player chooses an $X \in \mathcal{P}_{\leq k}(E(H))$. The robber player responds by choosing an $r \in V(G) \setminus \bigcup X$. In each step of the game, say in position (X, r) , the marshal player chooses a set $Y \in \mathcal{P}_{\leq k}(E(H))$. Then the robber player chooses an $r' \in V(G) \setminus \bigcup Y$ that is connected to r by a path in $G \setminus (\bigcup X \cap \bigcup Y)$.

Let (X, u) and (X, v) be game positions with $u \in R$ and $v \in R$, where R is a connected component of $G \setminus \bigcup X$. Now suppose the marshals choose the new position Y . Let (Y, r) be a position which the robber can reach from (X, u) . Then he can reach (Y, r) from (X, v) as well (and vice versa). For this reason a game position will be represented by (X, R) instead of (X, u) , and we define the following.

For $W \subseteq V(G)$ a connected component $R \subseteq V(G)$ of $G \setminus W$ is called an *escape space (with respect to W)*. For $R \subseteq V(G)$ we call

$$\mathcal{R}(W'; W, R) = \{R' \mid R' \text{ is an escape space w.r.t. } W' \text{ and there is a path from } R \text{ to } R' \text{ in } G \setminus (W \cap W')\}$$

the *set of possible escape spaces w.r.t. W'* .

With these definitions, suppose the game is at position (X, R) and the marshals choose a set $Y \in \mathcal{P}_{\leq k}(E(H))$. Then $\mathcal{R}(\bigcup Y; \bigcup X, R)$ is the set of escape spaces w.r.t. $\bigcup Y$ that can be reached by the robber.

Suppose the game is at position (X, R) , where R is an escape space in G w.r.t. $\bigcup X$. The marshal player makes a *monotone move*, if she chooses a set $Y \in \mathcal{P}_{\leq k}(E(H))$ such that each $R' \in \mathcal{R}(\bigcup Y; \bigcup X, R)$ satisfies $R' \subsetneq R$.

A *game* is a sequence of moves of the marshal player and the robber player moving alternately. The marshal player is only allowed to make monotone moves. If there is a step in which the marshal player cannot make a monotone move, then the robber player wins.

The marshal player wins if she can make sure that for every $v \in V(G)$ there is a move in the game such that after this move the robber can never visit v again. Note that this includes the case that the robber cannot move at all.

In the case that (G, H) is finite, we can equivalently define that the marshal player wins, if at some point of the game the robber player cannot move any more. Otherwise, the robber player wins. The marshal player has a *winning strategy* if she can win every possible game.

Let (G, H) be a hypergraph pair. A *marshal strategy* in $\text{mon-mars}((G, H), k)$ is a triple (T, σ, ρ) satisfying:

- (a) T is a directed tree.
- (b) $\sigma : V(T) \rightarrow \mathcal{P}_{\leq k}(E(H))$.
- (c) $\rho : V(T) \rightarrow \mathcal{P}(V(G))$.
- (d) The root r of T satisfies $\rho_r = V(G)$. Every node s of T which is not the root satisfies $\rho_s \in \mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}}, \rho_t)$, where $t = \text{pred}(s)$ and $\text{pred}(s)$ denotes the unique predecessor of s in T .

Here we have made use of the abbreviation

$$\sigma_t^{\text{pred}} = \begin{cases} \emptyset & \text{if } t \text{ is the root of } T, \\ \sigma_{\text{pred}(t)} & \text{otherwise.} \end{cases}$$

- (e) For each $t \in V(T)$ and each $R \in \mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}}, \rho_t)$ there is exactly one successor $s \in V(T)$ with $\rho_s = R$.

- (f) (T, σ, ρ) is *monotone*, i.e. for all $t \in V(T) \setminus \{r\}$ the condition $\rho_t \subsetneq \rho_{\text{pred}(t)}$ holds.

A *branch* D of T is the vertex set $D \subseteq V(T)$ of a maximal path in T that begins with the root. (T, σ, ρ) is a *winning strategy* for $\text{mon-mars}((G, H), k)$, if all infinite branches D of T satisfy $\bigcap_{t \in D} \rho_t = \emptyset$. In the case that (G, H) is finite, this condition is always satisfied.

Let (G, H) be a hypergraph pair. The *monotone marshal-width* of (G, H) is

$$\text{mon-mw}(G, H) := \min \{k \mid \text{the marshals have a winning strategy in } \text{mon-mars}((G, H), k)\} \in \mathbb{N} \cup \{\infty\}.$$

Figure 4.1 shows a monotone winning strategy for two marshals and a nonmonotone winning strategy for one marshal on the hypergraph pair (G, H) of Figure 2.1. The nodes of a strategy tree are the marshals' moves and the edges are labeled by the corresponding robber's escape spaces.

The strategy on the right-hand side is not monotone: after the marshals' first move, the vertex 1 is no longer in the robber's escape space. If the robber now moves to the vertex 2, the marshals move to $\{2, 3\}$ and the robber can reach 1 again.

FIG. 4.1. A monotone winning strategy for two marshals and a nonmonotone winning strategy for one marshal on the hypergraph pair (G, H) of Figure 2.1.

For the monotone robber and cops game as defined⁴ in [14] we set

$$\text{mon-cw}(H) := \min\{k \in \mathbb{N} \mid k \text{ cops can win the monotone} \\ \text{robber and cops game played on } H\} \in \mathbb{N} \cup \{\infty\}.$$

For the monotone robber and marshals game as defined in [8] we set

$$\text{mon-mw}(H) := \min\{k \mid k \text{ marshals can win the monotone} \\ \text{robber and marshals game played on } H\} \in \mathbb{N} \cup \{\infty\}.$$

It is easy to see that the monotone robber and cops game and the monotone robber and marshals game on hypergraphs are special cases of the monotone robber and marshals game played on a hypergraph pair (G, H) :

REMARK 8. (a) Let (G, H) be a hypergraph pair where $E(H) = \{\{v\} \mid v \in V(G)\}$. Then $\text{mon-mars}((G, H), k)$ is the monotone robber and cops game played on G , and $\text{mon-mw}(G, H) = \text{mon-cw}(G)$.

(b) Let H be a connected hypergraph. Then $\text{mon-mars}((H, H), k)$ is the monotone robber and marshals Game played on H , and $\text{mon-mw}(H, H) = \text{mon-mw}(H)$.

4.2. Equivalence of decompositions and strategies. In this section we will prove the following theorem.

THEOREM 9. Let (G, H) be a hypergraph pair, and let $k \geq 0$ be an integer. Then $\text{hw}(G, H) \leq k$ if and only if there is a winning strategy⁵ for $\text{mon-mars}((G, H), k)$.

Together with Remarks 8 and 2 this implies the following corollary.

COROLLARY 10. Let H be a hypergraph, and let $k \geq 0$ be an integer.

(a) (see Seymour and Thomas [14]) $\text{tw}(H) + 1 \leq k$ if and only if k cops can win the monotone robber and cops game on H .

(b) (see Gottlob, Scarcello and Leone [8]) $\text{hw}(H) \leq k$ if and only if k marshals can win the monotone robber and marshals game on H .

To prove the “if” part of Theorem 9, we make use of the following lemma.

LEMMA 11. Let (T, σ, ρ) be a winning strategy for $\text{mon-mars}((G, H), k)$.

(i) For every $v \in V(G)$ there is one and only one $t_v \in V(T)$ with

$$v \in \bigcup \sigma_{t_v} \cap \rho_{t_v}.$$

(ii) For every $e \in E(G)$ there is a node $t_e \in V(T)$ with

$$e \subseteq \bigcup \sigma_{t_e} \text{ and } e \cap \rho_{t_e} \neq \emptyset.$$

Proof. The proof is left to the reader. $\square$

Proof of the “if” part of Theorem 9. Let (T, σ, ρ) be a winning strategy for $\text{mon-mars}((G, H), k)$.

Set $C := \sigma$, and define B_t^{pred} and B_t inductively as follows:

$$B_t^{\text{pred}} := \begin{cases} \emptyset & \text{if } t \text{ is the root of } T, \\ B_{\text{pred}(t)} & \text{otherwise,} \end{cases}$$

$$B_t := \bigcup \sigma_t \cap (B_t^{\text{pred}} \cup \rho_t) \text{ for } t \in V(T).$$

⁴Note that while the monotone robber and cops game in [14] is only defined in the case that H is a graph, that definition can be translated literally from graphs to hypergraphs by replacing the word “graph” by “hypergraph” and “edge” by “hyperedge.” This does not really add any generality, since the robber and cops game on a hypergraph is essentially the same as the game on its underlying graph.

⁵Note that the winning strategy is monotone by definition.

We now show that (T, B, C) is a hypertree decomposition of (G, H) of width $\leq k$: Since $|C_t| = |\sigma_t|$ for all $t \in V(T)$, it is sufficient to prove that (T, B, C) satisfies the three conditions from the definition of a hypertree decomposition of (G, H) .

Condition 1. (T, B) is a tree-decomposition of G : We first show that every hyperedge $e \in E(H)$ is covered by some B_t . Choose $t = t_e$ for e according to Lemma 11 (ii). Then $e \subseteq B_{t_e} = \bigcup \sigma_{t_e} \cap (B_{t_e}^{\text{pred}} \cup \rho_{t_e})$: By the choice of t_e , $e \subseteq \bigcup \sigma_{t_e}$. Hence it remains to show that $e \subseteq B_{t_e}^{\text{pred}} \cup \rho_{t_e}$, or, equivalently, $e \setminus \rho_{t_e} \subseteq B_{t_e}^{\text{pred}}$. For showing this, choose for $v \in e \setminus \rho_{t_e}$ a node t_v according to Lemma 11 (i). Then $v \in B_{t_v}$ and t_v lies on the path from the root of T to t_e . For all $s \neq t_v$ on the path from t_v to t_e , v is a neighbor of $\rho_{t_e} \subseteq \rho_s$ and hence v is a neighbor of ρ_s . Therefore $v \in \bigcup \sigma_s$ for all $s \neq t_e$ on the path from t_v to t_e . Hence $v \in B_s$ for all $s \neq t_e$ on the path from t_v to t_e , in particular $v \in B_{t_e}^{\text{pred}}$.

Suppose for $v \in V(G)$ the set $Z = \{t \in V(T) \mid v \in B_t\}$ is not connected. Then Z has (at least) two connected components Z_1 and Z_2 . Let z_1 be the vertex from Z_1 with the shortest path from the root r to z_1 . Likewise, choose $z_2 \in Z_2$ with the shortest path from r to z_2 . Then $z_1 \neq z_2$ and both vertices satisfy Lemma 11 (i), a contradiction to uniqueness.

Condition 2. $B_t \subseteq \bigcup \sigma_t = \bigcup C_t$.

Condition 3. Claim: $B_{T_t} \subseteq B_t^{\text{pred}} \cup \rho_t$.

The claim implies condition 3: $\bigcup C_t \cap B_{T_t} = \bigcup \sigma_t \cap B_{T_t} \subseteq \bigcup \sigma_t \cap (B_t^{\text{pred}} \cup \rho_t) = B_t$.

Proof of the claim. Assuming that $v \in B_{T_t} \setminus (B_t^{\text{pred}} \cup \rho_t)$ exists, choose $s \in V(T)$ for v satisfying $v \in \bigcup \sigma_s \cap \rho_s \subseteq B_s$ as in Lemma 11 (i). Since $v \notin B_t^{\text{pred}}$, the connectedness condition of a tree-decomposition implies $s \in V(T_t)$. The monotonicity of the strategy implies $\rho_s \subseteq \rho_t$, hence $v \in \rho_t$. This is contrary to the choice of v . $\square$

To prove the “only if” part, we construct a winning strategy for k marshals from a hypertree decomposition of width $\leq k$ of (G, H) . For this purpose we introduce *weak strategies*. Let (T, σ, ρ) satisfy all the axioms of a strategy except for (f), and let r be the root of T . Then (T, σ, ρ) is called a *weak strategy* if every $t \in V(T) \setminus \{r\}$ satisfies $\rho_t \subseteq \rho_{\text{pred}(t)}$. *Weak winning strategies* are defined analogously to winning strategies, i.e. a weak strategy (T, σ, ρ) is a *weak winning strategy* for $\text{mon-mars}((G, H), k)$, if all infinite branches D of T satisfy $\bigcap_{t \in D} \rho_t = \emptyset$.

Clearly, every winning strategy is a weak winning strategy. Conversely we have the following lemma.

LEMMA 12. *Every weak winning strategy for $\text{mon-mars}((G, H), k)$ gives rise to a winning strategy.*

Proof. Intuitively, we modify a weak winning strategy by skipping all moves that do not change the robber’s escape space, thus obtaining a winning strategy. Let (T, σ, ρ) be a weak winning strategy for $\leq k$ marshals. Define a function $g : V(T) \rightarrow V(T)$ as follows: Set $g(t) = t$ if all children s of t satisfy $\rho_s \neq \rho_t$. Otherwise, t has exactly one child s and we set $g(t) = s$. Then for all $t \in V(T)$ there is an integer $n \geq 0$ such that $g^n(t) = g^{n+1}(t)$. (Otherwise, $\{g^n(t) \mid n \geq 0\}$ is an end piece of an infinite branch D of T and hence $\bigcap_{s \in D} \rho_s = \rho_t \neq \emptyset$, a contradiction to (T, σ, ρ) being a weak winning strategy.) Define $f : V(T) \rightarrow V(T)$ by setting $f(t) =$ the eventual value $g^n(t)$, for big n .

Now define (T', σ', ρ') by setting

- $V(T') := \{f(t) \mid t \in V(T)\}$,
- $E(T') = \{\{f(s), f(t)\} \mid \{s, t\} \in E(T) \text{ and } f(s) \neq f(t)\}$,
- $\sigma' = \sigma \upharpoonright V(T')$, and $\rho' = \rho \upharpoonright V(T')$.

(T', σ', ρ') is a winning strategy for $\text{mon-mars}((G, H), k)$:

T' is the result of contracting connected subsets of T , so T' is again a directed tree. Hence, T' satisfies the conditions (a), (b), and (c) of a marshal strategy.

The root r' of T' satisfies $\rho_{r'} = \rho_r = V(G)$. Let $s \in V(T')$, $s \neq r'$. We have to show that $\rho_s \in \mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}'}, \rho_t)$, where $t = \text{pred}'(s)$ is the predecessor of s in T' . For $t \in V(T)$ define $f'(t) := t'$, where $t' \in V(T)$ is the node nearest to the root of T such that $f(t) = f(t')$.

1. ρ_s is an escape space w.r.t. $\bigcup \sigma_t$, since $\rho_{f'(s)}$ is an escape space w.r.t. $\bigcup \sigma_t$ and $\rho_s = \rho_{f'(s)}$.

2. There is a path from ρ_t to ρ_s in $G \setminus (\bigcup \sigma_t^{\text{pred}'} \cap \bigcup \sigma_t)$, since $\rho_s \neq \emptyset$, $\rho_s \subseteq \rho_t$ and $\rho_s \subseteq V(G) \setminus \bigcup \sigma_t$.

Together, 1 and 2 show that (d) holds.

For (e) we have to show that $\mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}'}, \rho_t) = \mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}}, \rho_t)$.

For an escape space R w.r.t. X , define

$$\partial R := \{v \in X \mid v \text{ is a neighbor of some } u \in R\}.$$

Since (T, σ, ρ) is weakly monotone, $\partial R \subseteq \bigcup \sigma_p$ for all $p \in V(T)$ with $f(p) = t$. Therefore, $\partial R \subseteq \bigcup \sigma_t \cap \bigcup \sigma_t^{\text{pred}'} \cap \sigma_t^{\text{pred}}$. Thus during the flight from $\sigma_t^{\text{pred}'}$ to σ_t , as well as during the flight from σ_t^{pred} to σ_t , the robber can only move within $\rho_t = \rho_t'$. Hence $\mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}'}, \rho_t) = \mathcal{R}(\bigcup \sigma_t; \bigcup \sigma_t^{\text{pred}}, \rho_t)$.

(f) holds by construction. Moreover, (T', σ', ρ') is a winning strategy since (T, σ, ρ) is a weak winning strategy. $\square$

Thus, it is sufficient to construct a weak winning strategy for k marshals from a hypertree decomposition of width k . Let (T, B, C) be a width k hypertree decomposition of (G, H) . The edge labels yield the positions of the marshals: The marshals move to C_r , where r is the root of T . The robber chooses an escape space R . R satisfies $R \subseteq B_{T_t}$ for exactly one successor t of r . Then the marshals fly to C_t . During the flight, the robber cannot leave R .

Towards a formalization of this intuition, let (T, B) be a tree-decomposition of the hypergraph G , $t \in V(T)$. The *tree component* of t is defined as follows:

$$\beta_t := B_{T_t} \setminus B_t^{\text{pred}}.$$

LEMMA 13. *Let (T, B) be a tree-decomposition of a hypergraph G . Then*

- (i) $\beta_t \subseteq \beta_{\text{pred}(t)}$, if $t \in V(T)$ is not the root of T .
- (ii) Any infinite branch D of T satisfies $\bigcap_{t \in D} \beta_t = \emptyset$.

Proof. (i):

$$\begin{aligned} \beta_t \setminus \beta_{\text{pred}(t)} &= [B_{T_t} \setminus B_t^{\text{pred}}] \setminus [B_{T_{\text{pred}(t)}} \setminus B_{\text{pred}(t)}^{\text{pred}}] \\ &= (B_{T_t} \setminus [B_{T_{\text{pred}(t)}} \setminus B_{\text{pred}(t)}^{\text{pred}}]) \setminus B_t^{\text{pred}} \\ &= ([B_{T_t} \setminus B_{T_{\text{pred}(t)}}] \cup [B_{T_t} \cap B_{\text{pred}(t)}^{\text{pred}}]) \setminus B_t^{\text{pred}} \\ &= [B_{T_t} \cap B_{\text{pred}(t)}^{\text{pred}}] \setminus B_t^{\text{pred}} \\ &= \emptyset, \end{aligned}$$

where the last equation holds by connectedness.

(ii): Suppose $v \in \bigcap_{t \in D} \beta_t = \bigcap_{t \in D} [B_{T_t} \setminus B_t^{\text{pred}}] = \bigcap_{t \in D} B_{T_t} \setminus \bigcup_{t \in D} B_t^{\text{pred}}$. Then all $t \in D$ satisfy $v \notin B_t^{\text{pred}}$. Since D is infinite, this implies that all $t \in D$ satisfy

$v \notin B_t$. Since $v \in V(G)$, there is an $s \in V(T)$ such that $v \in B_s$. Let $t \in V(T)$ be the last vertex of D on the path from the root of T to s . Let t' be the successor of t in D . By assumption, we have $v \in B_{T_{t'}}$. Connectedness implies that $v \in B_t$ a contradiction. $\square$

LEMMA 14. *Let (T, B) be a tree-decomposition of G , and $t \in V(T)$. Let $R \in \mathcal{R}(B_t; B_t^{\text{pred}}, \beta_t)$. Then $R \subseteq \beta_s$ for a successor s of t .*

Proof. Let $v \in R$. Let W be a path in $G \setminus (B_t \cap B_t^{\text{pred}})$ that connects a vertex $u \in \beta_t$ to v . Every edge of W is covered by a node from T_t or from $T \setminus T_t$. But no edge of W can be covered by a node from $T \setminus T_t$, because otherwise a vertex $r \in W$ would be covered by T_t and $T \setminus T_t$, implying $r \in B_t \cap B_t^{\text{pred}}$, a contradiction. Therefore every vertex of W is covered by a node from T_t , and in particular we have $v \in B_{T_t}$. Thus $v \in B_{T_t} \setminus B_t$, showing that $v \in B_{T_s}$ for a successor s of t and hence $v \in \beta_s$. Equally, a neighbor v' of v satisfies $v' \in \beta_{s'}$ for a successor s' of t . Since $v, v' \notin B_t$ and since $\{v, v'\}$ must be covered by some node of T , connectedness implies that $s = s'$. $\square$

The following lemma proves the “only if” part of Theorem 9.

LEMMA 15. *Let (T, B, C) be a hypertree decomposition of (G, H) of width $\leq k$. Then there is a weak winning strategy (T', σ, ρ) of $\text{mon-mars}((G, H), k)$ and a function $f : V(T') \rightarrow V(T)$ such that*

- $f(r') = r$ for the roots r of T and r' of T' ,
- $f(\text{pred}(t')) = \text{pred}(f(t'))$ for all $t' \in V(T') \setminus \{r'\}$,
- $\sigma_{t'} = C_{f(t')}$ for all $t' \in V(T')$,
- $\rho_{t'} \subseteq \beta_{f(t')}$ for all $t' \in V(T')$.

Proof. We define (T', σ, ρ) and f by an informal induction, starting with the root r' of T' . (The function f keeps the induction going.)

We start by choosing a root r' for T' and setting $f(r') := r$, $\sigma_{r'} := C_r$ and $\rho_{r'} := V(G) = \beta_r$.

For each $t' \in V(T')$ we need to make sure that for every $R' \in \mathcal{R}(\bigcup \sigma_{t'}; \bigcup \sigma_{t'}^{\text{pred}}, \rho_{t'})$ there is exactly one successor s' of t' such that $\rho_{t'} = R'$.

Claim 1. There is a successor s of $f(t')$ such that $R' \subseteq \beta_s$.

Proof of Claim 1. Let $t' = \text{pred}(s')$ and $t = f(t')$. $B_t \subseteq \bigcup C_t = \bigcup \sigma_{t'}$ and therefore $R' \subseteq R$ for some connected component R of $G \setminus B_t$. Since $B_t^{\text{pred}} \subseteq \bigcup C_t^{\text{pred}} = \bigcup \sigma_{t'}^{\text{pred}}$ and $\rho_{t'} \subseteq \beta_t$, we have $R \in \mathcal{R}(B_t; B_t^{\text{pred}}, \beta_t)$. By Lemma 14 there is a successor s of t such that $R \subseteq \beta_s$. Therefore $R' \subseteq \beta_s$. Set $f(s') := s$, $\sigma_{s'} := C_s$ and $\rho_{s'} := R'$.

Claim 2. $\rho_{s'} \subseteq \rho_{t'}$.

Proof of Claim 2. Otherwise, there is a $v \in \rho_{s'} \setminus \rho_{t'}$. Let v_0 be the first vertex on a path from $\rho_{t'}$ to v in $G \setminus (\bigcup \sigma_{t'}^{\text{pred}} \cap \bigcup \sigma_{t'})$ such that $v_0 \notin \rho_{t'}$. $v_0 \notin \rho_{t'}$ implies $v_0 \in \bigcup \sigma_{t'}^{\text{pred}}$, and hence $v_0 \notin \bigcup \sigma_{t'}$. Therefore $v_0 \in \bigcup \mathcal{R}(\bigcup \sigma_{t'}; \bigcup \sigma_{t'}^{\text{pred}}, \rho_{t'}) \subseteq \bigcup \mathcal{R}(\bigcup B_t; \bigcup B_t^{\text{pred}}, \beta_t)$. Choose a successor $\hat{s}$ of t according to Lemma 14 such that $v_0 \in \beta_{\hat{s}}$. Since $v_0 \in \bigcup \sigma_{t'}^{\text{pred}} = \bigcup C_t^{\text{pred}}$ and $v_0 \in \beta_{\hat{s}} = B_{T_{\hat{s}}} \setminus B_t \subseteq B_{T_{\text{pred}(t)}}$, condition 3 of a hypertree decomposition implies that $v_0 \in B_t^{\text{pred}}$. But from this it follows that $v_0 \notin B_{T_t} \setminus B_t^{\text{pred}} = \beta_t$, hence $v_0 \in \beta_{\hat{s}} \setminus \beta_t$, a contradiction to Lemma 13 (i).

Since $\rho_{t'} \subseteq \beta_{f(t')}$ for all $t' \in V(T')$, Lemma 13 (ii) shows that all infinite branches D of T' satisfy $\bigcap_{t \in D} \rho_t = \emptyset$ and the proof is completed. $\square$

As an application, we sketch a proof of $k\text{-HW}^{\text{pair}} \in \text{P}$, which uses the game theoretic characterization.

COROLLARY 16. *For every fixed integer $k \geq 0$, the problem $k\text{-HW}^{\text{pair}}$ is solvable in polynomial time.*

Proof. Given a finite hypergraph pair (G, H) , the algorithm has to decide whether

$\text{hw}(G, H) \leq k$ holds. By game theoretic characterization (Theorem 9) this is equivalent to deciding whether $\text{mon-mw}(G, H) \leq k$ holds. There is a straightforward dynamic programming algorithm that decides whether k marshals have a winning strategy.

List all pairs (X, r) with $X \subseteq E(H)$, $|X| \leq k$ and $r \in V(G)$. Since k is fixed, this is possible in polynomial time. Then mark all pairs (X, r) with $r \in \bigcup X$ as *winning positions*. Given the list of all pairs, some of which are marked as winning positions, we mark a pair (X', r') as a winning position if there is a set $X \subseteq E(H)$ satisfying:

- The connected component R' of $G \setminus \bigcup X'$ containing r' is the component of $G \setminus ((\bigcup X') \cap (\bigcup X))$ that contains r' (monotonicity).
- For all vertices $r \in V(G)$ that are connected to r' in $G \setminus ((\bigcup X') \cap (\bigcup X))$, the pair (X, r) is marked as a winning position.

This can be done in polynomial time. Since the strategy must be monotone, after $|V(G)|$ iterations we can check whether all initial positions $(\emptyset, r)$ with $r \in V(G)$ are marked as winning positions. If this is the case, then k marshals have a monotone winning strategy the algorithm returns $\text{hw}(G, H) \leq k$. Otherwise it returns $\text{hw}(G, H) > k$. $\square$

5. Compactness of generalized hypertree-width.

5.1. A compactness theorem. Let (G, H) be a hypergraph pair. For a finite set $X_0 \subseteq V(G)$, we call

$$c_H(X_0) := \min \{ |Y| \mid Y \subseteq E(H), X_0 \subseteq \bigcup Y \}$$

the *cover number* of X_0 . A hypergraph H has *finite character*, if for all infinite $X \subseteq V(H)$ and for all integers $k \geq 0$ there is a finite subset $X_0 \subseteq X$ with $c_H(X_0) > k$. A hypergraph pair (G, H) has finite character, if H has finite character. We call a hypergraph *bounded* if there is a $\kappa \in \mathbb{N}$ such that for all $e \in E(H)$: $|e| \leq \kappa$. Obviously, if H is bounded, then (G, H) has finite character. An edge which joins two vertices of a cycle but is not itself an edge of the cycle is called a *chord*. A graph is *chordal* if every cycle of length ≥ 4 has a chord. G' is a *triangulation of G* if G' is chordal, then $V(G) = V(G')$ and $E(G) \subseteq E(G')$.

Our aim is to prove the following theorem.

THEOREM 17. *Let (G, H) be a hypergraph pair with finite character. Then*

$$\text{ghw}(G, H) \leq k$$

if and only if

$$\text{ghw}(G_0, H_0) \leq k \text{ for all finite induced subhypergraph pairs } (G_0, H_0) \text{ of } (G, H).$$

This implies the following corollary.

COROLLARY 18. *A hypergraph H with finite character satisfies*

$$\text{ghw}(H) \leq k$$

if and only if

$$\text{ghw}(H_0) \leq k \text{ for all finite induced subhypergraphs } H_0 \text{ of } H.$$

For the proof of Theorem 17 we use the following theorem.

THEOREM 19. *Let G be a graph containing no infinite clique. Then G is chordal if and only if G admits a tree-decomposition into complete pieces (i.e., for all $t \in V(T)$, B_t induces a clique in G).*

Theorem 19 can be derived from Halin's theory of simplicial decompositions, which will be done in section 5.2.⁶

LEMMA 20. *Let G be a finite graph. G is chordal if and only if G has a tree-decomposition (T, B) into complete pieces.*

A proof is given in [4, Proposition 12.3.11].

Proof of Theorem 17. For the “only if” part, restrict a generalized hypertree decomposition of (G, H) to (G_0, H_0) .

Proof of the “if” part:⁷ We may assume that G is a graph. Let $\text{ghw}(G_0, H_0) \leq k$ for all finite induced subhypergraph pairs (G_0, H_0) of (G, H) .

Claim 1. Every finite subgraph G_0 of G has a triangulation G'_0 such that every complete subgraph C of G'_0 satisfies $c_{H_0}(V(C)) \leq k$.

Proof of the claim. Let (T, B, C) be a generalized hypertree decomposition of (G_0, H_0) of width $\leq k$. We obtain G'_0 by setting $V(G'_0) := V(G_0)$ and

$$E(G'_0) := \{\{u, v\} \subseteq V(G_0) \mid \text{there is a } t \in V(T) \text{ such that } \{u, v\} \subseteq B_t\}.$$

By Lemma 20, G'_0 is chordal, and Remark 1 shows that every complete subgraph of G'_0 is covered by at most k hyperedges of H_0 .

Claim 2. G has a triangulation G' such that every complete subgraph C of G' satisfies $c_H(V(C)) \leq k$.

Proof of the claim. We use Zorn's lemma. For a hypergraph pair (G, H) let I be the set of all supergraphs G' of G with $V(G') = V(G)$ satisfying:

(*) Every finite subgraph G_0 of G' has a triangulation G'_0 s.t. every complete subgraph C of G'_0 satisfies $c_H(V(C)) \leq k$.

I is ordered inductively by inclusion: For a transfinite sequence $(G_\alpha)_{\alpha < \delta}$ in I with $G_\alpha \subseteq G_\beta$ for all $\alpha \leq \beta$, $\bigcup_{\alpha < \delta} G_\alpha$ satisfies (*), since a finite subgraph G_0 of $\bigcup_{\alpha < \delta} G_\alpha$ is already contained in some G_α .

Let $G' \in I$ be a maximal element. The following two claims finish the proof:

Claim (i). Let C be a clique in G' . Then $c_H(V(C)) \leq k$.

Claim (ii). G' is chordal.

(i) If C is finite, this is true since C is contained in some G_α . C cannot be infinite since (G, H) has finite character, and hence there would be a finite $C_0 \subseteq C$ with $c_H(V(C_0)) > k$, a contradiction.

(ii) Suppose $O = v_1, \dots, v_m, v_m = v_1$ is an induced cycle of length at least four in G' . By maximality of G' , we cannot add a chord $\{v_i, v_j\}$ to O without producing a finite subgraph $G_{ij} \subseteq G'$ that does not satisfy (*). But $G'[V(O) \cup \bigcup_{ij} V(G_{ij})]$ is a finite subgraph of G' and hence is contained in some G_α . A contradiction to (*).

If G' contains no infinite clique, we apply Theorem 19, obtaining a tree-decomposition (T, B) of G' into complete pieces. We extend (T, B) to a generalized hypertree decomposition (T, B, C) of (G', H) by choosing for each $t \in V(T)$ a cover $C_t \subseteq E(H)$ of B_t with $|C_t| \leq k$. Then (T, B, C) is a generalized hypertree decomposition of width $\leq k$ of (G, H) as well.

Let C be an infinite clique in G' . It suffices to show that in this case the generalized hypertree-width of the finite induced subhypergraph pairs of (H, G) is unbounded. By the finite character of (G, H) there is a finite subset $X_k \subseteq V(C)$ for each k , such that

⁶A slightly weaker version of Theorem 19 is proved in [12].

⁷Here we adapt Thomassen's elegant proof of compactness of tree-width of graphs, cf. [16].

$c_H(X_k) > k$. Remark 1 shows that each X_k induces a finite subhypergraph pair (H_k, G_k) of (H, G) with $\text{ghw}(G_k, H_k) > k$. $\square$

Now we give an example showing that generalized hypertree-width is not compact for hypergraphs without finite character.

LEMMA 21. $H = (\aleph_1, \mathcal{P}_{<\omega}(\aleph_1))$ satisfies the following.

1. $\text{ghw}(H_0) \leq 1$ for all finite induced subhypergraphs H_0 of H .
2. $\text{ghw}(H) = \infty$.

Proof. 1. is obvious. For 2., suppose (T, B, C) is a generalized hypertree decomposition of $(\underline{H}, H)$ of width $\leq k$. Then

- (i) Each $t \in V(T)$ has maximum one successor s s.t. $\beta_s \neq \emptyset$.
- (ii) Such a successor s satisfies $B_t \subseteq B_s$.

Proof of (i). Otherwise, there are (at least) two successors s and s' of t with $v \in \beta_s$ and $v' \in \beta_{s'}$. By connectedness, $v \neq v'$. But the edge $\{v, v'\}$ has to be covered in some node of T , a contradiction to connectedness.

Proof of (ii). Let s be a successor of t with $u \in \beta_s$. Suppose $v \in B_t \setminus B_s$. Again, the edge $\{u, v\}$ has to be covered in some node of T , a contradiction to connectedness.

Together, (i) and (ii) show that $V(H) = \aleph_1$ can be obtained as a countable union of an increasing sequence of finite subsets of $V(H)$, a contradiction. $\square$

Note that this example also shows that hypertree-width is not compact. In section 6.2 we give an example showing that even for bounded hypergraphs, hypertree-width is not compact.

5.2. Proof of Theorem 19.

Proof of the “if” part of Theorem 19. Let (T, B) be a tree-decomposition of G into complete pieces. Let O be a cycle of length ≥ 4 in G . For each edge e of O choose $t_e \in V(T)$ covering e . Let T' be the subtree of T spanned by the nodes $\{t_e \mid e \text{ an edge of } O\}$. Since T' is finite, we can apply Lemma 20 to the subgraph of G covered by T' . Therefore O has a chord. $\square$

For a proof of the “only if” part of Theorem 19, we develop Halin’s theory a little further.

Let G be a graph, δ an ordinal, and $(G_\alpha)_{\alpha < \delta}$ a family of subgraphs of G . $(G_\alpha)_{\alpha < \delta}$ is called a *simplicial decomposition* of G , if it satisfies

1. $G = \bigcup_{\alpha < \delta} G_\alpha$.
2. $C_\beta = G_\beta \cap \bigcup_{\alpha < \beta} G_\alpha$ is a clique for every $\beta < \delta$.
3. $G_\beta \supsetneq C_\beta$ and $\bigcup_{\alpha < \beta} G_\alpha \supsetneq C_\beta$.

LEMMA 22. Let $(G_\alpha)_{\alpha < \delta}$ be a simplicial decomposition of G such that all C_β , $\beta < \delta$ are finite. Then G has a tree-decomposition (T, B) with pieces exactly the G_α .

Proof. Define (T^0, B^0) by setting $T^0 = (\emptyset, \emptyset)$. Then (T^0, B^0) is a tree-decomposition of $\bigcup_{\alpha < 0} G_\alpha$. Let (T^α, B^α) be already defined, (T^α, B^α) a tree-decomposition of $\bigcup_{\beta < \alpha} G_\beta$. Since $C_\alpha = G_\alpha \cap \bigcup_{\beta < \alpha} G_\beta$ is finite, by Remark 1 there is a $t \in V(T^\alpha)$ such that $V(C_\alpha) \subseteq B_t^\alpha$. We now join $V(G_\alpha)$ to the node t :

- Set $V(T^{\alpha+1}) := V(T^\alpha) \cup \{s\}$ for a new node $s \notin V(T^\alpha)$,
- $E(T^{\alpha+1}) := E(T^\alpha) \cup \{\{s, t\}\}$, and
- $B_t^{\alpha+1} := B_t^\alpha$ for all $t \in V(T^\alpha)$, $B_s^{\alpha+1} := V(G_\alpha)$.

It is easy to see that $(T^{\alpha+1}, B^{\alpha+1})$ is a tree-decomposition of $\bigcup_{\beta < \alpha+1} G_\beta$.

Let λ be a limit ordinal. For each $\alpha < \lambda$, let (T^α, B^α) be already defined, (T^α, B^α) a tree-decomposition of $\bigcup_{\beta < \alpha} G_\beta$. Set $T^\lambda := \bigcup_{\alpha < \lambda} T^\alpha$ and $B^\lambda := \bigcup_{\alpha < \lambda} B^\alpha$. It is easy to see that (T^λ, B^λ) is a tree-decomposition of $\bigcup_{\beta < \lambda} G_\beta$. Hence, (T^δ, B^δ) is a tree-decomposition of G . $\square$

A *prime* graph G is a connected graph $G \neq \emptyset$ containing no clique C such that $G \setminus C$ is disconnected. We say G contains no *separating* clique.

LEMMA 23. *Let P be a prime chordal graph. Then P is complete.*

Proof. Suppose not. Then there are $p_1, p_2 \in V(P)$ with $\{p_1, p_2\} \notin E(P)$. Our aim is to find a clique in P separating p_1 and p_2 , a contradiction to P being prime.

Claim (i). There exists a minimal set $S \subseteq V(P)$ separating p_1 and p_2 .

Claim (ii). A minimal set S separating p_1 and p_2 induces a clique in P .

These claims complete the proof: Since P is prime P cannot contain such an S .

Proof of (i). Let $V(P) \setminus \{p_1, p_2\} = S_0 \supseteq S_1 \supseteq S_2 \supseteq \dots$ be a maximal decreasing sequence of subsets of $V(P)$ separating p_1 and p_2 . Then $S = \bigcap_i S_i$ separates p_1 and p_2 . If not, there is a path $p_1 = v_1, v_2, \dots, v_n = p_2$ in $P \setminus S$. Hence some S_{i_0} satisfies $S_{i_0} \cap \{v_i \mid i = 1, \dots, n\} = \emptyset$. But then S_{i_0} does not separate p_1 and p_2 , a contradiction to our assumption. Therefore S is a minimal set separating p_1 and p_2 .

Proof of (ii). If not, there are $s, t \in S$ such that $\{s, t\} \notin E(P)$. Let C_1 be the connected component of $P \setminus S$ containing p_1 , and let C_2 be the connected component of $P \setminus S$ containing p_2 . Since S is minimal, both s and t have a neighbor in C_1 and a neighbor in C_2 . Let P_1 be the shortest path from s to t in $C_1 \cup \{s, t\}$ and let P_2 be the shortest path from s to t in $C_2 \cup \{s, t\}$. Then $P_1 \cup P_2$ is a cycle of length ≥ 4 without a chord, a contradiction. $\square$

Our proof of Theorem 19 is based on a theorem of Halin (cf. [11, Satz 5]), which we do not prove here.

THEOREM 24 (Halin's theory). *Any graph G containing no infinite clique has a simplicial decomposition $(G_\alpha)_{\alpha < \delta}$ into prime induced subgraphs G_α of G .*

Proof of the "only if" part of Theorem 19. Let G be a chordal graph containing no infinite clique. By Fact 24, G has a simplicial decomposition $(G_\alpha)_{\alpha < \delta}$ into prime induced subgraphs. By Lemma 22, $(G_\alpha)_{\alpha < \delta}$ yields a tree-decomposition (T, B) with pieces exactly as G_α . Since all the G_α are prime and chordal, they are complete by Lemma 23. $\square$

6. Examples of noncompactness.

6.1. Noncompactness of hypertree-width of hypergraph pairs. In this section, we define a hypergraph pair (G, H) such that

- (i) $\text{hw}(G, H) = 2$,
- (ii) $\text{hw}(G_0, H_0) \leq 1$ for all finite induced subhypergraph pairs (G_0, H_0) of (G, H) , and
- (iii) all hyperedges $e \in E(H)$ satisfy $|e| \leq 3$.

Let (G', H') be the hypergraph pair defined by $V(G') = \{a, b, d, e, f, g, a_*\}$, $E(G') = \{\{a, b\}, \{b, d\}, \{d, e\}, \{e, f\}, \{f, g\}, \{g, a_*\}\}$, and $E(H') = \{\{a, b\}, \{b, d, f\}, \{d, e\}, \{e, f\}, \{f, g\}, \{g, a_*\}\}$ (see Figure 6.1).

Intuitively, the idea is that one marshal can catch the robber monotonely on (G', H') by chasing him from right to left, but not by chasing him from left to right. Gluing together infinitely many copies of (G', H') as explained below allows the robber to make sure that he is always on the right side of the marshal and thus he can elude capture.

For each $i \in \mathbb{Z}$, let (G^i, H^i) be an isomorphic copy of (G', H') with vertex set $\{a^i, b^i, d^i, e^i, f^i, g^i, a_*^i\}$. By identifying the "rightmost" vertex of the i th copy with the first vertex of the $(i+1)$ th copy, we obtain the hypergraph pair of Figure 6.2,

$$(G, H) := \bigcup_{i \in \mathbb{Z}} (G^i, H^i) / (a_*^i = a^{i+1}).$$

FIG. 6.1. The hypergraph pair (G', H') .

The characterization of $\text{hw}(G, H)$ by the robber and marshals game (cf. section 4.2) allows us to argue the game theoretically: It is easy to see that two marshals have a winning strategy on (G, H) , and we will not prove this here.

Let (G_0, H_0) be a finite induced subhypergraph pair of (G, H) . Then one marshal has a winning strategy. He starts by occupying the rightmost hyperedge of (G_0, H_0) and then he chases the robber to the left.

Nevertheless, one marshal does not have a winning strategy on (G, H) . The robber can escape as follows: After the marshal's first move to a hyperedge $h \in E(H)$, the robber goes to the right side of h , choosing the unoccupied vertex e^i which is as far "left" as possible such that there is a vertex $v \in V(G)$ on the "left side" of e^i with $v \in h$. From then on, the robber stays on e^i . By monotonicity it is easy to see that each of the marshal's following moves is uniquely determined until at some point the marshal occupies the hyperedge $\{b^i, d^i, f^i\}$. Now he cannot make a move at all, and therefore the robber wins. Hence (G, H) satisfies (i), (ii), and (iii).

Let us remark that the hypergraph pair (G, H) has finite character and all finite subhypergraphs (G_0, H_0) of (G, H) satisfy $\text{ghw}(G_0, H_0) \leq 1$. With Theorem 17 it follows that $\text{ghw}(G, H) \leq 1$. It is left to the reader as an exercise to find a generalized hypertree decomposition of width 1 for (G, H) .

6.2. Noncompactness of hypertree-width. In this section we prove the following theorem.

THEOREM 25. *There is a hypergraph H satisfying*

- (i) $\text{hw}(H) = 4$,
- (ii) $\text{hw}(H_0) \leq 3$ for all finite induced subhypergraphs H_0 of H , and
- (iii) all hyperedges $e \in E(H)$ satisfy $|e| \leq 3$.

Although the presentation will be independent from the previous paragraph, the idea of the construction is to code the hypergraph pair (G, H) of the previous paragraph in a single hypergraph, in such a way that the winning strategies for few marshals on the "implementation" of (G, H) as a hypergraph are basically the same as on (G, H) . So we will have to implement the *marshal edges* (i.e., the edges from $E(H) \setminus E(G)$) and the *robber edges* (i.e., the edges from $E(G) \setminus E(H)$) using ordinary edges that can be used both by the marshals and by the robber. The implementation of the marshal edges will increase the number of marshals necessary to catch the robber by two. Intuitively, a marshal edge will be implemented by some highly con-

FIG. 6.2. The hypergraph pair (G, H) .

FIG. 6.3. The hypergraph M . In addition to the hyperedges shown in the figure, every vertex from P is connected to every vertex from Q by a 2-edge. Also, for every $v \in V(M)$, M contains the hyperedge $\{v\}$.

nected vertices, which the marshals have to occupy during the whole game (because otherwise the robber can reach almost every vertex he likes). In this way we make sure that the robber cannot use the marshal edge.

As in the previous section, we again construct the example by gluing together infinitely many copies of a certain “module.” Let M be the hypergraph from Figure 6.3, with $V(M) = P \cup Q \cup \{c_1, c_2, \dots, c_5\}$, where $P = \{\alpha, \beta, \gamma, \alpha', \beta', \gamma'\}$, and $Q = \{a, b, d, e, f, g, a_*\}$,

- $E(M) = \{\{a, b\}, \{d, e\}, \{e, f\}, \{f, g\}, \{g, a_*\}, \{\alpha, \beta, \gamma\}, \{\alpha', \beta', \gamma'\}\},$
- $\cup \{\{b, c_i\} \mid i = 1, \dots, 5\} \cup \{\{c_i, d\} \mid i = 1, \dots, 5\} \cup \{\{\alpha, b, \alpha'\}, \{\beta, d, \beta'\}, \{\gamma, f, \gamma'\}\},$
- $\cup \{\{p, q\} \mid p \in P, q \in Q\} \cup \{\{v\} \mid v \in V(M)\}.$

Intuitively, the vertices of P are the highly connected vertices, which the marshals will have to occupy during the whole game. We add the singletons $\{v\}$ for $v \in V(M)$ to the hyperedges so that it is no advantage for the marshals to use an edge of type $\{p, q\}$ for $p \in P, q \in Q$. It does not help the marshals chasing the robber on $Q \cup \{c_1, \dots, c_5\}$, since the marshal occupying $\{p, q\}$ can use the edge $\{q\}$ instead. Furthermore, occupying an edge $\{p, q\}$ does not allow to cover P with few marshals, so the marshals can avoid such edges.

The robber edge $\{b, d\} \in E(G')$ of the hypergraph pair of Figure 6.1 is implemented by 5 paths of length two between b and d (via the vertices $c_1, \dots, c_5$, respectively). This makes sure that 4 marshals cannot chase the robber from b to d or vice versa, without covering b and d at the same time—as in (G', H') (see Figure 6.1).

Let $(M^i)_{i \in \mathbb{Z}}$ be a family of isomorphic copies of M . We denote the vertices of M^i by $\{v^i \mid v \in V(M)\}$. By identifying the rightmost vertex of the i th copy with the

first vertex of the $(i + 1)$ th copy, we obtain the hypergraph

$$H := \bigcup_{i \in \mathbb{Z}} (M^i) / (a_*^i = a^{i+1}).$$

Proof of Theorem 25, (i). It is easy to see that four marshals can win on H . The following three lemmas show that $\text{mon-mw}(H) > 3$:

LEMMA 26. *On H as defined above, the robber can win against three marshals.*

Proof. We describe such a winning strategy, which is similar to the robber's winning strategy on the hypergraph pair (G, H) defined in the previous paragraph. Let $S := \bigcup_{i \in \mathbb{Z}} \{a^i, b^i, c_1^i, d^i, e^i, f^i, g^i, a_*^i\}$. As long as no vertex from S is occupied by a marshal, the robber stays in the connected component of H containing S . Sooner or later, the marshals will have to first occupy one or more vertices of S . Let v be the rightmost such. Then the robber reacts by moving to the leftmost vertex a^i that is to the right of v . Let H' be the restriction of H to M^i together with the path from v to a^i (in the sense of induced subhypergraph). The following lemma shows that the robber can elude capture. $\square$

LEMMA 27. *Let N be the hypergraph defined by $V(N) = \{v_i \mid i < n\} \cup V(M)$ and $E(N) = \{\{v_n, v_{n-1}\}, \{v_{n-1}, v_{n-2}\}, \dots, \{v_0, a\}\} \cup E(M)$. The robber can win on N against three marshals, if in the first move the marshals occupy v_n .*

Proof. The robber remains on a until a marshal occupies a . Then the robber plays according to his winning strategy from Lemma 28 below. $\square$

LEMMA 28. *The robber can win against three marshals on M , if the first game position is (X, a) with some $X \subseteq E(M)$, $|X| \leq 2$ and if in the second move some marshal occupies an edge containing the vertex a .*

Proof. As long as a vertex from P is not occupied by the marshals, the robber stays on such a vertex. All this time the marshals have to occupy a . As soon as the marshals occupy all vertices from P (the marshals still have to occupy a), we have one of the two following situations:

The marshals occupy $\{\alpha, \beta, \gamma\}$, $\{\alpha', \beta', \gamma'\}$, and $\{a\}$, or they occupy $\{\alpha, \beta, \gamma\}$, $\{\alpha', \beta', \gamma'\}$, and $\{a, b\}$.

In the first case the robber stays on b until the marshals occupy b , by which we are in the second case. In the second case the robber moves to e . Now the marshals can either additionally occupy a vertex c_i (and then give up), or rearrange themselves to occupy $\{\alpha, b, \alpha'\}$, $\{\beta, d, \beta'\}$, and $\{\gamma, f, \gamma'\}$ (and then give up as well). $\square$

Proof of Theorem 25, (ii). Three marshals have a winning strategy on a finite induced subhypergraph H_0 of H . First, we may assume that H_0 is the union of finitely many “modules” M_i . The proof idea is that two marshals occupy hyperedges of the type $\{\alpha^i, \beta^i, \gamma^i\}$ and $\{\alpha'^i, \beta'^i, \gamma'^i\}$ almost all the time. The third marshal chases the robber from right to left, while the other two marshals do not change position except when the third marshal reaches an edge of type $\{d^j, e^j\}$. Then the next step for the marshals is to occupy $\{\alpha^j, b^j, \alpha'^j\}$, $\{\beta^j, d^j, \beta'^j\}$, and $\{\gamma^j, f^j, \gamma'^j\}$. After that, the robber is either caught on a vertex c_i^j , $i \in \{1, \dots, 5\}$, or two marshals again occupy the hyperedges $\{\alpha^i, \beta^i, \gamma^i\}$ and $\{\alpha'^i, \beta'^i, \gamma'^i\}$ and the third marshal continues chasing the robber towards the left end of the finite hypergraph, until the robber finally cannot move. Whenever the third marshal reaches a point of type a_i , the two other marshals move from $\{\alpha^i, \beta^i, \gamma^i\}$ and $\{\alpha'^i, \beta'^i, \gamma'^i\}$ to $\{\alpha^{i-1}, \beta^{i-1}, \gamma^{i-1}\}$ and $\{\alpha'^{i-1}, \beta'^{i-1}, \gamma'^{i-1}\}$.

Thus, $\text{mon-mw}(H_0) \leq 3$ for all finite induced subhypergraphs H_0 of H . Altogether, H satisfies (i), (ii), and (iii) as required. $\square$

FIG. 6.4. A width 3 generalized hypertree decomposition of M of Figure 6.3.

Let us remark that the hypergraph H of Theorem 25 has finite character and satisfies $\text{ghw}(H_0) \leq 3$ for all finite subhypergraphs H_0 of H . With Corollary 18 it follows that $\text{ghw}(H) \leq 3$. To obtain a generalized hypertree decomposition for H of width at most 3, the main ingredient is a width 3 generalized hypertree decomposition for M “from left to right.” Figure 6.4 shows such a generalized hypertree decomposition. Note that this is not a hypertree decomposition, because the second tree node does not satisfy condition 3.

Acknowledgments. The author thanks Prof. J. Flum for helpful hints, Prof. C. Thomassen for his elegant proof of compactness of tree-width and H. Scheuermann for many discussions.

RECONFIGURATIONS IN GRAPHS AND GRIDS*

GRUIA CĂLINESCU[†], ADRIAN DUMITRESCU[‡], AND JÁNOS PACH[§]

Abstract. Let G be a connected graph, and let V and V' be two n -element subsets of its vertex set $V(G)$. Imagine that we place a chip at each element of V and we want to move them into the positions of V' (V and V' may have common elements). A move is defined as shifting a chip from v_1 to v_2 ($v_1, v_2 \in V(G)$) on a path formed by edges of G so that no intermediate vertices are occupied. We give upper and lower bounds on the number of moves that are necessary and analyze the computational complexity of this problem under various assumptions: labeled versus unlabeled chips, arbitrary graphs versus the case when the graph is the rectangular (infinite) planar grid, etc. We prove hardness and inapproximability results for several variants of the problem. We also give a linear time algorithm which performs an optimal (minimum) number of moves for the unlabeled version in a tree, and a constant-ratio approximation algorithm for the unlabeled version in a graph. The graph algorithm uses the tree algorithm as a subroutine.

Key words. reconfiguration algorithms, approximation algorithms, local ratio method, proper function, NP-hardness

1. Introduction. Consider a set system (set) of n pairwise disjoint objects in the Euclidean space that need to be brought from a given *start* (initial) configuration S into a desired *target* (goal) configuration T . In many cases, the problem admits the following abstraction: we have an underlying finite or infinite graph, the start configuration is represented by a set of n chips at n distinct start vertices, and the target configuration is represented by another set of n distinct target vertices. A vertex can be both a start and target position. The cases when the chips are labeled or unlabeled give two different variants of the problem. In one move a chip can follow an arbitrary path in the graph and end up at another vertex, provided the path (including the end vertex) is free of other chips. The *motion planning* problem for such a system is that of computing a sequence of object motions (schedule) that achieves this task. If such a sequence of motions exists, we say that the problem is *feasible* and that it is *infeasible* otherwise. To avoid trivial questions, we always assume the graph is connected.

In certain applications, objects are indistinguishable, and therefore the chips are unlabeled; for instance, a modular robotic system consists of a number of identical modules (robots) that have identical capabilities [10, 11]. In another application, the chips are indivisible packets (copies) of the same data that need to be moved from

one site to another of a wide-area communication network without ever exceeding the capacities of the communication buffers at each site [5, 16].

In this variant with unlabeled chips, the problem is easier and always feasible; therefore, one is interested in minimizing the number of moves. For the variant with labeled chips the problem may be infeasible: it is known, for instance, that the 15-puzzle on a 4×4 grid—introduced by Sam Loyd in 1878—has a solution if and only if the start permutation is an even permutation [15, 20] (see [3] for a recent approach).

Other reconfiguration rules (models) for systems of disks in the plane have been examined recently [1, 7, 8]; see also [9]. These models do not fall in the graph reconfiguration framework in this paper, because a disk may partially overlap several target positions. A model that fits in the graph reconfiguration framework has been analyzed in [10]: it deals with reconfiguration of modular systems acting in a grid-like environment, where moves must maintain connectivity of the whole system, and the motion rules are very local: a chip can only move to an adjacent position in one move. Denoting the configuration of the modules at time t by V_t , the system remains connected if for each $t = 0, 1, 2, \dots$ the graph $G_t = (V_t, E_t)$ is connected, where E_t is the set of edges connecting pairs of cells in V_t that are side-adjacent.

The general form of the reconfiguration problem we consider is to find a reconfiguration sequence with a minimum number of moves. Depending on whether we refer to the graph or grid version, or to the labeled or unlabeled version, we call the problem U-GRAPH-RP, L-GRAPH-RP, U-GRID-RP, or L-GRID-RP. In the grid version, the underlying graph is the infinite planar integer grid.

Consider, for example, the reconfiguration problem in the infinite grid with unlabeled (or labeled) chips (objects). The following simple algorithm does $2n$ moves for reconfiguration of n chips. In the first step (n moves), move in a suitable order all the chips away in the free grid space. In the second step (n moves), bring the chips “back” to their target positions. We will show that minimizing the number of moves is intractable in both (labeled and unlabeled) variants in the grid.

A move is called a *target move* if it moves a chip to a final target position. Otherwise it is called a *nontarget move*. Our lower bounds use the following argument: if no target chip coincides with a start chip (so each chip must move), then a schedule with x nontarget moves consists of at least $n + x$ moves.

It is worth noting that, in contrast with the variant with moves along free paths studied here, the variant of the reconfiguration problem (with unlabeled chips) in which we count as one move each edge traversed by a chip can be solved exactly (optimally). This will be explained at the end of section 2.

Previous related work. Most of the work done so far concerns labeled versions of the reconfiguration problem, and we give here only a very brief survey.

For the generalization of the 15-puzzle on an arbitrary graph (with $k = v - 1$ labeled chips in a connected graph on v vertices), Wilson [21] gave an efficiently checkable characterization of the solvable instances of the problem. Kornhauser, Miller, and Spirakis have extended his result to any $k \leq v - 1$ and provided bounds on the number of moves for solving any solvable instance [16].

Ratner and Warmuth have shown that finding a solution with a minimum number of moves for the $(N \times N)$ -extension of the 15-puzzle is intractable [19], so the reconfiguration problem in graphs with labeled chips is NP-hard.

Auletta et al. gave a linear time algorithm for the *pebble motion on a tree* [5]. This problem is the labeled variant of the same reconfiguration problem we study here; however, each move is along one edge only.

Papadimitriou et al. studied a problem of *motion planning on a graph* in which there is a mobile robot at one of the vertices s , which has to reach a designated vertex t using the smallest number of moves, in the presence of obstacles (pebbles) at some of the other vertices [17]. Robot and obstacle moves are done along edges. Obstacles have no destination assigned and may end up at any vertex of the graph. The problem has been shown to be NP-complete even for planar graphs, and a ratio $O(\sqrt{n})$ polynomial time approximation algorithm was given in [17].

Dumitrescu, Suzuki, and Yamashita have addressed several basic questions in the analysis of modular metamorphic systems [11]. In particular the next two questions have been shown to be decidable: (i) whether a given set of motion rules maintains connectivity, (ii) whether a goal configuration is reachable from a given initial configuration (at specified locations) using a given set of motion rules. Other seemingly similar questions have been shown to be undecidable.

Our results are the following:

- (1) The reconfiguration problem in graphs with unlabeled chips U-GRAPH-RP is NP-hard and even APX-hard.
- (2) The reconfiguration problem in graphs with labeled chips L-GRAPH-RP is APX-hard.
- (3) For the infinite planar rectangular grid, both the labeled and unlabeled variants L-GRID-RP and U-GRID-RP are NP-hard.
- (4) There exists a ratio 3 approximation algorithm for the unlabeled version in graphs U-GRAPH-RP. Thereby we also get a ratio 3 approximation algorithm for the unlabeled version U-GRID-RP in the (infinite) rectangular grid.
- (5) We show that n moves are always enough (and sometimes necessary) for the reconfiguration of n unlabeled chips in graphs. For the case of trees, we present a linear time algorithm which performs an optimal (minimum) number of moves.
- (6) We show that $7n/4$ moves are always enough, and $3n/2$ are sometimes necessary, for the reconfiguration of n labeled chips in the infinite planar rectangular grid (L-GRID-RP).

2. Chips in graphs. Let G be a connected graph, and let V and V' be two n -element subsets of its vertex set $V(G)$. Imagine that we place a chip at each element of V and we want to move them into the positions of V' (V and V' may have common elements). A move is defined as shifting a chip from v_1 to v_2 ($v_1, v_2 \in V(G)$) along a path in G so that no intermediate vertices are occupied.

THEOREM 1. *In G one can get from any n -element initial configuration V to any n -element final configuration V' using at most n moves, so that no chip moves twice. Moreover, for the case of a tree T with r vertices, there is an $O(r)$ -time algorithm which performs the optimal (minimum) number of moves.*

Proof. It is sufficient to prove the theorem for trees. We argue by induction on the number of chips. Take the smallest tree T containing V and V' , and consider an arbitrary leaf l of T . Assume first that the leaf l belongs to V : say $l = v$. If v also belongs to V' , then the result trivially follows by induction, so assume that this is not the case. Choose a path π in T , connecting v to an element v' of V' such that no internal point of π belongs to V' . Apply the induction hypothesis to $V \setminus \{v\}$ and $V' \setminus \{v'\}$ to obtain a sequence of at most $n - 1$ moves, and add a final (unobstructed) move from v to v' .

The remaining case when the leaf l belongs to V' is symmetric, say $l = v'$; choose a path π in T , connecting v' to an element v of V such that no internal point of π

belongs to V . First move v to v' and append the sequence of at most $n - 1$ moves obtained from the induction hypothesis applied to $V \setminus \{v\}$ and $V' \setminus \{v'\}$.

We further refine this algorithm so as to minimize the number of moves. We call a vertex that is both a start and a target position an *obstacle*. We have four types of vertices: free vertices, chip-only vertices, target-only vertices, and obstacles. Denote by c (resp., t) the number of chip-only (resp., target-only) vertices and by o the number of obstacles. We have $c + o = o + t = n$. We call a tree *balanced* if it contains an equal number of chip-only and target-only vertices. Clearly, the initial tree T is balanced. If there exists an obstacle whose removal from T breaks T into balanced subtrees, then we keep this obstacle fixed and proceed recursively (by induction) on the subtrees. If no obstacle removal breaks T into balanced subtrees, then all obstacles must move (each at least once), hence the number of moves necessary is at least $o + c = n$, and the algorithm in the first part of our proof can be used to obtain an optimal schedule.

We continue with the description of the linear time algorithm. We traverse the tree in postorder and compute for every vertex v four doubly linked lists, M_v , Q_v , A_v , and C_v . Let T_v denote the subtree rooted at v . We say that a sequence of moves *solves* T_v if, after executing the moves in this sequence, all the chips in T_v cover exactly every target of T_v (including obstacles). Note that by itself the definition of solving does not imply solving with a minimum number of moves.

We now discuss the four lists and give intuition on their use; a formal proof follows the description of the algorithm. A_v and C_v are lists of vertices inside T_v which require moves involving nodes outside T_v : for A_v those moves mean bringing a chip from outside T_v to a vertex of A_v , and for C_v those moves mean taking a chip from a vertex of C_v to a node outside T_v . Either A_v or C_v (possibly both) will be empty after node v is processed. A move is described by a pair of vertices: the place where we take hold of the chip and the place where we release it. M_v and Q_v are lists of moves inside T_v . Moves involving elements of A_v or C_v will use the edge from v to its parent. Moves not involving elements of $A_v \cup C_v$ will be done inside T_v and are all in M_v and Q_v . The goal is to obtain a sequence of moves solving T_v such that this sequence starts with the moves in M_v , followed by some moves on the edge from v to its parent (all these moves involve vertices from C_v or A_v), followed by the moves in Q_v . If v has no parent (i.e., v is the root of T), then the list of moves on the edge from v to its parent is empty. The final reconfiguration sequence (output by the algorithm) is the sequence of moves in the list M_v followed by the moves in the list Q_v at the root of the tree.

We now describe how A_v, C_v, M_v, Q_v are initialized and computed. Two examples of the execution of the algorithm are shown in Figure 1. If v is a leaf, then M_v and Q_v are empty, $A_v = \langle v \rangle$ if v is a target-only vertex and empty otherwise, and $C_v = \langle v \rangle$ if v is a chip-only vertex, and empty otherwise. We now show how the four lists M_v, Q_v, A_v , and C_v are obtained from the lists of the children of v . There are four cases, depending on whether v is free, target-only, chip-only, or an obstacle.

In all four cases, we first compute M_v, Q_v, A_v , and C_v by concatenating the corresponding lists of the children of v . We also make use of a procedure *Cancel*, which works as follows: iterate the following step until either A_v or C_v is empty; remove the first element from each list and add the corresponding pair at the end of M_v .

In the *first* case, v is a free vertex. After applying *Cancel*, we are done.

In the *second* case, v is a target-only vertex. We apply *Cancel*. Now, if C_v is empty, we put v at the end of A_v and we are done. If C_v is nonempty, we remove

FIG. 1. Two examples of execution of the linear time algorithm for reconfiguration in a tree. Chips are drawn as empty circles, obstacles as black circles, and targets as gray circles.

from it the last element q . Insert the move (q, v) at the beginning of Q_v and we are done.

In the *third* case, v is a chip-only vertex. If A_v is empty, we put v at the beginning of C_v and we are done. If A_v is nonempty, we remove from it the first element q . We add the move (v, q) at the end of M_v , then we apply *Cancel* and we are done.

In the *fourth* and last case, v is an obstacle. (i) If A_v and C_v are both empty, we are done. (ii) If A_v is empty and C_v is nonempty, let q be the last chip from C_v . Remove q from C_v , insert the move (q, v) at the beginning of Q_v , add v at the beginning of C_v , and we are done. (iii) If A_v is nonempty, let p be the first target in A_v . Remove p from A_v and add the move (v, p) at the end of M_v . Apply *Cancel*. Now, if C_v is empty, add v at the end of A_v and we are done. If C_v is nonempty (note, A_v must be empty after *Cancel*), let q be the last chip from C_v . Remove q from C_v , insert the move (q, v) at the beginning of Q_v , and we are done.

We need to prove that this algorithm returns an optimum solution and then analyze its running time. First, we prove that it returns a correct solution, and then we justify separately its optimality. For the correctness, we prove by induction on the size of T_v that the following three conditions hold:

- If T_v contains an equal number of start and target vertices, then $A_v = C_v = \emptyset$. The sequence of moves obtained by concatenating M_v and Q_v solves T_v .
- If T_v contains q more start vertices than target vertices, then $|C_v| = q$ and $A_v = \emptyset$. Consider the sequence of moves obtained by concatenating (i) M_v , (ii) any q moves taking chips from vertices of C_v in the order they appear in C_v and placing them on vertices outside T_v , and (iii) Q_v . This sequence solves T_v .
- If T_v contains q more target vertices than start vertices, then $|A_v| = q$ and $C_v = \emptyset$. Consider the sequence of moves obtained by concatenating (i) M_v , (ii) any q moves taking chips from vertices outside T_v and placing them on vertices of A_v in the order they appear in A_v , and (iii) Q_v . This sequence solves T_v .

The base case is obvious, and the inductive step follows directly from the description of the algorithm, thereby proving that the algorithm returns a correct solution. Regarding the optimality of the number of moves, notice that an obstacle v whose

removal breaks T into balanced subtrees is not moved by the algorithm, and any other chip is moved only once; hence, the algorithm returns an optimum solution.

The time spent at vertex v is proportional to one plus the number of children of v plus the number of moves added to M_v and Q_v . Summing over the vertices, we obtain that the time is proportional to the number of vertices in the tree plus the total number of moves; hence, it is $O(n + r) = O(r)$, since $n \leq r$. $\square$

Remark. Theorem 1 implies that in the infinite rectangular grid, we can get from any starting position to any ending position of the same size n in at most n moves. It is perhaps interesting to compare this to the problem of sliding congruent unlabeled disks in the plane: here one can come up with “cage-like” constructions that require about $\frac{16n}{15}$ moves [7].

2.1. Hardness results.

THEOREM 2. *The unlabeled version in graphs U-GRAPH-RP is NP-complete. Moreover, assuming $P \neq NP$, there is an absolute constant $\epsilon_1 > 0$ such that no polynomial time algorithm has approximation guarantee at most $1 + \epsilon_1$. That is, U-GRAPH-RP is APX-hard.*

Proof. The decision version of U-GRAPH-RP is clearly in NP, so we only have to prove its NP-hardness. We reduce the *set cover* problem SC to U-GRAPH-RP. An instance of the set cover problem consists of a family $\mathcal{F}$ of subsets of a finite set U . The problem is to decide whether there is a set cover of size k for $\mathcal{F}$, i.e., a subset $\mathcal{F}' \subseteq \mathcal{F}$, with $|\mathcal{F}'| \leq k$, such that every element in U belongs to at least one member of $\mathcal{F}'$. SC is known to be NP-complete [12].

FIG. 2. The “broom” graph G corresponding to a set cover instance with $|U| = 12$ and $|\mathcal{F}| = 6$. The vertices occupied only by chips are white, those occupied by both chips and targets are black, and those occupied only by targets are shaded. An optimal reconfiguration takes 15 moves (an optimal set cover has size 3: the third, fourth, and fifth sets counting from the top).

Consider an instance of SC represented by a bipartite graph $(B \cup C, E)$, where $U = C$, $\mathcal{F} = B$, and edges describe the membership relation. Construct the undirected graph G shown in Figure 2 with $|A| = |C|$. The chips are $S = A \cup B$, and the targets are $T = B \cup C$. Clearly, G can be constructed in polynomial time. The reduction is complete once we establish the following claim.

Claim. There is a set cover consisting of at most q sets if and only if reconfiguration in G can be done using at most $|A| + q$ moves.

Proof of claim. Let q be the size of an optimal set cover. The direct implication is clear: move one chip from each element of B in the optimal cover to a target in

C ; then move the elements of A to targets in C and to the emptied targets in B using the required number of moves. For the converse implication, assume that there is a reconfiguration sequence with fewer than $|A| + q$ moves. Since all elements of A must move, fewer than q elements of B move away from their original positions. By the definition of set cover, it means that some target in C will not be filled, a contradiction.

To prove the approximation hardness we use the same reduction and the fact that 3-SC, the set cover problem in which the size of each set in $\mathcal{F}$ is bounded from above by 3, is APX-hard [2, 18]. Thus q , as in the previous paragraph, is between $|A|/3$ and $|A|$. Approximating $|A| + q$ within $1 + \epsilon$ will approximate q within $1 + 4\epsilon$. $\square$

A similar reduction can be made for the labeled version. The chips in A have targets in C , labeled as in Figure 3 (here $|A| = |C| = m$).

FIG. 3. The graph constructed in the reduction for labeled chips. Free vertices are drawn as squares. An optimal reconfiguration takes 18 moves (an optimal set cover has size 3: the third, fourth, and fifth sets counting from the top).

The obstacle chips in B coincide with their targets. Each vertex in B is adjacent to a “twin” free vertex. The reduction follows from the next claim. Its proof is similar to that for the previous claim, using the fact that a chip representing a selected set must move twice—once to make way for the chips whose targets are on the vertices representing elements, and once to come back.

Claim. There is a set cover consisting of at most q sets if and only if reconfiguration in G can be done using at most $|A| + 2q$ moves.

We thus obtain the following result.

THEOREM 3. *The labeled version in graphs L-GRAPH-RP is APX-hard.*

2.2. Approximation algorithms.

THEOREM 4. *There exists a 3-approximation algorithm for U-GRAPH-RP.*

Proof. The algorithm is obtained by applying the local ratio method of Bar-Yehuda [6] to a graph H whose construction we describe below.

The vertex set of the input graph G is partitioned into four sets:

- $C = V \setminus V'$, the chip-only vertices,
- $A = V' \setminus V$, the target-only vertices,
- $B = V \cap V'$, the obstacles,
- $F = V(G) \setminus (V \cup V')$, the free vertices.

Then $V(H) = A \cup B \cup C$. Observe that $|A| = |C|$. For every pair of vertices u and v of H , we put in $E(H)$ the edge uv if $uv \in E(G)$ or there is a path in G from u

to v having all the internal vertices from F .

A set of vertices (in $V(H)$) is called *balanced* if it contains an equal number of chip-only and target-only vertices. In H , we use the local ratio method to find a small set of edges Q such that every connected component D of $(V(H), Q)$ is balanced. We call this the U-STEINER problem. U-STEINER is a network design problem given by a 0-1 *proper function* [13, 14], for which both the primal-dual schema and the local ratio method were known to give a 2-approximation. The local-ratio 2-approximation algorithm is also implicit later in this section. We briefly recall here that for a ground set V , a 0-1 function $f : 2^V \rightarrow \{0, 1\}$ is proper (cf. [13, 14]) if it satisfies the following three conditions: (i) $f(V) = 0$, (ii) if A and B are disjoint, then $f(A \cup B) \leq \max(f(A), f(B))$, and (iii) f is symmetric, i.e., $f(S) = f(V - S)$ for all $S \subseteq V$.

In our case, the function, defined over all subsets of vertices, is one if the set is unbalanced and zero otherwise. It can be shown that this is a proper function; however, this fact is not needed in the ratio 3 approximation algorithm, whose proof is self-contained. From the next claim, one can easily obtain a 4-approximation for U-GRAPH-RP, as shown after the proof of claim.

One more piece of notation: given a solution R for U-GRAPH-RP in G , consider the edges of G traversed by the moving chips during the reconfiguration process. These edges, together with their endpoints (including the free vertices through which chips pass) form a number $k \geq 1$ of connected components. We then say that R has k connected components. Write $c = |C| = |A|$.

CLAIM 1. *Given a feasible solution R for U-GRAPH-RP in G with m moves and k connected components, there is a feasible solution Q for U-STEINER in H with at most $m + c - k$ edges. Conversely, given a feasible solution Q for U-STEINER in H with e edges, there is a feasible solution R for U-GRAPH-RP in G with at most $e - c + k$ moves, where k is the number of connected components of Q which intersect A (and C).*

Proof. For the first part, let S be the set of vertices of G involved in the moves of R , and let S_i , for $i = 1, 2, \dots, k$, be the connected components of R . Then the number of moves inside S_i is at least $|S_i \cap C| + |S_i \cap B|$. Let $S'_i = S_i \cap V(H)$, and note that S'_i is also connected in H . In each S'_i pick a spanning tree T_i ; the union of the trees T_i is the feasible solution Q for U-STEINER. In each T_i , the number of edges is $|V(T_i)| - 1 = |V(T_i) \cap C| + |V(T_i) \cap B| + |V(T_i) \cap A| - 1$. Summing over i gives the needed inequality.

For the second part, let T_i , for $i = 1, \dots, k$, be one such connected component (w.l.o.g. a tree) with e_i edges. Then $|A \cap V(T_i)| = |C \cap V(T_i)|$, and by using Theorem 1 one can move all the chips of $V(T_i)$, including those sitting on obstacles, to all the targets of $V(T_i)$ using $|V(T_i)| - |C \cap V(T_i)|$ moves: the chips from $(C \cup B) \cap V(T_i)$ move along the edges of T_i , passing, if necessary, through vertices of F (in G). Since $|V(T_i)| = |E(T_i)| + 1$, this second part of the claim follows by adding up over the components, since no move puts a chip on a vertex in F . (As a side remark, if Q is an optimal solution in H , then each T_i is a tree intersecting A and C .) $\square$

Here is a short account for the ratio 4 approximation algorithm. By the first part of Claim 1 applied to an optimal solution for U-GRAPH-RP in G with m_{OPT} moves and k_{OPT} components, the number of edges e_{OPT} in an optimal solution for U-STEINER in H satisfies

$$e_{OPT} \leq m_{OPT} + c - k_{OPT} \leq m_{OPT} + c \leq 2m_{OPT}.$$

Therefore, by the second part of Claim 1, the number of moves m in the solution for U-GRAPH-RP in G returned by the algorithm satisfies (since $k_1 \leq c$, where k_1 is

the number of components in the solution for U-STEINER in H which intersect A and C)

$$m \leq e - c + k_1 \leq e \leq 2e_{OPT} \leq 4m_{OPT}.$$

We now present the ratio 3 approximation algorithm. To this end, we have to enter the details of the local ratio method. The local ratio algorithm approximately solves U-STEINER instances with nonnegative weight δ on the edges. The algorithm below, given in [6], is recursive. Each recursive call is given a set S of already selected edges and a nonnegative edge weight function, and it returns a set of edges (in step 8). Given a set of edges $F \subseteq E(H)$, call a connected component X of $(V(H), F)$ *balanced* if $|V(X) \cap A| = |V(X) \cap C|$ and *unbalanced* otherwise. For the first call of the algorithm, $S = \emptyset$, and $\delta = 1$ on all edges. By feasible solution we mean feasible solution for the original U-STEINER instance.

1. The input parameters are the set of edges $S \subseteq E(H)$ and nonnegative weight δ on $E(H)$.
2. If all of the connected components of $(V(H), S)$ are balanced, then return $\emptyset$.
3. Define weight function δ_1 on edges of $E(H)$ as follows: edges going between two unbalanced components of $(V(H), S)$ get weight 1, edges going between one unbalanced component of $(V(H), S)$ and one balanced component of $(V(H), S)$ get weight $1/2$, and all other edges get weight 0.
4. Compute a positive real number α such that the weight function δ_2 on edges of H given by $\delta_2 = \delta - \alpha \cdot \delta_1$ is nonnegative, and for at least one edge e we have $\delta_2(e) = 0 < \delta(e)$.
5. Let $M = \{e \mid \delta_2(e) = 0\}$.
6. Recursively solve the instance with parameters $S \cup M$ and weight δ_2 on $E(H)$, producing a set of edges L such that $S \cup M \cup L$ is a feasible solution.
7. Obtain minimal $M' \subseteq M$ such that $S \cup M' \cup L$ is a feasible solution.
8. Return $L \cup M'$.

We are guaranteed that $M \neq \emptyset$ and thus the algorithm terminates. For the approximation ratio, we need the following claim.

CLAIM 2. *During the execution of a recursive call of the algorithm, let k be the number of unbalanced components of $(V(H), S)$. Then $\delta_1(P) \geq k/2$ for any feasible solution P . The set of edges Q returned by the recursive call of the algorithm satisfies $\delta_1(Q) \leq k - q$, where q is the number of connected components of $(V(H), Q \cup S)$.*

Proof. Consider a feasible solution P . If an edge of P goes between two unbalanced components of $(V(H), S)$, we assign $1/2$ to each such component, and if it goes from one unbalanced component of $(V(H), S)$ to one balanced component of $(V(H), S)$, we assign $1/2$ to the unbalanced component. Each unbalanced component of $(V(H), S)$ must have at least one edge of P going to some other component, and thus it is assigned at least $1/2$. Therefore $\delta_1(P) \geq k/2$.

Consider now the edges Q selected (returned) by one recursive call of the algorithm and let Q_i , for $i = 1, \dots, q$, be the connected components of $(V(H), Q \cup S)$. Fix one component Q_i . Inside Q_i , contract to a single vertex the vertices from the same component of $(V(H), S)$, obtaining $\bar{Q}_i$. The minimal property of Q as ensured by step 7 of the algorithm ensures that $\bar{Q}_i$ is acyclic (and thus it is a tree) and every leaf of $\bar{Q}_i$ is an unbalanced component of S . Note that all of the edges of Q_i with positive δ_1 -weight are in $\bar{Q}_i$. Root $\bar{Q}_i$ at an arbitrary vertex v given by an unbalanced component of S .

For every $u \in (V(\bar{Q}_i) \setminus \{v\})$ given by an unbalanced component of S , charge to u either one or two edges of total δ_1 -weight 1 as follows: consider the path from u to v

in $\bar{Q}_i$, and let u' be the next vertex on this path given by an unbalanced component of S . If the path has only one edge, then charge this edge to u . If this path has more than one edge, then charge to u the first and last edges of the path. It is easy to check that every edge of positive δ_1 -weight of $\bar{Q}_i$ is charged at least once. Thus $\delta_1(Q_i) = \delta_1(\bar{Q}_i) \leq s_i - 1$, where s_i is the number of unbalanced components of S included in Q_i ; here we used that v is not being charged.

Summing over i yields the second part of the claim. $\square$

We now continue with the proof of Theorem 4. First we note that, by using Claim 2 and induction, the local ratio algorithm ensures that its output LR satisfies, for any feasible solution P , the following:

$$(2.1) \quad \delta(LR) = \alpha\delta_1(LR) + \delta_2(LR) \leq \alpha 2\delta_1(P) + 2\delta_2(P) = 2\delta(P).$$

Let OPT be a solution with a minimum number of moves, $m(OPT)$ be the number of moves of OPT , and OP be the set of edges of the U-STEINER feasible solution obtained from OPT in Claim 1. Recall that LR is the set of edges selected by the local ratio approximation algorithm when applied to the U-STEINER instance, and let $k(LR)$ be the number of connected components of LR which intersect A , and $m(LR)$ be the number of moves of the solution obtained in Claim 1 from LR . The weight functions δ , δ_1 , and δ_2 refer to the first call of the local ratio algorithm, as does the real α , which we note is at least 1. We now have the following:

$$\begin{aligned} m(LR) &\leq |LR| + k(LR) - c \quad \text{by Claim 1} \\ &= \delta(LR) + k(LR) - c \\ &= \alpha\delta_1(LR) + \delta_2(LR) + k(LR) - c \\ &\leq \alpha(2\delta_1(OP) - k(LR)) + \delta_2(LR) + k(LR) - c \quad \text{by Claim 2} \\ &\leq 2\alpha\delta_1(OP) - k(LR) + \delta_2(LR) + k(LR) - c \quad \text{since } \alpha \geq 1 \\ &\leq 2\alpha\delta_1(OP) + 2\delta_2(OP) - c \quad \text{by (2.1)} \\ &\leq 2\delta(OP) - c \\ &= 2|OP| - c \\ &\leq 2(m(OPT) + c) - c \quad \text{by Claim 1} \\ &= 2m(OPT) + c \\ &\leq 3m(OPT) \quad \text{since } m(OPT) \geq c. \end{aligned}$$

This concludes the proof of Theorem 4. $\square$

Remark. In the graph version with unlabeled chips, if we count as one move every edge traversed by a chip, then minimizing the number of moves can be solved in polynomial time, as described below. Construct a complete weighted bipartite graph $B = (V \cup V', E)$ with bipartition V being the vertices containing chips and V' being the vertices containing targets (with obstacles in both sides of the bipartition). The weight of an edge in E is equal to the length of the shortest path in G connecting the endpoints of the edge. Now apply an algorithm for Minimum Weight Perfect Matching in B and move accordingly: if the path a chip c_1 would take to reach its destination has another chip c_2 on it, then have the two chips switch destinations and continue moving c_2 . One can check that the number of moves does not exceed the weight of the perfect matching. On the other hand, the optimum solution must move chips to targets and cannot do better than the total length of the shortest paths in a minimum matching.

3. Chips in grids. In this section we analyze the reconfiguration problem with labeled and unlabeled chips, respectively, in an infinite grid. However, a sufficiently large finite section of the grid containing all start and target positions clearly suffices for this purpose.

3.1. Hardness results.

THEOREM 5. *The unlabeled version in the grid U-GRID-RP is NP-complete.*

Proof. The decision version of U-GRID-RP is clearly in NP, so we only have to prove its NP-hardness. We reduce the *Rectilinear Steiner Tree* problem R-STEINER to U-GRID-RP. An instance of R-STEINER consists of n points in the plane, and the problem is to decide whether there is a rectilinear Steiner tree (that is, a tree containing only horizontal and vertical edges) of length at most q which connects all points. For convenience the points can be chosen with integer coordinates. R-STEINER is known to be strongly NP-complete [12], and thus we can assume all the coordinates are given in unary.

FIG. 4. Unlabeled chips in the grid obtained from a Rectilinear Steiner Tree instance with $n = 9$ (sketch). Chip-only vertices are drawn as empty circles, and target-only vertices are drawn as filled (black) circles. Obstacles (not shown) are placed at each other integer point in the axis-aligned bounding rectangle.

Consider an instance $P = \{p_1, \dots, p_n\}$ of R-STEINER with n points. Assume that the x -coordinate of a leftmost point $p_1 \in P$ is equal to zero. The instance of U-GRID-RP is illustrated in Figure 4. It has $n - 1$ chip-only vertices having the same y -coordinate with p_1 and x -coordinates $0, -1, -2, \dots, -n + 1$, and $n - 1$ target-only vertices located at the other points $\{p_2, \dots, p_n\}$ of the R-STEINER instance. Let B be a smallest axis-aligned bounding rectangle of all chip-only and target-only vertices and Δ_x, Δ_y be the dimensions of B . Consider a sufficiently large axis-aligned rectangle A enclosing the chip-only and target-only vertices (thus A encloses B) with obstacles placed at each other integer point. The boundary of A is at distance $\Delta_x + \Delta_y$ from the boundary of B . This construction is done in time polynomial in $\Delta_x \times \Delta_y$, which is polynomial in the size of the R-STEINER instance since the coordinates are given in unary. The reduction is complete once we establish the following claim.

Claim. There is a rectilinear Steiner tree of length at most q if and only if reconfiguration can be done using at most q moves.

Proof of claim. We start with the direct implication. Let T be a Steiner tree of length q connecting all target-only vertices and p_1 . Pick a leaf of T which is a target-only vertex and fill it with a chip (obstacle or chip-only) that is closest to it in

T by moving it along the corresponding path in T . If the chip comes from an obstacle vertex, then a new target-only vertex results in place of the leaf. The length of the resulting tree connecting all target-only vertices and p_1 is one less than the length of T . Continue by repeating this step until all targets have been filled (note that there is a leaf target-only vertex at each step); q moves are performed in total.

We continue with the converse implication. Denote by q the length of a minimum Steiner tree T connecting the points in P . Consider a valid reconfiguration sequence of moves $m_1, \dots, m_t$, w.l.o.g., having a minimum number of moves. Each move m_i is an orthogonal path in the grid covering a set of elements $V(m_i)$ in rectangle B (since A is large enough, each move going outside rectangle B would result in a nonoptimal reconfiguration sequence). In addition, we can assume that all chips pass through p_1 . Note that $V = V(m_1) \cup \dots \cup V(m_t)$ is the vertex set of a connected grid graph G that includes all chip-only elements, all target-only elements, and other obstacles.

The number of edges of G is at least $q + (n - 2)$, as in addition to the Steiner tree $n - 2$ edges appear to the left of p_1 ; thus $|V| \geq q + (n - 2) + 1$. Note that $V \setminus \{p_2, \dots, p_n\}$ consists of chips or obstacles. Each of these chips or obstacles must participate at least once in a move, and their number is at least $(q + 1) + (n - 2) - (n - 1) = q$, as required.

This also concludes the proof of Theorem 5. $\square$

Remark. From the results of [4], there exists a polynomial time approximation scheme for a Rectilinear Steiner Tree. Thus our reduction does not give an inapproximability result for U-GRID-RP, and we leave open the question of whether U-GRID-RP admits a polynomial time approximation scheme or not.

THEOREM 6. *The labeled version in the grid L-GRID-RP is NP-complete.*

Proof. The argument, similar to that in the proof of Theorem 5, still uses a reduction from R-STEINER. Consider an instance $P = \{p_1, \dots, p_n\}$ of R-STEINER with n grid points, and let p_n be a rightmost point in P .

FIG. 5. Labeled chips in the grid obtained from a Rectilinear Steiner Tree instance with $n = 8$ (sketch). Chip-only vertices are drawn as empty circles, and target-only vertices are drawn as filled (black) circles. Obstacles (not shown) are placed at every other integer point in the axis-aligned bounding rectangle. The corridor and most of the target area R (except its bottom row) are free.

The instance of L-GRID-RP, illustrated in Figure 5, has n labeled chips $s_1, \dots, s_n$ located at the points in P (s_i at p_i). Consider a sufficiently large axis-aligned rectangle enclosing the n chips mentioned previously and filled with obstacles placed at every other integer point, except the following: make a thin (width is one), long corridor

connecting the rightmost chip s_n to a large rectangular “target area” R located to the right of all the n chips mentioned previously; both the corridor and all rows of R except its bottom row are free. The bottom row contains all n targets $t_1, \dots, t_n$; here t_i denotes the target of s_i . R has $\Delta_x + \Delta_y + 2$ rows and n columns, where Δ_x, Δ_y are as before.

Informally, the obstacles which form a minimum rectilinear Steiner tree of the n points must go out in the target area and then come back in to their original positions. More precisely, the reduction is complete once we establish the following claim (analogous to the claim in the proof of Theorem 5).

Claim. There is a rectilinear Steiner tree of length at most q if and only if reconfiguration can be done using at most $2q + 2 - n$ moves.

This concludes the proof of Theorem 6. $\square$

3.2. Labeled chips: Upper and lower bounds on the number of moves.

THEOREM 7. *For the reconfiguration of n labeled chips in the infinite planar rectangular grid (L-GRID-RP), $7n/4$ moves are always enough, while $3n/2$ moves are sometimes necessary.*

Proof. The lower bound is trivial (however, it does not appear to be trivial to improve on it): take a pair of chips labeled 1 and 2, say next to each other, and have the target positions switch them; that is, $t_1 = s_2$ and $t_2 = s_1$. Clearly three moves are needed to rearrange this group of two, and by repeating it (with different labels), one gets a pair of configurations which require $3n/2$ moves.

We now describe a reconfiguration algorithm which executes no more than $7n/4$ moves (as mentioned in the introduction, the problem can be solved trivially in $2n$ moves).

Let S and T be the start and target configurations. Consider the directed graph G with n edges (loops allowed) given by $S \rightarrow T$. Vertices are grid points of $S \cup T$ (the number of vertices is between n and $2n$). Each edge originates at a start chip and ends at some (free or occupied) target cell. Note that each in-degree and out-degree is at most one, so G can be partitioned into a collection of disjoint paths and cycles (and loops).

Consider the rows of S numbered from top to bottom: $1, 2, \dots, r$. Let D (resp., E) be the set of elements in the odd (resp., even) rows; we can assume w.l.o.g. that $|D| \leq |E|$, thus $|D| \leq n/2$. Let A be the set of elements of E whose target lies in E , and let B (resp., C) be the set of elements of E whose target lies in rows of D congruent to 1 (resp., to 3) modulo 4. Write $a = |A|$, $b = |B|$, $c = |C|$. We can assume without loss of generality that $c \leq b$.

1. Move (far) away the elements of D (row by row, and for each row, move elements one by one, say from left to right) to form a set of corridors.
2. Move away the elements of C (elements of the even rows are adjacent to corridors, therefore any subset of chips of an even row can be moved away).
3. Select and move away an element from each cycle of the directed graph G remaining among the elements of A (not from the loops).
4. Fill (say, from left to right) the odd rows congruent to 1 modulo 4 with the elements of B and elements far away as follows: note that each even row is adjacent to an odd row congruent to 3 modulo 4; take out an element of B from the even row through the empty corridor congruent to 3 modulo 4, and then move the element to its target on the odd row congruent to 1 modulo 4.
5. Fill the even rows using the adjacent empty corridors (congruent to 3 modulo 4), with elements from A and elements far away. The elements of A move

directly to their destination, and such a move is possible as long as some elements of A still need to move, since we moved away one element from each cycle of the directed graph G contained in A .

6. Fill (say, from left to right) the odd rows congruent to 3 modulo 4 (the corridors) with elements far away.

The number of nontarget moves is at most

$$n - (a + b + c) + \frac{a}{2} + c \leq n - \frac{a}{2} - b \leq \frac{3n}{4},$$

since $a + 2b \geq a + b + c \geq n/2$. Therefore the total number of moves is not more than $n + 3n/4 = 7n/4$. $\square$

Remark. The above lower bound clearly holds even in the stronger *lifting model*, when chips can be lifted and placed back in the plane (see [7, 8] for related aspects of disk reconfiguration problems).

LIST-COLORING SQUARES OF SPARSE SUBCUBIC GRAPHS*

ZDENĚK DVOŘÁK[†], RISTE ŠKREKOVSKI[‡], AND MARTIN TANCER[†]

Abstract. The problem of coloring the square of a graph naturally arises in connection with the distance labelings, which have been studied intensively. We consider this problem for sparse subcubic graphs. We show that the choosability $\chi_\ell(G^2)$ of the square of a subcubic graph G of maximum average degree d is at most four if $d < 24/11$ and G does not contain a 5-cycle, at most five if $d < 7/3$, and at most six if $d < 5/2$. Wegner's conjecture claims that the chromatic number of the square of a subcubic planar graph is at most seven. Let G be a planar subcubic graph of girth g . Our result implies that $\chi_\ell(G^2)$ is at most four if $g \geq 24$, at most 5 if $g \geq 14$, and at most 6 if $g \geq 10$. For lower bounds, we find a planar subcubic graph G_1 of girth 9 such that $\chi(G_1^2) = 5$ and a planar subcubic graph G_2 of girth 5 such that $\chi(G_2^2) = 6$. As a consequence, we show that the problem of 4-coloring of the square of a subcubic planar graph of girth $g = 9$ is NP-complete. We conclude the paper by posing a few conjectures.

AMS subject classification. 05C15

DOI. 10.1137/050634049

1. Introduction. We study the coloring of squares of graphs and consider simple undirected graphs. Let $\chi(G)$ and $\chi_\ell(G)$ be the chromatic number and the choosability of a graph G , respectively. The *square* G^2 of a graph G is the graph with the same vertex set in which two vertices are joined by an edge if their distance in G is at most 2. It is easy to see that $\Delta + 1 \leq \chi(G^2) \leq \chi_\ell(G^2) \leq \Delta^2 + 1$, where Δ is the maximum degree of G . However, by Brooks' theorem, it is not hard to infer that there are only finitely many connected graphs for which the upper bound is attained. On the other hand, the chromatic number of the square of a planar graph is bounded by a function linear in the maximum degree (note that this bound does not follow directly from the 5-degeneracy of planar graphs [8]).

The notion of coloring of the square of a graph, as well as the other variants of a distance coloring, arise from the problem of assigning frequencies to transmitters. We are given a set of locations of transmitters, and we want to assign frequencies to them in such a way that they do not interfere. The transmitters interfere if they are close enough and the frequencies assigned to them are similar. The choosability version of the problem corresponds to the situation where we are not allowed to use all frequencies on all transmitters. The notion of closeness can often be approximated by forming the graph of the neighboring transmitters, and coloring of the square or a higher power of this graph enables us to take into account the interference between farther transmitters.

Let us briefly survey the rich history of the coloring of the squares of planar graphs. Wegner [16] proved that the squares of cubic planar graphs are 8-colorable. He conjectured that his bound can be improved as follows.

CONJECTURE 1. *Let G be a planar graph with maximum degree Δ . The chromatic number of G^2 is at most 7 if $\Delta = 3$, at most $\Delta + 5$ if $4 \leq \Delta \leq 7$, and at most $\lfloor \frac{3\Delta}{2} \rfloor + 1$ otherwise.*

If this conjecture were true, then the bounds would be the best possible. The reader is referred to section 2.18 in [9] for more details. Although Conjecture 1 has been verified for several special classes of planar graphs, including the outerplanar graphs [11], it remains open for all values of $\Delta \geq 3$. The best known upper bounds are due to Molloy and Salavatipour [12, 13]: $\lceil 5\Delta/3 \rceil + 78$ for all Δ and $\lceil 5\Delta/3 \rceil + 25$ for $\Delta \geq 241$. Sharper results can be obtained for special classes of graphs. Dvořák et al. [5] proved that the chromatic number of the square of a planar graph G with a sufficiently large maximal degree is $\Delta + 1$ if the girth of G is at least 7 and is bounded by $\Delta + 2$ if the girth of G is 6. Independently, Borodin et al. [2] proved a similar result: The chromatic number of the square of a planar graph G with girth 7 and $\Delta \geq 30$ is $\Delta + 1$, and for every $\Delta \geq 3$, there exist planar graphs with girth 6 whose squares have chromatic number $\Delta + 2$.

A graph G is called *subcubic* if $\Delta(G) \leq 3$. We consider (not necessarily planar) subcubic graphs of small maximum average degree d and show the following bounds on the choosability of G^2 (section 3):

- If $d < 24/11$ and G does not contain a 5-cycle, then $\chi_\ell(G^2) \leq 4$.
- If $d < 7/3$, then $\chi_\ell(G^2) \leq 5$.
- If $d < 5/2$, then $\chi_\ell(G^2) \leq 6$.

For planar subcubic graphs of large girth g , this implies the following (section 4):

- If $g \geq 24$, then $\chi_\ell(G^2) \leq 4$.
- If $g \geq 14$, then $\chi_\ell(G^2) \leq 5$.
- If $g \geq 10$, then $\chi_\ell(G^2) \leq 6$.

Montassier and Raspaud [14] have shown similar results for coloring of the squares of planar subcubic graphs. They have shown that $\chi(G^2) \leq 5$ if $g \geq 14$ and $\chi(G^2) \leq 6$ if $g \geq 10$, and their proof can be easily generalized to work for choosability as well. They use some of the same reducible configurations that we do; however, their proofs of reducibility are simpler because they use the girth assumptions (not just the sparseness of the graph).

Regarding the lower bounds, we construct subcubic planar graphs G_1 and G_2 of girths $g(G_1) = 9$ and $g(G_2) = 5$ such that $\chi(G_1^2) = 5$ and $\chi(G_2^2) = 6$ (section 5).

The problem of finding the chromatic number of the square of a planar graph is NP-complete. It is NP-complete even to decide whether the square of a planar graph can be colored by seven colors [15]—note that this implies that determining the chromatic number of the square of a planar graph is NP-complete when restricted to graphs of maximum degree 6. It is also NP-complete to decide whether the square of a cubic (not necessarily planar) graph can be colored by four colors [7]. On the other hand, the problem can be solved in polynomial time for partial k -trees [17]. For further complexity and structural results we refer to the survey [3]. We are interested in the complexity of the problem for planar graphs of large girth. The graphs used in the reduction of Ramanathan [15] contain many triangles, and thus they do not provide any guidance in this direction.

We show that the problem of determining the chromatic number of the square of a graph is NP-complete even for subcubic planar graphs of girth 9 (section 6);

more precisely, we show that it is NP-complete to decide whether such a graph can be colored by four colors.

2. Notation. Let $\mathbb{N}$ denote the set of all nonnegative integers. A d -vertex is a vertex of degree d . The *maximum average degree* $d(G)$ of a graph G is the maximum of $2|E(H)|/|V(H)|$ over all induced subgraphs H of G .

A k -cycle is a cycle of length k . The *girth* g of G is the length of the shortest cycle in G , and it is infinity if G is a forest. A *thread* is an induced path in G whose vertices are all of degree 2 in G . A k -thread for $k \geq 1$ is a thread with k vertices. The *length* of a thread is the number of its vertices, i.e., a k -thread has length k .

If G is a connected plane graph, then let $F(G)$ be the set of all faces of G . Denote by $\ell(f)$ the length of a face f (we count multiple occurrences of an edge if f is not a simple cycle, which can happen if G is not 2-connected). An ℓ -face is a face of length ℓ .

We say that a graph G is k -minimal, if G^2 is not k -choosable, but the square of every proper subgraph of G is k -choosable. Obviously, a k -minimal graph is connected. A *configuration* is an induced subgraph of G , and we say that a configuration is k -reducible if it cannot appear in a k -minimal graph. Note that a k -reducible configuration is also k' -reducible for every $k' \geq k$.

We introduce the following notation to simplify the description of reducible configurations: Let $Y_{a,b,c}$ be a 3-vertex v together with an a -thread, a b -thread, and a c -thread incident to v such that the threads are vertex-disjoint and there are no edges between the end-vertices of the threads. Note, however, that the end-vertices may have a common neighbor. We allow the possibility that $a = 0$ or $b = 0$ or $c = 0$, and in this case v is adjacent to one or more vertices of degree 3.

Let $Y_{a,b} - j - Y_{c,d}$ be two 3-vertices v_1 and v_2 joined by a j -thread together with an a -thread and a b -thread incident to v_1 and a c -thread and a d -thread incident to v_2 . Again, the threads are vertex-disjoint and there are no edges between the end-vertices of the threads. We also allow that a, b, j, c , or d could be 0. Thus if $j = 0$, then v_1 and v_2 are adjacent.

Let G be a graph and let L be an assignment of lists to the vertices of G . We say that L is a p -list assignment for a given function $p : V(G) \rightarrow \mathbb{N}$ if $|L(v)| = p(v)$ for each vertex v of G . If p is a constant function with value k , we say that L is a k -list assignment.

3. Coloring sparse graphs. In this section we show that the squares of sparse subcubic graphs can be colored by few colors. We proceed by showing that if a subgraph induced by vertices close to any vertex v is too sparse, then it is k -reducible for given k . Thus we show that in the k -minimal graph, each such subgraph is dense, and thus that the k -minimal graph itself is dense, which is a contradiction.

We first identify the reducible configurations in subsection 3.1. Then, in subsection 3.2, we discuss the possible neighborhoods of vertices in a k -minimal graph. Finally, we derive the bounds on the density of k -minimal graphs for $k = 4, 5$, and 6.

3.1. Reducible configurations. In this section, we give k -reducible configurations for $k = 4, 5$, and 6. Let us first show that a k -minimal graph has minimum degree at least 2.

LEMMA 1. *A 1-vertex is a k -reducible configuration for each $k \geq 4$.*

Proof. Let G be a k -minimal graph and let L be a k -list assignment of G such that G^2 is not L -colorable. Assume for contradiction that G contains a 1-vertex v . By the k -minimality of G , the graph $(G - v)^2 = G^2 - v$ has an L -coloring c . The

vertex v has at most three neighbors in G^2 . We let $c(v)$ be a color that does not appear in the neighborhood of v in G^2 . Thus we extend c to an L -coloring of G^2 , a contradiction. $\square$

Let R be a configuration in a graph G . We define the function $s_R : V(R) \rightarrow \mathbb{N}$. The value $s_R(v)$ is the number of neighbors of v in G^2 that are not its neighbors in R^2 , i.e., $s_R(v) = \deg_{G^2}(v) - \deg_{R^2}(v)$. Note that some of such neighbors may belong to R .

Suppose that we want to show k -reducibility of a configuration R . We can use the following approach: We assume that R appears in a k -minimal graph G . We remove R from G and color the graph $G \setminus R$, which is always possible by k -minimality of G . We want to extend this coloring to the vertices of R . For each vertex v of R , we remove the colors used at the vertices in a distance of at most 2 from the list of v . At most $s_R(v)$ colors are removed in this way. Then we consider the coloring of R from these new lists. In the next lemma, we describe this idea more precisely.

LEMMA 2. *Let R be a configuration in a graph G and p a function from vertices of R such that $p(v) \leq k - s_R(v)$ for every vertex v of R . Suppose that*

- (a) *no two vertices of $G \setminus R$ have a common neighbor in R , and*
- (b) *no two vertices u and v of R such that $uv \notin E(R^2)$ have a common neighbor in $G \setminus R$.*

If R^2 can be colored from any p -list assignment L , then G is not k -minimal.

Proof. Let G be a k -minimal graph and let L be a k -list assignment such that G is not L -colorable. Assume for the contradiction that G contains the configuration R satisfying the assumptions of the lemma. Let $G' = G - R$. By the k -minimality of G , the graph G'^2 has an L -coloring c . We show that we can extend this coloring to G^2 , which is a contradiction.

We remove the colors used on the neighbors in G^2 from the lists of the vertices of R . The length of the new list of each vertex $v \in V(R)$ is at least $k - s_R(v) \geq p(v)$. We can color R^2 from these lists, thus obtaining the values of the coloring c on $V(R)$. By the assumptions of the lemma, the subgraph of G^2 induced by $V(R)$ is equal to R^2 and the subgraph induced by $V(G')$ is equal to G'^2 . Consequently, c is a proper L -coloring of G^2 , a contradiction. $\square$

Condition (a) of the above lemma is equivalent to saying that each vertex of R has at most one neighbor outside of R . This is satisfied in all of our applications of this lemma. Condition (b) is more complicated to satisfy. In the case $k = 4$, all the configurations for that lemma are used satisfy this property trivially. In the case of $k \geq 5$, we need to consider the cases when two separate vertices of R share a common neighbor outside of R .

Using $p(v) = k - s_R(v)$ in the applications of this lemma is not practical, since it requires us to know the exact neighborhood of R in G . Instead, we use upper bounds on s derived from the knowledge about the degrees of vertices in the neighborhood of R . In particular, we often use $p(v) = k - s'_R(v)$, where

$$s'_R(v) = 3(\deg_G(v) - \deg_R(v)) + \sum_{uv \in E(R)} (\deg_G(u) - \deg_R(u)).$$

A *block* of a graph G is its maximal 2-connected subgraph. A connected graph G is said to be a *Gallai tree* if each of the blocks of G is a complete graph or an odd cycle. In several proofs of the reducibility of configurations, we use the following theorem, which is proved independently by Borodin [1] and Erdős, Rubin, and Taylor [6].

THEOREM 3. *Let G be a connected graph with a list assignment L such that $|L(v)| \geq \deg(v)$ for each vertex v of G and G is not L -colorable. Then, $|L(v)| = \deg(v)$ for every v and G is a Gallai tree. Moreover, if G is 2-connected, then the lists $L(v)$ of all the vertices v of G are the same.*

Let us show a stronger version of this theorem for a particular graph.

LEMMA 4. *Let G be a path on four vertices $v_1v_2v_3v_4$ and let L be a list assignment to the vertices of G such that $|L(v_1)| = |L(v_4)| = 2$ and $|L(v_2)| = |L(v_3)| = 3$. Then G^2 has two L -colorings c_1 and c_2 such that $c_1(v_2) \neq c_2(v_2)$.*

Proof. Since G^2 is not a Gallai tree, at least one coloring c_1 of G^2 exists by Theorem 3.

Let $a_1 = c_1(v_2)$ and $L(v_2) = \{a_1, a_2, a_3\}$. Let us assume for the sake of contradiction that all colorings of G use the color a_1 on the vertex v_2 . This means that if we color v_2 by a_2 , then this coloring cannot be extended. Let $L'(v_1) = L(v_1) \setminus \{a_2\}$, $L'(v_3) = L(v_3) \setminus \{a_2\}$, and $L'(v_4) = L(v_4) \setminus \{a_2\}$. By Theorem 3, if v_1 , v_3 , and v_4 cannot be colored from lists L' , then $|L'(v_1)| = |L'(v_4)| = 1$ and $|L'(v_3)| = 2$. But then $a_2 \in L(v_1) \cap L(v_4)$. Now observe that the coloring c_2 defined by $c_2(v_1) = c_2(v_4) = a_2$, $c_2(v_2) = a_3$, and $c_2(v_3) \in L(v_3) \setminus \{a_2, a_3\}$ satisfies the requirements of the lemma. $\square$

Let us first consider cycles that contain at most one 3-vertex in k -minimal graphs.

LEMMA 5. *Let R be a configuration formed by a cycle $v_1v_2 \cdots v_s$ such that $v_2, v_3, \dots, v_s$ are 2-vertices. Then R is k -reducible for $k \geq 4$ unless $k = 4$ and $s = 5$.*

Proof. Since there is at most one edge joining R and $G \setminus R$, all the assumptions of Lemma 2 are trivially satisfied. It suffices to show 4-reducibility if $s \neq 5$ and 5-reducibility if $s = 5$, and we may assume that v_1 is a 3-vertex.

Suppose first that $s \neq 5$. We use the function p defined by $p(v_1) = 1$, $p(v_2) = p(v_s) = 3$, and $p(v_i) = 4$ for the remaining vertices. Let L be any p -list assignment. We need to show that R^2 can be colored from L . Observe that this is the case if $s = 3$ or $s = 4$.

In case $s > 5$, let $c(v_1)$ be the single color in $L(v_1)$. Let $p'(v_2) = p'(v_s) = 2$, $p'(v_3) = p'(v_{s-1}) = 3$, and $p'(v_i) = 4$ for the remaining vertices, and let L' be an arbitrary p' -list assignment such that $L'(v_i) \subseteq L(v_i) \setminus \{c(v_1)\}$ for $i = 2, 3, s-1$; and s and $L'(v_i) = L(v_i)$ for the remaining vertices. We need to find a coloring of vertices $v_2, \dots, v_s$ from the lists L' .

If $s > 6$, we choose $c(v_2) \in L'(v_2)$ and $c(v_s) \in L'(v_s)$ so that $c(v_2) \neq c(v_s)$. We remove the color $c(v_2)$ from the lists $L'(v_3)$ and $L'(v_4)$ and the color $c(v_s)$ from the lists $L'(v_{s-1})$ and $L'(v_{s-2})$ (note that all these vertices are mutually distinct, since $s > 6$). Finally, we color the subgraph of R^2 induced by the path $v_3 \cdots v_{s-1}$ from the new lists using Theorem 3, thus obtaining a proper coloring c .

Finally, consider the case $s = 6$. If $L'(v_2) \neq L'(v_6)$, we select $c(v_2)$ from $L'(v_2) \setminus L'(v_6)$, remove $c(v_2)$ from the lists of v_3 and v_4 , and color the vertices v_3, v_4, v_5 , and v_6 using Lemma 4. Therefore, suppose that $L'(v_2) = L'(v_6) = \{a_1, a_2\}$. If $L'(v_2) \subset L'(v_3)$ and $L'(v_2) \subset L'(v_5)$, then set $c(v_2) = c(v_5) = a_1$, $c(v_3) = c(v_6) = a_2$ and choose $c(v_4)$ from $L'(v_4) \setminus L'(v_2)$ arbitrarily. If this is not the case, we may assume that $a_1 \notin L'(v_3)$. Then we set $c(v_2) = a_1$, $c(v_6) = a_2$, remove the color a_1 from the list of v_4 and the color a_2 from the lists of v_4 and v_5 , and then color v_3, v_4 , and v_5 from their lists using Theorem 3.

In the case $s = 5$, we let $p(v_1) = 2$, $p(v_2) = p(v_5) = 4$ and $p(v_3) = p(v_4) = 5$. Note that we can color the vertices v_1, v_2, v_5, v_3 , and v_4 one by one in this order. $\square$

We are now ready to identify several 4-reducible configurations.

LEMMA 6. *The following configurations are 4-reducible:*

- (1) *a 6-thread;*
- (2) $Y_{1,4,5};$
- (3) $Y_{2,3,4};$
- (4) $Y_{5,5} - 0 - Y_{4,5};$ *and*
- (5) *a 7-cycle $v_1v_2 \cdots v_7$ such that v_1 incident to a 2-thread x_1x_2 , the vertex v_2 incident to a 2-thread y_1y_2 (where the 2-threads are vertex-disjoint), and each v_i is a 2-vertex for $3 \leq i \leq 7$.*

Proof. Let us prove the reducibility of each configuration separately. Let R be one of the configurations. We use Lemma 2 for the configuration R' obtained from R by removing all 2-vertices that have degree 1 in R , i.e., those that have a neighbor in $G - R$. We remove the vertices x_2 and y_2 in case (5) even if they are adjacent. Note that we then know that the neighbors of R' in $G - R'$ are mutually distinct 2-vertices, and thus the assumptions of Lemma 2 are trivially satisfied for R' . We can also use the function p defined for vertices of R' as

$$p(v) = 4 - 2(\deg_G(v) - \deg_{R'}(v)) - \sum_{uv \in E(R')} (\deg_G(u) - \deg_{R'}(u)).$$

It suffices to show that the configuration R' can be colored from any p -list assignment L . This will imply that R' with the additional assumptions on the degrees of surrounding vertices cannot appear in a 4-minimal graph, and hence that R is reducible.

- (1) Let R be a 6-thread. In this case, R' is a 4-thread $v_1v_2v_3v_4$ with $p(v_1) = p(v_4) = 2$ and $p(v_2) = p(v_3) = 3$. By Theorem 3, R'^2 can be colored from the lists L .
- (2) Let R be $Y_{1,4,5}$. In this case, the configuration R' is a path $u_3u_2u_1vw_1w_2w_3w_4$, with $p(w_4) = p(u_3) = p(v) = 2$, $p(w_1) = p(w_3) = p(u_1) = p(u_2) = 3$, and $p(w_2) = 4$.

First, we try to construct an L -coloring of R'^2 in the following way. We fix a coloring c' of the subgraph of R'^2 induced by vertices v , u_1 , u_2 , and u_3 . Notice that such a coloring always exists by Lemma 4. We choose $c'(w_1) \in L(w_1) \setminus \{c'(v), c'(u_1)\}$, and afterwards set $L'(w_2) = L(w_2) \setminus \{c'(v), c'(w_1)\}$, $L'(w_3) = L(w_3) \setminus \{c'(w_1)\}$, and $L'(w_4) = L(w_4)$. Each of the lists L' contains at least two colors. If we can color w_2 , w_3 , and w_4 from lists L' , then we obtain a proper coloring of R'^2 . If this is not the case, then by Theorem 3, $L'(w_2) = L'(w_3) = L'(w_4) = \{a_1, a_2\}$ for some two colors a_1 and a_2 . Let $a_3 = c'(w_1)$, $a_4 = c'(v)$, and $a_5 = c'(u_1)$. Then $L(w_3) = \{a_1, a_2, a_3\}$ and $L(w_2) = \{a_1, a_2, a_3, a_4\}$.

Note that if we can choose color for w_1 distinct from a_3 , i.e., if $|L(w_1) \setminus \{a_4, a_5\}| > 1$, then we are able to extend the coloring to the rest of the configuration. Therefore, let us assume that $L(w_1) = \{a_3, a_4, a_5\}$. The colors $a_4 = c'(v)$ and $a_5 = c'(u_1)$ such that the coloring c' cannot be extended to w_1 , w_2 , w_3 , and w_4 are determined uniquely. By Lemma 4, we can choose a coloring c of v , u_1 , u_2 , and u_3 such that $c(u_1) \neq a_5$. Hence, we can extend c to R'^2 .

- (3) Let R be $Y_{2,3,4}$. In this case, the configuration R' is $Y_{1,2,3}$. Let v be the 3-vertex of R' , and let u_1 , w_1w_2 , and $y_1y_2y_3$ be the threads incident to v , where u_1 , w_1 , and y_1 are adjacent to v . The lengths of the lists are $p(u_1) = p(w_2) = p(y_3) = 2$, $p(w_1) = p(y_2) = p(v) = 3$, and $p(y_1) = 4$.

Let us first fix a coloring c' of the subgraph of R'^2 induced by u_1, v, w_1 , and w_2 , which exists by Lemma 4. Let $L'(y_1) = L(y_1) \setminus \{c'(u_1), c'(w_1), c'(v)\}$, $L'(y_2) = L(y_2) \setminus \{c'(v)\}$, and $L'(y_3) = L(y_3)$. Note that $|L'(y_1)| \geq 1$, $|L'(y_2)| \geq 2$, and $|L'(y_3)| = 2$. If y_1, y_2 , and y_3 can be colored from lists L' , we obtain a proper coloring of R'^2 . Assume this is not the case. Then $|L'(y_2)| = 2$ and $L'(y_1) \subseteq L'(y_2) = L'(y_3)$. This implies that $L(y_2) = L(y_3) \cup \{c'(v)\}$. But by Lemma 4 we may choose a coloring c of a subgraph of R'^2 induced by u_1, v, w_1 , and w_2 such that $c(v) \neq c'(v)$, and such a coloring can be extended to R'^2 .

- (4) Let R be $Y_{5,5} - 0 - Y_{4,5}$. The configuration R' is $Y_{4,4} - 0 - Y_{3,4}$. Let v_1 and v_2 be the two adjacent 3-vertices of R' , and let $u_1 u_2 u_3 u_4, w_1 w_2 w_3 w_4, y_1 y_2 y_3 y_4$, and $z_1 z_2 z_3$ be the threads of R' , where u_1 and w_1 are adjacent to v_1 , and y_1 and z_1 are adjacent to v_2 . Notice that $p(u_4) = p(w_4) = p(y_4) = p(z_3) = 2$, $p(u_3) = p(w_3) = p(y_3) = p(z_2) = 3$, and $p(x) = 4$ for every other vertex x of R' .

Suppose that we have a coloring c' of the square of the path

$$P = w_4 w_3 w_2 w_1 v_1 v_2 z_1 z_2 z_3,$$

and suppose that this coloring cannot be extended to a coloring of R'^2 . The colorings of the threads $P_u = u_1 u_2 u_3 u_4$ and $P_y = y_1 y_2 y_3 y_4$ are independent, because the distance of u_1 and y_1 is 3. Assume that c' cannot be extended to P_u . Similarly as in the proof of the second claim of this lemma, we conclude that the lists of vertices of P_u uniquely determine the color $a_u = c'(v_1)$. Also, if c' cannot be extended to P_y , then the lists of vertices of P_y uniquely determine the color $a_y = c'(v_2)$. Let $L'(v_1) = L(v_1) \setminus \{a_u\}$, $L'(v_2) = L(v_2) \setminus \{a_y\}$, and $L'(x) = L(x)$ for the other vertices of P . If we can find an L' -coloring c of P^2 , then c can be extended to a proper coloring of R'^2 .

Let us choose a color $a_1 \in L'(z_2) \setminus L'(z_3)$. Using Theorem 3, fix an L' -coloring c of the square of the path $w_4 w_3 w_2 w_1 v_1 v_2$ such that $c(v_2) \neq a_1$. We extend c to the vertices z_1, z_2 , and z_3 in the following way. We assign lists $L''(z_1) = L'(z_1) \setminus \{c(v_1), c(v_2)\}$, $L''(z_2) = L'(z_2) \setminus \{c(v_2)\}$, and $L''(z_3) = L'(z_3)$ to these vertices. Note that each of these lists has size at least 2. If an L'' -coloring of the square of $z_1 z_2 z_3$ exists, it extends c to a proper L' -coloring of P^2 . If such a coloring does not exist, then by Theorem 3, $L''(z_1) = L''(z_2) = L''(z_3)$. Hence, $L'(z_2) = L'(z_3) \cup \{c(v_2)\}$. But this is impossible, because $c(v_2) \neq a_1$.

- (5) Let R be the last configuration given in the lemma. The configuration R' is induced by vertices $v_1, \dots, v_7, x_1$, and y_1 , and the lengths of the lists are $p(x_1) = p(y_1) = 2$, $p(v_1) = p(v_2) = 3$, and 4 for the remaining vertices. Let us construct the coloring c from the lists L .

We first color the subgraph induced by vertices x_1, v_1, v_2 , and y_1 , which is possible by Lemma 4. In the case when $L(v_4) \setminus L(v_5)$ contains precisely one element, say a , we may also assume that the color $c(v_2)$ is distinct from a . Let us choose colors $c(v_3)$ and $c(v_7)$ from their lists such that they extend this coloring. Then, we construct the assignment of lists to the rest of the vertices in the following way: $L'(v_6) = L(v_6) \setminus \{c(v_1), c(v_7)\}$, $L'(v_5) = L(v_5) \setminus \{c(v_3), c(v_7)\}$, and $L'(v_4) = L(v_4) \setminus \{c(v_2), c(v_3)\}$. If we can extend the coloring c to these vertices from lists L' , we properly color the whole configuration R'^2 . By Theorem 3, this is possible unless $L'(v_4) = L'(v_5) = L'(v_6) = S$ and the length of S is exactly 2. This implies that $L(v_4) = S \cup \{c(v_2), c(v_3)\}$ and

$L(v_5) = S \cup \{c(v_3), c(v_7)\}$. But this means that $c(v_2)$ is the single color of $L(v_4) \setminus L(v_5)$, which contradicts the choice of the coloring of vertices x_1 , v_1 , v_2 , and y_1 . $\square$

Now let us focus on 5-reducible configurations.

LEMMA 7. *The following two configurations are 5-reducible:*

- (1) a 3-thread, and
- (2) $Y_{1,2,2}$.

Proof. Let us prove the reducibility of each configuration R separately. We use Lemma 2. Let L be an arbitrary p -list assignment to the vertices of R , where $p(v) = 5 - s'_R(v)$ for each vertex v of R . In order to be able to apply the lemma, we need to consider the case when two of the vertices of R share a neighbor outside of R , and to show that R can be colored from any p -list assignment.

- (1) The configuration R is a 3-thread $v_1v_2v_3$ with the lengths of lists $p(v_1) = p(v_3) = 2$ and $p(v_2) = 3$. If v_1 and v_3 have a common neighbor outside of R , then R together with this vertex forms a 4-cycle with at least three 2-vertices. Such a configuration is reducible by Lemma 5. Also, if v_1 and v_3 do not have a common neighbor outside R , then we can apply Lemma 2, since R can be colored from any p -list assignment by Theorem 3.
- (2) Let v be the 3-vertex of the configuration and let the threads be u_1 , w_1w_2 , and y_1y_2 , where u_1 , w_1 , and y_1 are the neighbors of v . Let u_2 , w_3 , and y_3 be the neighbors (not necessarily distinct) of u_1 , w_2 , and y_2 outside of the configuration, respectively. Let L be any assignment of lists of length 5 to the vertices of a 5-minimal graph G that contains this configuration and let c be a coloring of the square of $G' = G \setminus \{w_1, v, y_1\}$ from these lists. Since y_2 is a 1-vertex in G' , it has at most three neighbors in G'^2 , and hence we may select one of at least two colors in $L(y_2)$ that are different from the colors of these neighbors for y_2 . Therefore, we may assume that if $c(y_3) \in \{c(w_2), c(w_3)\}$, then $c(y_2) \notin \{c(w_2), c(w_3)\}$.
Let $L'(w_1) = L(w_1) \setminus \{c(w_2), c(w_3), c(u_1)\}$, $L'(y_1) = L(y_1) \setminus \{c(y_2), c(y_3), c(u_1)\}$, and $L'(v) = L(v) \setminus \{c(u_1), c(u_2), c(y_2), c(w_2)\}$. If $|L'(w_1)| = 2$, then $L'(w_1) \neq L'(y_1)$, since otherwise $\{c(w_2), c(w_3)\} = \{c(y_2), c(y_3)\}$, which contradicts our choice of $c(y_2)$. It follows that we can assign mutually distinct colors from the lists L' to y_1 , v , and w_1 , and thus extend c to a proper coloring of G^2 . $\square$

Finally, we identify the 6-reducible configurations.

LEMMA 8. *The following configurations are 6-reducible:*

- (1) a 2-thread;
- (2) a 3-cycle containing two 3-vertices and one 2-vertex;
- (3) a 4-cycle containing two nonadjacent 3-vertices and two 2-vertices; and
- (4) $Y_{1,1} - 1 - Y_{0,1}$.

Proof. Let us prove the reducibility of each configuration R separately. In the first three cases, we use Lemma 2 directly. Let L be an arbitrary p -list assignment to the vertices of R , where $p(v) = 6 - s'_R(v)$ for each vertex v of R . Note that in each of these cases, R^2 is a complete graph; hence regardless of whether any vertices of R share a neighbor outside of R , the assumptions of Lemma 2 are satisfied.

- (1) The configuration R is a 2-thread v_1v_2 such that $p(v_1) = p(v_2) = 2$. The graph R^2 can obviously be colored from L .
- (2) Let v_1 , v_2 , and v_3 be the vertices of the configuration R , where v_3 is the 2-vertex. Then $p(v_1) = p(v_2) = 2$ and $p(v_3) = 4$. The graph R^2 can be colored by Theorem 3.

- (3) Let v_1, v_2, v_3 , and v_4 be the vertices of the configuration R , where v_2 and v_4 are the 2-vertices. Then $p(v_1) = p(v_3) = 3$ and $p(v_2) = p(v_4) = 4$. Again, the graph R^2 can be colored by Theorem 3.
- (4) For this configuration, we do not use Lemma 2. Let v_1 and v_2 be the 3-vertices of the configuration, with the common neighbor z . The 1-threads are u_1, w_1 , and y_1 , where u_1 and w_1 are the neighbors of v_1 and y_1 is a neighbor of v_2 . Let G be the 6-minimal graph in that this configuration appears, and let c be a coloring of the square of the graph $G' = G \setminus \{v_1, z, v_2, y_1\}$. Since u_1 is a 1-vertex in G' , it has at least three colors in its list that are not used on any of its neighbors in G'^2 ; hence we may choose its color so that $c(u_1) \neq c(w_1)$. For a vertex $x \in \{v_1, z, v_2, y_1\}$, let $L'(x)$ be the list be obtained from $L(x)$ by removing the colors of its neighbors in G^2 that are colored by c . The sizes of the lists are $|L'(v_1)| \geq 2$, $|L'(z)| \geq 3$, $|L'(v_2)| \geq 2$, and $|L'(y_1)| \geq 2$. Note that Lemma 4 implies that the square of the path $v_1zv_2y_1$ can be colored from the lists L' . This coloring extends c to a proper coloring of the whole G^2 . $\square$

3.2. Neighborhoods of vertices. Let us consider the possible neighborhoods of 3-vertices in k -minimal graphs. We prove that these neighborhoods cannot contain too many 2-vertices, which we later use to show that any k -minimal graph must be dense. All of the following lemmata are proved by a straightforward case analysis using the results of the previous subsection.

Given a graph G and a vertex v , let $G_2(v)$ be the subgraph of G induced by v and all 2-vertices reachable from v by paths consisting only from 2-vertices.

LEMMA 9. *Let G be a 4-minimal graph different from a 5-cycle and v a 3-vertex in G such that v is not adjacent to any 3-vertex. Then $G_2(v)$ is a subgraph of $Y_{1,3,5}$ or $Y_{1,4,4}$ or $Y_{2,2,5}$ or $Y_{3,3,3}$.*

Proof. Let x, y , and z be the 3-vertices (not necessarily distinct) that are joined by threads with v . By the 4-minimality, G cannot contain a 5-cycle, and any other cycle containing at most one 3-vertex is reducible by Lemma 5. Therefore, x, y , and z are distinct from v . Let l_x, l_y , and l_z be the lengths of the threads joining x, y , and z with v , and assume $1 \leq l_x \leq l_y \leq l_z$. By Lemma 6(1), $l_z \leq 5$, and by Lemma 6(3), $l_x \leq 3$. If $l_x = 1$, then $l_z < 5$ or $l_y < 4$ by Lemma 6(2), and $G_2(v)$ is a subgraph of $Y_{1,3,5}$ or $Y_{1,4,4}$. If $2 \leq l_x \leq 3$, then $l_x = l_y = 2$ (and $G_2(v)$ is a subgraph of $Y_{2,2,5}$) or $l_z \leq 3$ (and $G_2(v)$ is a subgraph of $Y_{3,3,3}$). $\square$

LEMMA 10. *Let G be a 4-minimal graph different from a 5-cycle and let v and w be two adjacent 3-vertices in G . Then, both $G_2(v)$ and $G_2(w)$ are subgraphs of $Y_{0,5,5}$, and at least one of the following conditions holds:*

- both $G_2(v)$ and $G_2(w)$ are subgraphs of $Y_{0,4,5}$; or
- $G_2(v)$ or $G_2(w)$ is a subgraph of $Y_{0,3,5}$; or
- $G_2(v)$ or $G_2(w)$ is a subgraph of $Y_{0,4,4}$.

Proof. Let x and y be the 3-vertices joined by threads with v and let s and t be the 3-vertices joined by threads with w . Let l_x, l_y, l_s , and l_t be the lengths of these threads, and assume $l_x \leq l_y \leq l_t$ and $l_s \leq l_t$. The vertices x and y are distinct from v and the vertices s and t are distinct from w by Lemma 5 and by the minimality of G . By Lemma 6(1), $l_t \leq 5$ and both $G_2(v)$ and $G_2(w)$ are subgraphs of $Y_{0,5,5}$.

Suppose that neither of the conditions of the lemma is satisfied by v and w . Then $l_y = l_s = l_t = 5$ and $4 \leq l_x \leq 5$. But if s and t are distinct from v , then this induces a copy of $Y_{5,5}-0-Y_{4,5}$ in G , which is reducible by Lemma 6(4). Thus we may assume $s = v$. Hence, v and w are a part of a 7-cycle $vwx_1 \cdots x_5$, where x_i are 2-vertices.

However, since $l_x \geq 4$, $l_y \geq 4$, $l_z \geq 4$, the vertices v and w are additionally incident to vertex-disjoint 2-threads, and the configuration is reducible by Lemma 6(5). $\square$

Let us now consider neighborhoods of vertices in 5-minimal graphs.

LEMMA 11. *Let G be a 5-minimal graph and v a 3-vertex in G . Then, $G_2(v)$ is a subgraph of $Y_{0,2,2}$ or $Y_{1,1,2}$.*

Proof. Let x , y , and z be the 3-vertices (not necessarily distinct) that are joined by threads with v . By Lemma 5, none of x , y , and z are equal to v . Let l_x , l_y , and l_z be the lengths of the threads joining x , y , and z with v , and assume $l_x \leq l_y \leq l_z$. By Lemma 7(1), $l_z \leq 2$, and by Lemma 7(2), $l_x = 0$ (then $G_2(v)$ is a subgraph of $Y_{0,2,2}$) or $l_y \leq 1$ (and $G_2(v)$ is a subgraph of $Y_{1,1,2}$). $\square$

For vertices in 6-minimal graphs, the situation may be a bit more complicated.

LEMMA 12. *Let G be a 6-minimal graph and v a 3-vertex in G . Then, either*

- $G_2(v)$ is a subgraph of $Y_{0,1,1}$, or
- $G_2(v)$ is $Y_{1,1,1}$, the 3-vertices x , y , and z incident with $G_2(v)$ are mutually distinct, and all the graphs $G_2(x)$, $G_2(y)$, and $G_2(z)$ are equal to $Y_{0,0,1}$.

Proof. Let x , y , and z be the 3-vertices (not necessarily distinct) that are joined by threads with v . By Lemma 5, x , y , and z are distinct from v . Let l_x , l_y , and l_z be the lengths of the threads joining x , y , and z with v , and again assume $l_x \leq l_y \leq l_z$. By Lemma 8(1), $l_z \leq 1$. If $l_x = 0$, then $G_2(v)$ is a subgraph of $Y_{0,1,1}$. Thus assume that $l_x = 1$ and $G_2(v)$ is $Y_{1,1,1}$. By Lemma 8(3), the vertices x , y , and z are mutually distinct. If $G_2(x)$ is not equal to $Y_{0,0,1}$, then neighborhoods of v and x form a supergraph of $Y_{1,1}-1-Y_{0,1}$, which is reducible by Lemma 8(4). Thus $G_2(x)$ (and similarly $G_2(y)$ and $G_2(z)$) is equal to $Y_{0,0,1}$. $\square$

3.3. Final step. In this section we combine the results of the previous subsections and prove the main results.

If G is a subcubic graph, let $n_2(G)$ be the number of 2-vertices of G and let $n_3(G)$ be the number of 3-vertices of G . Let $V_3(G)$ be the set of 3-vertices of G . By Lemmata 9–12, $G_2(v)$ is equal to $Y_{a,b,c}$ for some a , b , and c whenever G is a k -minimal graph for $k \in \{4, 5, 6\}$. We let $d_2(v) = a + b + c$. Note that

$$\sum_{v \in V_3} d_2(v) = 2n_2.$$

Let G be a 4-minimal graph and let v be a 3-vertex in G such that $G_2(v)$ is distinct from $Y_{0,5,5}$. Let $P(v)$ be the set of all 3-vertices u adjacent to v such that $G_2(u)$ is $Y_{0,5,5}$. Then, we define

$$d_3(v) = d_2(v) + \sum_{u \in P(v)} d_2(u) = d_2(v) + 10|P(v)|.$$

Let us show some estimates on d_2 and d_3 in the minimal graphs.

LEMMA 13. *Let G be a 4-minimal graph and let v be a 3-vertex of G such that $G_2(v)$ is distinct from $Y_{0,5,5}$. Then, $d_3(v) \leq 9(|P(v)| + 1)$.*

Proof. Let $P(v) = \{u_1, \dots, u_s\}$ with $s \leq 3$. Note that by Lemmata 9 and 10, $d_2(x) \leq 10$ for every 3-vertex x of G . Let us consider several cases regarding s :

$s = 0$: If v is not adjacent to any 3-vertex, then $d_2(v) \leq 9$ by Lemma 9. Otherwise, $G_2(v)$ is a subgraph of $Y_{0,5,5}$ by Lemma 10. The graph $G_2(v)$ is distinct from $Y_{0,5,5}$, and thus $d_2(v) \leq 9$ in this case as well.

$s = 1$: By Lemma 10, $G_2(v)$ is a subgraph of $Y_{0,3,5}$ or $Y_{0,4,4}$. Therefore, $d_3(v) = d_2(v) + 10 \leq 18$.

$s = 2$: Since $G_2(v)$ is a subgraph of $Y_{0,5,5}$ and v has at least two neighbors that are 3-vertices, $d_2(v) \leq 5$. Consequently, $d_3(v) = d_2(v) + 20 \leq 27$.

$s = 3$: In this case $d_2(v) = 0$ and $d_3(v) = 30 < 36$. $\square$

LEMMA 14. *Let G be a 6-minimal graph. If u and v are two 3-vertices of G joined by a path consisting of 2-vertices, then $d_2(u) + d_2(v) \leq 4$.*

Proof. We use Lemma 12. If $G_2(v)$ is $Y_{1,1,1}$, then $G_2(u)$ is $Y_{0,0,1}$ and $d_2(u) + d_2(v) = 4$. One can apply a similar argument if $G_2(u)$ is $Y_{1,1,1}$. If neither $G_2(u)$ nor $G_2(v)$ is $Y_{1,1,1}$, then both of them are subgraphs of $Y_{0,1,1}$ and $d_2(u) + d_2(v) \leq 4$. $\square$

We are now ready to prove the main results.

THEOREM 15. *Let G be a subcubic graph of maximum average degree $d < 24/11$. The graph G^2 is 4-choosable if and only if G does not contain a 5-cycle.*

Proof. If G contains a 5-cycle, then G^2 contains a clique of size 5 and therefore G^2 is not 4-colorable. For the other implication, assume for contradiction that G does not contain a 5-cycle and that G^2 is not 4-choosable. Hence G contains a 4-minimal subgraph G' whose average degree is at most $d < 24/11$. We show that the average degree of any 4-minimal graph is at least $24/11$, thus obtaining a contradiction.

By the 4-minimality, G' is connected and contains at least one 3-vertex. Let U be the set of all 3-vertices v of G' such that $G'_2(v)$ is not $Y_{0,5,5}$. Let us now calculate the following sum in two ways:

$$S = \sum_{v \in U} d_3(v).$$

Since $Y_{5,5} - 0 - Y_{5,5}$ is reducible,

$$S = \sum_{v \in V_3(G')} d_2(v) = 2n_2.$$

On the other hand, by Lemma 13,

$$S \leq \sum_{v \in U} 9(|P(v)| + 1) = 9n_3(G').$$

Therefore, $2n_2 = S \leq 9n_3$ and we infer that $n_2 \leq 4.5n_3$. This means that the average degree of G' is

$$\frac{2n_2 + 3n_3}{n_2 + n_3} = 2 + \frac{n_3}{n_2 + n_3} \geq 2 + \frac{n_3}{5.5n_3} = \frac{24}{11}. \quad \square$$

THEOREM 16. *Let G be a subcubic graph of maximum average degree $d < 7/3$. Then, G^2 is 5-choosable.*

Proof. Assume for contradiction that G^2 is not 5-choosable. Then G contains a 5-minimal subgraph G' whose average degree is at most $d < 7/3$. We show that the average degree of any 5-minimal graph is at least $7/3$, thus obtaining a contradiction.

By the 5-minimality, G' is connected and contains at least one 3-vertex. Let us now consider the following sum:

$$S = \sum_{v \in V_3(G')} d_2(v) = 2n_2(G').$$

By Lemma 11, $d_2(v) \leq 4$ for each 3-vertex of G' . Thus, $2n_2(G') = S \leq 4n_3(G')$ and we get that $n_2(G') \leq 2n_3(G')$. This means that the average degree of G' is

$$\frac{2n_2 + 3n_3}{n_2 + n_3} = 2 + \frac{n_3}{n_2 + n_3} \geq 2 + \frac{n_3}{3n_3} = \frac{7}{3}. \quad \square$$

THEOREM 17. *Let G be a subcubic graph of maximum average degree $d < 5/2$. Then G^2 is 6-choosable.*

Proof. Assume for contradiction that G^2 is not 6-choosable. Then G contains a 6-minimal subgraph G' whose average degree is at most $d < 5/2$. We show that the average degree of any 6-minimal graph is at least $5/2$, thus obtaining a contradiction.

By the 6-minimality, G' is connected and contains at least one 3-vertex. Let X be the set of all unordered pairs of 3-vertices $\{u, v\}$ such that u and v are connected by a thread. The length of the thread is at most 1 by Lemma 8(1). Note that two 3-vertices u and v are connected by at most one such path, since otherwise the configuration formed by u , v , and the two paths is reducible by Lemma 8(2) or (3). Let us now calculate the following sum in two ways:

$$S = \sum_{\{u,v\} \in X} [d_2(u) + d_2(v)].$$

Each vertex v appears in exactly three pairs in X (since a cycle with at most one 3-vertex is excluded by Lemma 5); thus the sum is equal to

$$S = 3 \sum_{v \in V_3(G')} d_2(v) = 6n_2(G').$$

On the other hand, consider an arbitrary pair $\{u, v\} \in X$. By Lemma 14, $d_2(u) + d_2(v) \leq 4$. Hence, $S \leq 4|X| = 6n_3(G')$. Thus, $6n_2(G') = S \leq 6n_3(G')$ and we get that $n_2(G') \leq n_3(G')$. This means that the average degree of G' is

$$\frac{2n_2 + 3n_3}{n_2 + n_3} = 2 + \frac{n_3}{n_2 + n_3} \geq 2 + \frac{n_3}{2n_3} = \frac{5}{2}. \quad \square$$

4. Coloring planar graphs of large girth. In this section we show bounds on the choosability of planar subcubic graphs of large girth. A well-known observation is that such graphs have a small maximum average degree.

LEMMA 18. *Let G be a planar graph of girth at least g . Then $d(G) < 2 + 4/(g-2)$.*

Proof. Since every induced subgraph of G is a planar graph of girth at least g , it suffices to show that $d = 2|E(G)|/|V(G)| < 2g/(g-2)$. We may also assume that G is connected. If G is a tree, then obviously $d(G) < 2$. So assume that G has a finite girth. Let $e = |E(G)|$, $v = |V(G)|$, and $f = |F(G)|$. By the Euler formula, $e + 2 = v + f$. The girth of G is at least g , and because G is not a tree every facial walk in G contains a cycle. Therefore, $2e \geq fg$. We obtain

$$\begin{aligned} e &< e + 2 \leq \frac{2e}{d} + \frac{2e}{g}, \\ 1 &< \frac{2}{d} + \frac{2}{g}, \\ d &< 2 + \frac{4}{g-2}. \quad \square \end{aligned}$$

Together with Theorems 15–17, this implies the following.

COROLLARY 19. *Let G be a planar subcubic graph of girth g . Then*

- if $g \geq 24$, then $\chi_\ell(G^2) \leq 4$.
- if $g \geq 14$, then $\chi_\ell(G^2) \leq 5$.
- if $g \geq 10$, then $\chi_\ell(G^2) \leq 6$.

FIG. 1. A 5-minimal graph.

FIG. 2. The graph H_4 .

5. Lower bounds. In this section, we show lower bounds on the girth of the planar subcubic graphs for which the analogue of Corollary 19 holds. It is easy to find a 5-minimal graph of girth 5 as follows.

PROPOSITION 20. *The graph from Figure 1 has girth 5 and its square is not 5-colorable.*

We also show that there exists a 4-minimal graph of girth 9. First, we need to prove several auxiliary lemmata. In their proofs, the following notation is used (where H is the fixed graph that we are trying to color): $(u, v, w) \rightarrow c(x) = k$ stands for the statement “The vertices u , v , and w are the neighbors of vertex x in H^2 . Let $c : V(H) \rightarrow \{1, 2, 3, 4\}$ be a proper coloring of H^2 such that $c(u)$, $c(v)$, and $c(w)$ are three mutually different colors distinct from color k . Then necessarily $c(x) = k$.”

LEMMA 21. *Let H_4 be the graph in Figure 2. Then there is no proper coloring $c : V(H_4) \rightarrow \{1, 2, 3, 4\}$ of H_4^2 such that $c(x_1) = c(x_2)$ and $\{c(y_1), c(z_1)\} \neq \{c(y_2), c(z_2)\}$.*

Proof. Without loss of generality, we may assume that $c(x_1) = c(x_2) = 1$, $c(y_1) = c(y_2) = 2$, $c(z_1) = 3$, and $c(z_2) = 4$. Then $(x_1, y_1, z_1) \rightarrow c(u_1) = 4$, and similarly $(x_2, y_2, z_2) \rightarrow c(u_4) = 3$, and then $(x_1, u_1, u_4) \rightarrow c(u_2) = 2$ and $(x_2, u_1, u_4) \rightarrow c(u_3) = 2$. But u_2 and u_3 are neighbors in H_4^2 , and thus the proper coloring does not exist. $\square$

LEMMA 22. *The graph $G_{\neq}(x_1, x_2)$ in Figure 3 has the following properties:*

1. $G_{\neq}$ is a planar subcubic graph.
2. The distance between the vertices x_1 and x_2 is 6.
3. The girth of $G_{\neq}$ is 9.
4. Every proper coloring $c : V(G_{\neq}) \rightarrow \{1, 2, 3, 4\}$ of $G_{\neq}^2$ satisfies $c(x_1) \neq c(x_2)$.

Proof. The first three properties are clear from the figure, and thus it is sufficient to prove the last property. For the contradiction suppose that $c : V(G_{\neq}) \rightarrow \{1, 2, 3, 4\}$ is a proper coloring of $G_{\neq}^2$ such that $c(x_1) = c(x_2)$. We may assume that $c(x_1) = c(x_2) = 1$.

First, we show that $c(y_1) \neq c(y_2)$. If $c(y_1) = c(y_2)$, then we may assume that $c(y_1) = c(y_2) = 2$ and $c(z_3) = 3$. Successively we observe that $(x_1, y_1, z_3) \rightarrow c(z_1) = 4$, $(x_1, y_1, z_1) \rightarrow c(z_7) = 3$, $(x_2, y_2, z_3) \rightarrow c(z_4) = 4$, $(y_1, z_4, z_7) \rightarrow c(z_6) = 1$, and

FIG. 3. The graph $G_{\neq}(x_1, x_2)$.

$(y_2, z_4, z_7) \rightarrow c(z_5) = 1$, but z_5 and z_6 are neighbors in $G_{\neq}^2$. That is a contradiction with assumption $c(y_1) = c(y_2)$.

Hence, we know that $c(y_1) \neq c(y_2)$. We may assume that $c(y_1) = 2$ and $c(y_2) = 3$. Then, $c(z_1) \in \{3, 4\}$ and $c(z_3) \in \{2, 4\}$. Since z_1 and z_3 are adjacent in $G_{\neq}^2$, they have distinct colors. Consider the following cases:

$c(z_1) = 3$ and $c(z_3) = 4$: We infer that $(y_1, z_1, z_3) \rightarrow c(z_2) = 1$, $(x_1, y_1, z_1) \rightarrow c(z_7) = 4$, $(z_1, z_2, z_3) \rightarrow c(u_4) = 2$, $(x_2, y_2, z_3) \rightarrow c(z_4) = 2$, $(z_4, y_2, z_7) \rightarrow c(z_5) = 1$, $(z_5, z_4, z_7) \rightarrow c(z_6) = 3$, $(z_5, z_6, z_7) \rightarrow c(u_1) = 2$, and $(y_2, z_4, z_5) \rightarrow c(u_7) = 4$. Vertex u_2 has neighbors in $G_{\neq}^2$ colored by 2 and 3, and thus $c(u_2) \in \{1, 4\}$. If $c(u_2) = 4$, then all the vertices u_3 , u_5 , and u_6 have neighbors colored by 2 and 4, and thus they are colored by 1 or 3. But it is impossible since they induce a triangle in $G_{\neq}^2$. Therefore, we know that $c(u_2) = 1$. Then $(u_2, u_4, u_7) \rightarrow c(u_5) = 3$, $(u_2, u_4, u_5) \rightarrow c(u_3) = 4$, $(z_2, u_3, u_4) \rightarrow c(v_4) = 3$, $(y_1, z_6, z_7) \rightarrow c(v_1) = 1$, $(z_7, v_1, v_4) \rightarrow c(v_2) = 2$, and $(v_1, v_2, v_4) \rightarrow c(v_3) = 4$. But by Lemma 21 this coloring cannot be extended to vertices v_5 , v_6 , v_7 , and v_8 .

$c(z_1) = 4$ and $c(z_3) = 2$: This case is straightforward: $(y_2, z_1, z_3) \rightarrow c(z_2) = 1$, $(x_1, y_1, z_1) \rightarrow c(z_7) = 3$, $(x_2, y_2, z_3) \rightarrow c(z_4) = 4$, $(y_1, z_4, z_7) \rightarrow c(z_6) = 1$, and $(z_4, z_6, z_7) \rightarrow c(z_5) = 2$. By Lemma 21, this coloring cannot be extended to vertices u_1 , u_2 , u_3 , and u_4 .

$c(z_1) = 3$ and $c(z_3) = 2$: First, observe that $(x_1, y_1, z_1) \rightarrow c(z_7) = 4$ and $(x_2, y_2, z_3) \rightarrow c(z_4) = 4$. Both of the vertices z_2 and u_4 have neighbors in $G_{\neq}^2$ colored by colors 2 and 3, and thus they are colored by 1 or 4. They are adjacent, and thus one of them has to be assigned the color 1 and the other the color 4. Hence, $c(u_3) \in \{2, 3\}$. The vertex z_6 has neighbors with colors 2 and 4, and thus $c(z_6) \in \{1, 3\}$. Now, we distinguish cases according to colors of u_3 and z_6 .

$c(z_6) = 1$ and $c(u_3) = 2$: In this case we infer $(z_6, z_7, u_3) \rightarrow c(u_1) = 3$, $(z_6, u_1, u_3) \rightarrow c(u_2) = 4$, $(z_6, z_7, u_1) \rightarrow c(z_5) = 2$, $(y_2, z_4, z_5) \rightarrow c(u_7) = 1$, $(z_4, u_3, u_7) \rightarrow c(u_6) = 3$, and $(u_2, u_3, u_7) \rightarrow c(u_5) = 3$, but this con-

FIG. 4. A graph whose square is not 4-colorable.

tradicts the fact that coloring is proper since u_5 and u_6 are neighbors.

$c(z_6) = 1$ and $c(u_3) = 3$: This is an easy case; $(z_7, z_6, u_3) \rightarrow c(u_1) = 2$, $(z_6, u_1, u_3) \rightarrow c(u_2) = 4$, and $(z_7, z_6, u_1) \rightarrow c(z_5) = 3$. But z_5 and y_2 are neighbors in $G_{\neq}^2$ and both of them are colored by 3. This is a contradiction.

$c(z_6) = 3$ and $c(u_3) = 2$: Note that $(z_6, z_7, u_3) \rightarrow c(u_1) = 1$, $(z_6, u_1, u_3) \rightarrow c(u_2) = 4$, $(z_7, z_6, u_1) \rightarrow c(z_5) = 2$, $(y_2, z_4, z_5) \rightarrow c(u_7) = 1$, $(z_4, u_3, u_7) \rightarrow c(u_6) = 3$, and $(u_2, u_3, u_7) \rightarrow c(u_5) = 3$, but this is a contradiction, since u_5 and u_6 are adjacent in $G_{\neq}^2$.

$c(z_6) = 3$ and $c(u_3) = 3$: If $c(u_4) = 4$, then $(z_1, z_3, u_4) \rightarrow c(z_2) = 1$, but by Lemma 21 this coloring cannot be extended to vertices v_1 , v_2 , v_3 , and v_4 . Thus necessarily $c(u_4) = 1$. Similarly, if $c(u_6) = 2$, then by Lemma 21 the coloring cannot be extended to vertices w_1 , w_2 , w_3 , and w_4 (note that neither u_5 nor u_7 is colored by 3, and thus the assumptions of the lemma are satisfied). Hence, it follows that $c(u_6) = 1$. Next, $(y_2, z_4, u_6) \rightarrow c(u_7) = 2$, $(u_3, u_6, u_7) \rightarrow c(u_5) = 4$, $(u_3, u_4, u_5) \rightarrow c(u_2) = 2$, $(z_7, u_2, u_3) \rightarrow c(u_1) = 1$, and $(z_6, z_7, u_1) \rightarrow c(z_5) = 2$, but z_5 and u_7 are neighbors in $G_{\neq}^2$ colored by the same color, a contradiction. $\square$

THEOREM 23. *There exists a planar subcubic graph G with $g(G) = 9$ such that G^2 is not 4-colorable.*

Proof. The graph consists of vertices x , y , z , u , and v , edges xy , yz , yu , and uv , and copies of $G_{\neq}(z, v)$ and $G_{\neq}(x, y)$ (see Figure 4). By the first three properties of $G_{\neq}$ from Lemma 22, G is a planar graph of girth 9. For the contradiction suppose that G is 4-colorable. Because of the distances of the vertices x , y , z , u , and v , and the forth property of $G_{\neq}$ from Lemma 22, all the vertices x , y , z , u , and v must have mutually distinct colors. However, this contradicts the 4-colorability. $\square$

6. NP-completeness. In this section we discuss the complexity aspects of the problem. Let us first show an auxiliary structural lemma.

LEMMA 24. *There exists a subcubic planar graph $G_{\text{copy}}(x, y)$ of girth 9 with the properties described below. The graph $G_{\text{copy}}(x, y)$ contains two 1-vertices x and y on the outer face. Let v_x and v_y be the neighbors of x and y in $G_{\text{copy}}(x, y)$, respectively. The graph $G_{\text{copy}}(x, y)$ satisfies the following properties:*

- The distance of x and y in $G_{\text{copy}}(x, y)$ is greater than 9;
- $c(x) = c(y)$ in any proper coloring c of the square of $G_{\text{copy}}(x, y)$, and
- for any $a_1, a_2, a_3 \in \{1, 2, 3, 4\}$ such that $a_1 \neq a_2$ and $a_1 \neq a_3$, there exists a proper coloring c of the square of $G_{\text{copy}}(x, y)$ with $c(x) = c(y) = a_1$, $c(v_x) = a_2$, and $c(v_y) = a_3$.

FIG. 5. Graphs used in Lemma 24.

Proof. We use the graph $G_{\neq}$ from Lemma 22. The graph $G_{\neq}$ has the following coloring c_1 : $c_1^{-1}(\{1\}) = \{x_1, y_2, v_1, u_1, u_4, u_6, w_2\}$, $c_1^{-1}(\{2\}) = \{z_1, x_2, z_6, v_2, v_7, u_3, u_7, w_1\}$, $c_1^{-1}(\{3\}) = \{y_1, z_3, z_5, v_4, v_5, v_8, u_5, w_3\}$, and $c_1^{-1}(\{4\}) = \{z_2, z_4, z_7, v_3, v_6, u_2, w_4\}$.

The steps of the construction of $G_{copy}(x, y)$ are depicted in Figure 5. First, we construct an auxiliary subcubic planar graph $G_{copy_0}(x, y)$ of girth 9 such that the vertices x and y are on the outer face, x is a 1-vertex and y is a 2-vertex, and $c(x) = c(y)$ in any proper coloring c of the square of $G_{copy_0}(x, y)$. The graph $G_{copy_0}(x, y)$ consists of vertices x, y, u, v , and w , edges xu, uv, uw , and wy , and a copy of $G_{\neq}(v, y)$. The girth of $G_{copy_0}(x, y)$ is 9, since the distance of v and y in $G_{\neq}(v, y)$ is 6, and they are joined by path $vuwy$ in $G_{copy_0}(x, y)$. The distance of x and y is 3. In any coloring of the square of $G_{copy_0}(x, y)$ by four colors, the vertices x, y, u, v , and w must have mutually distinct colors, with the exception of vertices x and y that can have the same color. Since we color the graph by four colors, the colors of x and y must in fact be equal in any proper coloring of $G_{copy_0}^2(x, y)$. Also note that there exists a proper coloring c_2 of the square of $G_{copy_0}(x, y)$ by four colors—let us color the copy of $G_{\neq}(v, y)$ using the coloring c_1 , and set $c_2(x) = 2$, $c_2(u) = 4$, and $c_2(w) = 3$.

In the second step, we construct the second auxiliary subcubic planar graph $G_{copy'}(x, y)$ of girth 9 such that the vertices x and y are on the outer face, x is a 1-vertex and y is a 2-vertex, $c(x) = c(y)$ in any proper coloring c of the square of $G_{copy'}(x, y)$, and additionally the distance of x and y is at least 6. The graph $G_{copy'}(x, y)$ consists of vertices x, v and y and of the copies of the graphs $G_{copy_0}(x, v)$ and $G_{copy_0}(v, y)$. By properties of G_{copy_0} , the vertices x and y must get the same color in any proper coloring of $G_{copy'}^2(x, y)$. Also, such a coloring exists—we simply use the coloring c_2 on both copies of G_{copy_0} . Obviously, the girth of $G_{copy'}(x, y)$ is 9 and the distance between x and y is exactly 6.

Next we construct the third auxiliary subcubic planar graph $G_{copy''}(x, y)$ of girth 9 such that the 1-vertices x and y are on the outer face, and $c(x) = c(y)$ in any proper coloring c of $G_{copy''}^2(x, y)$. The graph $G_{copy''}(x, y)$ consists of vertices $x, x', y, y', z_1, z_2, v_1$ and v_2 , edges $x'z_1, y'z_2, z_1z_2, z_1v_1, z_2v_2$, and the following copies of graph $G_{copy'}$: $G_{copy'}(x, x')$, $G_{copy'}(y, y')$, and $G_{copy'}(v_1, v_2)$. The distance of x and y is 15, and the cycle consisting of vertices v_1, z_1, z_2, v_2 and of $G_{copy'}(v_1, v_2)$ has length 9, and hence the girth of $G_{copy''}(x, y)$ is 9.

In any coloring c of $G_{copy''}^2(x, y)$, by properties of $G_{copy'}$ it holds that $c(x) = c(x')$,

FIG. 6. $G_{\text{cross}}(x_1, y_1, x_2, y_2)$.

$c(y) = c(y')$, and $c(v_1) = c(v_2)$. Let us assume that exists such a coloring c with $c(x) \neq c(y)$. We may assume that $c(x) = 1$ and $c(y) = 2$, and also that $c(z_1) = 3$ and $c(z_2) = 4$. But then $c(v_1) = c(y') = c(y) = 2$ and $c(v_2) = c(x') = c(x) = 1$, which contradicts the properties of $G_{\text{copy}'}(v_1, v_2)$. On the other hand, there exists the following coloring c_3 of $G_{\text{copy}''}^2(x, y)$: color $G_{\text{copy}'}(x, x')$ by c_2 and $G_{\text{copy}'}(y, y')$ by c_2 with colors 3 and 4 swapped, so that $c_3(x) = c_3(x') = c_3(y) = c_3(y') = 2$, neighbors of x' have colors 1 and 3, and neighbors of y' have colors 1 and 4. Then set $c_3(z_1) = 4$, $c_3(z_2) = 3$, and finally color $G_{\text{copy}'}(v_1, v_2)$ by the coloring c_2 with colors 1 and 2 and colors 3 and 4 swapped, i.e., $c_3(v_1) = c_3(v_2) = 1$.

The graph $G_{\text{copy}''}(x, y)$ satisfies almost all properties of $G_{\text{copy}}(x, y)$, except possibly for the last property that any proper coloring of x, y , and their neighbors can be extended—we only constructed the coloring c_3 where $c_3(x) = c_3(y) = 2$, the color of the neighbor of x is 3, and the color of the neighbor of y is 4. We construct the graph $G_{\text{copy}}(x, y)$ by taking vertices x, z , and y and adding copies of $G_{\text{copy}''}(x, z)$ and $G_{\text{copy}''}(z, y)$. Obviously, the distance of x and y is greater than 9, and the graph has girth 9. Let v_x be the neighbor of x and v_y the neighbor of y in this graph. Let v_{zx} be the neighbor of z in $G_{\text{copy}''}(x, z)$ and v_{zy} be the neighbor of z in $G_{\text{copy}''}(z, y)$. Up to the permutation of colors, there are only two proper colorings of x, y, v_x , and v_y —either $c(x) = c(y) = 1, c(v_x) = 2, c(v_y) = 3$, or $c(x) = c(y) = 1, c(v_x) = 2 = c(v_y) = 2$. In both cases we can color $G_{\text{copy}''}(x, z)$ and $G_{\text{copy}''}(z, y)$ by the permutations of c_3 such that in addition to the prescribed colors on x, y, v_x , and v_y , we have $c(v_{zx}) = 3$ and $c(v_{zy}) = 4$. This shows that indeed, any precoloring of vertices x, y, v_x , and v_y can be extended to a proper coloring of $G_{\text{copy}}^2(x, y)$ and finishes the proof of the lemma. $\square$

The main result of this section follows.

THEOREM 25. *It is NP-complete to decide whether the square of a subcubic planar graph of girth 9 is 4-colorable.*

Proof. We use the copy gadget from Lemma 24. The special vertices x and y of $G_{\text{copy}}(x, y)$ have degree 1. Thus, we can form a binary tree, where the edges are replaced by the copies of $G_{\text{copy}}(x, y)$, and copy the color of the root of the tree to an arbitrary number of vertices of degree 1. Note that by the properties of $G_{\text{copy}}(x, y)$, this graph does not impose any additional constraints on colors of the neighbors of these vertices.

The other gadget we need is a crossover gadget $G_{\text{cross}}(x_1, y_1, x_2, y_2)$, which consists of vertices x_1, y_1, x_2, y_2, w_1 , and w_2 and edges $x_1w_1, w_1y_2, w_1w_2, y_1w_2$, and w_2x_2 ; see Figure 6. In any coloring c of the square of $G_{\text{cross}}(x_1, y_1, x_2, y_2)$ with $c(x_1) \neq c(y_1)$, it holds that $c(x_1) = c(x_2)$ and $c(y_1) = c(y_2)$, there exists such a coloring, and a cyclic order of the 1-vertices of the gadget on the outer face is x_1, y_1, x_2 ,

and y_2 . This gadget allows us to transfer information across the edges of the graph.

The proof of the NP-completeness proceeds by a reduction from the problem of 3-coloring of a planar graph, which is NP-complete due to Dailey [4]. Given an instance of this problem—a 2-connected planar graph G —we need to create a subcubic planar graph H of girth 9 of a size polynomial in $|V(G)|$ such that H^2 is 4-colorable if and only if G is 3-colorable. The idea of the construction is that we put a vertex into each face of G and force the color of all these vertices to be the same, say 4. We then join them to all the vertices of G , so the original vertices must have color 1, 2, or 3. Then we replace the edges by gadgets that ensure large enough girth. A 4-coloring of H^2 then straightforwardly corresponds to a 3-coloring of G .

The graph H is constructed in the following way (see Figure 7): We replace each d -vertex v of G by a tree of copy gadgets that copy the color of v to $2d$ vertices of degree 1. Let $e_1, f_1, e_2, f_2, \dots, e_d, f_d$ be a cyclic order of the edges and the faces incident to v , and let $v_{e_1}, v_{f_1}, \dots, v_{e_d}, v_{f_d}$ be a cyclic order of the copies of v .

We add a vertex u_f for each ℓ -face f of G and add a tree of copy gadgets that copy its color to 2ℓ vertices $u_{v_1}^f, u_{e_1}^f, \dots, u_{v_\ell}^f$, and $u_{e_\ell}^f$, where $v_1, e_1, v_2, e_2, \dots, v_\ell, e_\ell$ is a cyclic order of the vertices and the edges around the face f .

If a vertex v of G is incident to a face f , we add a new vertex x and a copy of the graph $G_{copy}(u_v^f, x)$ and join x and v_f by a 1-thread. This ensures that u_f and v have distinct colors.

If $e = vw$ is an edge of G incident to faces f_1 and f_2 , we add vertices x_1, x_2, x_3 , and x_4 and the following copies of gadgets: $G_{copy}(v_e, x_1)$, $G_{cross}(x_1, u_e^{f_2}, x_2, u_e^{f_1})$, $G_{copy}(x_2, x_3)$, and $G_{copy}(x_4, w_e)$, and join x_3 and x_4 by a 1-thread. Since we already know that u_{f_1} and v have distinct colors, this ensures that the vertices v and w have distinct colors, and that u_{f_1} and u_{f_2} have the same color.

Given a proper 3-coloring G by the colors $\{1, 2, 3\}$, we can color all the vertices u_f of H by the color 4 and preserve the coloring of the copies of the vertices of G inside H . We extend this coloring to the whole H^2 by the properties of the gadgets. Conversely, in a proper 4-coloring of H^2 , all the vertices u_f have the same color (say, 4) and the colors of the original vertices of G are distinct from it, i.e., belong to $\{1, 2, 3\}$. It follows that this coloring restricted to the vertices of G is a proper 3-coloring of G .

The construction of H can be performed in polynomial time, and H is a subcubic planar graph of girth 9. This finishes the proof of the NP-completeness of the problem. $\square$

7. Conclusion. The gap between the upper bounds and the examples showing the lower bounds obtained in sections 4 and 5 is large and it would be of independent interest to find sharper bounds. In particular, we believe that the upper bounds can be improved significantly by taking into account more complicated reducible configurations.

We were unable to find a 7-minimal planar subcubic graph of girth larger than 3. So we pose the following conjecture.

CONJECTURE 2. *The square of every triangle-free planar subcubic graph is 6-colorable.*

The graph in Figure 1 shows that the conjecture is tight.

In fact we propose the following more general conjecture. A coloring c of a plane graph is an ℓ -facial coloring if any two distinct vertices on a facial walk of length ℓ have distinct colors. Notice that 1-facial coloring is the usual coloring. Also notice that for subcubic graphs, 2-facial coloring corresponds to coloring of the square of the graph. This concept is introduced in [10], which poses the following conjecture.

FIG. 7. The NP-completeness reduction.

FIG. 8. A graph that is not ℓ -facial colorable with $3\ell - 1$ colors.

$(3\ell + 1)$ -CONJECTURE. Let G be a plane graph and $\ell \geq 1$. Then, G is ℓ -facial colorable by $3\ell + 1$ colors.

For $\ell = 1$ the conjecture is equivalent to the four colors theorem. For $\ell = 2$ we obtain Wegner's conjecture for subcubic graphs. If the conjecture is true, it is tight for all values of ℓ , as shown by the graph obtained from K_4 in the following way: Let v be the vertex that does not lie on the outer face. Subdivide each of the edges incident with v by $\ell - 1$ new vertices of degree 2. In a similar fashion, we propose the following 3ℓ -conjecture.

3ℓ -CONJECTURE. Let G be a plane triangle-free graph and $\ell \geq 1$. Then G is ℓ -facial colorable by 3ℓ colors.

For $\ell = 1$ this statement is equivalent to Grötzsch's theorem. For $\ell = 2$, it implies Conjecture 2. Note that the bound in this conjecture is tight, as shown by graphs depicted in Figure 8. All the faces of the graph form cliques for the purposes of ℓ -facial coloring, and at most one of the vertices in thread between x and y may have the same color as vertex z .

If 3ℓ -Conjecture and Conjecture 2 are not false, then they are probably hard. The following nice consequence of these two conjectures might be easier for consideration.

CONJECTURE 3. The square of every bipartite planar subcubic graph is 6-colorable.

Acknowledgments. We would like to thank Jiří Fiala, Pascal Ochem, and Christian Sloper for fruitful discussions about the problem. We are also indebted to the anonymous referee, whose comments helped us to simplify some of our proofs and to fix several errors.

PHASE CHANGES IN SUBTREE VARIETIES IN RANDOM RECURSIVE AND BINARY SEARCH TREES*

QUNQIANG FENG[†], HOSAM M. MAHMOUD[‡], AND ALOIS PANHOLZER[§]

Abstract. We study the variety of subtrees lying on the fringe of recursive trees and binary search trees by analyzing the distributional behavior of $X_{n,k}$, which counts the number of subtrees of size k in a random tree of size n , with $k = k(n)$ dependent on n . Using analytic methods we can characterize for both tree families the phase change behavior of $X_{n,k}$ as follows. In the subcritical case, when $k(n)/\sqrt{n} \rightarrow 0$, we show that $X_{n,k}$ is (after normalization) asymptotically normally distributed, whereas in the supercritical case, when $k(n)/\sqrt{n} \rightarrow \infty$, $X_{n,k}$ converges to 0. In the critical case, when $k(n) = \Theta(\sqrt{n})$, we show that if $k/\sqrt{n}$ approaches a limit, then $X_{n,k}$ converges in distribution to a Poisson random variable, whereas if $k/\sqrt{n}$ does not approach a finite nonzero limit, the size oscillates and does not converge in distribution to any random variable. In regard to recursive trees and binary search trees, this provides an understanding of the complete spectrum of phases of $X_{n,k}$ and the gradual change from the subcritical to the supercritical phase.

Key words. random trees, recurrence, moments, Riccati equation

1. Introduction. The occurrence of patterns in random objects is an important area of modern research. The prime example is the interest one may have in the number of occurrences of a word in a given text, or the occurrence of words of a certain length in that text. Applications abound in linguistics, where one wishes to analyze grammatical frequencies, and in genetics, where one tries to identify genes in strands of DNA. The equivalent and equally important view in random trees is to find patterns (which are trees of a certain size or a certain shape) in a given tree generated randomly. This area has already attracted attention in the recent literature on random trees (see Flajolet, Gourdon, and Martínez (1997), Chyzak et al. (2007), and Feng, Mahmoud, and Su (2007)). In this paper we investigate this area for two of the most important random tree models. We look at the number of subtrees of a certain size on the fringe of random recursive trees and random binary search trees.

The random recursive tree is a naturally growing structure that underlies many stochastic phenomena, such as contagion, and algorithms such as the union-find algorithm. For numerous applications of recursive trees we refer the reader to the survey in Smythe and Mahmoud (1994). The binary search tree is another naturally growing structure that underlies many algorithms, such as combinatorial sorting and searching algorithms, and serves well as a data structure that supports fast retrieval of data.

For numerous applications of binary search trees we refer the reader to Knuth (1998) and Mahmoud (2000).

2. Scope. We consider the variety of sizes that appear on the fringe of trees. For both classes of random recursive trees and binary search trees we analyze the random variable $X_{n,k}$, which counts the number of subtrees of size k in a random tree of size n , with both k fixed or $k = k(n)$ dependent on n . For k fixed it was shown in Feng, Mahmoud, and Su (2007) for recursive trees by using the contraction method and modeling via Pólya urns, and in Flajolet, Gourdon, and Martínez (1997) for binary search trees by using analytic techniques, that $X_{n,k}$ is (after normalization) asymptotically normally distributed. Furthermore, in Feng, Mahmoud, and Su (2007) the three “phases” of $X_{n,k}$ could be identified for recursive trees by computing explicit formulas for the first two moments of $X_{n,k}$.

To show the characterization of the distributional behavior of $X_{n,k}$ for $k = k(n)$ dependent on n obtained in the present paper we utilize analytic methods based on functional equations for generating functions. Such methods proved to be very effective in combinatorial analysis. It is well accepted folklore that when analytic methods are applicable, they provide fuller asymptotic expansion (hence better approximation) than purely probabilistic methods; compare, for example, the very detailed asymptotic expansion in Panholzer and Prodinger (1998) with the probabilistic approach in Lent and Mahmoud (1996).

The result we establish for recursive trees is the following.

THEOREM 2.1. *Let $X_{n,k}$ be the number of subtrees of size k on the fringe of a random recursive tree of size n .*

(a) *In the subcritical case, when $k/\sqrt{n} \rightarrow 0$,*

$$\frac{X_{n,k} - \frac{n}{k(k+1)}}{\sqrt{\frac{(2k^2-1)n}{k(k+1)^2(2k+1)}}} \xrightarrow{D} \mathcal{N}(0, 1).$$

(b) *We are in the critical case when $k = \Theta(\sqrt{n})$. In the critical case, when $k/\sqrt{n} \rightarrow c > 0$,*

$$X_{n,k} \xrightarrow{D} \text{Poi}\left(\frac{1}{c^2}\right),$$

and if $k/\sqrt{n}$ does not converge to a limit, no limiting distribution exists for $X_{n,k}$.

(c) *In the supercritical case, when $k/\sqrt{n} \rightarrow \infty$,*

$$X_{n,k} \xrightarrow{D} 0.$$

The analytic method employed for recursive trees extends naturally to binary search trees, which we include in this paper, and possibly to other tree classes, too, which we leave for future research. The result we establish for binary search trees is the following.

THEOREM 2.2. *Let $X_{n,k}$ be the number of subtrees of size k on the fringe of a random binary search tree of size n .*

(a) *In the subcritical case, when $k/\sqrt{n} \rightarrow 0$,*

$$\frac{X_{n,k} - \frac{2n}{(k+1)(k+2)}}{\sqrt{\frac{2k(4k^2+5k-3)n}{(k+1)(k+2)^2(2k+1)(2k+3)}}} \xrightarrow{D} \mathcal{N}(0, 1).$$

- (b) *We are in the critical case when $k = \Theta(\sqrt{n})$. In the critical case, when $k/\sqrt{n} \rightarrow c > 0$,*

$$X_{n,k} \xrightarrow{D} \text{Poi}\left(\frac{2}{c^2}\right),$$

and if $k/\sqrt{n}$ does not converge to a limit, no limiting distribution exists for $X_{n,k}$.

- (c) *In the supercritical case, when $k/\sqrt{n} \rightarrow \infty$,*

$$X_{n,k} \xrightarrow{D} 0.$$

We remark that $X_{n,k}$ can also be interpreted as the number of nodes in a random tree of size n , which have exactly k *descendants* (if we assume that a node itself is counted as its own descendant). From this point of view the “counterpart” of $X_{n,k}$ is the level polynomial $L_{n,k}$, i.e., the random variable that counts the number of nodes in a random tree of size n , which have exactly k *ascendants*. The distributional behavior $L_{n,k}$, i.e., the number of nodes at level k in a random tree of size n , has been analyzed recently for recursive trees and binary search trees by Fuchs, Hwang, and Neininger (2006).

The rest of the paper is organized as follows. In section 3 we first give the definition of random recursive trees and derive a partial differential equation for the number of subtrees of a given size (possibly dependent on n). This involves setting up a basic stochastic recurrence based on a decomposition property of random recursive trees. In subsection 3.1 we show how to compute the exact moments. The critical and supercritical cases fall out directly from the raw moments, as shown in subsections 3.2 and 3.3. However, the subcritical case needs centering (and scaling) to get a Gaussian limit. Therefore, to reach the limit distribution via moments, we need to have them centered. This is done in subsection 3.4, where several technical subsections are dedicated to deriving estimates for the centered moments (subsections 3.4.1–3.4.4).

After showing the mechanics of the method applied to recursive trees, we present a brief sketch for binary search trees, modeled after the exposition of recursive trees, starting with the definition of random binary search trees and its partial differential equation in section 4, then moving on to the exact moments (section 4.1). Then we show how to compute the limit distributions in the critical and supercritical cases (subsections 4.2 and 4.3). The subcritical case is dealt with in subsection 4.4, and the string of technical estimates is in subsections 4.4.1–4.4.5. We conclude in section 5 with a few remarks on the choice of an analytic methodology.

2.1. Notation. In the discourse we shall use the following notation. The symbol $\llbracket A \rrbracket$ denotes Iverson’s bracket for the predicate A , i.e., $\llbracket A \rrbracket = 1$ if A is true and 0 otherwise. For any number x , and nonnegative integer m , the notation $x^{\underline{m}}$ stands for the falling factorial $x(x-1)\dots(x-m+1)$; we interpret $x^{\underline{0}}$ as 1. The notation $\left\{ \begin{smallmatrix} r \\ s \end{smallmatrix} \right\}$ stands for the r th Stirling number (of the second kind) of order s . The operator $[z^n]$ extracts the n th coefficients when applied to a function; that is, $[z^n]f(z)$ is the coefficient of z^n in the power series expansion of $f(z)$.

For probabilistic convergence we use $\xrightarrow{D}$ to denote convergence in distribution. The standard random variables $\text{Poi}(\lambda)$ (the Poisson distributed with parameter λ) and $\mathcal{N}(\mu, \sigma^2)$ (the normally distributed with mean μ and variance σ^2) appear in the results as limiting random variables. Other standard nomenclature is employed, and we assume it is familiar to the reader and needs no special mention here.

3. The variety of subtree sizes in a recursive tree. The *random recursive tree* is an outgrowth from a single node labeled 1. Progressively, nodes are added in stages: At the n th stage a node in the existing tree is chosen at random as a parent for the n th entrant (labeled n). In this context *random* means that all nodes in the tree of size $n - 1$ are equally likely parents. According to this construction algorithm, the nodes along any root-to-leaf path carry increasing labels, and hence these trees are also members of the class of *increasing trees*.

The model of randomness in the growth of random recursive trees induces a uniform distribution on the trees: All $(n - 1)!$ recursive trees of size n are generated with equal probability. Many important properties of recursive trees have been analyzed from the convenient viewpoint of recurrence occurring naturally in the stochastic growth. Nonetheless, the uniform distribution of the trees also gave rise to analyses based on generating functions and analytic methods such as integral transforms (see Bergeron, Flajolet, and Salvy (1992)).

Let $X_{n,k}$ be the number of nodes in a random recursive tree of size n that are the roots of subtrees of size k . (A subtree rooted at a node is the entire structure of descendant nodes from the given one.) Equivalently, $X_{n,k}$ is the number of subtrees on the fringe of the recursive tree with size k . Our count of the size of a subtree includes its root. Thus, for example, a leaf roots a subtree of size 1. Applications of $X_{n,k}$ include finding out the number of participants in a chain letter scheme who will attain a certain profit (see Gastwirth and Bhattacharya (1984)), or the number of copies of a particular ancient text in a philological study (see Najock and Heyde (1982)).

We denote by $T_n = (n - 1)!$ the number of different recursive trees of size n . Let $M_k(z, v)$ be the moment generating function

$$M_k(z, v) = \sum_{n \geq 1} \sum_{m \geq 0} P\{X_{n,k} = m\} T_n \frac{z^n}{n!} v^m = \sum_{n \geq 1} \sum_{m \geq 0} P\{X_{n,k} = m\} \frac{z^n}{n} v^m.$$

According to the recursive nature of these trees, we can read right off the definition the probabilities that the subtrees have certain sizes. For all $k \geq 1$, the probabilities $P\{X_{n,k} = m\}$ satisfy (for $n > k$)

$$\begin{aligned} P\{X_{n,k} = m\} &= \sum_{r \geq 1} \frac{1}{r!} \sum_{\substack{n_1 + \dots + n_r = n-1 \\ n_i \geq 1, 1 \leq i \leq r}} \binom{n-1}{n_1, \dots, n_r} \frac{T_{n_1} \dots T_{n_r}}{T_n} \\ &\quad \times \sum_{\substack{m_1 + \dots + m_r = m \\ m_i \geq 0, 1 \leq i \leq r}} P\{X_{n_1,k} = m_1\} \dots P\{X_{n_r,k} = m_r\} \end{aligned}$$

with initial values $P\{X_{k,k} = 1\} = 1$ and $P\{X_{n,k} = 0\} = 1$ for $1 \leq n < k$.

Multiply this recurrence by $T_n \frac{z^{n-1}}{(n-1)!} v^m$ and sum up over $n > k$ and $m \geq 0$ to obtain the functional equation, for $k \geq 1$,

$$(3.1) \quad \frac{\partial}{\partial z} M_k(z, v) = e^{M_k(z, v)} + (v - 1)z^{k-1},$$

with initial condition $M_k(0, v) = 0$.

It can be easily checked that the function

$$(3.2) \quad M_k(z, v) = \frac{(v - 1)z^k}{k} + \log \left(\frac{1}{1 - \int_0^z e^{\frac{(v-1)t^k}{k}} dt} \right)$$

is a solution to the partial differential equation (3.1) that also satisfies the initial conditions. The solution (3.2) can be found by using the substitution $Q(z, v) := \exp(M_k(z, v))$ in (3.1), which leads to a solvable Riccati differential equation.

From the solution (3.2) we can obtain the r th factorial moments, which directly furnish a limiting distribution for the critical and supercritical cases.

3.1. Exact moments. To get the r th factorial moments we use the substitution $w := v - 1$ in $M_k(z, v)$, and extract coefficients:

$$\mathbf{E}(X_{n,k}^r) = \mathbf{E}(X_{n,k}(X_{n,k} - 1) \cdots (X_{n,k} - r + 1)) = nr! [z^n w^r] M_k(z, 1 + w).$$

In order to expand $M_k(z, 1 + w)$ around $w = 0$ we consider

$$\begin{aligned} \log \left(\frac{1}{1 - \int_0^z e^{\frac{wt^k}{k}} dt} \right) &= \log \left(\frac{1}{1 - \int_0^z \sum_{j \geq 0} \frac{w^j t^{kj}}{j! k^j} dt} \right) \\ &= \log \frac{1}{1 - z} + \log \left(\frac{1}{1 - \frac{z}{1-z} \sum_{j \geq 1} \frac{w^j z^{kj}}{j! k^j (kj+1)}} \right) \end{aligned}$$

and obtain from (3.2)

$$(3.3) \quad M_k(z, 1 + w) = \log \frac{1}{1 - z} + \frac{wz^k}{k} + \log \left(\frac{1}{1 - \frac{z}{1-z} \sum_{j \geq 1} \frac{w^j z^{kj}}{j! k^j (kj+1)}} \right).$$

Next we extract coefficients and get for $r \geq 1$,

$$\begin{aligned} [w^r] \log \left(\frac{1}{1 - \frac{z}{1-z} \sum_{j \geq 1} \frac{w^j z^{kj}}{j! k^j (kj+1)}} \right) &= [w^r] \sum_{\ell \geq 1} \frac{\left(\frac{z}{1-z}\right)^\ell}{\ell} \left(\sum_{j \geq 1} \frac{w^j z^{kj}}{j! k^j (kj+1)} \right)^\ell \\ &= \sum_{\ell \geq 1} \frac{\left(\frac{z}{1-z}\right)^\ell}{\ell} \sum_{\substack{j_1 + \dots + j_\ell = r \\ j_q \geq 1, 1 \leq q \leq \ell}} \frac{z^{kr}}{k^r \prod_{i=1}^\ell j_i! \prod_{i=1}^\ell (j_i k + 1)} \\ &= \sum_{\ell=1}^r \frac{\left(\frac{z}{1-z}\right)^\ell}{\ell} \times \frac{z^{kr}}{k^r} \sum_{\substack{j_1 + \dots + j_\ell = r \\ j_q \geq 1, 1 \leq q \leq \ell}} \frac{1}{\prod_{i=1}^\ell j_i! \prod_{i=1}^\ell (j_i k + 1)} \\ &= \frac{1}{r!} \sum_{\ell=1}^r \frac{\left(\frac{z}{1-z}\right)^\ell}{\ell} \times \frac{z^{kr}}{k^r} \sum_{\substack{j_1 + \dots + j_\ell = r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} \frac{1}{\prod_{i=1}^\ell (j_i k + 1)}. \end{aligned}$$

This immediately leads from (3.3) to the following formula for the r th coefficients ($r \geq 1$):

$$(3.4) \quad \begin{aligned} [w^r] M_k(z, v) &= \frac{z^k}{k} [r = 1] \\ &+ \frac{1}{r!} \sum_{\ell=1}^r \frac{\left(\frac{z}{1-z}\right)^\ell}{\ell} \times \frac{z^{kr}}{k^r} \sum_{\substack{j_1 + \dots + j_\ell = r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} \frac{1}{\prod_{i=1}^\ell (j_i k + 1)}. \end{aligned}$$

The formula (3.4) gives

$$\begin{aligned}\mathbf{E}(X_{n,k}) &= n[z^n w]M_k(z, 1+w) \\ &= n[z^n] \left(\frac{z^k}{k} + \frac{z^{k+1}}{k(k+1)(1-z)} \right) \\ &= n \left(\frac{1}{k} \llbracket n = k \rrbracket + \frac{1}{k(k+1)} \llbracket n \geq k+1 \rrbracket \right),\end{aligned}$$

and thus the following result ensues for the expectation of $X_{n,k}$, as given in Feng, Mahmoud, and Su (2007):

$$(3.5) \quad \mathbf{E}(X_{n,k}) = \begin{cases} \frac{n}{k(k+1)} & \text{for } n \geq k+1, \\ 1 & \text{for } n = k, \\ 0 & \text{for } 1 \leq n < k. \end{cases}$$

Owing to the explicit form of (3.4), we also get the following closed form solution for the r th factorial moments with $r \geq 2$:

$$\begin{aligned}(3.6) \quad \mathbf{E}(X_{n,k}^r) &= nr! [z^n w^r] M_k(z, v) \\ &= \frac{\llbracket n \geq kr+1 \rrbracket n}{k^r} \sum_{\ell=1}^r \frac{\binom{n-kr-1}{\ell-1}}{\ell} \\ &\quad \times \sum_{\substack{j_1+\dots+j_\ell=r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} \frac{1}{\prod_{i=1}^\ell (j_i k + 1)}.\end{aligned}$$

As an example, we compute the second factorial moment:

$$\mathbf{E}(X_{n,k}(X_{n,k} - 1)) = \frac{n(n-2k-1)}{k^2(k+1)^2} - \frac{n}{k^2(2k+1)} \quad \text{for } n \geq 2k+1,$$

which is 0 otherwise.

In view of the classical relation

$$\mathbf{E}(X_{n,k}^r) = \sum_{\ell=1}^r \left\{ \begin{matrix} r \\ \ell \end{matrix} \right\} \mathbf{E}(X_{n,k}^\ell),$$

one could also get (at least in principle) closed formulas for every ordinary r th moment.

3.2. The critical case. We are in the critical case when $k = \Theta(\sqrt{n})$. There are two flavors within this case: One flavor is when $k/\sqrt{n}$ converges to a limit, such as, for example, the case $k = 3\lfloor\sqrt{n} + \log n\rfloor$; the other is when k is asymptotic to $g(n)\sqrt{n}$ with $g(n)$ being a function of bounded variation, but oscillating and not converging to any limit, such as, for example, the case $k = \lfloor(2 + \sin n)\sqrt{n} + 6\rfloor$.

First, we consider the critical case having the flavor $\frac{n}{k^2} \rightarrow \lambda$ for some $\lambda > 0$. It is evident from (3.5) that we have $\mathbf{E}(X_{n,k}) \rightarrow \lambda$. Next we consider a fixed $r \geq 2$. We split the sum appearing in (3.6) as follows:

$$\begin{aligned} \mathbf{E}(X_{n,k}^r) &= \underbrace{\frac{\llbracket n \geq kr+1 \rrbracket n}{k^r} \times \frac{\binom{n-kr-1}{r-1}}{r} \sum_{\substack{j_1+\dots+j_r=r \\ j_q \geq 1, 1 \leq q \leq r}} \frac{\binom{r}{j_1, \dots, j_r}}{\prod_{i=1}^r (j_i k + 1)}}_{=:A} \\ &+ \underbrace{\frac{\llbracket n \geq kr+1 \rrbracket n}{k^r} \sum_{\ell=1}^{r-1} \frac{\binom{n-kr-1}{\ell-1}}{\ell} \sum_{\substack{j_1+\dots+j_\ell=r \\ j_q \geq 1, 1 \leq q \leq \ell}} \frac{\binom{r}{j_1, \dots, j_\ell}}{\prod_{i=1}^\ell (j_i k + 1)}}_{=:B}. \end{aligned}$$

For large n we can drop Iverson's brackets in both A and B . Using

$$\sum_{r \geq 0} \sum_{\substack{j_1+\dots+j_\ell=r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} \frac{z^r}{r!} = (e^z - 1)^\ell,$$

we obtain the inequality

$$\sum_{\substack{j_1+\dots+j_\ell=r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} = r! [z^r] (e^z - 1)^\ell \leq r! [z^r] e^{\ell z} = \ell^r,$$

and further by trivial estimates:

$$\begin{aligned} B &\leq \sum_{\ell=1}^{r-1} \frac{n^\ell}{\ell! k^r k^\ell} \ell^r \\ &\leq \frac{r^{r-1}}{k} \sum_{\ell=1}^{r-1} \frac{1}{k^{r-1-\ell}} \left(\frac{n}{k^2}\right)^\ell \frac{1}{(\ell-1)!} \\ &\leq \frac{r^{r-1}}{k} \times \frac{n}{k^2} \sum_{\ell \geq 0} \frac{\left(\frac{n}{k^2}\right)^\ell}{\ell!} \\ &= \frac{r^{r-1}}{k^3} n e^{\frac{n}{k^2}}. \end{aligned}$$

Since $\frac{n}{k^2} \rightarrow \lambda$, we further have

$$B = O\left(\frac{1}{k}\right) = O\left(\frac{1}{\sqrt{n}}\right).$$

The expression A simplifies considerably, since the only possible composition of r in r integers $j_q \geq 1$ is obtained for $j_1 = \dots = j_r = 1$; thus for large n we have

$$\begin{aligned} A &= \frac{n}{k^r} \times \frac{\binom{n-kr-1}{r-1}}{r} \times \frac{r!}{(k+1)^r} \\ &= \frac{n^r}{k^{2r}} \left(1 + O\left(\frac{k}{n}\right) + O\left(\frac{1}{k}\right)\right) \\ &= \left(\frac{n}{k^2}\right)^r \left(1 + O\left(\frac{1}{\sqrt{n}}\right)\right). \end{aligned}$$

Therefore, if $\frac{n}{k^2} \rightarrow \lambda$, we also get for every $r \geq 1$

$$\mathbf{E}(X_{n,k}^r) = \left(\frac{n}{k^2}\right)^r + O\left(\frac{1}{\sqrt{n}}\right) \rightarrow \lambda^r.$$

Since λ^r are the moments of $\text{Poi}(\lambda)$, and convergence of all moments to a random variable uniquely characterized by its moments implies weak convergence, we get

$$X_{n,k} \xrightarrow{D} \text{Poi}(\lambda).$$

This proves the convergence part of Theorem 2.1(b), where we used the substitution $c := \frac{1}{\sqrt{\lambda}}$, and thus $\frac{k}{\sqrt{n}} \rightarrow c$. When k is of the order $\sqrt{n}$, but fluctuations persist, as in the case involving sinusoids mentioned at the beginning of this subsection, all the moments oscillate, and no limit distribution can exist.

3.3. The supercritical case. We consider the supercritical case in passing, as it does not require additional effort. Assume that $k := k_n$ grows with n such that $\frac{n}{k^2} = o(1)$.

Crude estimates for (3.6) are sufficient for our purpose. We get for $r \geq 2$

$$\begin{aligned} \mathbf{E}(X_{n,k}^r) &\leq \frac{n}{k^r} \sum_{\ell=1}^r \frac{n^{\ell-1}}{\ell!} \sum_{\substack{j_1+\dots+j_\ell=r \\ j_q \geq 1, 1 \leq q \leq \ell}} \binom{r}{j_1, \dots, j_\ell} \frac{1}{k^\ell} = \frac{1}{k^r} \sum_{\ell=1}^r \frac{n^\ell}{\ell! k^\ell} \ell^r \\ &\leq r^{r-1} \sum_{\ell=1}^r \frac{1}{k^{r-\ell}} \left(\frac{n}{k^2}\right)^\ell \frac{1}{(\ell-1)!} \leq r^{r-1} \frac{n}{k^2} \sum_{\ell \geq 0} \frac{\left(\frac{n}{k^2}\right)^\ell}{\ell!} \\ &= r^{r-1} \frac{n}{k^2} e^{\frac{n}{k^2}}. \end{aligned}$$

Since $\frac{n}{k^2} \rightarrow 0$, we have that for all $r \geq 1$, $\mathbf{E}(X_{n,k}^r) \rightarrow 0$. Again we have convergence of all moments, and subsequently convergence of $X_{n,k}$ to a degenerate distribution with mass at 0. Part (c) of Theorem 2.1 is proved. Because the limit is constant, this convergence is in probability, too.

3.4. The subcritical case. For the critical and supercritical cases, it was sufficient to work with raw moments and establish their convergence to the moments of a known simple distribution. For the subcritical case, we need centering and scaling, too. We appeal to the method of recursive moments (see Chern, Hwang, and Tsai (2002)), although here we are not forced to “pump out” the behavior of the moments in an inductive way, but we are able to obtain exact (but rather involved) expressions for the moments directly by extracting coefficients of the moment generating function of the centered random variable. Consider the centered random variable $\tilde{X}_{n,k} := X_{n,k} - \mathbf{E}(X_{n,k})$ and introduce the generating function

$$\tilde{M}_k(z, s) := \sum_{n \geq 1} \mathbf{E}(e^{\tilde{X}_{n,k}s}) \frac{z^n}{n} = \sum_{n \geq 1} e^{-\mathbf{E}(X_{n,k})s} \mathbf{E}(e^{X_{n,k}s}) \frac{z^n}{n}.$$

Using the explicit formula for $\mathbf{E}(X_{n,k})$ as given by (3.5), we obtain by routine manipulations

$$\tilde{M}_k(z, s) = M_k\left(e^{-\frac{s}{k(k+1)}} z, e^s\right) + \left(1 - e^{\frac{ks}{k+1}}\right) \frac{z^k}{k} + \sum_{1 \leq n < k} \frac{z^n}{n} - \sum_{1 \leq n < k} \frac{\left(e^{-\frac{s}{k(k+1)}} z\right)^n}{n}.$$

Plugging in the formula for $M_k(z, v)$ given by (3.2), we further obtain after

simplifications

$$(3.7) \quad \begin{aligned} \tilde{M}_k(z, s) = \log & \left(\frac{1}{1 - \int_0^{e^{-\frac{s}{k(k+1)}} z} e^{\frac{(e^s-1)t^k}{k}} dt} \right) \\ & + \sum_{1 \leq n \leq k} \frac{z^n}{n} - \sum_{1 \leq n \leq k} \frac{\left(e^{-\frac{s}{k(k+1)}} z \right)^n}{n}. \end{aligned}$$

In the following chain of technical subsections, we analyze the centered moments, identify the main contribution, and put upper bounds on the negligible terms.

3.4.1. Expanding around $s = 0$. We first expand $\int_0^{e^{-\frac{s}{k(k+1)}} z} e^{\frac{(e^s-1)t^k}{k}} dt$ around $s = 0$ and $z = 1$:

$$\begin{aligned} & \int_0^{e^{-\frac{s}{k(k+1)}} z} e^{\frac{(e^s-1)t^k}{k}} dt \\ &= \int_0^{e^{-\frac{s}{k(k+1)}} z} \sum_{j \geq 0} \frac{(e^s-1)^j t^{kj}}{j! k^j} dt = \sum_{j \geq 0} \frac{(e^s-1)^j e^{-\frac{s(kj+1)}{k(k+1)}} z^{kj+1}}{j! (kj+1) k^j} \\ &= e^{-\frac{s}{k(k+1)}} z + \sum_{j \geq 1} \frac{(e^s-1)^j e^{-\frac{s(kj+1)}{k(k+1)}} z^{kj+1}}{j! (kj+1) k^j} \\ &= z + \sum_{j \geq 1} \left[\frac{(e^s-1)^j e^{-\frac{s(kj+1)}{k(k+1)}} z^{kj+1}}{j! (kj+1) k^j} + \frac{(-1)^j s^j z}{j! k^j (k+1)^j} \right] \\ &= z + \sum_{j \geq 1} \left[\frac{\sum_{m \geq j} \{ \begin{smallmatrix} m \\ j \end{smallmatrix} \} \frac{j! s^m}{m!} \sum_{m \geq 0} \frac{(-1)^m (kj+1)^m s^m}{k^m (k+1)^m m!} z^{kj+1} + \frac{(-1)^j s^j z}{j! k^j (k+1)^j} \right] \\ &= z + \sum_{\ell \geq 1} s^\ell \left(\sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} (-1)^m (kj+1)^m z^{kj+1}}{m! (\ell-m)! (kj+1) k^{j+m} (k+1)^m} + \frac{(-1)^\ell z}{\ell! k^\ell (k+1)^\ell} \right) \\ &= z + \sum_{\ell \geq 1} s^\ell \left(\sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} (-1)^m (kj+1)^m}{m! (\ell-m)! (kj+1) k^{j+m} (k+1)^m} \right. \\ & \quad \times \sum_{i=0}^{kj+1} (-1)^i \binom{kj+1}{i} (1-z)^i + \frac{(-1)^\ell}{\ell! k^\ell (k+1)^\ell} + \frac{(-1)^{\ell-1}}{\ell! k^\ell (k+1)^\ell} (1-z) \Big) \\ &= z + \sum_{\ell \geq 1} s^\ell \left(\sum_{i=0}^{\ell k+1} (-1)^i (1-z)^i \sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} (-1)^m (kj+1)^m \binom{kj+1}{i}}{m! (\ell-m)! (kj+1) k^{j+m} (k+1)^m} \right. \\ & \quad \left. + \frac{(-1)^\ell}{\ell! k^\ell (k+1)^\ell} + \frac{(-1)^{\ell-1}}{\ell! k^\ell (k+1)^\ell} (1-z) \right). \end{aligned}$$

So, we obtain the following simple structure for the integral considered:

$$\int_0^{e^{-\frac{s}{k(k+1)}} z} e^{\frac{(e^s-1)t^k}{k}} dt = z + \sum_{\ell \geq 1} s^\ell \sum_{i=0}^{\ell k+1} c_{\ell,i}(k) (1-z)^i,$$

where the functions $c_{\ell,i}(k)$ are given by

$$(3.8) \quad c_{\ell,i}(k) = (-1)^i \sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} (-1)^m (kj+1)^m \binom{kj+1}{i}}{m! (\ell-m)! (kj+1) k^{j+m} (k+1)^m} \\ + \frac{(-1)^{\ell} \llbracket i=0 \rrbracket}{\ell! k^{\ell} (k+1)^{\ell}} + \frac{(-1)^{\ell-1} \llbracket i=1 \rrbracket}{\ell! k^{\ell} (k+1)^{\ell}}.$$

Next we consider

$$\log \left(\frac{1}{1 - \int_0^e e^{-\frac{s}{k(k+1)}} z e^{\frac{(e^s-1)t^k}{k}} dt} \right) \\ = \log \frac{1}{1-z} + \log \left(\frac{1}{1 - \frac{1}{1-z} \sum_{\ell \geq 1} s^{\ell} \sum_{i=0}^{\ell k+1} c_{\ell,i}(k) (1-z)^i} \right),$$

and extract coefficients. This gives for $r \geq 1$

$$[s^r] \log \left(\frac{1}{1 - \int_0^e e^{-\frac{s}{k(k+1)}} z e^{\frac{(e^s-1)t^k}{k}} dt} \right) \\ = [s^r] \log \left(\frac{1}{1 - \frac{1}{1-z} \sum_{\ell \geq 1} s^{\ell} \sum_{i=0}^{\ell k+1} c_{\ell,i}(k) (1-z)^i} \right) \\ = \sum_{m=1}^r \frac{1}{m} [s^r] \left(\frac{1}{1-z} \sum_{\ell \geq 1} s^{\ell} \sum_{i=0}^{\ell k+1} (1-z)^i c_{\ell,i}(k) \right)^m \\ = \sum_{m=1}^r \frac{1}{m(1-z)^m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \prod_{j=1}^m \sum_{i=0}^{r_j k+1} (1-z)^i c_{r_j,i}(k) \\ = \sum_{m=1}^r \frac{1}{m(1-z)^m} \sum_{t=0}^{rk+m} (1-z)^t \times \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=t \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j,t_j}(k),$$

and thus

$$[s^r] \log \left(\frac{1}{1 - \int_0^e e^{-\frac{s}{k(k+1)}} z e^{\frac{(e^s-1)t^k}{k}} dt} \right) = \sum_{p=-r}^{rk} f_{r,p}(k) (1-z)^p,$$

with

$$f_{r,p}(k) := \sum_{m=\max\{1,-p\}}^r \frac{1}{m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=p+m \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j,t_j}(k),$$

where the functions $c_{\ell,i}(k)$ are defined by (3.8).

Since

$$[s^r] \sum_{1 \leq n \leq k} \frac{(e^{-\frac{s}{k(k+1)}} z)^n}{n} = \sum_{1 \leq n \leq k} \frac{z^n}{n} [s^r] e^{-\frac{sn}{k(k+1)}} = \sum_{1 \leq n \leq k} z^n \frac{(-1)^r n^{r-1}}{r! k^r (k+1)^r},$$

we obtain for the coefficients at s^r of $\tilde{M}_k(z, s)$, as given by (3.7) for $r \geq 1$,

$$[s^r]\tilde{M}_k(z, s) = \sum_{p=-r}^{rk} f_{r,p}(k)(1-z)^p + \sum_{1 \leq n \leq k} z^n \frac{(-1)^{r-1} n^{r-1}}{r! k^r (k+1)^r},$$

which can be written as

$$[s^r]\tilde{M}_k(z, s) = \sum_{p=1}^r \frac{1}{(1-z)^p} \tilde{f}_{r,p}(k) + \sum_{n=0}^{rk} g_{r,n}(k) z^n$$

with

$$(3.9) \quad \tilde{f}_{r,p}(k) := f_{r,-p}(k) = \sum_{m=p}^r \frac{1}{m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j, t_j}(k)$$

for $1 \leq p \leq r$, and

$$g_{r,n}(k) := (-1)^n \sum_{p=n}^{rk} \binom{p}{n} f_{r,p}(k) + \frac{(-1)^{r-1} n^{r-1}}{r! k^r (k+1)^r} \llbracket 1 \leq n \leq k \rrbracket.$$

This representation of $[s^r]\tilde{M}_k(z, s)$ immediately leads to the following explicit formula for the r th moments of $\tilde{X}_{n,k}$, which is valid for $n \geq rk+1$:

$$(3.10) \quad \mathbf{E}(\tilde{X}_{n,k}^r) = r! n [z^n s^r] \tilde{M}_k(z, s) = r! n \sum_{p=1}^r \tilde{f}_{r,p}(k) \binom{n+p-1}{p-1},$$

where the functions $\tilde{f}_{r,p}(k)$ are given by (3.9).

We now examine the functions $c_{\ell,i}(k)$ as given by (3.8). Using the identity

$$\sum_{m=j}^{\ell} \binom{\ell}{m} \left\{ \begin{matrix} m \\ j \end{matrix} \right\} = \left\{ \begin{matrix} \ell+1 \\ j+1 \end{matrix} \right\},$$

we get by very crude estimates

$$\begin{aligned} & \left| (-1)^i \sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\left\{ \begin{matrix} \ell-m \\ j \end{matrix} \right\} (-1)^m (kj+1)^m \binom{kj+1}{i}}{m! (\ell-m)! (kj+1) k^{j+m} (k+1)^m} \right| \\ & \leq \sum_{j=1}^{\ell} \frac{\binom{kj+1}{i}}{(kj+1) k^j} \sum_{m=0}^{\ell-j} \frac{\left\{ \begin{matrix} \ell-m \\ j \end{matrix} \right\} (kj+1)^m}{m! (\ell-m)! k^m (k+1)^m} \\ & \leq \sum_{j=1}^{\ell} \frac{k^i (j+1)^i}{\ell! i! k^{j+1}} \sum_{m=0}^{\ell-j} \frac{\left\{ \begin{matrix} \ell-m \\ j \end{matrix} \right\} (j+1)^m \binom{\ell}{m}}{(k+1)^m} \\ & \leq \sum_{j=1}^{\ell} \frac{k^i (j+1)^i (j+1)^{\ell-j}}{\ell! i! k^{j+1}} \sum_{m=0}^{\ell-j} \binom{\ell}{m} \left\{ \begin{matrix} \ell-m \\ j \end{matrix} \right\} \\ & = \sum_{j=1}^{\ell} \frac{k^i (j+1)^i (j+1)^{\ell-j}}{\ell! i! k^{j+1}} \left\{ \begin{matrix} \ell+1 \\ j+1 \end{matrix} \right\} \end{aligned}$$

$$\begin{aligned}
(3.11) \quad & \leq \frac{k^i(\ell+1)^i(\ell+1)^{\ell-1}}{\ell! i! k^2} \sum_{j=2}^{\ell+1} \left\{ \begin{matrix} \ell+1 \\ j \end{matrix} \right\} \\
& \leq \frac{(\ell+1)^\ell B_{\ell+1}}{(\ell+1)!} \times \frac{(\ell+1)^i}{i!} k^{i-2},
\end{aligned}$$

where B_ℓ denote the Bell numbers (number of partitions of a set with ℓ elements). Since

$$\left| \frac{(-1)^\ell}{k^\ell(k+1)^\ell \ell!} \right| \leq \frac{1}{k^2} = \frac{1}{k^2} \left\{ \begin{matrix} \ell+1 \\ 1 \end{matrix} \right\},$$

we can add this summand in the preceding computations at step (3.11) and thus get the same bound. Therefore, we arrive at the following bound, which holds uniformly for all ℓ , i , and k :

$$|c_{\ell,i}(k)| \leq q_{\ell,i} k^{i-2} \quad \text{with} \quad q_{\ell,i} := \frac{(\ell+1)^\ell B_{\ell+1}}{(\ell+1)!} \times \frac{(\ell+1)^i}{i!}.$$

The two functions that exert the most influence on the asymptotic distribution $c_{\ell,i}(k)$, and which can be computed easily from (3.8), are

$$\begin{aligned}
c_{1,0}(k) &= \frac{1}{k(k+1)} - \frac{1}{k(k+1)} = 0, \\
c_{2,0}(k) &= \frac{\nu(k)}{2} \quad \text{with} \quad \nu(k) := \frac{2k^2 - 1}{k(k+1)^2(2k+1)}.
\end{aligned}$$

3.4.2. Estimates for $\tilde{f}_{r,p}(k)$. We next treat the functions $\tilde{f}_{r,p}(k)$ as given by (3.9). Since $1 \leq p \leq r$ holds in (3.10), this implies that in the compositions appearing in the definition of $\tilde{f}_{r,p}(k)$ we always have $r_q, t_q \leq r$ for all $1 \leq q \leq m$. Thus, we obtain the following estimate, which holds for all $1 \leq p \leq r$ and all r_q, t_q :

$$|c_{r_j, t_j}(k)| \leq q_{r_j, t_j} k^{t_j-2} \leq c_r k^{t_j-2},$$

with the universal constant

$$(3.12) \quad c_r := \frac{(r+1)^{2r} B_{r+1}}{(r+1)!}.$$

This gives for $1 \leq p \leq r$ the estimate

$$\begin{aligned}
& \left| \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j, t_j}(k) \right| \\
& \leq \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_r k^{t_j-2} \\
& = c_r^m k^{-p-m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} 1 \\
& \leq c_r^m k^{-p-m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ t_q \geq 0, 1 \leq q \leq m}} 1
\end{aligned}$$

$$\begin{aligned}
&= c_r^m k^{-p-m} [z^r] \left(\frac{z}{1-z} \right)^m [z^{m-p}] \left(\frac{1}{1-z} \right)^m \\
&= c_r^m k^{-p-m} \binom{r-1}{p-1} \binom{2m-p-1}{m-1} \\
&\leq c_r^m \binom{2m-2}{m-1} \binom{r-1}{m-1} k^{-p-m},
\end{aligned}$$

and further

$$\begin{aligned}
|\tilde{f}_{r,p}(k)| &= \left| \sum_{m=p}^r \frac{1}{m} \sum_{\substack{r_1+\dots+r_m=r \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-p \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j, t_j}(k) \right| \\
&\leq \sum_{m=p}^r \frac{1}{m} c_r^m \binom{2m-2}{m-1} \binom{r-1}{m-1} k^{-p-m} \\
&\leq \binom{2r-2}{r-1} (r-1)! c_r^r \sum_{m=p}^r \frac{1}{k^{p+m}} = \binom{2r-2}{r-1} (r-1)! c_r^r \frac{1}{k^{2p}} \sum_{q=0}^{r-p} \frac{1}{k^q} \\
&\leq \binom{2r-2}{r-1} (r-1)! c_r^r \frac{1}{k^{2p}} r.
\end{aligned}$$

Thus, we obtain the following estimate, which holds for all $1 \leq p \leq r$ and $r, k \geq 1$:

$$|\tilde{f}_{r,p}(k)| \leq \kappa_r \frac{1}{k^{2p}}$$

with

$$\kappa_r := \binom{2r-2}{r-1} r! c_r^r.$$

The constants c_r appearing here are given by (3.12).

3.4.3. Cancellation of $\tilde{f}_{r,p}(\mathbf{k})$. We shall demonstrate that the functions $\tilde{f}_{r,p}(k)$ as defined by (3.9) satisfy $\tilde{f}_{r,p}(k) = 0$ for all $p \geq \lfloor \frac{r}{2} \rfloor + 1$. We will do this by simply showing that for every composition $m, r_1, \dots, r_m, t_1, \dots, t_m$ of r and $m-p$, respectively, there exists a factor $c_{1,0}(k)$, which is zero, and thus the product $\prod_{j=1}^m c_{r_j, t_j}(k)$ vanishes.

Let us take $p \geq \lfloor \frac{r}{2} \rfloor + 1$. This implies then by (3.9) that also $m \geq \lfloor \frac{r}{2} \rfloor + 1$. We consider now an arbitrary but fixed composition $m, r_1, \dots, r_m, t_1, \dots, t_m$ with $r_q \geq 1$ and $t_q \geq 0$ such that $r_1 + \dots + r_m = r$ and $t_1 + \dots + t_m = m-p$. We define the sets $T = \{q : t_q = 0\}$ and $R = \{q : r_q = 1\}$. Then the relations

$$|T| \geq m - (m-p) = p \quad \text{and} \quad |R| \geq 2m - r$$

hold. Otherwise, if $|T| \leq p-1$ this would imply $\sum_{q=1}^m t_q \geq m-p+1 > m-p$, and if $|R| \leq 2m-r-1$ this would imply $\sum_{q=1}^r r_q \geq (2m-r-1) + 2(m-(2m-r-1)) = r+1 > r$, which is a contradiction to the choice of r_q and t_q .

Next we consider the set $R \cap T = \{q : t_q = 0 \wedge r_q = 1\}$. Since $|R \cup T| \leq m$, we get by a simple application of the inclusion-exclusion principle for $p \geq \lfloor \frac{r}{2} \rfloor + 1$ the estimate

$$|R \cap T| = |R| + |T| - |R \cup T| \geq 2m - r + p - m = m + p - r \geq 2 \left\lfloor \frac{r}{2} \right\rfloor - r + 2 \geq 1.$$

The latter equation guarantees that in every composition there exists a number q such that $r_q = 1$ and $t_q = 0$, and consequently there is always a factor $c_{1,0}(k) = 0$ in every product $\prod_{j=1}^m c_{r_j, t_j}(k)$. Hence, we have

$$\tilde{f}_{r,p}(k) = 0 \quad \text{for } p \geq \left\lfloor \frac{r}{2} \right\rfloor + 1.$$

We also consider the special case $r = 2d$ and $p = d$; i.e., we examine

$$\tilde{f}_{2d,d}(k) = \sum_{m=d}^{2d} \frac{1}{m} \sum_{\substack{r_1+\dots+r_m=2d \\ r_q \geq 1, 1 \leq q \leq m}} \sum_{\substack{t_1+\dots+t_m=m-d \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq m}} \prod_{j=1}^m c_{r_j, t_j}(k).$$

If $m \geq d+1$, we can show by arguments as above that there always exists a factor $c_{1,0}(k) = 0$ in every product $\prod_{j=1}^m c_{r_j, t_j}(k)$. Thus all summands with $m \geq d+1$ are zero. This gives

$$\tilde{f}_{2d,d}(k) = \frac{1}{d} \sum_{\substack{r_1+\dots+r_d=2d \\ r_q \geq 1, 1 \leq q \leq d}} \sum_{\substack{t_1+\dots+t_d=0 \\ 0 \leq t_q \leq r_q k+1, 1 \leq q \leq d}} \prod_{j=1}^d c_{r_j, t_j}(k) = \frac{1}{d} \sum_{\substack{r_1+\dots+r_d=2d \\ r_q \geq 1, 1 \leq q \leq d}} \prod_{j=1}^d c_{r_j, 0}(k).$$

Now, since $c_{1,0}(k) = 0$, we see that the only nonzero contribution is obtained if $r_1 = \dots = r_d = 2$, which implies

$$\tilde{f}_{2d,d}(k) = \frac{1}{d} c_{2,0}^d(k) = \frac{\nu^d(k)}{d2^d},$$

with $\nu(k) = \frac{2k^2-1}{k(k+1)^2(2k+1)}$.

3.4.4. Asymptotics of the centered moments. Summarizing the results of the previous subsections, we have for $r \geq 1$ that for all $n \geq rk+1$ the r th centered moments are given by

$$\mathbf{E}(\tilde{X}_{n,k}^r) = r! n \sum_{p=1}^{\lfloor \frac{r}{2} \rfloor} \tilde{f}_{r,p}(k) \binom{n+p-1}{p-1}$$

with

$$|\tilde{f}_{r,p}(k)| \leq \frac{\kappa_r}{k^{2p}} \quad \text{and} \quad \tilde{f}_{2d,d}(k) = \frac{\nu^d(k)}{d2^d}.$$

We are now going to evaluate the centered moments asymptotically for the subcritical case, i.e., $\frac{k^2}{n} = o(1)$; thus, we may always assume that we choose n large enough such that $\frac{(d-1)^2}{n} \leq 1$ and $\frac{k^2}{n} \leq \frac{1}{2}$ are satisfied.

We consider the case $r = 2d$ with $d \geq 1$, which gives

$$\begin{aligned} \mathbf{E}(\tilde{X}_{n,k}^{2d}) &= (2d)! \frac{\nu^d(k)}{d2^d} \times \frac{(n+d-1)^{d-1}n}{(d-1)!} + \sum_{p=1}^{d-1} (2d)! \tilde{f}_{2d,p}(k) \binom{n+p-1}{p-1} n \\ &= \frac{(2d)!}{d! 2^d} \nu^d(k) n^d (1 + R(n, k)), \end{aligned}$$

with

$$R(n, k) := \prod_{j=1}^{d-1} \left(1 + \frac{j}{n}\right) - 1 + \sum_{p=1}^{d-1} \frac{2^d d! \tilde{f}_{2d,p}(k)}{\nu^d(k) n^{d-1}} \binom{n+p-1}{p-1}.$$

We obtain the simple estimate

$$\begin{aligned} \left| \prod_{j=1}^{d-1} \left(1 + \frac{j}{n}\right) - 1 \right| &= \prod_{j=1}^{d-1} \left(1 + \frac{j}{n}\right) - 1 \leq \left(1 + \frac{d-1}{n}\right)^{d-1} - 1 \\ &\leq e^{\frac{(d-1)^2}{n}} - 1 \leq \frac{(d-1)^2}{n} e^{\frac{(d-1)^2}{n}} \\ &\leq \frac{(d-1)^2 e}{n}. \end{aligned}$$

Using the trivial bounds

$$\frac{1}{12k^2} \leq \nu(k) \leq \frac{1}{k^2},$$

which hold for all $k \geq 1$, we obtain the following estimates:

$$\begin{aligned} \left| \sum_{p=1}^{d-1} \frac{2^d d! \tilde{f}_{2d,p}(k) \binom{n+p-1}{p-1}}{\nu^d(k) n^{d-1}} \right| &\leq 2^d d! \kappa_{2d} \sum_{p=1}^{d-1} \frac{n^{p-1} \prod_{j=1}^{p-1} \left(1 + \frac{j}{n}\right)}{\nu^d(k) n^{d-1} k^{2p}} \\ &\leq 2^d d! \kappa_{2d} e^{\frac{(d-1)^2}{n}} \sum_{p=1}^{d-1} \frac{1}{n^{d-p} \nu^d(k) k^{2p}} \\ &\leq 2^d d! \kappa_{2d} e \sum_{p=1}^{d-1} \frac{12^d k^{2d}}{n^{d-p} k^{2p}} \\ &= (24)^d d! \kappa_{2d} e \frac{k^2}{n} \sum_{q=0}^{d-2} \left(\frac{k^2}{n}\right)^q \\ &\leq (24)^d d! \kappa_{2d} e \frac{k^2}{n} \times \frac{1}{1 - \frac{k^2}{n}} \\ &\leq 2e(24)^d d! \kappa_{2d} \frac{k^2}{n}. \end{aligned}$$

Combining these estimates yields, in the subcritical case,

$$|R(n, k)| \leq \frac{(d-1)^2 e}{n} + 2e(24)^d d! \kappa_{2d} \frac{k^2}{n} = o(1),$$

and further

$$\mathbf{E}(\tilde{X}_{n,k}^{2d}) \sim \frac{(2d)!}{2^d d!} (\nu(k)n)^d \quad \text{for } d \geq 1.$$

We have to consider also the case $r = 2d + 1$ with $d \geq 0$, which gives

$$\begin{aligned}
\left| \mathbf{E}(\tilde{X}_{n,k}^{2d+1}) \right| &= \left| (2d+1)! n \sum_{p=1}^d \tilde{f}_{2d+1,p}(k) \binom{n+p-1}{p-1} \right| \\
&\leq (2d+1)! \sum_{p=1}^d \frac{\kappa_{2d+1}}{k^{2p}} \frac{n^p}{(p-1)!} \prod_{j=1}^{p-1} \left(1 + \frac{j}{n}\right) \\
&\leq (2d+1)! \kappa_{2d+1} e^{\frac{(d-1)^2}{n}} \sum_{p=1}^d \left(\frac{n}{k^2}\right)^p \\
&\leq (2d+1)! \kappa_{2d+1} e \left(\frac{n}{k^2}\right)^d \sum_{q=0}^{d-1} \left(\frac{k^2}{n}\right)^q \\
&\leq (2d+1)! \kappa_{2d+1} e \left(\frac{n}{k^2}\right)^d \frac{1}{1 - \frac{k^2}{n}} \\
&\leq 2e[(2d+1)!] \kappa_{2d+1} \left(\frac{n}{k^2}\right)^d \\
&\leq 2e(12)^d [(2d+1)!] \kappa_{2d+1} (\nu(k)n)^d,
\end{aligned}$$

and thus

$$\mathbf{E}(\tilde{X}_{n,k}^{2d+1}) = O((\nu(k)n)^d) \quad \text{for } d \geq 0.$$

Therefore, considering

$$\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}} = \frac{X_{n,k} - \mathbf{E}(X_{n,k})}{\sqrt{\nu(k)n}},$$

with $\nu(k) = \frac{2k^2-1}{k(k+1)^2(2k+1)}$, we have for $k = o(\sqrt{n})$

$$\mathbf{E} \left(\left(\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}} \right)^{2d} \right) \rightarrow \frac{(2d)!}{d! 2^d} \quad \text{for } d \geq 1,$$

and

$$\mathbf{E} \left(\left(\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}} \right)^{2d+1} \right) = O \left(\frac{1}{\sqrt{\nu(k)n}} \right) = O \left(\frac{k}{\sqrt{n}} \right) \rightarrow 0 \quad \text{for } d \geq 0.$$

For the subcritical case, the moments of $\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}}$ converge to the moments of a standard normal distribution, which proves the convergence

$$\frac{X_{n,k} - \frac{n}{k(k+1)}}{\sqrt{\frac{(2k^2-1)n}{k(k+1)^2(2k+1)}}} \xrightarrow{D} \mathcal{N}(0, 1).$$

Part (a) of Theorem 2.1 has been established.

4. The variety of subtree sizes in binary search trees. A binary search tree is constructed from the permutation $(\pi_1, \dots, \pi_n)$ of the set $\{1, 2, \dots, n\}$ by the following algorithm. The first element of the permutation is inserted in an empty tree, and a root node is allocated for it. A subsequent element π_j (with $j \geq 2$) is directed to the left subtree if $\pi_j < \pi_1$; otherwise it is directed to the right subtree. In whichever subtree π_j goes, it is subjected to the same insertion algorithm recursively, until it is inserted in an empty subtree, in which case a node is allocated for it and linked appropriately as a left (resp., right) child if its rank is less than (resp., at least as much as) the value of the last node on the path.

Several models of randomness are in common use on binary trees. The uniform model in which all trees are equally likely has been proposed for applications in formal languages, compilers, computer algebra, etc. (see Kemp (1984)). However, for the searching and sorting algorithms alluded to, the *random permutation model* is considered to be more appropriate. In this model of randomness we assume that the tree is built from permutations of $\{1, \dots, n\}$, where a uniform probability model is imposed on the *permutations* instead of the trees. When all $n!$ permutations are equally likely or *random*, binary search trees are not equally likely. Several permutations give rise to the same tree, favoring shorter and well balanced trees rather than scrawny and tall shapes, which is a desirable property in searching and sorting algorithms (see Mahmoud (1992)). The term *random binary search tree* will refer to a binary search tree built from a random permutation. The random permutation model is not restrictive, as it covers a rather wide variety of instances, such as when the input is a sample drawn from *any* continuous probability distribution, and the construction algorithm is concerned only with the ranks of the keys, not their actual values.

Let $X_{n,k}$ be the random variable that counts the number of subtrees of size k on the fringe of a random binary search tree of size n , and let $M_k(z, v)$ be its generating function

$$M_k(z, v) = \sum_{n \geq 1} \sum_{m \geq 0} P\{X_{n,k} = m\} z^n v^m.$$

The binary dichotomy of the ranks in the permutation (relative to the first element) preserves the probabilistic structure in the conditionally independent subtrees. For all $n > k \geq 1$ the probabilities $P\{X_{n,k} = m\}$ satisfy the following recurrence:

$$P\{X_{n,k} = m\} = \frac{1}{n} \sum_{\substack{n_1 + n_2 = n-1 \\ m_1 + m_2 = m \\ m_1, m_2 \geq 0, n_1, n_2 \geq 0}} P\{X_{n_1,k} = m_1\} P\{X_{n_2,k} = m_2\},$$

with initial values $P\{X_{k,k} = 1\} = 1$ and $P\{X_{n,k} = 0\} = 1$, for $1 \leq n < k$. After multiplication with $nz^{n-1}v^m$ and summing up over $n > k$ and $m \geq 0$, we obtain a functional equation for the generating function and find

$$\frac{\partial}{\partial z} M_k(z, v) = (1 + M_k(z, v))^2 + (v - 1)kz^{k-1}$$

for $k \geq 1$, with initial condition $M_k(0, v) = 0$.

Substituting $Q_k(z, v) := M_k(z, v) + 1$, we obtain the Riccati differential equation

$$\frac{\partial}{\partial z} Q_k(z, v) = Q_k^2(z, v) + (v - 1)kz^{k-1}, \quad Q_k(0, v) = 1.$$

The solution to this differential equation already appears in Flajolet, Gordon, and Martínez (1997). Using this solution, we obtain a representation for our generating function:

$$(4.1) \quad M_k(z, v) = -1 + \frac{1 + \sum_{j \geq 1} \delta_j(k)(v-1)^j z^{(k+1)j} - \sum_{j \geq 1} \gamma_j(k)(v-1)^j z^{(k+1)j-1}}{1 - z - \sum_{j \geq 1} \beta_j(k)(v-1)^j z^{(k+1)j+1} + \sum_{j \geq 1} \alpha_j(k)(v-1)^j z^{(k+1)j}},$$

with the functions

$$(4.2) \quad \alpha_j(k) = \xi_{j,-1,0}(k), \quad \beta_j(k) = \xi_{j,1,0}(k),$$

$$(4.3) \quad \gamma_j(k) = \xi_{j,-1,-1}(k), \quad \delta_j(k) = \xi_{j,1,1}(k),$$

where

$$\xi_{j,m,s}(k) = \frac{(-1)^j k^j ((k+1)j + \llbracket s=1 \rrbracket)^s}{\prod_{i=1}^j [(ik+i)(ik+i+m)]}.$$

4.1. The factorial moments for binary search trees. From the solution (4.1) we can obtain the r th factorial moments, which lead directly to the limiting distribution for the critical and supercritical cases.

To get the r th factorial moments we use the substitution $w := v - 1$ in $M_k(z, v)$ and expand this function in powers of w . Straightforward computations then lead to the following expression:

$$M_k(z, 1+w) = -1 + \frac{1}{1-z} \left(1 + \sum_{j \geq 1} w^j (\delta_j(k) z^{(k+1)j} - \gamma_j(k) z^{(k+1)j-1}) \right) \\ \times \sum_{\ell \geq 0} \left(\frac{z}{1-z} \sum_{j \geq 1} w^j (\beta_j(k) z^{(k+1)j} - \alpha_j(k) z^{(k+1)j-1}) \right)^\ell.$$

Extract coefficients of w^r in $M_k(z, 1+w)$ eventually give for $r \geq 1$

$$[w^r]M_k(z, 1+w) \\ = \frac{z^{(k+1)r}}{(1-z)^{r+1}} (\beta_1(k)z - \alpha_1(k))^r \\ + z^{(k+1)r} \sum_{\ell=1}^{r-1} \frac{1}{(1-z)^{\ell+1}} \sum_{\substack{j_1+\dots+j_\ell=r \\ j_i \geq 1}} \prod_{i=1}^{\ell} (\beta_{j_i}(k)z - \alpha_{j_i}(k)) \\ + z^{(k+1)r-1} \sum_{j=1}^{r-1} (\delta_j(k)z - \gamma_j(k)) \sum_{\ell=1}^{r-j} \frac{1}{(1-z)^{\ell+1}} \\ \times \sum_{\substack{j_1+\dots+j_\ell=r-j \\ j_i \geq 1}} \prod_{i=1}^{\ell} (\beta_{j_i}(k)z - \alpha_{j_i}(k)) + \frac{z^{(k+1)r-1}}{1-z} (\delta_r(k)z - \gamma_r(k)).$$

Using

$$(\beta_1(k)z - \alpha_1(k))^r = (\beta_1(k) - \alpha_1(k))^r + (\beta_1(k) - \alpha_1(k))^r \\ \times \sum_{m=1}^r \binom{r}{m} (-1)^m \left(\frac{\beta_1(k)}{\beta_1(k) - \alpha_1(k)} \right)^m (1-z)^m$$

and analogous expansions, and $[z^n] \frac{1}{(1-z)^{\alpha+1}} = \binom{n+\alpha}{n}$, we can expand the above expression also around $z = 1$ and get the following formula for the r th factorial moment of $X_{n,k}$, which is valid for all $n \geq (k+1)r$ and $r \geq 1$:

$$\begin{aligned}
\mathbf{E}(X_{n,k}^r) &= r! [z^n w^r] M_k(z, 1+w) \\
&= r! \binom{n-kr}{r} \left(\frac{2}{(k+1)(k+2)} \right)^r \\
&\quad + r! \left(\frac{1}{(k+1)(k+2)} \right)^r \sum_{p=1}^r \binom{n-(k+1)r+p-1}{p-1} \binom{r}{p-1} \left(\frac{k}{2} \right)^{r+1-p} \\
&\quad + r! \sum_{p=1}^r \binom{n-(k+1)r+p-1}{p-1} \sum_{\ell=\max(1,p-1)}^{r-1} (-1)^{\ell+1-p} \\
&\quad \times \sum_{\substack{j_1+\dots+j_\ell=r \\ j_i \geq 1}} \prod_{i=1}^{\ell} (\beta_{j_i}(k) - \alpha_{j_i}(k)) \\
&\quad \times \sum_{1 \leq i_1 < \dots < i_{\ell+1-p} \leq \ell} \prod_{q=1}^{\ell+1-p} \left(\frac{\beta_{j_{i_q}}(k)}{\beta_{j_{i_q}}(k) - \alpha_{j_{i_q}}(k)} \right) \\
&\quad + r! \sum_{p=1}^r \binom{n-(k+1)r+p}{p-1} \sum_{j=1}^{\min(r+1-p, r-1)} (\delta_j(k) - \gamma_j(k)) \\
&\quad \times \sum_{\ell=\max(1,p-1)}^{r-j} (-1)^{\ell+1-p} \sum_{\substack{j_1+\dots+j_\ell=r-j \\ j_i \geq 1}} \prod_{i=1}^{\ell} (\beta_{j_i}(k) - \alpha_{j_i}(k)) \\
&\quad \times \sum_{1 \leq i_1 < \dots < i_{\ell+1-p} \leq \ell} \prod_{q=1}^{\ell+1-p} \left(\frac{\beta_{j_{i_q}}(k)}{\beta_{j_{i_q}}(k) - \alpha_{j_{i_q}}(k)} \right) \\
&\quad - r! \sum_{p=1}^{r-1} \binom{n-(k+1)r+p}{p-1} \sum_{j=1}^{\min(r-p, r-1)} \delta_j(k) \\
&\quad \times \sum_{\ell=\max(1,p)}^{r-j} (-1)^{\ell-p} \sum_{\substack{j_1+\dots+j_\ell=r-j \\ j_i \geq 1}} \prod_{i=1}^{\ell} (\beta_{j_i}(k) - \alpha_{j_i}(k)) \\
&\quad \times \sum_{1 \leq i_1 < \dots < i_{\ell-p} \leq \ell} \prod_{q=1}^{\ell-p} \left(\frac{\beta_{j_{i_q}}(k)}{\beta_{j_{i_q}}(k) - \alpha_{j_{i_q}}(k)} \right) + r! (\delta_r(k) - \gamma_r(k)).
\end{aligned} \tag{4.4}$$

This yields, in particular, results for the expectation and the variance:

$$\begin{aligned}
(4.5) \quad \mathbf{E}(X_{n,k}) &= \frac{2(n+1)}{(k+1)(k+2)} \quad \text{for } n \geq k+1, \\
\mathbf{V}(X_{n,k}) &= \frac{2k(4k^2+5k-3)(n+1)}{(k+1)(k+2)^2(2k+1)(2k+3)} \quad \text{for } n \geq 2(k+1).
\end{aligned}$$

4.2. The critical case. We consider the critical case and assume that $k := k_n$ grows with n such that $\frac{n}{k^2} \rightarrow \lambda$ for some $\lambda > 0$.

Finding the limiting distribution requires some estimates on the functions appearing in (4.4). Using the definition of $\alpha_j(k)$, $\beta_j(k)$, $\gamma_j(k)$, and $\delta_j(k)$ given by (4.2)–(4.3), the following estimates, which hold for all $k \geq 2$ and $j \geq 1$, are not hard to show:

$$(4.6) \quad |\beta_j(k) - \alpha_j(k)| \leq \frac{2}{k^{j+1}}, \quad \left| \frac{\beta_j(k)}{\beta_j(k) - \alpha_j(k)} \right| \leq 4^j k,$$

$$(4.7) \quad |\delta_j(k) - \gamma_j(k)| \leq \frac{3}{k^j}, \quad |\delta_j(k)| \leq \frac{1}{k^{j-1}}.$$

We can now deduce the asymptotic behavior of the r th factorial moments of $X_{n,k}$ by inspecting the summands of (4.4). Considering a fixed $r \geq 1$, we trivially obtain for the first summand

$$\begin{aligned} r! \binom{n-kr}{r} \left(\frac{2}{(k+1)(k+2)} \right)^r &= \left(\frac{2n}{k^2} \right)^r \left(1 + O\left(\frac{1}{k}\right) + \left(\frac{k}{n}\right) \right) \\ &= (2\lambda)^r \left(1 + O\left(\frac{1}{\sqrt{n}}\right) \right). \end{aligned}$$

Let us denote by B the remaining summands of (4.4). They can then be estimated for fixed $r \geq 1$ by using (4.6) and (4.7), which finally gives

$$|B| = O\left(\frac{1}{k}\right) = O\left(\frac{1}{\sqrt{n}}\right).$$

Summarizing, we obtain for all $r \geq 1$ and sequences (n, k) such that $\frac{n}{k^2} \rightarrow \lambda$ the following asymptotic expansion:

$$\mathbf{E}(X_{n,k}^r) = (2\lambda)^r \left(1 + O\left(\frac{1}{\sqrt{n}}\right) \right).$$

This shows convergence in distribution of $X_{n,k}$ to a Poisson random variable with parameter 2λ . Thus we proved the convergence asserted in Theorem 2.2(b), where we used the substitution $c := \frac{1}{\sqrt{\lambda}}$, and thus $\frac{k}{\sqrt{n}} \rightarrow c$. When we have a critical case with $k/\sqrt{n}$ not converging to a limit, all factorial (and ordinary) moments oscillate, and no limit distribution exists for $X_{n,k}$.

4.3. The supercritical case. Again, by using the estimates (4.6) and (4.7), one can show $\mathbf{E}(X_{n,k}) \rightarrow 0$ for $\frac{n}{k^2} = o(1)$ under the natural restriction $n > k$. Thus, we have convergence of $X_{n,k}$ to a degenerate distribution with mass at 0.

4.4. The subcritical case. We consider the centered random variables $\tilde{X}_{n,k} := X_{n,k} - \mathbf{E}(X_{n,k})$ and introduce the generating function

$$\tilde{M}_k(z, s) := \sum_{n \geq 1} \mathbf{E}(e^{\tilde{X}_{n,k}s}) z^n = \sum_{n \geq 1} e^{-\mathbf{E}(X_{n,k})s} \mathbf{E}(e^{X_{n,k}s}) z^n.$$

Using the explicit formula for $\mathbf{E}(X_{n,k})$ as given by (4.5), we obtain

$$\begin{aligned} \tilde{M}_k(z, s) &= e^{-\frac{2s}{(k+1)(k+2)}} M_k(e^{-\frac{2s}{(k+1)(k+2)}} z, e^s) + (1 - e^{\frac{ks}{k+2}}) z^k \\ &\quad + \sum_{1 \leq n < k} z^n - \sum_{1 \leq n < k} e^{-\frac{2(n+1)s}{(k+1)(k+2)}} z^n, \end{aligned}$$

which, by using (4.1) and (4.2)–(4.3), further leads to

$$\begin{aligned}\tilde{M}_k(z, s) &= \frac{e^{-\frac{2s}{(k+1)(k+2)}} U}{V} - e^{-\frac{2s}{(k+1)(k+2)}} + (1 - e^{\frac{ks}{k+2}}) z^k \\ &\quad + \sum_{1 \leq n < k} z^n - \sum_{1 \leq n < k} e^{-\frac{2(n+1)s}{(k+1)(k+2)}} z^n,\end{aligned}$$

with the expressions

$$\begin{aligned}U &:= 1 + \sum_{j \geq 1} \delta_j(k) (e^s - 1)^j e^{-\frac{2js}{k+2}} z^{(k+1)j} \\ &\quad - \sum_{j \geq 1} \gamma_j(k) (e^s - 1)^j e^{-\frac{2((k+1)j-1)s}{(k+1)(k+2)}} z^{(k+1)j-1}, \\ V &:= 1 - e^{-\frac{2s}{(k+1)(k+2)}} z - \sum_{j \geq 1} \beta_j(k) (e^s - 1)^j e^{-\frac{2((k+1)j+1)s}{(k+1)(k+2)}} z^{(k+1)j+1} \\ &\quad + \sum_{j \geq 1} \alpha_j(k) (e^s - 1)^j e^{-\frac{2js}{k+2}} z^{(k+1)j}.\end{aligned}$$

4.4.1. Expanding around $s = 0$. We expand $\tilde{M}_k(z, s)$ around $s = 0$ and $z = 1$. It is straightforward, though rather laborious, to come up with the following representation:

$$M_k(e^{-\frac{2s}{(k+1)(k+2)}} z, e^s) = -1 + \frac{\sum_{\ell \geq 0} s^\ell \sum_{i=0}^{\ell(k+1)} d_{\ell,i}(k) (1-z)^i}{1 - z - \sum_{\ell \geq 1} s^\ell \sum_{i=0}^{\ell(k+1)+1} c_{\ell,i}(k) (1-z)^i},$$

where the functions $d_{\ell,i}(k)$ and $c_{\ell,i}(k)$ are given as follows:

$$\begin{aligned}(4.8) \quad d_{\ell,i}(k) &= (-1)^i \sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{j! \{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} (-1)^m}{m! (\ell-m)! (k+2)^m} \\ &\quad \times \left(\binom{(k+1)j-1}{i} \left((2j)^m \delta_j(k) - \frac{(2((k+1)j-1))^m \gamma_j(k)}{(k+1)^m} \right) \right. \\ &\quad \left. + \binom{(k+1)j-1}{i-1} (2j)^m \delta_j(k) \mathbb{I}[i \geq 1] \right) \quad \text{for } \ell \geq 1,\end{aligned}$$

$$d_{0,0}(k) = 1,$$

$$\begin{aligned}(4.9) \quad c_{\ell,i}(k) &= (-1)^i \sum_{j=1}^{\ell} \sum_{m=0}^{\ell-j} \frac{\{ \begin{smallmatrix} \ell-m \\ j \end{smallmatrix} \} j! (-1)^m}{m! (\ell-m)! (k+2)^m} \\ &\quad \times \left(\binom{(k+1)j}{i} \left(\frac{(2((k+1)j+1))^m \beta_j(k)}{(k+1)^m} - (2j)^m \alpha_j(k) \right) \right. \\ &\quad \left. + \binom{(k+1)j}{i-1} \frac{(2((k+1)j+1))^m \beta_j(k)}{(k+1)^m} \mathbb{I}[i \geq 1] \right) \\ &\quad + \frac{(-1)^\ell 2^\ell}{\ell! (k+1)^\ell (k+2)^\ell} \mathbb{I}[i=0] - \frac{(-1)^\ell 2^\ell}{\ell! (k+1)^\ell (k+2)^\ell} \mathbb{I}[i=1].\end{aligned}$$

Thus, $\tilde{M}_k(z, s)$ can be written as

$$(4.10) \quad \tilde{M}_k(z, s) = \frac{e^{-\frac{2s}{(k+1)(k+2)}} \left(\sum_{\ell \geq 0} s^\ell \sum_{i=0}^{\ell(k+1)} d_{\ell,i}(k) (1-z)^i \right)}{1 - z - \sum_{\ell \geq 1} s^\ell \sum_{i=0}^{\ell(k+1)+1} c_{\ell,i}(k) (1-z)^i} - e^{-\frac{2s}{(k+1)(k+2)}} \\ + (1 - e^{\frac{ks}{k+2}}) z^k + \sum_{1 \leq n < k} z^n - \sum_{1 \leq n < k} e^{-\frac{2(n+1)s}{(k+1)(k+2)}} z^n.$$

The only interesting part in (4.10) is the first summand, since the remaining summands do not give a contribution for $n > k$ (the remainder is a polynomial in z of degree k). The first summand of (4.10) can be expanded around $s = 0$ and $z = 1$, and for $r \geq 1$ finally leads to the following representation:

$$[s^r] \frac{e^{-\frac{2s}{(k+1)(k+2)}} \left(\sum_{\ell \geq 0} s^\ell \sum_{i=0}^{\ell(k+1)} d_{\ell,i}(k) (1-z)^i \right)}{1 - z - \sum_{\ell \geq 1} s^\ell \sum_{i=0}^{\ell(k+1)+1} c_{\ell,i}(k) (1-z)^i} \\ = \sum_{p=0}^r \frac{1}{(1-z)^{p+1}} f_{r,p}(k) + \sum_{p=0}^{r-1} \frac{1}{(1-z)^{p+1}} g_{r,p}(k) + \sum_{p=0}^{r(k+1)-1} h_{r,p}(k) z^p$$

with

$$(4.11) \quad f_{r,p}(k) = \sum_{m=p}^r \sum_{\substack{r_1 + \dots + r_m = r \\ r_q \geq 1}} \sum_{\substack{t_1 + \dots + t_m = m-p \\ 0 \leq t_q \leq r_q(k+1)+1}} \prod_{j=1}^m c_{r_j, t_j}(k), \\ (4.12) \quad g_{r,p}(k) = \sum_{c=1}^r \sum_{a=p}^{r-c} \left(\sum_{m=a}^{r-c} \sum_{\substack{r_1 + \dots + r_m = r-c \\ r_q \geq 1}} \sum_{\substack{t_1 + \dots + t_m = m-a \\ 0 \leq t_q \leq r_q(k+1)+1}} \prod_{j=1}^m c_{r_j, t_j}(k) \right) \\ \times \left(\sum_{b=\lceil \frac{a-p}{k+1} \rceil}^c \frac{(-1)^{c-b} 2^{c-b} d_{b, a-p}(k)}{(k+1)^{c-b} (k+2)^{c-b} (c-b)!} \right)$$

and certain functions $h_{r,p}(k)$, which are of course irrelevant for our purpose.

This also leads to the required representation

$$[s^r] \tilde{M}_k(z, s) = \sum_{p=0}^r \frac{1}{(1-z)^{p+1}} f_{r,p}(k) + \sum_{p=0}^{r-1} \frac{1}{(1-z)^{p+1}} g_{r,p}(k) + \sum_{p=0}^{r(k+1)-1} \tilde{h}_{r,p}(k) z^p,$$

where the functions $f_{r,p}(k)$, and $g_{r,p}(k)$ are defined by (4.11) and (4.12). The functions $\tilde{h}_{r,p}(k)$ are irrelevant and thus not given explicitly.

The representation in the last display gives the following explicit formula for the r th moments of $\tilde{X}_{n,k}$, which is valid for $n \geq r(k+1)$:

$$\mathbf{E}(\tilde{X}_{n,k}^r) = r! [z^n s^r] \tilde{M}_k(z, s) = r! \sum_{p=0}^r \binom{n+p}{p} f_{r,p}(k) + r! \sum_{p=0}^r \binom{n+p}{p} g_{r,p}(k),$$

where the functions $f_{r,p}(k)$ and $g_{r,p}(k)$ are given by (4.11) and (4.12).

4.4.2. Estimates for $c_{\ell,i}(\mathbf{k})$ and $d_{\ell,i}(\mathbf{k})$. One obtains easily the following estimates of the functions $c_{\ell,i}(\mathbf{k})$ and $d_{\ell,i}(\mathbf{k})$ given by (4.8) and (4.9):

$$\begin{aligned} |d_{\ell,i}(\mathbf{k})| &\leq 2\ell^2(2\ell)^{2\ell+1}B_\ell(2\ell)^i k^{i-1} && \text{for } \ell \geq 1, i \geq 0, k \geq 1, \\ |c_{\ell,i}(\mathbf{k})| &\leq B_\ell 2^{2\ell+3}\ell^{\ell+3}(2\ell)^i k^{i-2} && \text{for } \ell \geq 1, i \geq 0, k \geq 1. \end{aligned}$$

Moreover, we have the following values:

$$c_{1,0}(\mathbf{k}) = 0 \quad \text{and} \quad c_{2,0}(\mathbf{k}) = \frac{\nu(\mathbf{k})}{2},$$

with

$$\nu(\mathbf{k}) := \frac{2k(4k^2 + 5k - 3)}{(k+1)(k+2)^2(2k+1)(2k+3)}.$$

4.4.3. Estimates for $f_{r,p}(\mathbf{k})$ and $g_{r,p}(\mathbf{k})$. It is possible to give suitable estimates on the growth of $f_{r,p}(\mathbf{k})$ and $g_{r,p}(\mathbf{k})$: There exist constants κ_r and η_r (depending only on r) such that

$$|f_{r,p}(\mathbf{k})| \leq \kappa_r \frac{1}{k^{2p}} \quad \text{and} \quad |g_{r,p}(\mathbf{k})| \leq \eta_r \frac{1}{k^{2p+2}}$$

for all $0 \leq p \leq r$ (resp., $0 \leq p \leq r-1$) and $k \geq 1$.

For instance one can choose the constants

$$\kappa_r = \frac{(2r-1)!(r+1)}{r!} c_r^r, \quad \eta_r = 2^{r+2} \binom{2r-1}{r-1} r! r c_r^r d_r,$$

with

$$c_r := B_r 2^{2r+3} r^{r+3} (2r)^r \quad \text{and} \quad d_r := 2B_r r^r (2r)^{3r+1}.$$

4.4.4. Cancellation of $\tilde{f}_{r,p}(\mathbf{k})$. Using the same “combinatorial argumentation” as for recursive trees, we can show that

$$\begin{aligned} f_{r,p}(\mathbf{k}) &= 0 && \text{for } p \geq \left\lfloor \frac{r}{2} \right\rfloor + 1, \\ g_{r,p}(\mathbf{k}) &= 0 && \text{for } p \geq \left\lceil \frac{r}{2} \right\rceil. \end{aligned}$$

Furthermore, one can show

$$f_{2d,d}(\mathbf{k}) = c_{2,0}^d(\mathbf{k}) = \frac{\nu^d(\mathbf{k})}{2^d}.$$

4.4.5. Asymptotics of the centered moments. In view of the development in subsection 4.4.3 we obtain the following explicit formulas for the r th moments of $X_{n,k}$:

$$\begin{aligned} \mathbf{E}(\tilde{X}_{n,k}^{2d}) &= (2d)! \left(\binom{n+d}{d} f_{2d,d}(\mathbf{k}) \right. \\ &\quad \left. + \sum_{p=0}^{d-1} \binom{n+p}{p} (f_{2d,p}(\mathbf{k}) + g_{2d,p}(\mathbf{k})) \right), \quad d \geq 1, \\ \mathbf{E}(\tilde{X}_{n,k}^{2d+1}) &= (2d+1)! \sum_{p=0}^d \binom{n+p}{p} (f_{2d+1,p}(\mathbf{k}) + g_{2d+1,p}(\mathbf{k})), \quad d \geq 0. \end{aligned}$$

Using the previous estimates, we can easily show that, for $\frac{k^2}{n} \rightarrow 0$,

$$\begin{aligned}\mathbf{E}(\tilde{X}_{n,k}^{2d}) &\rightarrow \frac{(2d)!}{d! 2^d} n^d \nu^d(k), \\ \mathbf{E}(\tilde{X}_{n,k}^{2d+1}) &= O\left(\left(\frac{n}{k^2}\right)^d\right) = O(n^d \nu^d(k)).\end{aligned}$$

Therefore, considering

$$\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}} = \frac{X_{n,k} - \mathbf{E}(X_{n,k})}{\sqrt{\nu(k)n}},$$

with $\nu(k) = \frac{2k(4k^2+5k-3)}{(k+1)(k+2)^2(2k+1)(2k+3)}$, we have for $k = o(\sqrt{n})$

$$\begin{aligned}\mathbf{E}\left(\left(\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}}\right)^{2d}\right) &\rightarrow \frac{(2d)!}{d! 2^d} \quad \text{for } d \geq 1, \\ \mathbf{E}\left(\left(\frac{\tilde{X}_{n,k}}{\sqrt{\nu(k)n}}\right)^{2d+1}\right) &= O\left(\frac{k}{\sqrt{n}}\right) \rightarrow 0 \quad \text{for } d \geq 0,\end{aligned}$$

whence for the subcritical case we have

$$\frac{X_{n,k} - \frac{2n}{(k+1)(k+2)}}{\sqrt{\frac{2k(4k^2+5k-3)n}{(k+1)(k+2)^2(2k+1)(2k+3)}}} \xrightarrow{D} \mathcal{N}(0,1),$$

completing the proof for the subcritical case (part (a) of Theorem 2.2).

5. Concluding remarks. Several methods have recently come into the repertoire of the analysis of algorithms, and there is a question of which method to choose for an analysis such as the one we conducted in this investigation. For example, the contraction method (introduced in Rösler (1991)), Pólya urns (Johnson and Kotz (1977)), the Chen–Stein method (Barbour, Holst, and Janson (1992)), methods for additive functions in subtrees (Devroye (1991) and Devroye (2002)) are all attractive for this kind of analysis. These methods have been used successfully in the analysis of algorithms (see, for example Neininger (2002) or Rösler and Rüschendorf (2001) for applications of the contraction method). However, experience shows that several of these methods will work with ease in some of the phases, but not systematically across all the phases. For instance, in our multiphase problem, Pólya urns work well in the very low range (small fixed k), as was attempted in Feng, Mahmoud, and Su (2007). The difficulty in this method is that one needs a detailed description of the fringe in terms of urns that are different from each other for each k and that become more complex as k increases. As for the contraction method, again it can be used in the case of small fixed k , but it does not lend itself easily to $k = k_n \rightarrow \infty$ in the subcritical case when k increases at a rate slower than $\sqrt{n}$. The difficulty stems from complicated toll functions. It is not clear how to apply the contraction method, or the other methods above, in the critical case. It is our experience that the analytic methods, based on generating functions, are systematic enough to cover all the ranges.

l -CHAIN PROFILE VECTORS*

DÁNIEL GERBNER[†] AND BALÁZS PATKÓ[‡]

Abstract. The l -chain profile vector of a set system $\mathcal{F}$ on an underlying set X of size n is defined to be the vector of length $\binom{n+1}{l}$ in which the α th component ($\alpha = (\alpha_1, \alpha_2, \dots, \alpha_l)$ $0 \leq \alpha_1 < \alpha_2 < \dots < \alpha_l \leq n$) is the number of l -chains in $\mathcal{F}$ with the smallest set having size α_1 , the second smallest α_2 , and so on. We modify the method of Erdős, Frankl, and Katona to determine the l -chain profile polytope of some sets of families including k -Sperner, complement-free, and complement-free k -Sperner families.

Key words. profile vectors, k -Sperner, intersecting, complement-free families

AMS subject classification. 05D05

1. Introduction. Basic problems in extremal set theory consider a set $\mathbb{A}$ of families of subsets of an n -element set all having some fixed property (Sperner, intersecting, complement-free, etc.) and ask for the family with the largest size. That is, we sum over all sets in the family, adding one for each set, and we ask for the family with the largest sum (largest *weight*). A natural generalization of this problem is in the summation we allow *weights* different from 1, but depending only on the size of the subset in question. For example, in the famous LYM-inequality a k -element set has weight $\frac{1}{\binom{n}{k}}$.

The tool that helps in dealing with this generalized problem is the so-called *profile vector* of a family $\mathcal{F}$. It is a vector $f(\mathcal{F}) \in \mathbb{R}^{n+1}$ whose components are defined by

$$f(\mathcal{F})_i = |\{F \in \mathcal{F} : |F| = i\}|.$$

Given a set of families $\mathbb{A}$, let $\mu(\mathbb{A})$ denote the set of the profile vectors of families in $\mathbb{A}$ (i.e., $\{f(\mathcal{F}) : \mathcal{F} \in \mathbb{A}\}$). Now determining the family in $\mathbb{A}$ with the largest weight (for a weight function w as above, where we denote the weight of an i -element set by w_i) is equivalent to finding the family of which the profile maximizes

$$w \cdot f(\mathcal{F}) = \sum_{i=0}^n w_i f(\mathcal{F})_i$$

among profiles in $\mu(\mathbb{A})$.

A basic fact of linear programming says that this maximum is attained at some *extreme point* of the *convex hull* of $\mu(\mathbb{A})$, which we call the *profile polytope* of $\mathbb{A}$; we denote it by $\langle \mu(\mathbb{A}) \rangle$. And if all w_i s are nonnegative, then the maximum is taken at an *essential extreme point* (i.e., an extreme point that is maximal with respect to the componentwise ordering). Therefore, to establish “all linear inequalities” concerning a set $\mathbb{A}$ of families, one has to determine its profile polytope and its extreme points. The

first result in this area (implicitly, without using the notion of the profile polytope) is due to Katona [7], and the systematic investigation of profile polytopes was started by Erdős, Frankl, and Katona in [4], [5], [6]. A survey on this topic can be found in the book of Engel [3].

However, there are problems dealing with other kinds of weight functions, and there are problems dealing not with sets of some families, but subfamilies of families. A family of sets is called k -Sperner (and Sperner or *antichain* if $k = 1$) if it does not contain a chain of length $k + 1$ (a sequence of sets of length $k + 1$ in which every set contains the previous one). By the dual version of Dilworth's theorem we know that being k -Sperner is equivalent to being the union of at most k antichains. A natural question is the following: Letting $l \leq k$ be two integers, how many l -chains can be contained in a family without a $k + 1$ -chain (i.e., in a k -Sperner family)? Note that this problem is analogous to the celebrated theorem of Turán [12], generalized by Sauer [11] (see also [2]), stating that for all integers $2 \leq r \leq s$ a graph on n vertices without a clique of size $s + 1$ can contain at most as many cliques of size r as does the s -partite Turán graph on n vertices (the complete s -partite graph with equipartite partition).

To deal with the above problem we introduce the notion of an l -chain profile vector of a family $\mathcal{F}$ on an n -element underlying set. This has $\binom{n+1}{l}$ components, and the α th component f_α , where $\alpha = (\alpha_1, \dots, \alpha_l)$ with $0 \leq \alpha_1 < \alpha_2 < \dots < \alpha_l \leq n$, denotes the number of l -chains in $\mathcal{F}$ in which the smallest set has size α_1 , the second smallest has size α_2 , and so on. Note that for $l = 1$ this is just the original notion of the profile vector.

The rest of the paper is organized as follows. In section 2 we provide some more definitions and make some easy remarks on the connection between the original notion of a profile vector and the newly introduced notion of an l -chain profile. In section 3 we prove our main tool in determining l -chain profile polytopes, and in section 4 we use this tool (the reduction method) to get some results on some sets of families.

2. Definitions and remarks. In this section we give some further definitions and describe some basic connections between the extreme points in the l -chain case and the extreme points in the original (1-chain) case.

Notation. For $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_l)$, $0 \leq \alpha_1 < \alpha_2 < \dots < \alpha_l \leq n$, we define the following multinomial coefficient:

$$\binom{n}{\alpha} = \prod_{i=1}^l \binom{n - \alpha_{i-1}}{\alpha_i - \alpha_{i-1}} = \frac{n!}{\alpha_1!(\alpha_2 - \alpha_1)! \dots (\alpha_l - \alpha_{l-1})!(n - \alpha_l)!},$$

where $\alpha_0 = 0$ and $0! = 1$ as usual. Note that $\binom{n}{\alpha}$ is the number of l -chains that can be formed from subsets of an n -element set in such a way that the smallest set has size α_1 , the second smallest has size α_2 , and so on.

Definition. Given an underlying set X and a family $\mathcal{F}$ of its subsets, the upset of $\mathcal{F}$ is $\mathcal{U}(\mathcal{F}) = \{G \subseteq X : \exists F \in \mathcal{F} \text{ such that } F \subseteq G\}$, and the downset of $\mathcal{F}$ is $\mathcal{D}(\mathcal{F}) = \{G \subseteq X : \exists F \in \mathcal{F} \text{ such that } F \supseteq G\}$.

Definition. A set $\mathbb{A}$ of families is upward (downward) closed if $\mathcal{F} \in \mathbb{A}$ implies $\mathcal{U}(\mathcal{F}) \in \mathbb{A}$ ($\mathcal{D}(\mathcal{F}) \in \mathbb{A}$).

Examples. Clearly the set of t -intersecting (t -cointersecting) families is upward (downward) closed. (A family $\mathcal{F}$ is said to be t -intersecting if, for any two $F_1, F_2 \in \mathcal{F}$, $|F_1 \cap F_2| \geq t$, and a family $\mathcal{G}$ is said to be t -cointersecting if $\overline{\mathcal{G}} = \{\overline{G} : G \in \mathcal{G}\}$ is t -intersecting or equivalently if, for any two $G_1, G_2 \in \mathcal{G}$, $|\overline{G_1} \cup \overline{G_2}| \geq t$.)

Definition. Let $\mu_l(\mathbb{A})$ denote the set of all l -chain profile vectors of families in $\mathbb{A}$, $\langle \mu_l(\mathbb{A}) \rangle$ its convex hull, $\mathcal{E}_l(\mathbb{A})$ the extreme points of $\langle \mu_l(\mathbb{A}) \rangle$, and $E_l(\mathbb{A})$ the families from $\mathbb{A}$ with an l -chain profile in $\mathcal{E}_l(\mathbb{A})$. Let, furthermore, $\mathcal{E}_l^*(\mathbb{A})$ denote the essential extreme points and $E_l^*(\mathbb{A})$ the corresponding families.

THEOREM 1. *For any upward or downward closed set of families $\mathbb{A} \subseteq 2^{2^X}$ and for any $l \geq 1$*

$$\mathcal{E}_l^*(\mathbb{A}) \subseteq \mu_l(E_1^*(\mathbb{A})).$$

Note that equality does not always hold, as the set of intersecting families, the family $\mathcal{F} = \{F \subseteq X : |F| > |X|/2\}$, and any $l > |X|/2$ show.

Proof. The proof is the same for downward and upward closed sets of families, so we assume that $\mathbb{A}$ is upward closed.

Let $E_1^*(\mathbb{A}) = \{\mathcal{F}_1, \mathcal{F}_2, \dots, \mathcal{F}_m\}$, and let f^i be the profile of $\mathcal{F}_i$, $f^{i,l}$ be the l -chain profile of $\mathcal{F}_i$, and $f_\alpha^{i,l}$ be its α th component.

We have to prove that the l -chain profile f^l of any family $\mathcal{F}$ in $\mathbb{A}$ can be dominated by a convex combination of the $f^{i,l}$'s. Denote the profile of $\mathcal{F}$ by f . Clearly we have

$$f_\alpha^l \leq f_{\alpha_1} \binom{n - \alpha_1}{\alpha^*},$$

where $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_l)$, $\alpha^* = (\alpha_2 - \alpha_1, \alpha_3 - \alpha_1, \dots, \alpha_l - \alpha_1)$. Inequality holds with equality for the $f_\alpha^{i,l}$'s and the $f_\alpha^{i,l}$'s. The fact that the f^i 's are the essential extreme points of $\langle \mu_1(\mathbb{A}) \rangle$ means that for some convex combination $c_i, i = 1, \dots, m$,

$$f \leq \sum_{i=1}^m c_i f^i.$$

But then

$$f_\alpha^l \leq f_{\alpha_1} \binom{n - \alpha_1}{\alpha^*} \leq \binom{n - \alpha_1}{\alpha^*} \sum_{i=1}^m c_i f_{\alpha_1}^i = \sum_{i=1}^m c_i f_\alpha^{i,l},$$

which completes the proof. $\square$

Since the convex hull of the profile polytope of the set of intersecting families was determined by Erdős, Frankl, and Katona in [5], Theorem 1 provides the essential extreme points of the convex hull of the l -chain profile polytopes.

Definition. For any family $\mathcal{F}$ on a base set X let $\text{conv}(\mathcal{F}) = \{G \subseteq X : \exists F, F' \in \mathcal{F} (F \subseteq G \subseteq F')\}$ denote its *convex closure*. $\mathcal{F}$ is said to be *convex* if $\mathcal{F} = \text{conv}(\mathcal{F})$.

Definition. A set of families $\mathbb{A}$ is said to be *convex closed* if $\mathcal{F} \in \mathbb{A}$ implies $\text{conv}(\mathcal{F}) \in \mathbb{A}$.

Example. The basic example for a convex closed set is the set of intersecting and counterintersecting families.

THEOREM 2. *For any convex closed set of families $\mathbb{A} \subseteq 2^{2^X}$ and for any $l \geq 2$*

$$\mathcal{E}_l^*(\mathbb{A}) \subseteq \mu_l(E_2^*(\mathbb{A})).$$

Proof. The proof is analogous to that of Theorem 1. The inequality needed is

$$f_\alpha^l \leq f_{\alpha_1, \alpha_l}^2 \binom{\alpha_l - \alpha_1}{\alpha^*},$$

where $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_l)$, $\alpha^* = (\alpha_2 - \alpha_1, \alpha_3 - \alpha_1, \dots, \alpha_{l-1} - \alpha_1)$, and for families with an essential extreme profile, the above inequality holds with equality. $\square$

Unfortunately the extreme points of neither the 1-chain nor the 2-chain profile polytope are known for the set of intersecting and counterintersecting families.

3. The reduction method. In this section we describe our main tool in determining the l -chain profile polytope of families of sets with some given property. We call this tool the reduction method. In fact, this is not a new method. Most of the proofs of results already obtained proceeded similarly. What we observed was that the method works for the l -chain case as well, and—what seems more important—in some cases it is enough to reduce the original problem to a maximal chain or to a pair of complementary chains (for the precise definitions, see below) instead of to the more complicated structures that previous proofs (see, for example, [4], [5]) used. We have to mention that Sali in [10] uses arguments involving reduction to a maximal chain, but we are not aware of any proofs with reduction to a pair of complementary chains.

Definition. For any l let $T_{\mathbf{C}}^l$ denote the following operator acting on the $\binom{n+1}{l}$ -dimensional $\mathbf{R}$ -space whose coordinates are indexed by l -tuples of integers $(\alpha_1, \alpha_2, \dots, \alpha_l)$, where $0 \leq \alpha_1 < \alpha_2 < \dots < \alpha_l \leq n$:

$$T_{\mathbf{C}}^l : e \mapsto T_{\mathbf{C}}^l(e), \quad \text{where} \quad T_{\mathbf{C}}^l(e)_{\alpha} = \binom{n}{\alpha} e_{\alpha}.$$

Definition. For a family $\mathcal{F}$ on a base set X and a maximal chain $\mathbf{C}$ in X let $\mathcal{F}(\mathbf{C}) = \{F \in \mathcal{F} \cap \mathbf{C}\}$, and for a set of families $\mathbb{A}$ let $\mathbb{A}(\mathbf{C}) = \{\mathcal{F}(\mathbf{C}) : \mathcal{F} \in \mathbb{A}\}$.

THEOREM 3. *For any set of families $\mathbb{A} \subseteq 2^{2^X}$ if the extreme points $e_1, e_2, \dots, e_m$ of $\langle \mu_l(\mathbb{A}(\mathbf{C})) \rangle$ do not depend on the choice of $\mathbf{C}$, then*

$$\langle \mu_l(\mathbb{A}) \rangle \subseteq \langle \{T_{\mathbf{C}}^l(e_1), \dots, T_{\mathbf{C}}^l(e_m)\} \rangle.$$

Proof. The modification of the argument in [5] works. Let $\mathcal{F}$ be an element of $\mathbb{A}$ with an l -profile $f = (\dots, f_{\alpha}, \dots)$. For $\mathbf{F} = \{F_1 \subset F_2 \subset \dots \subset F_l\}$ with $|F_i| = \alpha_i, i = 1, \dots, l$, let $\underline{w}(\mathbf{F})$ be the vector of length $\binom{n+1}{l}$ with $1/n!$ in the α th component and 0 everywhere else (where n is the size of the base set). Consider the sum $\sum \underline{w}(\mathbf{F})$ for all pairs $(\mathbf{C}, \mathbf{F})$, where $\mathbf{C}$ is a maximal chain on X and $\mathbf{F} \subset \mathcal{F} \cap \mathbf{C}$ is an l -chain. For a fixed $\mathbf{C}$ we have

$$\sum_{\mathbf{F} \in \mathcal{F}(\mathbf{C})} \underline{w}(\mathbf{F}) = \frac{1}{n!} (\text{profile of } \mathcal{F}(\mathbf{C})).$$

Here the profile of $\mathcal{F}(\mathbf{C})$ is a convex linear combination $\sum_{i=1}^m \lambda_i(\mathbf{C}) e_i$ of the e_i 's. Therefore,

$$(1) \quad \sum_{\mathbf{C}, \mathbf{F}} \underline{w}(\mathbf{F}) = \sum_{\mathbf{C}} \sum_{\mathbf{F}} \underline{w}(\mathbf{F}) = \sum_{\mathbf{C}} \frac{1}{n!} \sum_{i=1}^m \lambda_i(\mathbf{C}) e_i = \sum_{i=1}^m \frac{1}{n!} \left(\sum_{\mathbf{C}} \lambda_i(\mathbf{C}) \right) e_i$$

holds where $\sum_{\mathbf{C}} \frac{1}{n!} \sum_{i=1}^m \lambda_i(\mathbf{C}) = 1$. Thus $\sum \underline{w}(\mathbf{F})$ is a convex linear combination of the e_i 's.

Summing in the other way around, we have

$$(2) \quad \begin{aligned} \sum_{\mathbf{C}, \mathbf{F}} \underline{w}(\mathbf{F}) &= \sum_{\mathbf{F}} \sum_{\mathbf{C}} \underline{w}(\mathbf{F}) \\ &= \sum_{\mathbf{F}} \left(0, 0, \dots, \frac{|F_1|! (|F_2| - |F_1|)! \dots (|F_l| - |F_{l-1}|)! (n - |F_l|)!}{n!}, \dots, 0 \right) \\ &= \left(\dots, \frac{f_{\alpha}}{\binom{n}{\alpha}}, \dots \right), \end{aligned}$$

since for a fixed $\mathbf{F} = \{F_1 \subset F_2 \subset \dots \subset F_l\}$ there are exactly $|F_1|!(|F_2|-|F_1|)!\dots(|F_l|-|F_{l-1}|)!(n-|F_l|)!$ chains containing $\mathbf{F}$. So (1) and (2) give that this last vector is a convex linear combination of the e_i 's, which implies that f is the linear combination of $T_{\mathbf{C}}^l(e_1), \dots, T_{\mathbf{C}}^l(e_m)$. $\square$

The structure of maximal chains is too simple, so using only them is not enough to determine the l -chain profile polytope of more difficult sets of families. But the proof of Theorem 3 works if we replace the chain by a pair of complementary maximal chains (i.e., for $i = 1, 2$ $\mathbf{C}^i = \{C_0^i, C_1^i, \dots, C_n^i\}$ with $C_j^i = X \setminus C_{n-j}^{3-i} = \overline{C}_{n-j}^{3-i}$ for all $j = 0, 1, \dots, n$). In the proof one has to write (instead of $\frac{1}{n!}$) $\frac{2}{(n!)}$ in the definition of $w(\mathbf{F})$ and modify the definition of the T -operator to

$$(T_{\mathbf{C}_1, \mathbf{C}_2}^l(e))_{\alpha} = \frac{1}{d_{\alpha}} \binom{n}{\alpha},$$

where d_{α} is the number of α -type l -chains in the pair of complementing chains.

4. Applications. In this section we determine the profile polytope of some sets of families using the reduction method. In the first subsection the problem will be reduced to the case of the maximal chain, while in the second subsection we will consider reduction to a pair of complementary chains. Using the results obtained by the latter we will give examples of when the extreme families of the l -profile polytope can really depend on l .

4.1. Reduction to the chain.

THEOREM 4. *For all $l \geq 1$ the extreme points of the convex hull of the l -chain profile vectors of convex families are the following: the all zero vector,*

$$\mathbf{0} = (0, \dots, 0),$$

and for all $0 \leq i \leq j \leq n$ the vectors $v_{i,j}$,

$$(3) \quad (v_{i,j})_{\alpha} = \begin{cases} \binom{n}{\alpha} & \text{if } i \leq \alpha_1 < \alpha_l \leq j, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. The vector $v_{i,j}$ is the l -profile of the family $\mathcal{F}_{i,j} = \{F \subseteq [n] : i \leq |F| \leq j\}$, which is convex.

On a chain any convex family must consist of some consecutive subsets of the chain. The theorem follows now from Theorem 3. $\square$

Note that the set of convex families is not hereditary; therefore, the extreme points (for the original profile vectors) need not be the ones obtained from the essential extreme points (in this case there is only one, and that is the profile of $2^{[n]}$) by changing some of the nonzero components to zero, and, as Theorem 4 shows, they are not those vectors, indeed.

THEOREM 5. *For any $l \leq k$ the extreme points of the l -chain profile polytope of k -Sperner families are the following: the all zero vector,*

$$\mathbf{0} = (0, \dots, 0, \dots, 0),$$

and for all $l \leq z \leq k$ and $\beta = \{\beta_1, \dots, \beta_z\}$ with $0 \leq \beta_1 < \dots < \beta_z \leq n$, the vectors v_{β} ,

$$(4) \quad (v_{\beta})_{\alpha} = \begin{cases} \binom{n}{\alpha} & \text{if } \alpha \subseteq \beta, \\ 0 & \text{otherwise.} \end{cases}$$

The case $l = 1$ is a result of Erdős, Frankl, and Katona [5].

Proof. It is trivial to see that these vectors are l -chain profiles of the corresponding levels, and they are convex linearly independent.

A k -Sperner family on a maximal chain consists of at most k sets; therefore, its l -chain profile vector has 1's in those components $\alpha = (\alpha_1, \dots, \alpha_l)$ for which there is an element in the family with size α_i for all $i = 1, \dots, l$. All these vectors are convex independent. Therefore, they form the convex hull of the profile polytope on the chain, and Theorem 3 now implies Theorem 5. $\square$

Applying Theorem 5 for the constant 1 weight function, one gets the following corollary.

COROLLARY. *For any $l \leq k$ if a family $\mathcal{F}$ on an n -element base set X does not contain a chain of length $k + 1$, then the number of l -chains in $\mathcal{F}$ is at most*

$$\max_{\beta \subset [0, n]; |\beta| = k} \sum_{\alpha \subseteq \beta; |\alpha| = l} \binom{n}{\alpha}.$$

Remarks. In the case $l = k$, even the very simple argument of [7] works. First we need an LYM-type inequality. To get this we double-count the pairs $(\mathbf{C}, \mathbf{F})$, where $\mathbf{C}$ is a maximal chain and $\mathbf{F}$ is an l -chain contained in $\mathbf{C}$. If we decompose the k -Sperner family into k antichains, then all sets of an $\mathbf{F}$ come from different antichains, and any $\mathbf{C}$ can contain at most k sets from our family, so by a standard calculation we obtain

$$(5) \quad \sum_{\alpha} \frac{f_{\alpha}}{\binom{n}{\alpha}} \leq \binom{k}{l}.$$

If $l = k$, then the right-hand side is 1, and we can finish the proof as follows:

$$(6) \quad \sum_{\alpha} w_{\alpha} f_{\alpha} = \sum_{\alpha} \frac{f_{\alpha} w_{\alpha}}{\binom{n}{\alpha}} \binom{n}{\alpha} \leq \max_{\alpha} \left\{ w_{\alpha} \binom{n}{\alpha} \right\} \sum_{\alpha} \frac{f_{\alpha}}{\binom{n}{\alpha}} \leq \max_{\alpha} \left\{ w_{\alpha} \binom{n}{\alpha} \right\},$$

where w_{α} is any nonnegative weight function and the last inequality in (6) uses (5).

If $l = k$, then (5) gives the maximum number of k -chains that a k -Sperner family can contain. This is $\binom{n}{\alpha}$, where $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_k)$ and the numbers $\alpha_1, \alpha_2 - \alpha_1, \dots, \alpha_k - \alpha_{k-1}$ differ by at most one. If $k + 1$ divides n , then we get the uniqueness of the extremal system (take all $F \subseteq X$ with $|F| = \alpha_i$ for some $i = 1, \dots, k$) automatically. If $k + 1$ does not divide n , then we can lift (5) up to an AZ-type identity (for more details see [9], and for the original AZ-identity see the paper of Ahlswede and Zhang [1]), which will ensure the uniqueness.

With the notation of section 3, Theorem 5 implies (if $\mathbb{S}_k$ denotes the set of k -Sperner families) $E_1(\mathbb{S}_k) = E_l(\mathbb{S}_k)$. But the bordering faces of the convex hulls $\langle \mu_1(\mathbb{S}_k) \rangle$ and $\langle \mu_l(\mathbb{S}_k) \rangle$ are “not the same.” If $l = 1$, the convex hull is determined by the faces given by the inequalities $0 \leq f_i \leq \binom{n}{i}$ and the LYM-inequality $\sum_i f_i / \binom{n}{i} \leq k$ (see [5]), while if $l > 1$, the hyperplanes given by $0 \leq f_{\alpha} \leq \binom{n}{\alpha}$ and the LYM-type inequality of (5) are bordering faces, but there are some additional bordering faces, which can be seen by the following observation. Choosing $\binom{k}{l}$ α 's in such a way that their union has size strictly larger than k and putting $f_{\alpha} = \binom{k}{\alpha}$ for these α 's and 0 for the others, we obtain an essential extreme point of the polytope determined by the above inequalities which is not an l -chain profile of any k -Sperner families.

In [8] the second author defined the distance of $\mathcal{F}$ -free families. For two $\mathcal{F}$ -free families $\mathcal{H}_1$ and $\mathcal{H}_2$ this is the number of copies of $\mathcal{F}$ in $\mathcal{H}_1 \cup \mathcal{H}_2$ (the edge (vertex) set of $\mathcal{H}_1 \cup \mathcal{H}_2$ is the union of the edge (vertex) sets of $\mathcal{H}_1$ and $\mathcal{H}_2$). For a collection

$\mathbb{C}$ of forbidden families, the $\mathbb{C}$ -free distance of two $\mathbb{C}$ -free families is the sum of $\mathcal{F}$ -free distances taken over all $\mathcal{F} \in \mathbb{C}$. If in the collection $\mathbb{C}$ we enumerate all kinds of $k+1$ -chains, then the $\mathbb{C}$ -free families are the k -Sperner systems. The union of two such systems is a $2k$ -Sperner family, and of course all $2k$ -Sperner families can be decomposed into two k -Sperner systems. So the maximum distance that two k -Sperner families can have is the maximum number of $k+1$ -chains that a $2k$ -Sperner family can contain, which by the corollary of Theorem 5 is

$$\max_{\beta \subset [0, n]; |\beta|=2k} \sum_{\alpha \subseteq \beta; |\alpha|=k+1} \binom{n}{\alpha}.$$

4.2. Reduction to a pair of complement chains.

THEOREM 6. *Let $n = 2m + 1$ and $k \leq m + 1$. Then the extreme points of the 1-chain profile polytope (i.e., the ordinary profile polytope) of the set of complement-free k -Sperner families are the following vectors (indexed with a z -element ($z \leq k$) subset α of $\{0, 1, 2, \dots, n\}$, where $\alpha_i \in \alpha$ implies $n - \alpha_i \notin \alpha$):*

$$v_\alpha = \left(0, \dots, 0, \binom{n}{\alpha_1}, 0, \dots, 0, \binom{n}{\alpha_2}, 0, \dots, 0, \dots, 0, \binom{n}{\alpha_z}, 0, \dots, 0 \right).$$

Proof. By the version of Theorem 3 just mentioned in the first paragraph of this section, it is enough to prove the following lemma.

LEMMA 1. *If $n = 2m + 1$ and $k \leq m + 1$, then the extreme points of the profile polytope of complement-free k -Sperner families on a pair of maximal complement chains are the vectors with at most k nonzero components, where all the nonzero components are 2 (except for the first or the last component; if one of them is nonzero, it equals 1), and if the i th component is nonzero, then the $(n - i)$ th component is zero.*

Proof of Lemma 1. If the nonzero components of such a vector are $\alpha_1, \alpha_2, \dots, \alpha_z$ (satisfying the condition of the lemma), then the sets in the two chains with cardinality α_i for some $i = 1, \dots, z$ form a complement-free k -Sperner family with the vector as profile.

Now let $\mathcal{F}$ be a complement-free k -Sperner family on a pair of complement chains $\mathbf{C}_1, \mathbf{C}_2$ with profile vector f . Let α be the set of indices of the nonzero components of f . Partition α into three subsets. Let CL (complete levels) denote the indices α_i with $f_{\alpha_i} = 2$, and, furthermore, CL contains 0 (n) provided $f_0 = 1$ ($f_n = 1$). Let, furthermore, CP (complementing pairs) denote the indices $\alpha_i \in \alpha$ with $n - \alpha_i \in \alpha$, and let $R = \alpha \setminus (CL \cup CP)$. Note that $CP \cap CL = \emptyset$, for otherwise $\mathcal{F}$ would not be complement-free. Now form two subsets α^1, α^2 of α in the following way. Put all indices in CL into both α^1 and α^2 . For all pairs of indices $i, n - i$ in CP (note that these are really pairs, for n is odd) put one of the indices into α^1 and the other into α^2 . Finally, choose α^1 or α^2 for all indices of R in such a way that $|\alpha^1| \leq k$ and $|\alpha^2| \leq k$ hold. (This is possible, for $\mathcal{F}$ is k -Sperner; therefore, $|\alpha| \leq 2k$.) Now let f^i , $i = 1, 2$, be the following vectors:

$$(7) \quad f_j^i = \begin{cases} 2 & (1) \text{ if } j \neq 0, n \text{ } (j = 0, n), \text{ } j \in \alpha^i, \\ 0 & \text{otherwise.} \end{cases}$$

By the facts that both f^i 's are of the form of the statement of the lemma and $f = \frac{1}{2}f^1 + \frac{1}{2}f^2$, furthermore f^1 and f^2 are both profile vectors of k -Sperner families on $\mathbf{C}_1, \mathbf{C}_2$, and the proof is completed. $\square$

The case of complement-free families is analogous (and even simpler); therefore, we just sketch the proof.

THEOREM 7. *The extreme points of the convex hull of the 1-chain profile vectors of complement-free families are the vectors corresponding to the families consisting of*

- (i) *a set I of levels with the property that the i th and the $(n - i)$ th levels cannot be both in I if n is odd, and*
- (ii) *a set I of levels with the property that the i th and the $(n - i)$ th levels cannot be both in I and possibly half of the sets with size $n/2$, one from each pair of complementary sets, if n is even.*

Proof. It is easy to see that it is enough to solve the problem reduced to a pair of maximal complement chains. There the statement holds, since there a complement-free family can contain at most two sets out of the four with size i or $n - i$, and the vectors $(1, 1), (0, 1), (1, 0)$ are convex combinations of the vectors $(2, 0), (0, 2), (0, 0)$. $\square$

Theorems 1 and 2 state that for a certain class of sets of families all candidates for the families with essential extreme l -chain profiles are among the families with essential extreme 1-chain (2-chain) profiles. Theorem 5 states that for k -Sperner families the above statement is true for all extreme profiles (not only for essential extreme profiles). It seems natural to conjecture (with the notation of section 2) that, for all sets of families $\mathbb{A}$ and $l > 1$, $E_l(\mathbb{A}) \subseteq E_1(\mathbb{A})$ and/or $E_l^*(\mathbb{A}) \subseteq E_1^*(\mathbb{A})$. But this is false. Here we present two counterexamples.

The first example is based on Theorem 6. Note that the families corresponding to the extreme points cannot contain sets of size i and $n - i$ at the same time. Hence all 2-chain profiles of those families have 0 in their components indexed with the sets $\{i, n - i\}$, and therefore all their convex combinations have 0 in those components. But a pair of subsets in inclusion with size i and $n - i$ is of course a complement-free k -Sperner family (if $k \geq 2$), and its profile is not in the convex hull of the above-mentioned vectors.

The second example is absolutely analogous to the first one. According to Theorem 7 in the extremal families of the set of complement-free systems there are no pairs of sets in inclusion with size i and $n - i$ (so the corresponding component is 0 in any convex combinations), but there are complement-free families with such pairs.

Acknowledgment. We would like to thank the two anonymous referees for helpful comments on the paper.

PLANARITY, COLORABILITY, AND MINOR GAMES*

DAN HEFETZ[†], MICHAEL KRIVELEVICH[‡], MILOŠ STOJAKOVIĆ[§], AND TIBOR SZABÓ[¶]

Abstract. Let m and b be positive integers, and let $\mathcal{F}$ be a hypergraph. In an (m, b) Maker-Breaker game $\mathcal{F}$ two players, called Maker and Breaker, take turns selecting previously unclaimed vertices of $\mathcal{F}$. Maker selects m vertices per move, and Breaker selects b vertices per move. The game ends when every vertex has been claimed by one of the players. Maker wins if he claims all of the vertices of some hyperedge of $\mathcal{F}$; otherwise Breaker wins. An (m, b) Avoider-Enforcer game $\mathcal{F}$ is played in a similar way. The only difference is in the determination of the winner: Avoider loses if he claims all of the vertices of some hyperedge of $\mathcal{F}$; otherwise Enforcer loses. In this paper we consider the Maker-Breaker and Avoider-Enforcer versions of the planarity game, the k -colorability game, and the K_t -minor game.

Key words. combinatorial games, planar graph, graph coloring, graph minors

1. Introduction. Let m and b be two positive integers. We are given a set X and a hypergraph $\mathcal{F} \subseteq 2^X$. During the (m, b) positional game $\mathcal{F}$, two players take turns claiming previously unclaimed elements of X . In every round, the first player claims m elements, and then the second player claims b elements. The set X is called the “board”; m and b are the biases of the first and second players, respectively. For the purposes of this paper $\mathcal{F}$ is assumed to be monotone-increasing. We investigate positional games with two different kinds of rules for determining the winner.

In a *Maker-Breaker-type* positional game, the two players are called Maker and Breaker, and $\mathcal{F}$ is referred to as the family of “winning sets.” Maker wins the game if the set M he has claimed by the end of the game (i.e., when every element of the board has been claimed by one of the players) is a winning set, that is, $M \in \mathcal{F}$. Otherwise Breaker wins. Observe that, since $\mathcal{F}$ is assumed to be monotone-increasing, the game could essentially be stopped as soon as Maker occupied a *minimal* (with respect to inclusion) winning set $F \in \mathcal{F}$; the position on $X \setminus F$ can no longer influence the outcome of the game. Hence, Breaker wins if and only if he claims at least one element in every minimal winning set. Since a monotone-increasing family and the family of its minimal elements uniquely determine each other, often, when there is no risk of confusion, we use $\mathcal{F}$ for the family of minimal winning sets as well. A classical example of the Maker-Breaker setting is the popular board game HEX.

In an *Avoider-Enforcer-type* positional game, the players are called Avoider and Enforcer, and $\mathcal{F}$ is called the family of “losing sets.” Avoider wins the game if the set A he has claimed by the end of the game (i.e., when every element of the board has been claimed by one of the players) is not a losing set, that is, $A \notin \mathcal{F}$. Otherwise Enforcer wins. Again, observe that the game could be stopped as soon as Avoider fully occupies a minimal losing set, since then Enforcer surely wins no matter how the game proceeds. Having this in mind, we will sometimes use $\mathcal{F}$ to denote the family of minimal losing sets.

The identity of the player making the first move does not affect the asymptotics of our results. However, for convenience, we will assume that Maker (Avoider) is the first player in all Maker-Breaker (Avoider-Enforcer) games we discuss.

In this paper, we investigate Maker-Breaker and Avoider-Enforcer positional games played on the board $E(K_n)$ —the edges of the complete graph on n vertices.

Maker-breaker games. The study of positional games on the edges of a (complete) graph was initiated by Lehman [20], who, in particular, proved that in the $(1, 1)$ game Maker can easily build a spanning tree (by “easily” we mean that he can do so within $n - 1$ moves). Chvátal and Erdős [10] suggested to “even out the odds” by giving Breaker more power, that is, by increasing his bias. They determined that the $(1, b)$ game $\mathcal{T}_n$ of “connectivity,” where the family $\mathcal{T}_n$ of minimal winning sets consists of the edge sets of all spanning trees of K_n , is won by Maker even when the bias b of Breaker is as large as $cn/\log n$ for some small constant $c > 0$, while for some large enough constant $C > 0$, Breaker wins if his bias is at least $Cn/\log n$. They also showed that the $(1, 1)$ game $\mathcal{H}_n$ of “Hamiltonicity,” where Maker’s goal is to build a Hamiltonian cycle (the family $\mathcal{H}_n$ of minimal winning sets consists of the edge sets of all Hamiltonian cycles of K_n), is won by Maker for sufficiently large n . They conjectured that in fact Maker can win the $(1, b)$ Hamiltonicity game for some b that tends to infinity with n . This was proved by Bollobás and Papaioannou [9], who showed that Maker wins Hamiltonicity against a bias of $\Omega(\log n / \log \log n)$. Finally, Beck [1] gave a winning strategy for Maker against a bias of $\Omega(n / \log n)$.

Following [14], it will be convenient to introduce the following notation. For a family $\mathcal{F}$ of winning sets, let $b_{\mathcal{F}}$ be the nonnegative integer for which Breaker has a winning strategy in the $(1, b)$ game $\mathcal{F}$ if and only if $b \geq b_{\mathcal{F}}$. Note that $b_{\mathcal{F}}$ is well-defined for any (monotone-increasing) family $\mathcal{F}$ (unless $\mathcal{F}$ contains a hyperedge of size at most one). By the above, $b_{\mathcal{T}_n} = \Theta(n / \log n)$ and $b_{\mathcal{H}_n} = \Theta(n / \log n)$.

There is an intriguing relation between the threshold biases of the connectivity and Hamiltonicity games and the threshold probability at which the random graph $G(n, p)$ first possesses these properties. The number of edges of the random graph $G(n, p)$ around this threshold $p = \log n / n$ has the same order of magnitude as the number of edges Maker has in his graph after playing against the threshold bias $b_{\mathcal{T}_n}$ or $b_{\mathcal{H}_n}$. This phenomenon (known as the Erdős paradigm) was pointed out by Beck [1], where this observation is attributed to Erdős (indeed the first such result appeared already in [10]). Since then, several other games have been found to have a threshold bias which is closely linked to a meaningful random graph threshold related to that particular game (see, e.g., [2, 4, 5, 6, 25]). Note that the asymptotic values of the threshold biases $b_{\mathcal{T}_n}$ and $b_{\mathcal{H}_n}$ are not known in general. It can still turn out that these threshold biases are asymptotically equal to the inverse of the corresponding sharp thresholds for the appropriate properties of random graphs.

In this paper we investigate this connection further and find three more instances where such an intuition proves to be correct. Let $\mathcal{N}_{\mathcal{P}_n}$, $\mathcal{N}\mathcal{C}_n^k$, $\mathcal{M}_n^t$ consist of the

edge sets of all nonplanar graphs on n vertices, the edge sets of all non- k -colorable graphs on n vertices, and the edge sets of all graphs on n vertices containing a K_t -minor (a graph G contains an H -minor if H can be obtained from G by the deletion and contraction of some of its edges), respectively. Obviously, all three families are monotone-increasing.

In the game $\mathcal{NP}_n$, which we call the “planarity game” (although perhaps “non-planarity” would have been a more appropriate name), Maker’s goal is to claim all edges of a nonplanar graph. In Theorem 2.1 we show that the corresponding threshold bias $b_{\mathcal{NP}_n}$ is asymptotically $n/2$. Note that this result is a consequence of the result for the minor game we obtain in Theorem 4.1, as the presence of a K_5 -minor guarantees nonplanarity. Nevertheless, we include an alternative, direct proof of Theorem 2.1 which approaches planarity from a different angle and, in our opinion, is more instructive and serves as a good example of how Maker can win by adopting the role of Avoider in a different game.

Coming back to the relation between the probability thresholds of random graphs and the thresholds for the game bias, we note that the threshold probability $p_{\mathcal{NP}_n}$ of nonplanarity in the random graph is $1/n$, that is, $p_{\mathcal{NP}_n} = \Theta(1/b_{\mathcal{NP}_n})$. However, the number of edges of $G(n, p_{\mathcal{NP}_n})$ is concentrated around *one-half* of the number of edges in Maker’s graph in the $(1, b_{\mathcal{NP}_n}, \mathcal{NP}_n)$ game (the nonplanarity threshold is sharp, so such a comparison makes sense).

In the “ k -colorability game,” the family of winning sets is $\mathcal{NC}_n^k$; that is, Maker wins the game if he claims a non- k -colorable graph. In Theorem 3.1 we show that the threshold bias is linear for a fixed k by establishing that there are absolute constants c_1, c_2 such that $c_1 \frac{n}{k \log k} \leq b_{\mathcal{NC}_n^k} \leq c_2 \frac{n}{k \log k}$ for any k . For the special case $k = 2$, that is, the bipartite game, a more accurate result was proved by Bednarska and Pikhurko [8]. They showed that $(1 - 1/\sqrt{2} - o(1))n \leq b_{\mathcal{NC}_n^2} \leq \lceil n/2 \rceil - 1$. Again, one can compare these results with the corresponding random graph threshold $p_{\mathcal{NC}_n^k} = \frac{2k \log k}{n}$ for non- k -colorability and find the reciprocal relation.

Finally, we turn to a more general setting. In the K_t -minor game the family of winning sets is $\mathcal{M}_n^t$; hence, Maker wins the game if he is able to claim the edges of some K_t -minor of K_n . This game is in some sense a generalization of both the planarity and the colorability games we have discussed. Indeed, Wagner’s theorem gives a full description of planarity via the language of forbidden minors. Furthermore, if a graph is not r -colorable, then it contains a K_s -minor for $s = r/(c\sqrt{\log r})$, where c is an absolute constant (see [17, 26]), and the famous and long-standing Hadwiger conjecture asserts that in fact it contains a K_r -minor. The opposite implication is trivially false, as, for every positive integer n , the complete bipartite graph $K_{n,n}$ admits a K_n -minor.

In Theorem 4.1 we prove that the corresponding threshold bias $b_{\mathcal{M}_n^t}$ is asymptotically $n/2$ for every $3 \leq t \leq c\sqrt{n/\log n}$, for an appropriate constant c . Note that for the case $t = 3$ an accurate threshold bias follows from a result of Bednarska and Pikhurko [7], as a graph is K_3 -minor free if and only if it is a forest (see the exact statement in Theorem 2.2 in section 2).

Avoider-enforcer games. At first sight, the definition of Avoider-Enforcer games seems less natural than that of Maker-Breaker games, and accordingly the theory is much less developed. We, however, argue that, besides being interesting in their own right (see [14] for a comprehensive discussion), they are essential in studying Maker-Breaker games. Avoider-enforcer games arise naturally whenever one would like to play (what looks like) Maker-Breaker games on a *monotone-decreasing family*. For

example, the set $\mathcal{P}_n$ of planar graphs is a monotone-decreasing family. If, for example, Maker's goal is to keep his graph planar to the end of the game, then he can be thought of as Avoider, playing an Avoider-Enforcer game on the (monotone-increasing) family of losing sets $2^{E(K_n)} \setminus \mathcal{P}_n = \mathcal{NP}_n$.

Moreover, for certain Maker-Breaker games the best known maker strategies involve building a pseudorandom graph with certain parameters (see [13, 15]). It is proved that the particular pseudorandom properties of Maker's graph imply the graph-theoretic properties in question, entailing his win. Here pseudorandom properties include bounds on the number of edges between pairs of disjoint vertex sets from *below* and from *above*. Hence, in such a game the family $\mathcal{F}$ is the intersection of a monotone-increasing family and a monotone-decreasing family.

Avoider-enforcer games were studied in [3, 14, 21, 22, 23]. Similarly to Maker-Breaker games, one would like to define for each monotone-increasing family $\mathcal{F}$ the Avoider-Enforcer threshold bias $f_{\mathcal{F}}$. A reasonable choice for $f_{\mathcal{F}}$ would be the non-negative integer for which Avoider wins the $(1, b)$ game $\mathcal{F}$ if and only if $b \geq f_{\mathcal{F}}$. While the similar threshold $b_{\mathcal{F}}$ does exist for Maker-Breaker games on (essentially) any hypergraph, for Avoider-Enforcer games it generally does not (see [14]).

Following [14], it will be convenient to introduce the following notation. For a hypergraph $\mathcal{F}$ we define the *lower threshold bias* $f_{\mathcal{F}}^-$ to be the largest integer such that Enforcer can win the $(1, b)$ game $\mathcal{F}$ for every $b \leq f_{\mathcal{F}}^-$ and the *upper threshold bias* $f_{\mathcal{F}}^+$ to be the smallest nonnegative integer such that Avoider can win the $(1, b)$ game $\mathcal{F}$ for every $b > f_{\mathcal{F}}^+$. Except for certain degenerate cases, $f_{\mathcal{F}}^-$ and $f_{\mathcal{F}}^+$ always exist and satisfy $f_{\mathcal{F}}^- \leq f_{\mathcal{F}}^+$. Whenever $f_{\mathcal{F}}^- = f_{\mathcal{F}}^+$, the threshold bias $f_{\mathcal{F}}$ of the Avoider-Enforcer game $\mathcal{F}$ does exist and satisfies $f_{\mathcal{F}} = f_{\mathcal{F}}^+$.

In [14] the existence of the threshold $f_{\mathcal{T}_n}$ was established for the connectivity game, and it was proved that $f_{\mathcal{T}_n}$ is roughly $n/2$. For the perfect matching game and Hamiltonicity game it was shown that $f_{\mathcal{M}_n}^- = \Omega(n/\log n)$ and $f_{\mathcal{H}_n}^- = \Omega(n \log \log \log \log n / \log n \log \log \log n)$, respectively. Note that it is not known if the threshold bias for any of these natural games exists.

In this paper, we give bounds on the lower and upper threshold biases for the planarity, k -colorability, and K_t -minor games. Note that, unlike the games of connectivity and Hamiltonicity, these Avoider-Enforcer games seem to be more natural than their Maker-Breaker analogues.

In Theorem 2.3 we prove that Avoider can keep his graph planar against any bias which is larger than $2n^{5/4}$, whereas Enforcer wins when playing with a bias no larger than $\frac{n}{2} - o(n)$. As in the case of the Maker-Breaker planarity game, the second part of this result is a direct consequence of our result for the minor game presented in Theorem 4.7. Nevertheless, we include an alternative, direct proof which relies on other properties of planar graphs. We believe it is more illustrative and gives more insight into the course of the game.

In Theorem 3.4 we show that, by playing against a bias of at least $2kn^{1+1/(2k-3)}$, Avoider can keep his graph k -colorable, whereas Enforcer wins if his bias is at most $\frac{n}{ck \log k}$.

In the Avoider-Enforcer version of the K_t -minor game, Avoider's task is to build a K_t -minor free graph. As in the planarity and colorability games, Avoider's goal in this game is very natural. Indeed, many graph-theoretic properties can be expressed in a "forbidden minor" fashion.

We show that, by playing with a linear bias, Enforcer can make Avoider build a graph that admits a K_t -minor for t which is as large as $c\sqrt{n/\log n}$. Moreover, in

Theorem 4.7 we prove that, even when playing with a bias which is arbitrarily close (from below) to $n/2$, Enforcer can make sure that by the end of the game Avoider will claim a K_t -minor for $t = n^{a_0}$, where $a_0 > 0$ is an appropriate constant.

For the sake of simplicity and clarity of presentation, we do not make a particular effort to optimize the constants obtained in theorems we prove. We also omit floor and ceiling signs whenever these are not crucial. All of our results are asymptotic in nature, and whenever necessary we assume that n is sufficiently large. Throughout the paper, $\log$ stands for the natural logarithm. Our graph-theoretic notation is standard and follows that of [11].

The rest of the paper is organized as follows: In section 2 we discuss the Maker-Breaker and Avoider-Enforcer planarity games, in section 3 we discuss the colorability games, and in section 4 we discuss the minor games. Finally, in section 5 we present some open problems.

2. Planarity games.

2.1. The Maker-Breaker planarity game. The following theorem states that the threshold bias at which Maker's win turns into a Breaker's win in the planarity game is "around" $n/2$.

THEOREM 2.1.

$$b_{\mathcal{NP}_n} = \frac{n}{2} - o(n).$$

Proof. Let $b \geq n/2$. The existence of a winning strategy for Breaker in the planarity game is an easy consequence of the following result of Bednarska and Pikhurko.

THEOREM 2.2 (see [7, Corollary 10]). *Suppose that CycleMaker and CycleBreaker select, respectively, 1 and b edges of K_n and CycleMaker wins if he builds a cycle. Then CycleMaker has a winning strategy (no matter who starts) if and only if $b < \lceil n/2 \rceil$.*

The assertion of Theorem 2.2 implies that with the bias $b \geq n/2$, Breaker can prevent Maker from building a cycle. It follows that at the end of the game Maker's graph will be a forest which is obviously planar.

Next, let $0 < \varepsilon < 1/3$ (the restriction $\varepsilon < 1/3$ is technical), and let $b \leq (1/2 - \varepsilon)n$, where $n = n(\varepsilon)$ is sufficiently large. We will provide Maker with a strategy for building a nonplanar graph. Let $\alpha = \frac{2\varepsilon}{1-2\varepsilon}$, and let $\alpha_n = \alpha_n(\varepsilon)$ be the real number satisfying the equation

$$(1 + \alpha_n)n = \frac{\binom{n}{2}}{(\frac{1}{2} - \varepsilon)n + 1}.$$

Then $\lim_{n \rightarrow \infty} \alpha_n = \alpha$. Let m_n denote the number of edges that Maker will claim by the end of the game on K_n . We have $m_n - (1 + \frac{\alpha}{2})n = \Omega(n)$.

Let $k = k(\varepsilon)$ be the smallest positive integer such that

$$\left(1 + \frac{\alpha}{2}\right) > \frac{k}{k-2}.$$

Maker's goal is to avoid cycles of length smaller than k , which we will call "short cycles," during the first $(1 + \frac{\alpha}{2})n$ moves. If he succeeds, Maker's graph will at that point of the game have

$$\left(1 + \frac{\alpha}{2}\right)n > \frac{k}{k-2}n$$

edges and girth at least k . But, it is well known that a planar graph with girth at least k cannot have more than $\frac{k}{k-2}(n-2)$ edges. Hence, Maker's graph will already be nonplanar, and he will win no matter how the game continues.

It remains to show that Maker can indeed avoid claiming a short cycle during the first $(1 + \frac{\alpha}{2})n$ moves. His strategy is the following. For as long as possible he claims edges (u, v) that satisfy the following two properties:

- (a) (u, v) does not close a short cycle;
- (b) the degrees of both u and v in Maker's graph are less than $n^{1/(k+1)}$.

It suffices to prove that when this is no longer possible, that is, every remaining unclaimed edge violates either (a) or (b), Maker has already claimed at least $(1 + \frac{\alpha}{2})n$ edges.

Every edge that violates property (b) must have at least one end point of degree $n^{1/(k+1)}$ in Maker's graph. Since Maker's graph at any point of the game contains at most $(1 + \alpha)n$ edges, there are at most $2(1 + \alpha)n^{1-1/(k+1)}$ vertices of degree at least $n^{1/(k+1)}$. Therefore, the number of edges that violate property (b) is at most

$$n \cdot 2(1 + \alpha)n^{1-1/(k+1)} = o(n^2).$$

For any fixed $s < k$ and every vertex v , the number of paths of length s that have v as one end point is at most Δ^s , where Δ is the maximum degree in Maker's graph. If we assume that property (b) has not been violated, then $\Delta \leq n^{1/(k+1)}$. Therefore, there are at most

$$n \cdot \sum_{s=3}^{k-1} n^{s/(k+1)} = o(n^2)$$

edges that close a short cycle.

Thus, the total number of edges that violate (a) or (b) if claimed by Maker is $o(n^2)$. On the other hand, after $(1 + \frac{\alpha}{2})n$ moves have been played, the number of unclaimed edges is $\Theta(n^2)$. Hence, in the first $(1 + \frac{\alpha}{2})n$ moves Maker can claim edges that satisfy properties (a) and (b), which means that he does not claim a short cycle. This completes the proof of the theorem. $\square$

2.2. The Avoider-Enforcer planarity game. In the following theorem we give an upper bound and a lower bound for the threshold bias at which Enforcer's win turns into Avoider's win in the planarity game.

THEOREM 2.3.

$$\frac{n}{2} - o(n) \leq f_{\mathcal{NP}_n}^- \leq f_{\mathcal{NP}_n}^+ \leq 2n^{5/4}.$$

Proof. Assume first that $b \geq 2n^{5/4}$. We will provide Avoider with a strategy for building a planar graph. The game is divided into four stages. Avoider's strategy is the following.

In the first stage, Avoider builds a matching by repeatedly claiming an edge that connects two vertices, neither of which is incident with any other edge previously claimed by him. The first stage ends when no such unclaimed edge remains and so Avoider cannot further extend his matching. We denote the set of vertices that are covered by Avoider's matching by M .

Next, in the second stage Avoider claims edges with one end point in M and the other in $V \setminus M$ such that throughout the second stage every vertex of $V \setminus M$ has degree at most one in Avoider's graph. The second stage ends when no such unclaimed edge remains.

In the third stage Avoider builds another matching on M . More precisely, he repeatedly claims edges that connect two vertices of M , neither of which is incident with any other edge previously claimed by him in the *third* stage. The third stage ends when no such unclaimed edge remains and Avoider cannot further extend this second matching.

In the fourth and final stage, Avoider claims edges arbitrarily to the end of the game. If we prove that in this stage Avoider will claim at most one edge, then the upper bound of the theorem will follow. Indeed, the graph that is spanned by Avoider's edges from the first and third stages is a union of two matchings, that is, a union of disjoint paths and cycles. Furthermore, if we add Avoider's edges from the second stage to this graph, then we simply add "hanging" edges (edges with one end point having degree one). Clearly, if we now add any single edge that may have been claimed by Avoider in the fourth stage to that graph, it remains planar.

Let e be the number of edges that Avoider claims in the entire game. By the end of the first stage, Enforcer must have claimed all of the edges with both end points in $V \setminus M$. Since Avoider's matching on M consists of at most e edges, we have $|V \setminus M| \geq n - 2e$, and therefore Enforcer has already claimed at least $\binom{n-2e}{2}$ edges. It follows that there are at most

$$\binom{n}{2} - \binom{n-2e}{2} \leq 2en$$

unclaimed edges left in the graph, and Avoider will claim at most $\frac{2en}{b}$ of them.

In the second stage, Avoider claims edges between M and $V \setminus M$. When this is no longer possible, every unclaimed edge between M and $V \setminus M$ is incident with a vertex of $V \setminus M$ which has degree one in Avoider's graph. It follows that, at this point, the number of unclaimed edges between M and $V \setminus M$ is at most

$$2e \cdot \frac{2en}{b} = \frac{4e^2n}{b}.$$

In the third stage, Avoider builds his second matching on M . When this is no longer possible, the number of unclaimed edges with both end points in M is at most

$$\binom{2e}{2} - \binom{2e - 4en/b}{2} \leq \frac{8e^2n}{b}.$$

To see this, it is enough to observe that the number of vertices that are incident with the second matching is at most $4en/b$ and that all edges with end points in M that are not adjacent to the second matching must be claimed by Enforcer after the third stage.

Putting everything together, the total number of unclaimed edges after the third stage is at most

$$\frac{4e^2n}{b} + \frac{8e^2n}{b} = \frac{12e^2n}{b}.$$

Since $e < n^2/2b$, we have that the number of edges to be played in the fourth stage is at most $\frac{12e^2n}{b} \leq \frac{3n^5}{b^3} \leq b$, which means that in the fourth stage Avoider will claim at most one edge.

Next, fix an $\varepsilon > 0$, and assume that $b \leq \frac{n}{2}(1 - \varepsilon)$. We will provide Enforcer with a strategy, which guarantees that Avoider will occupy the edges of a nonplanar graph.

If $b \leq n/7$, then the number of edges Avoider claims in the entire game is at least $\lfloor \binom{n}{2} \cdot (b+1)^{-1} \rfloor > 3n$, and thus Avoider surely loses regardless of Enforcer's strategy. Hence, from now on we can assume that $b > n/7$. Let $k = k(\varepsilon)$ be the smallest positive integer such that $\frac{1}{1-\varepsilon/2} > \frac{k}{k-2}$. Enforcer's strategy will be to prevent Avoider from claiming a cycle of length smaller than k , which we will call a "short cycle." If he succeeds, then at the end of the game Avoider's graph will have at least

$$\left\lfloor \frac{\binom{n}{2}}{b+1} \right\rfloor \geq \frac{n}{1-\varepsilon/2} > \frac{k}{k-2}n$$

edges, for sufficiently large n , and girth at least k . As we have mentioned before, a graph with such properties cannot be planar, and thus Enforcer wins.

It remains to show that Enforcer can indeed prevent Avoider from claiming a short cycle. In order to do that we will use the following theorem of Bednarska and Luczak.

THEOREM 2.4 (see [5, Theorem 1]). *For every graph G which contains at least three nonisolated vertices there exist positive constants c and n_0 such that, playing the $(1, q)$ game on K_n , G -Breaker can prevent G -Maker from building a copy of G provided that $n > n_0$ and $q > cn^{1/m_2(G)}$, where*

$$m_2(G) = \max_{\substack{H \subseteq G \\ v(H) \geq 3}} \frac{e(H) - 1}{v(H) - 2}.$$

For a cycle C_i of length i , we have $m_2(C_i) = \frac{i-1}{i-2}$. Therefore, there exist constants c_i , $i = 3, \dots, k-1$, such that, for sufficiently large n , Enforcer can prevent Avoider from claiming a copy of C_i , if the number of edges he is allowed to claim per move is at least $c_i n^{\frac{i-2}{i-1}}$. Since for sufficiently large n

$$\sum_{i=3}^{k-1} c_i n^{\frac{i-2}{i-1}} \leq \frac{n}{7} \leq b,$$

Enforcer can simultaneously prevent Avoider from claiming any short cycle C_i , $3 \leq i < k$, by simply playing all $k-3$ games in parallel. That is, after Avoider claims an edge, Enforcer responds by claiming $c_3 n^{\frac{1}{2}}$ edges according to the strategy in the "triangle avoidance game," then he claims $c_4 n^{\frac{2}{3}}$ edges according to the strategy in the "4-cycle avoidance game," and so on. His different strategies, for the different cycle games, might call for claiming the same edge more than once, in which case he just claims an arbitrary unclaimed edge instead. It is easy to see that this cannot harm him. This concludes the proof of the theorem. $\square$

3. k -colorability games.

3.1. The Maker-Breaker k -colorability game. The following theorem states that the threshold bias at which Maker's win turns into Breaker's win in the k -colorability game, where k is fixed and n is sufficiently large, is of order n . This is true for every $k \geq 2$. However, for convenience, and since the case $k = 2$ was treated in [8], we will assume that $k \geq 3$.

THEOREM 3.1. *For every $k \geq 3$ and sufficiently large n , there exist constants s_k and s'_k such that*

$$s'_k n \leq b_{NC_n^k} \leq s_k n,$$

where $s_k \sim \frac{2}{k \log k}$ and $s'_k \sim \frac{\log 2}{2k \log k}$ as $k \rightarrow \infty$.

Proof. Assume first that $b \leq \frac{n}{ck \log k}$, where $c > 2/\log 2$. We will provide Maker with a strategy for building a non- k -colorable graph. Maker's goal will be to prevent Breaker from building a clique of size $\lceil n/k \rceil$, and this is enough to ensure his win. Indeed, Maker's graph is surely not k -colorable if it does not admit an independent set of size $\lceil n/k \rceil$.

Let $\mathcal{F}$ be the hypergraph whose vertices are the edges of K_n and whose hyperedges are the $\lceil n/k \rceil$ -cliques of K_n . We name the players of the $(b, 1, \mathcal{F})$ game CliqueMaker and CliqueBreaker. As was mentioned before, Maker wins the k -colorability game if he claims a vertex in every hyperedge of $\mathcal{F}$, that is, if he is able to win the $\mathcal{F}$ game as CliqueBreaker. We will use Beck's criterion, which is applicable to any Maker-Breaker-type game.

THEOREM 3.2 (see [1, Theorem 1]). *If*

$$\sum_{D \in \mathcal{H}} (1+q)^{-|D|/p} < \frac{1}{q+1},$$

then Breaker wins the (p, q) game $\mathcal{H}$.

We have

$$\begin{aligned} \sum_{D \in \mathcal{F}} 2^{-|D|/b} &\leq \binom{n}{\lceil n/k \rceil} 2^{-\binom{\lceil n/k \rceil}{2}/b} \leq (ek)^{\lceil n/k \rceil} 2^{-\binom{\lceil n/k \rceil}{2}/b} \\ &\leq 2^{\frac{n \log_2 e}{k} + \frac{n \log_2 k}{k} + \log_2(ek) - \frac{cn^2 k \log k}{2k^2 n} + \frac{nc k \log k}{2kn}} = o(1). \end{aligned}$$

Hence, Maker can win the k -colorability game.

Assume now that $b \geq s_k n$, where s_k is a constant depending on k that will be determined later. We will provide Breaker with a strategy, to force Maker into building a k -colorable graph. We will make use of the following theorem of Kim.

THEOREM 3.3 (see [16, Corollary 1.2]). *If G is a graph with maximum degree Δ and girth at least 5, then*

$$\chi(G) \leq (1 + \nu(\Delta)) \frac{\Delta}{\log \Delta},$$

where $\nu(\Delta) \rightarrow 0$ as $\Delta \rightarrow \infty$.

Let Δ_0 be the maximal value of Δ for which

$$(1 + \nu(\Delta)) \frac{\Delta}{\log \Delta} \leq k$$

(if no such Δ_0 exists or if $\Delta_0 < 2$, then we take $s_k = 1/2$, and so Breaker wins by Theorem 2.2).

Since $\nu(\Delta) \rightarrow 0$ as $\Delta \rightarrow \infty$, we have that $\Delta_0 \sim k \log k$ as $k \rightarrow \infty$. Breaker's goal will be to force Maker to build a graph with maximum degree at most Δ_0 and girth at least 5. By Theorem 3.3 Maker's graph will then be k -colorable. In each move, Breaker will use $c_3 n^{1/2}$ of his edges to prevent Maker from building a triangle (recall that $m_2(C_3) = 2$) and $c_4 n^{2/3}$ of his edges to prevent Maker from building a cycle of length 4 ($m_2(C_4) = 3/2$), where c_3 and c_4 are the constants whose existence is guaranteed by Theorem 2.4. Breaker will use all of his remaining $b' := b - c_3 n^{1/2} - c_4 n^{2/3} = (1 - o(1))b$ edges to make sure that the maximum degree in Maker's graph does not surpass Δ_0 . Hence, if Maker claims the edge (u, v) , then Breaker will claim $\frac{1}{2}b'$ edges incident with u and $\frac{1}{2}b'$ edges incident with v (if there

are only $r < \frac{1}{2}b'$ unclaimed edges incident with u or v , then Breaker will claim all of them and additional $\frac{1}{2}b' - r$ arbitrary unclaimed edges). It follows that the maximum degree in Maker's graph will be at most

$$1 + \frac{n-1}{b'/2} \leq 1 + \frac{2n}{(1-o(1))b} \leq 1 + \frac{2}{s_k} + o(1),$$

where the $o(1)$ term tends to zero as n tends to infinity. Therefore, if $s_k = \lceil \frac{2}{\Delta_0 - 1.5} \rceil$, then Maker's graph will have maximum degree at most Δ_0 . Hence, Breaker can force Maker to build a graph with maximum degree at most Δ_0 and girth at least 5, and thus he can win. Note that s_k , defined this way, satisfies $s_k \sim \frac{2}{k \log k}$ as $k \rightarrow \infty$. This concludes the proof of the theorem. $\square$

3.2. The Avoider-Enforcer k -colorability game. In the following theorem we give an upper bound and a lower bound for the threshold bias at which Enforcer's win turns into Avoider's win in the k -colorability game.

THEOREM 3.4. *For every $k \geq 3$ there exists a constant s'_k such that*

$$s'_k n \leq f_{\mathcal{NC}_n}^- \leq f_{\mathcal{NC}_n}^+ \leq 2kn^{1+\frac{1}{2k-3}}.$$

Moreover, $s'_k \sim \frac{\log 2}{2k \log k}$ as $k \rightarrow \infty$.

Proof. Assume first that $b \leq \frac{n}{ck \log k}$. We will provide Enforcer with a strategy which ensures that by the end of the game Avoider's graph will not be k -colorable. Enforcer's goal will be to avoid building a clique of size $\lceil n/k \rceil$. If he achieves this goal, Avoider's graph will not contain an independent set of size $\lceil n/k \rceil$ and so will not be k -colorable; thus Enforcer will win. Let $\mathcal{F}$ be the hypergraph whose vertices are the edges of K_n and whose hyperedges are the $\lceil n/k \rceil$ -cliques of K_n . We name the players of the $(b, 1, \mathcal{F})$ game CliqueAvoider and CliqueEnforcer. As mentioned above, Enforcer will win the k -colorability game if he will not claim all vertices in any hyperedge of $\mathcal{F}$, that is, if he is able to win as CliqueAvoider.

We will use the following criterion, applicable to any Avoider-Enforcer-type game.

THEOREM 3.5 (see [14, Theorem 1.1]). *If*

$$\sum_{D \in \mathcal{H}} \left(1 + \frac{1}{b}\right)^{-|D|} < \left(1 + \frac{1}{b}\right)^{-b},$$

then Avoider wins the $(b, 1)$ game $\mathcal{H}$.

We have

$$\begin{aligned} \sum_{D \in \mathcal{F}} \left(1 + \frac{1}{b}\right)^{-|D|} &\leq \binom{n}{\lceil n/k \rceil} \left(1 + \frac{1}{b}\right)^{-\binom{\lceil n/k \rceil}{2}} \leq (ek)^{\lceil n/k \rceil} 2^{-\binom{\lceil n/k \rceil}{2}/b} \\ &\leq 2^{\frac{n \log 2 e}{k} + \frac{n \log 2 k}{k} + \log_2(ek) - \frac{cn^2 k \log k}{2k^2 n} + \frac{nc k \log k}{2kn}} = o(1). \end{aligned}$$

By applying Theorem 3.5 we conclude that there exists a winning strategy for CliqueAvoider, and thus Enforcer wins the k -colorability game.

Next, let $b > 2kn^{1+\frac{1}{2k-3}}$. We will provide Avoider with a strategy for building a $(k-1)$ -degenerate graph (a graph G is called r -degenerate if there is an ordering of the vertices $v_1, \dots, v_n$ such that every vertex has at most r neighbors with a higher index). Clearly, that would entail Avoider's win in the k -colorability game as every $(k-1)$ -degenerate graph is k -colorable.

Avoider will play several auxiliary minigames one after the other, never starting a new minigame before finishing the previous one, until all edges are claimed and the k -colorability game is over. Before we describe his strategy in detail, let us define two basic types of *minigames*.

Minigame type I. For a set of vertices A , the (A) -minigame is played on those edges with both end points in A which are still unclaimed at the beginning of this minigame. Note that some edges within A may have already been claimed during previous minigames. We say that the vertices of A are *designated* to the (A) -minigame. When we say that *Avoider is playing the (A) -minigame*, we mean that Avoider is repeatedly claiming independent edges with both end points in A for as long as possible; that is, he extends a matching on A until it is no longer possible. When Avoider cannot further extend his matching, the (A) -minigame is over. At this point we denote the set of vertices of A incident with an edge, claimed by Avoider in *this* minigame by A_1 , and let $A_2 = A \setminus A_1$. Note that by the end of the (A) -minigame all edges with both end points in A_2 have already been claimed by one of the players.

Minigame type II. Let A and B be two disjoint sets of vertices. The $(A : B)$ -minigame is played on those edges with one end point in A and the other in B which are still unclaimed at the beginning of this minigame. Again, we assume that the (big) game is in progress, meaning that some of the edges between A and B may have already been claimed in previous minigames. We say that the vertices of B are *designated* to the $(A : B)$ -minigame. When we say that *Avoider is playing the $(A : B)$ -minigame*, we mean that Avoider is repeatedly claiming edges between A and B such that no vertex in B is incident with more than one of Avoider's edges claimed in *this* minigame. When this is no longer possible, the $(A : B)$ -minigame is over. At this point, let B_1 denote the set of vertices of B that are incident with an edge claimed by Avoider in *this* minigame, and let $B_2 = B \setminus B_1$. Note that all edges with one end point in A and the other in B_2 have already been claimed by one of the players. The vertices in B_2 are called *finished*.

Now we can describe the way Avoider plays the game. We introduce a *minigame pool* $\mathcal{P}$, which is a dynamic collection of minigames that will be updated during the game—it will contain minigames waiting to be played by Avoider. At each moment $\mathcal{P}$ will contain at most one minigame of type I and at most $k - 1$ minigames of type II.

Avoider will maintain a partial ordering of the vertices, which he will refine whenever a minigame is over. In this partial ordering, the vertices designated to the same minigame will be incomparable to each other, the vertices designated to the lone minigame of type I in the pool will be above all of the other vertices, and for any minigame $(A : B)$ of type II every vertex of A will be above every vertex of B .

Given a partial ordering, let the *up-degree* of v be the number of Avoider's edges (v, u) where either u is above v or they are incomparable.

To each minigame in the pool, we assign an integer parameter that will help us keep track of the degeneracy of Avoider's graph throughout the game. Thus, instead of the (A) -minigame (or the $(A : B)$ -minigame), we will consider the $(A)_l$ -minigame (or the $(A : B)_l$ -minigame) for an appropriate integer l . During play, Avoider maintains the following property: If a vertex is designated to a minigame with parameter l , then its up-degree is at most l .

In the beginning of the game $\mathcal{P}$ contains only one minigame—the $(V(K_n))_0$ -minigame. The partially ordered set on $V(K_n)$ contains no relations.

We say that the size of an (A) -minigame is $\frac{1}{2}|A|^2$ and the size of an $(A : B)$ -minigame is $|A| \cdot |B|$. Note that the size of a minigame is an upper bound on the number of edges it contains.

When the game is played, Avoider repeatedly chooses a minigame of the largest size in the pool $\mathcal{P}$, removes it from the pool, plays it to its end, and then updates $\mathcal{P}$ and the partial ordering as follows. If the minigame played was an $(A)_l$ -minigame, then he places two new minigames into $\mathcal{P}$: the $(A_1)_{l+1}$ -minigame and the $(A_1 : A_2)_l$ -minigame. Furthermore, the designation of the vertices of A is lifted and replaced by that of the vertices of A_1 to the $(A_1)_{l+1}$ -minigame and that of the vertices of A_2 to the $(A_1 : A_2)_l$ -minigame. The partial order is refined by placing every vertex of A_1 above every vertex of A_2 .

On the other hand, if the minigame played was an $(A : B)_l$ -minigame, then Avoider places only the $(A : B_1)_{l+1}$ -minigame back into $\mathcal{P}$. Furthermore, the designation of the vertices of B is lifted—the vertices of B_2 are finished, and the vertices of B_1 are designated to the $(A : B_1)_{l+1}$ -minigame. The partial order is not affected.

This shows that indeed in every stage of the game $\mathcal{P}$ will contain at most (in fact, exactly) one minigame of type I.

Note that at any point of the game every unclaimed edge is in exactly one of the minigames in $\mathcal{P}$. Moreover, every vertex of K_n will be either finished or designated to exactly one minigame in the pool.

After having played an $(A : B)$ -minigame of type II, the up-degree of the finished vertices, that is, the vertices of B_2 , is fixed and in particular will not be increased in later stages of the game. This is because there are simply no more unclaimed edges which go to higher or incomparable vertices left. Indeed, the edges with both end points in B were all claimed during that minigame of type I after which the vertices of B were designated to a type II minigame. The edges (u, v) , where $u \in B_2$ and v is above u , were all claimed during the $(A : B)$ -minigame. Furthermore, the up-degree of every vertex of B_2 was not changed during the $(A : B)$ -minigame, so if the parameter of the $(A : B)$ -minigame was l , then the up-degree of the vertices in B_2 is at most l at the end of the game.

It is clear that, as long as Avoider follows this strategy and the parameter of every minigame in $\mathcal{P}$ is at most l , Avoider's graph is l -degenerate. Therefore, it suffices to prove that, after the first minigame with parameter $k-2$ is taken out of the pool to be played, Avoider plays at most one more move in the whole game. Note that whenever a minigame of type II is played the size of the pool $\mathcal{P}$ is not changed, and whenever a minigame of type I is played both the size of the pool $\mathcal{P}$ and the parameter of the new minigame of type I are increased by one. It follows that proving the above will show that indeed, throughout the game, there will be at most $k-1$ minigames of type II in $\mathcal{P}$.

We will prove by induction on l that any minigame in the pool which has parameter $0 \leq l \leq k-2$ is of size at most $n^2 \left(\frac{2k^2 n^2}{b^2} \right)^l$. First, for the base step, note that the size of any minigame with parameter $l=0$ is less than n^2 . Now let us assume that l is an integer with $0 < l \leq k-2$ and the induction hypotheses holds for all games with parameter less than l . For a minigame M in the pool with parameter l we consider three cases.

Case 1. M is an $(A_1)_l$ -minigame that was inserted into the pool after the $(A)_{l-1}$ -minigame has ended. Just before Avoider started playing the $(A)_{l-1}$ -minigame, there was no minigame in the pool of larger size. Since the total number of games in the pool was at most k , the total number of unplayed edges at that point was at most k times the size of the $(A)_{l-1}$ -minigame. By the induction hypotheses, this is at most $kn^2 \left(\frac{2k^2 n^2}{b^2} \right)^{l-1}$. The number of edges Avoider will play during the $(A)_{l-1}$ -minigame is certainly bounded from above by the total number of edges that Avoider will claim un-

til the end of the whole k -colorability game, which is at most $\frac{kn^2}{b} \left(\frac{2k^2n^2}{b^2}\right)^{l-1}$. Avoider's strategy for the $(A)_{l-1}$ -minigame guarantees that the set A_1 will be of size at most twice this much, and hence the $(A_1)_l$ -minigame will be of size at most

$$\frac{1}{2}|A_1|^2 \leq \frac{1}{2} \left(\frac{2kn^2}{b} \left(\frac{2k^2n^2}{b^2} \right)^{l-1} \right)^2 \leq n^2 \cdot \left(\frac{2k^2 \cdot n^2}{b^2} \right)^l.$$

Case 2. M is an $(A_1 : A_2)_l$ -minigame that was inserted into the pool after the $(A_1 \cup A_2)_l$ -minigame has ended. The size of the $(A_1 : A_2)_l$ -minigame is obviously bounded from above by the size of the $(A_1 \cup A_2)_l$ -minigame, which we already upper-bounded in Case 1.

Case 3. M is an $(A : B)_l$ -minigame that was inserted into the pool after the $(A : B)_{l-1}$ -minigame has ended. As in Case 1, we can bound the number of edges Avoider will play during the $(A : B)_{l-1}$ -minigame from above by the total number of edges that Avoider will claim until the end of the whole k -colorability game. Thus, by knowing that the $(A : B)_{l-1}$ -minigame was of maximal size in $\mathcal{P}$ before it was played, we get that Avoider will make at most

$$\frac{k|A||B|}{b} \leq \frac{kn^2}{b} \left(\frac{2k^2n^2}{b^2} \right)^{l-1}$$

moves until the end of the game. Therefore, the size of B_1 is also at most that much. Since the size of A is at most n^2/b (the total number of vertices that can have positive degree in Avoider's graph), the total size of the $(A : B)_l$ -minigame is at most $n^2 \left(\frac{2k^2n^2}{b^2}\right)^l$. This concludes the induction step.

At the point when a minigame with parameter $k - 2$ becomes the largest size in the pool, then the total number of edges to be played in the remainder of the game is at most $kn^2 \left(\frac{2k^2n^2}{b^2}\right)^{k-2}$, which is less than b , meaning that Avoider will play at most one move before the game ends. However, at this point Avoider's graph is $(k - 2)$ -degenerate, so we are done. $\square$

Remark. The graph built by Avoider in the proof of Theorem 2.3 is clearly 3-colorable. It follows that if $k \geq 3$ and $b \geq 2n^{5/4}$, then Avoider can win the $(1, b)$ k -colorability game. For $k = 3$ this yields a better result than the one given in Theorem 3.4. Moreover, it is easy to see that if $b > n^{3/2}$, then Avoider can build a graph which consists of a matching and one additional edge; clearly such a graph is 2-colorable. Hence, by using Enforcer's strategy from Theorem 3.4 we get

$$cn \leq f_{\mathcal{NC}_n^2}^- \leq f_{\mathcal{NC}_n^2}^+ \leq n^{3/2}$$

for an appropriate constant $c > 0$.

4. Minor games.

4.1. The Maker-Breaker minor game. In the Maker-Breaker version of the game, Maker's goal is to build a graph that contains a K_t -minor. The following theorem states that the threshold bias at which Maker's win turns into Breaker's win in the K_t -minor game for every $3 \leq t \leq c\sqrt{n/\log n}$, for an appropriate constant c , is asymptotically $n/2$.

THEOREM 4.1. *For every fixed $\varepsilon > 0$, there exists a constant $C = C(\varepsilon)$ such that if n is sufficiently large and $b \leq (1 - \varepsilon)n/2$, then Maker has a winning strategy for the $(1, b)$ game $\mathcal{M}_n^t$ for every $t < C\sqrt{n/\log n}$.*

As a corollary we have the asymptotics of $b_{\mathcal{M}_n^t}$ for arbitrary fixed t .

COROLLARY 4.2. *Let $t \geq 3$ be a positive integer. Then*

$$b_{\mathcal{M}_n^t} = \frac{n}{2} - o_t(n).$$

The lower bound in the corollary follows from Theorem 4.1, while if $b \geq n/2$, then Breaker, as in the proof of Theorem 2.1, can force Maker to build a forest, which does not contain a K_t -minor for any $t \geq 3$.

In the proof of Theorem 4.1 we will use the following result of Kostochka and of Thomason.

THEOREM 4.3 (see [17, 26]). *There exists a constant c' such that every graph of average degree at least $c'r\sqrt{\log r}$ admits a K_r -minor.*

Proof of Theorem 4.1. Assume that $b \leq (1 - \varepsilon)n/2$. We will provide Maker with a strategy for building a graph that admits a large minor. Maker's strategy is divided into two stages. In the first stage that lasts exactly $m-1$ (where m is to be determined later) rounds, Maker builds a tree $T = (V, E)$ that satisfies the following properties:

1. $|V| = m \geq \varepsilon n$;
2. the degree of every $u \in V$ is at most 3;
3. there remain at least $\varepsilon^2 n^2/3$ unclaimed edges with both end points in V .

Maker's strategy for building such a tree is very simple: He starts by claiming an arbitrary edge, and then, for as long as possible, he claims a previously unclaimed edge (u, v) such that, in his current graph, u has degree 1 or 2 and v is isolated; such an edge, when it exists, is chosen arbitrarily. Clearly this results in a tree with maximum degree at most 3. Now assume that by using this strategy Maker was able to build a tree on m vertices but could not extend it to a tree on $m+1$ vertices (while maintaining the maximum degree criterion). This means that every edge (u, v) such that, in Maker's graph, u has degree 1 or 2 and v is isolated must have been claimed by Breaker. Since Maker's graph is a tree, at least half its vertices have degree at most 2, and so Breaker must have claimed at least $\frac{m}{2}(n-m)$ edges. But at this point, Breaker has at most $m(1 - \varepsilon)n/2$ edges entailing $m \geq \varepsilon n$. Furthermore, the number of edges with both end points in V that Breaker could have claimed is at most $m(1 - \varepsilon)n/2 - \frac{m}{2}(n-m) = \frac{m^2}{2} - \frac{m\varepsilon n}{2}$. It follows that there must be at least $\frac{m\varepsilon n}{2} - \frac{3m}{2} \geq \varepsilon^2 n^2/3$ unclaimed edges with both end points in V . This ends the first stage.

Before claiming edges in the second stage, Maker would like to partition T into roughly $\sqrt{n}$ connected components of roughly the same size. The following result of Krivelevich and Nachmias asserts that he can.

LEMMA 4.4 (see [18, Proposition 4.5]). *Let $G = (V, E)$ be a connected graph on r vertices with maximum degree at most k . Then for every positive integer l there exist pairwise disjoint sets $V_1, \dots, V_s \subseteq V$, with the following properties:*

1. $lk \leq |V_i| \leq lk^2$ for every $1 \leq i \leq s$.
2. $\sum_{i=1}^s |V_i| \geq r - lk$.
3. $G[V_i]$ is connected for every $1 \leq i \leq s$.

By using Lemma 4.4 with $r = m$, $l = \varepsilon^{-1}\sqrt{m}$, and $k = 3$ we conclude that at least $m - 3\varepsilon^{-1}\sqrt{m}$ of the vertices of T can be partitioned into parts $V_1, \dots, V_s$ such that $3\varepsilon^{-1}\sqrt{m} \leq |V_i| \leq 9\varepsilon^{-1}\sqrt{m}$ and $T[V_i]$ is connected for every $1 \leq i \leq s$. Note that $\varepsilon\sqrt{m}/10 \leq s \leq \varepsilon\sqrt{m}/3$.

A pair (V_i, V_j) will be called *good* if there are at least $b+1$ unclaimed edges (u, v) where $u \in V_i$ and $v \in V_j$. We claim that at least an $\varepsilon^2/20$ fraction of the total number

of pairs is good. Indeed, assume for the sake of contradiction that there are less than $\varepsilon^2 \binom{s}{2}/20$ good pairs; then there are at most

$$3m\varepsilon^{-1}\sqrt{m} + \sum_{i=1}^s \binom{|V_i|}{2} + b \binom{s}{2} + \varepsilon^2 \binom{s}{2} (9\varepsilon^{-1}\sqrt{m})^2/20$$

unclaimed edges in V (the first term stands for the edges incident with vertices outside $\bigcup_{i=1}^s V_i$, the second term stands for edges inside the V_i 's, the third term stands for unclaimed edges that might remain between any pair, even if it is not good, and the fourth term stands for edges between good pairs). For sufficiently large n this is strictly less than $\varepsilon^2 n^2/3$; this contradicts Maker's strategy for the first stage.

For every good pair (V_i, V_j) , let $A_{i,j}$ be any set of $b+1$ unclaimed edges with one end point in V_i and the other in V_j . Trivially, by simply not claiming more than one edge from any $A_{i,j}$ (and not claiming edges outside the $A_{i,j}$'s for as long as possible), Maker can claim an edge of $A_{i,j}$ for at least half of the good pairs (V_i, V_j) . In the second stage, Maker will use this strategy; denote Maker's graph at the end of the second stage by H . Consider the graph $\tilde{H}$ on the vertex set $V(\tilde{H}) = \{V_1, \dots, V_s\}$, where (V_i, V_j) is an edge if and only if Maker has claimed an edge (x, y) such that $x \in V_i$ and $y \in V_j$. The average degree in $\tilde{H}$ is at least

$$\frac{\varepsilon^2 \binom{s}{2}/20}{s} \geq \varepsilon^3 \sqrt{m}/400 \geq \varepsilon^4 \sqrt{n}/400,$$

and so by Theorem 4.3 it admits a K_t -minor for $t = C\sqrt{n/\log n}$, for an appropriate constant C . Since $T[V_i]$ is connected for every $1 \leq i \leq s$, H admits the same minor, and the proof of Theorem 4.1 is complete. $\square$

4.2. The Avoider-Enforcer minor game. In this game, Enforcer would like to make Avoider build a graph that admits a K_t -minor. As in the Maker-Breaker case, we allow t to be a function of n .

In the first theorem, we show that with a linear bias Enforcer can win the game for t which is as large as $c\sqrt{n/\log n}$.

THEOREM 4.5. *If $b \leq n/19$, then Enforcer has a winning strategy for the $(1, b)$ game $\mathcal{M}_n^t$ for every $t < c\sqrt{n/\log n}$, where c is some absolute constant.*

In the proof of Theorem 4.5, we will use a result of Plotkin, Rao, and Smith. Before we can state their result, we need the following definition.

DEFINITION. *Let $G = (V, E)$ be a graph on n vertices. A set $S \subset V$ is called a separator if every connected component of $G[V \setminus S]$ contains at most $2n/3$ vertices.*

THEOREM 4.6 (see [24, Corollary 2.4]). *Let G be a graph on n vertices, and let h be a function of n . If G does not have a separator of size at most $O(h\sqrt{n \log n})$, then G admits a K_h -minor.*

Proof of Theorem 4.5. Assume that $b \leq n/19$; we will present a winning strategy for Enforcer. We will prove that Enforcer can make Avoider build a graph in which there is an edge between any two disjoint vertex sets of size at least $s = (1/3 - \varepsilon)n$ each, where $\varepsilon > 0$ is some small constant. Let $\mathcal{H}_n$ denote the hypergraph whose vertices are the edges of K_n and whose hyperedges are all of the subgraphs of K_n , isomorphic to $K_{s,s}$. Enforcer's goal is to avoid claiming any hyperedge of $\mathcal{H}_n$. By using the criterion given by Theorem 3.5, we obtain

$$\sum_{D \in \mathcal{H}_n} \left(1 + \frac{1}{b}\right)^{-|D|} \leq \binom{n}{n/3} \binom{n}{n/3} 2^{-n^2/(9+\varepsilon')b} = o(1).$$

Thus, Enforcer can make sure that Avoider's graph will not contain a separator of size at most εn , and so, by Theorem 4.6, Avoider's graph will admit a K_h -minor for $h = \Theta(\sqrt{n/\log n})$. This concludes the proof of the theorem. $\square$

In the following theorem we show that, even when the bias b is almost as large as $n/2$, Enforcer can still make Avoider claim all edges of a K_t -minor, where t is some constant power of n . On the other hand, we also prove an upper bound for the upper threshold bias of this game.

THEOREM 4.7. *For every $\varepsilon > 0$ there exists a constant $a_0 = a_0(\varepsilon) > 0$ such that for every $4 \leq t \leq n^{a_0}$ we have*

$$\left(\frac{1}{2} - \varepsilon\right)n \leq f_{\mathcal{M}_n^t}^- \leq f_{\mathcal{M}_n^t}^+ \leq 2n^{5/4}.$$

Before proving this theorem, we will state and prove a graph-theoretic lemma, which may also be of independent interest.

LEMMA 4.8. *Let $G = (V, E)$ be a graph with average degree $2 + \alpha$, for some $\alpha > 0$, and girth $g^* \geq (1 + \frac{2}{\alpha})(4 \log_2 t + 2 \log_2 \log_2 t + c)$, where c is an appropriate constant. Then G admits a K_t -minor.*

Proof. In the proof of the lemma we will use the following result of Kühn and Osthus (a similar result was also obtained by Diestel and Rempel [12]).

THEOREM 4.9 (see [19, Corollary 5]). *Let $t \geq 3$ be an integer. There exists a constant c such that every graph of minimum degree at least 3 and girth at least $4 \log_2 t + 2 \log_2 \log_2 t + c$ contains a K_t -minor.*

We repeatedly apply two deletion operations on G , which do not decrease the average degree and (trivially) do not decrease the girth. The first operation is the deletion of a vertex of degree at most one. Such an operation obviously does not decrease the average degree. In the second type of operation, given a path $u_1, u_2, \dots, u_k$, with $k \geq 2 + 2/\alpha$, such that each of the internal vertices $u_2, u_3, \dots, u_{k-1}$ has degree two in G , we remove $u_2, \dots, u_{k-1}$. Again the average degree of the new graph is at least $2 + \alpha$. To verify this, let us assume that from a graph with e edges and v vertices satisfying $\frac{2e}{v} \geq 2 + \alpha$ we remove the internal vertices of a path with $k \geq 2 + 2/\alpha$ vertices. Then we obtain a graph with average degree at least

$$\frac{2(e - k + 1)}{v - (k - 2)} \geq 2 + \alpha,$$

as claimed. Let G_2 be the graph we obtain from G by repeated applications of these two operations. Since the average degree was not decreased in any step of the process, G_2 is not empty. It also follows that $\delta(G_2) \geq 2$, the girth of G_2 , is at least g^* and every path of G_2 , with internal vertices of degree two, is of length at most $1 + 2/\alpha$. Let G_3 denote the graph obtained from G_2 by contracting every path $u_1, u_2, \dots, u_k$, such that u_i has degree two in G_2 for every $1 < i < k$, into a single edge. Again, this operation does not decrease the average degree, and therefore G_3 is not empty. Clearly $\delta(G_3) \geq 3$. Moreover, since every such path in G_2 is of length at most $1 + 2/\alpha$ it follows that the girth of G_3 is at least $g = \frac{g^*}{1 + 2/\alpha} \geq 4 \log_2 t + 2 \log_2 \log_2 t + c$. By applying Theorem 4.9 we conclude that G_3 admits a K_t -minor. Since G_3 was obtained from G by the deletion and contraction of edges (and the removal of isolated vertices), G admits the same minor, and the proof is complete. $\square$

Proof of Theorem 4.7. Let $\varepsilon > 0$, and let $n = n(\varepsilon)$ be sufficiently large. Assume that $b \leq (1/2 - \varepsilon)n$, and $4 \leq t \leq n^{a_0}$, where $a_0 = a_0(\varepsilon)$ is a “small” positive constant

whose value will be determined later. If $b \leq n/19$, then by Theorem 4.5 Enforcer wins. Hence, from now on we can assume that $n/19 < b \leq (1/2 - \varepsilon)n$.

Let $\alpha = \alpha(n, \varepsilon) > 0$ be the real number that satisfies

$$(1 + \alpha)n = \frac{\binom{n}{2}}{(1/2 - \varepsilon)n + 1},$$

and let

$$\ell = 5a_0 \left(1 + \frac{2}{\alpha}\right) \log_2 n.$$

Enforcer's goal is to make sure that Avoider claims the edges of at most $o(n)$ cycles of length at most ℓ , throughout the game. In order to prove that Enforcer is able to do so, we will use a generalization of the Erdős–Selfridge theorem that applies to Maker–Breaker games in which the goal of Maker is to claim d (instead of just one) winning sets.

THEOREM 4.10 (see [1, 5]). *If for positive integers d and b we have*

$$\sum_{A \in \mathcal{F}} (1 + b)^{-|A|} < d,$$

then Breaker (as the first player) has a winning strategy in the $(1, b)$ Maker–Breaker game $\{\cup_{B \in \mathcal{F}} B : F \in \binom{\mathcal{F}}{d}\}$ (a minimal hyperedge of $\{\cup_{B \in \mathcal{F}} B : F \in \binom{\mathcal{F}}{d}\}$ is the union of d , not necessarily disjoint, hyperedges of $\mathcal{F}$).

Assume that, on his first move, Avoider claims some edge e . Enforcer will claim the role of Breaker, as the first player, in the game on $E(K_n) \setminus \{e\}$, in which the winning sets are the cycle of length at most ℓ . We have

$$\begin{aligned} \sum_{A \in \mathcal{F}} (1 + b)^{-|A|} &\leq \sum_{A \in \mathcal{F}} \left(\frac{n}{19}\right)^{-|A|} \\ &\leq \sum_{3 \leq i \leq \ell} \frac{\binom{n}{i}}{2^i} \left(\frac{n}{19}\right)^{-i} \\ &\leq \sum_{3 \leq i \leq \ell} 19^i \\ &\leq \ell \cdot n^{5a_0(1 + \frac{2}{\alpha}) \log_2 19} = o(n), \end{aligned}$$

where the last equality follows from an appropriate choice of a_0 .

By applying Theorem 4.10, we conclude that, in the entire game, Avoider will claim the edges of at most $o(n)$ cycles of length at most ℓ in $E(K_n) \setminus \{e\}$.

Let G_A denote Avoider's graph after he has played exactly $(1 + \alpha)n$ moves. The average degree in G_A is $2 + 2\alpha$. We will prove that Enforcer has won the game already at this point. Remove the edge e , as well as one edge from every cycle of length at most ℓ in G_A ; denote the resulting graph by G'_A . Clearly the girth of G'_A is at least ℓ . Moreover, the average degree in G'_A is at least $2 + \alpha$ since we removed just $o(n)$ edges from G_A .

Since $\ell \geq (1 + \frac{2}{\alpha})(4 \log_2 t + 2 \log_2 \log_2 t + c)$, where c is the constant given by Theorem 4.9, we conclude that G'_A admits a K_t -minor by Lemma 4.8. Clearly G_A admits the same minor.

If $b \geq 2n^{5/4}$, then by playing as in the proof of Theorem 2.3 Avoider builds a graph that does not admit a K_4 -minor.

Remark. As in the remark following the proof of Theorem 3.4, if $b > n^{3/2}$, then Avoider can create a K_3 -minor-free graph (i.e., a forest). Moreover, our strategy for Enforcer is valid also for $t = 3$.

5. Concluding remarks and open problems.

Maker-breaker thresholds. In section 3 it was proved that $b_{\mathcal{NC}_n^k} = \Theta(n)$ for every fixed k . We believe that in fact the following stronger statement holds.

CONJECTURE 5.1. *There is a constant c such that for every $k \geq 3$ and sufficiently large n we have*

$$b_{\mathcal{NC}_n^k} = \frac{(c + o(1))}{k \log k} n.$$

For both the planarity and the K_t -minor Maker-Breaker games, the second order terms are unknown; this is worth studying, in particular the dependence of the threshold $b_{\mathcal{M}_n^t}$ on t .

Asymptotic monotonicity of Avoider-Enforcer games. We say that an Avoider-Enforcer game $\mathcal{F}$ is *monotone* if the existence of Avoider's winning strategy for the $(1, q, \mathcal{F})$ game implies his win in the $(1, q + 1, \mathcal{F})$ game or, equivalently, if $f_{\mathcal{F}}^+ = f_{\mathcal{F}}^-$. Following [14], the function $f(n)$ is called an *asymptotic threshold bias* of the game $\mathcal{B}_n$ if both $f_{\mathcal{B}_n}^- = \Theta(f(n))$ and $f_{\mathcal{B}_n}^+ = \Theta(f(n))$. If an asymptotic threshold bias exists, that is, if $f_{\mathcal{B}_n}^- = \Theta(f_{\mathcal{B}_n}^+)$, then the game $\mathcal{B}_n$ is called *asymptotically monotone*. In [14] it was conjectured that the perfect matching and Hamiltonicity games are monotone. Here we conjecture the following.

CONJECTURE 5.2. *The Avoider-Enforcer nonplanarity, non- k -colorability, and K_t -minor games are asymptotically monotone.*

Avoider's strategies. For all of the Avoider-Enforcer games studied in this paper, there is a significant gap between the upper and lower bounds on the threshold biases. It would be interesting to close, or at least to reduce, these gaps. We do not believe that any of the upper bounds for $f_{\mathcal{F}}^+$ proved in this paper are tight. As a first step, it would be desirable to obtain an upper bound for the upper threshold bias $f_{\mathcal{M}_n^t}^+$ of the K_t -minor game which does depend on t .

The reason for the difficulty of finding upper bounds is due partly to the lack of a usable criterion for Avoider's win, similar to Theorem 3.5, in a $(1, q)$ game where $q > 1$. This is reminiscent of the difficulties that arise in the Hamiltonicity game $\mathcal{H}_n$ and in the perfect matching game $\mathcal{M}_n$ (see [14]). Let us recall that it is not even known whether Avoider can win $(1, n/100, \mathcal{M}_n)$ or $(1, n/100, \mathcal{H}_n)$. It seems quite reasonable that he can, knowing that Avoider wins $(1, n, \mathcal{M}_n)$ and $(1, n/2, \mathcal{H}_n)$ regardless of his strategy.

Acknowledgment. The authors thank the anonymous referee for helpful comments.

$L(2, 1)$ -LABELING OF HAMILTONIAN GRAPHS WITH MAXIMUM DEGREE 3*

JEONG-HYUN KANG[†]

Abstract. An integer coloring f of the vertices of a graph G is an $L(2, 1)$ -labeling if $|f(u) - f(v)| \geq 2$ for each edge uv and $|f(u) - f(v)| \geq 1$ for each pair $u, v \in V(G)$ at distance 2 apart. The $L(2, 1)$ -labeling span of G , denoted by $\lambda(G)$, is the smallest number t such that G has an $L(2, 1)$ -labeling using labels $\{0, 1, \dots, t\}$. Griggs and Yeh [*SIAM J. Discrete Math.*, 5 (1992), pp. 586–595] conjectured that always $\lambda(G) \leq (\Delta(G))^2$, where $\Delta(G)$ is the maximum degree of G and $\Delta(G) \geq 2$. In this paper, we will prove that the conjecture holds if G is a Hamiltonian graph with maximum degree 3.

Key words. $L(2, 1)$ -labeling, channel assignment, graph labeling, generalized coloring

1. Introduction. In ordinary graph coloring, adjacent vertices must be given different colors, and the actual values of the colors used are irrelevant. However, in many applications, it is also important to separate labels on vertices at farther distances, where the labels used have some numerical meaning. A natural problem of this type is the channel assignment problem, where channels (nonnegative integers) are assigned to each radio transmitter (vertex) so that interfering (adjacent) transmitters get channels that are far apart. Roberts proposed a variation of the channel assignment problem, which Griggs and Yeh [5] introduced in 1992 and called the $L(2, 1)$ -labeling problem. Keeping the radio transmitter analogy in mind, vertices in a graph need to be labeled such that “close” vertices (at distance 2) get different labels, while “very close” vertices (at distance 1) get labels that are farther apart. More precisely, for a given graph G , a mapping $f : V(G) \rightarrow \mathbb{N} \cup \{0\}$ is called an $L(2, 1)$ -labeling if $|f(u) - f(v)| \geq 2$ for each edge uv of G and $|f(u) - f(v)| \geq 1$ for each pair $u, v \in V(G)$ at distance 2 apart. The $L(2, 1)$ -labeling number of G , denoted by $\lambda(G)$, is the smallest number t such that G has an $L(2, 1)$ -labeling that does not use any label greater than t .

As with the chromatic number of a graph G , it is natural to seek a bound on $\lambda(G)$ in terms of the maximum degree $\Delta(G)$. The obvious lower bound for $\lambda(G)$ is $\Delta(G) + 1$, which holds with equality for stars. A greedy labeling (as shown in [5]) gives $\lambda(G) \leq \Delta^2(G) + 2\Delta(G)$. This upper bound was improved to $\Delta^2(G) + \Delta(G)$ by Chang and Kuo [1], $\Delta^2(G) + \Delta(G) - 1$ by Král’ and Škrekovski [8], and $\Delta^2(G) + \Delta(G) - 2$ by Gonçalves [4]. Griggs and Yeh [5] conjectured that $\lambda(G) \leq \Delta^2(G)$ for every graph G . This has been a motivating problem for research in this field, and some results are known. Note that it is enough to consider connected regular graphs. If G is a 2-regular graph (a cycle), then $\lambda(G) = 4$, as proved in [5]. Tight bounds have been obtained for special classes of graphs like paths, cycles, wheels, complete k -partite graphs, and graphs with diameter 2 [5], trees [1, 5], the incidence graphs of projective planes [2], etc. Bounds have also been obtained for various other graph families like

FIG. 1. $L(2, 1)$ -labeling of C .

chordal graphs and unit interval graphs [9], hypercubes [5, 6, 10], planar graphs [6], and certain classes of Kneser graphs [7]. The list version of the problem has been also investigated [8]. All of the known bounds for these families satisfy the conjecture of Griggs and Yeh.

In this paper, we prove the Griggs–Yeh conjecture for Hamiltonian graphs with maximum degree 3.

THEOREM 1. *If G is a Hamiltonian graph with maximum degree 3, then G has a $L(2, 1)$ -labeling of $\lambda(G) \leq 9$.*

The graphs considered here consist of a spanning cycle and a perfect matching. Georges and Mauro [3] worked on a similar graph, namely a generalized Petersen graph that is two identical cycles plus a matching between them. The best known upper bound for general graphs of maximum degree 3 is 10, by Goncalves [4]; that is just one above the conjecture. The conjectured bound 9 is achieved by the Petersen graph, and no other examples achieving it are known for the maximum degree being 3.

Sections 2, 3, 4, and 5.1 deal exclusively with the case of vertex sets of size 0 (mod 3). In sections 2, 3, and 4, we consider 3-regular Hamiltonian graphs and lay down the foundations for the proof of this case. We first label the vertices based on the Hamiltonian cycle and then explore the properties of an auxiliary graph of badly labeled pairs of vertices. In section 5.1, using the results from sections 2, 3, and 4, we describe an explicit labeling for the case $n(G) \equiv 0 \pmod{3}$. In section 5.2, we adapt the labeling to the other two residue classes.

2. Prelabeling and a graph of bad pairs.

2.1. Definitions and notation. Let G be a 3-regular Hamiltonian graph on n vertices with $n \equiv 0 \pmod{3}$, and let C be a specific Hamiltonian cycle in G . Deleting the edges of C from G leaves a perfect matching, say M . For $u, v \in V$, we will often call u and v G -neighbors, C -neighbors, or the M -neighbors/ M -mates to each other if $uv \in E(G)$, $uv \in E(C)$, or $uv \in M$, respectively. An edge is called *monochromatic* if both its endpoints have the same labels.

Let ρ be a reference coloring that assigns to the vertices of C colors 0, 3, 7, 0, 3, 7, $\dots$, 0, 3, 7 in order along C . Note that ρ is an $L(2, 1)$ -labeling of C . (See Figure 1.) Adding the edges of M to C introduces “bad” pairs of vertices in G . Let H be the graph of these bad pairs; that is, $V(H) = V(G)$, and $uv \in E(H)$ if $\rho(u)$ and $\rho(v)$ violate the conditions of $L(2, 1)$ -labeling for G . Since the colors $\{0, 3, 7\}$ pairwise differ by at least two, $uv \in E(H)$ if and only if u and v receive the same color, and (i) $uv \in M$, (ii) there exists $w \in V$ such that $vw \in M$ and $wu \in E(C)$, or (iii) there exists $w \in V$ such that $vw \in E(C)$ and $wu \in M$. Observe that, for each $v \in V(G)$, there is exactly one vertex $u \in V(G)$ of either (i) or (ii). Hence no vertex of $V(G)$ is an isolated vertex in H , and $\Delta(H) \leq 3$.

FIG. 2. Orienting an edge uv of H .FIG. 3. Double edges $v \rightarrow u, u \rightarrow v$ in D .

In the figures of this paper, we denote the edges of C, M , and H by irregular dashed lines $\cdots\cdots$, thick solid lines — , and regular dashed lines $- - -$, respectively.

Let $X = \rho^{-1}(0)$, $Y = \rho^{-1}(3)$, and $Z = \rho^{-1}(7)$. Let $X_1, X_2, \dots, X_r$ be the vertex sets of the components of $H[X]$, and similarly define $Y_1, Y_2, \dots, Y_s$ and $Z_1, Z_2, \dots, Z_t$ for the vertex sets of the components of $H[Y]$ and $H[Z]$ in colors 3 and 7, respectively. Note that $|X| = |Y| = |Z|$.

To study the structure of H , we will orient its edges (possibly both ways). For each ordered pair (u, v) with $vu \in E(H)$, orient $v \rightarrow u$ if u occurs as either the M -neighbor of v or one of the C -neighbors of the M -mate of v . (See Figure 2). It is helpful to view the result as a digraph D , with opposed edges vu and uv when we orient $uv \in E(H)$ as both $v \rightarrow u$ and $u \rightarrow v$. A double edge can arise in D in two ways as follows (see Figure 3):

- (i) a monochromatic M -edge uv in G ,
- (ii) a cycle (u, u', v, v') of length 4 with edges alternating between C and M , in which the M -edges are not monochromatic. In particular, suppose that $uu', vv' \in E(C)$, $u'v, v'u \in M$ such that $u'v$ and $v'u$ are not monochromatic. By the pigeonhole principle and the definition of the coloring, at least one of the two pairs $\{u, v\}$ and $\{u', v'\}$ must receive the same color, since we have only three color classes. If $\{u, v\}$ is the monochromatic pair, then we obtain $uv, vu \in E(D)$.

2.2. Structure of the graph H of bad pairs. We show that every component of H is either a tree or a unicyclic graph. For this, we show first that every component of D is a unicyclic digraph, which requires a proposition about the vertex degrees in D .

PROPOSITION 1.

- (a) $d_D^+(v) = 1$ for all $v \in V(D)$.
- (b) $d_D^-(v) \leq 3$ for all $v \in V(D)$, with equality only if v is incident to a double edge in D arising from a monochromatic edge in M .

FIG. 4. Components of the orientation D .FIG. 5. Types of components of H : Type I, Type II, Type III.

Proposition 1 yields the unicyclic structure for components of D .

LEMMA 1 (see Figure 4). *Each component of D is unicyclic (i.e., has exactly one cycle), and each vertex outside the cycle has exactly one out-neighbor toward the cycle and at most two in-neighbors farther from the cycle.*

Proof. Proposition 1(a) implies that every component of D is unicyclic. Proposition 1(b) implies that three edges enter only when one of them is on the cycle. $\square$

By collapsing the double edges in D , we can describe our “bad graph” H precisely. We show the possible types of components in Figure 5, where the drawing of edges follows the conventions adopted in section 2.1.

LEMMA 2 (see Figure 5). *Each component of H is one of the following three types:*

Type I: *Either a tree obtained by collapsing the double edge created by a C , M -alternating 4-cycle in G , or a unicyclic graph with an even cycle.*

Type II: *A tree containing one M -edge of G obtained by collapsing the double edge arising from a monochromatic M -edge.*

Type III: *A unicyclic graph whose cycle has odd length.*

It is illustrated in Figure 6 how a cycle in D (hence in H) can occur. The cycle $(x_1, x_2, x_3, x_4, x_5)$ in $D[X]$ is introduced by a cycle $(x_1, y_2, x_2, y_3, x_3, z_4, x_4, z_5, x_5, y_1)$ in G , where each x_s belongs to X and y_s or z_s is one of the C -neighbors of x_s in $Y \cup Z$.

From the structure of H , a desired coloring for H that yields a $L(2, 1)$ -labeling for G can be specified as follows.

FIG. 6. A cycle $(x_1, x_2, x_3, x_4, x_5)$ in D and a cycle $(x_1, y_1, y_2, y_3, x_3, z_4, x_4, z_5, x_5, y_1)$ in G .

THEOREM 2. *Given a 3-regular Hamiltonian graph G , $|V(G)| \equiv 0 \pmod{3}$, with precoloring ρ and the resulting “bad graph” H (as defined in section 2.1), an $L(2, 1)$ -labeling for G can be obtained by giving ordinary proper colorings of the components of $H[X]$, $H[Y]$, and $H[Z]$ with colors $\{0, 1, 2\}$, $\{3, 4, 5\}$, and $\{7, 8, 9\}$, respectively, satisfying the following conditions:*

- (a) *the M -edges of the components of $H[X]$, $H[Y]$, and $H[Z]$ of Type II receive $\{0, 2\}$, $\{3, 5\}$, and $\{7, 9\}$, respectively, on their endpoints, and*
- (b) *the vertices of X colored with 2 are not adjacent to those of Y colored with 3.*

Proof. The only edges of H that are also edges of G are the M -edges in components of Type II. Hence we may use two consecutive colors in modifying ρ on the vertices of a component of Type I or II, except that the colors on the endpoints of an M -edge must differ by at least 2. On components of Type III, we may use any proper 3-coloring. The edges of G between X and Y should satisfy part (b) to ensure that it is an $L(2, 1)$ -labeling. Note that the edges of G between Y and Z automatically satisfy the condition of $L(2, 1)$ -labeling due to the buffer color 6. $\square$

Vertices that have to be colored with 2 or 3 belong to a monochromatic M -edge or to an odd cycle of a component in H (while the rest of the vertices can receive colors from $\{0, 1\}$ or $\{4, 5\}$ that are far apart). To take care of the condition (b) of Theorem 2, it is critical to know how monochromatic M -edges or odd cycles in H are connected to each other. In this sense, we define *trouble part* to be the monochromatic M -edge or the odd cycle of the component in H of Type II or III.

3. Structure of subgraphs. Theorem 2(b) requires us to study the interaction between color classes under ρ in G . In this section, we study how certain edges in D imply the existence of some substructure in G , and vice versa.

3.1. Definitions and notation. When F is a graph and A and B are disjoint subsets of $V(F)$, we write $F[A]$ for the subgraph of F induced by A and $F[A, B]$ for the set of edges of F with one endpoint in A and the other endpoint in B . We will abuse these notations even when F is not a graph (such as matching M) when the context is clear. Continuing with the partition X, Y, Z of $V(G)$ as introduced in section 2, the structure of $G[X \cup Y]$ consists of a perfect matching $C[X, Y]$ and a (not necessarily perfect) matching $M[X \cup Y]$. Hence each component of $G[X \cup Y]$ is an M -alternating cycle or an M -augmenting path (see Figure 7). The same description holds for $G[Y \cup Z]$ and $G[X \cup Z]$ using $C[Y, Z] \cup M[Y \cup Z]$ and $C[X, Z] \cup M[X \cup Z]$, respectively. Note that a vertex of degree 1 in $G[X \cup Y]$ has its M -neighbor in Z .

Let D_{XY} be the subgraph D defined as follows. The vertex set is $X \cup Y$. The edge set is the edges in $D[X \cup Y] = D[X] \cup D[Y]$ whose endpoints have a common neighbor (in G) in Y or X . Such a common neighbor must be an M -neighbor of the

FIG. 7. Examples of components of $G[X \cup Y]$.FIG. 8. Wedges in $G[X \cup Y]$ and directed edges in D_{XY} forced by each other.

tail and a C -neighbor of the head. Precisely,

$$E(D_{XY}) = \{uv \in E(D[X]) \mid uy \in M \text{ and } vy \in C \text{ for some } y \in Y\} \\ \cup \{uv \in E(D[Y]) \mid ux \in M \text{ and } vx \in C \text{ for some } x \in X\}.$$

Similarly, let $V(H_{XY}) = X \cup Y$, and $uv \in E(H_{XY})$ if $uv \in H[X] \cup H[Y]$ have a common neighbor (in G) in Y or X . Note that H_{XY} is the underlying graph of D_{XY} , as before, by collapsing the double edges in D_{XY} .

Remark. H_{XY} differs from $H[X] \cup H[Y]$, and so does D_{XY} from $D[X] \cup D[Y]$. Although $E(H_{XY}) \subset E(H[X] \cup H[Y])$ and $E(D_{XY}) \subset E(D[X] \cup D[Y])$, H_{XY} lacks all the edges of $M[X] \cup M[Y] \subset H[X] \cup H[Y]$ and, more importantly, the edges of $H[X] \cup H[Y]$ whose endpoints have a common neighbor (in G) in Z . From Figure 6, $H[\{x_1, \dots, x_5\}]$ (resp., $D[\{x_1, \dots, x_5\}]$) is an odd cycle $(x_1, x_2, x_3, x_4, x_5)$ in $H[X \cup Y]$ (resp., $D[X \cup Y]$), while $H_{XY}[\{x_1, \dots, x_5\}]$ (resp., $D_{XY}[\{x_1, \dots, x_5\}]$) is a path (x_5, x_1, x_2, x_3) of length 3.

3.2. Relation between subgraphs of H and G . Now, we will show a closer relation between D_{XY} and $G[X \cup Y]$: a given configuration in one forces a certain configuration in the other, and vice versa. The relation holds between D_{YZ} and $G[Y \cup Z]$ analogously. Let us start with a restatement combining the definition of D and that of D_{XY} . A *wedge* from $x_1 \in X$ to $x_2 \in X$ in $G[X \cup Y]$ is a path of length 2 from x_1 to x_2 in which the first edge (incident to x_1) is in $M[X, Y]$ and the second edge (incident to x_2) is in $C[X, Y]$. By this definition, we get the following proposition.

PROPOSITION 2 (see Figure 8). $D_{XY}[X]$ has an edge x_1x_2 (resp., y_1y_2) if and only if $G[X \cup Y]$ has a wedge from $x_1 \in X$ to $x_2 \in X$ (resp., $y_1 \in Y$ to $y_2 \in Y$).

Applying Proposition 2 twice, we can obtain the next proposition that describes configurations occurring in $D_{XY}[Y]$ forced by edges in $D_{XY}[X]$ (or vice versa). This is easily extended to the corresponding results for paths and cycles in $D_{XY}[X]$, Corollary 1, and this will be used later to help produce the desired coloring.

PROPOSITION 3 (see Figure 9). Let $x_1x_2 \in E(D_{XY}[X])$ be a directed edge. If $y_i \in Y$ is the C -neighbor of x_i for $i = 1, 2$, then

- (a) y_2 is the M -neighbor of x_1 , and hence $y_1x_1y_2x_2$ is a path in $G[X \cup Y]$;
- (b) $y_2y_1 \in E(D_{XY}[Y])$.

FIG. 9. The path (y_1, x_1, y_2, x_2) in $G[X \cup Y]$ and the directed edge $y_2 y_1$ in $D_{XY}[Y]$ forced by $x_1 x_2$ in $D_{XY}[X]$.

FIG. 10. The path $(y_1, x_1, y_2, x_2, \dots, y_k, x_k)$ in $G[X \cup Y]$ and the directed path $(y_k, y_{k-1}, \dots, y_1)$ in $D_{XY}[Y]$ forced by $(x_1, x_2, \dots, x_k)$.

Proof. We apply both directions of Proposition 2 to work back and forth between D_{XY} and $G[X \cup Y]$.

(a) By Proposition 2, the existence of an edge $x_1 x_2$ in $D_{XY}[X]$ requires a vertex in Y that is both the M -neighbor of x_1 and the C -neighbor of x_2 , and it must be y_2 .

(b) With y_2 being the M -neighbor of x_1 by part (a), we apply Proposition 2 to the path $y_2 x_1 y_1$ in $G[X \cup Y]$ to obtain $y_2 y_1 \in E(D_{XY}[Y])$. $\square$

Proposition 3 immediately extends to transfer paths and cycles between $D_{XY}[X]$ and $D_{XY}[Y]$.

COROLLARY 1 (see Figure 10). *If $x_1 x_2 \dots x_k$ is a directed path in $D_{XY}[X]$, then*

- (a) *there is a path $y_1 x_1 y_2 x_2 \dots y_k x_k$, in $G[X \cup Y]$, where y_i is the C -neighbor of x_i for $1 \leq i \leq k$, and $y_{i+1} \in Y$ is both the M -neighbor of x_i and the C -neighbor of x_{i+1} for $1 \leq i \leq k-1$;*
- (b) *the vertices $y_k, y_{k-1}, \dots, y_1$ defined in part (a) form a path in that order in $D_{XY}[Y]$;*
- (c) *(see Figure 11) if also $x_k x_1 \in D_{XY}[X]$, then also $x_k y_1 \in M$ and $y_1 y_k \in D_{XY}[Y]$.*

We henceforth call the two corresponding cycles $(x_1, x_2, \dots, x_k)$ and $(y_k, y_{k-1}, \dots, y_1)$ in Corollary 1(c) *twin cycles*. A pair of twin cycles of odd length will play an important role later.

Remark. We comment on the significance of choosing $D_{XY}[X]$ and $D_{XY}[Y]$ as subgraphs of D_{XY} instead of choosing $D[X]$ and $D[Y]$ as subgraphs of $D[X \cup Y]$ (see Figure 12). Unlike the results $D_{XY}[X]$ and $D_{XY}[Y]$ in Corollary 1, a cycle of length k in $D[X]$ need not force a cycle of length $2k$ in $G[X \cup Y]$ or a cycle of length k in $D[Y]$, because a cycle in $D[X]$ may use edges that result from wedges that pass through Z . For example, in Figure 6, $(x_1, x_2, x_3, x_4, x_5)$ is a directed cycle in $D[X]$. But it corresponds to only a path $(y_5, x_5, y_1, x_1, y_2, x_2, y_3, x_3)$ of length 7 in $G[X \cup Y]$ plus one isolated edge $x_4 y_4$, where $y_4, y_5 \in Y$ are the C -neighbors of x_4, x_5 , respectively. This forces a directed path (y_3, y_2, y_1, y_5) and an isolated vertex y_4 in $D[Y]$.

FIG. 11. The cycle $(y_1, x_1, y_2, x_2, \dots, y_k, x_k)$ in $G[X \cup Y]$, and the directed cycle $(y_k, y_{k-1}, \dots, y_1, y_k)$ in $D_{XY}[Y]$ forced by $(x_1, x_2, \dots, x_k, x_1)$.

FIG. 12. The significance of choosing $D_{XY}[X]$ instead of $D[X]$.

4. Trouble parts in color classes. To give a coloring as described in Theorem 2, we need to study the interaction between M -edges and odd cycles of $H[X \cup Y]$. Let us introduce some vertex subsets and subgraphs of G and H on $X \cup Y$ that intersect not all but most of such M -edges and odd cycles of $H[X]$ and $H[Y]$.

4.1. Definitions and notation. Let X' (resp., Y') be the subset of X (resp., Y) consisting of all the elements $x \in X$ (resp., $y \in Y$) whose M -neighbor is *not* in Y (resp., X). Let G_0 be the subgraph of $G[X \cup Y]$ induced by $X' \cup Y_{X'} \cup Y'$, where $Y_{X'}$ is the set of neighbors of the vertices of X' in Y . Let M_0 and C_0 be the set of M -edges and C -edges, respectively, of G_0 . Note that all the edges of $M[X] \cup M[Y]$ appear in G_0 . Note also that each component of G_0 is a C, M -alternating cycle, a C, M -alternating path, or an isolated vertex v that is in Y' such that the C -neighbor of v in X is not in X' . (See Figure 13.) Note that $M_0 = M[X] \cup M[Y]$ and $M_0 \cap M[X, Y] = \emptyset$.

Let $\mathcal{O}$ be the family of odd cycles in $H[X] \cup H[Y]$ that have a common vertex with $X' \cup Y_{X'} \cup Y'$. It is *not* necessary that all the vertices of such a cycle lie in $X' \cup Y_{X'} \cup Y'$.

4.2. Interaction of trouble parts between color classes. By Lemma 2, two trouble parts of components of H , a cycle in $\mathcal{O}$ and an M_0 -edge, cannot share a vertex. Therefore, a component of G_0 has a common vertex with a cycle in $\mathcal{O}$ only if the component is an M_0 -alternating path and the common vertex is an endpoint of the path incident to a C_0 -edge.

LEMMA 3.

- (a) Let $yy' \in E(D[Y])$ with $y \notin Y', y' \in Y'$. If y' is not incident to an $M[Y]$ -edge, then y' is an isolated vertex in G_0 .
- (b) For a cycle $O \in \mathcal{O}$ in $H[Y]$, there is always $y \in V(O)$ such that $y \in Y'$.

FIG. 13. *Types of components of G_0 .*

- (c) If a cycle O in $H[Y]$ has exactly one vertex from $Y_{X'} \cup Y'$, then the unique vertex is an isolated vertex in G_0 .

Proof. (a) Since $y \notin Y'$, y has its M -neighbor in X , say x . By the uniqueness of the out-neighbor (of y) in H , the C -neighbor of x in Y must be y' . Since y' is not incident to an $M[Y]$ -edge and its C -neighbor x in X is not in X' , the vertex y' must be isolated in G_0 .

(b) Suppose that $y \in V(O) \in \mathcal{O}$ in $H[Y]$ and $y \in Y_{X'} \setminus Y'$. Let $xy \in C$ so that $x \in X'$. Consider the in-neighbor y' of y in O . Then we claim that $y' \in Y'$. Otherwise, the uniqueness of the out-neighbor (of y') in H implies that the M -neighbor of y' in X must be x , which contradicts $x \in X'$.

(c) Let y' be the unique vertex. Then (b) implies that $y' \in Y'$. If y is the in-neighbor of y' in O , the conclusion is immediate from (a). $\square$

LEMMA 4.

- (a) Suppose that a cycle $O \in \mathcal{O}$ in $H[X]$ has exactly one vertex from X' . Then the unique vertex and its C -neighbor in Y form an isolated edge in G_0 .
(b) Let $O \in \mathcal{O}$ be a cycle and xy be an isolated edge in (a), where $x \in V(O)$ and $y \in Y$. If y is a vertex of a cycle $O' \in \mathcal{O}$ in $H[Y]$, the cycle O' has an isolated vertex in G_0 .

Proof. (a) Let $x \in V(O)$ be the unique vertex, and y be its C -neighbor in Y . If x' is the in-neighbor of x in O , then $x' \notin X'$. The uniqueness of the out-neighbor (of x') in H implies that $x'y \in M$ and hence $y \notin Y'$. The M_0 -augmenting path in G_0 beginning with the edge xy has to stop at y .

(b) We have seen that $y \notin Y'$ in the proof of (a). On the other hand, since $O' \in \mathcal{O}$ is a cycle in $H[Y]$, there is a vertex in O' from Y' by Lemma 3(b). Since the cycle O' has vertices in Y' and outside of Y' , we can find an edge of Lemma 3(a), and O' has an isolated vertex in G_0 . $\square$

The following proposition is critical for choosing vertices of colors 2 and 3 from trouble parts in $H[X \cup Y]$.

PROPOSITION 4. $V(G_0)$ has a bipartition A, B with the property that A has at least one vertex in

- (a) every edge of M_0 , and
(b) every cycle of $\mathcal{O}$.

Proof. We have observed that the components of G_0 are C, M -alternating cycles, C, M -alternating paths, and isolated vertices (arising from a cycle of $\mathcal{O}$ in $H[Y]$). Hence G_0 is bipartite. Furthermore, we have observed that $V(G_0)$ intersects cycles in $\mathcal{O}$ only at the ends of its path components. If a path component meets a cycle in $\mathcal{O}$

only at one end, then choose the bipartition on that component to put that end in A . The bipartition can be chosen arbitrarily on C , M -alternating cycles in G_0 , since they do not intersect cycles in $\mathcal{O}$. Isolated vertices can freely be placed in A . It remains to choose the bipartition of the M -augmenting paths in G_0 that have both end cycles in $\mathcal{O}$.

Define an auxiliary multigraph Q whose vertices are the cycles in $\mathcal{O}$. Join O and O' by an edge in Q when G_0 has a path with endpoints in O and O' (loop and multiple edges may arise).

We show that Q has an orientation such that every vertex has positive outdegree except possibly for one vertex of degree 1 in each component of Q as follows. If a component of Q has a cycle, then orient some cycle consistently. For each vertex not on the cycle, there is a neighbor whose distance from the cycle is smaller; orient that edge toward the cycle. If a component of Q has no cycle, then choose a leaf as a root. Orient the component as a directed tree of paths toward this root.

Now we complete the desired bipartition of G_0 as follows: for each oriented edge of Q , the end of the corresponding component of G_0 corresponding to the tail goes into A , and the end corresponding to the head goes into B . Except for the root, all vertices have positive outdegree.

Let O be a cycle corresponding to the root of a tree in Q . If $|V(O) \cap X'| \geq 2$ or $|V(O) \cap (Y_{X'} \cup Y')| \geq 2$, there is one vertex in $V(O)$ from which an M_0 -augmenting path starts and does not end at another cycle in $\mathcal{O}$. This vertex is in A . If O has only one vertex from $X' \cup Y_{X'} \cup Y'$, the cycle O must be in $H[X]$ by Lemma 3(c). Let x be the unique vertex of $V(O) \cap X'$. Lemma 4(b) gives us that $O' \in \mathcal{O}$ and $y, y' \in V(O')$ such that xy is the C_0 -edge connecting O and O' , and y' is an isolated vertex in G_0 . We can swap the A, B on x, y so that $x \in A$, $y \in B$, and then put $y' \in A$. $\square$

5. $L(2, 1)$ -labeling for Hamiltonian graphs with maximum degree 3. In this section, we will use the results from the previous sections to give a proof of the main theorem, Theorem 1 (see section 1).

In section 5.1, we give the proof when $n(G) \equiv 0 \pmod{3}$, and in section 5.2, we handle the other residue classes.

5.1. Vertex sets of size 0 (mod 3). First, we apply Theorem 2 to obtain an $L(2, 1)$ -labeling for 3-regular Hamiltonian graphs. A discussion for Hamiltonian graphs with maximum degree 3 follows after that.

Case 1. G is a 3-regular Hamiltonian graph. We will color componentwise depending on the types given in Lemma 2.

Step 1: Coloring of $H[X]$. If a component $H[X_i]$ is of Type I, a bipartite graph, then color X_i with $\{0, 1\}$.

Let us suppose that $H[X_i]$ is of Type II or III. Then, recall that $H[X_i]$ needs three colors, but deleting one vertex from the trouble part makes $H[X_i]$ 2-colorable.

If the trouble part is covered by A of Proposition 4, which is all $M[X]$ and odd cycles of $\mathcal{O}$, we choose exactly one vertex from A , color it with 2, and color the rest of the vertices of X_i with $\{0, 1\}$. Otherwise, the trouble part has to be an odd cycle all of whose vertices have their M -neighbors in $H[Y]$. By Corollary 1(c), this odd cycle induces its twin cycle in $H_{XY}[Y]$. We pick one arbitrary vertex of the cycle for color 2, then color the rest with $\{0, 1\}$.

Step 2: Coloring of $H[Y]$. If a component $H[Y_i]$ is of Type I, color Y_i with $\{4, 5\}$.

Suppose that $H[Y_i]$ is of Type II or III. We want to choose one vertex from the trouble part for color 3, and color the rest with $\{4, 5\}$.

If the trouble part is covered by A , we choose exactly one vertex from A for color 3. Two vertices colored with 2 and 3 are not adjacent because both of them are in A , which is an independent set in G . A trouble part of the Type II and cycles of $\mathcal{O}$ will always be covered by A by Proposition 4. An odd cycle O that is not contained in $\mathcal{O}$ yields its twin cycle O' in $H[X]$ as in Corollary 1. We chose one vertex from $V(O')$ for color 2 in Step 1, and it has two neighbors in O . Since $|V(O)| \geq 3$, there is a vertex in $V(O)$ that is not adjacent to the vertex of color 2. That is the right vertex for color 3.

Step 3: Coloring of $H[Z]$. For a component $H[Z_i]$ of Type I, color Z_i with $\{8, 9\}$.

For a component $H[Z_i]$ of Type II or III, we pick an arbitrary vertex from the trouble part for color 7, and color the rest with $\{8, 9\}$.

Case 2. G is a Hamiltonian graph with maximum degree 3. Since G has a Hamiltonian cycle C , each vertex has degree either 2 or 3, and those of degree 2 miss their M -mates. Intuitively, there is less conflict than in the regular case since we have potentially fewer M -edges. In detail, if there are at least 2 vertices of degree 2, we modify the graph as follows. If two vertices of degree 2 are not adjacent in C , we throw in an edge between them. If they are adjacent in C , we duplicate the graph G and connect each of those two vertices to its own copy. Now, we may assume that there is exactly one vertex of degree 2. The fact that there is exactly one degree-2 vertex in G makes the graph “almost” regular; hence it is easier to relate the regular case. Let v be the unique vertex of degree 2 in G . We construct a bad graph H and an orientation D as in section 2.1. All the structure of D is still the same except that (i) v has no out-neighbor, (ii) v can occur as an isolated vertex in D when v does not have any in-neighbor, and (iii) one component of D containing v does not have a cycle. However, the types of H in Lemma 2 are still the same, and hence Theorem 2 is valid for a Hamiltonian graph with maximum degree 3. Observe that v is not a vertex of the trouble part. Hence it does not affect the structure of twin cycles in section 3 nor Proposition 4 in section 4 that are the keys for choosing vertices for colors 2 and 3 in trouble parts—the only nontrivial labeling in Theorem 2.

5.2. Vertex sets of size 1 (mod 3) or 2 (mod 3). In this section, we will construct $L(2, 1)$ -labelings for Hamiltonian graphs with maximum degree 3 of order 1 (mod 3) or 2 (mod 3). We add a few vertices and matching edges to a given graph G to obtain an “almost” supergraph $\widehat{G}$ whose vertex-set is of size 0 (mod 3). Then we give an $L(2, 1)$ -labeling to the supergraph according to the labeling in section 5.1 and rearrange the labeling for G .

The rearrangement will occur locally at the vertices at distance 1 or 2 from the added vertices. In particular, we will have cases depending on the color classes (in ρ) of the relevant M -neighbors. Hence having vertices of degree 2 near the added vertices reduces the number of cases that we have to consider. In the following proof, we will assume that all the vertices of G have M -mates, instead of always writing “if it exists” next to the color class of a possible M -neighbor being considered.

Let us start by reminding readers of the “freedom of the coloring of $H[Z]$ ” (FCZ) from Step 3 in section 5.1: For a component of $H[Z]$ of Type II or III, we choose a vertex to have the color 7 from the trouble part arbitrarily. Moreover, an $L(2, 1)$ -labeling of $H[Z]$ using $\{7, 8, 9\}$ is independent of the labeling on $X \cup Y$, since our $L(2, 1)$ -labeling of $G[X \cup Y]$ does not use color 6.

FIG. 14. $\widehat{G}$ on $V(G) \cup \{x, y\}$.

Proof of Theorem 1 for $1 \pmod{3}$. Let uv be a chord in a Hamiltonian cycle C of G . We define a related graph $\widehat{G}$ on a vertex-set of size $0 \pmod{3}$: Subdivide two edges of C that are incident to u , and make the two new vertices adjacent in $\widehat{G}$. (See Figure 14.) Now $\widehat{G}$ has a $L(2, 1)$ -labeling as in section 5.1, say $\widehat{f}$. We will put $\widehat{}$ on top of the names of sets or graphs precisely defined for graph of order divisible by 3 to denote the corresponding sets or graphs for $\widehat{G}$ such as $\widehat{M}, \widehat{X}, \widehat{H}$, etc. We will call the resulting subsets $\widehat{X}, \widehat{Y}, \widehat{Z}$ the *pre-color classes* of the vertices. By symmetry, we may assume that u belongs to $\widehat{Z}$ and that v is contained in $\widehat{Z} \cup \widehat{X}$. We name u, v and their nearby vertices so that x and y are vertices not in G . We also rename u as z and rename v as z_0 if $v \in \widehat{Z}$ and x_0 if $v \in \widehat{X}$ (see Figure 14). Name the vertices along the modified Hamiltonian cycle so that they are $z_1, x_1, y, z, x, y_1, z_2$ in order around z . We have named them so that $z_1, z, z_2 \in \widehat{Z}$, $x_1, x \in \widehat{X}$, and $y, y_1 \in \widehat{Y}$.

For $\widehat{f}$ to be an $L(2, 1)$ -labeling not only for $\widehat{G}$ but also restricted to an $L(2, 1)$ -labeling for G , we need to check the following conditions:

- (a) $|\widehat{f}(z) - \widehat{f}(x_1)| \geq 2$, $|\widehat{f}(z) - \widehat{f}(y_1)| \geq 2$,
- (b) $\widehat{f}(x_1) \neq \widehat{f}(y_1)$,
- (c) $\widehat{f}(z) \neq \widehat{f}(z_1)$, $\widehat{f}(z) \neq \widehat{f}(z_2)$, and
 $\widehat{f}(z) \neq \widehat{f}(z_3)$, $\widehat{f}(z) \neq \widehat{f}(z_4)$ if $x_1 z_3, y_1 z_4 \in M$,
- (d) $\widehat{f}(x_1) \neq \widehat{f}(x_0)$ when $v = x_0 \in X$.

Some of the conditions are guaranteed, and the others need a relabeling on some vertices. During the relabeling, new requirements can arise on $\widehat{f}$ at nearby vertices of the newly labeled vertices. We give an explicit relabeling f , according to the conditions (a)–(d) above, that satisfies all the requirements as follows.

- Conditions (a) and (b) are guaranteed by the precolor classes.
- Condition (c): We relabel z as $f(z) = 6$. This relabeling requires

- (1) $\widehat{f}(y_1) \neq 5$,
- (2) $\widehat{f}(z_0) \neq 7$ when $v = z_0 \in Z$.

For (2), FCZ allows us to assume that $\widehat{f}(z_0) = 9$ and $\widehat{f}(z) = 7$. For (1), suppose that $\widehat{f}(y_1) = 5$. Let $\widehat{Y}_j$ induce the component of $\widehat{H}[\widehat{Y}]$ containing y_1 , and let y' be the vertex of color 3 if $\widehat{H}[\widehat{Y}_j]$ is of Type II or Type III. If $\widehat{H}[\widehat{Y}_j]$ is a bipartite graph as Type I, or if y_1 belongs to a bipartite subgraph $\widehat{H}[\widehat{Y}_j - y']$ in case that $\widehat{H}[\widehat{Y}_j]$ is of Type III, we exchange the bipartition of $\widehat{H}[\widehat{Y}_j - y']$ to change the color on y_1 to 4.

Suppose that $\widehat{H}[\widehat{Y}_j]$ is of Type II. Let $y'y''$ be the M -edge in the component. In the subgraph $\widehat{H}[\widehat{Y}_j - y']$, we denote the component containing y'' by $T(y'')$. If y_1 belongs to components $\widehat{H}[\widehat{Y}_j - y'] \setminus T(y'')$, then we exchange the bipartition of $\widehat{H}[\widehat{Y}_j - y] \setminus T(y'')$ as before. If $y_1 \in V(T(y''))$, we cannot simply exchange the bipartition of $T(y'')$ because y'' must receive the color 5. Consider the component $\mathcal{T}$ of the auxiliary graph Q , as in the proof of Proposition 4, corresponding to the component in G_0 containing the edge $y'y''$. If $y'y''$ corresponds to an edge of a cycle in $\mathcal{T}$, we give a consistent orientation on the cycle so that $y'' \in A$. If $y'y''$ corresponds to an edge of a tree in $\mathcal{T}$, we flip the orientation along the longest path containing $y'y''$ so that $y'' \in A$. This would not uncover any odd cycle by A ; the possible odd cycle uncovered by A is the one that corresponds to a leaf of $\mathcal{T}$. Observe that this cycle is guaranteed to be covered by A , not by an orientation, as shown at the end of the proof of Proposition 4; we used an extra vertex from G_0 or an isolated vertex of the cycle, or its adjacent cycle in Q .

- Condition (d): Observe that (x_0, x, x_1) is a path in a component $\widehat{H}[\widehat{X}_i]$. If deleting x separates x_0 and x_1 in $\widehat{H}[\widehat{X}_i]$, we can choose colors freely on the vertices of $\widehat{H}[\widehat{X}_i - x]$ so that $f(x_1) \neq f(x_0)$. If deleting x does not separate x_0 and x_1 in $\widehat{H}[\widehat{X}_i - x]$, the path (x_0, x, x_1) is part of the cycle of $\widehat{H}[\widehat{X}_i]$. If it is an odd cycle, the path from x_0 to x_1 in $\widehat{H}[\widehat{X}_i - x]$ has odd length and guarantees that $\widehat{f}(x_1) \neq \widehat{f}(x_0)$. If it is an even cycle, all the vertices of $\widehat{X}_i$ receive colors from $\{0, 1\}$ under $\widehat{f}$. Hence we can relabel

$$f(x_1) = 2,$$

as long as

$$\widehat{f}(y_2) \neq 3 \quad \text{if } x_1 y_2 \in M \text{ for some } y_2 \in Y.$$

If $\widehat{f}(y_2) = 3$, then y_2 is a vertex of an odd cycle in $\widehat{G}$. Observe that (y_2, y, y_1) is a path in the cycle by the uniqueness of the out-neighbor in $\widehat{D}$. In G , this odd cycle is destroyed, and we can color the component left in G with only colors 4 and 5. $\square$

Proof of Theorem 1 for 2 (mod 3). We will relate $\widehat{G}$ and $\widehat{f}$ again. We consider two cases depending on whether G has a chord st that induces a cycle of length 1 (mod 3) with a path in C ending at s and t . Observe that the other path of C with endpoints s and t induces a cycle of length 0 (mod 3). Hence, if no chord induces a cycle of length 1 (mod 3), every chord induces cycles of length only 2 (mod 3) with both paths in C ending at the vertices of the chord.

Case 1. G has a chord that induces a cycle of length 1 (mod 3) with a path in C . Let st be the chord, and let u be the C -neighbor of s at the side of the cycle of 0 (mod 3). For $\widehat{G}$ and $\widehat{f}$, we name the vertices in a similar way as before, except that we subdivide the two new edges incident to u twice so that four new vertices and two new M -edges are introduced in a way that a pair of vertices closer to u forms one edge, and the other pair the other edge: x', y, x, y' are new vertices, $xy, x'y' \in E(\widehat{G})$. Note that s is z_1 or z_2 , so that one of z_1 and z_2 has its M -neighbor t in Z , say z_3 . We set $z_2 z_3 \in M$ and $z_1 w \in M$ (while we do not know the precolor class of w); see Figure 15. For $\widehat{f}$ to be an $L(2, 1)$ -labeling for G , we need to check on some vertices as in the case of 1 (mod 3). We give detailed relabeling f for the cases $v = z_0 \in Z$ and $v = x_0 \in X$ satisfying the requirements.

FIG. 15. $\widehat{G}$ on $V(G) \cup \{x, y, x', y'\}$.

Case $v = z_0 \in Z$. We need to check the following conditions:

- (a) $\widehat{f}(z) \neq \widehat{f}(x_1)$, $\widehat{f}(z) \neq \widehat{f}(y_1)$,
- (b) $|\widehat{f}(z) - \widehat{f}(z_1)| \geq 2$, $|\widehat{f}(z) - \widehat{f}(z_2)| \geq 2$,
- (c) $\widehat{f}(z) \neq \widehat{f}(z_3)$, $\widehat{f}(z) \neq \widehat{f}(w)$ if $w \in Z$,
- (d) all the colors of $\widehat{f}(z_0)$, $\widehat{f}(z_1)$, $\widehat{f}(z_2)$ are distinct.

A relabeling f goes as follows:

- Condition (a) is guaranteed by the precolor classes.
- Conditions (b) and (c): Assign

$$f(z) \in \{0, 1, 2, 3, 4, 5\} \setminus \{\widehat{f}(x_1), \widehat{f}(x_2), \widehat{f}(y_1), \widehat{f}(y_2), \widehat{f}(w)\}$$

to ensure that the color of u is distinct from the colors of the vertices at distance 2 in G . Also, the color $f(u)$ is two apart from the colors of its G -neighbors, z_0 , z_1 , and z_2 .

- Condition (d): Our aim is having all distinct colors for $f(z_0)$, $f(z_1)$, and $f(z_2)$ in $\{7, 8, 9\}$. Note that the edges zz_0 and z_2z_3 are in distinct components because both of them are trouble parts. Let $\widehat{Z}_i$ and $\widehat{Z}_j$ be the components containing zz_0 and z_2z_3 , respectively. If $z_1 \in \widehat{Z}_i$, a proper coloring of $\widehat{H}[\widehat{Z}_i - z]$ with $\{8, 9\}$ gives $f(z_0) \neq f(z_1)$ in $\{8, 9\}$. We can set $\widehat{f}(z_2) = 7$ by FCZ. Suppose that $z_1 \notin \widehat{Z}_i$. We may assume $\widehat{f}(z_1) \neq \widehat{f}(z_2)$ by FCZ, regardless of whether z_1 is in $\widehat{Z}_j$ or not. If $\{\widehat{f}(z_1), \widehat{f}(z_2)\} = \{8, 9\}$, we will assume $\widehat{f}(z_0) = 7$ on $\widehat{Z}_i$ by FCZ. If $\{\widehat{f}(z_1), \widehat{f}(z_2)\} \ni 7$, relabel on a bipartite graph $\widehat{H}[\widehat{Z}_i - z]$, if necessary, to obtain f in colors $\{8, 9\}$ such that $f(z_0) \in \{8, 9\} \setminus \{\widehat{f}(z_1), \widehat{f}(z_2)\}$.

Case $v = x_0 \in X$. We need to check the following conditions:

- (a) $\widehat{f}(z) \neq \widehat{f}(x_1)$, $\widehat{f}(z) \neq \widehat{f}(y_1)$,
- (b) $|\widehat{f}(z) - \widehat{f}(z_1)| \geq 2$, $|\widehat{f}(z) - \widehat{f}(z_2)| \geq 2$,
- (c) $\widehat{f}(z) \neq \widehat{f}(z_3)$, $\widehat{f}(z) \neq \widehat{f}(w)$ if $w \in Z$,
- (d) $\widehat{f}(z_1) \neq \widehat{f}(z_2)$.

A relabeling f is as follows:

- Condition (a) is guaranteed by the precolor classes.
- Conditions (b) and (c): If $w \in \widehat{X} \cup \widehat{Z}$, assign

$$f(u = z) \in \{3, 4, 5\} \setminus \{\widehat{f}(y_1), \widehat{f}(y_2)\}.$$

FIG. 16. $\widehat{G}$ on $V(G) \cup \{x, y, z', z''\}$.

Suppose that $w \in \widehat{Y}$. First, we observe that $x_0x \in E(\widehat{D})$ and xx' is a double edge in $\widehat{D}[\widehat{X}]$. Hence, the component of $\widehat{H}$ containing x_0 is of Type I, and we may assume that

$$\widehat{f}(x_0) = 0.$$

We want to relabel

$$f(z) = 2,$$

which requires

$$\widehat{f}(x_1) \neq 2.$$

If $\widehat{f}(x_1) = 2$, then x_1 is either in a twin cycle or a vertex of the trouble part of Type II or III that is chosen for $A \subset X'$ as in Proposition 4. If it is the former, we can freely choose another vertex of the cycle to receive color 2. Suppose the case is the latter. If more than one vertex of the trouble part is in X' , we can choose another vertex to be in A by flipping the orientation of the auxiliary graph Q in the proof of Proposition 4, if needed. (A similar iteration was done to Y in the case of $1 \pmod{3}$ for the condition (c).) Note that this takes care of Type II. Suppose that $O \in \mathcal{O}$ is the odd cycle containing x_1 , and x_1 is the only vertex of O in X' . We will find a vertex of O that has an M -neighbor in Y , yet is not adjacent to a vertex colored 3, so that it can receive color 2. Let (x_3, x_2, x_1) be a path in O and $\widehat{D}[\widehat{X}]$, and let $y'_2, y'_1 \in Y$ be the C -neighbors of x_2, x_1 , respectively. The edge $x_1y'_1$ is an isolated edge in G_0 by Lemma 4(a), and furthermore, $x_3y'_2, x_2y'_1 \in M$. Observe that $\widehat{f}(y'_1) \neq 3$ because $\widehat{f}(x_1) = 2$, and that $\widehat{f}(y'_2) \neq 3$ because $y_2 \notin Y_{X'} \cup Y'$. The vertex x_2 , whose neighbors in Y are y'_1 and y'_2 , is the desired one.

Case 2. Every chord of G induces cycles of length $2 \pmod{3}$ with a path in C . We relate, again, $\widehat{G}$ and $\widehat{f}$, and name the vertices in a similar way as before except that we subdivide four consecutive edges of C near u , and make the first two new vertices adjacent and the last two vertices adjacent in $\widehat{G}$: The vertices along $\widehat{C}$ are $x_1, y_3, z', x_2, y, z, x, y_1, z'', x_3, y_2$ in order around z , where $u = z$ as before, y, z', x, z'' are new vertices, $z'y, xz'' \in E(\widehat{G})$. (See Figure 16.)

The assumption that every chord of G induces cycles of length $2 \pmod{3}$ determines the precolor class of the M -neighbor of each vertex. The vertex v always belongs to Z so that $v = z_0$, and no other vertex has its M -neighbor in its own

precolor class. Hence there is no component of Type II in $\widehat{H}$, except for the one containing zz_0 . Having no M -edge in $\widehat{H}[\widehat{X}] \cup \widehat{H}[\widehat{Y}]$ gives us a convenient property that is a similar but weaker version of FCZ, namely “weak freedom of the coloring of $H[X]$ or $H[Y]$ ” (WFCX or WFCY, respectively): We can freely exchange colors 0 and 1, or 4 and 5, respectively.

We consider cases depending on whether there is an M -edge in $G[x_1, y_3, x_2, z, y_1, z, x_3, y_2]$. Observe that the possible M -edges are $x_i y_i$ for $i = 1, 2, 3$.

Case of no M -edge in $G[x_1, y_3, x_2, z, y_1, x_3, y_2]$. We know the precolor classes of the M -neighbors of $x_1, x_2, x_3, y_1, y_2, y_3$. Set $x_1 z_3, x_2 y_4, x_3 y_5, y_1 x_4, y_2 z_4, y_3 x_5 \in M$. (See Figure 16(a).) We need to check the following conditions:

- (a) $|\widehat{f}(x_2) - \widehat{f}(y_3)| \geq 2$,
- (b) $\widehat{f}(x_2) \neq \widehat{f}(x_1), \widehat{f}(x_2) \neq \widehat{f}(x_5)$,
- (c) $\widehat{f}(y_3) \neq \widehat{f}(y_4)$,
- (d) $|\widehat{f}(y_1) - \widehat{f}(x_3)| \geq 2$,
- (e) $\widehat{f}(y_1) \neq \widehat{f}(y_2), \widehat{f}(y_1) \neq \widehat{f}(y_5)$,
- (f) $\widehat{f}(x_3) \neq \widehat{f}(x_4)$.

A relabeling f goes as follows:

- Conditions (a)–(c): Recolor

$$f(y_3) = 6, \quad f(x_2) = 3.$$

This requires

$$\widehat{f}(y_4) = 5.$$

If $\widehat{f}(y_4) = 4$, then we can exchange colors 4 and 5 by WFCY. For the case $\widehat{f}(y_4) = 3$, observe that (y_4, y, y_3) is a path in $\widehat{D}[\widehat{Y}]$. The labeling $\widehat{f}(y_4) = 3$ implies that y_4 is a vertex of an odd cycle in $\widehat{D}[\widehat{Y}]$, and so are y and y_3 by the uniqueness of out-neighbors. Since $y \notin V(G)$, this odd cycle is destroyed in H , and we can color the component left in G with $\{4, 5\}$ so that $f(y_4) = 5$.

- Conditions (d)–(f): We will recolor y_1 and x_3 depending on $\widehat{f}(y_2)$ and $\widehat{f}(y_5)$.

To begin with, note that $y_5 y_2 \in E(\widehat{D})$, and hence $\widehat{f}(y_2) \neq \widehat{f}(y_5)$.

If $\{\widehat{f}(y_2), \widehat{f}(y_5)\} = \{4, 5\}$, recolor

$$f(x_3) \in \{0, 1, 2\} \setminus \{\widehat{f}(x_4), \widehat{f}(x_6)\}, \quad f(y_1) = 6,$$

where x_6 is the C -neighbor of y_5 . This requires

$$\widehat{f}(z) \neq 7.$$

By FCZ, we may assume that $\widehat{f}(z) = 9, \widehat{f}(z_0) = 7$.

If $\{\widehat{f}(y_2), \widehat{f}(y_5)\} \ni 3$, we may assume that $\{\widehat{f}(y_2), \widehat{f}(y_5)\} = \{3, 4\}$ by WFCY.

Recolor

$$f(x_3) = 6, \quad f(y_1) = 2.$$

This requires

$$\widehat{f}(x_4) = 0.$$

If $\widehat{f}(x_4) = 1$, then we can exchange colors 0 and 1 by WFCX. If $\widehat{f}(x_4) = 2$, then x_4 is a vertex of an odd cycle, and the path (x_4, x, x_3) in $\widehat{D}[\widehat{X}]$ is a part of the cycle. With an argument along the line of the case $\widehat{f}(y_4) = 3$ above, we may assume $f(x_4) \in \{0, 1\}$ so that $f(x_4) = 0$.

It is worth mentioning that the previous assumption that none of the possible M -edges $x_i y_i$, $1 \leq i \leq 3$, occurs is critical; two vertices of color 6 under f can be at distance 1 or 2. If there are seven consecutive vertices along C without induced M -edges, it falls into the previous case. Now, assume that we cannot find seven such vertices.

Case that $G[x_1, y_3, x_2, z, y_1, x_3, y_2]$ has an M -edge. If $x_i y_i \in M$ for all $i = 1, 2, 3$, (see Figure 16(b)), then we assign

$$(3) \quad \text{to } x_1, y_3, x_2, y_1, x_3, y_2 \quad \text{colors } 2, 4, 0, 5, 1, 3 \quad \text{in order under } f.$$

Note that $z_0 = z_1 = z_2$ can occur, in which case we can set $f(z) = 7$ and $f(z_0) = 6$.

If exactly one of $x_i y_i$ is missing, say $x_j y_j$, then recolor

$$f(x_j) = f(y_j) = 6,$$

while keeping the other colors in (3) the same. However, in case $x_3 y_3 \notin M$, we recolor $f(y_1) = 4$ to have $|f(y_1) - f(x_3)| \geq 2$.

If there is exactly one M -edge, we may assume $x_3 y_3 \in M$: Suppose that we have seven consecutive vertices along C , say $u_1, u_2, \dots, u_7$, that induce one M -edge. We want that $u_2 u_6 \in M$. If either $u_1 u_5 \in M$ or $u_3 u_7 \in M$, say $u_3 u_7 \in M$, consider shifted seven vertices $u_2, u_3, \dots, u_8$, where u_8 is the vertex next to u_7 in C . If u_8 does not introduce an M -edge with any of $u_2, u_3, \dots, u_7$, then $u_2, u_3, \dots, u_8$ are the desired ones. If u_8 does, then it is u_4 , and $G[u_2, u_3, \dots, u_8]$ has exactly two M -edges, $u_3 u_7$ and $u_4 u_8$. We were in this situation before.

As before, the precolor classes of M -neighbors are determined. Set $x_1 z_3, x_2 y_4, y_1 x_4, y_2 z_4, z_1 y_5, z_2 x_5 \in M$, where z_1, z_2 are the C -neighbors of x_1, y_2 , respectively. (See Figure 16(c).) We need to check the following:

- (a) $|\widehat{f}(x_2) - \widehat{f}(y_3)| \geq 2$,
- (b) $\widehat{f}(x_2) \neq \widehat{f}(x_1), \widehat{f}(x_2) \neq \widehat{f}(x_3)$,
- (c) $|\widehat{f}(y_1) - \widehat{f}(x_3)| \geq 2$,
- (d) $\widehat{f}(y_1) \neq \widehat{f}(y_2), \widehat{f}(y_1) \neq \widehat{f}(y_3)$.

Observe that (x_4, x, x_3, x_1) is a path in $\widehat{D}[\widehat{X}]$, and that the in-degrees of x, x_3 and x_1 in $\widehat{D}$ are 1. Hence, if one of those vertices is in a cycle, then the path is also in the cycle, by the uniqueness of the in-neighbor and also by the uniqueness of the out-neighbor in general. Since $y \notin Y$, we can assume that

$$(4) \quad \widehat{f}(x_1), \widehat{f}(x_3), \widehat{f}(x_4) \in \{0, 1\}.$$

Applying the same argument to (y_4, y, y_3, y_2) in $\widehat{D}[\widehat{Y}]$, we assume that

$$(5) \quad \widehat{f}(y_2), \widehat{f}(y_3), \widehat{f}(y_4) \in \{4, 5\}.$$

For the conditions (c) and (d), recolor

$$f(y_1) = 6.$$

Moreover, this recoloring and the assumptions (4) and (5) enable us to use color 2 freely on x_2 or x_3 , as long as x_2 receives a different color from the C -neighbor of y_4 , say x_6 . We recolor x_2 or x_3 depending on $\widehat{f}(x_6)$:

$$f(x_2) = 2 \quad \text{if } \widehat{f}(x_6) \in \{0, 1\}$$

or

$$f(x_3) = 2 \quad \text{and} \quad f(x_2) \in \{0, 1\} \setminus \widehat{f}(x_1) \quad \text{if } \widehat{f}(x_6) = 2. \quad \square$$

Remarks. Arguments of sections 2, 3, 4, and 5.1 can easily be extended to the case that a 3-regular graph G has a 2-factor, each cycle of which is $0 \pmod{3}$: We can color each cycle with only 0, 3, 7, as in the Hamiltonian case. Then, we have the same bad graph H and the same subgraph of G between color classes. This does not work when the 2-factor has cycles of length $1 \pmod{3}$ or $2 \pmod{3}$ because such cycles cannot be labeled with only 0, 3, 7. Our $L(2, 1)$ -labeling in section 5.1 depends only on H and its interaction with G .

The author, with Douglas West, is currently working on extending the result in this paper to 3-regular graphs. As a by-product of this work, an explicit structure of $\mathcal{O}$ in $H[Y]$ in section 4 has been found.

Acknowledgments. This work was done as a part of the author's Ph.D thesis at the University of Illinois at Urbana-Champaign. She thanks Professor D. West for fruitful conversations and his help with improving the manuscript. She also thanks the referees for helpful comments and updated progress toward the problem.

3-FACIAL COLORING OF PLANE GRAPHS*

FRÉDÉRIC HAVET[†], JEAN-SÉBASTIEN SERENI[‡], AND RISTE ŠKREKOVSKI[§]

Abstract. A plane graph is ℓ -facially k -colorable if its vertices can be colored with k colors such that any two distinct vertices on a facial segment of length at most ℓ are colored differently. We prove that every plane graph is 3-facially 11-colorable. As a consequence, we derive that every 2-connected plane graph with maximum face-size at most 7 is cyclically 11-colorable. These two bounds are just one higher than those that are proposed by the $(3\ell + 1)$ -conjecture and the cyclic conjecture.

Key words. facial coloring, cyclic coloring, plane graph

AMS subject classification. 05C15

DOI. 10.1137/060664124

1. Introduction. The concept of facial colorings, introduced by Král', Madaras, and Škrekovski [11, 12], extends the well-known concept of cyclic colorings. A *facial segment* of a plane graph G is a sequence of vertices in the order obtained when traversing a part of the boundary of a face. The *length* of a facial segment is the number of its edges. Two vertices u and v of G are ℓ -*facially adjacent* if there exists a facial segment of length at most ℓ between them. An ℓ -*facial coloring* of G is a function which assigns a color to each vertex of G such that any two distinct ℓ -facially adjacent vertices are assigned with distinct colors. Notice that a vertex of G that is ℓ -facially adjacent to itself does not prevent G from being colored. A graph admitting an ℓ -facial coloring with k colors is called ℓ -*facially k -colorable*.

The following conjecture is called the $(3\ell + 1)$ -conjecture [11].

CONJECTURE 1 (see Král', Madaras, and Škrekovski). *Every plane graph is ℓ -facially colorable with $3\ell + 1$ colors.*

Observe that the bound offered by Conjecture 1 is tight: as shown by Figure 1, for every $\ell \geq 1$, there exists a plane graph that is not ℓ -facially 3ℓ -colorable.

Conjecture 1 can be considered as a counterpart for ℓ -facial coloring of the following famous conjecture by Ore and Plummer [13] concerning the cyclic coloring. A plane graph G is *cyclically k -colorable* if it admits a vertex coloring with k colors such that any two vertices incident to the same face are assigned distinct colors.

CONJECTURE 2 (see Ore and Plummer). *Every plane graph is cyclically $\lfloor \frac{3\Delta^*}{2} \rfloor$ -colorable, where Δ^* is the size of the largest face of G .*

Note that Conjecture 1 implies Conjecture 2 for odd values of Δ^* . The best known result towards Conjecture 2 has been obtained by Sanders and Zhao [16], who

FIG. 1. The plane graph $G_\ell = (V, E)$: each thread represents a path of length ℓ . The graph G_ℓ is not ℓ -facially 3ℓ -colorable: any two vertices are ℓ -facially adjacent, and therefore any ℓ -facial coloring must use $|V| = 3\ell + 1$ colors.

proved the bound $\lceil \frac{5\Delta^*}{3} \rceil$.

Define $f_c(x)$ to be the minimum number of colors needed to cyclically color every plane graph of maximum face size x . The value of $f_c(x)$ is known for $x \in \{3, 4\}$: $f_c(3) = 4$ (the problem of finding $f_c(3)$ being equivalent to the four color theorem proved by Appel and Haken [1]) and $f_c(4) = 6$ (see [3, 5]). It is also known that $f_c(5) \in \{7, 8\}$ and $f_c(6) \leq 10$ [6], and that $f_c(7) \leq 12$ [4].

Conjecture 1 is trivially true for $\ell = 0$, and is equivalent to the four color theorem for $\ell = 1$. It is open for all other values of ℓ . As noted by Král', Madaras, and Škrekovski [11], if Conjecture 1 were true for $\ell = 2$, it would have several interesting corollaries. Besides giving the exact value of $f_c(5)$ (which would then be 7), it would allow the upper bound on the number of colors needed to 1-diagonally color every plane quadrangulation to decrease from 16 to 14 (by applying a method from [11]). (For more details on this problem, consult [9, 14, 15, 11].) It would also imply Wegner's conjecture on 2-distance colorings (i.e., colorings of squares of graphs) restricted to plane cubic graphs since colorings of the square of a plane cubic graph are precisely its 2-facial colorings (refer to the book by Jensen and Toft [10, Problem 2.18] for more details on Wegner's conjecture).

Let $f_f(\ell)$ be the minimum number of colors needed to ℓ -facially color every plane graph. Note that $f_c(2\ell + 1) \leq f_f(\ell)$. So far, no value of ℓ is known for which this inequality is strict. The following problem is offered by [11].

PROBLEM 1. *Is it true that, for every integer $\ell \geq 1$, $f_c(2\ell + 1) = f_f(\ell)$?*

Another conjecture that should maybe be mentioned is the so-called 3ℓ -conjecture proposed by Dvořák, Škrekovski, and Tancer [7], stating that every plane triangle-free graph is ℓ -facially 3ℓ -colorable. As for the $(3\ell + 1)$ -conjecture, if this conjecture were true, then its bound would be tight and it would have several interesting corollaries (see [7] for more details).

Král', Madaras, and Škrekovski [11] proved that every plane graph has an ℓ -facial coloring using at most $\lfloor \frac{18}{5}\ell \rfloor + 2 \lfloor \frac{18}{5}\ell \rfloor + 2$ colors (and this bound is decreased by 1 for $\ell \in \{2, 4\}$). So, in particular, every plane graph has a 3-facial 12-coloring. In this paper, we improve this last result by proving the following theorem.

THEOREM 1. *Every plane graph is 3-facially 11-colorable.*

To prove this result, we suppose that it is false. In section 2, we exhibit some properties of a minimal graph (regarding the number of vertices) that contradict Theorem 1. Relying on these properties, we use the discharging method in section 3 to obtain a contradiction.

2. Properties of (3,11)-minimal graphs. Let us start this section by introducing some definitions. A vertex of degree d (at least d , at most d) is said to be a d -vertex (a $(\geq d)$ -vertex, a $(\leq d)$ -vertex, respectively). The notion of a d -face (a

($\leq d$)-face, a ($\geq d$)-face, respectively) is defined analogously regarding the size of a face. An ℓ -path is a path of length ℓ .

Two faces are *adjacent*, or *neighboring*, if they share a common edge. A 5-face is *bad* if it is incident to at least four 3-vertices. It is said to be *very bad* if it is incident to five 3-vertices.

If u and v are 3-facially adjacent, then u is a 3-facial neighbor of v . The set of all 3-facial neighbors of v is $\mathcal{N}_3(v)$. The 3-facial degree of v is $\deg_3(v) = |\mathcal{N}_3(v)|$. A vertex is *dangerous* if it has degree three and is incident to a face of size three or four. A 3-vertex is *safe* if it is not dangerous, i.e., is not incident to a (≤ 4)-face.

Let $G = (V, E)$ be a plane graph, and $\mathcal{U} \subseteq V$. Let $G_3[\mathcal{U}]$ be the graph with vertex set $\mathcal{U}$ such that xy is an edge in $G_3[\mathcal{U}]$ if and only if x and y are 3-facially adjacent vertices in G . If c is a partial coloring of G and u an uncolored vertex of G , we let $L_c(u)$ (or just $L(u)$) be the set $\{x \in \{1, 2, \dots, 11\} : \text{for all } v \in \mathcal{N}_3(u), c(v) \neq x\}$. The graph $G_3[\mathcal{U}]$ is *L-colorable* if there exists a proper vertex coloring of the vertices of $G_3[\mathcal{U}]$ such that for every $u \in \mathcal{U}$ we have $c(u) \in L(u)$.

The next two results are used by Král', Madaras, and Škrekovski [11].

LEMMA 1. *Let v be a vertex whose incident faces in a 2-connected plane graph G are $f_1, f_2, \dots, f_d$. Then*

$$\deg_3(v) \leq \left(\sum_{i=1}^d \min(|f_i|, 7) \right) - 2d,$$

where $|f_i|$ is the size of the face f_i .

Suppose that Theorem 1 is false: a $(3, 11)$ -minimal graph G is a plane graph that is not 3-facially 11-colorable, with $|V(G)| + |E(G)|$ as small as possible.

LEMMA 2. *Let G be a $(3, 11)$ -minimal graph. Then the following hold:*

1. G is 2-connected.
2. G has no separating cycle of length at most 7.
3. G contains no adjacent f_1 -face and f_2 -face with $f_1 + f_2 \leq 9$.
4. G has no vertex whose 3-facial degree is less than 11. In particular, the minimum degree of G is at least three.
5. G contains no edge uv separating two (≥ 4)-faces with $\deg_3(u) \leq 11$ and $\deg_3(v) \leq 12$. In particular, if two adjacent dangerous vertices do not lie on a same (≤ 4)-face, then none of them is incident to a 3-face.

In the remainder of this section, we give additional local structural properties of $(3, 11)$ -minimal graphs.

LEMMA 3. *Let G be a $(3, 11)$ -minimal graph. Suppose that v and w are two adjacent 3-vertices of G , both incident to a same 5-face and a same 6-face. Then the size of the third face incident to w is at least 7.*

Proof. By contradiction, suppose that the size of the last face incident to w is at most 6. Then, according to Lemma 1, we infer that $\deg_3(v) \leq 12$ and $\deg_3(w) \leq 11$, but this contradicts Lemma 2(v). $\square$

A *reducible configuration* is a (plane) graph that cannot be an induced subgraph of a $(3, 11)$ -minimal graph. The usual method to prove that a configuration is reducible is the following: first, we suppose that a $(3, 11)$ -minimal graph G contains a prescribed induced subgraph H . Then we contract some subgraphs $H_1, H_2, \dots, H_k$ of H . In most of the cases, $k \leq 2$. This yields a proper minor G' of G , which by the minimality of G admits a 3-facial 11-coloring c' . The goal is to derive from c' a 3-facial 11-coloring c of G , which would give a contradiction. To do so, each noncontracted vertex v of G keeps its color $c'(v)$. Let h_i be the vertex of G' created by the contraction of the

vertices of H_i : some vertices of H_i are assigned the color $c'(h_i)$ (in doing so, we must take care that these vertices are not 3-facially adjacent in G). Last, we show that the remaining uncolored vertices can also be colored.

In other words, we show that the graph $G_3[\mathcal{U}]$ is L -colorable, where for each $u \in \mathcal{U}$, $L(u)$ is the list of the colors that are assigned to no vertex in $\mathcal{N}_3(u) \setminus \mathcal{U}$ (defined in section 1) and $\mathcal{U}$ is the set of uncolored vertices. In most of the cases, the vertices of $\mathcal{U}$ will be greedily colored.

In all figures of the paper, the following conventions are used: a triangle represents a 3-vertex, a square represents a 4-vertex, and a circle may be any kind of vertex whose degree is at least the maximum between three and the one it has in the figure. The edges of each subgraph H_i are drawn in bold, and the circled vertices are the vertices of $\mathcal{U} = \{u_1, u_2, \dots\}$. A dashed edge between two vertices indicates a path of length at least one between those two vertices. An (in)equality written in a bounded region indicates a face whose size achieves the (in)equality. Last, vertices that are assigned the color $c'(h_i)$ are v, w , and t if a unique subgraph is contracted or x_1, x_2 for $i = 1$ and y_1, y_2 for $i = 2$ if two subgraphs are contracted.

Note that the graph G' may contain loops and parallel edges. One way to consider them is as follows. If there is a face of size at most two, then we can just remove the loop, or one of the parallel edges. Otherwise, there is a separating cycle C of length at most two, and we can first color the subgraph of G' induced by C and the vertices inside C , and then the subgraph of G' induced by C and the vertices outside C .

LEMMA 4. *Configurations in Figures 2, 3, and 4 are reducible.*

Proof. Let H be an induced subgraph of G . We suppose that H is isomorphic to one of the configurations stated and derive a way to construct a 3-facial 11-coloring of G , a contradiction.

L1. Suppose that H is isomorphic to the configuration (L1) of Figure 2. The edge u_2u_3 cannot be incident to a 3-face, since otherwise the edge u_2u_5 would contradict Lemma 2.5. More precisely, it would be incident to two (≥ 7)-faces by Lemma 2.3, and the 3-facial degree of u_2 and u_5 would be at most 11. Let H_1 be the subgraph induced by the bold edges. Contract the vertices of H_1 , thereby creating a new vertex h_1 . By minimality of G , let c' be a 3-facial 11-coloring of the obtained graph. Assign to each vertex x not in H_1 the color $c'(x)$, and to each of v, w, t the color $c'(h_1)$. Observe that, since the edge u_2u_3 does not lie on a 3-face, no two vertices among v, w, t are 3-facially adjacent in G ; otherwise there would be a (≤ 7)-separating cycle in G , thereby contradicting Lemma 2.2. According to Lemma 1, $\deg_3(u_1) \leq 15$, $\deg_3(u_i) \leq 14$ if $i \in \{2, 3\}$, and $\deg_3(u_i) \leq 11$ if $i \in \{4, 5\}$. Note that any two vertices of $\mathcal{U} = \{u_1, u_2, \dots, u_5\}$ are 3-facially adjacent; that is, $G_3[\mathcal{U}] \simeq K_5$. Hence, the number of colored 3-facial neighbors of u_1 is at most 11; i.e., $|\mathcal{N}_3(u_1) \setminus \{u_2, u_3, u_4, u_5\}| \leq 11$. Moreover, at least two of them are assigned the same color, namely v and w . Therefore, $|L(u_1)| \geq 1$. For $i \in \{2, 3\}$, the vertex u_i has at most 10 colored 3-facial neighbors. Furthermore, at least two 3-facial neighbors of u_2 are identically colored, namely w and t . Thus, $|L(u_2)| \geq 2$. Now, observe that at least three 3-facial neighbors of u_3 are colored the same, namely v, w , and t . Hence, $|L(u_3)| \geq 3$. For $i \in \{4, 5\}$, the vertex u_i has at most 7 colored 3-facial neighbors. Thus, $|L(u_4)| \geq 4$, and because at least two 3-facial neighbors of u_5 are identically colored (w and t), $|L(u_5)| \geq 5$. So, the graph $G_3[\mathcal{U}]$ is greedily L -colorable, according to the ordering u_1, u_2, u_3, u_4, u_5 . This allows us to extend c to a 3-facial 11-coloring of G .

L2. Suppose that H is isomorphic to the configuration (L2) of Figure 2. Assume first that the edge u_2u_3 is not incident to a 3-face. Let c' be a 3-facial 11-coloring

(L1)

(L2)

(L3)

(L4)

FIG. 2. Reducible configurations (L1)–(L8).

FIG. 3. Reducible configurations (L9)–(L15).

of the minor of G obtained by contracting the bold edges into a single vertex h_1 . Let $c(x) = c'(x)$ for every vertex $x \neq h_1$. Define $c(v) = c(w) = c(t) = c'(h_1)$. The obtained coloring is still 3-facial since no two vertices among v, w, t are 3-facially adjacent in G by Lemma 2.2, and because of our assumption. Note that $G_3[\mathcal{U}] \simeq K_5$. In particular, each vertex u_i has four uncolored 3-facial neighbors. By Lemma 1, $\deg_3(u_1) \leq 15$, $\deg_3(u_i) \leq 14$ if $i \in \{2, 3\}$, and $\deg_3(u_i) \leq 11$ if $i \in \{4, 5\}$. Moreover, each of u_1 and u_2 has at least two 3-facial neighbors colored the same; for u_1 , these vertices are w, t , and for u_2 they are w, v . So, there exists at least one color which is assigned to no vertex of $\mathcal{N}_3(u_1)$ and at least two colors assigned to no vertex of $\mathcal{N}_3(u_2)$. Also, u_3 has at least three 3-facial neighbors colored the same, namely w ,

FIG. 4. Reducible configurations (L16)–(L23).

v , and t ; hence at least three colors are assigned to no vertex of $\mathcal{N}_3(u_3)$. Therefore, $|L(u_1)| \geq 1$, $|L(u_2)| \geq 2$, and $|L(u_3)| \geq 3$. Furthermore, $|L(u_4)| \geq 4$ and $|L(u_5)| \geq 5$ because w and t are both 3-facial neighbors of u_5 . So $G_3[\mathcal{U}]$ is L -colorable, and hence G is 3-facially 11-colorable.

If the edge u_2u_3 is incident to a 3-face, then the same proof works, except that at the beginning the edge u_2v is not contracted. Thus, only the vertices w and t have the same color, but the partial coloring extends as previously to G since u_2 and u_3 both have now 3-facial degree 11.

L3. Suppose that H is isomorphic to the configuration (L3) of Figure 2. Contract the bold edges into a new vertex h_1 , and let c' be a 3-facial 11-coloring of the obtained graph. This coloring can be extended to a 3-facial 11-coloring c of G as follows: first, let $c(v) = c(w) = c(t) = c'(h_1)$. Note that no two of these vertices can be 3-facially adjacent in G without contradicting Lemma 2.2. By Lemma 1, $\deg_3(u_1) \leq 14$, $\deg_3(u_2) \leq 13$ and for $i \in \{3, 4\}$, and $\deg_3(u_i) \leq 12$. Observe that $G_3[\mathcal{U}] \simeq K_4$. Moreover, each of u_1, u_2, u_3 has a set of two 3-facial neighbors colored by $c'(h_1)$. These sets are $\{w, t\}$, $\{w, v\}$, and $\{v, t\}$ for u_1, u_2 , and u_3 , respectively. Thus, $|L(u_1)| \geq 1$, $|L(u_2)| \geq 2$, and $|L(u_3)| \geq 3$. Also $|L(u_4)| \geq 4$ because u_4 has at least three identically colored 3-facial neighbors, namely v, w , and t . Hence, $G_3[\mathcal{U}]$ is L -colorable, and so G is 3-facially 11-colorable.

L4. First, observe that if $v \in \mathcal{N}_3(t)$, then $v' \notin \mathcal{N}_3(t')$, since G is a plane graph. So, by symmetry, we may assume that v and t are not 3-facially adjacent in G . Now, contract the bold edges into a new vertex h_1 . Again, let c' be a 3-facial 11-coloring of the obtained graph, and define c to be equal to c' on all vertices of $V(G) \setminus \{v, w, t, u_1, u_2, u_3, u_4\}$. Let $c(v) = c(w) = c(t) = c'(h_1)$. Note that the partial coloring c is still 3-facial due to the above assumption. The graph $G_3[\mathcal{U}]$ is isomorphic to K_4 , and according to Lemma 1, $\deg_3(u_i) \leq 12$ for all $i \in \{1, 2, 3, 4\}$. Moreover, for $i \in \{2, 3\}$, the vertex u_i has at least two 3-facial neighbors that are colored the same, namely, v and w . Last, the vertex u_4 has at least three such 3-facial neighbors, namely v, w, t . Therefore, $|L(u_1)| \geq 2$, $|L(u_i)| \geq 3$ for $i \in \{2, 3\}$, and $|L(u_4)| \geq 4$. So, $G_3[\mathcal{U}]$ is L -colorable, and hence G is 3-facially 11-colorable.

L5. The same remark as in the previous configuration allows us to assume that $t \notin \mathcal{N}_3(v)$. Again, the graph obtained by contracting the bold edges into a new vertex h_1 admits a 3-facial 11-coloring c' . As before, define a 3-facial 11-coloring c of the graph induced by $V(G) \setminus \mathcal{U}$. Then, for every $i \in \{1, 2, 3, 4\}$, $\deg_3(u_i) \leq 12$ and $G_3[\mathcal{U}] \simeq K_4$. Thus, $|L(u_1)| \geq 2$ and $|L(u_2)| \geq 2$. Note that u_3 has at least two identically colored 3-facial neighbors, namely v and w , so $|L(u_3)| \geq 3$. Last, the vertex u_4 has at least three such neighbors, hence $|L(u_4)| \geq 4$. Therefore, the graph $G_3[\mathcal{U}]$ is L -colorable, and so the graph G admits a 3-facial 11-coloring.

L6. Let H_1 be the path $x_1u_3u_5x_2$, H_2 the path $y_1u_2u_4u_1y_2$, and c' a 3-facial coloring of the graph obtained from G by contracting each path H_i into a vertex h_i . Notice that $c'(h_1) \neq c'(h_2)$. For every $v \notin V(H_1) \cup V(H_2)$, let $c(v) = c'(v)$. Observe that x_1 and x_2 cannot be 3-facially adjacent in G , otherwise G would have a separating (≤ 7)-cycle, contradicting Lemma 2.2. Note that the same holds for y_1 and y_2 ; therefore defining $c(x_1) = c(x_2) = c'(h_1)$ and $c(y_1) = c(y_2) = c'(h_2)$ yields a partial 3-facial 11-coloring of G , since $c'(h_1) \neq c'(h_2)$. It remains to color the vertices of $\mathcal{U} = \{u_1, u_2, \dots, u_5\}$. Note that $G_3[\mathcal{U}] \simeq K_5$. According to Lemma 2.2, $\deg_3(u_1) \leq 15$ and $\deg_3(u_i) \leq 12$ if $i \geq 2$. The number of colored 3-facial neighbors of u_1 , i.e., its number of 3-facial neighbors in $V(G) \setminus \{u_2, u_3, u_4, u_5\}$, is at most 11 because each u_i with $i \geq 2$ is a 3-facial neighbor of u_1 . Furthermore, u_1 has two 3-facial neighbors colored with the same color, namely x_1 and x_2 . Hence, $|L(u_1)| \geq 1$. The vertex u_2 has four uncolored 3-facial neighbors, so $|L(u_2)| \geq 3$. For $i \in \{3, 4\}$, the vertex u_i has at least two 3-facial neighbors colored the same, namely x_1, x_2 for u_3 , and y_1, y_2 for u_4 , so $|L(u_i)| \geq 4$. Finally, observe that u_5 has two pairs of identically colored 3-facial neighbors; the first pair being x_1, x_2 and the second y_1, y_2 . Thus, $|L(u_5)| \geq 5$, and hence the graph $G_3[\mathcal{U}]$ is L -colorable, which yields a contradiction.

L7. We contract the bold edges into a new vertex h_1 , take a 3-facial 11-coloring of the graph obtained, and define a 3-facial 11-coloring c of $V(G) \setminus \mathcal{U}$ as usual. By

Lemma 1, $\deg_3(u_i) \leq 15$ if $i \in \{1, 2\}$, $\deg_3(u_i) \leq 12$ if $i \in \{3, 4, 5\}$, and $\deg_3(u_6) \leq 11$. Moreover, $G_3[\mathcal{U}] \simeq K_6$. As v, w , and t are colored the same, and $\{v, w\} \subset \mathcal{N}_3(u_2)$, $\{w, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{4, 5\}$, and $\{v, t\} \subset \mathcal{N}_3(u_6)$, we obtain $|L(u_i)| \geq i$ for every $i \in \{1, 2, 3, 4, 5, 6\}$. Thus, the graph $G_3[\mathcal{U}]$ is L -colorable, and hence G admits a 3-facial 11-coloring.

L8. We contract the bold edges into a new vertex, take a 3-facial 11-coloring of the graph obtained, and define a 3-facial 11-coloring of $V(G) \setminus \mathcal{U}$ as usual. Then, $G_3[\mathcal{U}] \simeq K_2$. Moreover, $\deg_3(u_1) \leq 12$ and $\deg_3(u_2) \leq 11$. Furthermore, $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 2\}$. Thus, we infer $|L(u_i)| \geq i$ for $i \in \{1, 2\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L9. We contract the bold edges into a new vertex, take a 3-facial 11-coloring of the graph obtained, and define a 3-facial 11-coloring of $V(G) \setminus \mathcal{U}$ as usual. Then, $G_3[\mathcal{U}] \simeq K_4$. Moreover, $\deg_3(u_1) \leq 13$, $\deg_3(u_2) \leq 12$, and $\deg_3(u_i) \leq 11$ for $i \in \{3, 4\}$. Furthermore, $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 4\}$. Thus, we infer $|L(u_i)| \geq 2$ for $i \in \{1, 2\}$, and $|L(u_i)| \geq i$ for $i \in \{3, 4\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L10. We contract the bold edges into a new vertex h_1 , take a 3-facial 11-coloring of the graph obtained, and define a 3-facial 11-coloring c of $V(G) \setminus \mathcal{U}$ as usual. By Lemma 1, $\deg_3(u_1) \leq 15$ and $\deg_3(u_i) \leq 11$ if $i \in \{2, 3, 4, 5\}$. Moreover, $G_3[\mathcal{U}] \simeq K_5$. As v and w are colored the same, and $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 4, 5\}$, we obtain $|L(u_1)| \geq 1$, $|L(u_i)| \geq 4$ if $i \in \{2, 3\}$, and $|L(u_i)| \geq 5$ if $i \in \{4, 5\}$. Thus, the graph $G_3[\mathcal{U}]$ is L -colorable, and hence G admits a 3-facial 11-coloring.

L11. Let c' be a 3-facial 11-coloring of the graph G' obtained by contracting the bold edges into a new vertex h_1 . Define $c(x) = c'(x)$ for every vertex $x \in V(G) \cap V(G')$, and let $c(v) = c(w) = c'(h_1)$. By Lemma 1, $\deg_3(u_i) \leq 15$ for $i \in \{1, 2\}$ and $\deg_3(u_i) \leq 11$ for $i \in \{3, 4, 5\}$. Moreover, $G_3[\mathcal{U}] \simeq K_6$. Hence, $|L(u_1)| \geq 1$ and $|L(u_i)| \geq i$ for $i \in \{3, 4, 5\}$. As v and w are colored the same, and $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{2, 6\}$, we infer that $|L(u_2)| \geq 2$ and $|L(u_6)| \geq 6$. Thus, the graph G is 3-facially 11-colorable.

L12. Let us define the partial 3-facial 11-coloring c as always, regarding the bold edges and the vertices v and w . From Lemma 1 we obtain that $\deg_3(u_1) \leq 15$, $\deg_3(u_i) \leq 12$ for $i \in \{2, 3, 4\}$, and $\deg_3(u_5) \leq 11$. Moreover, since $G_3[\mathcal{U}] \simeq K_5$ and $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 4, 5\}$, we obtain $|L(u_1)| \geq 1$, $|L(u_i)| \geq 3$ for $i \in \{2, 3\}$, $|L(u_4)| \geq 4$, and $|L(u_5)| \geq 5$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L13. Define the partial 3-facial 11-coloring c as usual, regarding the bold edges and the vertices v and w . By Lemma 1, $\deg_3(u_1) \leq 15$ and $\deg_3(u_i) \leq 11$ for $i \in \{2, 3, 4, 5\}$. Moreover, since $G_3[\mathcal{U}] \simeq K_5$ and $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 5\}$, we obtain $|L(u_1)| \geq 1$, $|L(u_i)| \geq 4$ for $i \in \{2, 3, 4\}$, and $|L(u_5)| \geq 5$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L14. Let us define the partial 3-facial 11-coloring c as always, regarding the bold edges and the vertices v and w . Again, $G_3[\mathcal{U}] \simeq K_5$. From Lemma 1 we obtain that $\deg_3(u_1) \leq 15$ and $\deg_3(u_i) \leq 11$ if $i \in \{2, 3, 4, 5\}$. Moreover, since $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 5\}$, we obtain $|L(u_1)| \geq 1$, $|L(u_i)| \geq 4$ for $i \in \{2, 3, 4\}$, and $|L(u_5)| \geq 5$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L15. Define the partial 3-facial 11-coloring c as always, regarding the bold edges and the vertices v, w , and t . Then, $G_3[\mathcal{U}] \simeq K_5$ and $\deg_3(u_i) \leq 15$ for $i \in \{1, 2\}$, $\deg_3(u_i) \leq 12$ for $i \in \{3, 4\}$, and $\deg_3(u_5) \leq 11$. Moreover, notice that $\{v, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 4\}$, $\{v, w, t\} \subset \mathcal{N}_3(u_2)$, and $\{v, w\} \subset \mathcal{N}_3(u_5)$. Thus, we obtain $|L(u_1)| \geq 1$, $|L(u_2)| \geq 2$, $|L(u_3)| \geq 3$, $|L(u_4)| \geq 4$, and $|L(u_5)| \geq 5$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L16. Define the partial 3-facial 11-coloring c as always, regarding the bold edges and the vertices v, w , and t . Then, $G_3[\mathcal{U}] \simeq K_5$ and $\deg_3(u_i) \leq 15$ for $i \in \{1, 2\}$, $\deg_3(u_3) \leq 12$, and $\deg_3(u_i) \leq 11$ for $i \in \{4, 5\}$. Moreover, notice that $\{v, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 5\}$, $\{v, w, t\} \subset \mathcal{N}_3(u_2)$, and $\{v, w\} \subset \mathcal{N}_3(u_3)$. Thus, we obtain $|L(u_1)| \geq 1$, $|L(u_2)| \geq 2$, $|L(u_i)| \geq 4$ for $i \in \{3, 4\}$, and $|L(u_5)| \geq 5$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L17. Let us define the partial 3-facial 11-coloring c as always, regarding the bold edges and the vertices v and w . Then, $G_3[\mathcal{U}] \simeq K_3$, $\deg_3(u_1) \leq 13$, and $\deg_3(u_i) \leq 11$ for $i \in \{2, 3\}$. Moreover, $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 2, 3\}$. Thus, we obtain $|L(u_1)| \geq 1$ and $|L(u_i)| \geq 3$ for $i \in \{2, 3\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L18. Again, $G_3[\mathcal{U}] \simeq K_5$ and $\deg_3(u_i) \leq 15$ for $i \in \{1, 2\}$, while $\deg_3(u_i) \leq 11$ for $i \in \{3, 4, 5\}$. Furthermore, $\{v, w\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 3, 4\}$, $\{v, t\} \subset \mathcal{N}_3(u_5)$, and $\{v, w, t\} \subset \mathcal{N}_3(u_2)$. Thus, we deduce $|L(u_1)| \geq 1$, $|L(u_2)| \geq 2$, and $|L(u_i)| \geq 5$ for $i \in \{3, 4, 5\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L19. Here, $G_3[\mathcal{U}] \simeq K_6$. Also, $\deg_3(u_i) \leq 15$ for $i \in \{1, 2, 3\}$, $\deg_3(u_4) \leq 13$, and $\deg_3(u_i) \leq 11$ for $i \in \{5, 6\}$. Furthermore, $\{w, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 6\}$, $\{v, w, t\} \subset \mathcal{N}_3(u_3)$, and $\{v, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{2, 4\}$. Thus, we infer $|L(u_i)| \geq 2$ for $i \in \{1, 2\}$, $|L(u_3)| \geq 3$, $|L(u_4)| \geq 4$, $|L(u_5)| \geq 5$, and $|L(u_6)| \geq 6$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L20. Again $G_3[\mathcal{U}] \simeq K_6$. Also, $\deg_3(u_i) \leq 15$ for $i \in \{1, 2, 3\}$, $\deg_3(u_i) \leq 12$ for $i \in \{4, 5\}$, and $\deg_3(u_6) \leq 11$. Furthermore, $\{w, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 5\}$, $\{v, w, t\} \subset \mathcal{N}_3(u_3)$, and $\{v, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{2, 6\}$. Thus, we infer $|L(u_i)| \geq 2$ for $i \in \{1, 2\}$ and $|L(u_i)| \geq i$ for $i \in \{3, 4, 5, 6\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L21. In this case, $G_3[\mathcal{U}] \simeq K_6$. Also, $\deg_3(u_i) \leq 13$ for $i \in \{1, 2, 3, 4\}$, and $\deg_3(u_i) \leq 12$ for $i \in \{5, 6\}$. Furthermore, $\{v, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{4, 5\}$, $\{v, w, t\} \subset \mathcal{N}_3(u_6)$, and $\{w, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{2, 3\}$. Thus, we infer $|L(u_1)| \geq 3$, $|L(u_i)| \geq 4$ for $i \in \{2, 3, 4\}$, $|L(u_5)| \geq 5$, and $|L(u_6)| \geq 6$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L22. In this case, $G_3[\mathcal{U}] \simeq K_3$. Also, $\deg_3(u_i) \leq 12$ for $i \in \{1, 2, 3\}$. Moreover, $\{v, w, t\} \subset \mathcal{N}_3(u_i)$ for $i \in \{1, 2, 3\}$. Thus, we infer $|L(u_i)| \geq 3$ for $i \in \{1, 2, 3\}$. Therefore, $G_3[\mathcal{U}]$ is L -colorable.

L23. Define the partial coloring c as always, regarding the bold edges and the vertex v . Note that $G_3[\mathcal{U}]$ is isomorphic to the complete graph on four vertices minus one edge K_4^- , since $u_1 \notin \mathcal{N}_3(u_2)$ (because the face has size at least 8). By Lemma 1, $\deg_3(u_i) \leq 11$ for every $i \in \{1, 2, 3, 4\}$. Thus, $|L(u_i)| \geq 2$ for $i \in \{1, 2\}$, and $|L(u_i)| \geq 3$ for $i \in \{3, 4\}$. Hence, the graph $G_3[\mathcal{U}]$ is L -colorable. This assertion can be directly checked, or seen as a consequence of a theorem independently proved by Borodin [2] and Erdős, Rubin, and Taylor [8] (see also [17]), stating that a connected graph is degree-choosable unless it is a *Gallai tree*, that is, each of its blocks is either complete or an odd cycle. $\square$

COROLLARY 1. *Every (3, 11)-minimal graph G has the following properties:*

1. *Let f_1, f_2 be two 5-faces of G with a common edge xy . Then, x and y are not both 3-vertices.*
2. *Let f be a 7-face whose every incident vertex is a 3-vertex. If f is adjacent to a 3-face, then every other face adjacent to f is a (≥ 7) -face.*
3. *Two dangerous vertices incident to a same 6-face are not adjacent.*
4. *There cannot be four consecutive dangerous vertices incident to a same (≥ 6) -face.*
5. *A very bad face is adjacent to at least three (≥ 7) -faces.*
6. *A bad face is adjacent to at least two (≥ 7) -faces.*

Proof. 1. By Lemma 2.5, $\deg_3(x) + \deg_3(y) \geq 23$. By Lemma 1, the 3-facial degree of a 3-vertex incident to two 5-faces is at most 11. Hence at least one of x and y is a (≥ 4) -vertex.

2. First note that, according to Lemma 2.3, the faces adjacent to both f and the 3-face have sizes at least 7. Hence, f is adjacent to at most four (≤ 6) -faces. Now, the assertion directly follows from the reducibility of the configurations (L1) and (L2) of Figure 2.

3. Suppose on the contrary that x and y are two such vertices. By Lemma 2.3, a 6-face is not adjacent to a 3-face; hence both x and y are incident to a 4-face. Then, $\deg_3(x) \leq 11$ and $\deg_3(y) \leq 11$, which contradicts Lemma 2.5.

4. Suppose that the assertion is false. Then, according to the third item of this corollary, the graph G must contain the configuration (L4) or (L5) of Figure 2, which are both reducible.

5. Let f be a very bad face. By the first item of this corollary and Lemma 3, two adjacent (≤ 6) -faces cannot be both adjacent to f . Hence, f is adjacent to at most two such faces.

6. Let f be a bad face, and $\{\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5\}$ its incident vertices in clockwise order. Without loss of generality, assume that, for every $i \in \{1, 2, 3, 4\}$, α_i is a 3-vertex. For $i \in \{1, 2, 3, 4\}$, let f_i be the face adjacent to f and incident to both α_i and α_{i+1} . According to the first item of this corollary and Lemma 3, at most two faces among f_1, f_2, f_3, f_4 can be (≤ 6) -faces. This concludes the proof. $\square$

3. Proof of Theorem 1. Suppose that Theorem 1 is false, and let G be a $(3, 11)$ -minimal graph. We obtain a contradiction by using the discharging method. Here is an overview of the proof: each vertex and face is assigned an initial charge. The total sum of the initial charges is known to be negative by Euler's formula. Then, some redistribution rules are defined, and each vertex and face gives or receives some charge according to these rules. The total sum of the charges is not changed during this step, but at the end we show, by case analysis, that the charge of each vertex and each face is nonnegative, a contradiction.

Initial charge. First, we assign a charge to each vertex and face. For every $v \in V(G)$, we define the initial charge

$$\text{ch}(v) = d(v) - 4,$$

where $d(v)$ is the degree of the vertex v in G . Similarly, for every $f \in F(G)$, where $F(G)$ is the set of faces of G , we define the initial charge

$$\text{ch}(f) = r(f) - 4,$$

with $r(f)$ the size of the face f . By Euler's formula the total sum is

$$\sum_{v \in V(G)} \text{ch}(v) + \sum_{f \in F(G)} \text{ch}(f) = -8.$$

Rules. We use the following discharging rules to redistribute the initial charge.

RULE R1. A (≥ 5) -face sends $1/3$ to each of its incident safe vertices and $1/2$ to each of its incident dangerous vertices.

RULE R2. A (≥ 7) -face sends $1/3$ to each adjacent 3-face.

RULE R3. A (≥ 7) -face sends $1/6$ to each adjacent bad face.

RULE R4. A 6-face sends $1/12$ to each adjacent very bad face.

RULE R5. A (≥ 5) -vertex v gives $2/3$ to an incident face f if and only if there exist two 3-faces both incident to v and both adjacent to f . (Note that the size of such a face f is at least 7.)

We now prove that the final charge $\text{ch}^*(x)$ of every $x \in V(G) \cup F(G)$ is non-negative. Therefore, we obtain

$$-8 = \sum_{v \in V(G)} \text{ch}(v) + \sum_{f \in F(G)} \text{ch}(f) = \sum_{v \in V(G)} \text{ch}^*(v) + \sum_{f \in F(G)} \text{ch}^*(f) \geq 0,$$

a contradiction.

Final charge of vertices. First, as noticed in Lemma 2.4, G has minimum degree at least three. Let v be an arbitrary vertex of G . We prove that its final charge $\text{ch}^*(v)$ is nonnegative. To this end, we consider a few cases regarding its degree. So, suppose first that v is a 3-vertex. If v is a safe vertex, then by Rule R1 its final charge is $\text{ch}^*(v) = -1 + 3 \cdot \frac{1}{3} = 0$. Similarly, if v is dangerous, then $\text{ch}^*(v) = -1 + 2 \cdot \frac{1}{2} = 0$. If v is a 4-vertex, then it neither receives nor sends any charge. Thus, $\text{ch}^*(v) = \text{ch}(v) = 0$.

Finally, suppose that v is of degree $d \geq 5$. Notice that v may send charge only by Rule R5. This may occur at most $d/2$ times if d is even, and at most $\lfloor d/2 \rfloor - 1$ times if d is odd (since two 3-faces are not adjacent). Thus, $\text{ch}^*(v) \geq d - 4 - \lfloor \frac{d}{2} \rfloor \cdot \frac{2}{3}$, which is nonnegative if $d \geq 6$. For $d = 5$, $\text{ch}^*(v) \geq 5 - 4 - \frac{2}{3} > 0$.

Final charge of faces. Let f be an arbitrary face of G . We define **fce** and **bad** to be the number of 3-faces and the number of bad faces, respectively, adjacent to f . We define **sfe** and **dgs** to be the number of safe vertices and the number of dangerous vertices, respectively, incident to f . We prove that the final charge $\text{ch}^*(f)$ of f is nonnegative. To this end, we consider a few cases regarding the size of f .

f is a 3-face. It is adjacent only to (≥ 7) -faces by Lemma 2.3. Thus, by Rule R2, f receives $1/3$ from each of its three adjacent faces, so we obtain $\text{ch}^*(f) = 0$.

f is a 4-face. It neither receives nor sends any charge. Thus, $\text{ch}^*(f) = \text{ch}(f) = 0$.

f is a 5-face. Then, f is adjacent only to (≥ 5) -faces due to Lemma 2.3. So a 5-face may send charge only to its incident 3-vertices, which are all safe. Consider the following cases regarding the number **sfe** of such vertices:

sfe ≤ 3 : Then, $\text{ch}^*(v) \geq 1 - 3 \cdot \frac{1}{3} = 0$.

sfe $= 4$: In this case, f is a bad face. According to Corollary 1.6, at least two of the faces that are adjacent to f have size at least 7. Thus, according to Rule R3, f receives $1/6$ from at least two of its adjacent faces. Hence, we conclude that $\text{ch}^*(v) \geq 1 - 4 \cdot \frac{1}{3} + 2 \cdot \frac{1}{6} = 0$.

sfe $= 5$: Then f is a very bad face, and so, according to Corollary 1.5, at least three faces adjacent to f have size at least 7. Moreover, all faces adjacent to f have size at least 6, by Lemma 2.3 and Corollary 1.1. By Rules R3 and R4, it follows that the neighboring faces of f send at least $4 \cdot 1/6$ to f , which implies that $\text{ch}^*(v) \geq 1 - 5 \cdot \frac{1}{3} + 4 \cdot \frac{1}{6} = 0$.

f is a 6-face. By Lemma 2.3, **fce** $= 0$. Let **vbd** be the number of very bad faces adjacent to f . The final charge of f is $2 - \text{dgs} \cdot \frac{1}{2} - \text{sfe} \cdot \frac{1}{3} - \text{vbd} \cdot \frac{1}{12}$ due to Rules R1 and R4.

According to Corollary 1.3, two dangerous vertices on f cannot be adjacent, so there are at most three dangerous vertices on f . Observe also that **vbd** $\leq \text{sfe}/2$ by Corollary 1.1 and because a very bad face adjacent to f is incident to two safe vertices of f . Let us consider the final charge of f regarding its number of dangerous vertices.

dgs $= 3$: Since a safe vertex is not incident to a (≤ 4) -face, there is at most one safe vertex incident to f , i.e., **sfe** ≤ 1 . Thus, **vbd** $= 0$, and hence $\text{ch}^*(f) \geq$

$$2 - 3 \cdot \frac{1}{2} - \frac{1}{3} > 0.$$

$\text{dgs} = 2$: Then, $\text{sfe} \leq 3$. Let us distinguish two cases according to the value of sfe .

$\text{sfe} = 3$: Notice that $\text{vbd} = 0$; otherwise it would contradict the reducibility of (L3). Hence, $\text{ch}^*(f) \geq 2 - 2 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} = 0$.

$\text{sfe} \leq 2$: In this case, there is at most one very bad face adjacent to f , so $\text{ch}^*(f) \geq 2 - 2 \cdot \frac{1}{2} - 2 \cdot \frac{1}{3} - \frac{1}{12} > 0$.

$\text{dgs} = 1$: Then, $\text{sfe} \leq 4$ and $\text{vbd} \leq 1$ because (L3) is reducible. So, $\text{ch}^*(f) \geq 2 - \frac{1}{2} - \frac{4}{3} - \frac{1}{12} > 0$.

$\text{dgs} = 0$: If $\text{sfe} \geq 5$ then, because (L3) is reducible, $\text{vbd} = 0$; therefore $\text{ch}^*(f) \geq 2 - \frac{6}{3} = 0$. And, if $\text{sfe} \leq 4$, then $\text{vbd} \leq 2$, so $\text{ch}^*(f) \geq 2 - 4 \cdot \frac{1}{3} - 2 \cdot \frac{1}{12} > 0$.

f is a 7-face. The final charge of f is at least $3 - \text{dgs} \cdot \frac{1}{2} - (\text{fce} + \text{sfe}) \cdot \frac{1}{3} - \text{bad} \cdot \frac{1}{6}$.

According to Corollary 1.4, four dangerous vertices cannot be consecutive on f ; hence there cannot be more than five dangerous vertices on f . Let $\alpha_1, \alpha_2, \dots, \alpha_7$ be the vertices of f in clockwise order. Let $\mathcal{D}$ be the set of dangerous vertices of f , so $\text{dgs} = |\mathcal{D}|$. We look at the final charge of f , regarding its number dgs of dangerous vertices.

$\text{dgs} = 5$: Up to symmetry, $\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_3, \alpha_5, \alpha_6\}$. Suppose first that α_5 and α_6 are not incident to a same (≤ 4)-face. Then, there can be neither a safe vertex incident to f nor a bad face adjacent to f , because a safe vertex is not incident to a (≤ 4)-face, and also a bad face is not adjacent to a (≤ 4)-face. Moreover, by Corollary 1.3, there is no 3-face adjacent to f . Therefore, $\text{ch}^*(f) \geq 3 - \frac{5}{2} > 0$. Now, if α_5 and α_6 are incident to a same (≤ 4)-face, then α_4 and α_7 must be (≥ 4)-vertices, by the reducibility of (L6) and because none of them is a dangerous vertex. Hence, there is no safe vertex and no bad face adjacent to f , so its charge is $\text{ch}^*(f) \geq 3 - \frac{5}{2} - \frac{1}{3} > 0$.

$\text{dgs} = 4$: We consider several subcases, according to the relative position of the dangerous vertices on f . Recall that, by Corollary 1.4, there are at most three consecutive dangerous vertices. Without loss of generality, we need only to consider the following three possibilities:

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_3, \alpha_5\}$: The charge of f is $\text{ch}^*(f) = 1 - (\text{fce} + \text{sfe}) \cdot \frac{1}{3} - \text{bad} \cdot \frac{1}{6}$. Moreover, $\text{sfe} \leq 2$, $\text{bad} \leq 1$, and $\text{fce} + \text{sfe} \leq 3$ by Corollary 1.3 and because a safe vertex is not incident to a (≤ 4)-face. So, $\text{ch}^*(f)$ is negative if and only if $\text{sfe} = 2$, $\text{bad} = 1$, and $\text{fce} = 1$. But in this case, the obtained configuration is (L7), which is reducible.

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_4, \alpha_5\}$: As a bad face is neither adjacent to a (≤ 4)-face nor incident to a dangerous vertex, we obtain that $\text{bad} \leq 1$. Observe also that, as α_3 is not dangerous, it has degree at least four by the reducibility of (L6) and (L10). Thus, $\text{sfe} \leq 2$. Suppose first that $\text{bad} = 1$, then sfe is one or two. According to the reducibility of (L9), we infer $\text{sfe} + \text{fce} \leq 2$. Hence, $\text{ch}^*(f) \geq 3 - 4 \cdot \frac{1}{2} - 2 \cdot \frac{1}{3} - \frac{1}{6} > 0$. Suppose now that $\text{bad} = 0$. We have $\text{fce} \leq 3$ and $\text{sfe} \leq 2$. If $\text{fce} = 3$, then $\text{sfe} = 0$, and if $\text{fce} = 2$, then $\text{sfe} \leq 1$ according to the reducibility of (L11). So, $\text{fce} + \text{sfe} \leq 3$. Therefore, $\text{ch}^*(f) \geq 3 - 4 \cdot \frac{1}{2} - (\text{fce} + \text{sfe}) \cdot \frac{1}{3} \geq 0$.

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_4, \alpha_6\}$: In this case, there is no bad face adjacent to f . Furthermore, by Corollary 1.3, $\text{fce} \leq 3$ and $\text{sfe} \leq 2$, as the dangerous vertices α_4 and α_6 prevent at least one nondangerous vertex from being safe. Observe that $\text{fce} + \text{sfe} \neq 5$ since otherwise it would contradict the reducibility of (L12). According to the reducibility of (L12), if $\text{fce} + \text{sfe} = 4$, then $\text{fce} = 3$ and no two 3-faces have a common vertex. Hence, the obtained configuration is isomorphic to

(L13) or (L14), which are both reducible. So, $\mathbf{fce} + \mathbf{sfe} \leq 3$, and thus $\mathbf{ch}^*(f) \geq 3 - 2 - (\mathbf{fce} + \mathbf{sfe}) \cdot \frac{1}{3} \geq 0$.

$\mathbf{dgs} = 3$: Again, we consider several subcases according to the relative position of the dangerous vertices on f :

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_3\}$: Then $\mathbf{fce} + \mathbf{sfe} \leq 3$ by Corollary 1.3, and $\mathbf{bad} \leq 2$. Thus, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} > 0$.

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_4\}$: Then, $\mathbf{fce} \leq 4$. We now examine the situation according to each possible value of $\mathbf{fce}$.

$\mathbf{fce} = 4$: Necessarily, $\mathbf{sfe} \leq 1$ and $\mathbf{bad} = 0$. Now, if $\mathbf{sfe} = 0$, then $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} > 0$. And, if $\mathbf{sfe} = 1$, then the safe vertex must be α_3 . Moreover, α_5 must be a (≥ 5) -vertex because (L8) is reducible. Hence, f is incident to α_5 between two 3-faces, so by Rule R5 the vertex α_5 gives $\frac{2}{3}$ to f . Thus, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 5 \cdot \frac{1}{3} + \frac{2}{3} > 0$.

$\mathbf{fce} = 3$: Suppose first that one of the dangerous vertices is incident to a 4-face. Necessarily, $\mathbf{sfe} \leq 1$ and $\mathbf{bad} \leq 1$. Thus, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

Suppose now that no dangerous vertex is incident to a 4-face. In particular, $\mathbf{sfe} \leq 2$. If $\mathbf{sfe} = 2$, then the obtained configuration contradicts the reducibility of (L18). Hence, $\mathbf{sfe} \leq 1$ and $\mathbf{bad} \leq 1$. Therefore, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

$\mathbf{fce} = 2$: We prove that $\mathbf{sfe} \leq 2$. This is true if α_1 and α_2 are not incident to a same 3-face. So, we may assume that the edge $\alpha_1\alpha_2$ lies on a 3-face. But then we obtain the inequality due to the reducibility of (L18) and (L19). Using Corollary 1.1, the reducibility of (L17), and $\mathbf{sfe} \leq 2$, we infer that $\mathbf{bad} \leq 1$. Hence, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

$\mathbf{fce} = 1$: Then $\mathbf{sfe} \leq 3$ and $\mathbf{bad} \leq 2$. If $\mathbf{sfe} = 3$ and $\mathbf{bad} = 2$, the obtained configuration contradicts the reducibility of (L19) or of (L20). So, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

$\mathbf{fce} = 0$: Again, $\mathbf{sfe} \leq 3$ and $\mathbf{bad} \leq 2$, so $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} > 0$.

$\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_5\}$: As in the previous case, $\mathbf{fce} \leq 4$, and we look at all the possible cases according to the value of $\mathbf{fce}$. Since a bad face is not incident to a dangerous vertex, notice that only edges $\alpha_3\alpha_4$ and $\alpha_6\alpha_7$ can be incident to a bad face. In particular, $\mathbf{bad} \leq 2$.

$\mathbf{fce} = 4$: In this case, $\mathbf{sfe} = 0$ and $\mathbf{bad} = 0$. Therefore, $\mathbf{ch}^*(f) = 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} > 0$.

$\mathbf{fce} = 3$: If one of the dangerous vertices is incident to a 4-face, then $\mathbf{sfe} = 0$; hence $\mathbf{bad} = 0$. Thus, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} \geq 0$. So now we infer that $\mathbf{sfe}$ cannot be 2; otherwise it would contradict the reducibility of (L15). Therefore, $\mathbf{sfe}$ is at most one, and so $\mathbf{bad} \leq 1$ by Corollary 1.1. Thus, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

$\mathbf{fce} = 2$: According to the reducibility of (L15) and (L16), $\mathbf{sfe} \leq 2$. As $\mathbf{ch}^*(f) = 3 - 3 \cdot \frac{1}{2} - (\mathbf{fce} + \mathbf{sfe}) \cdot \frac{1}{3} - \mathbf{bad} \cdot \frac{1}{6}$, we deduce $\mathbf{ch}^*(f) < 0$ if and only if $\mathbf{sfe} = 2$ and $\mathbf{bad} = 2$. In this case, the obtained configuration is (L17), which is reducible.

$\mathbf{fce} = 1$: Because (L15) and (L16) are reducible, $\mathbf{sfe} \leq 2$. So, $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 3 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} > 0$.

$\mathbf{fce} = 0$: Then $\mathbf{sfe} \leq 3$, and so $\mathbf{ch}^*(f) \geq 3 - 3 \cdot \frac{3}{2} - 3 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} > 0$.

$\mathcal{D} = \{\alpha_1, \alpha_3, \alpha_5\}$: In this case, $\mathbf{sfe} \leq 2$ since a safe vertex is not incident to a (≤ 4)-face, and $\mathbf{bad} \leq 1$, since a bad face cannot be incident to a dangerous vertex. Moreover, $\mathbf{fce} \leq 4$. Let us examine the possible cases regarding the value of $\mathbf{fce}$.

$\mathbf{fce} = 4$: Observe that $\mathbf{sfe} \leq 1$ and $\mathbf{bad} = 0$. Note also that one of $\alpha_2, \alpha_4, \alpha_6, \alpha_7$ is adjacent to a dangerous vertex, and incident to f between two triangles. Hence, by the reducibility of (L8), it has degree at least five, and by Rule R5, it sends $\frac{2}{3}$ to f . Thus, $\text{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 5 \cdot \frac{1}{3} + \frac{2}{3} > 0$.

$\mathbf{fce} = 3$: If $\mathbf{sfe} \leq 1$, then $\text{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$. And, if $\mathbf{sfe} = 2$, then, up to symmetry, the two safe vertices are either α_6 and α_7 or α_2 and α_6 . In the former case, one of α_2, α_4 is incident to f at the intersection of two 3-faces. Furthermore, it must be a (≥ 5)-vertex due to the reducibility of (L8). In the latter case, the same holds for α_4 due to the reducibility of (L8). Hence, in both cases the face f receives $2/3$ from one of its incident vertices by Rule R5.

Recall that $\mathbf{bad} \leq 1$, and therefore $\text{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 5 \cdot \frac{1}{3} - \frac{1}{6} + \frac{2}{3} > 0$.

$\mathbf{fce} \leq 2$: As $\mathbf{sfe} \leq 2$ and $\mathbf{bad} \leq 1$, we infer that $\text{ch}^*(f) \geq 3 - 3 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} - \frac{1}{6} = 0$.

$\mathbf{dgs} = 2$: Again, we consider several subcases, regarding the position of the dangerous vertices on f .

$\mathcal{D} = \{\alpha_1, \alpha_2\}$: Observe that $\mathbf{bad} \leq 3$, and according to Corollary 1.3, $\mathbf{fce} + \mathbf{sfe} \leq 6$. We consider three cases, according to the value of $\mathbf{fce} + \mathbf{sfe}$:

$\mathbf{fce} + \mathbf{sfe} = 6$: All the vertices incident to f have degree three, and f is adjacent to a 3-face. Thus, by Corollary 1.2, f is not adjacent to any (≤ 6)-face. In particular, no bad face is adjacent to f ; i.e., $\mathbf{bad} = 0$. Hence, $\text{ch}^*(f) \geq 3 - 1 - 6 \cdot \frac{1}{3} = 0$.

$\mathbf{fce} + \mathbf{sfe} = 5$: If $\mathbf{bad} \leq 2$, then $\text{ch}^*(f) \geq 3 - 1 - 5 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} = 0$. Otherwise, $\mathbf{bad} = 3$. Note that the edge $\alpha_1\alpha_2$ must be incident to a (≤ 4)-face. If this face is of size four, then we obtain configuration (L21). Suppose now that this face is of size three. Since there are no three consecutive bad faces around f , we can assume that each of the edges $\alpha_3\alpha_4$ and $\alpha_6\alpha_7$ lies on a bad face. By the reducibility of (L17), we conclude that α_3 and α_7 have degree at least four. But then, $\mathbf{fce} + \mathbf{sfe} < 5$.

$\mathbf{fce} + \mathbf{sfe} \leq 4$: In this case, $\text{ch}^*(f) \geq 3 - 1 - 4 \cdot \frac{1}{3} - 3 \cdot \frac{1}{6} > 0$.

$\mathcal{D} = \{\alpha_1, \alpha_3\}$ or $\mathcal{D} = \{\alpha_1, \alpha_4\}$: Again $\mathbf{fce} + \mathbf{sfe} \leq 6$, and we consider two cases regarding the value of $\mathbf{fce} + \mathbf{sfe}$. Since a bad face is not incident to a dangerous vertex, we infer that $\mathbf{bad} \leq 3$.

$\mathbf{fce} + \mathbf{sfe} = 6$: Suppose first that $\mathcal{D} = \{\alpha_1, \alpha_3\}$. Let $P_1 = \alpha_1\alpha_2\alpha_3$ and $P_2 = \alpha_3\alpha_4\alpha_5\alpha_6\alpha_7\alpha_1$. In order to assure $\mathbf{fce} + \mathbf{sfe} = 6$, observe that all edges of P_1 are incident to 3-faces, and all inner vertices of P_2 are safe, or vice versa. Thus, α_2 or α_4 is a (≥ 5)-vertex by the reducibility of (L8). Hence, it gives $\frac{2}{3}$ to f by Rule R5. Therefore, $\text{ch}^*(f) \geq 3 - 2 \cdot \frac{1}{2} - 6 \cdot \frac{1}{3} - 3 \cdot \frac{1}{6} + \frac{2}{3} > 0$.

Suppose now that $\mathcal{D} = \{\alpha_1, \alpha_4\}$. Similarly as above, one can show that α_2 or α_5 is a (≥ 5)-vertex that donates $\frac{2}{3}$ to f . Hence, $\text{ch}^*(f) \geq 3 - 2 \cdot \frac{1}{2} - 6 \cdot \frac{1}{3} - \frac{3}{6} + \frac{2}{3} > 0$.

$\mathbf{fce} + \mathbf{sfe} \leq 5$: Notice that $\mathbf{bad} \leq 2$. Therefore, $\text{ch}^*(f) \geq 3 - 2 \cdot \frac{1}{2} - 5 \cdot \frac{1}{3} - 2 \cdot \frac{1}{6} = 0$.

dgs = 1: Then **fce** + **sfe** ≤ 6 and, by Corollary 1.1, we infer that **bad** ≤ 3 . So, $\text{ch}^*(f) \geq 3 - \frac{1}{2} - 6 \cdot \frac{1}{3} - 3 \cdot \frac{1}{6} = 0$.

dgs = 0: By Corollary 1.1, **fce** + **sfe** ≤ 7 and **bad** ≤ 4 . So, $\text{ch}^*(f) \geq 3 - 7 \cdot \frac{1}{3} - 4 \cdot \frac{1}{6} = 0$.

f is an 8-face. By Lemma 2.5 and because (L22) is reducible, there cannot be three consecutive dangerous vertices on *f*. Hence, **dgs** ≤ 5 . Let α_i , $i \in \{1, 2, \dots, 8\}$, be the vertices incident to *f* in clockwise order, and let $\mathcal{D}$ be the set of dangerous vertices incident to *f*.

dgs = 5: Up to symmetry, $\mathcal{D} = \{\alpha_1, \alpha_2, \alpha_4, \alpha_5, \alpha_7\}$. Since a bad face is not incident to a dangerous vertex, necessarily **bad** = 0. For $i \in \{1, 4\}$, let f_i be the face adjacent to *f* and incident to both α_i and α_{i+1} . Since (L23) is reducible, at most one of f_1 and f_4 is a 3-face. Furthermore, at most two of $\alpha_3, \alpha_6, \alpha_8$ can be safe vertices, since at least one of α_6, α_8 is a (≥ 4) -vertex. Therefore, **fce** ≤ 2 , **sfe** ≤ 2 , and so $\text{ch}^*(f) \geq 4 - 5 \cdot \frac{1}{2} - 4 \cdot \frac{1}{3} > 0$.

dgs = 4: Up to symmetry the set of dangerous vertices comprises $\{\alpha_1, \alpha_2, \alpha_4, \alpha_5\}$, $\{\alpha_1, \alpha_2, \alpha_5, \alpha_6\}$, $\{\alpha_1, \alpha_2, \alpha_4, \alpha_6\}$, $\{\alpha_1, \alpha_2, \alpha_4, \alpha_7\}$, or $\{\alpha_1, \alpha_3, \alpha_5, \alpha_7\}$. In any case, **bad** ≤ 2 and **fce** + **sfe** ≤ 6 . Moreover, **fce** + **sfe** + **bad** ≤ 6 . Indeed, if **bad** = 0, then the inequality holds by the prior remark. This solves the fifth case for $\mathcal{D}$ since a bad face is not incident to a dangerous vertex. If **bad** = 2, then we are in the first or second case for $\mathcal{D}$. We infer that **fce** + **sfe** ≤ 4 by the reducibility of (L17) and (L23), and by Corollary 1.1. Finally, if **bad** = 1, then we deduce that **fce** + **sfe** ≤ 5 by the reducibility of (L17). Hence, $\text{ch}^*(f) \geq 4 - \frac{4}{2} - \frac{6}{3} = 0$.

dgs = 3: Then, **fce** + **sfe** ≤ 6 and **bad** ≤ 3 . So, $\text{ch}^*(f) \geq 4 - \frac{3}{2} - \frac{6}{3} - \frac{3}{6} = 0$.

dgs = 2: Then, **fce** + **sfe** ≤ 7 , and by Corollary 1.1, **bad** ≤ 4 . Thus, $\text{ch}^*(f) \geq 4 - \frac{2}{2} - \frac{7}{3} - \frac{4}{6} = 0$.

dgs = 1: Again, **fce** + **sfe** ≤ 7 and **bad** ≤ 4 , so $\text{ch}^*(f) \geq 4 - \frac{1}{2} - \frac{7}{3} - \frac{4}{6} > 0$.

dgs = 0: By Corollary 1.1, **bad** ≤ 5 . So, $\text{ch}^*(f) \geq 4 - \frac{8}{3} - \frac{5}{6} > 0$.

f is a (≥ 9) -face. Let *f* be a *k*-face with $k \geq 9$. We use the following averaging scheme for the rules followed by *f*: the face *f* sends the charge to incident vertices or adjacent faces *through* its incident edges. More precisely, for Rules R2 and R3, if f' is a bad face or a triangle incident to *f*, then we say that *f* sends the corresponding charge *through* the edge that is incident to both *f* and f' . As for Rule R1, let *u* be a vertex incident to *f*, and let *v* and *w* be its two neighbors on *f*. If *u* is a safe vertex, then *f* sends $\frac{1}{6}$ to *u* through each of the two edges *uv* and *uw*. If *u* is dangerous, let *uv* be the edge incident with a (≤ 4) -face: if *v* is dangerous, then *f* sends $\frac{1}{9}$ to *u* through *uv* and $\frac{7}{18}$ to *u* through *uw*. Otherwise (i.e., when *v* is a (≥ 4) -vertex), *f* sends $\frac{2}{9}$ to *u* through *uv* and $\frac{5}{18}$ to *u* through *uw*.

By Lemma 2.5 and the reducibility of (L22), there cannot be three consecutive dangerous vertices on *f*. So, we deduce that all the vertices incident to *f* receive the same charge as if *f* applied the original Rule R1. We prove now that *f* sends at most $\frac{5}{9}$ to each of its edges, and hence $\text{ch}^*(f) \geq k(1 - \frac{5}{9}) - 4 \geq 0$ since $k \geq 9$.

Let *uv* be an edge incident to *f*. We consider three cases.

uv is incident to a bad face f' : Then, *u* and *v* are not dangerous. So *f* sends through *uv* $\frac{1}{6}$ to *u* plus $\frac{1}{6}$ to *v* and $\frac{1}{6}$ to f' . Thus, the charge sent by *f* through the edge *uv* is at most $3 \cdot \frac{1}{6} = \frac{1}{2} < \frac{5}{9}$.

uv is incident to a triangle f' : In this case, *f* sends $\frac{1}{3}$ to f' . If neither of *u* or *v* is dangerous, then *f* sends nothing more through *uv*. If exactly one of *u* and *v* is dangerous, say *u*, then *f* sends $\frac{2}{9}$ to *u* through *uv*. Thus, the charge sent by *f* through *uv* is $\frac{1}{3} + \frac{2}{9} = \frac{5}{9}$. Finally, assume that both *u* and *v* are dangerous.

Then, f sends $\frac{1}{9}$ to each of u and v through uv . Hence, f sends $\frac{1}{3} + 2 \cdot \frac{1}{9} = \frac{5}{9}$ through uv .

uv is incident to neither a bad face nor a triangle: Again, if neither of u or v is dangerous, then f sends at most $2 \cdot \frac{1}{6} = \frac{1}{3}$ through uv . Suppose that both u and v are dangerous. If uv is incident to a 4-face, then f sends $2 \cdot \frac{1}{9} = \frac{2}{9}$ through uv . Otherwise, let t be the neighbor of u on f different from v , and let w be the neighbor of v on f different from u . By Lemma 2.5, each of tu and vw is incident to a 4-face, and t and w are not dangerous since (L22) is reducible. Therefore, f sends $\frac{5}{18}$ to each of u and v through uv , and thus f sends $\frac{5}{9}$ through uv . Finally, if exactly one of u and v is dangerous, say u , then f sends at most $\frac{7}{18}$ to u through uv , and at most $\frac{1}{6}$ to v through uv . In total, f sends at most $\frac{7}{18} + \frac{1}{6} = \frac{5}{9}$ through uv .

The proof of Theorem 1 is now complete. $\square$

Acknowledgments. The authors are grateful to Mr. Aron Koldenbach, whose remarks helped to improve this paper. They are also grateful to both the referees for their careful reading; they are especially indebted to one of them for pointing out the averaging argument for (≥ 9) -faces, which allowed a shortening of the very last part of the proof.

NORMALIZED MATCHING PROPERTY OF RESTRICTED SUBSPACE LATTICES*

JUN WANG[†] AND HUAJUN ZHANG[‡]

Abstract. Let V be the n -dimensional vector space over the finite field with q elements and $L(V)$ the lattice of subspaces of V ordered by inclusion. Let $V_1, V_2, \dots, V_r$ be r selected subspaces of V such that $\{0\} = V_0 \subseteq V_1 \subseteq \dots \subseteq V_r = V$ and $\dim(V_i) = \sum_{j=1}^i k_j$. Let $\mathcal{I}_i$ be a subinterval of $[0, k_i]$, $i = 1, \dots, r$, let $I = \{\mathcal{I}_1, \dots, \mathcal{I}_r\}$, and let $C[n, r, I] = \{K \in L(V) : \dim(K \cap V_i) - \dim(K \cap V_{i-1}) \in \mathcal{I}_i, i = 1, 2, \dots, r\}$. Then $C[n, r, I]$ is a graded poset. In this paper, using group actions and flow morphisms we show that $C[n, r, I]$ is log concave and has the NM property, which yields that $C[n, r, I]$ has the strong Sperner property and the LYM property.

Key words. poset, subspace lattice, Sperner property, normalized matching property

1. Introduction. A finite poset P is *graded* if every maximal chain of P has the same length, which is called the rank of P denoted by $r(P)$. Thus, for each $x \in P$, every maximal chain with x as the top element has the same length, which is called the rank of the element x and denoted by $r(x)$. Here the length of a chain with k elements is $k - 1$. Let P_i denote the i th level of P , which consists of all $x \in P$ with $r(x) = i$ ($0 \leq i \leq r(P)$). An *antichain* is a subset $A \subseteq P$ of which no two elements are comparable in P . A *k-family* is a subset of P that contains no chains of length k . Clearly, each P_i is an antichain, and each union of k levels of P is a k -family. We say P is *unimodal* if the sequence of the Whitney numbers of P is unimodal, i.e., $W_0 \leq \dots \leq W_{\ell-1} \leq W_{\ell} \geq W_{\ell+1} \geq \dots \geq W_n$ for some ℓ , where $n = r(P)$ and $W_i = |P_i|$. Similarly, P is *log concave* if the sequence of Whitney numbers of P is log concave: $W_m^2 \geq W_{m-1}W_{m+1}$ for all m . It is clear that the log concavity of P implies that P is unimodal. For $A \subseteq P_i$ where $0 \leq i < r(P)$, define $\nabla(A) = \{b \in P_{i+1} : b \geq a \text{ for some } a \in A\}$.

As stated in [3], some extremal problems can be considered in a weighted poset (P, w) , which is a poset P together with a function (called a weight function) w from P into the set of nonnegative real numbers. The weight $w(A)$ of a subset A of P is defined by $w(A) = \sum_{a \in A} w(a)$. Every poset P can be considered to be a weighted poset (P, w) , where $w \equiv 1$; that is, $w(x) = 1$ for all $x \in P$.

We say a graded poset (P, w) is *k-Sperner*, or has the *k-Sperner property*, if a union of k ranks of P is a maximal-weight k -family in P . 1-Sperner is referred to simply as Sperner. We say (P, w) is *strongly Sperner*, or has the *strong Sperner property* if it is k -Sperner for all k . We say (P, w) has the normalized matching (NM) property if

$$(1) \quad \frac{w(\nabla(A))}{w(A)} \geq \frac{w(P_{i+1})}{w(P_i)} \quad \text{for all } A \subseteq P_i, \quad i = 0, 1, 2, \dots, r(P) - 1.$$

We say (P, w) has the *Lubell–Yamamoto–Meshalkin (LYM) property* if for every antichain A in P the following inequality holds:

$$\sum_{i=0}^{r(P)} \frac{w(A \cap P_i)}{w(P_i)} \leq 1.$$

These properties are called the properties of Sperner type. It is well known that the NM property and the LYM property are equivalent, and that they imply the strong Sperner property [8].

Let $C(n, k)$ be the collection of all subsets of an n -set Y which intersect a fixed k -subset of X . In fact, $C(n, k)$ constitutes a natural generalization for the subset lattice. Lih [14] first observed this and showed that $C(n, k)$ has the Sperner property. Griggs [9] further showed that $C(n, k)$ has several strong properties.

Let V be the n -dimensional vector space over the finite field with q elements and $L(V)$ the lattice of subspaces of V ordered by inclusion. Let $V_1, V_2, \dots, V_r$ be r selected subspaces of V such that $\{0\} = V_0 \subseteq V_1 \subseteq \dots \subseteq V_r = V$ and $\dim(V_i) = \sum_{j=1}^i k_j$. Let $\mathcal{I}_i$ be a subinterval of $[0, k_i]$, $i = 1, \dots, r$, let $I = \{\mathcal{I}_1, \dots, \mathcal{I}_r\}$, and let $C[n, r, I] = \{K \in L(V) : \dim(K \cap V_i) - \dim(K \cap V_{i-1}) \in \mathcal{I}_i, i = 1, 2, \dots, r\}$.

In this paper we prove that $C[n, r, I]$ is log concave and has the NM property, which can be regarded as a vector-space analog of some results in [9, 14]. We shall make preparations for proving the theorem and present some preliminary results in the next section. The main results will be proved in sections 3 and 4.

2. Quotient posets and flow morphism. From algebra we know that some properties of a group, ring or module etc. can be partly reflected by their homomorphic image. Is this approach available for properties of Sperner type of a poset? In other words, if there is an order preserving map (homomorphism) from (P, w) onto (Q, v) and (Q, v) has a property of Sperner type, can one correctly infer this to be a property of (P, w) ? A first step in this direction is a theorem of Kleitman, Edelberg, and Lubell in [13] (see also [5]) as follows.

THEOREM 2.1 (see [13]). *Let P be a poset and Γ a permutation group acting on P which preserves the order relation on P . Then P contains a maximal sized antichain which is invariant under the action of Γ .*

This theorem provides a powerful method to study the Sperner property of a poset. For each $x \in P$, let $\Gamma(x) = \{\gamma(x) : \gamma \in \Gamma\}$. Then we have the quotient poset $(P/\Gamma, w_\Gamma)$, where P/Γ consists of the Γ -orbits ordered as follows: $\Gamma(x) \leq \Gamma(y)$ in P/Γ if $x' \leq y'$ for some $x' \in \Gamma(x)$ and $y' \in \Gamma(y)$, and the weight function w_Γ is given by $w_\Gamma(\Gamma(x)) = |\Gamma(x)|$. Then, $\psi : x \mapsto \Gamma(x)$ for $x \in P$ is an order and rank preserving map from P onto P/Γ . Then, the above theorem says that P has the Sperner property if and only if $(P/\Gamma, w_\Gamma)$ does. By this result the first author of this paper proved a conjecture on the Sperner property of the subgroup lattice of an abelian p -group [15]. The group theoretic approach was also used for intersecting Sperner families [4].

As shown in [13], Theorem 2.1 may be generalized in two directions. First, we can consider a k -family instead of an antichain, as done in [7]. Second, if we consider the weighted poset (P, v) where $v(x)$ is defined to be $1/|P_i|$ for $x \in P_i$, then the same argument will yield the LYM version or, equivalently, the NM version of the theorem, of which a direct and short proof was given in [16]. We state these results in the following theorem.

THEOREM 2.2. *P has the Sperner (strong Sperner, LYM or NM) property if and only if $(P/\Gamma, w_\Gamma)$ does.*

A remarkable step in this direction was given by Harper [10] (see also [11]), who introduced the concept of flow morphism between two bipartite graphs. For the purpose of this paper, we adopt the terminologies in [3, p. 157].

DEFINITION 2.3. *Let (P, w) and (Q, v) be two weighted posets. A flow morphism is a mapping $\phi : P \rightarrow Q$ such that*

- (i) ϕ is surjective,
- (ii) ϕ is order preserving and rank preserving, that is, that p_1 covers p_2 in P , which implies that $\phi(p_1)$ covers $\phi(p_2)$ in Q ,
- (iii) $v(q) = w(\phi^{-1}(q))$ for all $q \in Q$,
- (iv) the weighted poset induced by $\phi^{-1}(q_1) \cup \phi^{-1}(q_2)$ has rank 1 and the NM property for all $q_1, q_2 \in Q$ such that q_1 covers q_2 in Q .

By the fundamental lemma and note 2 in [10] we obtain the following theorem.

THEOREM 2.4. *Suppose that there is a flow morphism ϕ from (P, w) onto (Q, v) . Then (P, w) has the NM property if and only if (Q, v) does.*

Note that the fundamental lemma in [10] is contained in an earlier paper by Graham and Harper [6]. Also, as pointed out by a referee, the proof given in [13] works for Theorem 2.4 without changes if one replaces orbits under a group action by preimages of a flow morphism.

Note also that for P and Γ as in Theorem 2.1, the map ψ from P onto P/Γ satisfies conditions (i)–(iii) by definition, and condition (iv) by Theorem 2.2. Therefore, ψ is a flow morphism from P onto P/Γ .

To achieve our aims, we first find a group acting on $C[n, r, I]$ which preserves its rank and partial order and obtain a quotient poset of $C[n, r, I]$, written as $\overline{C}[n, r, I]$. Next, we construct a flow morphism from $\overline{C}[n, r, I]$ to another “smaller” poset. Then Theorems 2.2 and 2.4 are seen to be applicable.

In the remainder of this section we shall introduce the group, describe the quotient poset $\overline{C}[n, r, I]$, and determine its weight function.

Let $GL(V)$ denote the general linear group over V consisting of all invertible linear transformations of V . Set $X = (V_1, \dots, V_r)$ and let $GL(X|V)$ denote the subgroup of $GL(V)$ that fixes every V_i for $1 \leq i \leq r$. It is easily seen that $GL(X|V)$ induces an order preserving permutation group acting on $C[n, r, I]$.

For any nonnegative integers $i_1, i_2, \dots, i_r$, let $\langle i_1, i_2, \dots, i_r \rangle$ denote the set of all subspaces $A \in C[n, r, I]$ such that $\dim(A) = i_1 + i_2 + \dots + i_r$ and $\dim(A \cap V_j) = i_1 + i_2 + \dots + i_j$. Then $\langle i_1, i_2, \dots, i_r \rangle$ is an orbit of $GL(X|V)$ and

$$C[n, r, I] = \bigcup_{i_j \in \mathcal{I}_j} \langle i_1, i_2, \dots, i_r \rangle.$$

Then we obtain the quotient poset as follows:

$$\overline{C}[n, r, I] = C[n, r, I]/GL(X|V) = \{\langle i_1, i_2, \dots, i_r \rangle : i_j \in \mathcal{I}_j\},$$

the ordering of which is defined as

$$\langle i_1, i_2, \dots, i_r \rangle \leq \langle i'_1, i'_2, \dots, i'_r \rangle \text{ if and only if } i_j \leq i'_j \text{ for } j = 1, \dots, r.$$

In order to obtain a suitable weight function for $\overline{C}[n, r, I]$ we introduce a few notations.

Define $\{1\} = 1$, $\{i\} = 1 + q + \dots + q^{i-1} = \frac{q^i - 1}{q - 1}$, and $\{i\}! = \{1\}\{2\}\dots\{i\}$. Then $\begin{bmatrix} n \\ m \end{bmatrix} := \frac{\{n\}!}{\{n-m\}!\{m\}!}$, the q -binomial coefficient, which enumerates the number of the m -subspaces of V . For convenience, we define $\begin{bmatrix} 0 \\ 0 \end{bmatrix} = 1$ and $\begin{bmatrix} i \\ j \end{bmatrix} = 0$ for $i > n$ or $i < 0$.

PROPOSITION 2.5. *Let $\langle i_1, i_2, \dots, i_r \rangle$ be an orbit of $C[n, r, I]$ under $G(X|V)$ and set $\bar{i}_j = k_j - i_j$, $j = 1, \dots, r$. Then the cardinality of $\langle i_1, i_2, \dots, i_r \rangle$ is given by*

$$\# \langle i_1, i_2, \dots, i_r \rangle = \begin{bmatrix} k_1 \\ i_1 \end{bmatrix} \dots \begin{bmatrix} k_r \\ i_r \end{bmatrix} q^{i_2 \bar{i}_1 + i_3 (\bar{i}_1 + \bar{i}_2) + \dots + i_r (\bar{i}_1 + \dots + \bar{i}_{r-1})}.$$

Proof. Set $\ell = i_1 + \dots + i_r$. If $r = 1$, then the result is trivial. Suppose $r > 1$ and let Z be an arbitrarily selected subspace of V_{r-1} with $\dim(Z) = i_1 + \dots + i_{r-1}$. As a little generalization of Proposition 2.2 in [2], it is straightforward that there are $\begin{bmatrix} k_r \\ i_r \end{bmatrix} q^{i_r (\bar{i}_1 + \dots + \bar{i}_{r-1})}$ ℓ -dimensional subspaces Y of $V_r = V$ such that $Y \cap V_{r-1} = Z$. If $r = 2$, then $\dim(Z) = i_1$ and we have $\begin{bmatrix} k_1 \\ i_1 \end{bmatrix}$ choices for Z , which implies the results. Suppose $r > 2$ and the result holds for $r - 1$. This means that in V_{r-1} , there are $\begin{bmatrix} k_1 \\ i_1 \end{bmatrix} \dots \begin{bmatrix} k_{r-1} \\ i_{r-1} \end{bmatrix} q^{i_2 \bar{i}_1 + i_3 (\bar{i}_1 + \bar{i}_2) + \dots + i_{r-1} (\bar{i}_1 + \dots + \bar{i}_{r-2})}$ subspaces Z with $\dim(Z) = i_1 + \dots + i_{r-1}$ such that $\dim(Z \cap V_j) - \dim(Z \cap V_{j-1}) = i_j$ for $j = 1, \dots, r - 1$. $\square$

For $1 \leq t \leq r$, set $n_t = k_1 + \dots + k_t$, $I_t = (\mathcal{I}_1, \dots, \mathcal{I}_t)$ and $X_t = (V_1, \dots, V_t)$. Define $C[n_t, t, I_t] = \{K \in L(V_t) : \dim(K \cap V_i) - \dim(K \cap V_{i-1}) \in \mathcal{I}_i, i = 1, 2, \dots, t\}$ and $\bar{C}[n_t, t, I_t]$ the quotient poset of $C[n_t, t, I_t]$ under the action of the group $GL(X_t|V_t)$. Also, we define a weight function on $\bar{C}[n_t, t, I_t]$ as

$$w_t(\langle i_1, \dots, i_t \rangle) = \begin{bmatrix} k_1 \\ i_1 \end{bmatrix} \dots \begin{bmatrix} k_t \\ i_t \end{bmatrix} q^{i_2 \bar{i}_1 + i_3 (\bar{i}_1 + \bar{i}_2) + \dots + i_t (\bar{i}_1 + \dots + \bar{i}_{t-1})}.$$

For $0 \leq \ell \leq n_t$, put $\bar{C}[n_t, t, I_t]_\ell = \{\langle i_1, i_2, \dots, i_t \rangle \in \bar{C}[n_t, t, I_t] : i_1 + i_2 + \dots + i_t = \ell\}$ and let $W_{(\ell, t)}$ denote the weight of $\bar{C}[n_t, t, I_t]_\ell$, that is,

$$W_{(\ell, t)} = \sum_{\mu \in \bar{C}[n_t, t, I_t]_\ell} w_t(\mu).$$

3. Log concavity of $C[n, r, I]$. We first present two lemmas.

LEMMA 3.1 (see [1]). *For $m \leq l$,*

$$\begin{bmatrix} n \\ m \end{bmatrix} \begin{bmatrix} n \\ l \end{bmatrix} - q^{l-m+1} \begin{bmatrix} n \\ m-1 \end{bmatrix} \begin{bmatrix} n \\ l+1 \end{bmatrix}$$

has nonnegative coefficients as a polynomial in q .

LEMMA 3.2. *Let $\{x_i\}_{i=0}^\infty$ be a sequence of positive numbers and let I be a subinterval of $[0, k]$ for an integer $k > 0$. If $x_i^2 \geq qx_{i-1}x_{i+1}$ for $i \geq 1$, then $y_\ell^2 \geq qy_{\ell-1}y_{\ell+1}$, where y_ℓ ($\ell \geq 1$) is defined to be*

$$y_\ell = \sum_{i \in I} x_{\ell-i} \begin{bmatrix} k \\ i \end{bmatrix} q^{i(n-\ell+i)}.$$

Proof. Put $a_i = x_i q^{i^2/2}$ for $i \geq 0$ and $b_i = \begin{bmatrix} k \\ i \end{bmatrix} q^{in+i^2/2}$ if $i \in I$ and $b_i = 0$ if $i \geq 0$ but $i \notin I$. It is easy to check that both $\{a_i\}_{i=0}^\infty$ and $\{b_i\}_{i=0}^\infty$ are log concave. Set $z_\ell = \sum_{i=0}^\ell a_{\ell-i} b_i$ for $\ell \geq 0$. Then $\{z_\ell\}_{\ell=0}^\infty$ is log concave by the *convolution theorem* of log concave sequences (see [10] or [12]). Moreover, we have that

$$\begin{aligned} y_\ell &= \sum_{i \in I} x_{\ell-i} \begin{bmatrix} k \\ i \end{bmatrix} q^{i(n-\ell+i)} \\ &= \sum_{i=0}^\ell a_{\ell-i} b_i q^{-\ell^2/2} \\ &= z_\ell q^{-\ell^2/2}. \end{aligned}$$

The log concavity of $\{z_\ell\}_{\ell=0}^\infty$ implies that $y_\ell^2 \geq qy_{\ell-1}y_{\ell+1}$ for $\ell \geq 1$. $\square$

Recall that $W_{(\ell, t)}$ denotes the Whitney numbers of $C[n_t, t, I_t]$ for $1 \leq t \leq r$.

THEOREM 3.3. *We have that*

$$W_{(\ell, r)}^2 \geq qW_{(\ell-1, r)}W_{(\ell+1, r)}.$$

Hence $C[n, r, I]$ is log concave and unimodal.

Proof. We apply induction on r . When $r = 1$, $W_{(\ell, 1)} = \begin{bmatrix} k_1 \\ \ell \end{bmatrix}$. Then the statement holds true by Lemma 3.1. Suppose $r \geq 2$ and the statement holds for $r - 1$. By Proposition 2.5 we have that

$$\begin{aligned} W_{(\ell, r)} &= \sum_{i_1 + \dots + i_r = \ell} \begin{bmatrix} k_1 \\ i_1 \end{bmatrix} \dots \begin{bmatrix} k_r \\ i_r \end{bmatrix} q^{i_2 \bar{i}_1 + i_3(\bar{i}_1 + \bar{i}_2) + \dots + i_r(\bar{i}_1 + \dots + \bar{i}_{r-1})} \\ &= \sum_{j \in \mathcal{I}_r} W_{(\ell-j, r-1)} \begin{bmatrix} k_r \\ j \end{bmatrix} q^{j(n_{r-1} - \ell + j)}. \end{aligned}$$

Then the assertion follows from the induction and Lemma 3.2. $\square$

4. Normalized matching property of $C[n, r, I]$. We first prove a useful lemma.

LEMMA 4.1. *Let $\{a_i\}_{i=0}^\infty$ and $\{b_i\}_{i=0}^\infty$ be two sequences and a and b be two real numbers. Suppose k_1, k_2, r , and s are indices such that $k_1 \leq r \leq s \leq k_2$. Write*

$$S_k[r, s] = \sum_{r \leq i \leq s} a_i b_{k-i} q^{-(i+a)(k-i+b)}.$$

If $\{a_i\}_{i=0}^\infty$ and $\{b_i\}_{i=0}^\infty$ satisfy that $a_i^2 \geq qa_{i-1}a_{i+1}$ and $b_i^2 \geq qb_{i-1}b_{i+1}$ for $i \geq 1$, then

$$\frac{S_{k+1}[r, s+1]}{S_k[r, s]} \geq \frac{S_{k+1}[k_1, k_2+1]}{S_k[k_1, k_2]}.$$

Proof. By the condition that $a_i^2 \geq qa_{i-1}a_{i+1}$ and $b_i^2 \geq qb_{i-1}b_{i+1}$, we can deduce that

$$(2) \quad \frac{a_j b_{k+1-j} q^{-(j+a)(k+1-j+b)}}{a_j b_{k-j} q^{-(j+a)(k-j+b)}} \leq \frac{a_{j+1} b_{k-j} q^{-(j+1+a)(k-j+b)}}{a_{j+1} b_{k-j-1} q^{-(j+1+a)(k-j-1+b)}}$$

and

$$(3) \quad \frac{a_{j+1} b_{k-j} q^{-(j+1+a)(k-j+b)}}{a_j b_{k-j} q^{-(j+a)(k-j+b)}} \geq \frac{a_{j+2} b_{k-j-1} q^{-(j+2+a)(k-j-1+b)}}{a_{j+1} b_{k-j-1} q^{-(j+1+a)(k-j-1+b)}}.$$

If $k_1 < r$, then by (2) we have

$$\frac{S_{k+1}[r, s+1]}{S_k[r, s]} \leq \frac{S_{k+1}[r-1, s+1]}{S_k[r-1, s]} \leq \dots \leq \frac{S_{k+1}[k_1, s+1]}{S_k[k_1, s]}.$$

If $s < k_2$, then by (3) we have

$$\frac{S_{k+1}[r, s+1]}{S_k[r, s]} \geq \frac{S_{k+1}[r, s+2]}{S_k[r, s+1]} \geq \dots \geq \frac{S_{k+1}[r, k_2+1]}{S_k[r, k_2]}.$$

Then, for each r and s such $k_1 \leq r \leq s \leq k_2$, we have

$$\frac{S_{k+1}[r, s+1]}{S_k[r, s]} \geq \frac{S_{k+1}[k_1, s+1]}{S_k[k_1, s]} \geq \frac{S_{k+1}[k_1, k_2+1]}{S_k[k_1, k_2]}.$$

Thus the statement follows and we complete the proof. $\square$

THEOREM 4.2. $C[n, r, I]$ has the NM property.

Proof. We apply induction on r . When $r = 1$, $C[n, r, I]_\ell = L(V)_\ell$ for $\ell \in I$. Then the statement holds since $L(V)$ has the NM property. Suppose $r \geq 2$ and $C[n_t, t, I_t]$ has the NM property for all $t < r$. We now proceed to prove that $C[n, r, I]$ has the property. By Theorem 2.2 it suffices to prove that $(\overline{C}[n, r, I], w)$ has the NM property.

Let $\Sigma_r = \{i_1 + i_2 + \cdots + i_{r-1} : i_j \in \mathcal{I}_j\}$ and $Q_r = \{(k, j) : k \in \Sigma_r \text{ and } j \in \mathcal{I}_r\}$. Define an order " $\leq$ " on Q_r as follows:

$$(k, j) \leq (k', j') \text{ in } Q_r \text{ if and only if } k \leq k' \text{ and } j \leq j'.$$

Then $(Q_r, \leq)$ is a graded poset of the same rank of that of $\overline{C}[n_r, r, I_r]$.

An order-preserving and rank-preserving map from $\overline{C}[n_r, r, I_r]$ onto Q_r is defined as follows:

$$\phi_r(\langle i_1, i_2, \dots, i_r \rangle) = (i_1 + i_2 + \cdots + i_{r-1}, i_r),$$

and a weight function v_r on Q_r is defined by

$$\begin{aligned} v_r(k, j) &= \sum_{\mu \in \phi^{-1}(k, j)} w_r(\mu) = w_{r-1}(\overline{C}[n_{r-1}, r-1, I_{r-1}]_k) \begin{bmatrix} k_r \\ j \end{bmatrix} q^{j(\bar{i}_1 + \cdots + \bar{i}_{r-1})} \\ (4) \quad &= W_{(k, r-1)} \begin{bmatrix} k_r \\ j \end{bmatrix} q^{j(n_{r-1}-k)}, \end{aligned}$$

where

$$\phi_r^{-1}(k, j) = \{\langle i_1, \dots, i_{r-1}, j \rangle \in \overline{C}[n_r, r, I_r] : i_1 + \cdots + i_{r-1} = k\}.$$

By Theorem 2.4 it suffices to show that ϕ_r is a flow morphism from $\overline{C}[n, r, I]$ onto (Q_r, v_r) and (Q_r, v_r) has the NM property. For brevity, we write $\phi_r = \phi$, $w_r = w$, and $v_r = v$.

First, we show that ϕ is a flow morphism. By definition we see that ϕ satisfies the conditions (i), (ii), and (iii) in Definition 2.3. We prove that it satisfies the fourth one, that is, for any $(k, j), (k+1, j), (k, j+1) \in (Q_r, v)$ (if they, in fact, exist), $\phi^{-1}(k, j) \cup \phi^{-1}(k+1, j)$ and $\phi^{-1}(k, j) \cup \phi^{-1}(k, j+1)$ have the NM property.

- For each $\mu = \langle i_1, \dots, i_{r-1}, j \rangle \in \phi^{-1}(k, j) \cup \phi^{-1}(k+1, j)$, define $f(\mu) = \langle i_1, \dots, i_{r-1} \rangle$, written as $\bar{\mu}$. Then, it is easy to see that f is a poset-isomorphism from $\phi^{-1}(k, j) \cup \phi^{-1}(k+1, j)$ to $\overline{C}[n_{r-1}, r-1, I_{r-1}]_k \cup \overline{C}[n_{r-1}, r-1, I_{r-1}]_{k+1}$. Also, for each $\mu \in \phi^{-1}(k, j) \cup \phi^{-1}(k+1, j)$, by Proposition 2.5 we have that

$$w(\mu) = w_{r-1}(\bar{\mu}) \begin{bmatrix} k_r \\ j \end{bmatrix} q^{j(n_{r-1}-k')},$$

where $k' = k$ if $\mu \in \phi^{-1}(k, j)$ and $k' = k+1$ if $\mu \in \phi^{-1}(k+1, j)$. Then, for each $S \subseteq \phi^{-1}(k, j)$, it is easy to verify that

$$\frac{w(\nabla(S))}{w(S)} = q^{-j} \frac{w_{r-1}(\overline{\nabla(S)})}{w_{r-1}(\overline{S})},$$

from which, along with induction, we obtain that $\phi^{-1}(k, j) \cup \phi^{-1}(k+1, j)$ has the NM property.

- If $(k, j), (k, j+1) \in Q_r$, it is easy to see that for $\mu = \langle i_1, \dots, i_{r-1}, j \rangle \in \phi^{-1}(k, j)$, there exists only $\nu = \langle i_1, \dots, i_{r-1}, j+1 \rangle \in \phi^{-1}(k, j+1)$ which covers μ , and from Proposition 2.5 it follows that

$$\frac{w(\nu)}{w(\mu)} = \frac{\begin{bmatrix} k_r \\ j+1 \end{bmatrix}}{\begin{bmatrix} k_r \\ j \end{bmatrix}} q^{(n_{r-1}-k)},$$

a constant. This implies that $\phi^{-1}(k, j) \cup \phi^{-1}(k, j+1)$ has the NM property. Hence ϕ is a flow morphism.

Next, we show that (Q_r, v) has the NM property.

Let $Q_{r,\ell} = \{(i, j) \in Q_r : i+j = \ell\}$, written as $\{(i_0, j_0), (i_0-1, j_0+1), \dots, (i_1, j_1)\}$. Let $T = \{(a, \ell-a), (a-1, \ell-a+1), \dots, (b, \ell-b)\} \subseteq Q_{r,\ell}$, where $i_1 \leq b \leq a \leq i_0$. If $(a+1, \ell-a) \notin Q_{r,\ell+1-a}$, then $W_{(r-1, a+1)} = 0$. For $i \geq 0$, set

$$\begin{bmatrix} k_r \\ i \end{bmatrix}' = \begin{cases} \begin{bmatrix} k_r \\ i \end{bmatrix} & \text{if } i \in \mathcal{I}_r, \\ 0 & \text{otherwise.} \end{cases}$$

Then, we have that

$$v(T) = \sum_{b \leq i \leq a} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell - i' q^{-(i-n_{r-1})(\ell-i)}$$

and

$$v(\nabla(T)) = \sum_{b \leq i \leq a+1} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell + 1 - i' q^{-(i-n_{r-1})(\ell+1-i)}.$$

Moreover, it is easy to find that $\begin{bmatrix} k_r \\ i \end{bmatrix}'^2 \geq q \begin{bmatrix} k_r \\ i-1 \end{bmatrix}' \begin{bmatrix} k_r \\ i+1 \end{bmatrix}'$ for all $i \geq 1$. Then, by Theorem 3.3 and Lemmas 3.1 and 4.1 we obtain that

$$\begin{aligned} \frac{v(\nabla(T))}{v(T)} &= \frac{\sum_{b \leq i \leq a+1} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell + 1 - i' q^{-(i-n_{r-1})(\ell+1-i)}}{\sum_{b \leq i \leq a} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell - i' q^{-(i-n_{r-1})(\ell-i)}} \\ &\geq \frac{\sum_{i_1 \leq i \leq i_0+1} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell + 1 - i' q^{-(i-n_{r-1})(\ell+1-i)}}{\sum_{i_1 \leq i \leq i_0} W_{(i, r-1)} \begin{bmatrix} k_r \end{bmatrix} \ell - i' q^{-(i-n_{r-1})(\ell-i)}} \\ (5) \quad &= \frac{v(Q_{r, \ell+1})}{v(Q_{r, \ell})}. \end{aligned}$$

Given a subset M of $Q_{r,\ell}$, let $M = T_1 \cup T_2 \cup \dots \cup T_r$ ($r \geq 1$), where $T_k = \{(a_k, \ell - a_k), (a_k - 1, \ell - a_k + 1), \dots, (b_k, \ell - b_k)\}$ ($k = 1, 2, \dots, r$), $i_1 \leq b_1 \leq a_1 < b_2 \leq a_2 < \dots < b_r \leq a_r \leq i_0$. Then $T_i \cap T_j = \emptyset$ and $\nabla(T_i) \cap \nabla(T_j) = \emptyset$ for $i \neq j$. We thus obtain that $v(M) = v(T_1) + \dots + v(T_r)$ and $v(\nabla(M)) = v(\nabla(T_1)) + \dots + v(\nabla(T_r))$. Then the inequality $\frac{v(\nabla(M))}{v(M)} \geq \frac{v(Q_{r, \ell+1})}{v(Q_{r, \ell})}$ follows from (5). Thus (Q_r, v) has the NM property, which completes the proof. $\square$

MATROID PATHWIDTH AND CODE TRELLIS COMPLEXITY*

NAVIN KASHYAP†

Abstract. We relate the notion of matroid pathwidth to the minimum trellis state-complexity (which we term trellis-width) of a linear code and to the pathwidth of a graph. By reducing from the problem of computing the pathwidth of a graph, we show that the problem of determining the pathwidth of a representable matroid is NP-hard. Consequently, the problem of computing the trellis-width of a linear code is also NP-hard. For a finite field $\mathbb{F}$, we also consider the class of $\mathbb{F}$ -representable matroids of pathwidth at most w , and correspondingly, the family of linear codes over $\mathbb{F}$ with trellis-width at most w . These are easily seen to be minor-closed. Since these matroids (and codes) have branchwidth at most w , a result of Geelen and Whittle shows that such matroids (and the corresponding codes) are characterized by finitely many excluded minors. We provide the complete list of excluded minors for $w = 1$ and give a partial list for $w = 2$.

Key words. matroids, pathwidth, linear codes, trellis complexity, NP-hard

1. Introduction. The notion of pathwidth of a matroid has received some recent attention in the matroid theory literature [7], [9]. This notion has long been studied in coding theory literature, where it is used as a measure of trellis complexity of a linear code [13], [5], [16]. However, there appears to be no standard coding-theoretic nomenclature for this notion. It has been called the state complexity of a code in [10], but the use of this term there conflicts slightly with its use in [16]. So to avoid ambiguity, we will give it a new name here—*trellis-width*—which acknowledges its roots in trellis complexity.

The relationship between matroid pathwidth and code trellis-width can be made precise as follows. To an arbitrary linear code $\mathcal{C}$ over a finite field $\mathbb{F}$, we associate a matroid, $M(\mathcal{C})$, which is simply the vector matroid, over $\mathbb{F}$, of any generator matrix of the code. Recall that in coding theory, a matrix G is called a generator matrix of a code $\mathcal{C}$ if $\mathcal{C}$ is the row space of G . Consequently, the matroid $M(\mathcal{C})$ does not depend on the actual choice of the generator matrix and, therefore, is a characteristic of the code $\mathcal{C}$. The code $\mathcal{C}$ may in fact be viewed as a representation over $\mathbb{F}$ of the matroid $M(\mathcal{C})$. The trellis-width of $\mathcal{C}$ is simply the pathwidth of $M(\mathcal{C})$; we will give the precise definition of matroid pathwidth in section 2.2.

It has repeatedly been conjectured in coding theory literature that computing the trellis-width of a linear code over a fixed finite field $\mathbb{F}$ is NP-hard [10], [11], [16, section 5]. This would imply that the corresponding decision problem (over a fixed finite field $\mathbb{F}$)—given a generator matrix for a code $\mathcal{C}$ over $\mathbb{F}$, and a positive integer w , deciding whether or not the trellis-width of $\mathcal{C}$ is at most w —is NP-complete. This decision problem has been given various names—“Maximum Partition Rank Permutation” [10], “Maximum Width” [11], and “Trellis State-Complexity” [16].

An equivalent statement of the trellis-width conjecture is the following:
 given a matrix A over $\mathbb{F}$, the problem of computing the pathwidth of
 the vector matroid $M[A]$ is NP-hard.

In this paper, we prove the above statement for any fixed field $\mathbb{F}$, not necessarily finite. Our proof is by reduction from the problem of computing the pathwidth of a graph, which is known to be NP-hard [1], [2]. Thus, in particular, computing the trellis-width of a linear code over $\mathbb{F}$ is NP-hard, which settles the aforementioned coding-theoretic conjecture.

The situation is rather different if we weaken the trellis-width decision problem above by *not* considering the integer w to be a part of the input to the problem. In other words, for a fixed finite field $\mathbb{F}$ and a *fixed* integer $w > 0$, consider the following problem:

given a length- n linear code $\mathcal{C}$ over $\mathbb{F}$, decide whether or not $\mathcal{C}$ has
 trellis-width at most w .

The equivalent decision problem for matroid pathwidth would be to decide (for a fixed finite field $\mathbb{F}$ and integer $w > 0$) whether or not a given $\mathbb{F}$ -representable matroid has pathwidth at most w . Based on results from the structure theory of matroids [6], we strongly believe that these problems are solvable in polynomial time.

In the process of studying matroids of bounded pathwidth, we observe that for any finite field $\mathbb{F}_q = GF(q)$ and integer $w > 0$, the class, $\mathcal{P}_{w,q}$, of $\mathbb{F}_q$ -representable matroids having pathwidth at most w , is minor-closed and has finitely many excluded minors. As a relatively easy exercise, we show that the list of excluded minors for $\mathcal{P}_{1,q}$ consists of¹ $U_{2,4}$, $M(K_4)$, $M(K_{2,3})$, and $M^*(K_{2,3})$. Unfortunately, the problem of finding excluded-minor characterizations of $\mathcal{P}_{w,q}$ for $w > 1$ becomes difficult very quickly. We give a list of excluded minors for $\mathcal{P}_{2,q}$, which is probably not complete.

The rest of the paper is organized as follows. In section 2, we lay down the definitions and notation used in the paper. In section 3, we prove that, for any fixed field $\mathbb{F}$, the problem of computing the pathwidth of an $\mathbb{F}$ -representable matroid is NP-hard, and therefore, so is the problem of computing the trellis-width of a linear code over $\mathbb{F}$. Finally, in section 4, we consider the class of matroids $\mathcal{P}_{w,q}$. We give the complete lists of excluded minors for $\mathcal{P}_{1,q}$ and the corresponding family of linear codes over $\mathbb{F}_q$ having trellis-width at most one. We also give a partial list of excluded minors for $\mathcal{P}_{2,q}$.

2. Preliminaries. We assume familiarity with the basic definitions and notation of matroid theory, as expounded by Oxley [14]. The main results and proofs in this paper will be given in the language of matroid theory, rather than that of coding theory, as it is easier to do so. However, as our results may be of some interest to coding theorists, we make an effort in this section to provide the vocabulary necessary to translate the language of matroid theory into that of coding theory. Definitions of coding-theoretic terms not explicitly defined here can be found in any text on coding theory (e.g., [12]).

2.1. Codes and their associated matroids. Let $\mathcal{C}$ be a linear code of length n over the finite field $\mathbb{F}_q = GF(q)$. The dimension of $\mathcal{C}$ is denoted by $\dim(\mathcal{C})$, and the coordinates of $\mathcal{C}$ are indexed by the integers from the set $[n] = \{1, 2, \dots, n\}$ as usual. We will also associate with the coordinates of $\mathcal{C}$ a set, $E(\mathcal{C})$, of *coordinate labels*, so

¹In this paper, we take the connectivity function of a matroid M with ground set E and rank function r to be $\lambda_M(X) = r(X) + r(E - X) - r(E)$ for $X \subseteq E$. Therefore, what we consider to be matroids of pathwidth one would be matroids of pathwidth two in [7], [9].

that there is a bijection $\alpha_C : [n] \rightarrow E(C)$. The *label sequence* of C is defined to be the n -tuple $(\alpha_1, \alpha_2, \dots, \alpha_n)$, where $\alpha_i = \alpha_C(i)$. For notational convenience, we will simply let α_C denote the label sequence of C . Unless specified otherwise (as in the case of code minors and duals below), we will, by default, set $E(C)$ to be $[n]$, and α_C to be the n -tuple $(1, 2, 3, \dots, n)$. In such a case, the label of each coordinate is the same as its index.

Given a code C over $\mathbb{F}_q$, specified by a generator matrix G , we define its *associated matroid* $M(C)$ to be the vector matroid, $M[G]$, of G . We identify the ground set of $M(C)$ with $E(C)$. Note that if G and G' are distinct generator matrices of the code C , then $M[G] = M[G']$, and hence, $M(C)$ is independent of the choice of generator matrix. Thus, any generator matrix of C is an $\mathbb{F}_q$ -representation of $M(C)$.

Conversely, if M is an $\mathbb{F}_q$ -representable matroid and G is an $\mathbb{F}_q$ -representation of M , then $M = M(C)$ for the code C generated by G . Thus, each $\mathbb{F}_q$ -representable matroid is associated with some code C over $\mathbb{F}_q$.

For any code C , the dual code, $C^\perp$, is specified to have the same label sequence as C , i.e., $\alpha_{C^\perp} = \alpha_C$. It is a particularly nice fact [14, Theorem 2.2.8] that the matroids associated with C and $C^\perp$ are dual to each other, i.e., $M(C^\perp) = (M(C))^* \stackrel{\text{def}}{=} M^*(C)$.

Given a $J \subseteq E(C)$, we will denote by $C \setminus J$ (resp., C/J) the code obtained from C by puncturing (resp., shortening at) those coordinates having labels in J . Thus, $C/J = (C^\perp \setminus J)^\perp$. A *minor* of C is a code of the form $C/X \setminus Y$ for disjoint subsets $X, Y \subseteq E(C)$. A minor of C that is not C itself is called a *proper minor* of C . The coordinates of a minor of C retain their labels from $E(C)$. More precisely, we set $E(C/X \setminus Y) = E(C) - (X \cup Y)$, and take the label sequence of $C/X \setminus Y$ to be the $(n - |X \cup Y|)$ -tuple obtained from $\alpha_C = (\alpha_1, \alpha_2, \dots, \alpha_n)$ by simply removing those entries that are in $X \cup Y$. The operations of puncturing and shortening correspond to the matroid-theoretic operations of deletion and contraction, respectively: for $J \subseteq E(C)$,

$$M(C \setminus J) = M(C) \setminus J \quad \text{and} \quad M(C/J) = M(C)/J.$$

We will find it convenient to use $C|_J$ to denote the restriction of C to the coordinates with labels in J , i.e., $C|_J = C \setminus J^c$, where J^c denotes the set difference $E(C) - J$. This allows us to express the rank function, $r : E(C) \rightarrow \mathbb{Z}$, of the matroid $M(C)$ as follows: for $J \subseteq E(C)$, $r(J) = \dim(C|_J)$.

Two length- n linear codes C and C' over $\mathbb{F}_q$ are defined to be *equivalent* if there is an $n \times n$ permutation matrix Π and an invertible $n \times n$ diagonal matrix Δ such that C' is the image of C under the vector space isomorphism $\phi : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^n$ defined by $\phi(\mathbf{x}) = (\Pi\Delta)\mathbf{x}$. Informally, C' is equivalent to C if C' can be obtained by first multiplying the coordinates of C by some nonzero elements of $\mathbb{F}_q$, and then applying a coordinate permutation. In such a case, we write $C \equiv C'$. The equivalence class of codes equivalent to C will be denoted by $[C]$. It is clear that if codes C and C' are equivalent, then their associated matroids are isomorphic.

We remark that code equivalence has been defined above according to the coding-theoretic convention. Note that, under this definition, if C' is obtained by applying an automorphism of the field $\mathbb{F}_q$ to C , then C and C' would, in general, be considered to be inequivalent.

A family, $\mathfrak{C}$, of codes over $\mathbb{F}_q$ is said to be *minor-closed* if, for each $C \in \mathfrak{C}$, any code equivalent to a minor of C is also in $\mathfrak{C}$. A code, $\mathcal{D}$, over $\mathbb{F}_q$ is said to be an *excluded minor* for a minor-closed family $\mathfrak{C}$ if $\mathcal{D} \notin \mathfrak{C}$, but every proper minor of $\mathcal{D}$ is

in $\mathfrak{C}$. It is easily verified that if $\mathfrak{C}$ is a minor-closed family, then a code $\mathcal{C}$ is in $\mathfrak{C}$ iff no minor of $\mathcal{C}$ is an excluded minor for $\mathfrak{C}$.

Given a collection, $\mathcal{M}$, of $\mathbb{F}_q$ -representable matroids, define the code family

$$(1) \quad \mathfrak{C}(\mathcal{M}) = \{\mathcal{C} : \mathcal{C} \text{ is a linear code over } \mathbb{F}_q \text{ such that } M(\mathcal{C}) \in \mathcal{M}\}.$$

Evidently, if $\mathcal{M}$ is a minor-closed class of $\mathbb{F}_q$ -representable matroids, then $\mathfrak{C}(\mathcal{M})$ is also minor-closed. In this case, if $\mathcal{F}$ is the set of all excluded minors for $\mathcal{M}$, then $\mathfrak{C}(\mathcal{F})$ is the set of all excluded minors for $\mathfrak{C}(\mathcal{M})$.

2.2. Pathwidth, trellis-width, and branchwidth. The definitions in this section rely on the notion of the connectivity function of a matroid. Let M be a matroid with ground set $E(M)$ and rank function r_M . Its *connectivity function*, λ_M , is defined by $\lambda_M(X) = r_M(X) + r_M(E(M) - X) - r_M(E(M))$ for $X \subseteq E(M)$. Note that $\lambda_M(X) = \lambda_M(E(M) - X)$ and $\lambda_M(E(M)) = \lambda_M(\emptyset) = 0$. It should be pointed out that in the matroid theory literature, the prevalent definition of the connectivity function adds a “+1” to the expression we have given. We have chosen not to follow suit in order that we can give a minimum-fuss definition of trellis-width below.

The connectivity function is nonnegative, i.e., $\lambda_M(X) \geq 0$ for all $X \subseteq E(M)$, and submodular, i.e., $\lambda_M(X \cup Y) + \lambda_M(X \cap Y) \leq \lambda_M(X) + \lambda_M(Y)$ for all $X, Y \subseteq E(M)$. It is monotone under the action of taking minors—if N is a minor of M , then for all $X \subseteq E(N)$, $\lambda_N(X) \leq \lambda_M(X)$. Finally, the connectivity function of a matroid is identical to that of its dual, i.e., $\lambda_M(X) = \lambda_{M^*}(X)$ for all $X \subseteq E(M)$.

Given an ordering $(e_1, e_2, \dots, e_n)$ of the elements of M , define the *width* of the ordering to be $w_M(e_1, e_2, \dots, e_n) = \max_{i \in [n]} \lambda_M(e_1, e_2, \dots, e_i)$. (For simplicity of notation, we use $\lambda_M(e_1, e_2, \dots, e_i)$ instead of $\lambda_M(\{e_1, e_2, \dots, e_i\})$.) The *pathwidth* of M is defined as $\text{pw}(M) = \min w_M(e_1, e_2, \dots, e_n)$, the minimum being taken over all orderings $(e_1, e_2, \dots, e_n)$ of $E(M)$. An ordering $(e_1, e_2, \dots, e_n)$ of $E(M)$ such that $w_M(e_1, e_2, \dots, e_n) = \text{pw}(M)$ is called an *optimal* ordering.

Since $\lambda_M \equiv \lambda_{M^*}$, it is clear that $\text{pw}(M) = \text{pw}(M^*)$. Another useful and easily verifiable property of pathwidth is that, for matroids M_1 and M_2 , the pathwidth of their direct sum, $\text{pw}(M_1 \oplus M_2)$, equals $\max\{\text{pw}(M_1), \text{pw}(M_2)\}$. The property of pathwidth most important for our purposes is stated in the following lemma.

LEMMA 2.1. *If N is a minor of M , then $\text{pw}(N) \leq \text{pw}(M)$.*

Proof. Let $(e_1, \dots, e_n)$ be an optimal ordering of $E(M)$. It is enough to show the result in the case when $N = M \setminus e_i$ or $N = M/e_i$ for some $i \in [n]$. In such a case, consider the ordering $(e_1, \dots, e_{i-1}, e_{i+1}, \dots, e_n)$ of $E(N)$. For $j \in \{1, \dots, i-1\}$, we have $\lambda_N(e_1, \dots, e_j) \leq \lambda_M(e_1, \dots, e_j)$. For $j \in \{i+1, \dots, n\}$, we have

$$\begin{aligned} \lambda_N(e_1, \dots, e_{i-1}, e_{i+1}, \dots, e_j) &= \lambda_N(e_{j+1}, \dots, e_n) \\ &\leq \lambda_M(e_{j+1}, \dots, e_n) = \lambda_M(e_1, \dots, e_j). \end{aligned}$$

It follows that $w_N(e_1, \dots, e_{i-1}, e_{i+1}, \dots, e_n) \leq w_M(e_1, \dots, e_n) = \text{pw}(M)$, and hence, $\text{pw}(N) \leq \text{pw}(M)$. $\square$

The *trellis-width* of a linear code $\mathcal{C}$ over $\mathbb{F}_q$ is defined to be $\text{tw}(\mathcal{C}) = \text{pw}(M(\mathcal{C}))$. For a discussion of the motivation and practical implications of this definition, we refer the reader to [16, section 5].

The pathwidth of a matroid is an upper bound on its branchwidth, a more well-known measure of matroid complexity. The branchwidth of a matroid is defined via cubic trees. A *cubic tree* is a tree in which the degree of any vertex is either one or three. The vertices of degree one are called *leaves*. A *branch-decomposition* of a

FIG. 1. A branch-decomposition of M having width equal to $w_M(e_1, e_2, \dots, e_n)$.

matroid M is a cubic tree, T , with $|E(M)|$ leaves, labelled in a one-to-one fashion by the elements of M . Each edge e of such a branch-decomposition T connects two subtrees of T , so $T \setminus e$ has two components. We say that edge e *displays* a subset $X \subseteq E(M)$ if X is the set of labels of leaves of one of the components of $T \setminus e$. The *width* of an edge e of T is defined to be $\lambda_M(X)$, where X is one of the label sets displayed by e . The *width* of T is the maximum among the widths of its edges.

The *branchwidth* of M is the minimum among the widths of all its branch-decompositions. Note that if T is the branch-decomposition of M shown in Figure 1, then the width of T is precisely $w_M(e_1, e_2, \dots, e_n)$. Indeed, the width of any edge of T is either $\lambda_M(e_i)$ or $\lambda_M(e_1, \dots, e_i)$ for some $i \in [n]$. Now, for any $i \in [n]$,

$$\begin{aligned} \lambda_M(e_1, \dots, e_{i-1}) + \lambda_M(e_1, \dots, e_i) &= \lambda_M(e_i, e_{i+1}, \dots, e_n) + \lambda_M(e_1, \dots, e_i) \\ &\geq \lambda_M(E(M)) + \lambda_M(e_i) = \lambda_M(e_i), \end{aligned}$$

the inequality above arising from the submodularity of λ_M . Since $\lambda_M(e_i) \in \{0, 1\}$, either $\lambda_M(e_1, \dots, e_{i-1})$ or $\lambda_M(e_1, \dots, e_i)$ is at least as large as $\lambda_M(e_i)$. Therefore, the width of T is given by $\max_{i \in [n]} \lambda_M(e_1, \dots, e_i) = w_M(e_1, \dots, e_n)$. It follows that the branchwidth of M is bounded from above by $\text{pw}(M)$.

3. NP-hardness of matroid pathwidth and code trellis-width. In this section, we prove that for any fixed field $\mathbb{F}$, the problem of computing the pathwidth of an $\mathbb{F}$ -representable matroid M , given a representation of M over $\mathbb{F}$, is NP-hard. We accomplish this by reduction from the known NP-hard problem of computing the pathwidth of a graph [1], [2].

The notion of graph pathwidth was introduced by Robertson and Seymour in [15]. Let $\mathcal{G}$ be a graph with vertex set V . An ordered collection $\mathcal{V} = (V_1, \dots, V_t)$, $t \geq 1$, of subsets of V is called a *path-decomposition* of $\mathcal{G}$ if

- (i) $\bigcup_{i=1}^t V_i = V$;
- (ii) for each pair of adjacent vertices $u, v \in V$, we have $\{u, v\} \subseteq V_i$ for some $i \in [t]$; and
- (iii) for $1 \leq i < j < k \leq t$, $V_i \cap V_k \subseteq V_j$.

The *width* of such a path-decomposition $\mathcal{V}$ is defined to be $w_{\mathcal{G}}(\mathcal{V}) = \max_{i \in [t]} |V_i| - 1$. The *pathwidth* of $\mathcal{G}$, denoted by $\text{pw}(\mathcal{G})$, is the minimum among the widths of all its path-decompositions. A path-decomposition $\mathcal{V}$ such that $w_{\mathcal{G}}(\mathcal{V}) = \text{pw}(\mathcal{G})$ is called an *optimal* path-decomposition of $\mathcal{G}$.

Let $\mathbb{F}$ be an arbitrary field. Given a graph $\mathcal{G}$ with vertex set V , our aim is to produce, in time polynomial in $|V|$, a matrix A over $\mathbb{F}$ such that $\text{pw}(\mathcal{G})$ can be directly computed from $\text{pw}(M[A])$. The NP-hardness of computing graph pathwidth then implies the NP-hardness of computing the pathwidth of an $\mathbb{F}$ -representable matroid.

The obvious idea of taking A to be a representation of the cycle matroid of $\mathcal{G}$ does not work. As observed by Robertson and Seymour [15], trees can have arbitrarily large pathwidth; however, the cycle matroid of any tree is $U_{n,n}$ for some n , and $\text{pw}(U_{n,n}) = 0$. What actually turns out to work is to take A to be a representation of

 FIG. 2. Construction of $\mathcal{G}'$ from $\mathcal{G}$.

 FIG. 3. Construction of $\bar{\mathcal{G}}$ from $\mathcal{G}'$.

the cycle matroid of a certain graph constructible from $\mathcal{G}$ in polynomial time, as we describe next.

Let $\mathcal{G}'$ be a graph defined on the same vertex set, V , as $\mathcal{G}$, having the following properties (see Figure 2):

- (P1) $\mathcal{G}'$ is loopless;
- (P2) a pair of distinct vertices is adjacent in $\mathcal{G}'$ iff it is adjacent in $\mathcal{G}$; and
- (P3) in $\mathcal{G}'$, there are exactly two edges between each pair of adjacent vertices.

It is evident from the definition that $(V_1, \dots, V_t)$ is a path-decomposition of $\mathcal{G}$ iff it is a path-decomposition of $\mathcal{G}'$. Therefore, $\text{pw}(\mathcal{G}') = \text{pw}(\mathcal{G})$.

Define $\bar{\mathcal{G}}$ to be the graph obtained by adding an extra vertex, henceforth denoted by x to $\mathcal{G}'$, along with a pair of parallel edges from x to each $v \in V$ (see Figure 3). Clearly, $\bar{\mathcal{G}}$ is constructible directly from $\mathcal{G}$ in $O(|V|^2)$ time. But more importantly, the pathwidth of the cycle matroid, $M(\bar{\mathcal{G}})$, of $\bar{\mathcal{G}}$ relates very simply to the pathwidth of $\mathcal{G}$, as made precise by the following proposition.

PROPOSITION 3.1. $\text{pw}(M(\bar{\mathcal{G}})) = \text{pw}(\mathcal{G}) + 1$.

Before proving the result, we present some of its implications. For any field $\mathbb{F}$, $M(\bar{\mathcal{G}})$ is $\mathbb{F}$ -representable. Indeed, if $D(\bar{\mathcal{G}})$ is any directed graph obtained by arbitrarily assigning orientations to the edges of $\bar{\mathcal{G}}$, then the vertex-arc incidence matrix of $D(\bar{\mathcal{G}})$ is an $\mathbb{F}$ -representation of $M(\bar{\mathcal{G}})$ [14, Proposition 5.1.2]. It is easily verified that such an $\mathbb{F}$ -representation of $M(\bar{\mathcal{G}})$ can be constructed directly from $\mathcal{G}$ in $O(|V|^3)$ time. Now, suppose there were a polynomial-time algorithm for computing the pathwidth of an arbitrary $\mathbb{F}$ -representable matroid, given an $\mathbb{F}$ -representation for it. Then, given any graph $\mathcal{G}$, we can construct an $\mathbb{F}$ -representation, A , of $M(\bar{\mathcal{G}})$, and then compute the pathwidth of $M[A] = M(\bar{\mathcal{G}})$, all in polynomial time. Therefore, by Proposition 3.1, we have a polynomial-time algorithm to compute the pathwidth of $\mathcal{G}$. However, the graph pathwidth problem is NP-hard. So, if there exists a polynomial-time algorithm for it, then we must have $P = NP$. This implies the following result.

THEOREM 3.2. *Let $\mathbb{F}$ be a fixed field. The problem of computing the pathwidth of $M[A]$, for an arbitrary matrix A over $\mathbb{F}$, is NP-hard.*

As a corollary, we have that computing the trellis-width of a code is NP-hard.

COROLLARY 3.3. *Let $\mathbb{F}$ be a fixed finite field. The problem of computing the trellis-width of an arbitrary linear code over $\mathbb{F}$, specified by any of its generator matrices, is NP-hard.*

The remainder of this section is devoted to the proof of Proposition 3.1. Since $\text{pw}(\mathcal{G}') = \text{pw}(\mathcal{G})$, for the purpose of our proof, we may assume that $\mathcal{G}' = \mathcal{G}$. Thus, from now until the end of this section, we take $\mathcal{G}$ to be a loopless graph satisfying property (P3) above. Note that $\bar{\mathcal{G}}$ also satisfies (P3). For each pair of adjacent vertices u, v in $\mathcal{G}$ or $\bar{\mathcal{G}}$, we denote by l_{uv} and r_{uv} the two edges between u and v . Let V and E denote the sets of vertices and edges of $\mathcal{G}$, and let $\bar{V}$ and $\bar{E}$ denote the corresponding sets of $\bar{\mathcal{G}}$. We thus have $\bar{V} = V \dot{\cup} \{x\}$ and $\bar{E} = E \dot{\cup} (\bigcup_{v \in V} \{l_{xv}, r_{xv}\})$.

Set $M = M(\bar{\mathcal{G}})$, so that $E(M) = \bar{E}$. Note that since $\bar{\mathcal{G}}$ is connected (each $v \in V$ is adjacent to x), we have $\text{rank}(M) = |\bar{V}| - 1 = |V|$.

We will first prove that $\text{pw}(M) \leq \text{pw}(\mathcal{G}) + 1$. Let $\mathcal{V} = (V_1, \dots, V_t)$ be a path-decomposition of $\mathcal{G}$. We need the following fact about $\mathcal{V}$: for each $j \in [t]$,

$$(2) \quad \bigcup_{i \leq j} V_i \cap \bigcup_{k \geq j} V_k = V_j.$$

The above equality follows from the fact that a path-decomposition, by definition, has the property that for $1 \leq i < j < k \leq t$, $V_i \cap V_k \subseteq V_j$.

For $j \in [t]$, let F_j be the set of edges of $\mathcal{G}$ that have both their endpoints in V_j . By condition (ii) in the definition of path-decomposition, $\bigcup_{j=1}^t F_j = E$. Now, let $\bar{F}_j = F_j \cup (\bigcup_{v \in V_j} \{l_{xv}, r_{xv}\})$, so that $\bigcup_{j=1}^t \bar{F}_j = \bar{E}$.

DEFINITION 3.1. *An ordering $(e_1, \dots, e_n)$ of the elements of a matroid M is said to induce an ordered partition $(E_1, \dots, E_t)$ of $E(M)$ if for each $j \in [t]$, $\{e_{n_{j-1}+1}, e_{n_{j-1}+2}, \dots, e_{n_j}\} = E_j$, where $n_j = |\bigcup_{i \leq j} E_i|$ (and $n_0 = 0$).*

Let $\pi = (e_1, \dots, e_n)$ be any ordering of $\bar{E}$ that induces the ordered partition $(E_1, E_2, \dots, E_t)$, where for each $j \in [t]$, $E_j = \bar{F}_j - \bigcup_{i < j} \bar{F}_i$. We claim that the width of π is at most one more than the width of the path-decomposition $\mathcal{V}$.

LEMMA 3.4. $w_M(\pi) \leq w_{\mathcal{G}}(\mathcal{V}) + 1$.

Proof. Observe first that

$$(3) \quad \begin{aligned} w_M(\pi) &= \max_{j \in [t]} \max_{1 \leq k \leq n_j - n_{j-1}} \lambda_M \left(\bigcup_{i < j} E_i \cup \{e_{n_{j-1}+1}, \dots, e_{n_{j-1}+k}\} \right) \\ &\leq \max_{j \in [t]} \max_{E' \subseteq E_j} \lambda_M \left(\bigcup_{i < j} E_i \cup E' \right). \end{aligned}$$

Let $X = \bigcup_{i < j} E_i \cup E'$ for some $j \in [t]$ and $E' \subseteq E_j$, and consider $\lambda_M(X) = r_M(X) + r_M(\bar{E} - X) - r_M(\bar{E})$. Since $\bar{\mathcal{G}}$ is a connected graph, $r_M(\bar{E}) = |\bar{V}| - 1 = |V|$.

If v is a vertex of $\bar{\mathcal{G}}$ incident with an edge in X , then $v \in \bigcup_{i \leq j} V_i \dot{\cup} \{x\}$. So, the subgraph of $\bar{\mathcal{G}}$ induced by X has its vertices contained in $\bigcup_{i \leq j} V_i \dot{\cup} \{x\}$. Therefore, $r_M(X) \leq |\bigcup_{i \leq j} V_i \dot{\cup} \{x\}| - 1 = |\bigcup_{i \leq j} V_i|$.

Next, consider $\bar{E} - X = (\bigcup_{k>j} E_k) \cup (E_j - E')$. Reasoning as before, the subgraph of $\mathcal{G}$ induced by $\bar{E} - X$ has its vertices contained in $\bigcup_{k \geq j} V_k \cup \{x\}$. Hence, $r_M(\bar{E} - X) \leq |\bigcup_{k \geq j} V_k|$.

Therefore, we have

$$\begin{aligned} \lambda_M(X) &\leq \left| \bigcup_{i \leq j} V_i \right| + \left| \bigcup_{k \geq j} V_k \right| - |V| \\ &= \left| \bigcup_{i \leq j} V_i \cap \bigcup_{k \geq j} V_k \right| = |V_j|, \end{aligned}$$

the last equality arising from (2). Hence, carrying on from (3),

$$w_M(\pi) \leq \max_{j \in [t]} |V_j| = w_{\mathcal{G}}(\mathcal{V}) + 1,$$

as desired. $\square$

The fact that $\text{pw}(M) \leq \text{pw}(\mathcal{G}) + 1$ easily follows from the above lemma. Indeed, we may choose $\mathcal{V}$ to be an optimal path-decomposition of $\mathcal{G}$. Then, by Lemma 3.4, there exists an ordering $(e_1, \dots, e_n)$ of $E(M)$ such that $w_M(e_1, \dots, e_n) \leq \text{pw}(\mathcal{G}) + 1$. Hence, $\text{pw}(M) \leq w_M(e_1, \dots, e_n) \leq \text{pw}(\mathcal{G}) + 1$.

We prove the reverse inequality in two steps, first showing that $\text{pw}(\bar{\mathcal{G}}) = \text{pw}(\mathcal{G}) + 1$, and then showing that $\text{pw}(M) \geq \text{pw}(\bar{\mathcal{G}})$.

LEMMA 3.5. $\text{pw}(\bar{\mathcal{G}}) = \text{pw}(\mathcal{G}) + 1$.

Proof. Clearly, if $\mathcal{V} = (V_1, \dots, V_t)$ is a path-decomposition of $\mathcal{G}$, then $\bar{\mathcal{V}} = (V_1 \cup \{x\}, \dots, V_t \cup \{x\})$ is a path-decomposition of $\bar{\mathcal{G}}$. Hence, choosing $\mathcal{V}$ to be an optimal path-decomposition of $\mathcal{G}$, we have that $\text{pw}(\bar{\mathcal{G}}) \leq w_{\bar{\mathcal{G}}}(\bar{\mathcal{V}}) = w_{\mathcal{G}}(\mathcal{V}) + 1 = \text{pw}(\mathcal{G}) + 1$.

For the inequality in the other direction, we will show that there exists an optimal path-decomposition, $\tilde{\mathcal{V}} = (\tilde{V}_1, \dots, \tilde{V}_s)$, of $\bar{\mathcal{G}}$ such that $x \in \tilde{V}_i$ for all $i \in [s]$. We then have $\mathcal{V} = (\tilde{V}_1 - \{x\}, \dots, \tilde{V}_s - \{x\})$ being a path-decomposition of $\mathcal{G}$, and hence, $\text{pw}(\mathcal{G}) \leq w_{\mathcal{G}}(\mathcal{V}) = w_{\bar{\mathcal{G}}}(\tilde{\mathcal{V}}) - 1 = \text{pw}(\bar{\mathcal{G}}) - 1$.

Let $\bar{\mathcal{V}} = (\bar{V}_1, \dots, \bar{V}_t)$ be an optimal path-decomposition of $\bar{\mathcal{G}}$, and let $i_0 = \min\{i : x \in \bar{V}_i\}$ and $i_1 = \max\{i : x \in \bar{V}_i\}$. Since $\bar{V}_i \cap \bar{V}_k \subseteq \bar{V}_j$ for $i < j < k$, we must have $x \in \bar{V}_i$ for each $i \in [i_0, i_1]$.

We claim that $(\bar{V}_{i_0}, \bar{V}_{i_0+1}, \dots, \bar{V}_{i_1})$ is a path-decomposition of $\bar{\mathcal{G}}$. We only have to show that $\bigcup_{i=i_0}^{i_1} \bar{V}_i = \bar{V}$, and that for each pair of adjacent vertices $u, v \in \bar{V}$, $\{u, v\} \subseteq \bar{V}_i$ for some $i \in [i_0, i_1]$. To see why the first assertion is true, consider any $v \in \bar{V}$, $v \neq x$. Since x is adjacent to v and $\bar{\mathcal{V}}$ is a path-decomposition of $\bar{\mathcal{G}}$, $\{x, v\} \subseteq \bar{V}_i$ for some $i \in [t]$. However, $x \in \bar{V}_i$ iff $i \in [i_0, i_1]$, and so, $\{x, v\} \subseteq \bar{V}_i$ for some $i \in [i_0, i_1]$. In particular, $v \in \bar{V}_i$ for some $i \in [i_0, i_1]$.

For the second assertion, suppose that u, v is a pair of vertices adjacent in $\bar{\mathcal{G}}$. Obviously, $\{u, v\} \subseteq \bar{V}_j$ for some $j \in [t]$. Suppose that $j \notin [i_0, i_1]$. We consider the case when $j > i_1$; the case when $j < i_0$ is similar. As $\bigcup_{i=i_0}^{i_1} \bar{V}_i = \bar{V}$, there exist $i_2, i_3 \in [i_0, i_1]$ such that $u \in \bar{V}_{i_2}$ and $v \in \bar{V}_{i_3}$. Without loss of generality, $i_2 \leq i_3$. If $i_2 = i_3$, then there exists $i \in [i_0, i_1]$ such that $\{u, v\} \subseteq \bar{V}_i$. If $i_2 < i_3$, then we have $u \in \bar{V}_{i_2} \cap \bar{V}_j$ and $i_2 < i_3 < j$. Hence, $u \in \bar{V}_{i_3}$ as well, and so once again, we have an $i \in [i_0, i_1]$ such that $\{u, v\} \subseteq \bar{V}_i$.

Thus, $(\bar{V}_{i_0}, \bar{V}_{i_0+1}, \dots, \bar{V}_{i_1})$ is a path-decomposition of $\bar{\mathcal{G}}$, with the property that $x \in \bar{V}_i$ for all $i \in [i_0, i_1]$. It must be an optimal path-decomposition, since it is a subsequence of the optimal path-decomposition $\bar{\mathcal{V}}$. $\square$

To complete the proof of Proposition 3.1, it remains to show that $\text{pw}(M) \geq \text{pw}(\overline{\mathcal{G}})$. We introduce some notation at this point. Recall that the two edges between a pair of adjacent vertices u and v in $\overline{\mathcal{G}}$ (or $\mathcal{G}$) are denoted by l_{uv} and r_{uv} . We define

$$\begin{aligned} L_{\mathcal{G}} &= \{l_{uv} : u, v \text{ are adjacent vertices in } \mathcal{G}\}, \\ R_{\mathcal{G}} &= \{r_{uv} : u, v \text{ are adjacent vertices in } \mathcal{G}\}, \end{aligned}$$

$L_x = \bigcup_{v \in V} \{l_{xv}\}$, and $R_x = \bigcup_{v \in V} \{r_{xv}\}$, where x is the distinguished vertex in $\overline{V} - V$. Thus, $L_{\mathcal{G}} \cup R_{\mathcal{G}} = E$ and $E \cup L_x \cup R_x = \overline{E}$. Note that, by construction of $\overline{\mathcal{G}}$, $\text{cl}_M(L_x) = \text{cl}_M(R_x) = \overline{E}$, where cl_M denotes the closure operator of M .

We will need the fact that there exists an optimal ordering $(e_1, \dots, e_n)$ of $\overline{E}$ that induces a certain ordered partition of $\overline{E}$ of the form

$$(L_1, A_1, B_1, R_1, L_2, A_2, B_2, R_2, \dots, L_t, A_t, B_t, R_t),$$

where for each $j \in [t]$, $L_j \subseteq L_x$, $A_j \subseteq L_{\mathcal{G}}$, $B_j \subseteq R_{\mathcal{G}}$, and $R_j \subseteq R_x$. This will follow from a reordering argument given below. But first, we make some simple observations about orderings of $\overline{E}$. Given an ordering of $\overline{E}$, we may assume, without loss of generality, that for each pair of adjacent vertices $u, v \in V$, l_{uv} appears before r_{uv} in the ordering; we denote this by $l_{uv} < r_{uv}$. We call such an ordering of $\overline{E}$ a *normal* ordering.

LEMMA 3.6. *Let $(e_1, \dots, e_n)$ be a normal ordering of $\overline{E}$. Then, for $1 \leq j \leq n-1$, we have*

- (a) $\lambda_M(e_1, \dots, e_{j+1}) = \lambda_M(e_1, \dots, e_j) + 1$ iff $e_{j+1} \notin \text{cl}_M(e_1, \dots, e_j)$ and
- (b) $\lambda_M(e_1, \dots, e_{j+1}) = \lambda_M(e_1, \dots, e_j) - 1$ iff $e_{j+1} \notin \text{cl}_M(e_{j+2}, \dots, e_n)$.

Proof. We prove only (a), as the proof of (b) is similar. It is easy to deduce from the definition of the connectivity function that $\lambda_M(e_1, \dots, e_{j+1}) = \lambda_M(e_1, \dots, e_j) + 1$ iff $e_{j+1} \notin \text{cl}_M(e_1, \dots, e_j)$ and $e_{j+1} \in \text{cl}_M(e_{j+2}, \dots, e_n)$.

Now, if $e_{j+1} \notin \text{cl}_M(e_1, \dots, e_j)$, then $e_{j+1} = l_{uv}$ for some u, v . (If not, i.e., if $e_{j+1} = r_{uv}$, then since $l_{uv} < r_{uv}$, we must have $l_{uv} \in \{e_1, \dots, e_j\}$, and so, $e_{j+1} = r_{uv} \in \text{cl}_M(l_{uv}) \subseteq \text{cl}_M(e_1, \dots, e_j)$, a contradiction.) Therefore, $\{e_{j+2}, \dots, e_n\}$ contains r_{uv} , and hence, $e_{j+1} = l_{uv} \in \text{cl}_M(e_{j+2}, \dots, e_n)$. We have thus shown that if $e_{j+1} \notin \text{cl}_M(e_1, \dots, e_j)$, then $e_{j+1} \in \text{cl}_M(e_{j+2}, \dots, e_n)$. Part (a) of the lemma now follows. $\square$

We now describe a procedure that takes as input a normal ordering of $\overline{E}$ and produces as output a reordering of $\overline{E}$ with certain desirable properties.

REORDERING ALGORITHM.

Input: a normal ordering $(e_1, \dots, e_n)$ of $\overline{E}$.

Initialization: $j = 0$.

Step 0: If $j = 0$, set $X_j = \emptyset$;
else, set $X_j = \text{cl}_M(e_1, \dots, e_j) - \{e_1, \dots, e_j\}$.

Step 1: If $X_j = \emptyset$,
find the least $k > j$ such that
for some $m > j$, $e_m \in L_x \cap \text{cl}_M(e_1, \dots, e_k)$;
set $(e'_1, \dots, e'_n) = (e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{m-1}, e_{m+1}, \dots, e_n)$.
If $X_j \neq \emptyset$,
if $L_x \cap X_j \neq \emptyset$, find an $m > j$ such that $e_m \in L_x \cap X_j$;
else, if $L_{\mathcal{G}} \cap X_j \neq \emptyset$, find an $m > j$ such that $e_m \in L_{\mathcal{G}} \cap X_j$;

else, if $R_G \cap X_j \neq \emptyset$, find an $m > j$ such that $e_m \in R_G \cap X_j$;
 else, if $R_x \cap X_j \neq \emptyset$, find an $m > j$ such that $e_m \in R_x \cap X_j$;
 set $(e'_1, \dots, e'_n) = (e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{m-1}, e_{m+1}, \dots, e_n)$.

Step 2: Replace j by $j + 1$.

If $j < n$, replace $(e_1, \dots, e_n)$ by $(e'_1, \dots, e'_n)$
 and return to Step 0;
 else, output $(e'_1, \dots, e'_n)$.

Denote by $(e_1^*, \dots, e_n^*)$ the final output generated by the above algorithm. Set $X_0^* = \emptyset$, and for $j \in [n]$, $X_j^* = \text{cl}_M(e_1^*, \dots, e_j^*) - \{e_1^*, \dots, e_j^*\}$. Stepping through the algorithm, one may easily check that $(e_1^*, \dots, e_n^*)$ has the following property: for $0 \leq j \leq n - 1$, if $X_j^* = \emptyset$, then $e_{j+1}^* \in L_x$, and if $X_j^* \neq \emptyset$, then

$$e_{j+1}^* \in \begin{cases} L_x \cap X_j^* & \text{if } L_x \cap X_j^* \neq \emptyset, \\ L_G \cap X_j^* & \text{if } L_x \cap X_j^* = \emptyset, \text{ but } L_G \cap X_j^* \neq \emptyset, \\ R_G \cap X_j^* & \text{if } L_x \cap X_j^* = L_G \cap X_j^* = \emptyset, \text{ but } R_G \cap X_j^* \neq \emptyset, \\ R_x \cap X_j^* & \text{if } L_x \cap X_j^* = L_G \cap X_j^* = R_G \cap X_j^* = \emptyset, \text{ but } R_x \cap X_j^* \neq \emptyset. \end{cases}$$

The following claim can be readily deduced from this property, and we leave the details to the reader.

CLAIM 3.7. (a) *The ordering $(e_1^*, \dots, e_n^*)$ induces an ordered partition of $\overline{E}$ of the form*

$$(L_1, A_1, B_1, R_1, L_2, A_2, B_2, R_2, \dots, L_t, A_t, B_t, R_t),$$

where for each $j \in [t]$, $L_j \subseteq L_x$, $A_j \subseteq L_G$, $B_j \subseteq R_G$, and $R_j \subseteq R_x$. Moreover, for each $u, v \in \overline{V}$, $l_{uv} \in L_j \cup A_j$ iff $r_{uv} \in B_j \cup R_j$.

(b) *For the ordered partition in (a), we have for each $j \in [t]$,*

$$A_j \cup B_j \subseteq \text{cl}_M \left(\bigcup_{i \leq j} L_i \right) - \text{cl}_M \left(\bigcup_{i < j} L_i \right).$$

The crucial property of $(e_1^*, \dots, e_n^*)$ is the following.

LEMMA 3.8. *If $(e_1^*, \dots, e_n^*)$ is the output of REORDERING ALGORITHM in response to the input $(e_1, \dots, e_n)$, then $w_M(e_1^*, \dots, e_n^*) \leq w_M(e_1, \dots, e_n)$.*

Proof. Steps 0–1 of the algorithm go through n iterations, indexed by $j \in \{0, 1, \dots, n - 1\}$. In the j th iteration, Step 1 is given a normal ordering $(e_1, \dots, e_n)$, in response to which it produces an ordering $(e'_1, \dots, e'_n)$, which is also normal. To prove the lemma, it is enough to show that $w_M(e'_1, \dots, e'_n) \leq w_M(e_1, \dots, e_n)$.

So, suppose that the algorithm is in its j th iteration ($0 \leq j \leq n - 1$). We first dispose of the case when $X_j \neq \emptyset$. Then,

$$(e'_1, \dots, e'_n) = (e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{m-1}, e_{m+1}, \dots, e_n)$$

for some $m > j$ such that $e_m \in X_j$. Observe that if $1 \leq s \leq j$ or if $m \leq s \leq n$, then $(e'_1, \dots, e'_s)$ is just a reordering of $(e_1, \dots, e_s)$, and hence, $\lambda_M(e'_1, \dots, e'_s) = \lambda_M(e_1, \dots, e_s)$.

So, consider $j < s < m$. In this case, $(e'_1, \dots, e'_s) = (e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{s-1})$. Since $e_m \in \text{cl}_M(e_1, \dots, e_j)$, we have $r_M(e'_1, \dots, e'_s) = r_M(e_1, \dots, e_j, e_{j+1}, \dots, e_{s-1})$.

On the other hand,

$$(4) \quad \begin{aligned} r_M(e'_{s+1}, \dots, e'_n) &= r_M(e_s, \dots, e_{m-1}, e_{m+1}, \dots, e_n) \\ &\leq r_M(e_s, \dots, e_{m-1}, e_m, e_{m+1}, \dots, e_n). \end{aligned}$$

Hence, $\lambda(e'_1, \dots, e'_s) \leq \lambda(e_1, \dots, e_{s-1})$. Therefore, for any $s \in [n]$, we have shown that there exists a $t \in [n]$ such that $\lambda(e'_1, \dots, e'_s) \leq \lambda(e_1, \dots, e_t)$. It follows that $w_M(e'_1, \dots, e'_n) \leq w_M(e_1, \dots, e_n)$.

We must now deal with the case when $X_j = \emptyset$, i.e., $\text{cl}_M(e_1, \dots, e_j) = \{e_1, \dots, e_j\}$. Note that if $L_x \subseteq \{e_1, \dots, e_j\}$, then since $\text{cl}_M(L_x) = \overline{E}$, we have $\text{cl}_M(e_1, \dots, e_j) = \overline{E}$. Therefore, $\{e_1, \dots, e_j\} = \overline{E}$, which means that $j = n$, a contradiction. Therefore, there must exist some $m > j$ such that $e_m \in L_x$.

Let k^* be the least integer $k > j$ such that there exists $e_m \in L_x \cap \text{cl}_M(e_1, \dots, e_k)$ for some $m > j$. By choice of k^* , we have $m \geq k^*$. For this m , we again have

$$(e'_1, \dots, e'_n) = (e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{m-1}, e_{m+1}, \dots, e_n).$$

As before, if $1 \leq s \leq j$ or if $m \leq s \leq n$, then $\lambda_M(e'_1, \dots, e'_s) = \lambda_M(e_1, \dots, e_s)$. For $k^* < s < m$, we have

$$r_M(e'_1, \dots, e'_s) = r_M(e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{s-1}) = r_M(e_1, \dots, e_j, e_{j+1}, \dots, e_{s-1}),$$

as $e_m \in \text{cl}_M(e_1, \dots, e_{k^*}) \subseteq \text{cl}_M(e_1, \dots, e_{s-1})$. And as in (4), $r_M(e'_{s+1}, \dots, e'_n) \leq r_M(e_s, \dots, e_n)$. Hence, $\lambda(e'_1, \dots, e'_s) \leq \lambda(e_1, \dots, e_{s-1})$.

We are left with $j+1 \leq s \leq k^*$. Note that by choice of k^* , $e_m \notin \text{cl}_M(e_1, \dots, e_{s-1})$. Therefore,

$$\begin{aligned} r_M(e'_1, \dots, e'_s) &= r_M(e_1, \dots, e_j, e_m, e_{j+1}, \dots, e_{s-1}) \\ &= 1 + r_M(e_1, \dots, e_j, e_{j+1}, \dots, e_{s-1}). \end{aligned}$$

Since (4) again applies, we have that

$$(5) \quad \lambda_M(e'_1, \dots, e'_s) \leq 1 + \lambda_M(e_1, \dots, e_{s-1}).$$

Observe that, since $e_{j+1} \notin \text{cl}_M(e_1, \dots, e_j)$, by Lemma 3.6(a),

$$(6) \quad \lambda_M(e_1, \dots, e_{j+1}) = \lambda_M(e_1, \dots, e_j) + 1.$$

Furthermore, by choice of k^* , $e_m \notin \text{cl}_M(e_1, \dots, e_{k^*-1})$, but $e_m \in \text{cl}_M(e_1, \dots, e_{k^*})$, which together imply that $e_{k^*} \notin \text{cl}_M(e_1, \dots, e_{k^*-1})$. Hence, again by Lemma 3.6(a),

$$(7) \quad \lambda_M(e_1, \dots, e_{k^*}) = \lambda_M(e_1, \dots, e_{k^*-1}) + 1.$$

Therefore, from (5)–(7), we find that for $s = j+1$ or $s = k^*$ we have $\lambda_M(e'_1, \dots, e'_s) \leq \lambda_M(e_1, \dots, e_s)$.

We claim that for $j+1 < s < k^*$ we have $\lambda_M(e_1, \dots, e_{s-1}) \leq \lambda_M(e_1, \dots, e_s)$, so that by induction, $\lambda_M(e_1, \dots, e_{s-1}) \leq \lambda_M(e_1, \dots, e_{k^*-1})$. This would then imply, via (5) and (7), that $\lambda_M(e'_1, \dots, e'_s) \leq \lambda_M(e_1, \dots, e_{k^*})$. Thus, for any $s \in [n]$, we have a $t \in [n]$ such that $\lambda(e'_1, \dots, e'_s) \leq \lambda(e_1, \dots, e_t)$. Therefore, $w_M(e'_1, \dots, e'_n) \leq w_M(e_1, \dots, e_n)$, which would complete the proof of the lemma.

To prove our claim, it is enough to show that when $j+1 < s < k^*$, we have $e_s \in \text{cl}_M(e_{s+1}, \dots, e_n)$. Indeed, it then follows from Lemma 3.6(b) that $\lambda_M(e_1, \dots, e_s) \geq$

$\lambda_M(e_1, \dots, e_{s-1})$. So, suppose that $e_s \notin \text{cl}_M(e_{s+1}, \dots, e_n)$ for some $j+1 < s < k^*$. Then, $e_s = r_{uv}$ for some $u, v \in \bar{V}$. (Otherwise, if $e_s = l_{uv}$, then since $r_{uv} > l_{uv}$, we would have $e_s \in \text{cl}_M(e_{s+1}, \dots, e_n)$.) Note that $l_{uv} \notin \{e_1, \dots, e_j\}$; otherwise, the fact that $\{e_1, \dots, e_j\}$ is a flat of M would imply that $r_{uv} \in \{e_1, \dots, e_j\}$. So, $l_{uv} \in \{e_{j+1}, \dots, e_{s-1}\}$.

Suppose that $e_s = r_{uv}$ for some $v \in \bar{V}$. Then, $l_{xv} \in \{e_{j+1}, \dots, e_{s-1}\}$, which contradicts the choice of k^* . Therefore, $e_s \notin R_x$, meaning that $e_s = r_{uv}$ for some $u, v \in V$.

Now, if $l_{xu}, l_{xv} \in \{e_{s+1}, \dots, e_n\}$, then $e_s \in \text{cl}_M(e_{s+1}, \dots, e_n)$, as (l_{xu}, l_{xv}, r_{uv}) is a triangle in $\bar{\mathcal{G}}$. So, without loss of generality, $l_{xu} \notin \{e_{s+1}, \dots, e_n\}$. By choice of k^* , $l_{xu} \notin \{e_{j+1}, \dots, e_s\}$. Therefore, $l_{xu} \in \{e_1, \dots, e_j\}$. But now, $l_{xv} \in \text{cl}_M(e_1, \dots, e_{s-1})$, as (l_{xu}, l_{uv}, l_{xv}) is a triangle in $\bar{\mathcal{G}}$. However, $l_{xv} \notin \{e_1, \dots, e_j\}$; otherwise, we would have $l_{xu}, l_{xv} \in \{e_1, \dots, e_j\}$, which, since $\{e_1, \dots, e_j\}$ is a flat and (l_{xu}, l_{uv}, l_{xv}) is a triangle, would imply that $l_{uv} \in \{e_1, \dots, e_j\}$. Thus, $l_{xv} = e_{m^*}$ for some $m^* > j$. As already noted, $l_{xv} \in \text{cl}_M(e_1, \dots, e_{s-1})$, and so once again, our choice of k^* is contradicted.

Therefore, our assumption that $e_s \notin \text{cl}_M(e_{s+1}, \dots, e_n)$ always leads to a contradiction, from which we conclude that the assumption is false. This completes the proof of the lemma. $\square$

We can now furnish the last remaining piece of the proof of Proposition 3.1.

LEMMA 3.9. $pw(M) \geq pw(\bar{\mathcal{G}})$.

Proof. Let $(e_1, \dots, e_n)$ be an optimal ordering of $\bar{E}$. Without loss of generality, $(e_1, \dots, e_n)$ may be assumed to be normal. Let $(e_1^*, \dots, e_n^*)$ be the output of REORDERING ALGORITHM in the response to the input $(e_1, \dots, e_n)$. Then, $(e_1^*, \dots, e_n^*)$ has the properties listed in Claim 3.7, and, by Lemma 3.8, is also an optimal ordering of $\bar{E}$.

Now, $(e_1^*, \dots, e_n^*)$ induces an ordered partition $(L_1, A_1, B_1, R_1, \dots, L_t, A_t, B_t, R_t)$ of $\bar{E}$, as in Claim 3.7(a). For $j \in [t]$, define $Y_j = \bigcup_{i < j} (L_i \cup A_i \cup B_i \cup R_i) \cup (L_j \cup A_j)$, and $Y'_j = \bar{E} - Y_j = \bigcup_{i > j} (L_i \cup A_i \cup B_i \cup R_i) \cup (B_j \cup R_j)$. Letting $\bar{\mathcal{G}}[Y_j]$ and $\bar{\mathcal{G}}[Y'_j]$ denote the subgraphs of $\bar{\mathcal{G}}$ induced by Y_j and Y'_j , respectively, set $V_j = V(\bar{\mathcal{G}}[Y_j]) \cap V(\bar{\mathcal{G}}[Y'_j])$. In other words, V_j is the set of vertices common to both $\bar{\mathcal{G}}[Y_j]$ and $\bar{\mathcal{G}}[Y'_j]$. It is easily checked that $\mathcal{V} = (V_1, \dots, V_t)$ is a path-decomposition of $\bar{\mathcal{G}}$. Note that

$$|V_j| = |V(\bar{\mathcal{G}}[Y_j])| + |V(\bar{\mathcal{G}}[Y'_j])| - |\bar{V}|.$$

We next observe that $\bar{\mathcal{G}}[Y_j]$ and $\bar{\mathcal{G}}[Y'_j]$ are connected graphs. From Claim 3.7(b), we have that $Y_j \subseteq \text{cl}_M(\bigcup_{i \leq j} L_i)$. Therefore, for any edge l_{uv} (or r_{uv}) in $Y_j - \bigcup_{i \leq j} L_i$, both l_{xu} and l_{xv} must be in some L_i , $i \leq j$. Thus, in $\bar{\mathcal{G}}[Y_j]$, each vertex $v \neq x$ is adjacent to x , which shows that $\bar{\mathcal{G}}[Y_j]$ is connected.

Consider any vertex $v \neq x$ in $\bar{\mathcal{G}}[Y'_j]$ such that $r_{xv} \notin Y'_j$. Then, $r_{uv} \in Y'_j$ for some $u \neq x$. So, $r_{uv} \in B_k$ for some $k \geq j$. By Claim 3.7(b), $r_{uv} \in \text{cl}_M(\bigcup_{i \leq k} L_i) - \text{cl}_M(\bigcup_{i < k} L_i)$. This implies that either $l_{xu} \in L_k$ or $l_{xv} \in L_k$. Hence, either $r_{xu} \in R_k$ or $r_{xv} \in R_k$. However, r_{xv} cannot be in R_k , since $r_{xv} \notin Y'_j$, and so, $r_{xu} \in R_k$. Thus, (r_{xu}, r_{uv}) forms a path in $\bar{\mathcal{G}}[Y'_j]$ from x to v . It follows that $\bar{\mathcal{G}}[Y'_j]$ is connected.

Therefore,

$$\begin{aligned} \lambda_M(Y_j) &= r_M(Y_j) + r_M(Y'_j) - r_M(\bar{E}) \\ &= (|V(\bar{\mathcal{G}}[Y_j])| - 1) + (|V(\bar{\mathcal{G}}[Y'_j])| - 1) - (\bar{V} - 1) = |V_j| - 1. \end{aligned}$$

Hence,

$$\text{pw}(M) = w_M(e_1^*, \dots, e_n^*) \geq \max_{j \in [t]} \lambda_M(Y_j) = \max_{j \in [t]} |V_j| - 1 = w_{\overline{\mathcal{G}}}(\mathcal{V}) \geq \text{pw}(\overline{\mathcal{G}}),$$

which proves the lemma. $\square$

The proof of Proposition 3.1 is now complete.

4. Matroids of bounded pathwidth. Theorem 3.2 shows that the following decision problem is NP-complete.

Problem: MATROID PATHWIDTH.

Let $\mathbb{F}$ be a fixed field.

Instance: An $m \times n$ matrix A over $\mathbb{F}$ and an integer $w > 0$.

Question: Is there an ordering $(e_1, \dots, e_n)$ of the elements of $M = M[A]$ such that $w_M(e_1, \dots, e_n) \leq w$?

Similarly, Corollary 3.3 shows that the corresponding decision problem for code trellis-width (over a fixed finite field $\mathbb{F}$) is NP-complete.

In this section, we consider the situation when the parameter w above is a fixed constant and therefore not considered to be part of the problem instance. In contrast to the NP-completeness of MATROID PATHWIDTH, we believe that the following decision problem and its coding-theoretic counterpart are solvable in polynomial time.

Problem: WEAK MATROID PATHWIDTH.

Let $\mathbb{F}_q = GF(q)$ be a fixed finite field and w a fixed positive integer.

Instance: An $m \times n$ matrix A over $\mathbb{F}_q$.

Question: Is there an ordering $(e_1, \dots, e_n)$ of the elements of $M = M[A]$ such that $w_M(e_1, \dots, e_n) \leq w$?

Our optimism above stems from the fact that the property of having pathwidth bounded by w is preserved by the minors of a matroid. To be precise, let $\mathcal{P}_{w,q}$ be the class of matroids representable over the finite field $\mathbb{F}_q = GF(q)$, which have pathwidth of at most w . By Lemma 2.1, $\mathcal{P}_{w,q}$ is minor-closed. Since pathwidth is an upper bound on the branchwidth of a matroid, all matroids in $\mathcal{P}_{w,q}$ have branchwidth at most w . Now, Geelen and Whittle have shown that if $\mathcal{M}$ is any minor-closed class of $\mathbb{F}_q$ -representable matroids having bounded branchwidth, then $\mathcal{M}$ has finitely many excluded minors [8, Theorem 1.4]. As a result, we have the following theorem.

THEOREM 4.1. *For any integer $w > 0$ and finite field $\mathbb{F}_q$, $\mathcal{P}_{w,q}$ has finitely many excluded minors. Consequently, the code family*

$$\mathfrak{C}(\mathcal{P}_{w,q}) = \{\mathcal{C} : \mathcal{C} \text{ is a linear code over } \mathbb{F}_q \text{ such that } \text{tw}(\mathcal{C}) \leq w\}$$

also has finitely many excluded minors.

Theorem 4.1 shows that deciding whether or not a given $\mathbb{F}_q$ -representable matroid M belongs to $\mathcal{P}_{w,q}$ can be accomplished by testing whether or not M contains as a minor one of the finitely many excluded minors of $\mathcal{P}_{w,q}$. The Minor-Recognition Conjecture of Geelen, Gerards, and Whittle [6, Conjecture 1.3] states that, for any fixed $\mathbb{F}_q$ -representable matroid N , testing a given $\mathbb{F}_q$ -representable matroid for the presence of an N -minor can be done in polynomial time. So, if this conjecture is true—and there is evidence to support its validity [6]—then membership of an $\mathbb{F}_q$ -representable matroid in the class $\mathcal{P}_{w,q}$ can be decided in polynomial time. Hence, assuming the validity of the Minor-Recognition Conjecture, WEAK MATROID PATHWIDTH is solvable in polynomial time.

While the finiteness of the list of excluded minors for $\mathcal{P}_{w,q}$ implies, modulo the Minor-Recognition Conjecture, the existence of a polynomial-time algorithm for

FIG. 4. An “umbrella” graph. A dotted line between a pair of vertices represents zero or more parallel edges between them.

WEAK MATROID PATHWIDTH, an actual implementation of such an algorithm would require the explicit determination of the excluded minors. As a relatively easy exercise, we prove the following theorem.

THEOREM 4.2. *A matroid is in $\mathcal{P}_{1,q}$ iff it contains no minor isomorphic to any of the matroids $U_{2,4}$, $M(K_4)$, $M(K_{2,3})$, and $M^*(K_{2,3})$.*

We first verify the easy “only if” part of the above theorem.

PROPOSITION 4.3. *$U_{2,4}$, $M(K_4)$, $M(K_{2,3})$, and $M^*(K_{2,3})$ are not in $\mathcal{P}_{1,q}$.*

Proof. If (e_1, e_2, e_3, e_4) is any ordering of the elements of $M = U_{2,4}$, then $\lambda_M(e_1, e_2) = r_M(e_1, e_2) + r_M(e_3, e_4) - \text{rank}(M) = 2 + 2 - 2 = 2$. It follows that $\text{pw}(U_{2,4}) = 2$.

Now consider $M = M(K_4)$. For any ordering $(e_1, \dots, e_6)$ of $E(K_4)$, we have $r_M(e_1, e_2, e_3) \geq 2$, with equality iff $\{e_1, e_2, e_3\}$ is a triangle, in which case $\{e_4, e_5, e_6\}$ is a triad. It follows that $r_M(e_1, e_2, e_3) + r_M(e_4, e_5, e_6) \geq 5$. Hence, $w_M(e_1, \dots, e_6) \geq \lambda_M(e_1, e_2, e_3) \geq 2$.

The proof for $M = M(K_{2,3})$ is very similar. For any $J \subseteq E(K_{2,3})$ with $|J| = 3$, $r_M(J) = 3$, since $K_{2,3}$ has no circuits of size less than 4. Therefore, for any ordering $(e_1, \dots, e_6)$ of $E(K_{2,3})$, $w_M(e_1, \dots, e_6) \geq \lambda_M(e_1, e_2, e_3) = 3 + 3 - 4 = 2$. Thus, $\text{pw}(M(K_{2,3})) \geq 2$, and by duality, $\text{pw}(M^*(K_{2,3})) \geq 2$ as well. $\square$

We now prove the “if” part of Theorem 4.2. For the duration of the proof, we take M to be a matroid that contains no minor isomorphic to the matroids listed in the statement of the theorem. Since $M(K_4)$ is a minor of each of the matroids F_7 , F_7^* , $M(K_5)$, $M^*(K_5)$, $M(K_{3,3})$, and $M^*(K_{3,3})$, M contains none of these as minors. Therefore, $M = M(\mathcal{G})$ for some planar graph $\mathcal{G}$ (cf. [14, Theorem 13.3.1 and Proposition 5.2.6]). Evidently, we may take $\mathcal{G}$ to be connected as a graph.

Since $\mathcal{P}_{1,q}$ is closed under direct sums, we may assume that M is 2-connected. Therefore, either $\mathcal{G}$ is a graph consisting of a single vertex with a self-loop incident with it, or $\mathcal{G}$ is a loopless graph. In the former case, $M \cong U_{0,1}$, which is in $\mathcal{P}_{1,q}$. So, we may assume that $\mathcal{G}$ is loopless. If $\mathcal{G}$ has exactly two vertices, then $M \cong U_{1,n}$ for some n , which is also in $\mathcal{P}_{1,q}$. Hence, we may assume that $|V(\mathcal{G})| \geq 3$, in which case $\mathcal{G}$ is 2-connected as a graph [14, Corollary 8.2.2]. Moreover, if $\mathcal{G}^*$ is any geometric dual of $\mathcal{G}$, then, since $M^* = M(\mathcal{G}^*)$ is 2-connected, by the same argument as above, we may assume that $\mathcal{G}^*$ is also 2-connected as a graph.

At this point, we need the following definition. We call a graph an *umbrella* if it is of the form shown in Figure 4. Formally, an umbrella is a graph H that consists of a circuit on $m + 1$ vertices $u_0, u_1, \dots, u_m$, and in addition, for each $i \in [m]$, zero or more parallel edges between u_0 and u_i . Note that $H - u_0$ is a simple path, where $H - u_0$ denotes the graph obtained from H by deleting the vertex u_0 and all edges incident with it.

Returning to our proof, we have $M = M(\mathcal{G})$ for a loopless, 2-connected, planar graph $\mathcal{G}$, such that any geometric dual of $\mathcal{G}$ is also 2-connected.

FIG. 5. If $\mathcal{G}^* - x$ has a vertex of degree at least 3, then $\mathcal{G}^*$ has a $K_{2,3}$ minor.

LEMMA 4.4. $\mathcal{G}$ has a geometric dual $\mathcal{G}^*$ that is isomorphic to an umbrella.

We prove the lemma using the concept of an outerplanar graph. A planar graph is said to be *outerplanar* if it has a planar embedding in which every vertex lies on the exterior (unbounded) face. We will refer to such a planar embedding of the graph as an *outerplanar embedding*. Outerplanar graphs were characterized by Chartrand and Harary [3] as graphs that do not contain K_4 or $K_{2,3}$ as a minor.

Proof of Lemma 4.4. Since $M(\mathcal{G})$ contains no $M(K_4)$ - or $M(K_{2,3})$ -minor, $\mathcal{G}$ cannot contain K_4 or $K_{2,3}$ as a minor. Therefore, by the Chartrand–Harary result mentioned above, $\mathcal{G}$ is outerplanar. Let $\mathcal{G}^*$ be the geometric dual of an outerplanar embedding of $\mathcal{G}$.

Let x be the vertex of $\mathcal{G}^*$ corresponding to the exterior face of the outerplanar embedding of $\mathcal{G}$. By a result of Fleischner, Geller, and Harary [4, Theorem 1], $\mathcal{G}^* - x$ is a forest. In fact, since $\mathcal{G}^*$ is 2-connected, $\mathcal{G}^* - x$ is a tree.

We claim that no vertex of $\mathcal{G}^* - x$ has degree greater than two, and hence, $\mathcal{G}^* - x$ is a simple path. Indeed, suppose that $\mathcal{G}^* - x$ has a vertex u adjacent to three other vertices v_1, v_2, v_3 . Since $\mathcal{G}^*$ is 2-connected, there are paths π_1, π_2 , and π_3 in $\mathcal{G}^*$ from v_1, v_2 , and v_3 , respectively, to x that do not pass through u . Also, since $\mathcal{G}^* - x$ is a tree, these paths must be internally disjoint in $\mathcal{G}^*$. The graph $\mathcal{G}^*$ thus has a subgraph as depicted in Figure 5. But this subgraph is obviously contractible to $K_{2,3}$, and hence $\mathcal{G}^*$ has $K_{2,3}$ as a minor. However, this is impossible as $M^* = M(\mathcal{G}^*)$ does not have $M(K_{2,3})$ as a minor.

Thus, $\mathcal{G}^* - x$ is a simple path. The two degree-one vertices (endpoints) of this path must be adjacent to x in $\mathcal{G}^*$; otherwise, $\mathcal{G}^*$ is not 2-connected. It follows that $\mathcal{G}^*$ is isomorphic to an umbrella. $\square$

To complete the proof of Theorem 4.2, we show that $M(\mathcal{G}^*) \in \mathcal{P}_{1,q}$, so that by duality, $M = M^*(\mathcal{G}^*) \in \mathcal{P}_{1,q}$. This is done by the following lemma.

LEMMA 4.5. If H is an umbrella, then $M(H) \in \mathcal{P}_{1,q}$.

Proof. Let H be an umbrella on $m + 1$ vertices $u_0, u_1, \dots, u_m$, where u_0 is the vertex such that $H - \{u_0\}$ is a simple path. For $i \in [m]$, let E_i denote the set of edges between u_0 and u_i . Also, for $j \in [m - 1]$, let e_j denote the edge between u_j and u_{j+1} . Consider any ordering of the edges of H that induces the ordered partition

$$(E_1, e_1, E_2, e_2, \dots, E_{m-1}, e_{m-1}, E_m).$$

Let $J = (\bigcup_{i=1}^{j-1} (E_i \cup \{e_i\})) \cup X$, with $X \subseteq E_j$ (X may be empty). Note that the subgraph $H[J]$ of H induced by the edges in J is incident only with vertices in $\{u_0, u_1, \dots, u_j\}$. Therefore, setting $M = M(H)$, $r_M(J) = |V(H[J])| - 1 \leq j$. Similarly, the subgraph of H induced by the edges in $E(H) - J$ is incident only with vertices in $\{u_j, u_{j+1}, \dots, u_m, u_0\}$, and so, $r_M(E(H) - J) \leq m - j + 1$.

 FIG. 6. Some of the planar graphs whose cycle matroids are excluded minors for $\mathcal{P}_{2,q}$.

Thus, $\lambda_M(J) \leq j + (m - j + 1) - m = 1$, and it follows that $\text{pw}(M) \leq 1$. Being graphic, M is $\mathbb{F}_q$ -representable, and hence, $M \in \mathcal{P}_{1,q}$. $\square$

This completes the proof of Theorem 4.2.

As a corollary to the theorem, we give a coding-theoretic characterization of the code family $\mathfrak{C}(\mathcal{P}_{1,q})$. In coding theory, an $\mathbb{F}_q$ -representation of a uniform matroid is called a *maximum-distance separable (MDS) code*. For any field $\mathbb{F}_q$, the matrices G_4 , $G_{2,3}$, and $G_{2,3}^*$ below are $\mathbb{F}_q$ -representations of $M(K_4)$, $M(K_{2,3})$, and $M^*(K_{2,3})$, respectively,

$$G_4 = \begin{bmatrix} 1 & 0 & 0 & 1 & 0 & -1 \\ 0 & 1 & 0 & 1 & 1 & -1 \\ 0 & 0 & 1 & 0 & 1 & -1 \end{bmatrix},$$

$$G_{2,3} = \begin{bmatrix} 1 & 0 & 0 & 0 & -1 & -1 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}, \quad G_{2,3}^* = \begin{bmatrix} 1 & -1 & 0 & -1 & 1 & 0 \\ 1 & 0 & -1 & -1 & 0 & 1 \end{bmatrix}.$$

The matroids $M(K_4)$, $M(K_{2,3})$, and $M^*(K_{2,3})$, being binary, are uniquely representable over $\mathbb{F}_q$ in the matroid-theoretic sense [14, section 6.3 and Theorem 10.1.3]. We let $\mathcal{C}(K_4)$, $\mathcal{C}(K_{2,3})$, and $\mathcal{C}(K_{2,3})^\perp$ denote the codes over $\mathbb{F}_q$ generated by the matrices G_4 , $G_{2,3}$, and $G_{2,3}^*$, respectively.

COROLLARY 4.6. *Let $\mathbb{F}_q$ be an arbitrary finite field. A linear code $\mathcal{C}$ over $\mathbb{F}_q$ has trellis-width at most one iff it contains no minor equivalent to any of the following:*

- (i) a $[4, 2]$ MDS code;
- (ii) a code obtainable by applying an automorphism of $\mathbb{F}_q$ to one of the codes $\mathcal{C}(K_4)$, $\mathcal{C}(K_{2,3})$, and $\mathcal{C}(K_{2,3})^\perp$.

The problem of finding the complete set of excluded minors for $\mathcal{P}_{w,q}$ quickly becomes difficult for $w > 1$. The main obstacle is that we may only assume the basic property of 2-connectedness for such excluded minors. The class $\mathcal{P}_{w,q}$ is not even closed under 2-sums, so excluded minors for the class need not be 3-connected. An illustration of this is given by the following result, which provides a partial list of excluded minors for $\mathcal{P}_{2,q}$.

PROPOSITION 4.7. *For any finite field $\mathbb{F}_q$, the matroids F_7 , F_7^* , $M(K_5)$, $M^*(K_5)$, $M(K_{3,3})$, $M^*(K_{3,3})$, and $M(\mathcal{G})$, where $\mathcal{G}$ is any of the planar graphs in Figure 6, are excluded minors for $\mathcal{P}_{2,q}$. If $q \geq 4$, then $U_{3,6}$ is also an excluded minor for $\mathcal{P}_{2,q}$.*

We omit the proof, as it is only a matter of verifying that for each matroid M listed in the proposition, $M \notin \mathcal{P}_{2,q}$, but $M \setminus e, M/e \in \mathcal{P}_{2,q}$ for any $e \in E(M)$. We point out that the cycle matroids of all but the three leftmost graphs in Figure 6 are not 3-connected.

Acknowledgments. The author would like to thank Jim Geelen for contributing some of his ideas to this paper, and Alexander Vardy for pointers to the prior literature on trellis complexity.

ON THE DUALS OF BINARY HYPER-KLOOSTERMAN CODES*

MARKO MOISIO†

Abstract. Binary hyper-Kloosterman codes $C(r, m)$ of length $(2^r - 1)^{m-1}$ are a quasi-cyclic generalization of the dual of the Melas code of length $2^r - 1$. In this paper the duals $C^\perp(r, m)$, i.e., a generalization of the Melas code $C^\perp(r, 2)$ itself, are studied. In particular, the minimum distance of $C^\perp(r, m)$ for all $r, m \geq 2$, the weight distribution of $C(2, m)$ and $C^\perp(2, m)$ for all $m \geq 2$, and the weight distribution of $C(r, 3)$ and $C^\perp(r, 3)$ for all $r \geq 2$ are obtained.

Key words. exponential sum, Fermat curve, hyper-Kloosterman code, Kloosterman sum, Melas code, Pless power moments, weight distribution

DOI. 10.1137/060668900

1. Introduction. Let $r, m \geq 2$ be integers and let $q = 2^r$. Let $\mathbb{F} := \mathbb{F}_q$ denote the finite field of q elements and let $\mathbb{F}^* := \mathbb{F} \setminus \{0\}$. For $\mathbf{a} := (a_1, \dots, a_m) \in \mathbb{F}^m$ we define a rational function in $m - 1$ variables:

$$f_{\mathbf{a}}(\mathbf{X}) := a_1 X_1 + \dots + a_{m-1} X_{m-1} + \frac{a_m}{X_1 \cdots X_{m-1}}.$$

Let $\mathbf{x}_1, \dots, \mathbf{x}_n$ be a fixed ordering of the elements of $(\mathbb{F}^*)^{m-1}$.

In [4] the following linear codes $C(r, m)$ were introduced and were called a *hyper-Kloosterman code*:

$$C(r, m) = \left\{ c(\mathbf{a}) := (\text{tr}(f_{\mathbf{a}}(\mathbf{x}_1)), \dots, \text{tr}(f_{\mathbf{a}}(\mathbf{x}_n))) \mid \mathbf{a} \in \mathbb{F}^m \right\};$$

here tr is the trace function from $\mathbb{F}$ onto $\mathbb{F}_2$. These codes are a quasi-cyclic generalization of the Kloosterman code, i.e., the dual of the Melas code, of length $2^r - 1$. For the proof of the quasi cyclicity we refer to [3, Theorem 4.2].

In this paper we are interested in the duals $C^\perp(r, m)$, which are a generalization of the Melas code $C^\perp(r, 2)$ ($r > 2$). We shall show that the minimum distance of $C^\perp(r, m)$ is three if $m > 2$, give the weight distribution of $C(2, m)$ and $C^\perp(2, m)$ for all $m \geq 2$, and give the weight distribution of $C(r, 3)$ and $C^\perp(r, 3)$ for all $r \geq 2$. We remark that the weight distributions of $C(r, 2)$ and $C^\perp(r, 2)$ ($r > 2$) were obtained in [5] and in [14], respectively.

The rest of this paper is organized as follows. In section 2 we first consider some simple basic properties of hyper-Kloosterman codes. Next, the weight distribution of $C(r, m)$ is given in terms of certain monomial exponential sums (Theorem 2), and then a recursion formula for the weight distribution of $C^\perp(r, m)$ involving the moments M_j of those exponential sums is obtained by using the Pless power moment identity (Theorem 4).

In section 3 we first connect the moments M_j to a Fermat curve $\mathcal{X}$ and then obtain the number of weight three codewords in $C^\perp(r, m)$ in terms of the number of

†Department of Mathematics and Statistics, Faculty of Technology, University of Vaasa, P.O. Box 700, FIN-65101 Vaasa, Finland (mamo@uwasa.fi).

rational points on $\mathcal{X}$ (Theorem 5). Finally, we determine the minimum distance of $C^\perp(r, m)$ either by using our explicit knowledge of the number of rational points on $\mathcal{X}$ or by estimating that number by either the Hasse–Weil bound or a bound which we shall derive by using Deligne’s bound on hyper-Kloosterman sums (Theorem 6). In a few cases we are forced to calculate the number of rational points numerically since neither of those bounds is then strong enough.

In sections 4 and 5 we determine the weight distribution of the codes $C(r, m)$ and $C^\perp(r, m)$ in the special cases $r = 2$, $m > 2$ ($r > 2$, $m = 3$, respectively). In the latter case a relation between one- and two-dimensional Kloosterman sums from [1] is used, and then the weight distribution of $C(r, 3)$ is obtained by using results on the distribution of values of Kloosterman sums obtained in [5] (Theorem 11). Finally, the weight distribution of $C^\perp(r, 3)$ is obtained in terms of even moments of Kloosterman sums calculated in [10] by using results from [14]. In particular, explicit formulae for the number of codewords of weights from 3 to 5 is given (Theorem 13).

2. On the weight distribution of $C(r, m)$ and $C^\perp(r, m)$. Let χ be the canonical additive character of $\mathbb{F}$. Let

$$k_{m-1}(\mathbf{a}) = \sum_{x_1, \dots, x_{m-1} \in \mathbb{F}^*} \chi(a_1 x_1 + \dots + a_{m-1} x_{m-1} + a_m (x_1 \cdots x_{m-1})^{-1})$$

be an $(m-1)$ -dimensional Kloosterman sum. If $\mathbf{a} = (1, 1, \dots, 1, a)$ with $a \neq 0$, we use the notation

$$k_{m-1}(a) := k_{m-1}(\mathbf{a}).$$

Let v be the number of zero-components of $\mathbf{a}$. Assume $v > 0$. If $a_m = 0$, then by the orthogonality of characters we get

$$k_{m-1}(\mathbf{a}) = \sum_{x_1, \dots, x_{m-1} \in \mathbb{F}^*} \chi(a_1 x_1 + \dots + a_{m-1} x_{m-1}) = (-1)^{m-v} (q-1)^{v-1}.$$

If $a_m \neq 0$ and, e.g., $a_1 = 0$, then by the substitution $y = x_1^{-1}$ we obtain

$$\begin{aligned} k_{m-1}(\mathbf{a}) &= \sum_{x_2, \dots, x_{m-1} \in \mathbb{F}^*} \chi(a_2 x_2 + \dots + a_{m-1} x_{m-1}) \sum_{y \in \mathbb{F}^*} \chi\left(\frac{a_m}{x_2 \cdots x_{m-1}} y\right) \\ &= - \sum_{x_2, \dots, x_{m-1} \in \mathbb{F}^*} \chi(a_2 x_2 + \dots + a_{m-1} x_{m-1}) \\ &= -(-1)^{m-2-(v-1)} (q-1)^{v-1}. \end{aligned}$$

Hence we have the following lemma.

LEMMA 1. *If exactly $v > 0$ of the components of $\mathbf{a} \in \mathbb{F}^m$ are zeros, then*

$$k_{m-1}(\mathbf{a}) = (-1)^{m-v} (q-1)^{v-1}.$$

If $v = 0$, then we have the following well-known bound by Deligne:

$$|k_{m-1}(\mathbf{a})| \leq m q^{\frac{m-1}{2}}.$$

LEMMA 2. *The dimension k of $C(r, m)$ over $\mathbb{F}_2$ is rm if $rm > 4$. If $r = m = 2$, then $k = 2$.*

Proof. Consider the group homomorphism

$$(1) \quad \Psi : (\mathbb{F}^m, +) \longrightarrow C(r, m), \mathbf{a} \mapsto (\mathrm{tr}(f_{\mathbf{a}}(\mathbf{x}_1)), \dots, \mathrm{tr}(f_{\mathbf{a}}(\mathbf{x}_n))).$$

If $\mathbf{a}$ belongs to $\mathrm{Ker}(\Psi)$, then $k_{m-1}(\mathbf{a}) = (q-1)^{m-1}$. If $rm > 4$, this can happen if and only if $\mathbf{a} = \mathbf{0}$, by Deligne's bound and by Lemma 1, and therefore ψ is an isomorphism.

If $r = m = 2$ and $a, b \in \mathbb{F}_4^*$, then $k_{m-1}((a, b)) = k_{m-1}(ab)$. If $ab = 1$, then $k_{m-1}(ab) = 3$; otherwise $k_{m-1}(ab) = -1$. Hence, in this case $|\mathrm{Ker}(\Psi)| = 4$, and consequently $|C(r, m)| = 16/4 = 4$. $\square$

Remark 1. A different proof for this result is given in [3, Theorem 3.1].

The Hamming weight $w(c(\mathbf{a}))$ of codeword $c(\mathbf{a})$ is given by

$$(2) \quad w(c(\mathbf{a})) = \sum_{\mathbf{x} \in (\mathbb{F}^*)^{m-1}} \frac{1}{2} \left(1 - (-1)^{\mathrm{tr}(f_{\mathbf{a}}(\mathbf{x}))} \right) = \frac{1}{2} ((q-1)^{m-1} - k_{m-1}(\mathbf{a})).$$

Next we express $w(c(\mathbf{a}))$ by means of a monomial exponential sum over $\mathbb{F}_{q^m}$. Let e denote the canonical additive character of $\mathbb{F}_{q^m}$. Let $t = (q^m - 1)/(q - 1)$ and let $N(\alpha) := \alpha^t$ denote the norm of α from $\mathbb{F}_{q^m}$ to $\mathbb{F}_q$. Let γ be a primitive element of $\mathbb{F}_{q^m}$ and let

$$s(\alpha) = \sum_{i=0}^{t-1} e(\alpha \gamma^{(q-1)i}).$$

We have the following result from [9, Theorem 3].

THEOREM 1. *Let $\alpha \in \mathbb{F}_{q^m}^*$ and let $a = N(\alpha)$. Then*

$$\sum_{x \in \mathbb{F}_{q^m}^*} e(\alpha x^{q-1}) = (-1)^{m-1} (q-1) k_{m-1}(a),$$

or, equivalently,

$$k_{m-1}(a) = (-1)^{m-1} s(\alpha).$$

LEMMA 3. *Let $\mathbf{a} \in (\mathbb{F}^*)^m$ and let $b = a_1 \cdots a_m$. Let $g := N(\gamma)$ be a primitive element of $\mathbb{F}$, $i = \mathrm{ind}_g(b)$, and $\beta = \gamma^i$. Then*

$$\begin{aligned} w(c(\mathbf{a})) &= \frac{1}{2} ((q-1)^{m-1} - k_{m-1}(b)) \\ &= \frac{1}{2} ((q-1)^{m-1} + (-1)^m s(\beta)). \end{aligned}$$

Proof. The first equality follows easily by (2), and the second one then follows by Theorem 1. $\square$

Let S denote the range of $s(\gamma^i)$ as i varies over the set $I := \{0, \dots, q-2\}$, and, for $j \in S$, let N_j denote the number of elements i in I such that $s(\gamma^i) = j$, i.e.,

$$S = \{s(\gamma^i) \mid i \in I\}$$

and

$$N_j = |\{i \in I \mid s(\gamma^i) = j\}|.$$

THEOREM 2. Assume $rm > 4$. For $\mathbf{a} \in \mathbb{F}^m$ let v be the number of zero-components of $\mathbf{a}$. If $v > 0$, there are

$$\binom{m}{v} (q-1)^{m-v} \text{ codewords } c(\mathbf{a}) \text{ of weight } ((q-1)^{m-1} - (-1)^{m-v}(q-1)^{v-1})/2,$$

and otherwise, for each $j \in S$, there are

$$N_j (q-1)^{m-1} \text{ codewords } c(\mathbf{a}) \text{ of weight } ((q-1)^{m-1} + (-1)^m j)/2$$

in $C(r, m)$. Moreover, these are the only weights in $C(r, m)$.

Proof. First, for each $\mathbf{a} \in \mathbb{F}^m$, there exists exactly one codeword $c(\mathbf{a}) \in C(r, m)$, by isomorphism (1). If $v > 0$, the claim follows now by Lemmas 1 and 3.

Assume $v = 0$. For each $b \in \mathbb{F}^*$ there are exactly $(q-1)^{m-1}$ vectors $\mathbf{a} \in (\mathbb{F}^*)^m$ such that the product of the components of $\mathbf{a}$ equals b . The second claim follows now by Lemma 3 since there is exactly one i in I such that $N(\gamma^i) = b$. The last claim is now obvious. $\square$

COROLLARY 1. The weights in $C(r, m)$ are divisible by $2^{\ell-1}$, where $\ell = \min\{r, m\}$.

Proof. Let $\alpha \in \mathbb{F}_{q^m}$. By [12, Theorem 2], the exponential sum

$$\sum_{x \in \mathbb{F}_{q^m}} e(\alpha x^{q-1})$$

is divisible by $2^{\lceil rm/s \rceil}$, where s is the binary weight of $q-1$. Now $s = r$, and therefore $\sum_{x \in \mathbb{F}_{q^m}} e(\alpha x^{q-1}) = 2^m z$ for some $z \in \mathbb{Z}$.

Let $\mathbf{a} \in (\mathbb{F}^*)^m$, and let $\beta \in \mathbb{F}_{q^m}^*$ such that $N(\beta) = a_1 \cdots a_m$. Now

$$\begin{aligned} (q-1)w(c(\mathbf{a})) &= \frac{1}{2}((q-1)^m + (-1)^m (q-1)s(\beta)) \\ &= \frac{1}{2} \left((q-1)^m + (-1)^m \sum_{x \in \mathbb{F}_{q^m}^*} e(\alpha x^{q-1}) \right) \\ &= \frac{1}{2} \left((q-1)^m + (-1)^m \sum_{x \in \mathbb{F}_{q^m}} e(\alpha x^{q-1}) - (-1)^m \right) \\ &= \frac{1}{2} (q^m - mq^{m-1} + \cdots + (-1)^{m-1} mq + (-1)^m 2^m z), \end{aligned}$$

and, as $q = 2^r$, the claim follows in this case. If some of the components of $\mathbf{a}$ are zero, then it is easily seen that 2^{r-1} is a factor of $w(c(\mathbf{a}))$. $\square$

Remark 2. A different proof for this result is given in [4, Corollary 4.3].

To obtain the weight distribution of $C^\perp(r, m)$ we use the Pless power moment identity proved in [13] (see also, e.g., [6, p. 131]).

THEOREM 3 (power moment identity). Let B be a binary linear $[n, k]$ code, and let B_i (resp., $B_i^\perp$) denote the number of codewords of weight i in B (resp., in $B^\perp$). Then, for $h = 0, 1, \dots$, we have

$$\sum_{i=0}^n i^h B_i = \sum_{i=0}^n (-1)^i B_i^\perp \sum_{t=0}^h t! S(h, t) 2^{k-t} \binom{n-i}{n-t},$$

where

$$S(h, t) := \frac{1}{t!} \sum_{j=0}^t (-1)^{t-j} \binom{t}{j} j^h \quad (\text{a Stirling number of the second kind}),$$

and the binomial coefficient $\binom{u}{v}$ is defined to be zero whenever $v > u$ or $v < 0$.

For a nonnegative integer j we denote by M_j the j th moment of the period $s(\gamma^l)$, or

$$M_j := \sum_{l=0}^{q-2} s(\gamma^l)^j.$$

THEOREM 4. Assume $rm > 4$, and let $w = 1 - q$. The number $C_h^\perp$ of codewords of weight h in $C^\perp(r, m)$ is given by

$$\begin{aligned} q^m h! C_h^\perp &= f(C_0^\perp, \dots, C_{h-1}^\perp) + g(M_0, \dots, M_h) \\ &\quad + (-1)^{(m+1)(h+1)} w^{-h} \left(w^m (1 - w^m)^h - \sum_{j=0}^h \binom{h}{j} (-1)^j (w^{j+1} - w^h)^m \right), \end{aligned}$$

where

$$\begin{aligned} f(C_0^\perp, \dots, C_{h-1}^\perp) &= q^m \sum_{i=0}^{h-1} (-1)^{h+i+1} C_i^\perp \sum_{t=i}^h t! S(h, t) 2^{h-t} \binom{n-i}{n-t}, \\ g(M_0, \dots, M_h) &= \sum_{j=0}^h \binom{h}{j} (-1)^{mj+h} (q-1)^{(m-1)(h-j+1)} M_j. \end{aligned}$$

Moreover, if $m = 3$, the formula simplifies to

$$\begin{aligned} q^3 h! C_h^\perp &= f(C_0^\perp, \dots, C_{h-1}^\perp) + g(M_0, \dots, M_h) \\ &\quad + 3(q-1)^2 (-q)^h ((q-2)^h + (q-1)^{h-1}). \end{aligned}$$

Proof. We choose $B = C(r, m)$ in the power moment identity. Then, by Theorem 2,

$$\begin{aligned} \sum_{i=0}^n i^h C_i &= \sum_{v=1}^m \binom{m}{v} (q-1)^{m-v} 2^{-h} ((q-1)^{m-1} - (-1)^{m-v} (q-1)^{v-1})^h \\ &\quad + \sum_{l=0}^{q-2} 2^{-h} (q-1)^{m-1} ((q-1)^{m-1} + (-1)^m s(\gamma^l))^h =: S_1 + S_2, \end{aligned}$$

where

$$2^h S_1 = \sum_{v=1}^m \binom{m}{v} (q-1)^{m-v} ((q-1)^{m-1} - (-1)^{m-v} (q-1)^{v-1})^h$$

and

$$2^h S_2 = (q-1)^{m-1} \sum_{l=0}^{q-2} ((q-1)^{m-1} + (-1)^m s(\gamma^l))^h.$$

First, we manipulate S_2 somewhat:

$$\begin{aligned} 2^h S_2 &= (q-1)^{m-1} \sum_{l=0}^{q-2} \sum_{j=0}^h \binom{h}{j} (-1)^{mj} s(\gamma^l)^j (q-1)^{(m-1)(h-j)} \\ &= \sum_{j=0}^h \binom{h}{j} (-1)^{mj} (q-1)^{(m-1)(h-j+1)} \sum_{l=0}^{q-2} s(\gamma^l)^j \\ &= \sum_{j=0}^h \binom{h}{j} (-1)^{mj} (q-1)^{(m-1)(h-j+1)} M_j. \end{aligned}$$

Second, we consider S_1 . If $m = 3$, then

$$2^h S_1 = 3(q-1)^2 q^h ((q-2)^h + (q-1)^{h-1}).$$

Next we write S_1 in the form from which we can derive explicit formulae for the number of low-weight codewords in the duals $C^\perp(r, m)$ for an arbitrary integer $m \geq 2$:

$$\begin{aligned} 2^h S_1 &= (q-1)^{m-1} \sum_{v=1}^m \binom{m}{v} (q-1)^{(v-1)(h-1)} ((q-1)^{m-v} + (-1)^{m-v-1})^h \\ &= (q-1)^{m-1} \sum_{v=1}^m \binom{m}{v} (q-1)^{(v-1)(h-1)} (-1)^{(m-v-1)h} (1 - (1-q)^{m-v})^h \\ &= (-1)^{(m-1)h} (-w)^{m-1} \sum_{j=0}^h \binom{h}{j} (-1)^j \sum_{v=1}^m \binom{m}{v} (-1)^{vh} (-w)^{(v-1)(h-1)} w^{(m-v)j} \\ &= (-1)^{(m-1)h} (-w)^{-h} \sum_{j=0}^h \binom{h}{j} (-1)^j \sum_{v=1}^m \binom{m}{v} w^{vh} (-w)^{m-v} w^{(m-v)j} \\ &= (-1)^{(m-1)h+m} (-w)^{-h} \sum_{j=0}^h \binom{h}{j} (-1)^j \sum_{v=1}^m \binom{m}{v} (-1)^v w^{vh} w^{(m-v)(j+1)} \\ &= (-1)^{m(h+1)} w^{-h} \sum_{j=0}^h \binom{h}{j} (-1)^j \left((w^{j+1} - w^h)^m - w^{m(j+1)} \right). \end{aligned}$$

Since

$$\begin{aligned} \sum_{j=0}^h \binom{h}{j} (-1)^j w^{m(j+1)} &= (1-q)^m \sum_{j=0}^h \binom{h}{j} (-1)^j (1-q)^{mj} \\ &= w^m (1 - w^m)^h, \end{aligned}$$

we have

$$\begin{aligned} 2^h S_1 &= (-1)^{m(h+1)} w^{-h} \sum_{j=0}^h \binom{h}{j} (-1)^j (w^{j+1} - w^h)^m \\ &\quad - (-1)^{m(h+1)} w^{m-h} (1 - w^m)^h. \end{aligned}$$

As the left-hand side of the power moment identity equals $S_1 + S_2$, and the right-hand side equals

$$\begin{aligned} &\sum_{i=0}^n (-1)^i C_i^\perp \sum_{t=0}^h t! S(h, t) 2^{rm-t} \binom{n-i}{n-t} \\ &= \sum_{i=0}^h (-1)^i C_i^\perp \sum_{t=i}^h t! S(h, t) 2^{rm-t} \binom{n-i}{n-t} \\ &= \frac{q^m}{2^h} \sum_{i=0}^h (-1)^i C_i^\perp \sum_{t=i}^h t! S(h, t) 2^{h-t} \binom{n-i}{n-t}, \end{aligned}$$

the claims now easily follows. $\square$

3. The minimum distance of $C^\perp(r, m)$. To determine the minimum distance of $C^\perp(r, m)$ we need some auxiliary results. We recall that $t = (q^m - 1)/(q - 1)$ and $\mathbb{F}_{q^m}^* = \langle \gamma \rangle$.

LEMMA 4. *The first four moments M_j in Theorem 4 are given by*

$$\begin{aligned} M_0 &= q - 1, \quad M_1 = -1, \quad M_2 = q^m - t, \\ M_3 &= \frac{|\mathcal{X}(\mathbb{F}_{q^m})| - 3(q - 1)}{(q - 1)^2} q^m - t^2, \end{aligned}$$

where $|\mathcal{X}(\mathbb{F}_{q^m})|$ is the number of rational points on the projective curve $\mathcal{X}$ over $\mathbb{F}_{q^m}$ defined by the equation

$$\mathcal{X} : x^{q-1} + y^{q-1} + z^{q-1} = 0.$$

Proof. Obviously $M_0 = q - 1$, and

$$M_1 = \sum_{l=0}^{q-2} s(\gamma^l) = \frac{q-1}{q^m-1} \sum_{l=0}^{q^m-2} s(\gamma^l) = \frac{1}{t} \sum_{i=0}^{t-1} \sum_{l=0}^{q^m-2} e(\gamma^{(q-1)i} \gamma^l) = -\frac{t}{t},$$

where the last equality follows by the orthogonality of characters. To prove the formula for M_2 we count the number N of solutions of the equation $x + y = 0$ in the group H of $(q-1)$ th powers in $\mathbb{F}_{q^m}^*$. On the one hand, $N = t$, and on the other hand, by the orthogonality of characters,

$$\begin{aligned} q^m t &= \sum_{x, y \in H} \sum_{u \in \mathbb{F}_{q^m}^*} e(u(x + y)) = t^2 + \sum_{u \in \mathbb{F}_{q^m}^*} \left(\sum_{x \in H} e(ux) \right)^2 = t^2 + t \sum_{l=0}^{q-2} s(\gamma^l)^2 \\ &= t^2 + t M_2, \end{aligned}$$

from which the formula for M_2 follows.

Let N denote the number of solutions of equation

$$(3) \quad x^{q-1} + y^{q-1} + z^{q-1} = 0$$

in $\mathbb{F}_{q^m}^3$. It is easy to see [9, section 3] that $N = N'_m + N_m$, where

$$N'_m = 3(q-1)(q^m-1) + 1$$

and

$$\begin{aligned} q^m N_m &= \sum_{u \in \mathbb{F}_{q^m}^*} \left(\sum_{x \in \mathbb{F}_{q^m}^*} e(ux^{q-1}) \right)^3 + (q^m - 1)^3 \\ &= (q-1)^3 \sum_{u \in \mathbb{F}_{q^m}^*} s(u)^3 + (q^m - 1)^3 \\ &= (q-1)^3 tM_3 + (q^m - 1)^3, \end{aligned}$$

and consequently,

$$q^m N = 3(q-1)(q^m-1)q^m + q^m + (q-1)^3 tM_3 + (q^m - 1)^3.$$

Since $|\mathcal{X}(\mathbb{F}_{q^m})| = (N-1)/(q^m-1)$, we obtain

$$(q-1)^3 \frac{q^m-1}{q-1} M_3 = q^m(q^m-1)|\mathcal{X}(\mathbb{F}_{q^m})| - 3(q-1)(q^m-1)q^m - (q^m-1)^3,$$

which simplifies to

$$(q-1)^2 M_3 = q^m |\mathcal{X}(\mathbb{F}_{q^m})| - 3(q-1)q^m - (q^m-1)^2.$$

Since $(q^m-1)^2 = (q-1)^2 t^2$, we see that the claim is true also for M_3 . $\square$

THEOREM 5. *The minimum distance of $C^\perp(r, m)$ is at least three. Moreover, if $rm > 4$, the number $C_3^\perp$ of weight three codewords in $C^\perp(r, m)$ is given by*

$$C_3^\perp = \frac{(q-1)^{m-3}((q-2)^m + (-1)^m(q^m + 3q - |\mathcal{X}(\mathbb{F}_{q^m})| - 5))}{6}.$$

Proof. Let $n = (q-1)^{m-1}$, and let $\mathbf{c} \in C^\perp(r, m)$. If $w(\mathbf{c}) = 2$, then

$$\text{tr}(f_{\mathbf{a}}(\mathbf{x}_i) + f_{\mathbf{a}}(\mathbf{x}_j)) = \text{tr}(f_{\mathbf{a}}(\mathbf{x}_i)) + \text{tr}(f_{\mathbf{a}}(\mathbf{x}_j)) = 0$$

for some $1 \leq i < j \leq n$, say $i = 1, j = 2$, and for all $\mathbf{a} \in \mathbb{F}_q^m$. Let $1 \leq l \leq m-1$ be the index of the coordinate place where $\mathbf{x}_1$ and $\mathbf{x}_2$ differ, say $l = 1$. By choosing $\mathbf{a} = (a, 0, \dots, 0)$, we have $\text{tr}(a(x+y)) = 0$ for all $a \in \mathbb{F}_q$ and for some $x, y \in \mathbb{F}_q^*$ with $x \neq y$. (Here x and y are the first components of $\mathbf{x}_1$ and $\mathbf{x}_2$.) This contradicts the surjectivity of tr . A similar argument also proves that $w(\mathbf{c}) \neq 1$.

Next we use Theorem 4 and Lemma 4 to prove the claimed formula for $C_3^\perp$. First,

$$\begin{aligned} f(C_0^\perp, C_1^\perp, C_2^\perp) &= f(1, 0, 0) = q^m \sum_{t=0}^3 t! S(3, t) 2^{3-t} \binom{n}{n-t} \\ &= q^m (4n + 6n(n-1) + (n-2)(n-1)n) \\ &= (q-1)^{2m-2} ((q-1)^{m-1} + 3) q^m, \end{aligned}$$

and second,

$$\begin{aligned}
g(M_0, M_1, M_2, M_3) &= \sum_{j=0}^3 \binom{3}{j} (-1)^{mj+h} (q-1)^{(m-1)(h-j+1)} M_j \\
&= -(q-1)^{4m-3} + 3(-1)^m (q-1)^{3(m-1)} - 3(q-1)^{2(m-1)} \left(q^m - \frac{q^m - 1}{q-1} \right) \\
&\quad - (-1)^m (q-1)^{m-1} \left(\frac{|\mathcal{X}(\mathbb{F}_{q^m})| - 3(q-1)}{(q-1)^2} q^m - \frac{(q^m - 1)^2}{(q-1)^2} \right),
\end{aligned}$$

or, equivalently,

$$\begin{aligned}
(q-1)^{3-m} g(M_0, M_1, M_2, M_3) &= (-1)^m - 3(q-1)^m + 3(-1)^m (q-1)^{2m} \\
&\quad - (q-1)^{3m} + ((-1)^m (q^m + 3q - |\mathcal{X}(\mathbb{F}_{q^m})| - 5) - 3(q-2)(q-1)^m) q^m.
\end{aligned}$$

Finally, since

$$\begin{aligned}
&(q-1)^{3-m} w^{-3} \left(w^m (1-w^m)^3 - \sum_{j=0}^3 \binom{3}{j} (w^{j+1} - w^3)^m \right) \\
&= -(-1)^m + 3(q-1)^m - 3(-1)^m (q-1)^{2m} + (q-1)^{3m} \\
&\quad - ((q-1)^m + 3)(q-1)^m q^m + (q-2)^m q^m,
\end{aligned}$$

we obtain

$$6C_3^\perp = (q-1)^{m-3} ((q-2)^m + (-1)^m (q^m + 3q - |\mathcal{X}(\mathbb{F}_{q^m})| - 5))$$

by Theorem 4. $\square$

Example 1. If $r = m = 2$, then $n = 3$, and therefore the minimum distance of $C^\perp(2, 2)$ is three. Hence, $C^\perp(2, 2)$ is a repetition code.

Example 2. Consider the Melas code $C^\perp(r, 2)$. By [9, Theorem 1],

$$|\mathcal{X}(\mathbb{F}_{q^2})| = (1 - (-1)^r)(q-1)^2 + 3(q-1),$$

and consequently,

$$C_3^\perp = (1 + (-1)^r)(q-1)/6,$$

which is in accordance with [14, Table 6.1].

Example 3. Consider code $C^\perp(r, 3)$. By [9, Theorem 2],

$$|\mathcal{X}(\mathbb{F}_{q^3})| = (2q + 1 - (-1)^r)(q-1)^2 + 3(q-1),$$

and therefore,

$$C_3^\perp = (2q - 5 - (-1)^r)(q-1)^2/6.$$

Remark 3. By generalizing the argument used in the proof of Theorem 5 to prove the nonexistence of weight two codewords, it is easy to see that a check matrix for

$C^\perp(r, m)$ is $(\mathbf{y}_1^T \mathbf{y}_2^T \dots \mathbf{y}_n^T)$, where $\mathbf{y}_i = (\mathbf{x}_i \ z_i)$ and z_i is the product of the inverses of the components of $\mathbf{x}_i$.

We shall see soon that the minimum distance of $C^\perp(r, m)$ is always three if $m > 2$. It will turn out that Theorem 5, together with the Hasse–Weil bound, proves most of the cases. On the other hand, in case $m = 4$ it is too weak, and we shall use the following upper bound.

LEMMA 5.

$$|\mathcal{X}(\mathbb{F}_{q^m})| < q^m + 3q + (q-1)^3 m^3 q^{\frac{m-3}{2}} - 4.$$

Proof. As we pointed out in the proof of Lemma 4, the number of solutions N of (3) satisfies

$$q^m N = (q-1)^3 \left(\sum_{u \in \mathbb{F}_{q^m}^*} e(ux^{q-1}) \right) + (q^m - 1)^3 + 3(q-1)(q^m - 1)q^m + q^m,$$

and then it is easily seen (see [9, section 3]) that

$$q^m N = (-1)^{m-1} t (q-1)^3 \sum_{u \in \mathbb{F}_q^*} k_{m-1}(u)^3 + (q^m - 1)^3 + 3(q-1)(q^m - 1)q^m + q^m.$$

Since $|\mathcal{X}(\mathbb{F}_{q^m})| = (N-1)/(q^m - 1)$, we obtain

$$(4) \quad q^m |\mathcal{X}(\mathbb{F}_{q^m})| = (-1)^{m-1} (q-1)^2 \sum_{u \in \mathbb{F}_q^*} k_{m-1}(u)^3 + (q^m - 1)^2 + 3(q-1)q^m.$$

Now Deligne's bound gives the inequality

$$(5) \quad \left| \sum_{u \in \mathbb{F}_q^*} k_{m-1}(u)^3 \right| \leq (q-1) m^3 q^{\frac{3(m-1)}{2}},$$

and therefore,

$$|\mathcal{X}(\mathbb{F}_{q^m})| \leq (q-1)^3 m^3 q^{\frac{m-3}{2}} + q^m - 2 + 3(q-1) + q^{-m}. \quad \square$$

THEOREM 6. *The minimum distance of $C^\perp(r, m)$ is three unless r is odd and $m = 2$, in which case it is at least five.*

Proof. Assume $m = 2$. If $r = 2$, the minimum distance $d = 3$ by Example 1, and if $r > 2$, then it is well known that $d = 3$ or $d \geq 5$ according to whether r is even or odd (see, e.g., [14]).

CLAIM. *If $m > 2$, then $d = 3$.*

If $m = 3$, the claim is true by Example 3. Assume $m > 3$. To prove the claim it is enough, by Theorem 5, to show that

$$\epsilon := (q-2)^m + (-1)^m (q^m + 3q - |\mathcal{X}(\mathbb{F}_{q^m})| - 5)$$

is positive. By separating the cases according to the parity of m , and by using the Hasse–Weil bounds

$$q^m + 1 - (q-2)(q-3)q^{\frac{m}{2}} \leq |\mathcal{X}(\mathbb{F}_{q^m})| \leq q^m + 1 + (q-2)(q-3)q^{\frac{m}{2}},$$

TABLE 3.1

r	ϵ
3	$2^3 \cdot 3 \cdot 7^2$
4	$2 \cdot 3^3 \cdot 5^2 \cdot 37$
5	$2^4 \cdot 3^2 \cdot 5 \cdot 31^2$
6	$2 \cdot 3^5 \cdot 7^2 \cdot 641$
7	$2^3 \cdot 3^2 \cdot 7 \cdot 31 \cdot 127^2$
8	$2 \cdot 3^3 \cdot 5^2 \cdot 7 \cdot 17^2 \cdot 1531$
9	$2^8 \cdot 3 \cdot 5 \cdot 7^2 \cdot 67 \cdot 73^2$
10	$2 \cdot 3^3 \cdot 11^5 \cdot 31^2 \cdot 131$
11	$2^3 \cdot 3^3 \cdot 11 \cdot 23^2 \cdot 89^2 \cdot 1759$
12	$2 \cdot 3^5 \cdot 5^2 \cdot 7^2 \cdot 13^2 \cdot 113 \cdot 24709$

we obtain

$$\epsilon > (q-2)^m - (q-2)(q-3)q^{\frac{m}{2}} - 3q - 6,$$

which is obviously positive if $m \geq 5$ and $r \geq 3$ (i.e., $q \geq 8$).

Assume $m = 4$ and $\epsilon = 0$. Then, by Lemma 5, we must have

$$\begin{aligned} (q-2)^4 &< 64\sqrt{q}(q-1)^3 + 1 \\ \Leftrightarrow (q-1)^4 &< 64\sqrt{q}(q-1)^3 + 4(q-1)^3 - 6(q-1)^2 + 4(q-1) \\ \Leftrightarrow q-1 &< 64\sqrt{q} + 4 - \frac{6}{q-1} + \frac{4}{(q-1)^2} < 64\sqrt{q} + 5. \end{aligned}$$

The inequality $q-6 < 64\sqrt{q}$ implies that we must have $q \leq 2^{12}$, i.e., $r \leq 12$. Hence, if $m = 4$ and $r > 12$, the minimum distance is three. In the cases $m = 4$, $3 \leq r \leq 12$, we have verified this by calculating $|\mathcal{X}(\mathbb{F}_{q^4})|$ numerically (see Table 3.1).

In the remaining cases $r = 2$, $m \geq 4$, the claim follows by Theorem 9 below, by which $C_3^\perp = 3^{m-3}(2^{m-1} \pm 1)$. $\square$

We computed $|\mathcal{X}(\mathbb{F}_{q^4})|$ by using (4). In the calculation of the three-dimensional Kloosterman sums $k_3(a)$ over $\mathbb{F}_q$, $q = 2^r$ with $3 \leq r \leq 12$, we took advantage of the following result by Carlitz from [1] which related one- and two-dimensional Kloosterman sums.

THEOREM 7. *For any $a \in \mathbb{F}_q^*$, we have*

$$k_2(a) = k(a)^2 - q,$$

where $k(a) := k_1(a)$.

By Theorem 7 we have

$$\begin{aligned} k_3(a) &= \sum_{x,y,z \in \mathbb{F}_q^*} \chi(x+y+z+a(xyz)^{-1}) = \sum_{x \in \mathbb{F}_q^*} \chi(x)k_2(ax^{-1}) \\ &= \sum_{x \in \mathbb{F}_q^*} \chi(x)k(ax^{-1})^2 - q \sum_{x \in \mathbb{F}_q^*} \chi(x) \\ &= \sum_{x \in \mathbb{F}_q^*} \chi(x)k(ax^{-1})^2 + q, \end{aligned}$$

and now it is easy to see that

$$\begin{aligned} k_3(a) &= 2 \sum_{\substack{x \in \mathbb{F}_q^* \\ \text{tr}(x)=0}} k(ax^{-1})^2 - \sum_{x \in \mathbb{F}_q^*} k(ax^{-1})^2 + q \\ &= 2 \sum_{\substack{x \in \mathbb{F}_q^* \\ \text{tr}(x)=0}} k(ax^{-1})^2 - (q^2 - q - 1) + q. \end{aligned}$$

By tabulating the traces of elements of $\mathbb{F}_q^*$, the indices of those elements of $\mathbb{F}_q^*$ having the trace equal to zero, and then the range of $k(u)$ as u varies over $\mathbb{F}_q^*$, before using the formula above, the data of Table 3.1 can quickly be verified.

Remark 4. The traces were calculated by making use of [3, Theorem 5.1].

4. The weight distribution of $C(2, m)$ and $C^\perp(2, m)$. In this section we assume that $m > 2$. Let γ be a primitive element of $\mathbb{F}_{2^{2m}}$. To determine the weight distribution of $C(2, m)$ and $C^\perp(2, m)$ we need the following result, which has been proved already in [2] (see, e.g., [8] for a different proof).

LEMMA 6. *Let $\alpha \in \mathbb{F}_{2^{2m}}^*$. Then*

$$\sum_{x \in \mathbb{F}_{2^{2m}}^*} e(\alpha x^3) = \begin{cases} (-1)^m 2^m - 1 & \text{if } 3 \nmid \text{ind}_\gamma \alpha, \\ (-1)^{m+1} 2^{m+1} - 1 & \text{if } 3 \mid \text{ind}_\gamma \alpha. \end{cases}$$

Lemma 6, together with Theorem 2, gives the weight distribution of $C(2, m)$.

THEOREM 8. *The weight distribution of $C(2, m)$ is given in the following table, where v runs over the integers $1, \dots, m$:*

Weight	Frequency
$\frac{3^{m-1} - (-1)^{m-v} 3^{v-1}}{2}$	$\binom{m}{v} 3^{m-v}$
$\frac{1}{2} \left(3^{m-1} + \frac{2^m - (-1)^m}{3} \right)$	$2 \cdot 3^{m-1}$
$\frac{1}{2} \left(3^{m-1} - \frac{2^{m+1} + (-1)^m}{3} \right)$	3^{m-1}

THEOREM 9. *For every nonnegative integer h the number $C_h^\perp$ of codewords of weight h in the dual $C^\perp(2, m)$ of $C(2, m)$ is given by the recursion of Theorem 4 with*

$$M_j = 2 \left(\frac{(-2)^m - 1}{3} \right)^j + \left(\frac{(-2)^{m+1} - 1}{3} \right)^j \quad \forall j = 0, 1, \dots$$

In particular,

$$C_0^\perp = 1, \quad C_1^\perp = C_2^\perp = 0, \quad C_3^\perp = 3^{m-3} (2^{m-1} \pm 1),$$

$$C_4^\perp = 3^{m-5} \left(\frac{7^m - 3^{m+3} + 66}{8} + 3 \cdot 2^{2m-2} \pm 2^m \right),$$

$$C_5^\perp = 3^{m-6} \left((5^{m-1} \pm 6) 2^{2m-3} - 3^{m+2} 2^{m-2} + 2^{3m-2} + 7 \cdot 2^{m+1} \pm \frac{55 - 3^{m+1}}{2} \right),$$

where $\pm = (-1)^m$.

Proof. By Lemma 6 the moments M_j in Theorem 4 are of the claimed form; the claimed formulae for the low-weight codewords can be verified, e.g., by using Mathematica. $\square$

Remark 5. In a similar manner as was done above, the weight distribution of the codes $C(r, m)$ and $C^\perp(r, m)$ with $r = 3$ and $r = 4$ can be calculated as well.

5. The weight distribution of $C(r, 3)$ and $C^\perp(r, 3)$. In this section we assume that $r > 2$. Let γ be a primitive element of $\mathbb{F}_{q^3}$, and let $g = N(\gamma)$ be a primitive element of $\mathbb{F} = \mathbb{F}_q$.

Now, by Theorems 1 and 7, we have the following.

LEMMA 7. *For each integer i satisfying $0 \leq i \leq q - 2$, we have*

$$s(\gamma^i) = k(g^i)^2 - q.$$

Hence, the question about the distribution of the values of $s(\gamma^i)$ is equivalent to the question about the distribution of the values of (one-dimensional) Kloosterman sums over $\mathbb{F}^*$. This question has been answered by Lachaud and Wolfmann in [5, Theorem 3.4 and Proposition 9.1].

THEOREM 10. *The set of values S of $k(a)$ as a runs over $\mathbb{F}_q^*$ is*

$$S = \{j \in \mathbb{Z} \mid |j| < 2\sqrt{q} \text{ and } j \equiv -1 \pmod{4}\}.$$

Moreover, each value $j \in S$ is attained exactly $H(j^2 - 4q)$ times, where $H(d)$ is the Kronecker class number of d .

As a corollary we obtain, by using Theorem 2, the weight distribution of $C(r, 3)$.

THEOREM 11. *The weight distribution of $C(r, 3)$ is given in the following table, where j runs over the set $\{|j| < 2^{(r+2)/2} \text{ and } j \equiv -1 \pmod{4}\}$:*

Weight	Frequency
0	1
$2^r(2^{r-1} - 1)$	$3(2^r - 1)^2$
$2^{r-1}(2^r - 1)$	$3(2^r - 1)$
$(2^r(2^r - 1) - j^2 + 1)/2$	$H(j^2 - 2^{r+2})(2^r - 1)^2$

To give the weight distribution of $C^\perp(r, 3)$ we denote by K_h the h th moment of the Kloosterman sum $k(a)$ over the field $\mathbb{F}$, i.e.,

$$K_h = \sum_{a \in \mathbb{F}^*} k(a)^h,$$

and use the following result from [10] which was proved by using results from [14].

THEOREM 12. *Let $q = 2^r$. Then*

$$K_0 = q - 1, \quad K_1 = 1, \quad K_2 = q^2 - q - 1, \quad K_3 = \pm q^2 + 2q + 1,$$

$$K_4 = 2q^3 - 2q^2 - 3q - 1,$$

$$K_5 = (t_7 \pm 4)q^3 + 5q^2 + 4q + 1,$$

$$K_6 = 5q^4 - (5 + (-1)^r)q^3 - 9q^2 - 5q - 1,$$

$$K_7 = (t_9 + 6t_7 \pm 14 + 1)q^4 + 14q^3 + 14q^2 + 6q + 1,$$

$$K_8 = 14q^5 - (15 \pm 7)q^4 - 28q^3 - 20q^2 - 7q - 1,$$

$$K_9 = (t_{11} + 8t_9 + 27t_7 + 8 \pm 48)q^5 + 42q^4 + 48q^3 + 27q^2 + 8q + 1,$$

$$K_{10} = 42q^6 - (51 \pm 35)q^5 - 90q^4 - 75q^3 - 35q^2 - 9q - 1 + 2048\tau(q/4) - \tau(q),$$

where $\pm$ denotes $(-1)^r$, $t_7 = \alpha_7^r + \bar{\alpha}_7^r$ with $\alpha_7 = (1 + \sqrt{-15})/4$, $t_9 = \alpha_9^r + \bar{\alpha}_9^r$ with $\alpha_9 = (-5 + \sqrt{-39})/8$, $t_{11} = \beta_{11}^r + \bar{\beta}_{11}^r + \eta_{11}^r + \bar{\eta}_{11}^r$ with $\beta_{11} = (-3 + \sqrt{505} + \sqrt{-510 - 6\sqrt{505}})/32$, $\eta_{11} = (-3 - \sqrt{505} + \sqrt{-510 + 6\sqrt{505}})/32$, and τ is the Ramanujan tau-function.

Remark 6. It is not hard to see that

$$\tau(q) - 2048\tau(q/4) = \mu_2^r + \bar{\mu}_2^r = D_r(-24, 2048),$$

where $\mu_2 = -12 + 4\sqrt{-119}$ and $D_r(x, 2048)$ is the Dickson polynomial of the first kind of degree r with parameter 2048 (see [11, section 2]).

THEOREM 13. *For every nonnegative integer h the number $C_h^\perp$ of codewords of weight h in the dual $C^\perp(r, 3)$ of $C(r, 3)$ is given by*

$$\begin{aligned} q^3 h! C_h^\perp &= f(C_0^\perp, \dots, C_{h-1}^\perp) + g(M_0, \dots, M_h) \\ &+ 3(q-1)^2 (-q)^h ((q-2)^h + (q-1)^{h-1}), \end{aligned}$$

where

$$\begin{aligned} f(C_0^\perp, \dots, C_{h-1}^\perp) &= q^3 \sum_{i=0}^{h-1} (-1)^{h+i+1} C_i^\perp \sum_{t=i}^h t! S(h, t) 2^{h-t} \binom{n-i}{n-t}, \\ g(M_0, \dots, M_h) &= \sum_{j=0}^h \binom{h}{j} (-1)^{j+h} (q-1)^{2(h-j+1)} \sum_{i=0}^j \binom{j}{i} (-q)^{j-i} K_{2i}. \end{aligned}$$

In particular,

$$\begin{aligned} C_0^\perp &= 1, \quad C_1^\perp = C_2^\perp = 0, \quad C_3^\perp = (q-1)^2 (2q-5 \mp 1)/3!, \\ C_4^\perp &= (q-1)^2 (q^3 - 6q^2 + (17 \mp 3)q - 24)/4!, \\ C_5^\perp &= (q-1)^2 (q^5 - 8q^4 + 14q^3 + 24q^2 - 4(7 \pm 5)q - 109 \mp 10 \\ &\quad + (2048\tau(q/4) - \tau(q))/q^3)/5!. \end{aligned}$$

Proof. The moments M_j in Theorem 4 are, by Lemma 7, of the form

$$\begin{aligned} M_j &= \sum_{l=0}^{q-2} (k(g^l)^2 - q)^j = \sum_{l=0}^{q-2} \sum_{i=0}^j \binom{j}{i} k(g^l)^{2i} (-q)^{j-i} \\ &= \sum_{i=0}^j \binom{j}{i} (-q)^{j-i} \sum_{l=0}^{q-2} k(g^l)^{2i} \\ &= \sum_{i=0}^j \binom{j}{i} (-q)^{j-i} K_{2i}, \end{aligned}$$

and the first claim follows now by Theorem 4. The validity of the formulae for the number of low-weight codewords can be verified by using Mathematica. $\square$

Remark 7. By Theorem 10, moments K_h can be calculated effectively for each nonnegative integer h by

$$K_h = \sum_{\substack{|j| < 2\sqrt{q} \\ j \equiv -1 \pmod{4}}} H(j^2 - 4q)j^h,$$

provided that r is not too large (an “ $H(d)$ -calculator” can be found in [7]).

Acknowledgments. The author would like to thank the anonymous reviewers for their detailed comments.

ORE CONDITION AND NOWHERE-ZERO 3-FLOWS*

GENGHUA FAN[†] AND CHUIXIANG ZHOU[†]

Abstract. Let G be a simple graph on n vertices, $n \geq 3$. It is well known that if G satisfies the Ore condition that $d(x) + d(y) \geq n$ for every pair of nonadjacent vertices x and y , then G has a Hamiltonian circuit, which implies that G has a nowhere-zero 4-flow. But it is not necessary for G to have a nowhere-zero 3-flow. In this paper, we prove that with six exceptions, all graphs satisfying the Ore condition have a nowhere-zero 3-flow. More precisely, if G is a graph on n vertices, $n \geq 3$, in which $d(x) + d(y) \geq n$ for every pair of nonadjacent vertices x and y , then G has no nowhere-zero 3-flow if and only if G is one of six completely described graphs.

Key words. Ore condition, degree sum, nowhere-zero 3-flow

1. Introduction. The vertex set and edge set of a graph G are denoted by $V(G)$ and $E(G)$, respectively. For $xy \in E(G)$, we call y a *neighbor* of x , and the set of neighbors of x in G is denoted by $N_G(x)$, or simply $N(x)$. Let H be a subgraph of G and $v \in V(G)$, and let $d_H(v) = |N(v) \cap V(H)|$ be the number of the neighbors of v in H . When $H = G$, $d_G(v)$ is called the *degree* of v and is abbreviated as $d(v)$. Denote by $\delta(G)$ and $\Delta(G)$ the minimum and maximum degree of G , respectively. For subgraphs A and B , $e(A, B)$ denotes the number of edges with one end in A and the other end in B .

An edge is *contracted* if it is deleted and its two ends are identified into a single vertex. Let H be a connected subgraph of G . G/H denotes the graph obtained from G by contracting all the edges of H and deleting all the resulting loops. For $S \subseteq V(G)$, $G - S$ denotes the graph obtained from G by deleting all the vertices of S together with all the edges with at least one end in S . When $S = \{v\}$, we simplify this notation to $G - v$. The complete graph on n vertices is denoted by K_n . Denote by K_n^- the graph obtained from K_n by deleting an edge.

A k -circuit is a circuit of k vertices. A *wheel* W_k is the graph obtained from a k -circuit by adding a new vertex, called the *center* of the wheel, which is joined to every vertex of the k -circuit. W_k is an *odd (even) wheel* if k is odd (even). For simplicity, A 3-circuit (triangle) on vertices $\{x, y, z\}$ is denoted by xyz .

Let G be a graph with an orientation. For each vertex $v \in V(G)$, $E^+(v)$ is the set of nonloop edges with tail v , and $E^-(v)$ is the set of nonloop edges with head v . Let $\mathbb{Z}_k$ denote an abelian group of k elements with identity 0. Let f be a function from $E(G)$ to $\mathbb{Z}_k$. Set

$$f^*(v) = \sum_{e \in E^+(v)} f(e) - \sum_{e \in E^-(v)} f(e).$$

FIG. 1.

f is a $\mathbb{Z}_k$ -flow in G if $f^*(v) = 0$ for each vertex $v \in V(G)$. For an edge $e \in E(G)$, we call $f(e)$ the *flow value* of e . The *support* of f is defined by $S(f) = \{e \in E(G) : f(e) \neq 0\}$. f is *nowhere-zero* if $S(f) = E(G)$. It is well known that a graph G has a nowhere-zero $\mathbb{Z}_k$ -flow if and only if there is an integer-valued function f on $E(G)$ such that $0 < |f(e)| < k$ for each $e \in E(G)$, and $f^*(v) = 0$ for each $v \in V(G)$, which is called a *nowhere-zero k -flow* in G . Therefore, we also call a $\mathbb{Z}_k$ -flow a *k -flow*. Tutte [7] conjectured that every 2-edge-connected graph has a nowhere-zero 5-flow. Seymour [6] proved that every 2-edge-connected graph has a nowhere-zero 6-flow. In this paper, we focus on the nowhere-zero 3-flow. Since loops play no role with respect to existence of nowhere-zero flows, we consider only loopless graphs. The well-known 3-flow conjecture of Tutte (see unsolved problem 48 of [1]) is as follows.

CONJECTURE 1.1. *Every 4-edge-connected graph has a nowhere-zero 3-flow.*

A subgraph H of G is *3-flow contractible* if G/H having a nowhere-zero 3-flow implies that G has a nowhere-zero 3-flow. It is well known that a 2-circuit (two parallel edges) is 3-flow contractible. By results in [2, Proposition 2.4 and Observation 1.3], the even wheel W_{2k} is 3-flow contractible for $k \geq 2$. Similarly, by [3, Corollary 3.5] and [2, Observation 1.3], K_n^- and K_n are 3-flow contractible for $n \geq 5$. In summary, we have the following.

PROPOSITION 1.2 (see [2, 3]). (i) W_{2k} is 3-flow contractible for $k \geq 2$; (ii) K_n^- and K_n are 3-flow contractible for $n \geq 5$.

PROPOSITION 1.3. *None of the six graphs in Figure 1 has a nowhere-zero 3-flow.*

Proof. G_1 is the complete graph K_4 , which does not have nowhere-zero 3-flows, and neither does G_2 since it is obtained from K_4 by subdividing an edge. It is known that the odd wheel has no nowhere-zero 3-flow, and thus G_3 has no nowhere-zero 3-flow. Since G_4 is a cubic graph with triangles, it is not bipartite, and thus has no nowhere-zero 3-flows. For the last two graphs G_5 and G_6 , suppose, to the contrary, that they have nowhere-zero 3-flows. By choosing orientations, we see that they have a $\mathbb{Z}_3$ -flow, in which each edge has a flow value of 1. Then, at each vertex of degree 3, all three edges are either out of or into the vertex, which means that the edge between the two vertices of degree 5 (in G_5) or degree 4 (in G_6) must have a flow value of zero, which is a contradiction. This shows that all six graphs in Figure 1 have no nowhere-zero 3-flows. $\square$

Let G be a simple graph on n vertices. It is well known that if G satisfies the Ore condition [5] that $d(x) + d(y) \geq n$ for every pair of nonadjacent vertices x and y , then G has a Hamiltonian circuit (an n -circuit in G), which implies that G has a nowhere-zero 4-flow. But it is not necessary for G to have a nowhere-zero 3-flow. It is easy to check that each of the six graphs in Figure 1 satisfies the Ore condition but has no nowhere-zero 3-flow. The main result of this paper is that these six graphs are the only ones that satisfy the Ore condition and have no nowhere-zero 3-flow.

MAIN THEOREM. *Let G be a simple graph on n vertices, $n \geq 3$. If $d(x) + d(y) \geq n$ for each $xy \notin E(G)$, then G has no nowhere-zero 3-flow if and only if G is one of the six graphs in Figure 1.*

The bound on the degree sum is best possible. For each $n \geq 7$, there exists a simple graph G on n vertices without a nowhere-zero 3-flow, in which $d(x) + d(y) \geq n - 1$ for each $xy \notin E(G)$. Let G be the graph obtained by joining vertex-disjoint K_3 and K_{n-3} with three independent edges, where $n \geq 7$. Then, $d(x) + d(y) \geq n - 1$ for every $xy \notin E(G)$. However, the contraction of the K_{n-3} results in a K_4 , which has no nowhere-zero 3-flow. Thus, G cannot have a nowhere-zero 3-flow.

2. Lemmas.

LEMMA 2.1. *If G is a cubic simple graph on six vertices, then either G is $K_{3,3}$ or G is G_4 in Figure 1.*

Proof. Clearly, if G contains no odd circuit, then G is $K_{3,3}$. Suppose that G has an odd circuit. Let C be the shortest odd circuit in G . If $|V(C)| = 5$, then C has no chord, which means that the only vertex not in C has degree 5, which is a contradiction. Thus, $|V(C)| = 3$. Since G is cubic and simple, vertices of C have no common neighbor in $V(G) \setminus V(C)$, and hence, G is G_4 in Figure 1. $\square$

LEMMA 2.2. *Let G be a simple graph on n vertices, where $3 \leq n \leq 6$. If $d(x) + d(y) \geq n$ for each $xy \notin E(G)$, then G has no nowhere-zero 3-flow if and only if G is one of the six graphs in Figure 1.*

Proof. If G is one of the six graphs in Figure 1, then, by Proposition 1.3, G has no nowhere-zero 3-flow. Conversely, suppose that G has no nowhere-zero 3-flow. We shall prove that it must be one of the six graphs. By the condition that $d(x) + d(y) \geq n$ for each $xy \notin E(G)$, $\delta(G) \geq 2$, and since G has no nowhere-zero 3-flow, we have that $n \geq 4$. If $n = 4$, by the given condition, G must be K_4 , the graph G_1 in Figure 1. Suppose therefore that $n \geq 5$.

(i) $n = 5$. If $\delta(G) = 2$, let $w \in V(G)$ with $d(w) = 2$ and $N(w) = \{u_1, u_2\}$. Let G' be the graph obtained from G by deleting w and adding u_1u_2 . If G' has a nowhere-zero 3-flow, then so does G , which is impossible. Therefore, G' must be K_4 , which implies that G is G_2 in Figure 1. If $\delta(G) \geq 3$, since n is odd, there is a vertex $u \in V(G)$ such that $d(u) = 4$. If $d(v) = 3$ for each $v \in V(G) \setminus \{u\}$, then G is the even wheel W_4 centered at u ; if there is $v \in V(G) \setminus \{u\}$ such that $d(v) = 4$, then G is K_5 or K_5^- . In either case, by Proposition 1.2, G has a nowhere-zero 3-flow, which is a contradiction.

(ii) $n = 6$. If $\delta(G) = 2$, let w be a vertex of degree 2 in G . Then, by the condition that $d(x) + d(y) \geq n$ for each $xy \notin E(G)$, all three vertices, not the neighbors of w , have degree at least 4, which means that $G - w$ is either K_5 or K_5^- . It follows from Proposition 1.2(ii) that G has a nowhere-zero 3-flow, which is a contradiction. Thus we may assume that $\delta(G) \geq 3$.

If $\Delta(G) = 3$, then G is cubic. By Lemma 2.1, G is G_4 in Figure 1.

If $\Delta(G) = 4$, since the number of the vertices of odd degrees in a graph must be even, G has at least two vertices of degree 4. If all the vertices of G have degree 4, then G has a nowhere-zero 2-flow, which is a contradiction. Suppose thus that G has at most four vertices of degree 4. Let x and y be two vertices of degree 4.

If $xy \notin E(G)$, then $N(x) = N(y)$. If there is a vertex $v \in N(x)$ with $d(v) = 4$, then there is an even wheel W_4 centered at v , and by Proposition 1.2, G has a nowhere-zero 3-flow; if $d(v) = 3$ for each $v \in N(x)$, then the subgraph induced by $N(x)$ consists of two independent edges. Then it is easy to check that G has a nowhere-zero 3-flow. In either case, we have a contradiction. Therefore, $xy \in E(G)$. By the arbitrariness of x

and y , we have that the subgraph induced by vertices of degree 4 in G is a complete subgraph.

If there are precisely two vertices of degree 4, say x and y , let G' be the graph obtained from G by removing the edge xy . Then G' is a cubic simple graph on six vertices. By Lemma 2.1, G' is either $K_{3,3}$ or G_4 in Figure 1. In the former case, G is the graph G_6 in Figure 1; in the later case, G is the graph obtained from G_4 by adding an edge between the two triangles, and it is easy to check that G has a nowhere-zero 3-flow, which is impossible. Suppose therefore that there are four vertices, say u, v, x , and y , of degree 4 in G . Recall that the subgraph induced by $\{x, y, u, v\}$ is K_4 . Let G' be the graph obtained from G by removing the edges xy and uv . Then G' is a cubic simple graph on six vertices. As before, by Lemma 2.1, G' is either $K_{3,3}$ or G_4 in Figure 1. It is not difficult to check that in either case, G has a nowhere-zero 3-flow, which is a contradiction.

If $\Delta(G) = 5$, let $u \in V(G)$ with $d(u) = 5$ and let N denote the subgraph induced by $N(u)$. We note that an even circuit in N together with u gives an even wheel centered at u , which implies, by Proposition 1.2(i), that G has a nowhere-zero 3-flow. Thus, we may assume that there is no even circuit in N . Then, each block of N is either K_1 or K_2 , or an odd circuit (see exercise 3.2.3 in [1]). But, $\delta(G) \geq 3$ and $|N(x)| = 5 = |V(G)| - 1$, and so each block of N is an odd circuit and N has at most two blocks. If N has exactly one block, then N is a circuit of length 5, and hence G is G_3 in Figure 1; if N has two blocks, then N consists of two triangles with exactly one vertex in common, and hence G is G_5 in Figure 1. This completes the proof of Lemma 2.2. $\square$

LEMMA 2.3. *Let G be a simple graph on n vertices, where $n \geq 7$. If $d(x) + d(y) \geq n$ for each $xy \notin E(G)$, then either G has a nowhere-zero 3-flow or G contains K_4^- .*

Proof. Suppose first that $\delta(G) \leq \frac{n-1}{2}$. Let $u \in V(G)$ with $d(u) = \delta(G)$. Let $R = G - (N(u) \cup \{u\})$. Then $|V(R)| \geq \frac{n-1}{2} \geq 3$. For any $v \in V(R)$, by the given condition, $d(v) + d(u) \geq n$, and so $d(v) \geq \frac{n+1}{2}$, which implies that there is an edge $xy \in E(R)$. Note that $d(x) + d(y) \geq \frac{n+1}{2} + \frac{n+1}{2} = n + 1$, but $u \notin N(x) \cup N(y)$, and so $|N(x) \cap N(y)| \geq 2$. Any two vertices in $N(x) \cap N(y)$ together with x and y induce a K_4^- . Therefore, we assume that $\delta(G) \geq \frac{n}{2}$. Let $e = |E(G)|$. Then $e \geq \frac{n^2}{4}$, and by the Turan theorem, either G contains a triangle or G is the complete bipartite graph $K_{m,m}$, where $m = \frac{n}{2}$.

(i) G contains a triangle $T = v_1v_2v_3$. For any $u \in V(G) \setminus V(T)$, if u has two neighbors in T , then we have a K_4^- . Suppose therefore that each vertex in $V(G) \setminus V(T)$ has at most one neighbor in T . It follows that

$$d(v_1) + d(v_2) + d(v_3) \leq (n - 3) + 6 = n + 3.$$

But $\delta(G) \geq \frac{n}{2}$, and thus we have that

$$d(v_1) + d(v_2) + d(v_3) \geq \frac{3n}{2}.$$

Combining the two inequalities yields that $n \leq 6$, which is a contradiction.

(ii) G is the complete bipartite graph $K_{m,m}$, where $m = \frac{n}{2}$. It is known that $K_{m,m}$ has a nowhere-zero 3-flow (see [4]). For completeness, we present a proof here. If m is even, then $K_{m,m}$ is Eulerian and has a nowhere-zero 2-flow; if m is odd, $K_{m,m}$ can be decomposed into a set of 2-factors (each has a nowhere-zero 2-flow) and a bipartite cubic graph, which is known to have a nowhere-zero 3-flow, and combining these flows yields a nowhere-zero 3-flow in $K_{m,m}$. In either case, G has a nowhere-zero 3-flow. This completes the proof of Lemma 2.3. $\square$

3. Proof of main theorem. If G is one of the six graphs in Figure 1, then, by Proposition 1.3, G has no nowhere-zero 3-flow. Conversely, suppose that G is not any of the six graphs in Figure 1. We shall prove that G has a nowhere-zero 3-flow. By the given degree-sum condition, we have that $\delta(G) \geq 2$.

We use induction on $n = |V(G)|$. If $n \leq 6$, the theorem holds by Lemma 2.2. Suppose thus that $n \geq 7$ and the theorem holds for any graph G' with $|V(G')| < n$. If G has a vertex of degree 2, let $w \in V(G)$ with $d(w) = 2$ and $H = G - w$. By the given degree-sum condition, each vertex in $V(H) \setminus N(w)$ has degree at least $n - 2$, which implies that H is either K_{n-1} or K_{n-1}^- . It follows from Proposition 1.2(ii) that G has a nowhere-zero 3-flow. In what follows, we assume that $\delta(G) \geq 3$.

CLAIM 1. *If there are distinct vertices $x, y \in V(G)$ such that $d(x) = d(y) = 3$, then G has a nowhere-zero 3-flow.*

By the given degree-sum condition, and since $n \geq 7$, we have that $xy \in E(G)$. Let $B = N(x) \cup N(y)$ and $R = G - B$. By the given condition again, for each vertex $v \in V(R)$, $d(v) \geq n - 3$. If $|V(R)| \geq 3$, then R together with any two vertices of $B \setminus \{x, y\}$ induces a K_m or K_m^- , where $m \geq 5$. By Proposition 1.2(ii), G has a nowhere-zero 3-flow. Therefore, we assume that $|V(R)| \leq 2$.

(i) $|V(R)| = 1$, then $n = 7$, and by the given degree-sum condition, there is a W_4 centered at the unique vertex of R . By Proposition 1.2(i), G has a nowhere-zero 3-flow.

(ii) $|V(R)| = 2$, then $|V(B)| = 6$ or 5 . If $|V(B)| = 6$, then as in case (i), we have a W_4 and are done. If $|V(B)| = 5$, then G is a graph on seven vertices, which either contains a K_5 or K_5^- , or each vertex, except for x and y , has degree 4. In any case, G has a nowhere-zero 3-flow. This proves the claim.

By Lemma 2.3, we may assume that G contains a K_4^- . Consider the K_4^- as the union of two triangles xyz and xyw , with edge xy in common. By Claim 1, either $d(z) \geq 4$ or $d(w) \geq 4$. Without loss of generality, we assume that $d(z) \geq 4$. Let G' be the graph obtained from G by deleting zx , zy and adding xy . In G' , we have a 2-circuit on $\{x, y\}$. Let G^1 be the graph obtained from G' by contracting the 2-circuit on $\{x, y\}$ into a single vertex u^* . Then, G^1 has a 2-circuit on $\{u^*, w\}$. Let G^2 be the graph obtained from G^1 by contracting the 2-circuit on $\{u^*, w\}$; for convenience, the resulting new vertex is still denoted by u^* . If there is a 2-circuit containing u^* , we continue to contract the 2-circuit into u^* and denote the resulting graph by G^3 . Keep going this way until no 2-circuit exists. Let $G^1, G^2, \dots, G^t$ be a sequence of graphs obtained in the above-described way of contracting 2-circuits. So, for each i , G^i is obtained from G^{i-1} by contracting a 2-circuit into u^* , $1 \leq i \leq t$, where $G^0 = G'$. Note that G^t is a simple graph, in which all vertices, except for u^* and z , have the same degree as in G . Since G^t is obtained from G' by consecutively contracting 2-circuits, if G^t has a nowhere-zero 3-flow, then so does G' . Moreover, there is a subgraph H such that $G^t = G'/H$. Let $|V(G^t)| = n^*$. Since $t \geq 2$, we have that $n^* \leq n - 2$. If $n^* \leq 3$, then G^t has a nowhere-zero 3-flow, which implies that G' , and so G , has a nowhere-zero 3-flow. Thus, assume that $n^* \geq 4$.

CLAIM 2. *For any distinct $u, v \in V(G^t)$ and $uv \notin E(G^t)$, $d_{G^t}(u) + d_{G^t}(v) \geq n^*$.*

If $u, v \in V(G^t) \setminus \{z, u^*\}$, then

$$d_{G^t}(u) + d_{G^t}(v) = d_G(u) + d_G(v) \geq n > n^*.$$

If $u \neq u^*$ and $v = z$, then, using that $d_{G^t}(z) = d_G(z) - 2$, we have

$$d_{G^t}(u) + d_{G^t}(v) = d_G(u) + d_G(v) - 2 \geq n - 2 \geq n^*.$$

If $u = u^*$ and $v \neq z$, then, since $d_{G^t}(u^*) \geq d_G(w) - (|V(H)| - 1)$, we have that

$$d_{G^t}(u) + d_{G^t}(v) \geq d_G(w) - (|V(H)| - 1) + d_G(v) \geq n - (|V(H)| - 1) = n^*.$$

What remains is the case that $u = u^*$ and $v = z$. Let $R = G - V(H)$. For any $a \in V(H) \setminus \{x, y\}$, we have that

$$d_{G^t}(u^*) \geq d_G(a) - (|V(H)| - 1) + e(H - a, R - z).$$

Since $d_{G^t}(z) = d_G(z) - 2$, it follows that

$$d_{G^t}(z) + d_{G^t}(u^*) \geq d_G(z) - 2 + d_G(a) - (|V(H)| - 1) + e(H - a, R - z).$$

Using that $d_G(z) + d_G(a) \geq n$ and $n - (|V(H)| - 1) = n^*$, we obtain that

$$d_{G^t}(z) + d_{G^t}(u^*) \geq n^* - 2 + e(H - a, R - z).$$

If $e(H - a, R - z) \geq 2$, then $d_{G^t}(z) + d_{G^t}(u^*) \geq n^*$ as claimed. Suppose therefore that for any $a \in V(H) \setminus \{x, y\}$,

$$(3.1) \quad e(H - a, R - z) \leq 1.$$

If $|V(H)| = 3$, that is, $V(H) = \{x, y, w\}$, then by (3.1), $e(xy, R - z) \leq 1$. We may assume that $e(x, R - z) = 0$. Then, $d_G(x) = 3$, and by the given degree-sum condition, for each $r \in V(R - z)$, we have $d_G(r) \geq n - 3$, which implies that $e(r, \{z, y, w\}) \geq 2$, and so

$$e(\{z, y, w\}, R - z) \geq 2|V(R - z)| = 2(n - 4).$$

But $d_{G^t}(z) + d_{G^t}(u^*) = e(\{z, y, w\}, R - z)$, and so $d_{G^t}(z) + d_{G^t}(u^*) \geq 2(n - 4) > n - 2 \geq n^*$ as claimed.

If $|V(H)| \geq 4$, for any $a \in V(H) \setminus \{x, y\}$, we have that

$$(3.2) \quad e(a, R) \geq 1;$$

otherwise, for each $r \in V(R - z)$, by the given degree-sum condition, we have $e(r, H) \geq 2$, contradicting the fact that G^t is simple. By (3.1) and (3.2), we see that $|V(H)| = 4$, say $V(H) = \{x, y, w, b\}$. Furthermore, since $u^*z \notin E(G^t)$, we have that $e(z, V(H) \setminus \{x, y\}) = 0$. It follows that

$$(3.3) \quad e(xy, R - z) = 0 \quad \text{and} \quad e(w, R - z) = e(b, R - z) = 1.$$

Since $n^* \geq 4$, we have that $|V(R - z)| \geq 2$. By Claim 1, there is a vertex in $R - z$ with degree at least 4 in G . It follows from (3.3) that $|V(R)| \geq 4$, and there is an $r \in V(R - z)$ such that $e(r, H) = 0$. Then $|N(r) \cap N(w)| \leq 1$, which implies that $d_G(r) + d_G(w) \leq n - 1$. This contradiction completes the proof of Claim 2.

By Claim 2 and the induction hypothesis, either G^t has a nowhere-zero 3-flow or G^t is one of the six graphs in Figure 1. In the former case, since G^t is obtained from G' by consecutively contracting 2-circuits, we see that G' , and thus G , has a nowhere-zero 3-flow, and we are done. In the latter case, G^t contains at least four vertices of degree 3, at least two of which have degree 3 in the original graph G , and by Claim 1, G has a nowhere-zero 3-flow. This completes the proof of the main theorem. $\square$

LARGE MONOCHROMATIC COMPONENTS IN TWO-COLORED GRIDS*

JIŘÍ MATOUŠEK[†] AND ALEŠ PŘÍVĚTIVÝ[‡]

Abstract. Let D_n^d denote the d -dimensional *grid with diagonals*, that is, the graph with vertex set $\{1, 2, \dots, n\}^d$ and with edges connecting every two vertices that differ by at most 1 in every coordinate. We prove that for an arbitrary coloring of the vertices of D_n^d by two colors there exists a monochromatic connected subgraph with at least $n^{d-1} - d^2 n^{d-2}$ vertices; and thus the “horizontal layer” coloring (by the parity of the first coordinate) is almost optimal. We also consider a d -dimensional *triangulated grid*; this is the graph (1-skeleton) of a triangulation of the solid cube $[1, n]^d$ that refines the subdivision of $[1, n]^d$ into the grid of unit cubes. Here every two-coloring has a monochromatic connected subgraph with $\Omega(n^{d-1}/\sqrt{d})$ vertices. These results are proved by combining combinatorial and topological arguments with suitable isoperimetric inequalities, and they can be viewed as d -dimensional generalizations of the planar HEX lemma.

1. Introduction. *The HEX lemma.* Let T_n^2 be the graph of an $n \times n$ triangulated square grid in the plane as in Figure 1. Here n counts the number of rows and columns of vertices; so the picture has $n = 6$. The well-known planar HEX lemma asserts that if the vertices of T_n^2 are colored red and blue in an arbitrary way, then there exists a path in T_n^2 connecting the top and bottom sides and having all vertices red, or a path connecting the left and right sides and having all vertices blue. In particular, under any two-coloring of the vertices of T_n^2 there is a monochromatic connected subgraph with at least n vertices.

Triangulated grids. Our results can be regarded as d -dimensional generalizations of the HEX lemma. First, we consider a d -dimensional *triangulated grid* T_n^d , which is defined geometrically as follows. We begin with the d -dimensional solid cube $[1, n]^d$ and subdivide it into the grid of unit cubes; each unit cube is of the form $[i_1, i_1 + 1] \times [i_2, i_2 + 1] \times \dots \times [i_d, i_d + 1]$, $1 \leq i_1, i_2, \dots, i_d \leq n - 1$. Then we triangulate each of the unit cubes in such a way that the simplices of all of these triangulations taken together form a triangulation of $[1, n]^d$ (here a triangulation is a simplicial complex in the sense of algebraic topology, i.e., a face-to-face triangulation with no additional vertices; see section 2). Then T_n^d is the graph (or 1-skeleton) of such a triangulation; that is, the vertex set is $[n]^d$ (where we use the shorthand $[n]$ for the set $\{1, 2, \dots, n\}$), and the edges of T_n^d are the edges of the triangulation. Thus, for given n and d , T_n^d is not defined uniquely, but rather it stands for an arbitrary graph from a (finite) family.

FIG. 1. A triangulated square grid.

We consider an arbitrary coloring of $[n]^d$ by two colors and we ask, What can be said about the number of vertices of the largest monochromatic connected subgraph of T_n^d ? The obvious “horizontal layer” coloring, by the parity of the first coordinate, shows an upper bound of n^{d-1} for this quantity in the worst case, and one might suspect this coloring to be optimal. However, it turns out that for $d \geq 3$, there are better colorings, at least for *some* of the possible triangulated grids. Namely, let us define the i th diagonal layer $L_n^d(i)$ by $L_n^d(i) = \{x \in [n]^d : \sum_{j=1}^d x_j = i\}$, and the *diagonal-layer coloring* by coloring all $L_n^d(i)$ with even i red and odd i blue. As we will verify in section 7, there are triangulated grids T_n^d with no edges connecting $L_n^d(i)$ and $L_n^d(i')$ with $|i - i'| \geq 2$, and, for these, the largest monochromatic connected component is the largest diagonal layer. For $d = 3$, for example, $\max_i |L_n^d(i)|$ is approximately $\frac{3}{4}n^2$.

We prove that the diagonal-layer coloring is not far from optimal in the worst case. To state the result precisely, let us define, for $\alpha \in [0, 1]$ and given n and d ,

$$i_\alpha = \min \left\{ i : \sum_{j \leq i} |L_n^d(j)| > \alpha n^d \right\}.$$

It can be checked that $i_{1/2} = \lceil \frac{(n+1)d}{2} \rceil$ and that $L_n^d(i_{1/2})$ is either the single largest diagonal layer or one of the two largest diagonal layers; see Lemma 5.3. We prove the following theorem.

THEOREM 1.1. *For an arbitrary two-coloring of the vertices of a d -dimensional triangulated grid T_n^d , $n \geq 3$, there exists a monochromatic connected subgraph with at least $|L_n^d(i_{2/3})| - |L_n^{d-1}(i_{1/2})|$ vertices. The last quantity is of order $\frac{n^{d-1}}{\sqrt{d}}$.*

We conjecture that the right answer is $|L_n^d(i_{1/2})|$ instead of $|L_n^d(i_{2/3})| - |L_n^{d-1}(i_{1/2})|$; that is, the diagonal-layer coloring is optimal in the worst case. This would follow from a natural and very plausible-looking conjecture stated in section 8. The numerical values of $|L_n^d(i_{1/2})|$ and $|L_n^d(i_{2/3})| - |L_n^{d-1}(i_{1/2})|$ are not too far from each other, as is illustrated by Table 1 (showing approximate values for small fixed d and $n \rightarrow \infty$).

TABLE 1

	$ L_n^d(i_{1/2}) $	$ L_n^d(i_{2/3}) - L_n^{d-1}(i_{1/2}) $
$d = 3$	$0.750n^2$	$0.698n^2$
$d = 4$	$0.667n^3$	$0.609n^3$
$d = 5$	$0.599n^4$	$0.549n^4$
$d = 10$	$0.430n^9$	$0.393n^9$
$d = 20$	$0.307n^{19}$	$0.280n^{19}$

Let us remark that the proof of Theorem 1.1 works for graphs G somewhat more general than T_n^d . However, since we do not see any good use of such greater generality at the moment, we stick to the concrete geometric formulation as before. If needed, the properties of the graph actually required can be reconstructed from the proof.

Grid with all diagonals. Next, we consider the d -dimensional grid with *all* diagonals of the unit cubes added. That is, we define the graph D_n^d , the d -dimensional *grid with diagonals*, as the graph with vertex set $[n]^d$ and edge set $\{\{u, v\} : u, v \in [n]^d, \|u - v\|_\infty \leq 1\}$, where $\|u - v\|_\infty = \max_i |u_i - v_i|$. In this case we show that the horizontal-layer coloring is almost optimal (the remaining lower order term is probably an artifact of the proof method).

THEOREM 1.2. *For an arbitrary two-coloring of the vertices of the grid with diagonals D_n^d , there exists a monochromatic connected subgraph with at least $n^{d-1} - d^2n^{d-2}$ vertices.*

Related work. There is a different and well-known d -dimensional generalization of the planar HEX lemma appearing, e.g., in Gale [G79] (also see Linial and Saks [LS93] for a different proof and an application in computer science). It asserts that if the vertices of T_n^d are colored by d colors, then there is a monochromatic path connecting two opposite facets of the cube $[1, n]^d$. In particular, there is a monochromatic connected component with at least n vertices.

The problem considered in this paper fits in the following general context. For an arbitrary graph G and an integer k , let us define $\text{mcc}_k(G)$ as the smallest m such that there exists a coloring of the vertices of G by k colors with no monochromatic connected subgraph having more than m vertices. (The letters mcc abbreviate “monochromatic connected component.” The usual chromatic number $\chi(G)$ equals $\min\{k : \text{mcc}_k(G) = 1\}$.)

The quantity $\text{mcc}_k(G)$ was investigated by Kleinberg, Motwani, Raghavan, and Venkatasubramanian [KMR+97] in the context of data storage management. They call a coloring witnessing $\text{mcc}_k(G) \leq c$ a (k, c) -*fragmented coloring*. They proved, among other things, that mcc_3 can be arbitrarily large for planar graphs (we note that $\text{mcc}_4 = 1$ for planar graphs by the four-color theorem), and that for a suitable absolute constant $\varepsilon > 0$ and for every Δ there is an infinite family $\{G_n\}$ of graphs of maximum degree Δ with $\text{mcc}_{\varepsilon\sqrt{\Delta}}(G_n) > \varepsilon|V(G_n)|$.

Apparently independent of the work of Kleinberg et al., $\text{mcc}_k(G)$ has been studied extensively by graph-theorists for graphs of bounded degree, mainly for $k = 2$. It is easy to see that any graph G of maximum degree 3 has $\text{mcc}_2(G) \leq 2$. Alon, Ding, Oporowski, and Vertigan [ADO+03] proved that every graph G of maximum degree 4 satisfies $\text{mcc}_2(G) \leq 57$. Haxell, Szabó, and Tardos [HST03] improved this to $\text{mcc}_2(G) \leq 6$ and proved that $\text{mcc}_2(G) \leq 20000$ for every graph G of maximum

degree 5. On the other hand, Alon et al. [ADO+03] constructed 6-regular graphs G with $\text{mcc}_2(G)$ arbitrarily large. For graphs G of maximum degree 3 it was also shown in [BS05] that they admit two-coloring where one color induces an independent set, while the other color induces components of size at most 189. Earlier work on this subject, [DOS+96] and [JW96], mainly focused on more specific questions concerning line graphs of 3-regular graphs. These investigations culminated in [Tho99] showing that the edges of every 3-regular graph can be two-colored so that each monochromatic component is a path of length at most 5. Recently Linial, Matoušek, Sheffet, and Tardos [LMST07] investigated the order of magnitude of mcc_k for several graph classes; for example, they showed that $\text{mcc}_2(G) = O(n^{2/3})$ for every planar graph on n vertices, and this bound is tight for some planar graphs.

Outline of the proofs of Theorems 1.1 and 1.2. To prove Theorem 1.1, we consider a red-blue coloring of $[n]^d$. Assuming that no monochromatic connected component in T_n^d is very large, we prove that T_n^d has a connected monochromatic *separator*, where a separator in a graph G is a subset $S \subseteq V(G)$ whose removal disconnects G into components of size at most $\frac{1}{2}|V(G)|$. The only property of T_n^d that we use for this part is that it is the graph of a simply connected simplicial complex. Theorem 1.1 then follows from a known result about the vertex expansion of the ordinary grid graph (not triangulated). Theorem 1.2 follows along similar lines: We verify that D_n^d is also the graph of a simply connected simplicial complex (which is not obvious here, unlike in the case of T_n^d), and then we apply a bound on the vertex expansion of D_n^d . We derive this bound from an edge-isoperimetric inequality for the ordinary grid.

2. Topological preliminaries. Here we present some material from elementary algebraic topology. We briefly recall even very standard things in order to make the paper more accessible; see, e.g., [Hat01] or [Mun84] for more details and background.

Simplicial complexes. A (geometric) *simplex* σ is the convex hull of a finite affinely independent set A in some $\mathbf{R}^d$. The points of A are the *vertices* of σ . The *dimension* of σ is $\dim \sigma := |A| - 1$. Thus a *k-simplex* (*k-dimensional simplex*) has $k + 1$ vertices. The convex hull of an arbitrary subset of vertices of a simplex σ is a *face* of σ (every face is itself a simplex).

A nonempty family K of simplices is a (geometric) *simplicial complex* if the following two conditions hold:

1. Each face of any simplex $\sigma \in K$ is also a simplex of K .
2. The intersection $\sigma_1 \cap \sigma_2$ of any two simplices $\sigma_1, \sigma_2 \in K$ is a face of both σ_1 and σ_2 .

In this paper we consider only simplicial complexes with finitely many simplices. A *subcomplex* of a simplicial complex K is a subset L of the simplices of K that constitutes a simplicial complex.

The union of all simplices in a simplicial complex K is the *polyhedron* of K and is denoted by $\|K\|$. In this situation K is called a *triangulation* of the topological space $\|K\|$.

The *vertex set* of K , denoted by $V(K)$, is the union of the vertex sets of all simplices of K . The *graph* (or *1-skeleton*) of K , denoted by $G(K)$, has the vertex set $V(K)$; two vertices are connected by an edge if they are contained in a common 1-simplex (edge) of K .

Simplicial maps and simplicial approximation. Let K and L be simplicial complexes. A *simplicial map* of K into L is a continuous map $f: \|K\| \rightarrow \|L\|$ such that the image of every simplex $\sigma \in K$ is a simplex of L (in particular, every vertex of K is mapped to a vertex of L); moreover, f restricted to each simplex $\sigma \in K$ is an affine

FIG. 2. A variant of the HEX lemma.

map.

Let K and $\tilde{K}$ be simplicial complexes. We call $\tilde{K}$ a *refinement* of K if $\|\tilde{K}\| = \|K\|$ and every simplex of $\tilde{K}$ is contained in some simplex of K (and thus for every nonempty simplex σ of K there is a subcomplex of $\tilde{K}$ that is a triangulation of σ).

We will need the following proposition, which is a variation of the standard *simplicial approximation theorem*.

PROPOSITION 2.1. *Let K and L be simplicial complexes, and let $f: \|K\| \rightarrow \|L\|$ be an arbitrary continuous map. Then there is a refinement $\tilde{K}$ of K and a simplicial map $\tilde{f}$ of $\tilde{K}$ into L such that*

- (*) *If $\sigma \in K$ is a simplex such that $f(\sigma)$ is completely contained in some simplex $\tau \in L$, then $\tilde{f}$ maps all vertices of K lying in σ to vertices of τ . In particular, if $f(v) \in V(L)$ for some $v \in V(K)$, then $\tilde{f}(v) = f(v)$.*

The usual simplicial approximation theorem also yields $\tilde{f}$ homotopic to f (but we do not need this part). On the other hand, condition (*) does not appear in the formulations of the simplicial approximation theorem in the literature, but it immediately follows from the standard proof; see, for example, [Hat01] or [Mun84].

A variant of the HEX lemma. Let T be a 2-dimensional simplicial complex with $\|T\|$ homeomorphic to B^2 , the unit disk in the plane, and let C_T be the cycle in the graph $G(T)$ corresponding to the boundary of B^2 . (So $G(T)$ can be drawn in the plane with the outer face bounded by C_T and with all inner faces being triangles.) We need the following variant of the HEX lemma.

LEMMA 2.2. *Let T and C_T be as above, and let the vertices of T be colored red and blue. Let the vertices of C_T be partitioned into four sets, forming consecutive segments along C_T (see Figure 2), as follows: a set A of red and blue vertices, a single red vertex u , a set B of red and blue vertices, and a single red vertex v . If there is no blue path (path consisting of blue vertices) from A to B , then u and v are connected by a red path. See Figure 2.*

Proof. The case where C_T has four vertices (and thus A and B are singletons) and A and B are blue is Claim 6.1.4 in [MN98]. The case of A, B arbitrarily reduces to the previous case by adding two new vertices a and b in the outer face (see Figure 3), coloring them blue, connecting a to all vertices of $A \cup \{u, v\}$, and connecting b to all vertices of $B \cup \{u, v\}$. $\square$

3. Monochromatic connected separators. We recall that a topological space X is *simply connected* if each continuous map $f: S^1 \rightarrow X$ can be extended to a continuous map $\tilde{f}: B^2 \rightarrow X$ (S^1 denotes the unit circle, the boundary of B^2). A sim-

FIG. 3. A reduction to the 4-cycle case.

plicial complex K is simply connected if the topological space $\|K\|$ is simply connected.

Here is the main result of this section.

PROPOSITION 3.1. *Let $G = G(K)$ be the graph of a (finite) simply connected simplicial complex K . For an arbitrary coloring of $V(G)$ by two colors there exists a monochromatic connected separator, that is, a subset $S \subseteq V(G)$ such that all vertices in S have the same color, the subgraph induced by S is connected, and each component of $G \setminus S$ has at most $\frac{1}{2}|V(G)|$ vertices.*

We need the following lemma.

LEMMA 3.2. *Let G be a graph as in Proposition 3.1 with $V(G)$ colored red and blue. Let C be a cycle in G , let $u, v \in V(C)$ be two distinct red vertices, and let A and B be the two connected components (arcs) of $C \setminus \{u, v\}$. If there is no blue path from a vertex of A to a vertex of B in G , then u and v are connected by a red path.*

Proof. The goal is to apply Lemma 2.2. Let us take a triangulated disk T with $\|T\|$ homeomorphic to the unit disk and with the boundary cycle C_T such that C_T has the same length as C . Let $f_0: V(C_T) \rightarrow V(C)$ be an isomorphism of the two cycles, and let $f: \|C_T\| \rightarrow \|C\|$ be the (unique) extension of f_0 to a simplicial map. (So here we also regard C_T as a 1-dimensional subcomplex of T and C as a 1-dimensional subcomplex of K .) Since $\|T\|$ is homeomorphic to B^2 and since K is simply connected, f can be extended to a continuous map $\tilde{f}: \|T\| \rightarrow \|K\|$.

Applying our version of the simplicial approximation theorem (Proposition 2.1) to the mapping $\tilde{f}$, we obtain a refinement $\tilde{T}$ of T and a simplicial map $\tilde{f}$ of $\tilde{T}$ into K . Let $\tilde{C}_T$ be the subcomplex of $\tilde{T}$ that refines C_T (so $\|\tilde{C}_T\| = \|C_T\|$ is the boundary of the disk $\|T\|$).

According to condition (*) in Proposition 2.1, we have $\tilde{f}(v) = f(v)$ for every vertex v of C_T , and for every edge (1-simplex) e of C_T with vertices u and v , all vertices of $\tilde{C}_T$ lying in e are mapped by $\tilde{f}$ to either $f(u)$ or $f(v)$.

Each vertex of $\tilde{T}$ is mapped to a vertex $\tilde{f}(v) \in V(G)$ since $\tilde{f}$ is a simplicial map, so we can define the color of each $v \in V(\tilde{T})$ as the color of $\tilde{f}(v)$. We note that if $x_1, x_2, \dots, x_k$ is a monochromatic path in $\tilde{T}$, then $\tilde{f}(x_1), \tilde{f}(x_2), \dots, \tilde{f}(x_k)$ is a monochromatic walk in G . A monochromatic walk can be shortcut to a monochromatic path.

Now we check that $\tilde{T}$, $\tilde{C}_T$, and the two red vertices $u_T = f^{-1}(u)$ and $v_T = f^{-1}(v)$ satisfy the conditions of Lemma 2.2. Since the two components A and B of

$C \setminus \{u, v\}$ are not connected by a blue path in G , it follows that the two components of $\tilde{C}_T \setminus \{u_T, v_T\}$ are not connected by a blue path in $\tilde{T}$ either. Therefore, by Lemma 2.2, u_T and v_T are connected by a red path, and u and v are connected by a red path too, as claimed. $\square$

Proof of Proposition 3.1. If the vertices of G are colored with only one color, we can take $V(G)$ for S and we are done. Otherwise, we choose S as the vertex set of a monochromatic connected subgraph of G that is

- inclusion-maximal (no vertex of the same color can be added), and
- such that the largest component G_1 of $G \setminus S$ has the smallest possible number of vertices.

Without loss of generality, let S be colored blue.

We claim that G_1 has at most $\frac{1}{2}|V(G)|$ vertices. For contradiction, we thus assume $|V(G_1)| > \frac{1}{2}|V(G)|$. We define S' as the union of all inclusion-maximal red connected subgraphs of G_1 that have at least one vertex connected to S (so S' is the “red foam” on the blue surface of S facing G_1). We will show that S' is “better” than S ; namely, that S' induces an inclusion-maximal connected red subgraph of G and that the largest component of $G \setminus S'$ is smaller than G_1 . The set S' is red by definition.

Next, we show that S' induces a connected subgraph (then it will also be clear that it is inclusion-maximal, by the choice of S'). It suffices us to show that any two vertices u and v of S' are connected by a red path in G . Moreover, it suffices us to show this only for u and v , that are both connected to S by an edge. Let $u' \in S$ be a blue neighbor of u , and let $v' \in S$ be a blue neighbor of v . Since S is a blue connected subgraph, there is a blue path $\mathcal{P}_1$ connecting u' and v' . Since G_1 is connected, u and v are connected by a path $\mathcal{P}_2$ in G_1 , which is vertex-disjoint from $\mathcal{P}_1$. The path $\mathcal{P}_2$ may consist of vertices of both colors, but there is no blue path from a vertex of $\mathcal{P}_2$ to $\mathcal{P}_1$ (by the inclusion-maximality of S). The paths $\mathcal{P}_1$ and $\mathcal{P}_2$ together form a cycle C in G . The graph G and the cycle C satisfy all conditions of Lemma 3.2, and so we have a red path connecting u and v . Hence S' indeed induces a connected subgraph.

Each component of $G \setminus S'$ is contained either in $G_1 \setminus S'$, or in $G \setminus G_1$. We have $|V(G_1) \setminus S'| < |V(G_1)|$ since $S' \neq \emptyset$, and $|V(G) \setminus V(G_1)| < \frac{1}{2}|V(G)|$. Thus the largest component of $G \setminus S'$ is strictly smaller than G_1 , and this contradicts the choice of S . $\square$

4. D_n^d as the graph of a simply connected complex. In order to apply Proposition 3.1 to some graph G , we need to know that G is the graph of a simply connected simplicial complex. This is obviously true for T_n^d , a graph of a triangulated grid, but for D_n^d , the grid with all diagonals, this has to be established. (One could say that this is a somewhat artificial-looking way of proving a purely combinatorial statement about D_n^d , but it is a convenient one.)

LEMMA 4.1. *For all $n, d \geq 2$ there exists a simply connected (2-dimensional) simplicial complex K such that D_n^d is (isomorphic to) the graph of K .*

Let us note that the simplicial complexes K constructed in the following proofs cannot be embedded in $\mathbf{R}^d$ (and they are probably hard to visualize).

First proof. (This proof was simplified using a suggestion of a referee.) First, let us fix a triangulation T of the grid, i.e., a geometric simplicial complex refining the subdivision of $[1, n]^d$ into unit cubes as in the definition of the graphs T_n^d . Let K_0 be the 2-skeleton of the triangulation (consisting of all simplices of this T_n^d of dimension at most 2). This K_0 is simply connected since T is simply connected (we use the fact that the fundamental group of a simplicial complex is determined by the 2-skeleton).

Let $E = E(D_n^d) \setminus E(K_0)$ be the set of all edges of D_n^d not present in K_0 , and let $e_1, e_2, \dots, e_t$ be an enumeration of E such that shorter edges precede longer ones; that is, $i < j$ implies that $\|e_i\|_1 \leq \|e_j\|_1$, where we write $\|e\|_1 = \sum_{k=1}^d |u_k - v_k|$ for $e = \{u, v\}$.

We are going to define a sequence $K_0, K_1, \dots, K_t$ of simplicial complexes inductively, and $K = K_t$ will be as in Lemma 4.1. The simplicial complex K_i is obtained from K_{i-1} by adding the edge e_i plus a triangle with e_i as one of the edges, while the remaining two edges of the triangle are already present in K_{i-1} . Obviously, K_i is homotopy equivalent to K_{i-1} and hence by induction we get that each K_i is simply connected. We also have $E(K_t) = E(D_n^d)$. It remains to check that the triangles can indeed be added as described.

Let us write $e_i = \{u, v\}$, and let $a = \min\{k \in [d] : u_k \neq v_k\}$. Let $x \in [n]^d$ be the vertex

$$x = (u_1, \dots, u_a, v_{a+1}, \dots, v_d).$$

Since all edges $e \in E(D_n^d)$ with $\|e\|_1 = 1$ are already present in K_0 , we have $\|e_i\|_1 \geq 2$ and $u \neq x \neq v$.

The edges $\{u, x\}$ and $\{x, v\}$ belong to $E(D_n^d)$ and have length strictly smaller than $\|e_i\|_1$, and hence they are present in K_{i-1} . The triangle added to K_{i-1} to form K_i is $\{u, x, v\}$. $\square$

Second proof. (This proof was suggested by a referee.) For each $u \in [n]^d$ let C_u be the axis-parallel unit cube centered at u , and let K be the nerve of the set system $\{C_u : u \in [n]^d\}$ (that is, a set $I \subseteq [n]^d$ forms a simplex if $\bigcap_{u \in I} C_u \neq \emptyset$). The 1-skeleton of K is exactly D_n^d . By the nerve theorem, K is homotopy equivalent to $\bigcup_{u \in [n]^d} C_u = [\frac{1}{2}, n + \frac{1}{2}]^d$, which is simply connected. $\square$

5. Isoperimetric inequalities. For a graph G and a set $A \subseteq V(G)$, the *vertex boundary* of A in G is the set

$$\text{vert-bd}_G(A) = \{v \in V(G) : v \notin A, \{u, v\} \in E(G) \text{ for some } u \in A\}.$$

An *isoperimetric inequality* for G (or more precisely, a vertex-isoperimetric inequality) bounds from below the quantity $\min\{|\text{vert-bd}_G(A)| : A \subseteq V(G), |A| = s\}$ as a function of s .

The ordinary grid. Let G_n^d be the graph of the ordinary grid (not triangulated). Explicitly, $V(G_n^d) = [n]^d$ and $u, v \in V(G_n^d)$ are connected by an edge if $\|u - v\|_1 = \sum_{i=1}^d |u_i - v_i| = 1$.

A vertex-isoperimetric inequality for G_n^d was established by Bollobás and Leader [BL91a]. To state the inequality, we define the *simplicial order* on $[n]^d$ by setting $x <_{\text{simpl}} y$ if either $\sum_{i=1}^d x_i < \sum_{i=1}^d y_i$, or if $\sum_{i=1}^d x_i = \sum_{i=1}^d y_i$ and x precedes y lexicographically; that is, for some $i \in [d]$ we have $x_j = y_j$ for $j = 1, 2, \dots, i-1$ and $x_i < y_i$.

THEOREM 5.1 ([BL91a]). *For every $A \subseteq [n]^d$ we have $|\text{vert-bd}_{G_n^d}(A)| \geq |\text{bd}_{G_n^d}(I_{\text{simpl}}(|A|))|$, where $I_{\text{simpl}}(s)$ denotes the set of the first s elements of $[n]^d$ in the ordering $<_{\text{simpl}}$.*

To bound from below the size of the vertex boundary of arbitrary set $A \subseteq [n]^d$ we use the following lemma.

LEMMA 5.2. *Let $A \subseteq [n]^d$ with $|A| = \beta n^d$. Then we have $|\text{vert-bd}_{G_n^d}(A)| \geq |L_n^d(i_\beta)| - |L_n^{d-1}(i_{1/2})|$.*

Proof. By Theorem 5.1 it suffices to prove the statement only for A of the form $I_{\text{simpl}}(|A|)$. Then A is a subset of the union of the first i_β diagonal layers and the first $i_\beta - 1$ layers are fully contained in A .

Let us write D for the intersection of A with $L_n^d(i_\beta)$. If $D = \emptyset$, then $\text{vert-bd}_{G_n^d}(A) = L_n^d(i_\beta)$ and we are done. If $D \neq \emptyset$, then $\text{vert-bd}_{G_n^d}(A)$ is a disjoint union of two sets B_1 and B_2 , where $B_1 \subseteq L_n^d(i_\beta)$ and $B_2 \subseteq L_n^d(i_\beta + 1)$. It is easy to check that $B_1 = L_n^d(i_\beta) \setminus D$, and if we show that $|B_2| \geq |D| - |L_n^{d-1}(i_{1/2})|$, then we are done.

Let D' be D shifted by 1 in the first component; that is, $D' = D + (1, 0, \dots, 0)$. Similarly, let L' be $L_n^d(i_\beta) + (1, 0, \dots, 0)$. Since $D' \subseteq L'$, we have $D' \setminus [n]^d \subseteq L' \setminus [n]^d$, and from the fact that $D' \cap [n]^d \subseteq B_2$ we arrive at $|B_2| \geq |D| - |L' \setminus [n]^d|$.

The rest follows from the fact that $L' \setminus [n]^d$ is an exact copy of the set $L_n^{d-1}(i_\beta - n)$, which always has a smaller size than the middle layer $L_n^{d-1}(i_{1/2})$, as will be shown in Lemma 5.3. $\square$

Let us remark that some error term in the previous estimate of $\text{vert-bd}_{G_n^d}(A)$ is needed. For example, $\text{vert-bd}_{G_n^d}(I_{\text{simpl}}(21)) = 5$ for the case $n = 3$, $d = 3$, but $|L_3^3(i_{21/27})| = 6$.

LEMMA 5.3. *For any $n, d \in \mathbf{N}$ the following hold:*

- (a) $|L_n^d(\frac{(n+1)d}{2} - i)| = |L_n^d(\frac{(n+1)d}{2} + i)|$ for every $i = 0, 1, 2, \dots$, and therefore, $i_{1/2} = \lceil \frac{(n+1)d}{2} \rceil$.
- (b) The function $i \mapsto |L_n^d(i)|$ is nondecreasing on integers $i \leq \lceil \frac{(n+1)d}{2} \rceil = i_{1/2}$ and nonincreasing on integers $i \geq \lfloor \frac{(n+1)d}{2} \rfloor$.

Proof. (a) The function $f((x_1, \dots, x_d)) = (n+1 - x_1, \dots, n+1 - x_d)$ maps $L_n^d(\frac{(n+1)d}{2} - i)$ to $L_n^d(\frac{(n+1)d}{2} + i)$ and it is easy to check from definition that $i_{1/2} = \lceil \frac{(n+1)d}{2} \rceil$.

(b) The proof is by induction on d . For $d = 1, 2$ and any $n \geq 1$ the statement holds trivially. Fix some n and $d > 2$. We can partition the set $L_n^d(i)$ into n sets $L_1, \dots, L_n$ according to the last component of the vertices; that is

$$L_t = \{x \in L_n^d(i) : x_d = t\} \quad \text{for all } t \in [n].$$

It is easy to check that each L_t is isomorphic to $L_n^{d-1}(i - t)$ and thus

$$\begin{aligned} |L_n^d(i+1)| - |L_n^d(i)| &= \sum_{t=1}^n |L_n^{d-1}(i+1-t)| - \sum_{t=1}^n |L_n^{d-1}(i-t)| \\ &= |L_n^{d-1}(i)| - |L_n^{d-1}(i-n)|. \end{aligned}$$

We distinguish four cases:

1. If $i \leq \lceil \frac{(n+1)(d-1)}{2} \rceil$, then by the inductive hypothesis we have $|L_n^{d-1}(i-n)| \leq |L_n^{d-1}(i)|$.
2. If $\lceil \frac{(n+1)(d-1)}{2} \rceil < i < \lceil \frac{(n+1)d}{2} \rceil$, then by (a) we have

$$|L_n^{d-1}(i)| = |L_n^{d-1}((n+1)(d-1) - i)|.$$

Since

$$(i-n) \leq (n+1)(d-1) - i \leq \lceil \frac{(n+1)(d-1)}{2} \rceil,$$

we have by the inductive hypothesis that

$$|L_n^{d-1}(i-n)| \leq |L_n^{d-1}((n+1)(d-1) - i)| = |L_n^{d-1}(i)|.$$

3. If $\lfloor \frac{(n+1)d}{2} \rfloor \leq i < \lfloor \frac{(n+1)(d+1)}{2} + n \rfloor$, then by (a) we have

$$|L_n^{d-1}(i-n)| = |L_n^{d-1}((n+1)(d-1) - (i-n))|.$$

Since

$$i \geq (n+1)(d-1) - (i-n) \geq \lfloor \frac{(n+1)(d-1)}{2} \rfloor,$$

we have by the inductive hypothesis that

$$|L_n^{d-1}(i)| \leq |L_n^{d-1}((n+1)(d-1) - (i-n))| = |L_n^{d-1}(i-n)|.$$

4. If $i \geq \lfloor \frac{(n+1)(d+1)}{2} + n \rfloor$, then by the inductive hypothesis we have $|L_n^{d-1}(i-n)| \geq |L_n^{d-1}(i)|$. $\square$

PROPOSITION 5.4. For every $\alpha \in (0, \frac{1}{2})$ and every $A \subseteq [n]^d$ with $\alpha n^d \leq |A| \leq (1-\alpha)n^d$ we have $|\text{vert-bd}_{G_n^d}(A)| \geq |L_n^d(i_{1-\alpha})| - |L_n^{d-1}(i_{1/2})|$.

Proof. Let $|A| = \beta n^d$. By Lemma 5.2 we have $|\text{vert-bd}_{G_n^d}(A)| \geq |L_n^d(i_\beta)| - |L_n^{d-1}(i_{1/2})|$. If $\alpha \leq \beta \leq \frac{1}{2}$, then also $i_\alpha \leq i_\beta \leq i_{1/2}$, and by Lemma 5.3 we have $|L_n^d(i_\beta)| \geq |L_n^d(i_\alpha)|$. Similarly, for $\frac{1}{2} < \beta \leq (1-\alpha)$ we have $|L_n^d(i_\beta)| \geq |L_n^d(i_{1-\alpha})|$. Since $i_{1/2} \leq (n+1)d - i_\alpha \leq i_{(1-\alpha)}$, by Lemma 5.3 we have $|L_n^d(i_\alpha)| = |L_n^d((n+1)d - i_\alpha)| \geq |L_n^d(i_{(1-\alpha)})|$, and thus $|\text{vert-bd}_{G_n^d}(A)| \geq |L_n^d(i_{(1-\alpha)})| - |L_n^{d-1}(i_{1/2})|$. $\square$

The grid with diagonals. Here we derive the following vertex-isoperimetric inequality.

PROPOSITION 5.5. For any set $A \subseteq [n]^d$ with $\frac{1}{4}n^d \leq |A| \leq \frac{3}{4}n^d$ we have $|\text{vert-bd}_{D_n^d}(A)| \geq n^{d-1} - d^2 n^{d-2}$.

We are going to derive this result from an edge-isoperimetric inequality for the ordinary grid G_n^d . For $A \subseteq [n]^d$, let

$$\text{edge-bd}_{G_n^d}(A) = \{\{u, v\} \in E(G_n^d) : u \in A, v \notin A\}$$

be the edge boundary of A in G_n^d .

THEOREM 5.6 (see Bollobás and Leader [BL91b]). Let $A \subseteq [n]^d$. Then

$$|\text{edge-bd}_{G_n^d}(A)| \geq \begin{cases} 4|A|/n & \text{for } |A| < n^d/4, \\ n^{d-1} & \text{for } n^d/4 \leq |A| \leq 3n^d/4, \\ 4(n^d - |A|)/n & \text{for } |A| > 3n^d/4. \end{cases}$$

First we show, following [BL91a] almost verbatim, that it suffices to prove Proposition 5.5 for sets A that are *down-sets*. We begin with the necessary definitions from [BL91a].

A set $A \subseteq [n]^d$ is a *down-set* if $x \in A$ implies $y \in A$ for all $y \in [n]^d$ satisfying $y_i \leq x_i$ for all $i \in [d]$. For $A \subseteq [n]^d$ and $1 \leq i \leq d$, let the *i-section* of A at $x \in [n]^{d-1}$ be defined as

$$A^i(x) = \{t \in [n] : (x_1, \dots, x_{i-1}, t, x_i, \dots, x_{d-1}) \in A\}.$$

For $A \subseteq [n]^d$ and $1 \leq i \leq d$, let the *i-compression* of A be defined by giving its *i-sections*:

$$(C_i(A))^i(x) = \{1, \dots, |A^i(x)|\} \quad \text{for all } x \in [n]^{d-1}.$$

In other words, C_i “compresses” each i -section of A downwards. We note that $|C_i(A)| = |A|$, and it is also easy to check that if a set A is i -compressed, then so is $C_j(A)$. So the set $A' = C_n(C_{n-1}(\dots C_1(A)\dots))$ is i -compressed for every $i \in [d]$, and thus it is a down-set.

LEMMA 5.7. *Let $A \subseteq [n]^d$. Then there is a down-set $A' \subseteq [n]^d$ with $|A'| = |A|$ and $|\text{vert-bd}_{D_n^d}(A')| \leq |\text{vert-bd}_{D_n^d}(A)|$.*

Proof. For $A \subseteq [n]^d$, let $N(A) = A \cup \text{vert-bd}_{D_n^d}(A)$ denote the *closed neighborhood* of A . By the above remarks it suffices to prove that $|N(C_i(A))| \leq |N(A)|$ for all $A \subseteq [n]^d$ and all $i \in [d]$.

Let us write B for $C_i(A)$. The case $d = 1$ is easy; we have $|N(A)| \geq |A| + 1 = |N(B)|$ for all $A \subseteq [n]$ apart from $A = \emptyset$ and $A = [n]$. For $A = \emptyset$ and $A = [n]$ we have $|N(A)| = |A| = |B| = |N(B)|$.

For $d > 1$ it is sufficient to show that for each $x \in [n]^{d-1}$ we have

$$|(N(B))^i(x)| \leq |(N(A))^i(x)|.$$

Fixing an arbitrary $x \in [n]^{d-1}$, we have

$$(N(A))^i(x) = \bigcup_{y \in [n]^{d-1} : \|y-x\|_\infty \leq 1} N(A^i(y))$$

and

$$(N(B))^i(x) = \bigcup_{y \in [n]^{d-1} : \|y-x\|_\infty \leq 1} N(B^i(y)).$$

The sets $N(B^i(y))$ are initial segments of $[n]$, hence they are nested, and thus

$$|(N(B))^i(x)| \leq \max_{y \in [n]^{d-1} : \|y-x\|_\infty \leq 1} |N(B^i(y))|.$$

From the 1-dimensional case we know

$$|N(B^i(y))| \leq |N(A^i(y))|,$$

and therefore,

$$|(N(B))^i(x)| \leq |(N(A))^i(x)|. \quad \square$$

Proposition 5.5 now follows from Theorem 5.6, the previous lemma, and the next lemma.

LEMMA 5.8. *Let $A \subseteq [n]^d$ be a down-set. Then $|\text{vert-bd}_{D_n^d}(A)| \geq |\text{edge-bd}_{G_n^d}(A)| - d^2 n^{d-2}$.*

To prove this lemma we need the following claim.

CLAIM 5.9. *Let $A \subseteq [n]^d$ be a down-set. Then $|\text{edge-bd}_{G_n^d}(A)| \leq dn^{d-1}$.*

Proof. Since A is a down-set, for each $k \in [d]$ and $x \in [n]^{d-1}$ there is at most one $t \in [n-1]$ such that $\{u, v\} \in \text{edge-bd}_{G_n^d}(A)$, where $u = (x_1, \dots, x_{k-1}, t, x_{k+1}, \dots, x_d)$ and $v = (x_1, \dots, x_{k-1}, t+1, x_{k+1}, \dots, x_d)$. Hence there can be at most dn^{d-1} edges in $\text{edge-bd}_{G_n^d}(A)$. $\square$

Proof of Lemma 5.8. Let

$$E = \text{edge-bd}_{G_n^d}(A) \setminus \{\{u, v\} \in E(G_n^d) : u_i = v_i = n \text{ for some } i\}.$$

We show that E can be injectively mapped into $\text{vert-bd}_{D_n^d}(A)$. Let us construct a mapping $f: E \rightarrow [n]^d$ in the following way: For arbitrary edge $\{u, v\} \in E$, let i be the number of the component in which u and v differ by 1, and without loss of generality, let $u_i \leq v_i$. Then we put

$$f(\{u, v\}) = u + \underbrace{(1, 1, \dots, 1, 0, \dots, 0)}_{i \text{ times } 1}.$$

It is easy to check that $u_j < n$ for $j \leq i$, and hence $z = f(\{u, v\}) \in [n]^d$ indeed. We have $u \in A$ and $v \notin A$. If we had $z \in A$, then since A is a down-set and $v_i \leq z_i$ for all $i \in [d]$, it would follow that $v \in A$ as well. Thus $z \notin A$, and since $\|u - z\|_\infty = 1$, we arrive at $f(\{u, v\}) \in \text{vert-bd}_{D_n^d}(A)$.

Now we suppose for contradiction that there exist two edges $\{u_1, v_1\}, \{u_2, v_2\} \in E$ that are mapped by f to the same vertex z . Let i_1 be the number of the components where u_1 and v_1 differ by 1, and let i_2 be the number of the component where u_2 and v_2 do so. Without loss of generality, let $i_1 < i_2$. Then

$$v_2 = (z_1 - 1, \dots, z_{i_2-1} - 1, z_{i_2}, z_{i_2+1}, \dots, z_d)$$

is in all components less than or equal to

$$u_1 = (z_1 - 1, \dots, z_{i_1-1} - 1, z_{i_1} - 1, z_{i_1+1}, \dots, z_d).$$

Since A is a down-set, $u_1 \in A$ implies $v_2 \in A$. This contradiction shows that f is injective as claimed.

It remains to estimate the size of E . For $i \in [d]$ let us put $F_i = \{\{u, v\} \in \text{edge-bd}_{G_n^d}(A) : u_i = v_i = n\}$. It is easy to see that

$$|F_i| = |\text{edge-bd}_{G_n^{d-1}}(A_i)|,$$

where

$$A_i = \{(x_1, \dots, x_{d-1}) \in [n]^{d-1} : (x_1, \dots, x_{i-1}, n, x_i, \dots, x_{d-1}) \in A\}.$$

Since A_i is a down-set, Claim 5.9 gives $|F_i| \leq (d-1)n^{d-2}$, and thus

$$|E| \geq |\text{edge-bd}_{G_n^d}(A)| - \sum_{i=1}^d |F_i| \geq |\text{edge-bd}_{G_n^d}(A)| - d(d-1)n^{d-2},$$

which is even slightly better than the bound claimed in the lemma. $\square$

6. Proofs of Theorems 1.1 and 1.2. *Monochromatic connected separators again.* We will need the following standard consequence of Proposition 3.1.

COROLLARY 6.1. *Let G be the graph of a simply connected simplicial complex, and let $V(G)$ be colored red and blue. Then there exists a partition of $V(G)$ into three disjoint sets A , B , and S such that*

- *no edge connects a vertex of A to a vertex of B ,*
- *S is a monochromatic connected subgraph of G , and*
- *$|A|, |B| \leq \frac{2}{3}|V(G)|$.*

Proof. Let S be as in Proposition 3.1, and let $V_1, V_2, \dots, V_m$ be the vertex sets of the components of $G \setminus S$ ordered by size in the descending order. Let i be the largest index with $|V_1 \cup V_2 \cup \dots \cup V_i| \leq \frac{2}{3}|V(G)|$. Then $|V_1| + \dots + |V_i| \leq \frac{2}{3}|V(G)|$

and $|V_{i+2}| + \dots + |V_m| \leq \frac{1}{3}|V(G)|$. Let us put $A = V_1 \cup V_2 \cup \dots \cup V_i$ and $B = V \setminus A \setminus S$. Obviously, $|A| \leq \frac{2}{3}|V(G)|$, and since $|V(G)| - |B| \geq |A| \geq |V_{i+1}|$ and $|B| = |V_{i+1}| + |V_{i+2}| + \dots + |V_m| \leq |V_{i+1}| + \frac{1}{3}|V(G)|$, we arrive at $|B| \leq \frac{2}{3}|V(G)|$ too. $\square$

Proof of Theorem 1.1. We consider a two-colored graph T_n^d as in the theorem and a partition $V(T_n^d) = A \cup B \cup S$ as in Corollary 6.1 (S is a monochromatic connected separator). We may assume $|S| \leq \frac{1}{3}n^d$, for otherwise we would be done. Then $|A|$ or $|B|$ is between $\frac{1}{3}n^d$ and $\frac{2}{3}n^d$; let us fix the notation A, B so that $\frac{1}{3}n^d \leq |A| \leq \frac{2}{3}n^d$.

We now consider the grid graph G_n^d as a subgraph of T_n^d . We have $S \supseteq \text{ver-bd}_{T_n^d}(A) \supseteq \text{ver-bd}_{G_n^d}(A)$, and $|\text{ver-bd}_{G_n^d}(A)| \geq |L_n^d(i_{2/3})| - |L_n^{d-1}(i_{1/2})|$ by Proposition 5.4. The required estimates for $|L_n^d(i_{2/3})|$ and $|L_n^{d-1}(i_{1/2})|$ are established in the appendix. Theorem 1.1 is proved. $\square$

Proof of Theorem 1.2. We consider a two-coloring of the graph D_n^d . Lemma 4.1 tells us that D_n^d is the graph of a simply connected simplicial complex, and so using Corollary 6.1 we again find a partition $V(D_n^d) = A \cup B \cup S$. We may assume $|S| \leq \frac{1}{3}n^d$, for otherwise we would be done. We can again assume $\frac{1}{3}n^d \leq |A| \leq \frac{2}{3}n^d$, and using Proposition 5.5 we get $|S| \geq |\text{ver-bd}_{D_n^d}(A)| \geq n^{d-1} - d^2n^{d-2}$. Theorem 1.2 is proved. $\square$

7. An upper bound for certain triangulated grids. In this section we show that there exists a triangulated grid T_n^d in which every edge connects either two vertices from the same diagonal layer $L_n^d(i)$ or vertices from two consecutive diagonal layers $L_n^d(i)$ and $L_n^d(i+1)$. Thus, each monochromatic connected component in the diagonal-layer coloring of such T_n^d is contained in some $L_n^d(i)$.

To see that such triangulation exists, we consider the arrangement $\mathcal{A}$ of the following hyperplanes: $H_j^i = \{x : x_i = j\}$ for $j \in [n]$, $i = 0, \dots, d$, and $S_j = \{x : \sum x_k = j\}$ for $j = d, \dots, nd$. The vertices of this arrangement are of two types: the vertices of the first type are formed as the intersection of d hyperplanes among H_j^i , and the vertices of the second type are formed as the intersection of one hyperplane S_j and $d-1$ of the hyperplanes H_j^i .

The vertices of the first type are the grid points of $[n]^d$. An intersection of $d-1$ hyperplanes H_j^i is either empty or a line parallel to one of the coordinate axes, and if we intersect this line by some hyperplane S_j we get a vertex with integral coordinates. Thus, if we restrict ourselves to the hypercube $[1, n]^d$, the only possible vertices of our arrangement are the grid points of $[n]^d$.

The arrangement $\mathcal{A}$ is a polyhedral complex. Let $\mathcal{C}$ be the subcomplex of $\mathcal{A}$ consisting of all faces contained in $[1, n]^d$. The union of all faces of $\mathcal{C}$ is exactly $[1, n]^d$, $\mathcal{C}$ refines the subdivision of $[1, n]^d$ into unit cubes, and it remains to refine $\mathcal{C}$ to a triangulation. This can be done, for example, using the *bottom-vertex triangulation* (or *canonical triangulation*) of Clarkson [Cla88].

For each face F of $\mathcal{C}$, which is a convex polytope, we define the *bottom vertex* v as the vertex of F with the lexicographically smallest coordinate vector.

The bottom-vertex triangulation of $\mathcal{C}$ is defined inductively. For $k \geq 1$, we assume that all faces of $\mathcal{C}$ dimension at most k have already been triangulated (for $k = 1$ this is satisfied automatically, since the 1-dimensional faces are segments). Given a $(k+1)$ -dimensional face F , we let v be the bottom vertex of F , and we triangulate F as follows. For each simplex σ from the union of the triangulations of all proper faces of F , we consider the cone over σ with apex v , that is, the simplex $\text{conv}(\sigma \cup \{v\})$. Taking all of these simplices plus all simplices in the triangulation of all proper faces of F yields the bottom-vertex triangulation of F .

It is not hard to verify that this indeed defines a simplicial complex refining $\mathcal{C}$, and thus the desired triangulated grid T_n^d .

8. Open problems. We have considered colorings of the vertices of $[n]^d$ by two colors. The case of d colors is essentially solved by the d -dimensional HEX lemma. A natural and, in our opinion, very interesting question is, What happens for colorings by k colors for $3 \leq k \leq d-1$? An obvious conjecture is that the minimum possible size of the largest monochromatic connected subgraph should be about n^{d+1-k} in this case (for d and k fixed and $n \rightarrow \infty$), but at present we have nothing nontrivial to say about this question.

A natural bound one would expect in Theorem 1.1 (for a triangulated grid) would be the size of the “middle diagonal layer” $L_n^d(i_{1/2})$. However, our method yields only $|L_n^d(i_{2/3})|$. The improved bound of $|L_n^d(i_{1/2})|$ would follow immediately by our method from the following conjecture: *If $A \subseteq [n]^d$ is such that removing it from the grid G_n^d leaves no connected component larger than $\frac{1}{2}n^d$, then $|A| \geq |L_n^d(i_{1/2})|$.* This does not seem to follow from the vertex-isoperimetric inequality for G_n^d , since, in principle, for example, we might have a situation where $G_n^d \setminus A$ has three connected components of size about $\frac{1}{3}n^d$ each, and A is a common boundary of all three. While this or similar situations seem unlikely, we currently do not have a proof of the conjecture. We note that Kleitman [Kle86] proved a similar conjecture for the hypercube (that is, for the grid G_2^d), but adapting his method to larger grids seems nontrivial.

In the appendix below, we derive asymptotic bounds for the size of the diagonal layers $|L_n^d(i_{1/2})|$ and $|L_n^d(i_{2/3})|$, using a quantitative version of the central limit theorem. However, the estimated quantity is of a quite basic nature and it might well be that considerably more precise results are known.

Appendix. Bounding the size of diagonal layers. Let us recall that $L_n^d(i) = \{x \in [n]^d : \sum_{j=1}^d x_j = i\}$ and $i_\alpha = \min\{i : \sum_{j \leq i} |L_n^d(j)| > \alpha n^d\}$. Here we prove the following estimates.

PROPOSITION A.1. *There exist constants $C \geq c > 0$ such that for all $n > 1$ and all d we have*

$$\frac{c}{\sqrt{d}} n^{d-1} \leq |L_n^d(i_{2/3})| \leq |L_n^d(i_{1/2})| \leq \frac{C}{\sqrt{d}} n^{d-1}.$$

We use the following quantitative version of the central limit theorem by Feller [Fel43].

THEOREM A.2. *Let $X_1, \dots, X_d$ be independent random variables and suppose that their second moments $\sigma_1^2, \dots, \sigma_d^2$ exist. Let $S_i = X_1 + \dots + X_i$ and $s_i^2 = \sigma_1^2 + \dots + \sigma_i^2$ for $i = 1, \dots, d$, let $F_d(t) = \text{Prob}[S_d \leq t]$ be the distribution function of S_d , and let $\Phi(u)$ be the distribution function of the standard normal distribution. Let there exist a nonincreasing sequence $\lambda_1, \dots, \lambda_d$, such that $|X_k| \leq \lambda_k s_k$ for $k = 1, \dots, d$.*

If $0 < \lambda_d u < (3 - \sqrt{5})/4$, then

$$1 - F_d(us_d) = e^{-(1/2)u^2 Q_d(u)} \left((1 - \Phi(u)) + \theta \lambda_d e^{-(1/2)u^2} \right).$$

Here θ has an upper bound independent of the sequence $\{X_k\}$ and of d ; furthermore,

$$Q_d(u) = \sum_{\nu=1}^{\infty} q_{d,\nu} u^\nu,$$

where coefficient $q_{d,\nu}$ depends only on the ν first moments of $X_1, \dots, X_d$.

If, more particularly,

$$0 < \lambda_d u < 1/12,$$

then

$$|\theta| < 9$$

and

$$|q_{d,\nu}| < (1/7)(12\lambda_d)^\nu.$$

Moreover, for any $0 < i < j \leq d$ we have

$$|Q_j(u) - Q_i(u)| \leq (1/2)(s_j^2 - s_i^2)/s_n^2.$$

Let us assume that n is odd, $n = 2k + 1$; the case of even n is similar. Let us consider the sequence of independent random variables $X_1, \dots, X_d$, where each X_i is uniformly distributed on the set of integers $\{-k, -k + 1, \dots, k\}$. For this sequence $X_1, \dots, X_d$ we define S_d, F_d, s_d as in Feller's theorem. It is easy to see that $n^d F_d(t - \frac{nd+d}{2}) = \sum_{i=0}^t |L_n^d(i)|$ for all $t \in \mathbf{N}$.

In our case $\frac{\sqrt{dk}}{3} \leq s_d \leq \sqrt{dk}$, so we can put $\lambda_d = \frac{3}{\sqrt{d}}$. For $0 \leq u \leq 1$ and $d > 10^6$ it is seen that $\lambda_d u < \frac{1}{300}$, and thus

$$\begin{aligned} |Q_d(u)| &\leq \sum_{\nu=1}^{\infty} |q_{d,\nu} u^\nu| \leq \sum_{\nu=1}^{\infty} |q_{d,\nu}| \leq \sum_{\nu=1}^{\infty} \frac{1}{7} (12\lambda_d)^\nu \\ &\leq \frac{12\lambda_d}{7} \sum_{\nu=0}^{\infty} (12\lambda_d)^\nu \leq \frac{36}{7\sqrt{d}} \sum_{\nu=0}^{\infty} \left(\frac{12}{300}\right)^\nu \leq \frac{6}{\sqrt{d}}. \end{aligned}$$

Therefore we arrive at

$$\begin{aligned} e^{-3d^{-1/2}} &\leq e^{-\frac{1}{2}u^2 Q_d(u)} \leq e^{3d^{-1/2}} \\ 1 - 3d^{-1/2} &\leq e^{-\frac{1}{2}u^2 Q_d(u)} \leq 1 + 4d^{-1/2}. \end{aligned}$$

From

$$1 - F_d(us_d) = e^{-(1/2)u^2 Q_d(u)} \left((1 - \Phi(u)) + \theta \lambda_d e^{-(1/2)u^2} \right)$$

we derive

$$\begin{aligned} 1 - F_d(us_d) &\leq \left(1 + 4d^{-1/2}\right) \left(1 - \Phi(u) + 27d^{-1/2}\right) \\ F_d(us_d) &\geq \Phi(u) - 32d^{-1/2} \end{aligned}$$

and also

$$\begin{aligned} 1 - F_d(us_d) &\geq \left(1 - 3d^{-1/2}\right) \left(1 - \Phi(u) - 27d^{-1/2}\right) \\ F_d(us_d) &\leq \Phi(u) + 32d^{-1/2}. \end{aligned}$$

Let $q_1 = \Phi^{-1}(0.7)$ and $q_2 = \Phi^{-1}(0.8)$; we have $0 < q_1, q_2 < 1$. Then the i -layers for $i \in [q_1 s_d + \frac{nd+d}{2}, q_2 s_d + \frac{nd+d}{2}]$ contain together at least $\frac{1}{30}n^d$ vertices, since

$$\begin{aligned} F_d(q_2 s_d) - F_d(q_1 s_d) &\geq \Phi(q_2) - 32d^{-1/2} - \Phi(q_1) - 32d^{-1/2} \\ &= 1/10 - 64d^{-1/2} \geq 1/30. \end{aligned}$$

There are at most $(q_2 s_d - q_1 s_d) \leq kd^{1/2}$ such layers, so the largest of them, $L_n^d(q_1 s_d + \frac{nd+d}{2})$, contains at least $\frac{1}{15d^{1/2}}n^{d-1}$ vertices. Now the i th layer for $i = q_1 s_d + \frac{nd+d}{2}$ cuts off a set of size at least $\frac{2}{3}n^d$ from the grid, since

$$\begin{aligned} F_d(q_1 s_d) &\geq \Phi(q_1) - 32d^{-1/2} \\ &= 7/10 - 32d^{-1/2} \geq 0.668 > 2/3. \end{aligned}$$

Thus, $|L_n^d(i_{2/3})| > |L_n^d(q_1 s_d + \frac{nd+d}{2})|$ and, therefore, $|L_n^d(i_{2/3})| \geq \frac{1}{15d^{1/2}}n^{d-1}$. Let us remind that during all the previous steps we still assume that $d > 10^6$.

In the following lemma we show the upper bound on the size of the middle layer. To prove this, we need to show that two consecutive layers cannot differ too much in size.

LEMMA A.3. *For any $n, d, i \in \mathbf{N}$ the following hold:*

- (a) $|L_n^d(i_{1/2})| \leq 1000 \frac{n^{d-1}}{\sqrt{d}}$,
- (b) $|L_n^d(i)| - |L_n^d(i+1)| \leq |L_n^{d-1}(i-n)| \leq 2000 \frac{n^{d-2}}{\sqrt{d}}$.

Proof. We prove both parts together by induction on d . First, we show that $|L_n^d(i)| - |L_n^d(i+1)| \leq |L_n^{d-1}(i-n)| \leq |L_n^{d-1}(i_{1/2})|$. Let L' be $L_n^d(i)$ shifted by 1 in the first component, i.e., $L' = L_n^d(i) + (1, 0, \dots, 0)$. Since $(L' \cap [n]^d) \subseteq L_n^d(i+1)$, we arrive at $|L_n^d(i)| - |L_n^d(i+1)| \leq |L' \setminus [n]^d|$. It is easy to check that $L' \setminus [n]^d$ is an exact copy of the set $L_n^{d-1}(i-n)$, which always has a smaller size than the middle layer $L_n^{d-1}(i_{1/2})$. The rest of (b) follows from (a).

To prove (a) for $d \leq 10^6$, we note that the size of any layer $L_n^d(i)$ is bounded above by n^{d-1} and for $d \leq 10^6$ we have $n^{d-1} \leq 1000 \frac{n^{d-1}}{\sqrt{d}}$. To prove (a) for $d > 10^6$, we estimate the size of the $\frac{n}{6}$ consecutive layers $L_n^d(i)$ for $i \in [i_{1/2}, i_{1/2} + \frac{n}{6}]$:

$$\begin{aligned} F_n^d\left(i_{1/2} + \frac{n}{6}\right) - F_n^d\left(i_{1/2}\right) &\leq \left(\Phi\left(\frac{n}{6s_d}\right) + \frac{32}{\sqrt{d}}\right) - \left(\Phi(0) - \frac{32}{\sqrt{d}}\right) \\ &\leq \Phi\left(\frac{1}{\sqrt{d}}\right) - \Phi(0) + \frac{64}{\sqrt{d}} \\ &\leq \frac{1}{\sqrt{2\pi}} \left(\int_0^{d^{-1/2}} e^{-(1/2)y^2} dy \right) + \frac{64}{\sqrt{d}} \\ &\leq 65d^{-1/2}. \end{aligned}$$

Among the $n/6$ layers the size of the smallest layer $L_n^d(i_{1/2} + \frac{n}{6})$ is at most

$$\left| L_n^d\left(i_{1/2} + \frac{n}{6}\right) \right| \leq \frac{65d^{-1/2}n^d}{n/6} \leq 400 \frac{n^{d-1}}{\sqrt{d}}.$$

Using (b) we estimate the size of the middle layer as

$$\begin{aligned} |L_n^d(i_{1/2})| &\leq \left| L_n^d\left(i_{1/2} + \frac{n}{6}\right) \right| + \frac{n}{6} \left(2000 \frac{n^{d-2}}{\sqrt{d}} \right) \\ &\leq 1000 \frac{n^{d-1}}{\sqrt{d}}. \quad \square \end{aligned}$$

Acknowledgments. We would like to thank Nati Linial for discussions that were the starting point of our research reported in this paper, and Imre Leader for useful advice concerning isoperimetric inequalities. We also thank two anonymous referees for many useful comments and suggestions.

MAXIMIZING SUPERMODULAR FUNCTIONS ON PRODUCT LATTICES, WITH APPLICATION TO MAXIMUM CONSTRAINT SATISFACTION*

ANDREI KROKHIN[†] AND BENOIT LAROSE[‡]

Abstract. Recently, a strong link has been discovered between supermodularity on lattices and tractability of optimization problems known as maximum constraint satisfaction problems. This paper strengthens this link. We study the problem of maximizing a supermodular function which is defined on a product of n copies of a fixed finite lattice and given by an oracle. We exhibit a large class of finite lattices for which this problem can be solved in oracle-polynomial time in n . We also obtain new large classes of tractable maximum constraint satisfaction problems.

Key words. supermodular function, lattices, optimization, tractability, constraint satisfaction

1. Introduction. Sub- and supermodular set functions are special real-valued functions defined on the powerset of a set. They are well studied in combinatorics (see bibliographical survey [10]) and have numerous applications in combinatorial optimization [9, 11] and elsewhere (see, e.g., [24, 28]). Minimization of submodular set functions is one of the most well-known tractable problems in combinatorial optimization [11, 27]. Examples of other combinatorial problems that can be solved by using submodular set function minimization include the minimum s - t cut problem in networks and finding the largest common independent set in two matroids. The submodular set function minimization problem was also considered for various relaxations of submodular functions such as intersecting or crossing submodular functions. Such relaxations are either defined on some family of subsets of a set, or use a slightly modified form of submodularity [27].

A more general form of sub- and supermodularity is the one where functions are defined on general (i.e., algebraic) lattices [28]. This form of supermodularity is very popular in financial and actuarial mathematics (see, e.g., supermodular games [28] and supermodular order on multivariate distributions [23, 25]), but it is relatively little studied in combinatorics and optimization (see, e.g., section 60.3a of [27]), except for the special case when the lattice is a chain, i.e., a totally ordered set. Sub- and supermodular functions on finite chains can be alternatively represented by matrices and arrays which are called Monge and anti-Monge, respectively, matrices and arrays. Such matrices and arrays are used to identify tractable cases of hard optimization problems such as TSP [1].

Recently, the general form of supermodularity (on lattices) has been applied to classify the complexity of maximum constraint satisfaction problems which are very actively studied optimization problems in artificial intelligence [6] and complexity theory [5]. In a maximum constraint satisfaction problem, informally speaking, one is given a finite collection of constraints on overlapping sets of variables, and the goal is to find an assignment of values to the variables with a maximum number (or total weight) of satisfied constraints. Some recent papers [3, 8, 19] discovered that there is a strong link between supermodularity on lattices and tractability of maximum constraint satisfaction problems with a restricted set of allowed constraints, and developing this connection is the main aim of this paper.

2. Sub- and supermodularity, and lattices. In this section we describe the problem of maximizing a supermodular function on a product lattice.

DEFINITION 2.1. *Let A be finite set. A function $f : 2^A \rightarrow \mathbb{R}$ is called a supermodular set function (on A) if the inequality*

$$f(X) + f(Y) \leq f(X \cap Y) + f(X \cup Y)$$

holds for all $X, Y \subseteq A$, and it is called submodular if the inverse inequality holds for all X, Y .

The *submodular function minimization problem* is, given a submodular function f on A , to find a subset $X \subseteq A$ with minimum $f(X)$. It is known [11, 17, 16, 26, 27] that a submodular function on a set A can be minimized in polynomial time (in $|A|$) provided getting a value of f is a primitive operation.

A partial order on a set D is called a *lattice order* if, for every $x, y \in D$, there exists a greatest lower bound $x \sqcap y$ and a least upper bound $x \sqcup y$. The corresponding algebra $\mathcal{L} = (D, \sqcap, \sqcup)$ is called a *lattice*. A subset of D closed under the operations $\sqcap$ and $\sqcup$ is called a *sublattice* of $\mathcal{L}$. If $\mathcal{L}_i$ is a lattice on D_i , $i = 1, \dots, n$, then the *product lattice* $\mathcal{L}_1 \times \dots \times \mathcal{L}_n$ is a lattice with base set $D_1 \times \dots \times D_n$ and operations acting componentwise. The lattice $\mathcal{L}^n$ is the (direct) product of n copies of $\mathcal{L}$, and it is known as the *n th power* of $\mathcal{L}$. For more information about lattices, see [13].

DEFINITION 2.2. *Let $\mathcal{L}$ be a lattice on D . A function $f : D^n \rightarrow \mathbb{R}$ is called supermodular on $\mathcal{L}$ if*

$$f(\mathbf{a}) + f(\mathbf{b}) \leq f(\mathbf{a} \sqcap \mathbf{b}) + f(\mathbf{a} \sqcup \mathbf{b}) \text{ for all } \mathbf{a}, \mathbf{b} \in \mathcal{L}^n,$$

and f is called submodular on $\mathcal{L}$ if the inverse inequality holds.

If A is a set with $|A| = n$, then, by identifying subsets of A with 0-1 n -tuples, one can easily check that the submodular (set) functions on A are simply the n -ary submodular functions on a lattice on $\{0, 1\}$ with order $0 < 1$. Therefore, it is natural to consider the problem of minimizing the submodular functions on a given fixed finite lattice $\mathcal{L}$, in the following form:

INSTANCE: A number $n \geq 1$ and a submodular function f on $\mathcal{L}^n$.

GOAL: Find an element $\mathbf{a} \in \mathcal{L}^n$ such that $f(\mathbf{a}) = \min \{f(\mathbf{b}) \mid \mathbf{b} \in \mathcal{L}^n\}$.

We will denote this problem by $\text{SFM}(\mathcal{L})$. We will say that $\text{SFM}(\mathcal{L})$ is *oracle-tractable* if it can be solved in polynomial time in n (provided getting the value of f on a tuple is a primitive operation). It was mentioned in [3] as an open question whether or not $\text{SFM}(\mathcal{L})$ is oracle-tractable for any fixed lattice $\mathcal{L}$. This question was motivated in [3] by its applications in constraint satisfaction which we will describe in the next section.

Note that a function f is submodular if and only if $-f$ is supermodular. Therefore, the $\text{SFM}(\mathcal{L})$ problem can also be understood as the *supermodular function maximization problem*. We will always use this reformulation because we will later apply algorithms for $\text{SFM}(\mathcal{L})$ to solve certain maximization problems.

Recall that a lattice is called *distributive* if it can be represented by subsets of a set A , where the operations $\sqcap$ and $\sqcup$ are interpreted as set-theoretic intersection and union, respectively. Note that, in some earlier papers on submodular functions, a family of subsets closed under intersection and union is simply called a lattice family (or a ring family). The following result is proved in section 49.3 of [27] (see also [26]).

THEOREM 2.3. *A submodular function defined on a lattice family L on a set A can be minimized in polynomial time in $|A|$, provided we can compute in polynomial time the largest and the smallest sets in the family, and the preorder $\preceq$ on A defined as follows: $u \preceq v$ if and only if each set $U \in L$ containing v also contains u .*

Assume that we fix a finite distributive lattice $\mathcal{L}$. It is well known that $\mathcal{L}$ can be represented by subsets of a set A such that $|A| \leq |\mathcal{L}|$. Clearly, we can compute in constant time the sets (as 0-1 $|A|$ -tuples) representing the largest and the smallest elements of $\mathcal{L}$, and we can also compute the preorder $\preceq$ in constant time. Obviously, for any n , the lattice $\mathcal{L}^n$ can be represented by subsets of a set B of cardinality $n|A|$ (since an element of $\mathcal{L}$ is represented by using $|A|$ bits), while the representations for the largest and the smallest elements of $\mathcal{L}^n$ and the preorder for $\mathcal{L}^n$ can be trivially obtained from those for $\mathcal{L}$. It follows that we can solve the problem $\text{SFM}(\mathcal{L})$ in polynomial time in n (in fact, in $n|\mathcal{L}|$, but $|\mathcal{L}|$ is a constant).

To the best of our knowledge, there was up to now not a single nondistributive finite lattice $\mathcal{L}$ for which the problem $\text{SFM}(\mathcal{L})$ is known to be oracle-tractable. We will provide such examples in this paper.

The problem of minimizing submodular functions on nondistributive lattices was mentioned in [17]. However, it was not clear in that paper what the parameter should be in this case, since, in combinatorics, submodular functions are traditionally considered to be defined on (some or all) subsets of a set, and the standard parameter in such situations was always the cardinality of the set. We believe that our formulation of the problem $\text{SFM}(\mathcal{L})$ is an appropriate form of generalization of the standard SFM problem to the case of arbitrary lattices.

We will generalize this problem even further, by considering classes of finite lattices. Let $\mathbf{C}$ be a fixed finite class of finite lattices. Define the optimization problem $\text{SFM}(\mathbf{C})$ as follows:

INSTANCE: A lattice $\mathcal{L}' = \mathcal{L}_1 \times \dots \times \mathcal{L}_n$ such that $\mathcal{L}_i \in \mathbf{C}$ for all $1 \leq i \leq n$, and a supermodular function f on $\mathcal{L}'$.

GOAL: Find an element $\mathbf{a} \in \mathcal{L}'$ such that $f(\mathbf{a}) = \max \{f(\mathbf{b}) \mid \mathbf{b} \in \mathcal{L}'\}$.

One can extend the notion of oracle-tractability to the problems $\text{SFM}(\mathbf{C})$ in a natural way, assuming that an instance is given by an n -tuple of names of lattices in the product and by an oracle for the function f . For any finite class of finite distributive lattices one can follow the same procedure as for a single distributive lattice, so, clearly, the following statement holds.

PROPOSITION 2.4. *$\text{SFM}(\mathbf{C})$ is oracle-tractable for any finite class $\mathbf{C}$ of finite distributive lattices.*

3. Maximum constraint satisfaction. Maximum constraint satisfaction problems are well-studied combinatorial optimization problems. The standard example of such problems are MAX k -CUT and MAX k -SAT.

Let D denote a finite set with $|D| > 1$. Let $R_D^{(m)}$ denote the set of all m -ary predicates over D , that is, functions from D^m to $\{0, 1\}$, and let $R_D = \bigcup_{m=1}^{\infty} R_D^{(m)}$. Also, let $\mathbb{Z}^+$ denote the set of all nonnegative integers.

DEFINITION 3.1. A constraint over a set of variables $V = \{x_1, x_2, \dots, x_n\}$ is an expression of the form $f(\mathbf{x})$, where

- $f \in R_D^{(m)}$ is called the constraint predicate, and
- $\mathbf{x} = (x_{i_1}, \dots, x_{i_m})$ is called the constraint scope.

The constraint f is said to be satisfied on a tuple $\mathbf{a} = (a_{i_1}, \dots, a_{i_m}) \in D^m$ if $f(\mathbf{a}) = 1$.

DEFINITION 3.2. For a finite $\mathcal{F} \subseteq R_D$, an instance of MAX CSP($\mathcal{F}$) is a pair (V, C) , where

- $V = \{x_1, \dots, x_n\}$ is a set of variables taking their values from the set D ,
- C is a collection of constraints $f_1(\mathbf{x}_1), \dots, f_q(\mathbf{x}_q)$ over V , where $f_i \in \mathcal{F}$ for all $1 \leq i \leq q$.

The goal is to find an assignment $\varphi : V \rightarrow D$ that maximizes the number of satisfied constraints, that is, to maximize the function $f : D^n \rightarrow \mathbb{Z}^+$, defined by $f(x_1, \dots, x_n) = \sum_{i=1}^q f_i(\mathbf{x}_i)$. If the constraints have (positive integral) weights ϱ_i , $1 \leq i \leq q$, then the goal is to maximize the total weight of satisfied constraints, that is, maximize the function $f : D^n \rightarrow \mathbb{Z}^+$, defined by $f(x_1, \dots, x_n) = \sum_{i=1}^q \varrho_i \cdot f_i(\mathbf{x}_i)$.

Example 3.3 (MAX k -CUT). In the MAX k -CUT problem, one is given an undirected graph $G = (V, E)$ with weighted edges, and the goal is to find a partition of V into k parts, $V = V_0 \cup V_1 \cup \dots \cup V_{k-1}$, maximizing the total weight of edges with endpoints in different parts. This problem is exactly the MAX CSP($\{\neq_k\}$) problem where $\neq_k$ is the binary disequality predicate on $\{0, 1, \dots, k-1\}$. To see this, think of vertices of a given graph as variables, and apply the predicate to every pair of variables x, y such that (x, y) is an edge in the graph, while keeping all weights the same.

Since predicates are functions, one can consider supermodular predicates on a lattice. For a finite lattice $\mathcal{L}$, we will denote by $\text{Spmod}_{\mathcal{L}}$ the set of all predicates that are supermodular on $\mathcal{L}$.

It is easy to see that if $f(x_1, \dots, x_n) = \sum_{i=1}^q \varrho_i \cdot f_i(\mathbf{x}_i)$ and, for some lattice $\mathcal{L}$, every f_i is supermodular on $\mathcal{L}$, then f is also supermodular on $\mathcal{L}$. Moreover, it is clear that one can compute the value of f on a given tuple in linear time in the size of the instance. Hence, we immediately obtain the following lemma.

LEMMA 3.4. Let $\mathcal{L}$ be a finite lattice such that the problem SFM($\mathcal{L}$) is oracle-tractable. Then, for any finite set $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{L}}$, the problem MAX CSP($\mathcal{F}$) is tractable.

It is intriguing that all known tractable problems MAX CSP($\mathcal{F}$) are essentially (i.e., possibly, after removing redundant elements from D) of this form (i.e., with $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{L}}$ for some lattice $\mathcal{L}$ on D). In particular, it is known [3] (and follows from Proposition 2.4 and Lemma 3.4) that MAX CSP($\mathcal{F}$) is tractable whenever $\mathcal{F}$ consists of supermodular predicates on some distributive lattice.

In the rest of this section, we present evidence that supermodularity on lattices probably is the right tool for studying the complexity of problems MAX CSP($\mathcal{F}$).

First, we will consider a form of supermodular constraints that can be defined on any lattice.

DEFINITION 3.5. A predicate $f \in R_D^{(n)}$ will be called 2-monotone¹ on a lattice $\mathcal{L}$

¹In [3], such predicates are called *generalized 2-monotone*.

on D if it can be expressed as follows:

$$(3.1) \quad f(\mathbf{x}) = 1 \Leftrightarrow ((x_{i_1} \sqsubseteq a_{i_1}) \wedge \dots \wedge (x_{i_s} \sqsubseteq a_{i_s})) \vee ((x_{j_1} \sqsupseteq b_{j_1}) \wedge \dots \wedge (x_{j_t} \sqsupseteq b_{j_t})),$$

where $\mathbf{x} = (x_1, \dots, x_n)$, $a_{i_1}, \dots, a_{i_s}, b_{j_1}, \dots, b_{j_t} \in D$, and either of the two disjuncts may be empty (i.e., the value of s or t may be zero).

It is straightforward to check that every 2-monotone predicate on a lattice is supermodular on it. The next theorem is, to the best of our knowledge, the only one available on the complexity of supermodular constraints on arbitrary lattices.

THEOREM 3.6 (see [3]). *Let $\mathcal{L}$ be a lattice on a finite set D . If $\mathcal{F}$ consists of 2-monotone predicates on $\mathcal{L}$, then $\text{MAX CSP}(\mathcal{F})$ is tractable.*

Note that 2-monotone predicates can be defined on any poset, since the definition does not use the property of the order to be lattice. However, it was shown in [20] that if $\mathcal{F}$ consists of all binary 2-monotone predicates on a *nonlattice* poset, then $\text{MAX CSP}(\mathcal{F})$ is **NP**-hard.

An *endomorphism* of $\mathcal{F}$ is a unary operation π on D such that, for all $f \in \mathcal{F}$ and all $(a_1, \dots, a_m) \in D^m$, we have $f(a_1, \dots, a_m) = 1 \Rightarrow f(\pi(a_1), \dots, \pi(a_m)) = 1$. We say that $\mathcal{F}$ is a *core* if every endomorphism of $\mathcal{F}$ is injective (i.e. a permutation). The intuition here is that if $\mathcal{F}$ is not a core, then it has a noninjective endomorphism π , which implies that, for every assignment φ , there is another assignment $\pi\varphi$ that satisfies all constraints satisfied by φ and uses only a restricted set of values, so the problem $\text{MAX CSP}(\mathcal{F})$ can be reduced to a similar problem over this smaller set.

THEOREM 3.7 (see [5, 3, 19]). *Let $|D| \leq 3$, and let $\mathcal{F} \subseteq R_D$ be a core. If there is a chain $\mathcal{C}$ on D such that $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{C}}$, then $\text{MAX CSP}(\mathcal{F})$ is tractable. Otherwise, $\text{MAX CSP}(\mathcal{F})$ is **NP**-hard.*

For an element $d \in D$, define the unary predicate u_d so that $u_d(x) = 1 \Leftrightarrow x = d$. Let $C_D = \{u_d \mid d \in D\}$.

THEOREM 3.8 (see [7, 8]). *Let D be any finite set, and assume that $C_D \subseteq \mathcal{F} \subseteq R_D$. If there is a chain $\mathcal{C}$ on D such that $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{C}}$, then $\text{MAX CSP}(\mathcal{F})$ is tractable. Otherwise, $\text{MAX CSP}(\mathcal{F})$ is **NP**-hard.*

Note that (assuming that supermodularity is the right tool) chains are the only lattices that could possibly appear in Theorems 3.7 and 3.8 because, as is easy to check, every lattice with at most three elements is a chain and every predicate of the form u_d is supermodular on a lattice if and only if the lattice is a chain (the latter assertion is essentially Lemma 5.1 of [3]).

However, it is known that classes of supermodular predicates on (essentially) different lattices are pairwise incomparable. More precisely, for any lattice $\mathcal{L}$, let $\mathcal{L}^\partial$ denote the dual lattice of $\mathcal{L}$, i.e., the one obtained from $\mathcal{L}$ by reversing the order (or by swapping the lattice operations, which is the same). It is obvious from the definition that the classes of supermodular functions on $\mathcal{L}$ and on $\mathcal{L}^\partial$ coincide. It was shown in [20] that, for any finite lattice $\mathcal{L}'$ (on the same set as $\mathcal{L}$) such that $\mathcal{L}'$ is neither $\mathcal{L}$ nor $\mathcal{L}^\partial$, there exists a predicate which is 2-monotone (and hence supermodular) on $\mathcal{L}$, but not supermodular on $\mathcal{L}'$. Hence, essentially, one cannot exclude *any* lattice from these considerations.

It follows that the problem $\text{SFM}(\mathcal{L})$ restricted to supermodular functions on a nondistributive lattice $\mathcal{L}$, such as the functions that can appear in instances of $\text{MAX CSP}(\mathcal{F})$, is of special interest.

It is a basic fact in lattice theory (see, e.g., [13]) that a lattice is distributive if it does not contain, as a sublattice, one of the two minimal nondistributive lattices: the pentagon $\mathcal{N}_5$ and the diamond $\mathcal{M}_3$. These two lattices are depicted in Figure 3.1.

FIG. 3.1. The pentagon $\mathcal{N}_5$ and the diamond $\mathcal{M}_3$.

It will follow from the results in this paper that $\text{MAX CSP}(\mathcal{F})$ is tractable if $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{N}_5}$ or $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{M}_3}$.

4. SFM and constructions on lattices. In this section we show that tractability of $\text{SFM}(\mathcal{L})$ is preserved under certain constructions on lattices, and exhibit a large class of nondistributive lattices for which $\text{SFM}(\mathcal{L})$ is tractable.

4.1. General constructions. A *congruence* on a lattice $\mathcal{L}$ is an equivalence relation θ such that, for all $a, b, c, d \in \mathcal{L}$, the conditions $a\theta b$ and $c\theta d$ imply that both $(a \sqcap c)\theta(b \sqcap d)$ and $(a \sqcup c)\theta(b \sqcup d)$ hold.

If θ is a congruence on $\mathcal{L}$ and $a \in \mathcal{L}$, then let $a[\theta]$ denote the θ -class containing a . It is well known that every θ -class is a sublattice of $\mathcal{L}$. It is also well known that the family of all θ -classes forms a lattice, called a *factor-lattice* of $\mathcal{L}$ and denoted $\mathcal{L}/\theta$, with operations defined as follows: $a[\theta] \sqcap a'[\theta] = (a \sqcap a')[\theta]$ and $a[\theta] \sqcup a'[\theta] = (a \sqcup a')[\theta]$.

We will now introduce a certain notion of a product of classes of lattices that was intensively studied in lattice theory (see, e.g., [14] or pp. 489–490 of [13]).

DEFINITION 4.1. *If $\mathbf{V}$ and $\mathbf{W}$ are classes of lattices, then their Mal'tsev product, denoted $\mathbf{V} \circ \mathbf{W}$, consists of all lattices $\mathcal{L}$ such that there is a congruence θ on $\mathcal{L}$ with the following properties:*

1. *the lattice $\mathcal{L}/\theta$ belongs to $\mathbf{W}$,*
2. *every θ -class is a lattice from $\mathbf{V}$.*

Let $\mathbf{D}$ denote the class of all distributive lattices, let $\mathbf{D}_k$ denote the class of all distributive lattices with at most k elements, and let $\mathbf{D}_{fin}$ denote the class of all finite lattices from $\mathbf{D}$.

Example 4.2. The lattice $\mathcal{N}_5$ belongs to $\mathbf{D}_3 \circ \mathbf{D}_2$. It is easy to check that the equivalence relation θ whose two classes are within the ovals in Figure 4.1 is a congruence. The classes of the congruence are distributive lattices (chains), and the lattice $\mathcal{N}_5/\theta$ is a distributive lattice (a two-element chain).

THEOREM 4.3. *Suppose that $\mathbf{V}, \mathbf{W}$ are finite classes of finite lattices. If $\text{SFM}(\mathbf{V})$ and $\text{SFM}(\mathbf{W})$ are both oracle-tractable, then $\text{SFM}(\mathbf{V} \circ \mathbf{W})$ is oracle-tractable as well.*

Proof. Let $\mathcal{L}' = \mathcal{L}_1 \times \cdots \times \mathcal{L}_n$ such that $\mathcal{L}_i \in \mathbf{V} \circ \mathbf{W}$ for all $1 \leq i \leq n$. Then, for every $1 \leq i \leq n$, there exist congruences θ_i such that the lattices $\mathcal{K}_i = \mathcal{L}_i/\theta_i$ belong to $\mathbf{W}$ and every θ_i -class belongs to $\mathbf{V}$.

Define a function f' on $\mathcal{K} = \mathcal{K}_1 \times \cdots \times \mathcal{K}_n$ by letting

$$f'(a_1[\theta_1], \dots, a_n[\theta_n]) = \max f|_{a_1[\theta_1] \times \cdots \times a_n[\theta_n]}.$$

Let us check that f' is a supermodular function on $\mathcal{K}$. Take two arbitrary elements in $\mathcal{K}$, say $(a_1[\theta_1], \dots, a_n[\theta_n])$ and $(b_1[\theta_1], \dots, b_n[\theta_n])$. Choose a'_i, b'_i , $1 \leq i \leq n$, so that $a_i\theta_i a'_i$ and $b_i\theta_i b'_i$ for all $1 \leq i \leq n$, and $f'(a_1[\theta_1], \dots, a_n[\theta_n]) = f(a'_1, \dots, a'_n)$ and

FIG. 4.1. The pentagon $\mathcal{N}_5$ is in $\mathbf{D}_3 \circ \mathbf{D}_2$.

$f'(b_1[\theta_1], \dots, b_n[\theta_n]) = f(b'_1, \dots, b'_n)$. Since each θ_i is a congruence, it follows that

$$\begin{aligned}
 f'(a_1[\theta_1], \dots, a_n[\theta_n]) + f'(b_1[\theta_1], \dots, b_n[\theta_n]) &= f(a'_1, \dots, a'_n) + f(b'_1, \dots, b'_n) \\
 &\leq f(a'_1 \sqcap b'_1, \dots, a'_n \sqcap b'_n) + f(a'_1 \sqcup b'_1, \dots, a'_n \sqcup b'_n) \\
 &\leq f'((a'_1 \sqcap b'_1)[\theta_1], \dots, (a'_n \sqcap b'_n)[\theta_n]) + f'((a'_1 \sqcup b'_1)[\theta_1], \dots, (a'_n \sqcup b'_n)[\theta_n]) \\
 &= f'((a_1 \sqcap b_1)[\theta_1], \dots, (a_n \sqcap b_n)[\theta_n]) + f'((a_1 \sqcup b_1)[\theta_1], \dots, (a_n \sqcup b_n)[\theta_n]) \\
 &= f'(a_1[\theta_1] \sqcap b_1[\theta_1], \dots, a_n[\theta_n] \sqcap b_n[\theta_n]) + f'(a_1[\theta_1] \sqcup b_1[\theta_1], \dots, a_n[\theta_n] \sqcup b_n[\theta_n]).
 \end{aligned}$$

Since $\mathcal{K}$ is a direct product of lattices from $\mathbf{W}$, we infer that f' can be maximized in polynomial time if the evaluation of f' on a given tuple is a primitive operation. That is, f' can be maximized in at most $p_1(n)$ number of steps, where p_1 is a fixed polynomial, and some of the steps are evaluations of f' on a given element of $\mathcal{K}$.

Assume that $\text{SFM}(\mathbf{V})$ can be solved in $p_2(n)$ steps, some of which are function evaluations. Now, to prove the theorem, it suffices to show that f' can be evaluated on any given element of $\mathcal{K}$ in $p_2(n)$ steps (assuming that evaluating f on a given element of $\mathcal{L}'$ is a primitive operation). Fix an element $(a_1[\theta_1], \dots, a_n[\theta_n])$ of $\mathcal{K}$. The goal now is to maximize f on $a_1[\theta_1] \times \dots \times a_n[\theta_n]$. Every $a_i[\theta_i]$ is a lattice from $\mathbf{V}$, so evaluating $f'(a_1[\theta_1], \dots, a_n[\theta_n])$ can be done in $p_2(n)$ steps by assumption of the theorem. Hence, f can be maximized in $p_1(p_2(n))$ steps, some of which are evaluations of f on a given tuple. $\square$

COROLLARY 4.4. *If $\mathcal{L}_1$ and $\mathcal{L}_2$ are finite lattices such that $\text{SFM}(\mathcal{L}_i)$ is oracle-tractable for $i = 1, 2$, then $\text{SFM}(\mathcal{L}_1 \times \mathcal{L}_2)$ is oracle-tractable as well.*

Proof. Let $\mathbf{V} = \{\mathcal{L}_1\}$ and $\mathbf{W} = \{\mathcal{L}_2\}$. It is immediate that $\text{SFM}(\mathbf{V})$ and $\text{SFM}(\mathbf{W})$ are oracle-tractable. The lattice $\mathcal{L}' = \mathcal{L}_1 \times \mathcal{L}_2$ belongs to $\mathbf{V} \circ \mathbf{W}$. Indeed, the relation θ on $\mathcal{L}'$ defined so that $(a_1, b_1)\theta(a_2, b_2)$ if and only if $b_1 = b_2$ is a congruence such that $\mathcal{L}'/\theta$ is isomorphic to $\mathcal{L}_2$ while every θ -class is isomorphic to $\mathcal{L}_1$. Clearly, when maximizing an n -ary supermodular function on $\mathcal{L}_1 \times \mathcal{L}_2$, one can identify $\mathcal{L}'/\theta$ with $\mathcal{L}_2$ and every θ -class with $\mathcal{L}_1$. The result now follows from Theorem 4.3. $\square$

DEFINITION 4.5. *A mapping φ from a lattice $\mathcal{L}_1$ to a lattice $\mathcal{L}_2$ is called a homomorphism if, for all $a, b \in \mathcal{L}_1$, it holds that $\varphi(a \sqcap b) = \varphi(a) \sqcap \varphi(b)$ and $\varphi(a \sqcup b) = \varphi(a) \sqcup \varphi(b)$. If such a mapping φ is onto, then $\mathcal{L}_2$ is said to be a homomorphic image of $\mathcal{L}_1$.*

FIG. 4.2. The lattice $\hat{\mathcal{L}}$.

THEOREM 4.6. *Fix a finite lattice $\mathcal{L}$. If $\mathcal{L}$ is a homomorphic image of some finite lattice $\mathcal{L}_1$ such that $\text{SFM}(\mathcal{L}_1)$ is oracle-tractable, then $\text{SFM}(\mathcal{L})$ is oracle-tractable as well.*

Proof. Every supermodular function f on $\mathcal{L}^n$ can be transformed into a supermodular function f_1 on $\mathcal{L}_1^n$ by letting $f_1(a_1, \dots, a_n) = f(\varphi(a_1), \dots, \varphi(a_n))$ where φ is a surjective homomorphism from $\mathcal{L}_1$ to $\mathcal{L}$. It is straightforward to check that f_1 is indeed supermodular on $\mathcal{L}_1$. Since φ is surjective, the maximum of f_1 coincides with the maximum of f . By assumption, one can find a tuple $\mathbf{a}$ maximizing f_1 in polynomial time in n , and the tuple maximizing f is obtained from $\mathbf{a}$ by applying φ componentwise. $\square$

It is clear, say, since the pentagon belongs to $\mathbf{D}_3 \circ \mathbf{D}_2$, that Theorem 4.3 extends (compared to $\mathbf{D}_{fin}$) the class of lattices $\mathcal{L}$ for which $\text{SFM}(\mathcal{L})$ is proved to be oracle-tractable. We note that Theorem 4.6 further extends this class. Consider, for example, the lattice $\hat{\mathcal{L}}$ shown in Figure 4.2. It is shown in the proof of Theorem 1 of [14] that this lattice is a homomorphic image of a lattice belonging to $(\mathbf{D}_4 \circ \mathbf{D}_4) \circ \mathbf{D}_4$, so $\text{SFM}(\hat{\mathcal{L}})$ is oracle-tractable. It is easy to verify that this lattice is *simple*, that is, it has no congruences except for the equality relation and the full binary relation. Lemma 1 of [14] states that if a simple lattice belongs to Mal'tsev product of two classes of lattices, then it belongs to one of these classes. Hence, since $\hat{\mathcal{L}}$ is simple and nondistributive, it does not belong to any class obtainable from $\mathbf{D}_{fin}$ by using Mal'tsev product.

It follows from Proposition 2.4 and Theorems 4.3 and 4.6 that if a finite lattice $\mathcal{L}$ belongs to a class obtained from finite sets of distributive lattices by (repeatedly) using Mal'tsev product and also taking homomorphic images, then $\text{SFM}(\mathcal{L})$ is oracle-tractable. What is the family $\mathbf{F}$ of finite lattices $\mathcal{L}$ which can be obtained as described above? Unfortunately, it seems quite difficult to give a precise characterization of this family because, by [22], the process of repeatedly applying Mal'tsev product to $\mathbf{D}$ results in different classes of lattices for different orders of applying the operation. However, in the next subsection we describe a well-understood and rich subclass of $\mathbf{F}$, which can be obtained by repeatedly applying Mal'tsev product only to $\mathbf{D}_2$. The subclass consists of the so-called *bounded* finite lattices.

We will now describe some lattices that definitely do not belong to the family $\mathbf{F}$. For $t \geq 3$, a t -diamond (or simply a diamond), denoted $\mathcal{M}_t$, is a lattice on an $(t+2)$ -element set such that $0_{\mathcal{M}_t}, 1_{\mathcal{M}_t}$ are the least and the greatest element, respectively, and all t elements in $\mathcal{M}_t \setminus \{0_{\mathcal{M}_t}, 1_{\mathcal{M}_t}\}$ are pairwise incomparable. The Hasse diagram of $\mathcal{M}_t$ is given in Figure 4.3. Note that $\mathcal{M}_3$ is often referred to as *the* diamond. It is well known and easy to check that every diamond is a simple nondistributive lattice. In addition, every diamond has the property that, for every finite lattice $\mathcal{L}$ having

FIG. 4.3. A diamond lattice $\mathcal{M}_t$.

$\mathcal{M}_t$ as a homomorphic image, $\mathcal{L}$ also contains $\mathcal{M}_t$ as a sublattice (see Lemma 6.21 of [15] or the more general Theorem 2.47 of [18]). Hence, in order to show that no diamond belongs to $\mathbf{F}$, it is sufficient to prove that if a finite lattice $\mathcal{L}$ containing $\mathcal{M}_t$ as a sublattice belongs to $\mathbf{X} \circ \mathbf{Y}$, then at least one of these two classes contains a lattice with the same property. So assume that $\mathcal{L} \in \mathbf{X} \circ \mathbf{Y}$. By definition, $\mathcal{L}$ has a congruence θ such that $\mathcal{L}/\theta \in \mathbf{Y}$ and every θ -class is in $\mathbf{X}$. It is well known and easy to show that the restriction θ' of θ on $\mathcal{M}_t$ is a congruence of $\mathcal{M}_t$. By simplicity of $\mathcal{M}_t$, all the elements of $\mathcal{M}_t$ belong either to a single θ' -class or to pairwise different θ' -classes. In the former case, $\mathcal{M}_t$ is entirely contained in some θ -class, so this class is the required lattice in $\mathbf{X}$. In the latter case, $\mathcal{L}/\theta \in \mathbf{Y}$ is the required lattice. This argument can be easily generalized to show that, in fact, no lattice containing $\mathcal{M}_3$ as a sublattice belongs to $\mathbf{F}$.

Even though we have been unable to prove that $\text{SFM}(\mathcal{M}_t)$ is oracle-tractable, we will show in section 5 that the problems $\text{MAX CSP}(\mathcal{F})$ with $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{M}_t}$ are tractable.

4.2. Finite bounded lattices. Let $\mathcal{L}$ be a lattice and $u \sqsubseteq v$ two comparable (and not necessarily distinct) elements of $\mathcal{L}$. Let I denote the interval $[u, v] = \{x \in \mathcal{L} \mid u \sqsubseteq x \sqsubseteq v\}$ in $\mathcal{L}$.

DEFINITION 4.7. *The lattice $\mathcal{L}[I]$ is said to be obtained from $\mathcal{L}$ by doubling the interval I if the base set of $\mathcal{L}[I]$ is $(\mathcal{L} \setminus I) \cup (I \times \{0, 1\})$ and $x \sqsubseteq y$ holds in $\mathcal{L}[I]$ if and only if*

- $x \sqsubseteq y$ in $\mathcal{L}$ and $x, y \notin I$, or
- $x \in \mathcal{L} \setminus I$, $y = (b, j)$ and $x \sqsubseteq b$ in $\mathcal{L}$, or
- $x = (a, i)$, $y \in \mathcal{L} \setminus I$ and $a \sqsubseteq y$ in $\mathcal{L}$, or
- $x = (a, i)$, $y = (b, j)$ such that $a, b \in I$ and $a \sqsubseteq b$ in $\mathcal{L}$, and $i \leq j$.

Essentially, doubling an interval I in $\mathcal{L}$ means replacing it with $I \times \{0, 1\}$.

DEFINITION 4.8. *A finite lattice $\mathcal{L}$ is called bounded² if there is a sequence $\mathcal{L}_1, \dots, \mathcal{L}_n$ such that $\mathcal{L}_1$ is one-element, $\mathcal{L}_n$ is isomorphic to $\mathcal{L}$, and, for $j = 1, \dots, n-1$, there exists an interval I_j in $\mathcal{L}_j$ such that $\mathcal{L}_{j+1}$ is isomorphic to $\mathcal{L}_j[I_j]$.*

In other words, a finite lattice is called bounded if it can be obtained from the one-element lattice by successive doubling of intervals. For example, Figure 4.4 demonstrates that the pentagon is a bounded lattice, while it is not hard to check the lattice $\hat{\mathcal{L}}$ from Figure 4.2 is not bounded. Bounded lattices play an important role in lattice theory [18]. The name “bounded” comes from an equivalent characterization of such lattices, which is usually used as the definition (but does not play any role in this

²Not to be confused with posets that have both the least and the greatest element.

FIG. 4.4. Obtaining the pentagon by doubling intervals (in three steps). In each step, the white elements indicate the interval to be doubled.

paper). Theorem 2.46 of [18] states that a finite lattice $\mathcal{L}$ is bounded if and only if there exists a free lattice $\mathcal{FL}$ and a congruence α on $\mathcal{FL}$ such that $\mathcal{L}$ is isomorphic to $\mathcal{FL}/\alpha$, and every α -class in $\mathcal{FL}$ has both the least and the greatest element.

It is easy to check that for any lattice $\mathcal{L}$ and any interval I in $\mathcal{L}$, the binary relation θ on $\mathcal{L}[I]$ defined by the rule

$$(x, y) \in \theta \Leftrightarrow \text{either } x = y \notin I \text{ or } x = (a, i), y = (a, j) \text{ for some } a \in I$$

is a congruence of $\mathcal{L}[I]$. Moreover, the lattice $\mathcal{L}[I]/\theta$ is isomorphic to $\mathcal{L}$, and every θ -class is either a one-element lattice $\mathcal{C}_1$ or a two-element chain $\mathcal{C}_2$. Therefore, we have that $\mathcal{L}[I]$ belongs to the Mal'tsev product $\{\mathcal{C}_1, \mathcal{C}_2\} \circ \{\mathcal{L}\}$. So, if we inductively define $\mathbf{D}_2^1 = \mathbf{D}_2$ and $\mathbf{D}_2^n = \mathbf{D}_2 \circ \mathbf{D}_2^{n-1}$ for $n > 1$, then we have that every finite bounded lattice belongs to $\mathbf{D}_2^n$ for a suitable n . Hence, Theorem 4.3 (together with Lemma 3.4) implies the following statement.

PROPOSITION 4.9. *Let $\mathcal{L}$ be a fixed finite bounded lattice. Then $\text{SFM}(\mathcal{L})$ is oracle-tractable and, for any finite set $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{L}}$, $\text{MAX CSP}(\mathcal{F})$ is tractable.*

It is known (see Lemma 2.40 of [18]) that the class of finite bounded lattices is a pseudovariety, that is, it is closed under taking homomorphic images, sublattices, and finite direct products. Since the two-element chain is a bounded lattice, it follows that every finite distributive lattice is bounded. Interestingly, if one allows not only finite, but arbitrary direct products (i.e., direct products of infinitely many lattices), then one can generate *all* lattices from finite bounded lattices (this fact immediately follows from Theorems 2.25 and 2.44 of [18]). In other words, every (not necessarily finite) lattice is a homomorphic image of a subalgebra of a direct product of (possibly infinitely many) finite bounded lattices. Unfortunately, this fact seems to be useless for the algorithmic aspects which we are interested in.

5. MAX CSP on diamonds. In this section, we consider problems $\text{MAX CSP}(\mathcal{F})$ where $\mathcal{F}$ consists of supermodular predicates on a diamond $\mathcal{M}_t$ (see Figure 4.3). The middle elements of $\mathcal{M}_t$ are called *atoms*. Note that, for every pair of distinct atoms a and b , we have $a \sqcap b = 0_{\mathcal{M}_t}$ and $a \sqcup b = 1_{\mathcal{M}_t}$. For simplicity, let $\mathcal{L}$ denote an arbitrary (fixed) t -diamond, $t \geq 3$, throughout this section.

5.1. The structure of supermodular predicates on diamonds. In this subsection, we describe the structure of supermodular predicates on $\mathcal{L}$ by representing them as logical formulas involving constants (elements of $\mathcal{L}$) and the order relation $\sqsubseteq$ of $\mathcal{L}$.

For a subset $D' \subseteq D$, let $u_{D'}$ denote the predicate such that $u_{D'}(x) = 1 \Leftrightarrow x \in D'$. The following lemma can be easily derived directly from the definition of supermodularity.

LEMMA 5.1. *A unary predicate $u_{D'}$ is in $\text{Spmod}_{\mathcal{L}}$ if and only if either both $0_{\mathcal{L}}, 1_{\mathcal{L}} \in D'$ or else $|D'| \leq 2$ and at least one of $0_{\mathcal{L}}, 1_{\mathcal{L}}$ is in D' .*

For a sequence $\mathbf{y} = (x_{i_1}, \dots, x_{i_m})$ of variables and a sequence $\mathbf{c} = (c_{i_1}, \dots, c_{i_m})$ of elements of $\mathcal{L}$, we write $\mathbf{y} \sqsubseteq \mathbf{c}$ to denote $\bigwedge_{1 \leq s \leq m} (x_{i_s} \sqsubseteq c_{i_s})$, and the condition $\mathbf{y} \sqsupseteq \mathbf{c}$ is defined dually.

THEOREM 5.2. *Every predicate $f(x_1, \dots, x_n)$ in $\text{Spmod}_{\mathcal{L}}$, such that f takes both values 0 and 1, can be represented as one of the following logical implications:*

1. $[(x_i \sqsubseteq a_1) \vee \dots \vee (x_i \sqsubseteq a_l)] \implies (x_i \sqsubseteq 0_{\mathcal{L}})$, where the a_j 's are atoms;
2. $\neg(\mathbf{y} \sqsupseteq \mathbf{c}) \implies (\mathbf{z} \sqsubseteq \mathbf{d})$, where $\mathbf{y}$ and $\mathbf{z}$ are some subsequences of $(x_1, \dots, x_n)$, and $\mathbf{c}, \mathbf{d}$ are tuples of elements of $\mathcal{L}$ (of corresponding length) such that $\mathbf{c}$ contains no $0_{\mathcal{L}}$ and $\mathbf{d}$ no $1_{\mathcal{L}}$;
3. $[(x_i \sqsubseteq b_1) \vee \dots \vee (x_i \sqsubseteq b_k) \vee \neg(\mathbf{y} \sqsupseteq \mathbf{c})] \implies (x_i \sqsubseteq a)$, where the b_j 's are atoms, $\mathbf{y}$ does not contain x_i , and $a \neq 1_{\mathcal{L}}$;
4. $\neg(x_i \sqsupseteq b) \implies [\neg(x_i \sqsupseteq a_1) \wedge \dots \wedge \neg(x_i \sqsupseteq a_l) \wedge (\mathbf{y} \sqsubseteq \mathbf{c})]$, where the a_j 's are atoms, $\mathbf{y}$ does not contain x_i , and $b \neq 0_{\mathcal{L}}$;
5. $\neg(\mathbf{y} \sqsupseteq \mathbf{c}) \implies \text{false}$, where $\mathbf{y}$ is a subsequence of $(x_1, \dots, x_n)$ and $\mathbf{c}$ contains no $0_{\mathcal{L}}$;
6. $\text{true} \implies (\mathbf{y} \sqsubseteq \mathbf{c})$, where $\mathbf{y}$ is a subsequence of $(x_1, \dots, x_n)$ and $\mathbf{c}$ contains no $1_{\mathcal{L}}$.

Conversely, every predicate that can be represented in one of the above forms belongs to $\text{Spmod}_{\mathcal{L}}$.

Example 5.3. The unary predicate of type (1) above is the same as $u_{D'}$ where $D' = D \setminus \{a_1, \dots, a_l\}$. The predicates $u_{D'} \in \text{Spmod}_{\mathcal{L}}$ with $|D'| \leq 2$ are the unary predicates of types (5) and (6).

Remark 5.4. Note that constraints of types (2), (5), and (6) are 2-monotone on $\mathcal{L}$, while constraints of types (3) and (4) (and most of those of type (1)) are not.

Proof of Theorem 5.2. It is straightforward to verify that all of the predicates in the list are actually supermodular. Now we prove the converse. Consider first the case where the predicate f is *essentially unary*, i.e., there is a variable x_i such that $f(x_1, \dots, x_n) = u_{D'}(x_i)$ for some $D' \subsetneq D$. If $D' = \{x : x \sqsubseteq a\}$ or $D' = \{x : x \sqsupseteq a\}$ for some atom a , then f is of the form (5) or (6); otherwise, both $0_{\mathcal{L}}$ and $1_{\mathcal{L}}$ are in D' by Lemma 5.1, and if $a_1, \dots, a_l$ denote the atoms of the lattice that are not in D' , then it is clear that f is described by the implication (1).

Now we may assume that f is not essentially unary. If it is 2-monotone, then it is easy to see that f must be described by an implication of type (2), (5), or (6). So now we assume that f is not essentially unary and it is not 2-monotone; we prove that it is described by an implication of type (3) or (4). We require a few claims:

Claim 0. *The set X of all tuples $\mathbf{u}$ such that $f(\mathbf{u}) = 1$ is a sublattice of $\mathcal{L}^n$, i.e., is closed under join and meet.*

This follows immediately from the supermodularity of f .

Claim 1. *There exist indices $1 \leq i_1, \dots, i_k, j_1, \dots, j_l \leq n$, atoms $e_1, \dots, e_k$ and $b_1, \dots, b_l$ of $\mathcal{L}$ such that $f(\mathbf{x}) = 1$ if and only if*

$$[\neg(x_{i_1} \sqsupseteq e_1) \wedge \dots \wedge \neg(x_{i_k} \sqsupseteq e_k)] \bigvee [\neg(x_{j_1} \sqsubseteq b_1) \wedge \dots \wedge \neg(x_{j_l} \sqsubseteq b_l)].$$

Notice first that the set Z of tuples $\mathbf{u}$ such that $f(\mathbf{u}) = 0$ is *convex* in $\mathcal{L}^n$; i.e., if $\mathbf{u} \sqsubseteq \mathbf{v} \sqsubseteq \mathbf{w}$ with $f(\mathbf{u}) = f(\mathbf{w}) = 0$, then $f(\mathbf{v}) = 0$. To show this we construct a tuple $\mathbf{v}'$ as follows: for each coordinate i it is easy to find an element v'_i such that $v_i \sqcap v'_i = u_i$ and $v_i \sqcup v'_i = w_i$. Hence $\mathbf{v} \sqcap \mathbf{v}' = \mathbf{u}$ and $\mathbf{v} \sqcup \mathbf{v}' = \mathbf{w}$ so by supermodularity of f neither $\mathbf{v}$ nor $\mathbf{v}'$ is in X . It follows in particular that neither $0_{\mathcal{L}^n}$ nor $1_{\mathcal{L}^n}$ is in

Z ; indeed, if $0_{\mathcal{L}^n} \in Z$, let $\mathbf{a}$ be the smallest element in X (the meet of all elements in X), which exists by Claim 0. Since Z is convex it follows that every element above $\mathbf{a}$ is in X so f is 2-monotone, a contradiction. The argument for $1_{\mathcal{L}^n}$ is identical.

Now let $\mathbf{w} \in Z$ be minimal, and let $\mathbf{v} \sqsubseteq \mathbf{w}$. As above we can find a tuple $\mathbf{v}'$ such that $\mathbf{v} \sqcup \mathbf{v}' = \mathbf{w}$ and $\mathbf{v} \sqcap \mathbf{v}' = 0_{\mathcal{L}^n}$; by supermodularity of f it follows that $\mathbf{v} = \mathbf{w}$ or $\mathbf{v}' = \mathbf{w}$. It is easy to deduce from this that there exists a coordinate s such that w_s is an atom of $\mathcal{L}$ and $w_t = 0_{\mathcal{L}}$ for all $t \neq s$. A similar argument shows that every maximal element of Z has a unique coordinate which is an atom and all others are equal to $1_{\mathcal{L}}$.

Since Z is convex, we have that $f(\mathbf{x}) = 0$ if and only if $\mathbf{x}$ is above some minimal element of Z and below some maximal element of Z ; Claim 1 then follows immediately.

For each index $i \in \{i_1, \dots, i_k\}$ that appears in the expression in Claim 1, there is a corresponding condition of the form

$$\neg(x_i \sqsupseteq e_{s_1}) \wedge \dots \wedge \neg(x_i \sqsupseteq e_{s_r});$$

let I_i denote the set of elements of $\mathcal{L}$ that satisfy this condition. Obviously it cannot contain $1_{\mathcal{L}}$ and must contain $0_{\mathcal{L}}$. Similarly, define for each index $j \in \{j_1, \dots, j_l\}$ the set F_j of all elements of $\mathcal{L}$ that satisfy the corresponding condition of the form

$$\neg(x_j \sqsubseteq b_{t_1}) \wedge \dots \wedge \neg(x_j \sqsubseteq b_{t_q});$$

it is clear that $0_{\mathcal{L}} \notin F_j$ and $1_{\mathcal{L}} \in F_j$.

The condition of Claim 1 can now be rephrased as follows: $f(\mathbf{x}) = 1$ if and only if $x_i \in I_i$ for all $i \in \{i_1, \dots, i_k\}$ or $x_j \in F_j$ for all $j \in \{j_1, \dots, j_l\}$. It is straightforward to verify that since f is not 2-monotone, one of the I_i or one of the F_j must contain 2 distinct atoms. We consider the first case, and we show that the predicate f is of type (4). The case where some F_j contains 2 atoms is dual and will yield type (3).

Claim 2. Suppose that I_i contains distinct atoms c and d for some $i \in \{i_1, \dots, i_k\}$. Then (a) i is the only index with this property, (b) $\{j_1, \dots, j_l\} = \{i\}$, and (c) F_i does not contain 2 distinct atoms.

We prove (b) first. We have that

$$f(0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}, c, 0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}) = f(0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}, d, 0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}) = 1$$

(where c and d appear in the i th position) and by supermodularity it follows that we also have $f(0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}, 1_{\mathcal{L}}, 0_{\mathcal{L}}, \dots, 0_{\mathcal{L}}) = 1$. Since I_i does not contain $1_{\mathcal{L}}$, we have that $x_j \in F_j$ for each $j \in \{j_1, \dots, j_l\}$; since F_j never contains $0_{\mathcal{L}}$, (b) follows immediately. Since $\{j_1, \dots, j_l\}$ is nonempty, (a) follows immediately from (b). Finally, if F_i contained distinct atoms, then by dualizing the preceding argument we would obtain that $\{i_1, \dots, i_k\} = \{i\}$ from which it would follow that f would be essentially unary, contrary to our assumption. This concludes the proof of the claim.

Let b denote the minimal element in F_i , and for each index $s \in \{i_1, \dots, i_k\}$ different from i let c_s denote the (unique) maximal element of I_s ; then we can describe f as follows: $f(\mathbf{x}) = 1$ if and only if

$$[x_i \in I_i \wedge (\mathbf{y} \sqsubseteq \mathbf{c})] \vee (x_i \sqsupseteq b),$$

where $\mathbf{y}$ is a tuple of variables different from x_i and $\mathbf{c}$ is the tuple whose entries are the c_s defined previously. It remains to rewrite the condition $x_i \in I_i$. Suppose first

that there exists at least one atom of $\mathcal{L}$ outside I_i , and let $a_1, \dots, a_l$ denote the atoms outside I_i . Then it is clear that $x_i \in I_i$ if and only if $\neg(x_i \sqsupseteq a_1) \vee \dots \vee \neg(x_i \sqsupseteq a_l)$ holds, so the predicate f is of type (4) (simply restate the disjunction as an implication). Now for the last possibility, where I_i contains all of D except $1_{\mathcal{L}}$; then it is easy to see that f can be described by the following:

$$[\neg(x_i \sqsupseteq b) \wedge (\mathbf{y} \sqsubseteq \mathbf{c})] \vee (x_i \sqsupseteq b),$$

and this completes the proof of the theorem. $\square$

We remark that the preceding theorem can be extended to give a similar characterization of the supermodular constraints on lattices in the larger class of so-called *relatively complemented lattices* [21].

5.2. Supermodular constraints on diamonds are tractable.

THEOREM 5.5. *If $\mathcal{F} \subseteq \text{Spmod}_{\mathcal{L}}$, then $\text{MAX CSP}(\mathcal{F})$ can be solved (to optimality) in $O(n^3 \cdot |\mathcal{L}|^3 + q^3)$ time where n is the number of variables and q is the number of constraints in an instance.*

Proof. We will show how the problem can be reduced to the well-known tractable problem MIN CUT.

Let $\mathcal{I} = \{\rho_1 \cdot f_1(\mathbf{x}_1), \dots, \rho_q \cdot f_q(\mathbf{x}_q)\}$, $q \geq 1$, be an instance of weighted MAX CSP ($\mathcal{F}$), over a set of variables $V = \{x_1, \dots, x_n\}$.

Construction.

Let ∞ denote an integer greater than $\sum \rho_i$. For each constraint f_i , fix a representation as described in Theorem 5.2. In the following construction, we will refer to the type of f_i which will be a number from 1 to 6 according to the type of representation. Every condition of the form $(\mathbf{y} \sqsubseteq \mathbf{c})$ will be read as $\bigwedge (x_{i_s} \sqsubseteq c_{i_s})$, and every condition of the form $\neg(\mathbf{y} \sqsupseteq \mathbf{c})$ as $\bigvee \neg(x_{i_s} \sqsupseteq c_{i_s})$, where i_s runs through the indices of variables in $\mathbf{y}$. Moreover, we replace every (sub)formula of the form $\neg(x \sqsupseteq 1_{\mathcal{L}})$ by $\bigvee_{i=1}^n \neg(x \sqsupseteq a_i)$, where $a_1, \dots, a_n$ are the atoms of $\mathcal{L}$.

Next, we construct a digraph $G_{\mathcal{I}}$.

- The vertices of $G_{\mathcal{I}}$ are as follows:
 - $\{T, F\} \cup \{x_d \mid x \in V, d \in \mathcal{L}\} \cup \{\bar{x}_d \mid x \in V, d \in \mathcal{L} \text{ is an atom}\} \cup \{e_i, \bar{e}_i \mid i = 1, 2, \dots, q\}$.³

For each f_i of type (5), we identify the vertex e_i with F . Similarly, for each f_i of type (6), we identify the vertex $\bar{e}_i$ with T .

- The arcs of $G_{\mathcal{I}}$ are defined as follows:
 - For each atom c in $\mathcal{L}$ and for each $x \in V$, there is an arc from $x_{0_{\mathcal{L}}}$ to x_c with weight ∞ , and an arc from $\bar{x}_c$ to $x_{1_{\mathcal{L}}}$ with weight ∞ .
 - For each pair of distinct atoms c, d in $\mathcal{L}$ and for each $x \in V$, there is an arc from x_c to $\bar{x}_d$ with weight ∞ .
 - For each f_i , there is an arc from $\bar{e}_i$ to e_i with weight ρ_i .
 - For each f_i of types (1–4), and each subformula of the form $(x \sqsubseteq a)$ or $\neg(x \sqsupseteq a)$ in the consequent of f_i , there is an arc from e_i to x_a or $\bar{x}_a$, respectively, with weight ∞ .
 - For each f_i of types (1–4), and each subformula of the form $(x \sqsubseteq a)$ or $\neg(x \sqsupseteq a)$ in the antecedent of f_i , there is an arc from x_a or $\bar{x}_a$, respectively, to $\bar{e}_i$, with weight ∞ .
 - For each f_i of type (5), and each subformula of the form $\neg(x \sqsupseteq a)$ in it, there is an arc from $\bar{x}_a$ to $\bar{e}_i$ with weight ∞ .

³The vertices x_d will correspond to the expressions $x \sqsubseteq d$ and $\bar{x}_d$ to $\neg(x \sqsupseteq d)$.

- For each f_i of type (6), and each subformula of the form $(x \sqsubseteq a)$ in it, there is an arc from e_i to x_a with weight ∞ .

Arcs with weight less than ∞ will be called *constraint arcs*.

It is easy to see that $G_{\mathcal{I}}$ is a digraph with source T (corresponding to **true**) and sink F (corresponding to **false**). Note that paths of nonconstraint arcs between vertices corresponding to any given variable $x \in V$ precisely correspond to logical implications that hold between the corresponding assertions. Throughout the proof, we say “a cut in $G_{\mathcal{I}}$ ” meaning a (T, F) -cut.

Define the *deficiency* of an assignment φ as the difference between $\sum_{i=1}^q \rho_i$ and the evaluation of φ on $\mathcal{I}$. In other words, the deficiency of φ is the total weight of constraints not satisfied by φ . We will prove that minimal cuts in $G_{\mathcal{I}}$ exactly correspond to optimal assignments to $\mathcal{I}$. More precisely, we will show that, for each minimal cut in $G_{\mathcal{I}}$ with weight ρ , there is an assignment for $\mathcal{I}$ with deficiency at most ρ , and, for each assignment to $\mathcal{I}$ with deficiency ρ' , there is a cut in $G_{\mathcal{I}}$ with weight ρ' .

The semantics of the construction of $G_{\mathcal{I}}$ will be as follows: the vertices of the form x_a or $\bar{x}_a$ correspond to assertions of the form $x \sqsubseteq a$ or $\neg(x \sqsupseteq a)$, respectively, and arcs denote implications about these assertions. Given a minimal cut in $G_{\mathcal{I}}$, we will call a vertex x_a *reaching* if F can be reached from it without crossing the cut. Furthermore, if a vertex x_a is reaching, then this will designate that the corresponding assertion is false, and otherwise the corresponding assertion is true. A constraint is not satisfied if and only if the corresponding constraint arc crosses the cut.

Let C be a minimal cut in $G_{\mathcal{I}}$. Obviously, C contains only constraint arcs. First we show that, for every variable $x \in V$, there is a unique minimal element $a \in \mathcal{L}$ such that x_a is nonreaching. All we need to show is the following: if c, d are distinct atoms such that both x_c and x_d are both nonreaching, then so is x_{0_c} . Assume that, on the contrary, x_{0_c} is reaching. Then there is a path from x_{0_c} to F not crossing the cut. It is easy to notice that such a path has to go through a vertex $\bar{x}_a$ for some atom $a \in \mathcal{L}$, since the second vertex on this path must be of the form x_b for some atom b , and it is followed either by a vertex $\bar{x}_a$ or else by three vertices $\bar{e}_i, e_i, x_{b'}$ for some $1 \leq i \leq q$ and some atom b' . However, we have an arc from at least one of the vertices x_c, x_d to $\bar{x}_a$, and hence at least one of these vertices would have a path to F not crossing the cut, a contradiction.

Note that, for every $x \in V$, there are no arcs coming out of x_{1_c} . Hence, for every $x \in V$, there is a unique minimal element $v \in \mathcal{L}$ such that F cannot be reached from x_v without crossing the cut.

Define an assignment φ_C as follows:

$\varphi_C(x)$ is the unique minimal element a such that x_a is nonreaching.

We now make some observations. Note that, for all $x \in V$ and $a \in \mathcal{L}$, we have that $\varphi_C(x) \sqsubseteq a$ if and only if x_a is nonreaching. Moreover, if $\bar{x}_a$ is reaching, then, for each atom $b \neq a$, we have an arc from x_b to $\bar{x}_a$ meaning that $\varphi_C(x) \not\sqsubseteq b$, and hence $\varphi_C(x) \sqsupseteq a$. Furthermore, if $\bar{x}_a$ is nonreaching, then $\varphi_C(x) \neq a$. Indeed, if $\varphi_C(x) = a$, then x_b is reaching for all atoms $b \neq a$, and, since every path from x_b to F has to go through a vertex $\bar{x}_c$ for some c , we have that $\bar{x}_c$ is reaching. Then $c \neq a$, and there is an arc from x_a to $\bar{x}_c$, so x_a is reaching, a contradiction. To summarize, we have the following:

- If a node of the form x_a or $\bar{x}_a$ is reaching, then the corresponding assertion is falsified by the assignment φ_C .
- If a node of the form x_a is nonreaching, then $\varphi_C(x) \sqsubseteq a$.

- If a node of the form $\bar{x}_a$ is nonreaching, then the truth value of the corresponding assertion is undecided.

Suppose that a constraint arc corresponding to a constraint f_i is not in the cut. We claim that f_i is satisfied by the assignment φ_C . To show this, we will go through the possible types of f_i .

If f_i is of type (1), (2), (5), or (6), then the claim is straightforward. For example, let f_i be of type (1). If the node $x_{0_{\mathcal{L}}}$ corresponding to the consequent is reaching, then so are all nodes corresponding to the antecedent. Hence, all atomic formulas are falsified by the assignment φ_C , and the implication is true. If $x_{0_{\mathcal{L}}}$ is nonreaching, then $\varphi_C(x) = 0_{\mathcal{L}}$, and the constraint is clearly satisfied. The argument for types (2), (5), and (6) is very similar.

Let f_i be of type (3). Then, if the node corresponding to the consequent is nonreaching, then the consequent is satisfied by φ_C , and so the constraint is satisfied. If this node is reaching, then every node corresponding to the disjuncts in the antecedent is reaching. Then both antecedent and consequent are falsified by φ_C , and the constraint is satisfied.

Let f_i be of type (4), that is, of the form

$$\neg(x_i \sqsupseteq b) \implies [\neg(x_i \sqsupseteq a_1) \wedge \cdots \wedge \neg(x_i \sqsupseteq a_l) \wedge (\mathbf{y} \sqsubseteq \mathbf{c})].$$

If a node corresponding to some conjunct in the consequent is reaching, then the node corresponding to the antecedent is also reaching. So $\varphi_C(x_i) \sqsupseteq b$, and the constraint is satisfied. More generally, if the node corresponding to the antecedent is reaching, then the constraint is satisfied regardless of what happens with the consequent. Assume that all nodes corresponding to conjuncts in the consequent and in the antecedent are nonreaching. Then the conjunct $(\mathbf{y} \sqsubseteq \mathbf{c})$ is satisfied by φ_C . Furthermore, we know (see the observations above) that $\varphi_C(x_i) \neq b$, and also that $\varphi_C(x_i) \neq a_s$ for $1 \leq s \leq l$. If $\varphi_C(x_i) = 1_{\mathcal{L}}$, then both the antecedent and the consequent of f_i are false, and hence f_i is satisfied. Otherwise, $\varphi_C(x_i) \not\sqsupseteq b$ and $\varphi_C(x_i) \not\sqsupseteq a_s$ for $1 \leq s \leq l$, so f_i is satisfied anyway.

Conversely, let φ be an assignment to $\mathcal{I}$, and let K be the set of constraints in $\mathcal{I}$ that are not satisfied by φ . Consider any path from T to F . It is clear that if all constraints corresponding to constraint arcs on this path are satisfied, then we have a chain of valid implications starting from **true** and finishing at **false**. Since this is impossible, at least one constraint corresponding to such an arc is not satisfied by φ . Hence, the constraint arcs corresponding to constraints in K form a cut in $G_{\mathcal{I}}$. Furthermore, by the choice of K , the weight of this cut is equal to the deficiency of φ .

It follows that the standard algorithm [12] for the MIN CUT problem can be used to find an optimal assignment for any instance of MAX CSP($\mathcal{F}$). This algorithm runs in $O(k^3)$, where k is the number of vertices in the graph. Since the number of vertices in $G_{\mathcal{I}}$ is at most $2(1 + n \cdot |D| + q)$, the result follows. $\square$

We remark that a partial converse to Theorem 5.5 was proved in [20] where it is shown that if $\mathcal{F}$ contains all 2-monotone predicates on a diamond and any predicate which is not supermodular on that diamond, then MAX CSP($\mathcal{F}$) is NP-hard.

6. Conclusion. We have described a large class of lattices on which the SFM problem is oracle-tractable, and an even larger class of lattices $\mathcal{L}$ such that MAX CSP($\mathcal{F}$) is tractable whenever all predicates in $\mathcal{F}$ are supermodular on $\mathcal{L}$. We believe that more progress in the study of maximum constraint satisfaction can be achieved by further blending supermodular optimization and algebraic lattice theory.

The three most standard constructions on algebras (and on lattices in particular) are the forming of homomorphic images, subalgebras, and direct products. We showed (Corollary 4.4 and Theorem 4.6) that two of them preserve oracle-tractability of the problems $\text{SFM}(\mathcal{L})$. However, it is an open problem whether, for any finite lattice $\mathcal{L}_1$, oracle-tractability of $\text{SFM}(\mathcal{L}_1)$ implies oracle-tractability of $\text{SFM}(\mathcal{L}_2)$ for any sublattice $\mathcal{L}_2$ of $\mathcal{L}_1$.

This paper explores two ways of obtaining tractability results for MAX CSP problems—one is via oracle-tractability of the SFM problem, and the other via explicit description of supermodular predicates. One other way that remains to be explored has to do with implicit methods (see [2, 4]) of showing that some predicates can be simulated (or “strictly implemented” [8, 19]) by other predicates. One interesting question in this connection is whether any supermodular predicate on a lattice can be simulated, i.e., strictly implemented, by 2-monotone predicates on that lattice. A positive answer to this question would, together with Theorem 3.6, imply that $\text{MAX CSP}(\mathcal{F})$ is tractable for arbitrary sets $\mathcal{F}$ of supermodular predicates on a lattice.

Finally, we hope that the study of sub- and supermodular functions on lattices will find more applications in combinatorial optimization.

ON PLANAR QUASI-PARITY GRAPHS*

CLÁUDIA LINHARES SALES[†], FRÉDÉRIC MAFFRAY[‡], AND BRUCE REED[§]

Abstract. A graph G is strict quasi parity (SQP) if every induced subgraph of G that is not a clique contains a pair of vertices with no odd chordless path between them (an even pair). Hougardy conjectured that the minimal forbidden subgraphs for the class of SQP graphs are the odd chordless cycles, the complements of odd or even chordless cycles, and some line-graphs of bipartite graphs. Here we prove this conjecture for planar graphs. We also give a constructive characterization of all the planar minimal forbidden subgraphs for the class of SQP graphs.

Key words. perfect graphs, even pairs, planar graphs

DOI. 10.1137/060672649

1. Introduction. A graph G is *perfect* if, for every induced subgraph H of G , the chromatic number of H is equal to the size of its largest clique. A *hole* is any chordless cycle of length at least five. A hole is odd or even according to its length. The most famous problem in the context of perfect graphs was Berge’s perfect graph conjecture: *A graph G is perfect if and only if neither G nor $\bar{G}$ contains an odd hole.* This was proved by Chudnovsky et al. [1]. However, other problems concerning perfect graphs remain open, some of which are related to the concept of an *even pair*. Two nonadjacent vertices of a graph G form an *even pair* (resp., *odd pair*) if every chordless path between them has an even (resp., odd) number of edges. A graph is *strict quasi parity* (SQP) if each of its induced subgraphs either contains an even pair or is a clique. Fonlupt and Uhry [3] introduced even pairs and showed that the graph obtained by contracting an even pair in a perfect graph is perfect. Meyniel also showed that no minimal imperfect graph contains an even pair [11]. He proposed the definition of SQP graphs, which, by his result, are perfect. The main interest of this class lies in the fact that many classical families of perfect graphs are SQP, as proved by Meyniel (see also the more recent survey [2]). Meyniel also suspected that the minimal non-SQP graphs must have a simple structural characterization. More formally, Hougardy [5] proposed the following conjecture.

CONJECTURE 1. *Every minimal non-SQP graph is either an odd hole, or the complement of a hole, or the line graph of a bipartite graph.*

Let us call *obstruction* any graph G which is not a clique, has no even pair, and is such that every proper induced subgraph of G has an even pair or is a clique. We will prove Hougardy’s conjecture for planar graphs; namely, we will prove the following theorem.

THEOREM 1 (main theorem). *Every planar obstruction is an odd hole or the line-graph of a bipartite graph.*

We say that the neighborhood of a vertex is *correct* if it consists of either (a) three vertices with exactly one edge between them, or (b) four vertices with exactly two, nonincident, edges between them. To prove the main theorem it suffices to establish the following.

THEOREM 2. *In a planar obstruction that is not an odd hole, every neighborhood is correct.*

Let us recall a classical result which we will use several times. Call *diamond* the graph that consists of a clique of size four minus one edge. Call *claw* the graph on four vertices with one vertex of degree three and three vertices of degree one.

THEOREM 3 (see [4]). *A graph G is the line-graph of a simple bipartite graph if and only if G contains no odd hole, no diamond, and no claw.*

Proof of Theorem 1 from Theorem 2. Let G be a planar obstruction different from an odd hole. By Theorem 2, every vertex belongs to exactly two maximal cliques, one of size three and the other of size three or two. Hence G contains no claw and no diamond. Thus G is the line-graph of a bipartite graph by Theorem 3.

The proof of Theorem 2 is the object of the next sections. It will be convenient to first prove it for 3-connected obstructions (Theorem 4), and then to derive it for all obstructions via some decomposition technique. In section 4 we will give a more precise description of planar obstructions.

For an introduction to planar graphs, see [12]. We finish this section with a few definitions and some simple lemmas.

We will frequently use “sees” and “misses” instead of “is adjacent to” and “is not adjacent to.” The subgraph of a graph G induced by a set $X \subseteq V(G)$ is denoted by $G[X]$. For vertices $x, y \in V(G)$, an x, y -path is a path whose endvertices are x and y . If P is a path and u, v are vertices in P , we let $P[u, v]$ denote the subpath of P between u and v . If two paths P, Q have a common endvertex, we use $P + Q$ to denote the path obtained by their concatenation. For any vertex x we let $N(x)$ denote the neighborhood of x . For a set $X \subseteq V(G)$, we let $N(X) = \{u \in V(G) - X \mid u \text{ sees some } x \in X\}$.

LEMMA 1. *Let G be a graph that contains no odd hole. Then*

1. *if P is a chordless path in G and x is a vertex of $G - P$ that sees the two endvertices of P , then P has even length if and only if it contains an even number of edges of $N(x)$.*
2. *if H is a hole in G and x is a vertex of $G - H$ that sees at least two nonadjacent vertices of H , then H contains an even number of edges of $N(x)$.*

Proof. If 1 fails, it is a routine matter to check that $P + x$ contains an odd hole. To prove 2, consider two nonadjacent vertices u, v of H that are neighbors of x and apply 1 to the two u, v -paths of H . $\square$

LEMMA 2. *An obstruction contains no clique cutset.*

Proof. Suppose that G is an obstruction which has a clique cutset C . First, assume that for some component B of $G - C$ the induced subgraph $G[B \cup C]$ is not a clique. So $G[B \cup C]$ has an even pair a, b . No chordless path between a and b can go through another component of $G - C$ because C is a clique; it follows that a, b is an even pair of G , a contradiction. Now assume that $G[B \cup C]$ is a clique for every component B of $G - C$. Pick any a, b in two different components of $G - C$: clearly a, b is an even pair of G , a contradiction. $\square$

LEMMA 3. *Let x, y be nonadjacent vertices in a minimal cutset C in a graph that contains no odd hole. Then all chordless x, y -paths in $G - (C - \{x, y\})$ have the same parity.*

Proof. Since C is a minimal cutset, every component D of $G - C$ contains a neighbor of x and a neighbor of y , and so there is a chordless x, y -path with interior in D . If the lemma fails, there must exist an even chordless x, y -path P whose interior lies in one component of $G - C$ and an odd chordless x, y -path Q whose interior lies in another component of $G - C$, and then $P + Q$ is an odd hole, a contradiction. $\square$

LEMMA 4. *In an obstruction different from an odd hole, every vertex has degree at least three and lies in a triangle.*

Proof. Let x be any vertex in such an obstruction G . If x either has degree one, or has degree two and its neighbors are adjacent, then $N(x)$ is a clique cutset, contradicting Lemma 2. Suppose x has degree at least two and its neighbors are pairwise nonadjacent. Let u, v be any two neighbors of x . If P is an odd chordless u, v -path in G , then $P + x$ contains an odd hole by Lemma 1. So there is no such path; but then u, v form an even pair, a contradiction. $\square$

2. 3-connected planar obstructions. Here we prove Theorem 2 for 3-connected planar obstructions.

THEOREM 4. *In a 3-connected planar obstruction every neighborhood is correct.*

Proof. Let G be a 3-connected planar obstruction, and let us fix one planar representation of G . We shall arrive at the desired conclusion of Theorem 4 through a succession of lemmas that gradually restrict the possible types of neighborhood in G . $\square$

LEMMA 5. *In G the neighborhood of every vertex induces either a chordless cycle or a collection of vertex-disjoint paths.*

Proof. Let x be any vertex of G . If $N(x)$ contains a vertex y of degree three in $N(x)$, then planarity implies that x and y are in a triangle cutset of G , contradicting Lemma 2. Thus the maximum degree in $N(x)$ is two. Moreover, if $N(x)$ properly contains a set S of vertices which induce a cycle, then planarity implies that $S \cup \{x\}$ contains a triangle cutset separating $N(x) - S$ from $V(G) - (N(x) \cup \{x\})$, again a contradiction. Lemma 5 follows. $\square$

LEMMA 6. *G has no vertex x such that $N(x) \cup \{x\}$ induces a diamond.*

Proof. Suppose on the contrary that there exists such a vertex x , and let y, z be the nonadjacent vertices in $N(x)$. Since G is an obstruction, there is an odd chordless path P between y and z . But then $P + x$ is an odd hole, a contradiction. $\square$

A *star-cutset* is a cutset C such that some vertex $x \in C$ sees all vertices of $C - x$.

LEMMA 7. *G has no star-cutset.*

Proof. Suppose that G contains a star*-cutset C , and let x be a vertex of C that sees all of $C - x$. We claim that each component K of $G - C$ has a nonneighbor of x . Suppose the contrary, that is, $K \subseteq N(x)$. By Lemma 5, K induces a cycle or a path. Let y be any vertex of K . Then $N(y) \cup \{y\}$ induces a diamond, a contradiction to Lemma 6. So our claim holds, and consequently we can assume that $C = \{x\} \cup N(x)$. As G is 3-connected, each component of $G - C$ is adjacent to at least three vertices of C and hence three vertices of $N(x)$. We can enumerate the neighbors of x as $x_1, \dots, x_d$ clockwise around x and choose a component K of $G - C$ with $x_1 \in N(K), x_j \in N(K), N(K) \subseteq \{x_1, \dots, x_j\}$, and such that j is as small as possible over all clockwise enumerations and all choices of K . This choice, the fact that $|N(K)| \geq 3$, and planarity imply that any other component L of $G - C$ satisfies $N_L \subseteq \{x_j, x_{j+1}, \dots, x_d, x_1\}$. It follows that $\{x, x_1, x_j\}$ is a cutset of G . Then $x_1 x_j$ is not an edge of G , for otherwise G has a clique cutset $\{x, x_1, x_j\}$. Furthermore, $\{x, x_1, x_j\}$ is a minimal cutset since G is 3-connected. Thus for every component L of $G - \{x, x_1, x_j\}$ there is a chordless x_1, x_j -path in $L \cup \{x_1, x_j\}$. Such paths must

all have the same parity, for otherwise we could find two paths of different parity in different components of $G - \{x, x_1, x_j\}$, and their union would be an odd hole in G . Actually all these paths are odd, for otherwise $\{x_1, x_j\}$ would be an even pair. There is a chordless x_1, x_j -path P in K since $\{x_1, x_j\} \subseteq N(K)$, and by the above remark, P is odd. Now, $P + x$ is an odd hole, a contradiction. This completes the proof of Lemma 7. $\square$

LEMMA 8. *If G has a cutset C of size three which induces a subgraph with just one edge, then there is a vertex w with $N(w) = C$.*

Proof. Assume that $C = \{x, y, z\}$ with $xy \in E(G)$ and $yz, xz \notin E(G)$. Since G is 3-connected, C is a minimal cutset. By Lemma 3, all chordless x, z -paths in $G - y$ have the same parity p_{xz} and all chordless y, z -paths in $G - x$ have the same parity p_{yz} . If p_{xz} is even and p_{yz} is odd (or vice versa), then x, z (or y, z) form an even pair, a contradiction. So p_{xz} and p_{yz} are the same. Since G has no star-cutset, there is a chordless x, z -path P_1 in $G - (N(y) \cup \{y\})$. The interior of P_1 is in some component K_1 of $G - C$. Similarly, there is a y, z -path P_2 in $G - (N(x) \cup \{x\})$. The interior of P_2 is also in K_1 , for otherwise $P_1 + xy + P_2$ forms an odd hole. Let K be any component of $G - C - K_1$, and let P be any chordless y, z -path with interior in K . Call w the neighbor of y along P . Let w' be the last neighbor of x along P , starting from y . If $w' \neq w$, then one of the paths $xw' + P[w', z] + P_1$ and $xw' + P[w', z] + P_2 + yx$ is chordless and odd, a contradiction. It follows that x sees w and no other vertex of $P - y$. Thus the set $W = N(x) \cap N(y) \cap K$ separates x and y from z in $K \cup \{x, y, z\}$. Suppose that W has two vertices w, w' . Let P_3 (resp., P_4) be a w, z -path (w', z -path) in $G \setminus (K \cup \{x, y\})$. If w, w' are adjacent, then it is easy to see that the subgraph induced by $P_1 \cup P_2 \cup P_3 \cup P_4$ contains a subdivision of K_5 , which contradicts the planarity. If w, w' are not adjacent, then, since they do not form an even pair, there is an odd w, w' -path Q in G , and any such path must be in $G - (K \cup \{x, y\})$. But then it is easy to see that the subgraph induced by $P_1 \cup P_2 \cup P_3 \cup P_4 \cup Q$ contains a subdivision of K_5 or of $K_{3,3}$, which contradicts planarity. So $|W| \leq 1$, say $W = \{w\}$. Now $K = \{w\}$; otherwise $\{w, z\}$ would be a cutset of size two in G . So $N(w) = \{x, y, z\}$, which completes the proof of Lemma 8. $\square$

LEMMA 9. *For every vertex x of degree three, the neighborhood of x contains exactly one edge.*

Proof. Clearly, $N(x)$ does not induce a triangle K_3 , for otherwise either $N(x)$ is a clique cutset or G is K_4 , both of which are impossible. Lemma 6 implies that $N(x)$ does not induce a path of length two. On the other hand, $N(x)$ must contain an edge, for otherwise any two vertices in $N(x)$ would form an even pair. This proves the lemma. $\square$

LEMMA 10. *Every face of G is a hole.*

Proof. Every face of G is a cycle because G is 2-connected. If a face F has a chord xy , planarity implies that $\{x, y\}$ is a clique cutset of G that separates one component of $F - \{x, y\}$ from the other, a contradiction to the fact that G is 3-connected. $\square$

LEMMA 11. *Any two intersecting faces in G intersect in an edge or a vertex.*

Proof. Suppose that two faces F, F' intersect in at least two nonadjacent vertices. Then it is easy to see that there are two vertices of $F \cap F'$ that form a cutset, a contradiction to the fact that G is 3-connected. $\square$

For any vertex x of G , we denote by F_x the face of $G - x$ such that x lies in the interior of F_x . Note that F_x is a cycle since $G - x$ is 2-connected.

LEMMA 12. *For every vertex x , if yz is an edge between two vertices of F_x that are not consecutive along F_x , then x misses y and z and there is a vertex w of F_x such that $N(w) = \{x, y, z\}$.*

Proof. In the opposite case, $\{x, y, z\}$ would be either a clique cutset or a cutset, contradicting Lemma 8. $\square$

LEMMA 13. *For every vertex x of degree at least four, F_x is a hole.*

Proof. Consider any such vertex x and assume that F_x is not chordless. By Lemma 12, there is a vertex w on F_x with $N(w) = \{x, y, z\}$, $y, z \in F_x$, edges $yz, yw, wz \in E(G)$, and $xy, xz \notin E(G)$. Let F_1 and F_2 be the two faces of G containing the edge wx . By Lemma 10, F_1 and F_2 both induce holes of G . Since each of F_1 and F_2 contains one of y or z , neither is a triangle and hence both are even. By Lemma 11, $F_1 \cap F_2 = \{w, x\}$. By Lemma 12 and the fact that $|N(x)| \geq 4$, there is no edge from $F_1 - \{w, x\}$ to $F_2 - \{w, x\}$. But now $F_1 + F_2 - w$ is an odd hole in G , a contradiction. $\square$

LEMMA 14. *For every vertex x of degree at least four in G , $N(x)$ induces a graph with an even number of edges.*

Proof. By Lemma 13, F_x is a hole. If $N(x)$ induces a disjoint set of paths with an odd number of edges, then $F_x \cup \{x\}$ contains an odd hole by Lemma 1, a contradiction. $\square$

LEMMA 15. *If G has a diamond on vertices $\{a, b, c, d\}$ such that $ad \notin E(G)$, then there is no path from a to d in $G - [N(b) \cup N(c) - \{a, d\}]$.*

Proof. Since $\{a, d\}$ is not an even pair there exists an odd chordless a, d -path in $G - b - c$. Choose such a path P_1 with $P_1 \cap (N(b) \cup N(c))$ minimal over all such paths. Suppose indirectly that there exists a chordless a, d -path P_2 in $G - [N(b) \cup N(c) - \{a, d\}]$. Let $x \in P_1 - a - d$ be such that $xb \in E(G)$; such an x exists or else $P_1 + b$ induces an odd hole. Let P_3, P_4 be the two subpaths of $P_1 - x$ such that $a \in P_3$ and $d \in P_4$. Clearly there is a chordless path from P_3 to P_4 whose interior vertices are in $P_2 - P_1$. Choose a shortest such path P_5 so that its endpoint f in P_3 is as close as possible to a along P_3 and its endpoint g in P_4 is as close as possible to d along P_4 . Then the path $P_6 = P_3[a, f] + P_5 + P_4[g, d]$ is a chordless path. Now, as $P_5 - f - g \subseteq P_2$ we know that $(P_5 - f - g) \cap (N(b) \cup N(c)) = \emptyset$. Observe that P_6 contains strictly fewer vertices of $N(b) \cup N(c)$ than P_1 . Thus, by the minimality in our choice of P_1 , P_6 is even. It follows that the subpath $P_1[f, g]$ is of different parity from P_5 . Note that by planarity $(P_1[f, g] - f - g) \cap N(c) = \emptyset$. Let r (resp., s) be the neighbor of c closest to f (resp., to g) along P_3 (resp., P_4). Then either $c + P_1[r, s]$ or $c + P_1[r, s] - P_1[f, g] + P_5$ is an odd hole. This contradiction completes the proof of Lemma 15. $\square$

LEMMA 16. *G contains no diamond.*

Proof. Suppose on the contrary that $\{a, b, c, d\}$ is a diamond in G , with $ad \notin E(G)$.

First, suppose that $N(a) \subseteq N(b) \cup N(c)$. Let $y_1, \dots, y_k$ ($k \geq 3$) be the neighbors of a clockwise in the planar representation of G , with $b = y_1$. If c is none of y_2, y_k , then $\{a, b, c\}$ is a triangle cutset, a contradiction to Lemma 2. So we may assume that $c = y_k$. Then b misses every y_i with $3 \leq i \leq k - 1$, for otherwise $\{a, b, y_i\}$ is a triangle cutset, again a contradiction. Likewise c misses y_j with $2 \leq j \leq k - 2$. It follows that $k \leq 4$. If $k = 3$, then Lemma 9 is contradicted by a . So $k = 4$, b sees y_2 , c sees y_3 , and by Lemma 14, $N(a)$ is the 4-cycle $b-y_2-y_3-c$. Since y_2, y_3 must not form an even pair, there is an odd path P between them; but then $P + a$ is an odd hole, a contradiction. Therefore $N(a) \not\subseteq N(b) \cup N(c)$.

Consider any $y \in N(a) - (N(b) \cup N(c))$, and let K be the component of $G - (N(b) \cup N(c))$ that contains y . By Lemma 15, no vertex of K sees d . By Lemma 7, $N(c) \cup \{c\}$ is not a cutset, and so there is a vertex in $N(b) - N(c)$ adjacent to K . Likewise there is a vertex in $N(c) - N(b)$ adjacent to K . By planarity, we can choose $e \in N(b) - N(c)$ and $f \in N(c) - N(b)$ such that both e and f see elements of K

and $\{e, b, c, f\}$ is a cutset separating K from d . (More precisely, if $z_1, \dots, z_k$ are the neighbors of b clockwise in the planar representation of G , with $z_1 = d, z_2 = c, z_3 = a$, then e is the vertex z_j that has a neighbor in K and such that j is the largest such integer. Vertex f is defined similarly.) There is a chordless e, f -path P_1 with interior in K by definition. This path must be odd or else $P_1 + b + c$ would be an odd hole.

We claim that $S = \{e, b, c, f\}$ is a minimal cutset. Suppose that some proper subset S' of S is a cutset. We have $|S'| = 3$ since G is 3-connected. Lemma 7 implies that S' is not $S - e$ or $S - f$. Thus, and by symmetry, S' is $S - b = \{e, c, f\}$. Then Lemmas 7 and 8 imply that e does not see f and that there is a vertex w with $N(w) = \{e, c, f\}$. But then $P_1 + w$ form an odd hole. So the claim holds.

Now, by Lemma 3, all chordless e, f -paths in $G - b - c$ have the same parity, which is odd since P_1 is one such path. By the same lemma, all chordless b, f -paths in $G - c - e$ have the same parity, which is odd, for otherwise $\{b, f\}$ would be an even pair. Similarly all chordless c, e -paths in $G - b - f$ are odd.

Suppose that e and f have no common neighbor in $G - K - a$. Since G is 3-connected, there exist paths from d to $\{e, f\}$ in $G - (K \cup \{a, b, c\})$. Consider a shortest one P_2 ; it can be assumed by symmetry that P_2 is from d to e . Note that there are no neighbors of f in $P_2 - e$ by the minimality of P_2 and the fact that e and f have no common neighbor in $G - K - a$. The path $P_2 + c$ contains a shortest c, e -path P'_2 , and P'_2 is odd as mentioned above. But now $P_1 + P'_2$ induces an odd hole (even if $P_1 = ef$), a contradiction. So e and f have a common neighbor in $G - K - a$. It follows that $ef \in E(G)$ since every chordless e, f -path in $G - b - c$ must be odd.

Let g be the common neighbor of e and f such that the cycle $gebef$ bounds a region of the plane containing d and no other common neighbor of e and f . If there exists a path from d to $\{e, f\}$ in $G - \{b, c, g\}$, then, as in the above case where e and f had no common neighbor, we obtain a contradiction. So $\{b, c, g\}$ is a cutset, and Lemma 8 implies $N(d) = \{b, c, g\}$. But then b, c, d, e, f, g induce a proper subgraph of G which is a $\bar{C}_6$, a contradiction. This completes the proof of Lemma 16. $\square$

LEMMA 17. *G contains no vertex of degree five or greater.*

Proof. Suppose that x is a vertex of degree at least five in G . By Lemmas 13, 14, and 16, F_x is an even hole, it contains an even number of edges of $N(x)$, and no three consecutive vertices of F_x are neighbors of x . We claim that

- (1) *no vertex of $G - x - F_x$ sees two nonadjacent vertices of F_x .*

Assume on the contrary that there exists a triple $\{a, s, t\}$ such that a is in $G - x - F_x$ and s, t are nonadjacent neighbors of a in F_x . Let P_1 and P_2 be the two chordless s, t -paths in F_x , where the length of P_1 is less than or equal to the length of P_2 . We choose a triple $\{a, s, t\}$ that minimizes the length of P_1 over all appropriate choices. Path P_1 has even length, for otherwise either $P_1 + a$ would be an odd hole or the minimality of P_1 would be contradicted. Then P_2 is also even since F_x is an even hole. Note that $\{a, s, t, x\}$ is a cutset that separates $P_1 - s - t$ from $P_2 - s - t$. For $i = 1, 2$, call K_i the component of $G - \{a, s, t, x\}$ that contains $P_i - s - t$. There is a neighbor of x on $P_1 - s - t$, or else $\{a, s, t\}$ would be a cutset contradicting Lemma 7. Call u (resp., v) the neighbor of x in $P_1 - s - t$ that is closest to s (resp., to t). Consider the chordless paths $P_1^s = P_1[s, u] + ux$ and $P_1^t = P_1[t, v] + vx$. Note that these two paths have their interiors in K_1 . Likewise there is a neighbor of x on $P_2 - s - t$. Call y (resp., z) the neighbor of x that is closest to s (resp., t) on $P_2 - s - t$. Consider the chordless paths $P_2^s = P_2[s, y] + yx$ and $P_2^t = P_2[t, z] + zx$. Note that these two paths have their interior in K_2 .

First suppose that either (a) $u = v$ or (b) u, v are different and not adjacent. In case (a), clearly P_1^s and P_1^t have the same parity p since P_1 has even length. In case (b), $P_1^s + sa + at + P_1^t$ is a hole, which is even, so P_1^s and P_1^t again have the same parity p . In either case, both P_2^s, P_2^t also have parity p , for otherwise either $P_2^s + P_1^s$ or $P_2^t + P_1^t$ would be an odd hole. Since $\{s, t\}$ is not an even pair, there is an odd chordless s, t -path Q in G . Clearly Q does not use a . If Q also does not use x , then its interior lies in some component of $G - \{a, s, t, x\}$ and so one of $Q + P_1$ or $Q + P_2$ is an odd hole, a contradiction. Thus Q contains x . So Q consists of a chordless s, x -path Q' in $G - a - t$ plus a chordless x, t -path Q'' in $G - a - s$, and the paths Q', Q'' have different parities. Note that each of Q', Q'' has its interior in some component of $G - \{a, s, t, x\}$. Up to symmetry, Q' is odd and Q'' is even, and so x does not see t . If the parity p is even, then x does not see s , and at least one of $Q' + P_1^s$ or $Q' + P_2^s$ is an odd hole, a contradiction. If p is odd, then at least one of $Q'' + P_1^t$ or $Q'' + P_2^t$ is an odd hole, a contradiction.

Now suppose that u, v are different and adjacent. Then P_1^s and P_1^t have different parities. By Lemma 14, P_2 has an odd number of edges of $N(x)$. Call s' and t' , respectively, the neighbor of s and t on P_2 . Vertex a sees no vertex of $P_2 - \{s, s', t, t'\}$, for otherwise there would exist a chordless a, x -path R in $a + x + P_2 - \{s, s', t, t'\}$ and then either $R + as + P_1^s$ or $R + at + P_1^t$ would be an odd hole. Moreover, if a sees one of s', t' , then it sees both, or else $F_x + a$ would contain an odd hole by Lemma 1 applied to P_2 and a . Suppose that a sees both s', t' . Let $F'_x = F_x + a - P_1$. So F'_x is a hole and must be even. Since G contains no diamond, x misses both s', t' . So x sees at least three vertices of F'_x (since x has degree at least five), and F'_x contains an odd number of edges of $N(x)$, so $x + F'_x$ contains an odd hole by Lemma 1, a contradiction. Thus a misses both s', t' . Call P'_1 the interior of P_1 and let $F'_x = F_x + a - P'_1$. A similar argument shows that $x + F'_x$ contains an odd hole, a contradiction. Thus (1) holds.

Let $E_x = \{e_0, \dots, e_{k-1}\}$ be the set of edges in $N(x)$, with $e_i = u_i v_i$. Lemmas 1, 4, 14, and 16 imply that E_x is a matching of even size $k \geq 2$, so we can enumerate the components of $G[F_x] - E_x$ as $C_0, \dots, C_{k-1}$ so that for $0 \leq i \leq k-1$ the endpoints of C_i are v_{i-1} and u_i (modulo k). By Lemma 1, each C_i is an even path, so it has a nonempty interior. Let W be the set of vertices of $G - x - F_x$ that have a neighbor in F_x . By Lemma 16 and (1), for every vertex $w \in W$ the set $N(w) \cap F_x$ consists of one or two consecutive vertices of some C_i . Thus W can be partitioned into $W_0, \dots, W_{k-1}$, where $W_i = \{w \in W \mid N(w) \cap F_x \subset C_i\}$. Let $W_i^* = \{w \in W_i \mid w \text{ has a neighbor in the interior of } C_i\}$, and $X_i = W_i - W_i^*$ (so every vertex $w \in X_i$ satisfies $N(w) \cap F_x = \{v_{i-1}\}$ or $\{u_i\}$). For $0 \leq i, j \leq k-1$ with $i \neq j$, call (i, j) -connection any path $P = f \cdots g$ in $G - x - F_x$ such that $f \in W_i, g \in W_j$, there are nonadjacent vertices $y \in C_i \cap N(f)$ and $z \in C_j \cap N(g)$, and the interior vertices of P are in $G - (W_0^* \cup \dots \cup W_{k-1}^*)$. Say that an (i, j) -connection is *pure* if its interior vertices are in $G - (W - X_i - X_j)$. We claim that

(2) *there exists a pure $(i, i+1)$ -connection for some i .*

By Lemma 7, the graph $G - \{x, u_0, v_0, \dots, u_{k-1}, v_{k-1}\}$ is connected, which implies that for each $i = 0, \dots, k-1$ there exists an (i, j) -connection for some j .

We remark that, for every $i \neq j$, every (i, j) -connection $P = f \cdots g$ contains a pure (i', j') -connection for some i', j' . We prove this remark by induction on the length of P . Suppose that P itself is not pure. So there is a vertex $h \in (P - f - g) \cap X_l$ for some $l \neq i, j$. Pick any $y \in F_x \cap N(f), z \in F_x \cap N(g), t \in F_x \cap N(h)$. It cannot be that t sees both y, z , so either $P[f, h]$ or $P[h, g]$ is a connection, which, by induction,

contains a pure connection. So the remark is proved, and in particular there exists a pure connection.

Let $P = f \cdots g$ be a pure (i, j) -connection. Let P' be any path of F_x between vertices $y \in F_x \cap N(f)$, $z \in F_x \cap N(g)$, and let R be the region of the plane that is bounded by $P \cup P'$ and does not contain x . We choose i, j, P, P' such that the length of P' is minimized. If $|j - i| = 1$, we are done. Otherwise, there is some l such that $e_{l-1} \cup C_l \cup e_l \subseteq P'$. We know that there exists an (l, m) -connection P'' for some m . By the planarity of G , either P'' lies entirely inside R , and then every pure connection contained in P'' contradicts the choice of P' ; or P'' intersects P , and then $P \cup P''$ contains an (l, i) - or an (l, j) -connection, which contains a pure connection that contradicts the minimality of P' . So (2) holds.

By (2) and up to symmetry we can assume that there exists a pure $(1, 2)$ -connection. We choose a shortest one $P = f \cdots g$, with $f \in W_1$ and $g \in W_2$. Let y (resp., y') be the neighbor of f on C_1 closest to v_0 (resp., to u_1). Recall that y, y' are either equal or adjacent. Likewise let z (resp., z') be the neighbor of g along C_2 closest to u_2 (resp., to v_1). Let Q be the y, z -path of F_x that does not contain $u_1 v_1$, and let Q' be the y', z' -path of F_x that contains $u_1 v_1$. Suppose $|E_x| \geq 4$. Then no interior vertex h of P sees v_0 or u_2 , for otherwise $P[h, g]$ or $P[f, h]$ would contradict the choice of P . Thus $P \cup Q$ induces a hole, which contains $|E_x| - 1$ edges of E_x ; so, by Lemma 1, G contains an odd hole, a contradiction. So $|E_x| = 2$. Now Q and Q' play a symmetric role. If no interior vertex of P sees any of u_0, v_0, u_1, v_1 , then $P \cup Q$ and $P \cup Q'$ induce two holes, each of them contains one edge of E_x , and at least one of them contains three neighbors of x ; so, by Lemma 1, G contains an odd hole, a contradiction. So we may assume, up to symmetry, that some interior vertex h of P is adjacent to u_1 . Then $z = v_1$, for otherwise $P[h, g]$ would contradict the choice of P ; no vertex g' of $P - g$ is adjacent to v_1 , for otherwise $P[f, g']$ would contradict the choice of P ; no vertex f' of $P - f$ is adjacent to v_0 , for otherwise $P[f', g]$ would contradict the choice of P ; and no vertex d of P is adjacent to u_0 , for otherwise $P[d, h]$ would contradict the choice of P . Thus $P \cup Q$ induces a hole, which contains one edge of E_x and at least three neighbors (v_1, u_0, v_0) of x , and so by Lemma 1, G contains an odd hole, a contradiction. This completes the proof of Lemma 17. $\square$

Now, since G is 3-connected, it has minimum degree three. This and the above lemmas yield that every vertex of G has a correct neighborhood, and Theorem 4 is established.

3. Obstructions that have a 2-cutset. In this section we consider obstructions that are not necessarily 3-connected. For this purpose we need some new definitions.

DEFINITION 1 (candidate). *A candidate is any planar graph G such that*

- (c1) *G is the line-graph of a bipartite graph;*
- (c2) *every neighborhood is correct;*
- (c3) *G is 2-connected;*
- (c4) *every 2-cutset is an odd pair.*

LEMMA 18. *Any candidate satisfies the following additional properties:*

- (c5) *If $\{a, b\}$ is a 2-cutset in a candidate G , then $G - \{a, b\}$ has exactly two components;*
- (c6) *a candidate has no clique-cutset;*
- (c7) *in a 3-connected candidate, every 3-cutset C contains at most one edge, and if it contains one edge, then C is the neighborhood of a vertex.*

Proof. If (c5) fails, then the neighborhood of a or b is incorrect.

To prove (c6), assume C is a clique cutset in a candidate G . By (c3) and (c4), C has at least three vertices. By (c2), G has no clique of size four, so $|C| = 3$. Let a be a vertex of C , and let B_1 and B_2 be components of $G - C$. Vertex a must have a neighbor in B_1 and a neighbor in B_2 , or else $C - \{a\}$ would be a 2-cutset violating (c4). But then the neighborhood of a is incorrect, a contradiction.

To prove (c7), consider a 3-cutset $C = \{a, b, c\}$ in a 3-connected candidate G . Let B_1 and B_2 be two components of $G - C$. By (c6) we can assume that a, c are not adjacent. Suppose ab is an edge. Vertex a must have a neighbor x in B_1 , as well as a neighbor y in B_2 , or else $\{b, c\}$ would be a cutset. Since the neighborhood of a is correct, we may assume by symmetry that b sees x and misses y . Vertex b must have a neighbor z in B_2 , or else $\{a, c\}$ would be a cutset separating $B_1 \cup \{b\}$ from B_2 . Then b has no neighbor in $B_1 - \{x\}$, or else the neighborhood of b would be incorrect. The same holds for a . Now if $B_1 - \{x\}$ is not empty, then $\{c, x\}$ is a cutset, a contradiction. So, $B_1 = \{x\}$, and then neighborhood correctness implies that x sees c and c misses b . This proves (c7). $\square$

An edge is called *flat* if it does not lie in a triangle. It is easy to see that an edge ab is flat in a graph G containing no odd hole if and only if the pair $\{a, b\}$ is an odd pair in the graph $G - ab$.

DEFINITION 2 (glueing). Let $M_1 = (V_1, E_1), \dots, M_k = (V_k, E_k)$ be some graphs. Assume that there exist two vertices a, b such that $V_i \cap V_j = \{a, b\}$ for all i, j with $1 \leq i < j \leq k$, where ab is an edge of each M_i . We will say that the graphs are *glueable (along ab)*. Given such graphs as above, we can build a graph with vertex-set $V_1 \cup \dots \cup V_k$ and edge-set $E_1 \cup \dots \cup E_k - \{ab\}$. This construction will be called *glueing the graphs $M_1, \dots, M_k$ along edge ab* .

DEFINITION 3 (unglueing). Let G be a graph with a 2-cutset $\{a, b\}$, where a and b are nonadjacent, and let $B_1, \dots, B_k$ be the components of $G - \{a, b\}$. For each i , we can build a graph with vertex-set $B_i \cup \{a, b\}$ and with all the edges of $G[B_i \cup \{a, b\}]$ plus the edge ab . This will be called *unglueing the graph G along ab* .

It is easy to see that the operations of glueing and unglueing preserve planarity, and that unglueing preserves the absence of odd holes. Conversely, if $M_1, \dots, M_k$ contain no odd hole and ab is a flat edge in each of them, then glueing them along ab produces a graph with no odd hole. Hence they are perfection-preserving for planar graphs. (The fact that they are perfection-preserving for general graphs is also true and is an easy consequence of a lemma of Tucker [14].)

LEMMA 19 (the glueing lemma for candidates).

1. Let M_1 and M_2 be two graphs that are glueable along an edge ab which is a flat edge in each of them. If M_1 and M_2 are candidates, then the graph obtained from glueing them along ab is a candidate.
2. Conversely, let M be a candidate which admits a 2-cutset $\{a, b\}$. Let M_1, M_2 be the two graphs obtained by unglueing M along this cutset. Then each of M_1, M_2 is a candidate.

Proof. To prove the first part, let H_1, H_2 be vertex-disjoint bipartite graphs such that $M_1 = L(H_1)$ and $M_2 = L(H_2)$. Since ab is an edge of M_i ($i = 1, 2$), the edges a and b in H_i are adjacent. We call z_i their common endpoint and a_i, b_i , respectively, the other endpoint of a and b . Vertex z_i has degree two in H_i because ab is a flat edge of M_i . Let H be the bipartite graph obtained from the union of H_1 and H_2 by removing z_1 and z_2 and adding edges a_1a_2 and b_1b_2 . It is a routine matter to check that $M = L(H)$ and that every neighborhood is correct in M . Also, M has no clique cutset Q , for otherwise Q would obviously be a clique cutset of either M_1 or M_2 . Thus (c1), (c2), (c3) hold for M . To check (c4), suppose on the contrary that

$\{x_1, x_2\}$ is an even 2-cutset of G . If x_1, x_2 both lie in some M_i , then $\{x_1, x_2\}$ would be an even 2-cutset of M_i , which is impossible. So we may assume $x_1 \in M_1 - \{a, b\}$ and $x_2 \in M_2 - \{a, b\}$. Let P_i (resp., Q_i) be any chordless x_i, a -path (resp., x_i, b -path) in $M_i - b$ (resp., in $M_i - a$). Note that P_1 and P_2 have the same parity since $P_1 + P_2$ is a chordless x_1, x_2 -path. Likewise Q_1 and Q_2 have the same parity. If P_1 is even and Q_1 is odd, then every chordless x_1, a -path in M_1 is even, which is impossible. It follows that P_1 and Q_1 have the same parity. There must be a chord from P_1 and Q_1 , for otherwise $P_1 + Q_1$ would be an even chordless a, b -path, which is impossible. This chord implies that $(P_1 + P_2 + Q_1 + Q_2) - \{x_1, x_2\}$ is a connected subgraph of $G - \{x_1, x_2\}$ that contains a and b . Thus a, b lie in the same component of $G - \{x_1, x_2\}$, which in turn implies that x_1, x_2 lie in the same component of $G - \{a, b\}$, a possibility that was excluded earlier.

To prove the second part, let M be a candidate which admits a 2-cutset $\{a, b\}$. Suppose that a has degree three and call a' the vertex such that aa' is a flat edge; then both $\{a, b\}$ and $\{a', b\}$ are 2-cutsets of M , so one of them is not an odd pair, contradicting (c3). Thus a and, similarly, b have degree four. It follows that in M_1 as well as in M_2 both a and b have a correct neighborhood (of degree three); note that any other vertex of M_1 and M_2 has the same neighborhood as in M ; so M_1 and M_2 have property (c2). Since the ungluing operation is perfection-preserving, M_1 and M_2 contain no odd hole. It follows that they are line-graphs of bipartite graphs by Theorem 3; i.e., (c1) holds for both of them. Suppose now that M_1 has a cut vertex x . Thus, x is one of a, b (say $x = a$), for otherwise x would be a cut vertex of M , a contradiction. There is a component C of $M_1 - a$ such that $b \notin C$ and there is no path in $M_1 - a$ joining b to any vertex of C . Hence a is also a cut vertex in M (separating b from C), a contradiction to M being a candidate. The same argument works for M_2 . So (c3) holds for M_1 and M_2 . Finally, suppose that $\{x, y\}$ is any 2-cutset of M_1 . Thus $\{x, y\}$ is also a 2-cutset of M , and by (c4) all chordless x, y -paths in M have odd length. Consider a chordless x, y -path P in M_1 . If P does not use the edge ab , then P is a path in M and it is odd by the argument in the preceding sentence. So assume P uses the edge ab . Suppose that x, y do not lie in the same component of $M - \{a, b\}$. This implies that any two vertices from $\{a, b, x, y\}$ form a 2-cutset of M . It is easy to see that at least one of these six cutsets would violate (c4) in M . So x, y must lie in the same component of $M - \{a, b\}$. Let Q be a chordless a, b -path of M whose interior vertices are in the component of $M - \{a, b\}$ that does not contain x and y ; then the path $P - ab + Q$ must be odd, and since Q is odd, this implies that P is odd. So M_1 and M_2 satisfy (c4), and the lemma is proved. $\square$

THEOREM 5. *Every candidate is even pair-free.*

Proof. This theorem is proved by induction on the number of vertices of the candidate. We distinguish between the candidates that are 3-connected and those that are not. For 3-connected planar candidates, the desired result is a consequence of a result of Hsu [8, Theorem 9.2] which we formulate as follows.

LEMMA 20 (Hsu [8]). *Let G be a 3-inseparable planar perfect graph such that the neighborhood of each vertex is correct. Then between any two nonadjacent vertices there are chordless paths of both parities.*

In this lemma, “3-inseparable” is a weaker condition than 3-connected, and it is easy to check that every 3-connected candidate is 3-inseparable. So Lemma 20 gives immediately the even pair-freeness of every 3-connected candidate. Now we look at candidates that are not 3-connected. A property of candidates will be useful.

LEMMA 21. *Let x, y be two nonadjacent vertices in a graph G that satisfies (c2). Let $v_0v_1 \cdots v_kv_{k+1}$ and $w_0w_1 \cdots w_lw_{l+1}$ be internally disjoint chordless paths from*

$x = v_0 = w_0$ to $y = v_{k+1} = w_{l+1}$. Then the only possible chords between these two paths are v_1w_1 and v_kw_l .

Proof. Let v_iw_j be any chord with $1 \leq i \leq k$, $1 \leq j \leq l$. Neighborhood correctness for v_i implies that there is exactly one edge induced by $\{v_{i-1}, v_{i+1}, w_j\}$; since there is no edge $v_{i-1}v_{i+1}$, by symmetry we can assume that w_j sees v_{i-1} and misses v_{i+1} . Now if $j \geq 2$, then neighborhood correctness is violated because w_j has four neighbors and there is no edge $w_{j-1}w_{j+1}$. If $j \leq 1$, the same holds unless $w_{j-1} = v_{i-1}$, i.e., $i = 1$, and so the chord is v_1w_1 . $\square$

LEMMA 22. *Any candidate G that admits a 2-cutset is even pair-free.*

Proof. Let $\{a, b\}$ be a 2-cutset of G . Recall from (c4) that $\{a, b\}$ is an odd pair and from (c5) that $G - \{a, b\}$ has exactly two components B_1, B_2 . Let G_1, G_2 be the two graphs obtained by ungluing G along ab . By the second part of the glueing lemma, G_1 and G_2 are candidates. By the induction hypothesis, G_1 and G_2 are even pair-free.

Consider any pair of nonadjacent vertices x, y in G . If x, y are both in one of G_1, G_2 , say in G_1 , then by the induction hypothesis there exists an odd chordless x, y -path P in G_1 . If P does not use the edge ab , then P is the desired odd chordless x, y -path in G . If P uses the edge ab , then replace in P the edge ab by any chordless a, b -path lying in $B_2 \cup \{a, b\}$. Since a, b is an odd pair the parity is not changed by this replacement and we get an odd chordless x, y -path in G .

Now, assume that x is in B_1 and y is in B_2 . Since G is 2-connected there exist two internally vertex-disjoint paths Q_1 and Q_2 from y to a and b , respectively. Clearly, Q_1 and Q_2 are entirely in $B_2 \cup \{a, b\}$. Call y_1 and y_2 the neighbors of y along Q_1 and Q_2 , respectively. Let R be any (odd) chordless a, b -path entirely in $B_1 \cup \{a, b\}$. By Lemma 21, there is no chord between the chordless y, a -paths Q_1 and $Q_2 + R$ except maybe for the chord y_1y_2 . We claim that we can assume that y_1y_2 is not an edge. Indeed, suppose that y_1 and y_2 are adjacent. By (c4), the set $\{y_1, y_2\}$ is not a cutset of G , so there exists a shortest path Q from y to $Q_1 \cup Q_2 - \{y, y_1, y_2\}$. By symmetry we can assume that the other endpoint of Q is on $Q_1 - \{y, y_1\}$. Then $Q \cup Q_1 - \{y_1\}$ connects y to a and is disjoint from Q_2 , so there exists a shortest path Q' in $Q \cup Q_1$ which connects y to a and is disjoint from Q_2 . The neighbor of y on Q' is not adjacent to y_2 , or else the neighborhood of y would be incorrect. Then we replace the pair of paths Q_1, Q_2 by the pair Q', Q_2 . So the claim holds.

Now, since y_1, y_2 are not adjacent, $Q_1 + Q_2 + R$ is a hole. Since R is odd, we may assume by symmetry that Q_1 is odd and Q_2 is even. By the induction hypothesis, G_1 contains an odd path P from x to b . If P does not use vertex a , then $P + Q_2$ is the desired odd chordless path from x to y . If P uses a , then $P - b$ is an even chordless x, a -path, and so $P - b + Q_1$ is the desired odd path. $\square$

Now the proof of Theorem 5 is complete. $\square$

THEOREM 6. *Every planar obstruction is an odd hole or a candidate.*

Proof. Let G be a planar obstruction different from an odd hole. We prove Theorem 6 by induction on the number of vertices of G . If G is 3-connected, the result holds by Theorem 4. Now assume G is not 3-connected. By Lemma 2, G is 2-connected. Let $\{a, b\}$ be a 2-cutset of G . By Lemma 3 and since G has no even pair, every chordless a, b -path in G is odd. Let $B_1, \dots, B_k$ be the connected components of $G - \{a, b\}$, and put $G_i = G[B_i \cup \{a, b\}] + ab$. Note that G_i is not a clique (because a, b have no common neighbor in G). Let Q_i be any chordless a, b -path in $B_i \cup \{a, b\}$.

We first claim that each G_i has no even pair. Indeed, let x, y be any two nonadjacent vertices in G_i . In G there exists an odd chordless x, y -path P from x to y . If P does not use both a, b , then P lies entirely in G_i and we are done. If P uses both

a, b , then $P[a, b]$ is odd; so $P[x, a] + ab + P[b, y]$ is an odd chordless x, y -path in G_i and we are done again.

Since each G_i is even pair-free, it contains an obstruction G'_i . For each i , both a, b lie in G'_i , or else G'_i would be a proper induced subgraph of G , which is impossible. Moreover, G'_i is not an odd hole, for otherwise replacing the edge ab in this hole by Q_j with $j \neq i$ would produce an odd hole in G , which is impossible. The induction hypothesis (and the fact that each G'_i has strictly fewer vertices than G) implies that each G'_i is a candidate. Note that the edge ab is flat in each G'_i , because a, b have no common neighbor in G . Let G' be the graph obtained by glueing G'_1 and G'_2 along the edge ab . The glueing lemma for candidates implies that G' is a candidate. Theorem 5 implies that G' has no even pair, and so it contains an obstruction G'' . Since G itself is an obstruction, we must actually have $G'' = G' = G$. In particular, G is a candidate. $\square$

Proof of Theorem 2. Let G be a planar obstruction different from an odd hole. Theorem 6 implies that G is a candidate. Thus every neighborhood is correct, and Theorem 2 is established.

LEMMA 23 (the glueing lemma for obstructions).

1. Let M_1 and M_2 be two obstructions that are glueable along an edge ab such that ab is a flat edge in each M_i . Then the graph M obtained by glueing them along ab is an obstruction.

2. Conversely, let M be an obstruction which admits a 2-cutset. Let M_1, M_2 be the two graphs obtained by unglueing M along this cutset. Then each of M_1, M_2 is an obstruction.

Proof. To prove the first part of the lemma, suppose that M is not an obstruction. We know by the glueing lemma for candidates that M is a candidate. So M contains strictly an obstruction M' . Note that M' cannot be entirely in $M_1 - ab$ or in $M_2 - ab$, for otherwise M' would be entirely in either $M_1 - \{a, b\}$ or $M_2 - \{a, b\}$, contradicting the fact that M_1 and M_2 are obstructions, or a or b would be an incorrect vertex in M' . Now $\{a, b\} \cap M'$ is a cutset of M' , and hence $\{a, b\} \subset M'$. Let M'_1 and M'_2 be the graphs obtained by unglueing M' along $\{a, b\}$. We know that M'_1 and M'_2 are candidates. Since M' is a proper subgraph of M , and by symmetry, we may assume that M'_1 is a proper subgraph of M_1 . But this is a contradiction to the fact that M_1 is an obstruction.

For the second part of the lemma, suppose that M_1 is not an obstruction. We know that M_1 is a candidate. So M_1 contains strictly an obstruction M'_1 . If M'_1 does not contain the edge ab , then M'_1 is a subgraph of M , contradicting the fact that M is an obstruction. If M'_1 contains the edge ab , then we can glue M'_1 with M_2 . We obtain a candidate which is a proper subgraph of M , again a contradiction. $\square$

Now we have proved that every planar obstruction is an odd hole or a candidate and that every candidate contains an obstruction, and thus *a planar perfect graph is an SQP graph if and only if it contains no candidate*. However, it is not true that every candidate is an obstruction: a counterexample is the line-graph of $K_{3,3}$. In the next section we study the difference between obstructions and mere candidates.

4. Distinguishing obstructions from candidates. Here we show how to find a subset of vertices of a candidate whose removal yields an obstruction.

DEFINITION 4 (danger). *In a candidate G , we denote by danger any proper subset of vertices D such that each component of $G - D$ is a candidate.*

For example, in the line-graph of $K_{3,3} - e$, two adjacent vertices of degree three form a danger.

The definition entails the following lemma, which is immediate.

LEMMA 24. *A candidate is an obstruction if and only if it contains no danger.*

The question now is how to find a danger in a graph. Given a vertex x , we can define iteratively a subset $D(x)$ as follows. First, remove x from G and let $H = G - x$. Then apply the following procedure:

Step 1. If H has an incorrect vertex y , then remove y and iterate with each component of $H - y$.

Step 2. If H has a cut vertex y , then remove y and iterate with each component of $H - y$.

Step 3. If H has a 2-cutset C that violates (c4) in H , then remove C and iterate with each component of $H - C$.

Step 2 (resp., Step 3) is applied only when there is no possibility of applying Step 1 (resp., Step 2). This procedure is applied as long as possible. We let $D(x)$ denote the set of all removed vertices at the end of the procedure. Clearly, this definition entails immediately that if $D(x)$ does not contain all vertices of G , then $D(x)$ is a danger. Furthermore, we have the next lemma.

LEMMA 25. *Let G be a candidate containing a danger D , and let x be any vertex of D . Then $D(x) \subseteq D$ and $D(x)$ is a danger.*

Proof. We prove that $D(x) \subseteq D$. This will imply that $D(x)$ does not consist of all vertices of G , and so $D(x)$ will be a danger. Consider any subset R of D . We claim that

If $G - R$ has an incorrect vertex y , then y is in D .

For otherwise, y would be an incorrect vertex in $G - D$, contradicting the fact that each component of $G - D$ is a candidate.

If a component H of $G - R$ has only correct vertices and has a cut vertex y , then y must be in D .

For otherwise, let B_1 and B_2 be the components of $H - y$, and let H' be the component of $G - D$ containing y . Clearly H' is a subgraph of H . By neighborhood correctness and by symmetry, we may assume that y has two neighbors in B_1 and one or two neighbors in B_2 . At least one vertex from $N(y) \cap B_1$ and one vertex from $N(y) \cap B_2$ must be in H' , or else y would have an incorrect neighborhood in H' . But then y is a cut vertex in H' , a contradiction.

If a component H of $G - R$ has only correct vertices, has no cut vertex, and has a cutset C violating (c4) in H , then $C \subseteq D$.

For otherwise, call B_1 and B_2 the components of $H - C$, assume that some vertex y in C is in $G - D$, and call H' the component of $G - D$ containing y . As above, at least one vertex from $N(y) \cap B_1$ and one vertex from $N(y) \cap B_2$ must be in H' , or else either y would be incorrect or $C - \{y\}$ would be a 1-cutset in H . But then $C \cap H'$ is either a 1-cutset or a 2-cutset violating (c4) in H' , a contradiction.

Now the fact that $D(x) \subseteq D$ follows from the definition of $D(x)$ and from the three points above, applied iteratively, starting with $R = \{x\}$. $\square$

The following lemma is now obvious.

LEMMA 26. *A candidate G is an obstruction if and only if $D(x) = V(G)$ for every vertex x of G .*

FIG. 1. *The two types of diabolo.*

As a consequence, we can decide if a candidate contains a danger, and if it does, we can find a danger efficiently; we have only to build $D(x)$ for each vertex until we find one such that $D(x)$ does not contain all vertices. Notice that the construction of $D(x)$ is polynomial, as it involves only degree and connectivity tests.

Finally, this allows us to find an obstruction in any given candidate G . If G contains no danger D , then G is an obstruction; if not, then find such a danger D and continue with the components of $G - D$, which is a candidate.

4.1. Constructing all candidates. We are going to describe a method for constructing a family $\mathcal{F}$ of graphs starting from $\bar{C}_6$. We will show that $\mathcal{F}$ is exactly the class of all candidates.

Let G be the line-graph of a connected bipartite graph H , where the vertices are colored blue or red along the natural bipartition. Using the one-to-one correspondence between the vertices of H and the maximal cliques of G , we can consider the edges of G colored blue or red accordingly.

DEFINITION 5 (diabolo). *The left and right graphs depicted in Figure 1 will be called, respectively, vertex-diabolo and edge-diabolo. Edges ab and cd are the bases of the diabolo, and vertex e (and f) is (are) the center(s) of the diabolo.*

DEFINITION 6 (splitting elements). *Let G be a planar graph without an odd hole and where every neighborhood is correct (so G is the line-graph of a bipartite graph). We call a splitting element of G any flat edge and any vertex of degree four. Then a splitting operation is the following:*

1. *Choose two splitting elements on the same face.*
2. *If one of the chosen elements is a vertex f , with neighbors x_1, x_2, x_3, x_4 such that x_1x_2 and x_3x_4 are edges, then replace it by a chordless path $f_1f_2f_3$ such that f_2 has degree two, f_1 is linked to x_1 and x_2 , and f_3 is linked to x_3 and x_4 . Edges f_1f_2 and f_2f_3 are called new.*
3. *If one of the chosen elements is an edge, then either call it new, or subdivide it into a path of length three (in this case, only the middle edge is called new).*
4. *A diabolo is introduced whose two bases are two new edges, one from each splitting element. The type of diabolo (edge or vertex) will be chosen so as to respect the blue/red bipartition of maximal cliques.*

Figures 2–4 illustrate the splitting operations, which allow us to create new planar graphs from old.

We can also view the splitting operations on the bipartite graph H , of which G is the line-graph, rather than on G . For example, in the first row in Figure 2, the hypothesis means that in H there exists a vertex x_{ab} of degree two incident with the edges a and b , there exists a vertex x_{cd} of degree two incident with the edges c and d , and the vertices x_{ab}, x_{cd} are on the same side of the bipartition of H . (In the

FIG. 2. *Edge-edge operations.*FIG. 3. *Edge-vertex operations.*

second row of Figure 2, the vertices x_{ab}, x_{cd} are on different sides of the bipartition.) For the first transformation illustrated in the first row of Figure 2, in H split the vertex x_{ab} into two vertices x_a and x_b to be the new endpoints of the edges a and b , respectively; likewise split x_{cd} into x_c and x_d . Add new vertices y_{ab}, y_{cd}, x and edges $x_a y_{ab}, x_b y_{ab}, x_c y_{cd}, x_d y_{cd}, x y_{ab}, x y_{cd}$. It is easy to check that this transformation on H corresponds exactly to the transformation on G . A similar transformation on H can be defined for each splitting operation illustrated in Figures 2–4.

DEFINITION 7 (class $\mathcal{F}$). *We define the class $\mathcal{F}$ of graphs by the following inductive scheme:*

- $\bar{C}_6 \in \mathcal{F}$;
- if a graph G is in $\mathcal{F}$, then any graph obtained from G by splitting is in $\mathcal{F}$;
- if two graphs of $\mathcal{F}$ are glueable along a flat edge, then the graph resulting from the corresponding glueing is in $\mathcal{F}$.

See Figure 6.

FIG. 4. Vertex-vertex operations.

THEOREM 7. *All graphs in $\mathcal{F}$ are candidates.*

Proof. The proof is by induction on the number of vertices. The theorem is true for $\bar{C}_6$. Now let us consider a graph $G' \neq \bar{C}_6$ in $\mathcal{F}$ and assume that the theorem is true for every graph smaller than G' . We know that G' is obtained either by splitting a graph G from $\mathcal{F}$ or by glueing two graphs G_1, G_2 from $\mathcal{F}$ along a common flat edge. If G' results from glueing, the desired conclusion is immediate from the glueing lemma and the induction hypothesis. So we may assume that G' results from splitting G . By the induction hypothesis, G is a candidate. Let H be the bipartite graph such that $G = L(H)$, with the vertices of H and the edges of G colored blue or red according to the bipartition. It is easy to see that G' is also the line-graph of a bipartite graph H' , because the splitting operation preserves the bipartition of the maximum cliques, and to see that G' is 2-connected. Clearly, splitting also preserves the fact that each neighborhood is correct. Also, it is a routine matter to check that the splitting operation maintains all path parities of G in G' ; i.e., if there exists a path between two vertices x, y of G , then G' contains a path of the same parity between the corresponding vertices. So we have established properties (c1)–(c3) for G' . Finally, suppose that G' has a cutset C which violates property (c4). Then C is necessarily a cutset of G , which contradicts the fact that G is a candidate. $\square$

It remains to prove that the operations generate all planar candidates. Thus we must prove that for each candidate we can, by performing inverse operations, obtain a bunch of $\bar{C}_6$'s.

We will say that G' arises from G by a *reduction* if G arises from G' via a splitting.

Recall that each neighborhood in a candidate must be correct. This implies that every vertex x and every flat edge e of a candidate corresponds to a possible reduction. Unfortunately, this reduction may fail to yield a proper smaller candidate, as we may create a graph that violates (c2) or (c4). We are going to show that these problems can be avoided by an appropriate choice of x or e . That is, we will show that if G is a 3-connected candidate, we can choose a reduction that yields a 3-connected candidate. If G is not 3-connected, then G arises from smaller candidates by glueing.

FIG. 5. A diabolo $\{b, c, d, W\}$ whose reduction generates a diamond

Putting these results together will give the desired result that every planar candidate is in $\mathcal{F}$.

Call *trivial cutset* a cutset C such that one component of $G - C$ is a vertex or an edge or a triangle. Let C be a trivial 3-cutset. Any diabolo associated with a vertex of C defines a reduction which does not change the connectivity of G .

Observe that only the vertex-edge and vertex-vertex reverse operations can produce an incorrect neighborhood for a candidate, by creating a diamond, and that they do so only if the vertices to be identified belong to a face of length four. We can see this situation in Figure 5.

LEMMA 27. *Let G be a 3-connected candidate. Let W be a diabolo whose reduction would generate a diamond. Then, there is another diabolo whose reduction will generate a 3-connected candidate.*

Proof. Let us label the vertices as in Figure 5. We must examine two cases. First, suppose that the face containing c, d, f, g is not of length four. Since the identification of d and g cannot produce a diamond, consider the diabolo W' having vertex e as the center. We claim that the reduction corresponding to W' generates a 3-connected candidate. The nontriangular face containing a and c cannot be of length four with a of degree three, since g and a neighbor of c in the other nontriangular face will form a 2-cutset which is an even pair. Also, if e is in a 3-cutset, this cutset is trivial (by a tedious but easy analysis) and so the graph obtained by the reduction remains 3-connected and is a candidate. Now, if the face containing c, d, f, g has length four, then cg must be an edge. Note that cg cannot be a flat edge, for otherwise $\{c, a\}$ would be a 2-cutset. So the reduction corresponding to the diabolo centered on df generates a 3-connected and diamond-free graph (it is easy to see that, in this case, all 3-cutsets containing f are trivial). $\square$

LEMMA 28. *If a vertex x of a 3-connected candidate G belongs to a nontrivial cutset, then one of the two nontriangular faces containing x has a vertex y such that any 3-cutset containing y is trivial.*

Proof. Let F_1 and F_2 be the nontriangular faces containing x . Let y' and z be the vertices of F_1 and F_2 , respectively, such that $G - \{x, y', z\}$ has the smallest component between all nontrivial 3-cutsets. Let y be a vertex of F_1 in $G - \{x, y', z\}$ such that y is a neighbor of y' and such that the edge $y'y$ belongs to a triangle. The vertex y is contained in a diabolo W which contains the intersection of F_1 and another nontriangular face F'_2 . We claim that every 3-cutset containing y is trivial. Otherwise, there exists a 3-cutset $\{y, y'', x'\}$ with y'' in F_1 and x' in F'_2 such that there is no component included in W . Therefore, either y' is not in the external face or $\{y'', y'\}$ or $\{x', x''\}$ is a 2-cutset, where x'' is the other vertex of W' that is on the external face, which in both cases is a contradiction. $\square$

FIG. 6. A graph G in $\mathcal{F}$. The gray vertices form a danger.

LEMMA 29. *In every 3-connected candidate, there exists a diablo whose reduction generates a candidate.*

Proof. Consider a candidate G . Choose some vertex x of G . If the reduction on the diablo defined by this vertex produces a 2-connected graph G' in which every neighborhood is correct, and in which all 2-cutsets form odd pairs, then clearly G' is a candidate and the lemma holds. Otherwise, by Lemma 28, there is a diablo in G centered in a vertex y such that the corresponding reduction produces a 3-connected graph. By Lemma 27, this diablo may be replaced by one whose corresponding reduction produces a graph with a correct neighborhood. This lemma also guarantees that this reduction will keep the 3-connectivity. So, the lemma follows. $\square$

THEOREM 8. *All candidates belong to $\mathcal{F}$.*

Proof. This proof is by induction on the number of vertices. The theorem is trivially true for the smallest candidate $\bar{C}_6$. Suppose it is true for candidates with less than n vertices and consider a candidate G with n vertices. If G has a 2-cutset, let G_1 and G_2 be the graphs obtained by ungluing G along this 2-cutset. Clearly, G_1 and G_2 are smaller than G and are candidates. So G is contained in $\mathcal{F}$. If G is 3-connected, by Lemma 29, there is an inverse operation that generates a candidate G' smaller than G . By the induction hypothesis, G' can be reduced to a set of $\bar{C}_6$'s. So, G can be obtained from G' by an operation of Definition 7 and then belongs to $\mathcal{F}$. $\square$

LEMMA 30. *A graph G in $\mathcal{F}$ is an obstruction if and only if G has no dangers.*

This is a mere reformulation of Lemma 24.

Let $\mathcal{F}^*$ be the subclass of $\mathcal{F}$ made of the graphs containing no danger. The following is a corollary of all the results in this section.

THEOREM 9. *The class $\mathcal{F}^*$ consists exactly of all obstructions.*

Proof. It is clear that every graph from $\mathcal{F}^*$ is an obstruction. By Theorem 8, we can reduce any candidate to a collection of $\bar{C}_6$'s, and so from this collection we can obtain the original graph by performing in reverse order the same operations. So every obstruction is in $\mathcal{F}^*$. $\square$

5. Conclusion and comments. We proved that Hougardy's conjecture is true for planar graphs. A related problem is to find a polynomial-time algorithm that decides if a graph is a planar SQP graph. We solved this problem in [9] using a decomposition technique due to Hsu [6], which is very different from the results presented here. Another related problem is to find an even pair (or decide that there is none) in a planar perfect graph. This problem was solved by Hsu and Porto [7] and by Linhares Sales and Sampaio [10]. Let us also recall that coloring can be done in polynomial time for all planar perfect graphs with an algorithm due to Hsu [6].

Acknowledgments. We are grateful to Claude Benzaken and Myriam Preissmann for their suggestions, and to the anonymous referees for useful comments.

AN EXPLICIT BOUND ON DOUBLE EXPONENTIAL SUMS RELATED TO DIFFIE–HELLMAN DISTRIBUTIONS*

MEI-CHU CHANG[†] AND CHUI ZHI YAO[†]

Abstract. Let p be a prime and V an integer of order t in the multiplicative group modulo p . In this paper, we give an explicit bound on the double exponential sums. For $\varepsilon > 0$, we have $\tilde{S}_{a,b,c}(t) =$

$$\sum_{x,y=1}^t e_p(aV^x + bV^y + cV^{xy}) \ll t^{2-r(\varepsilon)}, \text{ where } r(\varepsilon) = \begin{cases} \frac{1}{4440} & \text{if } p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}, \\ \frac{1}{20}\varepsilon^3(\log \frac{1}{\varepsilon})^{-6} & \text{if } p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}. \end{cases}$$

Key words. Diffie–Hellman triples, Diffie–Hellman distributions, exponential sums

1. Introduction. The Diffie–Hellman key exchange algorithm [6] is the first practical public key cryptosystem published and it remains one of the cornerstones of modern cryptography to date. The algorithm is a simple but ingenious way for two parties to establish a common secret key over an insecure channel. The security of this algorithm is based on the assumption that certain desirable properties are possessed by the Diffie–Hellman triples (V^x, V^y, V^{xy}) , where V is an integer of multiplicative order t modulo $p \geq 3$ that is $V^x \not\equiv 1 \pmod{p}$, $x = 1, \dots, t-1$, $V^t \equiv 1 \pmod{p}$. It has been shown in [5] and then improved in [4] that such triples are uniformly distributed in the sense of Weyl when $x, y = 0, \dots, t$ (see [17] for details on this notion of uniformity). Although such results do not guarantee the security of the Diffie–Hellman key, they are nevertheless very desirable since it provides evidence that the Diffie–Hellman cryptosystem can withstand statistic-based attacks. On the other hand, studying the distribution of these triples via finding bounds on double exponential sums is a very natural and attractive number theoretic question. Various other applications and generalizations of the exponential sums bounds and related results of [5] and [4] can be found in [1], [7], [8], [2], [10], [9], [11], and [16].

In this paper we continue the study of double exponential sums related to the Diffie–Hellman triples (V^x, V^y, V^{xy}) as initiated in [5]. For integers a, b, c , we define the following exponential sums:

$$\tilde{S}_{a,b,c}(t) = \sum_{x,y=1}^t e_p(aV^x + bV^y + cV^{xy}),$$

where

$$e_p(\theta) = \exp\left(\frac{2\pi i\theta}{p}\right).$$

[†]Department of Mathematics, University of California, Riverside, Riverside, CA 92521 (mcc@math.ucr.edu, zhi@math.ucr.edu).

We obtain an explicit bound on sums $\tilde{S}_{a,b,c}(t)$ by studying slightly different sums

$$S_{a,c}(t) = \sum_{y=1}^t \left| \sum_{x=1}^t e_p(aV^x + cV^{xy}) \right|$$

for which obviously $|\tilde{S}_{a,b,c}(t)| \leq S_{a,c}(t)$. An estimate of the sums $S_{a,c}(t)$ obtained in [5] was improved and generalized by [4]. It had been shown in [4] that $S_{a,c}(t) \ll t^{5/3}p^{1/4}$ for $t > p^{3/4+\varepsilon}$ and the authors posted an open question to find an estimate of the sum for t in a lower range. In response to their open question, Bourgain [3] obtained a bound of the sum that was nontrivial for $t \geq p^\varepsilon$. Although his bound $S_{a,c}(t) \ll t^{2-\delta}$ was not explicit in the sense that there was no clear relationship between ε and δ , his estimates remained nontrivial over remarkably short intervals. At about the same time, Garaev [12] was not only able to improve the bound obtained in [4], but more importantly he was able to extend the range. His bound $S_{a,c}(t) \ll t^{7/4}p^{1/8+\varepsilon}$ was nontrivial beginning with $t > p^{1/2+\varepsilon}$. Later on, Garaev and Karatsuba [13] obtained the bound $S_{a,c}(t) \ll tp^{7/8+o(1)}$ by introducing a new ingredient to the argument of [12]. Their bound includes the one in [12] and improves it for any thin set β where $|\beta| < p^{1-d}$ for some $d > 0$. In this paper, we are able to give an explicit bound on the range beginning with $t > p^{1/4+\varepsilon}$. Although our bound is not as sharp as the Garaev–Karatsuba estimate contained in [13], nor our applicable range as wide as Bourgain’s in [3], we are able to give an explicit bound that will work in the range that was not covered by any explicit bound so far.

2. Lemmas. Our bound on the exponential sum $S_{a,c}(t)$ relies on the following lemmas. Each lemma is used to prove the subsequent lemmas or to prove our main result. Our first lemma is a simple identity which is a basic tool for using exponential sums in the study of different problems module m , but we state the lemma here only for case p as a prime.

LEMMA 1. *For any integer u ,*

$$\sum_{\lambda=0}^{p-1} e_p(\lambda u) = \begin{cases} p & \text{if } u \equiv 0 \pmod{p}, \\ 0 & \text{if } u \not\equiv 0 \pmod{p}. \end{cases}$$

The next lemma is a generalization of Lemma 1 to elements in finite fields $\mathbb{F}_p^d$. For $d \geq 2$ and $\mathbb{F}_p^d = \mathbb{F}_p \times \cdots \times \mathbb{F}_p$, we identify $\mathbb{F}_p$ with $\{0, 1, \dots, p-1\}$. Furthermore, for $y = (y_1, \dots, y_d)$ and $x = (x_1, \dots, x_d) \in \mathbb{F}_p^d$, we denote

$$x \cdot y = \sum_{i=1}^d x_i y_i.$$

LEMMA 2. *With the above notation and for an arbitrarily fixed element $\hat{y}$ of $\mathbb{F}_p^d$, we have*

$$\sum_{x \in \mathbb{F}_p^d} e_p(x \cdot \hat{y}) = \begin{cases} p^d & \text{if } y_i \equiv 0 \pmod{p} \ \forall i, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Note that if $y_i \equiv 0 \pmod{p}$ for each i , then $x \cdot \hat{y} \equiv 0 \pmod{p}$ and

$$\sum_{x \in \mathbb{F}_p^d} e_p(x \cdot \hat{y}) = \sum_{x \in \mathbb{F}_p^d} 1 = p^d.$$

Otherwise, there exists an i such that $y_i \neq 0$.

Without loss of generality, we may assume $y_1 \neq 0$; then

$$\begin{aligned} \sum_{x \in \mathbb{F}_p^d} e_p(x \cdot \hat{y}) &= \sum_{x \in \mathbb{F}_p^d} e_p \left(\sum_{i=1}^d x_i y_i \right) \\ &= \sum_{x \in \mathbb{F}_p^d} e_p(x_1 y_1) \cdots e_p(x_d y_d) \\ &= \sum_{x_d=0}^{p-1} e_p(x_d y_d) \cdots \sum_{x_1=0}^{p-1} e_p(x_1 y_1). \end{aligned}$$

Applying Lemma 1 to the quantity $\sum_{x_1=0}^{p-1} e_p(x_1 y_1)$ gives us the desired result. $\square$

We let $h : \mathbb{F}_p^d \longrightarrow \mathbb{C}$, and denote

$$(1) \quad \|h\|_2 = \left(\sum_{x \in \mathbb{F}_p^d} |h(x)|^2 \right)^{\frac{1}{2}}.$$

LEMMA 3. *With the above notation and if $f, g : \mathbb{F}_p^d \longrightarrow \mathbb{C}$, then*

$$\left| \sum_{x, y \in \mathbb{F}_p^d} f(x) g(y) e_p(x \cdot y) \right| \leq p^{\frac{d}{2}} \|f\|_2 \|g\|_2.$$

Proof. Note that $|\sum_{x, y \in \mathbb{F}_p^d} f(x) g(y) e_p(x \cdot y)| = |\sum_{x \in \mathbb{F}_p^d} f(x) \sum_{y \in \mathbb{F}_p^d} g(y) e_p(x \cdot y)|$.

To prove the lemma, we first apply the triangle inequality and then apply the Cauchy-Schwarz inequality

$$\begin{aligned} &\left| \sum_{x, y \in \mathbb{F}_p^d} f(x) g(y) e_p(x \cdot y) \right| \\ &\leq \sum_{x \in \mathbb{F}_p^d} |f(x)| \left| \sum_{y \in \mathbb{F}_p^d} g(y) e_p(x \cdot y) \right| \\ &\leq \left(\sum_{x \in \mathbb{F}_p^d} |f(x)|^2 \right)^{\frac{1}{2}} \left(\sum_{x \in \mathbb{F}_p^d} \left| \sum_{y \in \mathbb{F}_p^d} g(y) e_p(x \cdot y) \right|^2 \right)^{\frac{1}{2}} \\ &= \|f\|_2 \left(\sum_{y_1, y_2 \in \mathbb{F}_p^d} g(y_1) \overline{g(y_2)} \sum_{x \in \mathbb{F}_p^d} e_p(x \cdot (y_1 - y_2)) \right)^{\frac{1}{2}}. \end{aligned}$$

Finally, we apply Lemma 2 to the quantity $\sum_{x \in \mathbb{F}_p^d} e_p(x \cdot (y_1 - y_2))$ to obtain

$$\begin{aligned} \left| \sum_{x, y \in \mathbb{F}_p^d} f(x) g(y) e_p(x \cdot y) \right| &\leq \|f\|_2 \left(p^d \sum_{y \in \mathbb{F}_p^d} |g(y)|^2 \right)^{\frac{1}{2}} \\ &= p^{\frac{d}{2}} \|f\|_2 \|g\|_2, \end{aligned}$$

which is the desired result. $\square$

The next lemma is a generalization of Lemma 2 to the multiplicative subgroup of $(\mathbb{F}_p^*)^d$; but first we define the following notations.

We let $k \in \mathbb{N}$, $\tilde{H} < (\mathbb{F}_p^*)^d$ with $|\tilde{H}| = H$, and denote

$$(2) \quad u_{4k} = \left| \left\{ (x_1, \dots, x_{4k}) \in \tilde{H}^{4k} : \sum_{i=1}^k x_i - \sum_{i=k+1}^{2k} x_i = \sum_{i=2k+1}^{3k} x_i - \sum_{i=3k+1}^{4k} x_i \right\} \right|.$$

Moreover, we let $x = (x_1, \dots, x_d), y = (y_1, \dots, y_d), z = (z_1, \dots, z_d) \in \tilde{H}$, and denote

$$x \cdot y \cdot z = \sum_{i=1}^d x_i y_i z_i.$$

LEMMA 4. *With the above notation and if $x \in \tilde{H}$ and $b \in (F_p^*)^d$, then*

$$\left| \sum_{x \in \tilde{H}} e_p(b \cdot x) \right| \leq H^{1-\frac{1}{k}} p^{\frac{d}{8k^2}} (u_{4k})^{\frac{1}{4k^2}}.$$

Proof. Note that for any fixed element y of $\tilde{H}$,

$$\sum_{x \in \tilde{H}} e_p(b \cdot x) = \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y).$$

Define

$$S = \left| \sum_{x \in \tilde{H}} e_p(b \cdot x) \right|.$$

Then,

$$S = \frac{1}{H} \sum_{y \in \tilde{H}} \left| \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y) \right|.$$

To prove the lemma, we first apply the Hölder's inequality to the right-hand side

with $q = 2k$ to obtain

$$\begin{aligned}
 S &\leq \frac{1}{H} \cdot H^{1-\frac{1}{2k}} \left(\sum_{y \in \tilde{H}} \left| \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y) \right|^{2k} \right)^{\frac{1}{2k}} \\
 (3) \quad &= H^{-\frac{1}{2k}} \left(\sum_{y \in \tilde{H}} \left| \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y) \right|^{2k} \right)^{\frac{1}{2k}}.
 \end{aligned}$$

Next, we will bound the quantity $\sum_{y \in \tilde{H}} \left| \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y) \right|^{2k}$ by again applying Hölder's inequality with $q = 2k$.

Note,

$$\begin{aligned}
 &\sum_{y \in \tilde{H}} \left| \sum_{x \in \tilde{H}} e_p(b \cdot x \cdot y) \right|^{2k} \\
 &= \sum_{y \in \tilde{H}} \sum_{x_1, \dots, x_{2k} \in \tilde{H}} e_p(b \cdot y \cdot (x_1 + \dots + x_k - x_{k+1} - \dots - x_{2k})) \\
 &\leq \sum_{x_1, \dots, x_{2k} \in \tilde{H}} \left| \sum_{y \in \tilde{H}} e_p \left(b \cdot y \cdot \left(\sum_{i=1}^k x_i - \sum_{j=k+1}^{2k} x_j \right) \right) \right| \\
 &\leq \left((H^{2k})^{1-\frac{1}{2k}} \right) \left(\sum_{x_1, \dots, x_{2k} \in \tilde{H}} \left| \sum_{y \in \tilde{H}} e_p \left(b \cdot y \cdot \left(\sum_{i=1}^k x_i - \sum_{j=k+1}^{2k} x_j \right) \right) \right|^{2k} \right)^{\frac{1}{2k}} \\
 &= H^{2k-1} \left(\sum_{\substack{x_1, \dots, x_{2k} \in \tilde{H} \\ y_1, \dots, y_{2k}}} e_p \left(b \cdot \left(\sum_{i=1}^k y_i - \sum_{j=k+1}^{2k} y_j \right) \cdot \left(\sum_{i=1}^k x_i - \sum_{j=k+1}^{2k} x_j \right) \right) \right)^{\frac{1}{2k}}.
 \end{aligned}$$

Now, we combine the above bound with (3) to obtain

$$(4) \quad S \leq H^{1-\frac{1}{k}} \left(\sum_{\substack{x_1, \dots, x_{2k} \in \tilde{H} \\ y_1, \dots, y_{2k}}} e_p \left(b \cdot \left(\sum_{i=1}^k y_i - \sum_{j=k+1}^{2k} y_j \right) \cdot \left(\sum_{i=1}^k x_i - \sum_{j=k+1}^{2k} x_j \right) \right) \right)^{\frac{1}{4k^2}}.$$

Furthermore, we define

$$f(x) = \left| \left\{ (x_1, \dots, x_{2k}) \in \tilde{H}^{2k} : \sum_{i=1}^k x_i - \sum_{j=k+1}^{2k} x_j = x \right\} \right|$$

and

$$f(by) = \left| \left\{ (y_1, \dots, y_{2k}) \in \tilde{H}^{2k} : \sum_{i=1}^k b \cdot y_i - \sum_{j=k+1}^{2k} b \cdot y_j = b \cdot y \right\} \right|.$$

Also, by (1) and (2), we have

$$\|f\|_2^2 = \sum_{x \in \mathbb{F}_p^d} |f(x)|^2 = u_{4k}.$$

With the above notation we can express (4) as follows;

$$S \leq H^{1-\frac{1}{k}} \left(\sum_{x, y \in \mathbb{F}_p^d} f(x) f(b \cdot y) e_p(b \cdot x \cdot y) \right)^{\frac{1}{4k^2}}.$$

Finally, we apply Lemma 3 to the right-hand side of the above equality to obtain

$$\begin{aligned} S &\leq H^{1-\frac{1}{k}} \left(p^{\frac{d}{2}} \|f\|_2^2 \right)^{\frac{1}{4k^2}} \\ &= H^{1-\frac{1}{k}} p^{\frac{d}{8k^2}} \left(\|f\|_2^2 \right)^{\frac{1}{4k^2}} \\ &= H^{1-\frac{1}{k}} p^{\frac{d}{8k^2}} (u_{4k})^{\frac{1}{4k^2}} \end{aligned}$$

which is the desired result. $\square$

Let m be a natural number and G a multiplicative subgroup of $\mathbb{Z}_p^*$ with $\text{ord}(G) = t$; then we define $T_m(G)$ to be the number of solutions of

$$x_1 + \dots + x_k = y_1 + \dots + y_k,$$

where $x_1, \dots, x_m, y_1, \dots, y_m$ are element of G .

Next, with the above notation, we will state a lemma due to Konyagin (see Lemma 5 in [14]) and a lemma due to Konyagin and Shparlinski (see [15] or Lemma 3 in [14]).

LEMMA 5 (see Konyagin [14]). *For every natural number m , there exists a constant $C(m)$ such that if $t = |G| < p^{\frac{2}{3}}$ and $m = 2$, or if $t < p^{\frac{1}{2}}$ and $m > 2$, then*

$$T_m(G) \leq C(m) t^{2m-2+\frac{1}{2m-1}}.$$

LEMMA 6 (see Konyagin and Shparlinski [15]). *Let $a, \theta \in \mathbb{F}_p^*$ with $\text{ord}(\theta) = t$. If k and l are elements of natural numbers, then*

$$\max_{a \in \mathbb{F}_p^*} \left| \sum_{x=1}^t e_p(a\theta^x) \right| \leq p^{\frac{1}{2l^m}} T_l^{\frac{1}{2l^m}} T_m^{\frac{1}{2l^m}} t^{1-\frac{1}{l}-\frac{1}{m}}.$$

The above sum has numerous applications in additive problems modulo p , pseudo-random generators, coding theory, and other problems. We will use its bound to prove

our result. Note that for ε in the interval $(0, \frac{1}{4})$ and $p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}$, we can combine Lemma 5 and Lemma 6 by taking $l = m$ to obtain the bound

$$(5) \quad \max_{a \in \mathbb{F}_p^*} \left| \sum_{x=1}^t e_p(a\theta^x) \right| \leq tp^{-\varepsilon(\log \frac{1}{\varepsilon})^{-2}}.$$

Next, we will state another lemma due to Konyagin and Shparlinski (see [15]), which gives us the bound for the above sum for $t \geq p^{\frac{1}{3}}$.

LEMMA 7 (see Konyagin and Shparlinski [15]). *Let $a, \theta \in \mathbb{F}_p^*$ with $\text{ord}(\theta) = t$; then*

$$\max_{a \in \mathbb{F}_p^*} \left| \sum_{x=1}^t e_p(a\theta^x) \right| \ll \begin{cases} p^{\frac{1}{2}} & \text{if } t > p^{\frac{2}{3}}, \\ p^{\frac{1}{4}} t^{\frac{3}{8}} & \text{if } p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}, \\ p^{\frac{1}{8}} t^{\frac{5}{8}} & \text{if } p^{\frac{1}{3}} \leq t \leq p^{\frac{1}{2}}. \end{cases}$$

3. Main theorem.

THEOREM 1. *Let a, c be integers that are coprime to p . Let $\varepsilon > 0$ and $\theta \in \mathbb{F}_p^*$ with $\text{ord}(\theta) = t$.*

If $p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}$ or $p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}$, then there exists a positive constant $r(\varepsilon)$ such that

$$S_{a,c}(t) = \sum_{y=1}^t \left| \sum_{x=1}^t e_p(a\theta^x + c\theta^{xy}) \right| \ll t^{2-r(\varepsilon)},$$

where

$$r(\varepsilon) = \begin{cases} \frac{1}{4440} & \text{if } p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}, \\ \frac{1}{20}\varepsilon^3 \left(\log \frac{1}{\varepsilon}\right)^{-6} & \text{if } p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}. \end{cases}$$

Proof. Case 1. $p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}$.

Let $\hat{H} = \hat{H}_y = \{(\theta^x, \theta^{xy}) : x = 1, \dots, t\} < (\mathbb{F}_p^*)^2$.

As before, we denote $(a, c) \cdot (\theta^x, \theta^{xy}) = a\theta^x + c\theta^{xy}$.

To prove the first case, we apply Lemma 4 to the quantity $|\sum_{x=1}^t e_p(a\theta^x + c\theta^{xy})|$ with $d = 2$, $r = 2k$, $b = (a, c)$, and $x = (\theta^x, \theta^{xy})$.

We obtain

$$\left| \sum_{x=1}^t e_p(a\theta^x + c\theta^{xy}) \right| \leq t^{1-\frac{2}{r}} p^{\frac{1}{r^2}} (u_{2r}(y))^{\frac{1}{r^2}},$$

where

$$u_{2r}(y) = \left| \left\{ (x_1, \dots, x_{2r}) \in \{1, \dots, t\}^{2r} : \theta^{x_1} + \dots + \theta^{x_r} = \theta^{x_{r+1}} + \dots + \theta^{x_{2r}} \right. \right. \\ \left. \left. \text{and } \theta^{yx_1} + \dots + \theta^{yx_r} = \theta^{yx_{r+1}} + \dots + \theta^{yx_{2r}} \right\} \right|.$$

Furthermore, we note that for $r \in 2\mathbb{N}$, $p^{-1}t^{2r-\frac{r}{20-20r^2}} \geq 0$. We let

$$(6) \quad \lambda = \frac{r}{20-20r^2};$$

then

$$\begin{aligned}
 S_{a,c}(t) &= \sum_{y=1}^t \left| \sum_{x=1}^t e_p(a\theta^x + c\theta^{xy}) \right| \\
 &\leq \sum_{\substack{1 \leq y \leq t \\ u_{2r}(y) \leq t^{2r-\lambda} p^{-1}}} t^{1-\frac{2}{r}} p^{\frac{1}{r^2}} (u_{2r}(y))^{\frac{1}{r^2}} + \sum_{\substack{1 \leq y \leq t \\ u_{2r}(y) > t^{2r-\lambda} p^{-1}}} \left| \sum_{x=1}^t e_p(a\theta^x + c\theta^{xy}) \right| \\
 &\leq \sum_{y=1}^t t^{1-\frac{2}{r}} p^{\frac{1}{r^2}} (t^{2r-\lambda} p^{-1})^{\frac{1}{r^2}} + vt \\
 (7) \quad &= t^{2-\frac{\lambda}{r^2}} + vt,
 \end{aligned}$$

where

$$v = |\{y : u_{2r}(y) > t^{2r-\lambda} p^{-1}\}|.$$

Next, we define

$$T = \left| \left\{ \begin{array}{l} (x_1, \dots, x_{2r}, y) \in \{1, \dots, t\}^{2r+1} : \theta^{x_1} + \dots + \theta^{x_r} = \theta^{x_{r+1}} + \dots + \theta^{x_{2r}} (*) \\ \text{and } \theta^{yx_1} + \dots + \theta^{yx_r} = \theta^{yx_{r+1}} + \dots + \theta^{yx_{2r}} (**) \end{array} \right\} \right|.$$

Then since $T \geq vt^{2r-\lambda} p^{-1}$, we have $v \leq Tt^{\lambda-2r} p$.

Furthermore, we write

$$T = \sum_{\bar{x} \in \Omega} T_{\bar{x}},$$

where

$$\Omega = \left\{ \bar{x} = (x_1, \dots, x_{2r}) \in \{1, \dots, t\}^{2r} : \bar{x} \text{ satisfy } (*) \right\},$$

$$T_{\bar{x}} = |\{y = 1, \dots, t\} : y \text{ satisfy } (**)|.$$

Next, note that for each ε in $(0, \frac{1}{4})$, we can find an even positive integer $r \geq \frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon}$ such that if $p^{\frac{1}{4}+\varepsilon} \leq t$ and $r \geq \frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon}$, then

$$(8) \quad \frac{t^{2r}}{p^{2r\varepsilon(\log \frac{1}{\varepsilon})^{-2}}} \leq \frac{t^{2r}}{p}.$$

Now we will bound $|\Omega|$ by applying the bound (5) and (8).

Let $r \geq \frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon}$ and recall that $p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}$ is part of our assumption.

Note that,

$$\begin{aligned}
|\Omega| &= \frac{1}{p} \sum_{j=0}^{p-1} \left| \sum_{x=1}^t e_p(j\theta^x) \right|^{2r} \\
&\leq \frac{t^{2r}}{p} + \max_{j \in \mathbb{F}_p^*} \left| \sum_{x=1}^t e_p(j\theta^x) \right|^{2r} \\
&< \frac{t^{2r}}{p} + \left(tp^{-\varepsilon \left(\log \frac{1}{\varepsilon}\right)^{-2}} \right)^{2r} \\
&= \frac{t^{2r}}{p} + \frac{t^{2r}}{p^{2r\varepsilon \left(\log \frac{1}{\varepsilon}\right)^{-2}}} \\
&\ll \frac{t^{2r}}{p}.
\end{aligned}$$

Next, we will bound $T_{\bar{x}}$ by following the same argument as in [4]. Let $\theta = g^m$, where $m = \frac{p-1}{t}$ and g is a primitive root of $\mathbb{F}_p^*$. To bound $T_{\bar{x}}$, we need to bound the solutions in $y = 1, \dots, t$ of

$$g^{yk_1} + \dots + g^{yk_r} = g^{yk_{r+1}} + \dots + g^{yk_{2r}} \text{ with } k_i = mx_i.$$

The number of these solutions is equal to $\frac{N}{m}$, where N is the number of solutions in $z \in \mathbb{F}_p^*$ of

$$z^{k_1} + \dots + z^{k_r} = z^{k_{r+1}} + \dots + z^{k_{2r}}.$$

Apply Lemma 7 of [4] with $n = 2r, \tau_i = k_i$, and $a_1 = \dots = a_r = 1 = -a_{r+1} = \dots = -a_{2r}$. We have $N \ll p^{1-\frac{1}{2r-1}} D^{\frac{1}{2r-1}}$, where $D = \min_{1 \leq i \leq 2r} \max_{j \neq i} (k_j - k_i, p-1) = m \min_{1 \leq i \leq 2r} \max_{j \neq i} (x_j - x_i, p-1)$. Hence, $T_{\bar{x}} \leq t^{1-\frac{1}{2r-1}} D(x_1, \dots, x_{2r})^{\frac{1}{2r-1}}$ with $D(x_1, \dots, x_{2r}) = \min_i \max_{j \neq i} (x_j - x_i, t)$. Thus,

$$T = \sum_{\bar{x} \in \Omega} T_{\bar{x}} \ll \sum_{\bar{x} \in \Omega} t^{1-\frac{1}{2r-1}} D(\bar{x})^{\frac{1}{2r-1}} = t^{1-\frac{1}{2r-1}} \sum_{\bar{x} \in \Omega} D(\bar{x})^{\frac{1}{2r-1}}.$$

Then, we follow the same argument as in [3] to bound T .

Let $\Omega = \bar{\Omega} \cup \tilde{\Omega}$, where $\bar{\Omega} = \{\bar{x} : D(\bar{x}) \leq t^{\frac{9}{10}}\}$ and $\tilde{\Omega} = \Omega \setminus \bar{\Omega}$; then

$$\begin{aligned}
T &= \sum_{\bar{x} \in \bar{\Omega}} T_{\bar{x}} + \sum_{\bar{x} \in \tilde{\Omega}} T_{\bar{x}} \\
&\leq |\Omega| t^{1-\frac{1}{2r-1}} \left(t^{\frac{9}{10}} \right)^{\frac{1}{2r-1}} + |\tilde{\Omega}| t \\
&= |\Omega| t^{1-\frac{1}{10(2r-1)}} + |\tilde{\Omega}| t.
\end{aligned}$$

Since $|\Omega| < 2\frac{t^{2r}}{p}$, we have

$$(9) \quad \begin{aligned} T &< 2\frac{t^{2r}}{p}t^{1-\frac{1}{10(2r-1)}} + \left|\tilde{\Omega}\right|t \\ &< 2t^{2r+1-\frac{1}{20r}}p^{-1} + t\left|\tilde{\Omega}\right|. \end{aligned}$$

Next, we will apply Bourgain's bound on $|\tilde{\Omega}|$ (see [3]) for which $D(\bar{x}) > t^{\frac{9}{10}}$. With $r = Q$ in Bourgain's bound, we have

$$(10) \quad \left|\tilde{\Omega}\right| < t^{\frac{8r}{5}}.$$

Next, note that for ε in $(0, \frac{1}{4})$ and $r \geq \frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon}$, we have $\varepsilon \geq \frac{80r-8r^2+1}{4(8r^2-1)}$. Also, one can easily check that if $p^{\frac{1}{4}+\varepsilon} \leq t$ and $\varepsilon \geq \frac{80r-8r^2+1}{4(8r^2-1)}$, then

$$(11) \quad t^{2r+1-\frac{1}{20r}}p^{-1} \geq t^{\frac{8r}{5}+1}.$$

Let $\varepsilon \geq \frac{80r-8r^2+1}{4(8r^2-1)}$ and recall that $p^{\frac{1}{4}+\varepsilon} \leq t \leq p^{\frac{1}{2}}$ is part of our assumption. Now we combine the bounds (9), (10), and (11) to bound T .

$$(12) \quad T \ll t^{2r+1-\frac{1}{20r}}p^{-1} + t\left|\tilde{\Omega}\right| \ll t^{2r+1-\frac{1}{20r}}p^{-1} + t^{\frac{8r}{5}+1} \ll t^{2r+1-\frac{1}{20r}}p^{-1}.$$

Next, we apply (12) to the inequality $v \leq Tt^{\lambda-2r}p$ to obtain a bound for v .

$$v \leq Tt^{\lambda-2r}p \ll \left(t^{2r+1-\frac{1}{20r}}p^{-1}\right)t^{\lambda-2r}p = t^{1+\lambda-\frac{1}{20r}}.$$

Then we apply the bound of v to (7); we therefore have

$$\begin{aligned} S_{a,c}(t) &= \sum_{y=1}^t \left| \sum_{x=1}^t e_p(a\theta^x + c\theta^{xy}) \right| \\ &\leq t^{2-\frac{\lambda}{r^2}} + t \cdot v \\ &\ll t^{2-\frac{\lambda}{r^2}} + t \cdot t^{1+\lambda-\frac{1}{20r}} \\ &= t^{2-\frac{\lambda}{r^2}} + t^{2+\lambda-\frac{1}{20r}} \\ &\ll t^{2-\frac{\lambda}{r^2}}. \end{aligned}$$

Substituting (6) to the above equation gives us

$$(13) \quad S_{a,c}(t) \ll t^{2-\frac{1}{20r+20r^3}}.$$

Finally, note that $2\lceil \frac{(\log \frac{1}{\varepsilon})^2}{4\varepsilon} \rceil$ is the least even positive integer greater than or equal to $\frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon}$ and $2\lceil \frac{(\log \frac{1}{\varepsilon})^2}{4\varepsilon} \rceil < \frac{(\log \frac{1}{\varepsilon})^2}{2\varepsilon} + 1$. Thus, we can substitute $r = \frac{(\log \frac{1}{\varepsilon})^2 + 2\varepsilon}{2\varepsilon}$ to

(13). Since

$$\frac{1}{20 \left(2 \left\lceil \frac{(\log \frac{1}{\varepsilon})^2}{4\varepsilon} \right\rceil \right) + 20 \left(2 \left\lceil \frac{(\log \frac{1}{\varepsilon})^2}{4\varepsilon} \right\rceil \right)^3} \geq \frac{1}{20} \varepsilon^3 \left(\log \frac{1}{\varepsilon} \right)^{-6},$$

we obtain the desired result.

Case 2. $p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}$.

The argument is similar to that of Case 1, with a few adjustments. First, we replace the bound (5) with the Konyagin–Shparlinski bound from Lemma 7. Next, we replace the conditions for (8) and (11) by assuming $r \geq 6$. Finally, we substitute $r = 6$ to (13) to obtain the desired result. $\square$

Remark 1. For $\varepsilon \geq 0$ and $p^{\frac{1}{3}+\varepsilon} \leq t \leq p^{\frac{1}{2}}$, we can obtain the bound $S_{a,c}(t) \ll t^{2-\frac{\varepsilon^3}{50}}$ by a similar argument presented above with a few adjustments. First, we replace the bound (5) with the Konyagin–Shparlinski bound from Lemma 7. Then, we substitute the conditions for the bounds (8) and (11) with the following assumptions:

$$(8') \quad \varepsilon \geq \frac{4}{3r},$$

$$(11') \quad \varepsilon \geq \frac{60r - 8r^2 + 1}{3(8r^2 - 1)}.$$

Finally, note that it is clear that for each ε there exists r which satisfies both inequalities; we may substitute $r = \frac{4}{3\varepsilon}$ to (13) to obtain the result. Also, note that $\frac{\varepsilon^3}{50} > \frac{1}{20}\varepsilon^3 \left(\log \frac{1}{\varepsilon} \right)^{-6}$ for $\varepsilon \geq \frac{1}{28}$. Thus, $t^{2-\frac{\varepsilon^3}{50}}$ is a better bound for $p^{\frac{29}{84}} \leq t \leq p^{\frac{1}{2}}$.

Theorem 1 and the inequality $|\tilde{S}_{a,b,c}(t)| \leq S_{a,c}(t)$ imply the following corollary.

COROLLARY 1. *Given $p \geq 3$ and $V \in \mathbb{Z}$ of multiplicative order $t \pmod{p}$, we have*

$$\max_{\gcd(a,b,c,p)=1} \left| \tilde{S}_{a,b,c}(t) = \sum_{x,y=1}^t e_p(aV^x + bV^y + cV^{xy}) \right| \ll t^{2-r(\varepsilon)},$$

where

$$r(\varepsilon) = \begin{cases} \frac{1}{4440} & \text{if } p^{\frac{1}{2}} \leq t \leq p^{\frac{2}{3}}, \\ \frac{1}{20}\varepsilon^3 \left(\log \frac{1}{\varepsilon} \right)^{-6} & \text{if } p^{\frac{1}{4}+\varepsilon} \leq t < p^{\frac{1}{2}}. \end{cases}$$

Acknowledgment. The authors are thankful to Professor I. E. Shparlinski for his useful comments, suggestions, and references.

CHARACTERIZING IDEAL WEIGHTED THRESHOLD SECRET SHARING*

AMOS BEIMEL[†], TAMIR TASSA[‡], AND ENAV WEINREB[†]

Abstract. Weighted threshold secret sharing was introduced by Shamir in his seminal work on secret sharing. In such settings, there is a set of users where each user is assigned a positive weight. A dealer wishes to distribute a secret among those users so that a subset of users may reconstruct the secret if and only if the sum of weights of its users exceeds a certain threshold. On one hand, there are nontrivial weighted threshold access structures that have an ideal scheme—a scheme in which the size of the domain of shares of each user is the same as the size of the domain of possible secrets (this is the smallest possible size for the domain of shares). On the other hand, other weighted threshold access structures are not ideal. In this work we characterize all weighted threshold access structures that are ideal. We show that a weighted threshold access structure is ideal if and only if it is a hierarchical threshold access structure (as introduced by Simmons), or a tripartite access structure (these structures generalize the concept of bipartite access structures due to Padró and Sáez), or a composition of two ideal weighted threshold access structures that are defined on smaller sets of users. We further show that in all those cases the weighted threshold access structure may be realized by a linear ideal secret sharing scheme. The proof of our characterization relies heavily on the strong connection between ideal secret sharing schemes and matroids, as proved by Brickell and Davenport.

1. Introduction. A *threshold secret sharing scheme* enables a dealer to distribute a secret among a set of users, by giving each user a piece of information called a *share*, such that only large sets of users will be able to reconstruct the secret from the shares that they got, while smaller sets gain no information on the secret. Threshold secret sharing schemes were introduced and efficiently implemented, independently, by Blakley [5] and Shamir [28]. Efficient threshold secret sharing schemes were used in many cryptographic applications, e.g., Byzantine agreement [26], secure multiparty computations [3, 10], and threshold cryptography [13].

In this paper we deal with *weighted* threshold secret sharing schemes. In these schemes, considered already by Shamir [28], the users are not of the same status. That is, each user is assigned a positive weight, and a set can reconstruct the secret if the sum of weights assigned to its users exceeds a certain threshold. As a motivation, consider sharing a secret among the shareholders of some company, each holding a different number of shares. Such settings are closely related to the concept of *weighted threshold functions*, which play an important role in complexity theory and learning theory.¹

¹A weighted threshold function is a Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, where each variable is assigned a positive weight and $f(x_1, \dots, x_n) = 1$ if and only if the sum of weights that are assigned to the variables whose value is 1 exceeds a given threshold.

Ito, Saito, and Nishizeki [16] generalized the notion of secret sharing such that there is an arbitrary monotone collection of authorized sets, called the *access structure*. The requirements are that only sets in the access structure are allowed to reconstruct the secret, while sets that are not in the access structure should gain no information on the secret. A simple argument shows that in every secret sharing scheme the domain of possible shares for each user is at least as large as the domain of possible secrets (see [19]). Shamir's threshold secret sharing scheme is *ideal* in the sense that the domain of shares of each user coincides with the domain of possible secrets. Ideal secret sharing schemes are the most space-efficient schemes. However, some access structures do not have an ideal secret sharing scheme that realizes them [4]. Namely, some access structures demand share domains that are larger than the domain of secrets. Access structures that may be realized by an ideal secret sharing scheme are called ideal. Ideal secret sharing schemes and ideal access structures have been studied in, e.g., [1, 6, 7, 17, 20, 21, 23, 25, 27, 32, 35, 36]. Ideal access structures are known to have certain combinatorial properties. In particular, there is a strong relation between ideal access structures and matroids [7].

While threshold access structures are ideal, weighted threshold access structures are not necessarily so. For example, the access structure on four users with weights 1, 1, 1, and 2, and a threshold of 3, has no ideal secret sharing scheme (see Example 4.9 for a proof). Namely, in any perfect secret sharing scheme that realizes this access structure, the share domain of at least one user is larger than the domain of secrets. On the other hand, there exist ideal weighted threshold access structures other than the trivial threshold ones. For example, consider the access structure on nine users, where the weights are 16, 16, 17, 18, 19, 24, 24, 24, and 24 and the threshold is 92. Even though this access structure seems more complicated than the previous one, it has an ideal secret sharing scheme (see Example 7.5). Another example of an ideal weighted threshold access structure is the one having weights 1, 1, 1, 1, 1, 3, 3, and 3 and threshold 6 (see Example 8.10).

In this paper we give a combinatorial characterization of ideal weighted threshold access structures. We show that if a weighted threshold access structure is ideal, then one of the following statements holds:

1. It is a *multilevel* or *hierarchical* threshold access structure. This type of access structure was introduced by Simmons in [29]. In such settings, the users are divided into a hierarchy of levels, and each level has an associated threshold. A set of users is authorized if it has a subset whose size is at least the threshold that corresponds to the level of the lowest member in that subset.
2. It is a *tripartite* access structure. In such access structures, the set of users is partitioned into three classes, and a given subset is authorized if and only if the sizes of its intersection with each of the three classes satisfy some threshold conditions (see section 7 for details).
3. The set of users is composed of *strong* users (users with larger weights) and *weak* users (users with smaller weights), and the access structure is a combinatorial composition of two ideal weighted threshold access structures, one that is defined on the subset of strong users and another that is defined on the subset of weak users.

(Formal definitions are given in section 3.)

Most of the access structures that play a part in our characterization are well known [25, 29, 35]. Tripartite access structures were considered by Collins [11], who gave a necessary condition for a tripartite access structure to be ideal. We consider a

specific family of tripartite access structures and design ideal secret sharing schemes for this family. Following our work, Herranz and Sáez [15] constructed ideal secret sharing schemes for a wider family of tripartite access structures, and Farràs, Martí-Farré, and Padró [14] exactly characterizes the tripartite access structures that are ideal.

The present study generalizes the work of Morillo et al. [23], who characterized the ideal weighted threshold access structures in which all the minimal authorized sets have at most two users. The proof of our characterization relies heavily on the strong connection between ideal secret sharing schemes and matroids, as presented in [7]. We utilize results regarding the structure of matroids in order to understand the structure of ideal weighted threshold access structures. An important tool in our analysis is composition of ideal access structures. When composing two access structures, defined on two disjoint sets, one gets an access structure on a larger set of users. The resulting access structure is ideal if and only if the original two are ideal. This enables us to characterize ideal weighted threshold access structures in a recursive manner, as described above. Composition of access structures was studied, e.g., in [1, 4, 8, 12, 22, 34].

Related work. Secret sharing schemes for general access structures were defined by Ito, Saito, and Nishizeki in [16]. More efficient schemes were presented in, e.g., [4, 6, 18, 31]. We refer the reader to [30, 33] for extensive surveys on secret sharing schemes. However, for most access structures the known secret sharing schemes are highly inefficient; that is, the size of the shares is exponential in n , the number of users. It is not known whether better schemes exist. For weighted threshold access structures the situation is somewhat better. Shamir [28] proposed a weighted threshold secret sharing scheme that is based on his ideal threshold secret sharing scheme. In that scheme, the ratio between the share size of each user and the size of the secret equals the weight assigned to that user, which may be exponential in the number of users n . In a recent work [2], secret sharing schemes were constructed for arbitrary weighted threshold access structures in which the shares are of size $O(n^{\log n})$. Furthermore, under reasonable computational assumptions, a secret sharing scheme with computational security was constructed in [2] for every weighted threshold access structure with a polynomial share size.

Organization. We begin in section 2 by supplying the necessary definitions. Then, in section 3, we state our characterization theorem and outline its proof. We proceed to describe in section 4 the connection between matroids and ideal secret sharing, and then prove, in section 5, several properties of matroids that are associated with weighted threshold access structures. Thereafter, we discuss the connection between ideal weighted threshold access structures and two families of access structures: hierarchical threshold access structures in section 6, and tripartite access structures in section 7. Finally, in section 8 we complete the proof of the characterization theorem by proving that if an ideal weighted threshold access structure is neither hierarchical nor tripartite, then it is a composition of two ideal weighted threshold access structures on smaller sets of users.

2. Definitions and notations.

2.1. Secret sharing. We next define secret sharing schemes and ideal secret sharing schemes. We start by defining an access structure which is the collection of authorized sets that can reconstruct the secret.

DEFINITION 2.1 (access structure). Let $U = \{u_1, \dots, u_n\}$ be a set of users. A collection $\Gamma \subseteq 2^U$ is monotone if $B \in \Gamma$ and $B \subseteq C$ imply that $C \in \Gamma$. An access structure is a monotone collection $\Gamma \subseteq 2^U$ of nonempty subsets of U . Sets in Γ are called authorized, and sets not in Γ are called unauthorized. A set B is called a minterm of Γ if $B \in \Gamma$ and for every $C \subsetneq B$ the set C is unauthorized. A user u is called self-sufficient if $\{u\} \in \Gamma$. A user is called redundant if there is no minterm that contains it. An access structure is called connected if it has no redundant users.

DEFINITION 2.2 (secret sharing scheme). Let S be a finite set of secrets, where $|S| \geq 2$. An n -user secret sharing scheme Π with domain of secrets S is a randomized mapping from S to a set of n -tuples $\prod_{i=1}^n S_i$, where S_i is called the share-domain of u_i . A dealer shares a secret $s \in S$ among the n users of some set U according to Π by first sampling (according to some predefined probability distribution) a vector of shares $\Pi(s) = (s_1, \dots, s_n) \in \prod_{i=1}^n S_i$, and then privately communicating each share s_i to the user u_i . We say that Π realizes an access structure $\Gamma \subseteq 2^U$ if the following two requirements hold:

1. *Correctness.* The secret s can be reconstructed by any authorized set of users. That is, for any set $B \in \Gamma$ (where $B = \{u_{i_1}, \dots, u_{i_{|B|}}\}$), there exists a reconstruction function² $\text{RECON}_B : S_{i_1} \times \dots \times S_{i_{|B|}} \rightarrow S$ such that for every $s \in S$ and for every possible value of $\Pi_B(s)$ the restriction of $\Pi(s)$ to its B -entries,

$$\text{RECON}_B(\Pi_B(s)) = s.$$

2. *Privacy.* Every unauthorized set can learn nothing about the secret (in the information theoretic sense) from the shares of the users in the set. Formally, for any set $C \notin \Gamma$, for every two secrets $a, b \in S$, and for every possible $|C|$ -tuple of shares $\langle s_i \rangle_{u_i \in C}$:

$$\Pr[\Pi_C(a) = \langle s_i \rangle_{u_i \in C}] = \Pr[\Pi_C(b) = \langle s_i \rangle_{u_i \in C}].$$

In every secret sharing scheme, the size of the domain of shares of each user is at least the size of the domain of the secrets [19], namely $|S_i| \geq |S|$ for all $i \in [n]$. This motivates the next definition.

DEFINITION 2.3 (ideal access structure). A secret sharing scheme with domain of secrets S is ideal if the domain of shares of each user is S . An access structure Γ is ideal if for some finite domain of secrets S there exists an ideal secret sharing scheme realizing it.

Most previously known secret sharing schemes are *linear*. The concept of linear secret sharing schemes was introduced by Brickell [6] in the ideal setting and was later generalized to nonideal schemes. Linear schemes are equivalent to monotone span programs [18]. For simplicity we define only ideal linear schemes.

DEFINITION 2.4 (ideal linear secret sharing scheme). Let $\mathbb{F}$ be a finite field. An ideal linear secret sharing scheme over $\mathbb{F}$ takes the following form. The domain of secrets and shares is $S = \mathbb{F}$. The scheme is specified by $n + 1$ vectors in $\mathbb{F}^t$ for some integer t : a vector $\mathbf{T}_i$ per user $u_i \in U$, where $i \in [n]$, and a so-called target vector $\mathbf{T}$. To share a secret $s \in \mathbb{F}$, the dealer chooses a random vector $\mathbf{R} \in \mathbb{F}^t$ such that $\mathbf{R} \cdot \mathbf{T} = s$, and then the share of user u_i is $\mathbf{R} \cdot \mathbf{T}_i$.

²We stress that there is no requirement that RECON_B can be efficiently implemented. However, this is the case for all the secret sharing schemes designed in this paper.

The next theorem characterizes the access structure that is realized by a linear secret sharing scheme.

THEOREM 2.5 (see [6, 18]). *A linear secret sharing scheme with vectors $\{\mathbf{T}_i\}_{i \in [n]}$ and $\mathbf{T}$ realizes the following access structure Γ :*

$$A \in \Gamma \text{ if and only if } \mathbf{T} \in \text{span}\{\mathbf{T}_i : u_i \in A\}.$$

2.2. Weighted threshold access structures. In this paper we concentrate on special access structures, so-called weighted threshold access structures, which were already introduced in [28].

DEFINITION 2.6 (weighted threshold access structure—WTAS). *Let $w : U \rightarrow \mathbb{N}$ be a weight function on U and $T \in \mathbb{N}$ be a threshold. Define $w(A) := \sum_{u \in A} w(u)$ and $\Gamma = \{A \subseteq U : w(A) \geq T\}$. Then Γ is called a weighted threshold access structure (WTAS) on U .*

It is easy to see that Definition 2.6 does not restrict generality when assuming that the weights and the threshold are integers. In other words, given a WTAS with real positive weights and threshold, there exist integer weights and threshold that induce the very same access structure.

2.3. Terminology and notation. First, for a positive integer n , we denote by $[n]$ the set $\{1, 2, \dots, n\}$. Throughout this paper we assume that the users are ordered in a nondecreasing order according to their weights, i.e.,

$$0 < w(u_1) \leq w(u_2) \leq \dots \leq w(u_n).$$

Let $A = \{u_{i_j}\}_{1 \leq j \leq k}$ be an ordered subset of U , where $1 \leq i_1 < \dots < i_k \leq n$. In order to avoid two-leveled indices, we will denote the users in such a subset with the corresponding lowercase letter, namely, $A = \{a_j\}_{1 \leq j \leq k}$. We denote the first (lightest) and last (heaviest) users of A by $A_{\min} = a_1$ and $A_{\max} = a_k$, respectively. For an arbitrary ordered subset A we let $A_{s,t} = \{a_j\}_{s \leq j \leq t}$ denote a run-subset. If $s > t$, then $A_{s,t} = \emptyset$. Two types of runs that we shall meet frequently are prefixes and suffixes. A prefix of a subset A is a run-subset of the form $A_{1,\ell}$, while a suffix takes the form $A_{\ell,k}$, where $1 \leq \ell \leq k$. A suffix $A_{\ell,k}$ is a proper suffix of $A_{1,k}$ if $\ell > 1$.

We conclude this section by introducing the precedence relation $\prec$. When applied to users, $u_i \prec u_j$ indicates that $i < j$ (and, in particular, $w(u_i) \leq w(u_j)$). This relation induces the following lexicographic order on subsets of U :

- $\emptyset \prec A$ for all $A \subseteq U$ such that $A \neq \emptyset$.
- If $a_1 \prec b_1$, then $A \prec B$; if $b_1 \prec a_1$, then $B \prec A$; otherwise, $A \prec B$ if and only if $(A \setminus \{a_1\}) \prec (B \setminus \{b_1\})$.

3. Characterizing ideal WTASs. The main result of this paper is a combinatorial characterization of ideal WTASs. We define in Definitions 3.1–3.4 the building blocks that play an essential role in this characterization. Using these definitions, we state Theorem 3.5, our main result, that characterizes ideal WTASs. We then outline the proof of that theorem, where the full proof is given in the subsequent sections.

3.1. Building blocks.

DEFINITION 3.1 (hierarchical threshold access structure—HTAS). *Let m be an integer, U be a set of users, and $\{L_i\}_{1 \leq i \leq m}$ be a partition of U into a hierarchy of m disjoint levels, i.e., $U = \bigcup_{i=1}^m L_i$. Furthermore, let $\{k_i\}_{1 \leq i \leq m}$ be a sequence of decreasing thresholds, $k_1 > k_2 > \dots > k_m$. This hierarchy and sequence of thresholds*

induces a hierarchical threshold access structure (HTAS) on U :

$$\Gamma_H = \left\{ A \subseteq U : \text{There exists } i \in [m] \text{ such that } \left| A \cap \bigcup_{j=i}^m L_j \right| \geq k_i \right\}.$$

That is, a set $A \subseteq U$ is in Γ_H if and only if it contains at least k_i users from the i th level and above, for some $i \in [m]$.

The family of HTASs was introduced by Simmons in [29] and further studied by Brickell, who proved their ideality [6]. An explicit ideal scheme for these access structures was constructed in [35].

Remark 3.2. Without loss of generality, we can assume that $|L_i| > k_i - k_{i+1}$ for every $i \in [m-1]$, and $|L_m| \geq k_m$. Indeed, if $|L_i| \leq k_i - k_{i+1}$ for some $i \in [m-1]$, then the i th threshold condition in the HTAS definition implies the $(i+1)$ th threshold condition, and, consequently, the $(i+1)$ th condition is redundant.

We next present tripartite access structures (TPASs), which are a generalization of bipartite access structures that were presented in [25]. In a *bipartite* access structure, the set of users is partitioned into two classes, and a subset is authorized if the sizes of its intersection with each of these classes satisfy some predefined conditions. In a *tripartite* access structure, the set of users is partitioned into three classes, and, similarly to bipartite access structures, a given subset is authorized if the sizes of its intersection with each of these classes satisfy some conditions. In the next definition we describe two special types of TPASs. We would like to stress that there exist other types of TPASs, but herein we concentrate only on those two types, since only they are relevant for the characterization of ideal WTASs. Later on we prove that these types of TPASs are ideal by constructing a linear ideal secret sharing scheme that realizes them. That scheme is a generalization of a scheme from [25] for bipartite access structures. Following our work, Farràs, Martí-Farré, and Padró [14] exactly characterized the TPASs that are ideal.

DEFINITION 3.3 (tripartite access structure—TPAS). *Let U be a set of n users such that $U = A \cup B \cup C$, where A , B , and C are disjoint and A and C are nonempty. Let m, d, t be positive integers such that $m \geq t$. Then the following is a tripartite access structure (a TPAS) on U :*

$$\Delta_1 = \{X \subseteq U : (|X| \geq m \text{ and } |X \cap (B \cup C)| \geq m - d) \text{ or } |X \cap C| \geq t\}.$$

Namely, a set X is in Δ_1 if either it has at least m users, $(m-d)$ of which are from $B \cup C$, or it has at least t users from C . If $|B| \leq d + t - m$, then the following is another type of TPAS:

$$\Delta_2 = \{X \subseteq U : (|X| \geq m \text{ and } |X \cap C| \geq m - d) \text{ or } |X \cap (B \cup C)| \geq t\}.$$

That is, a set X is in Δ_2 if either it has at least m users, $(m-d)$ of which are from C , or it has at least t users from $B \cup C$.

DEFINITION 3.4 (composition of access structures). *Let U_1 and U_2 be disjoint sets of users, and let Γ_1 and Γ_2 be access structures on U_1 and U_2 , respectively. Let $u_1 \in U_1$, and set $U = U_1 \cup U_2 \setminus \{u_1\}$. Then the composition of Γ_1 and Γ_2 via u_1 is*

$$\Gamma = \left\{ X \subseteq U : \begin{array}{l} X_1 \in \Gamma_1 \text{ or } (X_2 \in \Gamma_2 \text{ and } X_1 \cup \{u_1\} \in \Gamma_1), \\ \text{where } X_1 = X \cap U_1 \text{ and } X_2 = X \cap U_2 \end{array} \right\};$$

namely, $X \subseteq U$ is authorized in this access structure if either $X_1 = X \cap U_1$ is authorized in Γ_1 , or $X_1 \cup \{u_1\}$ is authorized in Γ_1 and $X_2 = X \cap U_2$ is authorized in Γ_2 .

The motivation behind this definition is as follows. We start with an access structure Γ_1 on U_1 . Then we allow the replacement of one of the users in U_1 , denoted u_1 , by substitute users of a disjoint set U_2 , where Γ_2 specifies the subsets of U_2 that are legitimate substitutes for u_1 . Hence, in the set $U = U_1 \cup U_2 \setminus \{u_1\}$ that is obtained from U_1 after replacing u_1 with U_2 , a subset is authorized if either it is a subset in Γ_1 that does not include u_1 or it was obtained from a subset in Γ_1 that did include u_1 , by replacing u_1 with an authorized subset of substitutes from Γ_2 . In Lemma 8.1 we show that Γ is ideal if and only if both Γ_1 and Γ_2 are ideal.

3.2. The characterization. Following the notation convention in section 2.3, the set U is viewed as a sequence which is ordered in a monotonic nondecreasing order according to the weights. Let M be the lexicographically minimal minterm of Γ (that is, $M \in \Gamma$ is a minterm, and $M \prec M'$ for all other minterms $M' \in \Gamma$). It turns out that the form of M plays a significant role in the characterization of an ideal WTAS Γ .

If M is a prefix of U , namely $M = U_{1,k} = \{u_1, \dots, u_k\}$ for some $k \in [n]$, then, as we prove in section 6.3, the access structure is an HTAS of at most three levels. If M is a lacunary prefix, in the sense that $M = U_{1,k} \setminus \{u_\ell\}$ for $1 \leq \ell < k \leq n$, then, as we prove in section 7, the access structure is a TPAS. Otherwise, if M is neither a prefix nor a lacunary prefix, the access structure is a composition of two WTASs on smaller sets. More specifically, we identify a prefix $U_{1,k}$, where $1 < k < n$, that could be replaced by a single substitute user u , and then show that Γ is a composition of a WTAS on $U_{1,k}$ and another WTAS on $U_{k+1,n} \cup \{u\}$. Since Γ is ideal, so are the two smaller WTASs, as implied by Lemma 8.1. Hence, this result, which we prove in section 8, completes the characterization of ideal WTASs in a recursive manner.

Hence, our main result in this paper is as follows.

THEOREM 3.5 (the characterization theorem). *Let U be a set of users, $w : U \rightarrow \mathbb{N}$ be a weight function, T be a threshold, and Γ be the corresponding WTAS. Then Γ is ideal if and only if one of the following three conditions holds:*

- *The access structure Γ is an HTAS of at most three levels.*
- *The access structure Γ is a TPAS.*
- *The access structure Γ is a composition of Γ_1 and Γ_2 , where Γ_1 and Γ_2 are ideal WTASs defined on sets of users smaller than U .*

In particular, if Γ is an ideal WTAS, then there exists a linear ideal secret sharing scheme that realizes it.

Remark 3.6. In the ideal schemes for WTASs that we construct in this paper, the size of the domain of secrets is at most $2^{\text{poly}(n)}$. This is the field size needed for the HTAS constructions of [35] and for the TPAS construction introduced in section 7. As the composition of ideal access structures does not change the size of the underlying field, we get that the field size for our entire construction is bounded by $2^{\text{poly}(n)}$. This is a comfortable bound since it implies that both the secret and the shares may be represented by $\text{poly}(n)$ bits.

4. Matroids and ideal secret sharing schemes. Matroids and ideal secret sharing schemes are strongly related. If an access structure is ideal, then there is a matroid that reflects its structure. On the other hand, every matroid that is representable over some finite field is the reflection of some ideal access structure. In this

section we review some basic results from the theory of matroids and describe their relation to ideal secret sharing schemes. For more background on matroid theory the reader is referred to [24].

Matroids are a combinatorial structure that generalizes both linear spaces and the set of circuits in an undirected graph. They are a useful tool in several fields of theoretical computer science, e.g., optimization algorithms. A matroid $\mathcal{M} = \langle V, \mathcal{I} \rangle$ is a finite set V and a collection $\mathcal{I}$ of subsets of V that satisfy the following three axioms:

- (I1) $\emptyset \in \mathcal{I}$.
- (I2) If $X \in \mathcal{I}$ and $Y \subseteq X$, then $Y \in \mathcal{I}$.
- (I3) If X and Y are members of $\mathcal{I}$ with $|X| = |Y| + 1$, then there exists an element $x \in X \setminus Y$ such that $Y \cup \{x\} \in \mathcal{I}$.

The elements of V are called the *points* of the matroid, and the sets in $\mathcal{I}$ are called the *independent* sets of the matroid. Axiom (I1) assures that there is at least one independent set in $\mathcal{I}$. Axiom (I2) asserts that the collection $\mathcal{I}$ is closed under containment. Finally, axiom (I3) enables the expansion of every small independent set in $\mathcal{I}$. A *dependent set* of the matroid is any subset of V that is not independent. The minimal dependent sets are called *circuits*. A matroid is said to be *connected* if for any two points there exists a circuit that contains both of them.

We now discuss the relations between ideal secret sharing schemes and matroids. Let Γ be an access structure on a set of users $U = \{u_1, \dots, u_n\}$. If Γ is ideal, then, by the results of [7, 21], there exists a matroid $\mathcal{M}$ corresponding to Γ . The points of $\mathcal{M}$ are the users in U together with an additional point, denoted u_0 , that could be thought of as representing the dealer. We denote hereinafter by

$$\mathcal{C}_0 = \{X \cup \{u_0\} : X \text{ is a minterm of } \Gamma\}$$

the set of all Γ -minterms, supplemented by u_0 .

THEOREM 4.1 (see [7, 21]). *Let Γ be a connected ideal access structure on U . Then there exists a connected matroid $\mathcal{M}$ on $U \cup \{u_0\}$ such that $\mathcal{C}_0$ is exactly the set of circuits of $\mathcal{M}$ containing u_0 .*

The next result implies the uniqueness of the matroid $\mathcal{M}$ that corresponds to a given connected ideal access structure, as discussed in Theorem 4.1, and, additionally, it provides means to identify *all* the circuits of that matroid.

LEMMA 4.2 (see [24, Theorem 4.3.2]). *Let e be an element of a connected matroid $\mathcal{M}$, and let $\mathcal{C}_e$ be the set of circuits of $\mathcal{M}$ that contain e . Then all of the circuits of $\mathcal{M}$ that do not contain e are the minimal sets of the form*

$$(C_1 \cup C_2) \setminus \bigcap \{C_3 : C_3 \in \mathcal{C}_e, C_3 \subseteq C_1 \cup C_2\},$$

where C_1 and C_2 are distinct circuits in $\mathcal{C}_e$.

The unique matroid whose existence and uniqueness are guaranteed by Theorem 4.1 and Lemma 4.2 is referred to as *the matroid corresponding to Γ* . This next definition will enable us to explicitly define the matroid corresponding to Γ using the authorized sets in Γ .

DEFINITION 4.3 (critical user). *Let M_1 and M_2 be distinct minterms of Γ . A user $x \in M_1 \cup M_2$ is critical for $M_1 \cup M_2$ if the set $M_1 \cup M_2 \setminus \{x\}$ is unauthorized. In addition, we define*

$$D(M_1, M_2) = (M_1 \cup M_2) \setminus \{x \in M_1 \cup M_2 : x \text{ is critical for } M_1 \cup M_2\}.$$

With this definition, the following corollary is a straightforward result of Theorem 4.1 and Lemma 4.2.

COROLLARY 4.4. *Let Γ be a connected ideal access structure on U . Then there exists a unique connected matroid $\mathcal{M}$ on $U \cup \{u_0\}$ such that $\mathcal{C}_0$ is exactly the set of circuits of $\mathcal{M}$ containing u_0 . Furthermore, the minimal sets in*

$$\{D(M_1, M_2) : M_1, M_2 \text{ are distinct minterms of } \Gamma\}$$

are the circuits of the matroid that do not contain u_0 .

In what follows we use the following simple consequence of Corollary 4.4.

COROLLARY 4.5. *Let M_1 and M_2 be two distinct minterms of Γ . Then $D(M_1, M_2)$ is a dependent set of $\mathcal{M}$.*

Note that $D(M_1, M_2)$ is a dependent set of $\mathcal{M}$, but is not necessarily a circuit of $\mathcal{M}$. The following basic result from matroid theory provides another way of establishing the dependency of a set in a matroid.

LEMMA 4.6 (see [24, p. 16]). *Let C_1 and C_2 be two distinct circuits in a matroid, $e \in C_1 \cap C_2$, and $d \in C_1 \setminus C_2$ such that $d \neq e$. Then there exists a circuit $C_3 \subseteq (C_1 \cup C_2) \setminus \{e\}$, where $d \in C_3$.*

In most applications of the lemma we will ignore d and the fact that $d \in C_3$. Since every minterm of Γ is properly contained in a circuit of $\mathcal{M}$, it forms an independent set of $\mathcal{M}$. However, these are not necessarily the only independent sets in $\mathcal{M}$. The following claim is a simple corollary of axiom (I3) in the matroid definition.

CLAIM 4.7. *Let $\mathcal{M}$ be a matroid and I be an independent set of size m . Then any independent set of size $\ell < m$ can be extended to an independent set of size m .*

Finally, the next lemma is applicable when adding an element to an independent set results in a dependent set.

LEMMA 4.8. *Let I be an independent set in a matroid $\mathcal{M}$, and let e be an element of $\mathcal{M}$ such that $I \cup \{e\}$ is dependent. Then $\mathcal{M}$ has a unique circuit contained in $I \cup \{e\}$, and that circuit contains e .*

To prove that an access structure is not ideal we use the above results that define the dependent sets in the matroid corresponding to Γ . In particular, we use the basic fact that an independent set of $\mathcal{M}$ cannot contain a dependent set (see axiom (I2)). By Theorem 4.1, for every minterm $M \in \Gamma$, the set $M \cup \{u_0\}$ is a circuit of $\mathcal{M}$. Thus, the set M is an independent set of $\mathcal{M}$. Therefore, if D is a dependent set of $\mathcal{M}$, it cannot be contained in any minterm of Γ . The next example shows how to use the above statements in order to demonstrate that a given access structure is not ideal.

Example 4.9. Consider the WTAS Γ on the set $U = \{u_1, u_2, u_3, u_4\}$ with weights $w(u_1) = w(u_2) = w(u_3) = 1$ and $w(u_4) = 2$ and threshold $T = 3$. The minterms of Γ are $\{u_1, u_2, u_3\}$, $\{u_1, u_4\}$, $\{u_2, u_4\}$, and $\{u_3, u_4\}$. It follows from Benaloh and Leichter [4] that this access structure is not ideal.³ We first give a simple proof, based on Corollary 4.5, showing that Γ is not ideal. Assume that it is ideal and consider the minterms $M_1 = \{u_1, u_4\}$ and $M_2 = \{u_2, u_4\}$. The set $\{u_1, u_2\}$ is unauthorized, and thus u_4 is critical for $M_1 \cup M_2$. On the other hand, the users u_1 and u_2 are not critical for $M_1 \cup M_2$. Therefore, by Corollary 4.5, the set $D(M_1, M_2) = \{u_1, u_2\}$ is a dependent set of $\mathcal{M}$, the matroid corresponding to Γ . However, the set $\{u_1, u_2, u_3\}$ is a minterm of Γ and, consequently, it is independent in $\mathcal{M}$. Since $\{u_1, u_2\} \subset \{u_1, u_2, u_3\}$, we

³In [9] it was shown that if the domain of secrets is S , the size of the domain of shares of at least one user in that access structure must be at least $|S|^{1.5}$. That result improved upon previous bounds that were derived in [8].

arrive at the absurd conclusion that a dependent set is contained in an independent set. This contradiction implies that Γ is not ideal.

We proceed to sketch an alternative proof for the nonideality of Γ , similar to the proof that was given in [4]. We present this proof for two reasons. First, we want to show that using matroids simplifies and shortens the proofs substantially. Matroid-based proofs, however, tend to be technical and, consequently, not very intuitive. The alternative proof that we present herein reveals some of the intuition that is sometimes obfuscated in matroid-based proofs.

Assume towards a contradiction that Γ has an ideal secret sharing scheme over some domain of secrets S . Letting s_i denote the share of user u_i for $1 \leq i \leq 4$, we will show that s_2 may be computed from s_1 . (This statement is equivalent to the statement in the first proof that the set $\{u_1, u_2\}$ is dependent.) Having shown that, we will conclude that $\{u_1, u_3\}$ can reconstruct the secret (since $\{u_1, u_2, u_3\}$ is an authorized set and u_2 is unnecessary in the presence of u_1), in contradiction to the definition of Γ .

We need to show that s_2 is uniquely determined by s_1 . Assume, by contradiction, that there exists $s_1 \in S_1$ and $s_2, s'_2 \in S_2$, where $s_2 \neq s'_2$, such that both assignments of shares to $\{u_1, u_2\}$, namely $\langle s_1, s_2 \rangle$ and $\langle s_1, s'_2 \rangle$, are possible. Since $\{u_1, u_2\}$ is unauthorized, that set cannot learn any information on the secret from its shares. Hence, given the pair of shares $\langle s_1, s_2 \rangle$, every secret is possible. Hence, for every $s \in S$, there exists at least one share $s_4(s)$ for u_4 such that $\langle s_1, s_2, s_4(s) \rangle$ is a possible assignment of shares to $\{u_1, u_2, u_4\}$, given the secret s . On the other hand, since the shares of $\{u_1, u_2, u_4\}$ determine the secret, $s_4(s)$ must be unique, since otherwise the domain of shares of u_4 would be larger than the domain of secrets, in a contradiction with ideality. Similarly, for every $s \in S$ there exists a unique share $s'_4(s)$ such that $\langle s_1, s'_2, s'_4(s) \rangle$ is another possible assignment of shares to $\{u_1, u_2, u_4\}$, given the secret s .

In view of the above, the sets $\{s_4(s) : s \in S\}$ and $\{s'_4(s) : s \in S\}$ are of size $|S|$. However, since they are both subsets of S_4 and, by ideality, $|S_4| = |S|$, they both equal S_4 . One conclusion is that each secret $s \in S$ is consistent with each share $s_4 \in S_4$. Another conclusion is that there are secrets $a, b \in S$ such that $s_4(a) = s'_4(b) := s_4$. If $a \neq b$, then the pair of shares $\langle s_1, s_4 \rangle$ is insufficient to determine whether the secret is a or b , in contradiction to the correctness requirement that $\{u_1, u_4\} \in \Gamma$ should be able to reconstruct the secret. Thus, $a = b$, whence both pairs of shares $\langle s_2, s_4 \rangle$ and $\langle s'_2, s_4 \rangle$ are possible assignments of shares to $\{u_2, u_4\}$, given that the secret is a . But this implies that the size of S_2 is at least $|S| + 1$ (by going over all secrets $s \in S$ and looking for a corresponding assignment of shares where the share of u_4 is s_4), thus contradicting ideality.

4.1. Restrictions.

DEFINITION 4.10 (restriction). *Let $Y, X \subseteq U$ be two disjoint subsets of users. The restriction of Γ that is induced by Y on X is defined as the following access structure:*

$$\Gamma_{Y,X} = \{Z \subseteq X : Z \cup Y \in \Gamma\}.$$

In other words, $\Gamma_{Y,X}$ consists of all subsets of X that complete Y to an authorized set in Γ . Since $\Gamma_{Y,X}$ is defined on a smaller set of users, restrictions can be helpful in recursively characterizing the structure of Γ . The following known result assures us that if Γ is ideal, $\Gamma_{Y,X}$ is ideal as well. For completeness, we give a proof herein.

LEMMA 4.11. *Let Γ be an access structure on a set of users U . Let $Y, X \subseteq U$ be sets such that $X \cap Y = \emptyset$. If Γ is ideal, then $\Gamma_{Y,X}$ is ideal.*

Proof. Let $Y = \{u_{i_1}, \dots, u_{i_{|Y|}}\}$. We construct an ideal secret sharing scheme Π' for $\Gamma_{Y,X}$ using an ideal scheme Π for Γ . Fix an arbitrary secret $s' \in S$, and let $s_Y = \langle s'_{i_1}, \dots, s'_{i_{|Y|}} \rangle = \Pi_Y(s')$ be a possible vector of shares for the users of Y . Let $s \in S$ be a secret to be distributed by Π' . The scheme Π' randomly chooses an n -tuple $\Pi(s) = \langle s_1, \dots, s_n \rangle$ such that $s_{i_j} = s'_{i_j}$ for all $1 \leq j \leq |Y|$ (such a selection is possible because Y is unauthorized, whence every assignment of shares to Y is consistent with every secret). Every user $u_j \in X$ is then assigned by Π' the share s_j . (The shares of Y , namely $\langle s'_{i_1}, \dots, s'_{i_{|Y|}} \rangle$, are considered “publicly known.”)

The scheme is correct since if $Z \in \Gamma_{Y,X}$, then $Y \cup Z \in \Gamma$, and thus the members of Z , who know the shares s_Y of Y , can reconstruct the secret as in the scheme Π for Γ . Similarly, the scheme is private, since if $Z \notin \Gamma_{Y,X}$, then $Y \cup Z \notin \Gamma$, and thus the users of Z , who know the shares of Y , will not have any information regarding the secret. The scheme is ideal since the share-domain of all the users is the same as in the original ideal scheme. $\square$

The following result gives a relation between the matroids corresponding to Γ and $\Gamma_{Y,X}$.

LEMMA 4.12. *Let Γ be an ideal access structure on a set of users U . Let $Y, X \subseteq U$ be sets such that $X \cap Y = \emptyset$ and Y is independent in the matroid corresponding to Γ . Then if a set $I \subseteq X$ is independent in the matroid corresponding to $\Gamma_{Y,X}$, it is also independent in the matroid corresponding to Γ .*

Proof. Let $\mathcal{M} = \langle U \cup \{u_0\}, \mathcal{I} \rangle$ be the matroid associated with Γ . We define the matroid $\mathcal{M}' = \langle X \cup \{u_0\}, \mathcal{I}' \rangle$ as follows: A set $Z \subseteq X \cup \{u_0\}$ is in $\mathcal{I}'$ if and only if $Y \cup Z \in \mathcal{I}$. This is indeed a matroid: axiom (I1) holds because $Y \in \mathcal{I}$ so that $\emptyset \in \mathcal{I}'$. As for axiom (I2), $Y \cup B \in \mathcal{I}$ for every $B \in \mathcal{I}'$; therefore, if $A \subseteq B$, then $Y \cup A \in \mathcal{I}$, whence $A \in \mathcal{I}'$. Axiom (I3) holds as well. Let $A, B \in \mathcal{I}'$ be such that $|A| > |B|$. Since $Y \cup A \in \mathcal{I}$ and $Y \cup B \in \mathcal{I}$ while $|Y \cup A| > |Y \cup B|$, there must be an element $x \in A \setminus B$ such that $Y \cup (B \cup \{x\}) \in \mathcal{I}$. Therefore, $B \cup \{x\} \in \mathcal{I}'$, as required.

We claim that $\mathcal{M}'$ is the unique matroid corresponding to $\Gamma_{Y,X}$. That is, for every $M \subseteq X$, the set $M \cup \{u_0\}$ is a circuit of $\mathcal{M}'$ if and only if M is a minterm of $\Gamma_{Y,X}$. Proving that, we get that if $I \in \mathcal{I}'$, then $Y \cup I \in \mathcal{I}$, and therefore I itself is independent in $\mathcal{M}$.

Suppose that $M \cup \{u_0\}$ is a circuit of $\mathcal{M}'$. Then $Y \cup M \cup \{u_0\}$ is dependent in $\mathcal{M}$ and consequently must contain a circuit of $\mathcal{M}$. That circuit must contain $M \cup \{u_0\}$ because otherwise there would be a proper subset $B \subset M \cup \{u_0\}$ such that $Y \cup B$ is dependent in $\mathcal{M}$, thus implying that B is dependent also in $\mathcal{M}'$, in a contradiction with our assumption that $M \cup \{u_0\}$ is a circuit of $\mathcal{M}'$. Let $Y' \cup M \cup \{u_0\}$ be that circuit of $\mathcal{M}$, where $Y' \subseteq Y$. Hence, by the characterization of the matroid that corresponds to a given access structure, $Y' \cup M$ is a minterm of Γ . Hence, $Y \cup M$ is in Γ , and, consequently, $M \in \Gamma_{Y,X}$. It is left to show that M is a minterm of $\Gamma_{Y,X}$. Let M' be a proper subset of M . Since $M \cup \{u_0\}$ is a circuit of $\mathcal{M}'$, the set $M' \cup \{u_0\}$ is independent in $\mathcal{M}'$. This implies that $Y \cup M' \cup \{u_0\}$ is independent in $\mathcal{M}$. Therefore $Y \cup M' \notin \Gamma$, and thus $M' \notin \Gamma_{Y,X}$. This completes the proof of the first direction.

For the second direction, assume that M is a minterm of $\Gamma_{Y,X}$. We next prove that $M \cup \{u_0\}$ is dependent in $\mathcal{M}'$. The set $Y \cup M$ is authorized in Γ . Let $Y' \subseteq Y$ be such that $Y' \cup M \in \Gamma$ and $|Y'|$ is minimal (it is possible that $Y' = \emptyset$). We claim that $Y' \cup M$ is a minterm of Γ : Indeed, every user in Y' is critical in $Y' \cup M$, as implied by the minimality of $|Y'|$; on the other hand, every user in M is critical, for otherwise

M would have a proper subset $M' \subset M$ such that $Y \cup M' \in \Gamma$, thus contradicting our assumption that M is a minterm of $\Gamma_{Y,X}$. It follows that $Y' \cup M \cup \{u_0\}$ is a circuit of $\mathcal{M}$. Therefore, the set $Y \cup M \cup \{u_0\}$ is dependent in $\mathcal{M}$. This implies that $M \cup \{u_0\}$ is dependent in $\mathcal{M}'$.

To complete the proof we need to prove that $M \cup \{u_0\}$ is a circuit in $\mathcal{M}'$. Assume towards a contradiction that $M \cup \{u_0\}$ properly contains a circuit of $\mathcal{M}'$. If this circuit is of the form $M' \cup \{u_0\}$, for some $M' \subset M$, then by the proof of the first direction, M' is a minterm of $\Gamma_{Y,X}$, contradicting the fact that M is a minterm of $\Gamma_{Y,X}$. Therefore, the circuit is some $M' \subseteq M$. This implies that $Y \cup M'$ is dependent in $\mathcal{M}$. Hence, there exists $Y'' \subseteq Y$ such that $Y'' \cup M'$ is a circuit of $\mathcal{M}$. However, as shown earlier, $Y' \cup M \cup \{u_0\}$ is a circuit of $\mathcal{M}$ as well, for some $Y' \subseteq Y$. Applying Lemma 4.6 for these two circuits, with e being an arbitrary user in M' , and $d = u_0$, we get that there is a circuit contained in $(M \setminus \{e\}) \cup Y \cup \{u_0\}$ that contains u_0 . This implies that $(M \setminus \{e\}) \cup Y \in \Gamma$, whence $(M \setminus \{e\}) \in \Gamma_{Y,X}$, in contradiction to our assumption that M is a minterm of $\Gamma_{Y,X}$. $\square$

A special family of restrictions of Γ are restrictions in which $Y = \emptyset$, i.e., $\Gamma_{\emptyset,X}$. Such a restriction consists of all subsets of X that are authorized in Γ . We shall refer to such a restriction simply as *the restriction of Γ to X* . We conclude with a trivial claim regarding restrictions of WTASs.

CLAIM 4.13. *Let $X, Y \in U$ such that $X \cap Y = \emptyset$. If Γ is a WTAS, then $\Gamma_{Y,X}$ is a WTAS.*

5. WTASs and matroids. In this section we prove several properties of matroids that are associated with ideal WTASs. These properties will serve us later in characterizing ideal WTASs. Let Γ be an ideal WTAS on $U = \{u_1, \dots, u_n\}$ corresponding to a weight function $w : U \rightarrow \mathbb{N}$ and a threshold T . Let $\mathcal{M}$ be the matroid corresponding to Γ .

An authorized set of Γ may contain many different minterms. The following simple lemma shows that one of these minterms is a suffix of the set.

LEMMA 5.1. *Any $X \in \Gamma$ contains a suffix minterm. Namely, if $X = \{x_1, \dots, x_k\}$ and $X \in \Gamma$, then there exists $i \in [k]$ such that $X_{i,k} = \{x_i, \dots, x_k\}$ is a minterm.*

Proof. Let $s \in [k]$ be the largest index such that $X_{s,k}$ is authorized. We claim that $X_{s,k}$ is a minterm. Indeed, x_s is critical for $X_{s,k}$ since, removing it from $X_{s,k}$, we get $X_{s+1,k}$, which is unauthorized by the choice of s . Consequently, every user $x_i \in X_{s,k}$ is critical because x_s has the smallest weight in $X_{s,k}$. Therefore, $X_{s,k}$ is a minterm. $\square$

We saw that minterms of Γ are independent sets of $\mathcal{M}$. Different minterms of Γ may be of different sizes. By Claim 4.7, if M and M' are minterms and $|M| < |M'|$, we can add (at least $|M'| - |M|$) users to M such that the resulting set is still an independent set of $\mathcal{M}$. The next lemma asserts that the users that may be added to M must have a smaller weight than the weight of every member of M .

LEMMA 5.2. *Let M be a minterm of Γ . Let $y \in U \setminus M$ be a user such that $w(M_{\min}) \leq w(y)$. Then $M \cup \{y\}$ is a dependent set of $\mathcal{M}$.*

Proof. Let $X = (M \setminus \{M_{\min}\}) \cup \{y\}$ be the set that is obtained by replacing the minimal element of M with y . Since $w(X) \geq w(M)$, the set X is authorized, and thus it contains a minterm M' . Moreover, $M \neq M'$ since $M_{\min} \in M \setminus M'$. Therefore, by Corollary 4.5, the set $M \cup M' = M \cup \{y\}$ is dependent in $\mathcal{M}$. $\square$

While Γ may have minterms of different cardinalities, we show in the next lemma that whenever two minterms have the same minimal member they must be of the same size.

LEMMA 5.3. *Let X and Y be minterms of the access structure Γ such that $X_{\min} = Y_{\min}$. Then $|X| = |Y|$.*

Proof. As X and Y are minterms, they are independent sets of the matroid $\mathcal{M}$. Assume that $|X| < |Y|$. Then, by axiom (I3) of the matroid definition, there exists $y \in Y \setminus X$ such that the set $X \cup \{y\}$ is independent. However, as $X_{\min} = Y_{\min}$ is a user with the minimal weight in both X and Y , we have that $w(X_{\min}) \leq w(y)$. Consequently, in view of Lemma 5.2, the set $X \cup \{y\}$ is dependent. This contradiction implies that $|X| \geq |Y|$. Arguing along the same lines, we conclude that also $|X| \leq |Y|$, whence both minterms are of the same size. $\square$

In the matroid $\mathcal{M}$ corresponding to an access structure Γ , each minterm M of Γ defined a circuit $M \cup \{u_0\}$ in $\mathcal{M}$. This may be viewed as a *local* relation between the minterms of Γ and the dependent sets of $\mathcal{M}$. However, when dealing with WTASs, the *global* structure of Γ enables us to prove the dependency of various sets in $\mathcal{M}$. It turns out that the lexicographic order on the minterms of Γ , with respect to the relation $\prec$ (defined in section 2.3), is strongly related to dependence in $\mathcal{M}$. This is demonstrated through the following definition and lemmas.

DEFINITION 5.4 (canonical complement). *Let P be a prefix of some minterm of Γ . Let $Y \subseteq U$ be the lexicographically minimal set such that*

- $P_{\max} \prec Y_{\min}$, and
- the set $P \cup Y$ is a minterm of Γ .

Then the set Y is called the canonical complement of P .

The following lemma shows that replacing the canonical complement by a user that precedes the first element of the canonical complement results in a dependent set.

LEMMA 5.5. *Let P be a prefix of some minterm of Γ . Let $Y = \{y_1, \dots, y_t\}$ be the canonical complement of P , and let b be a user such that $P_{\max} \prec b \prec y_1$. Then $P \cup \{b\}$ is dependent. Furthermore, the set $P \cup \{b\}$ includes a unique circuit, and that circuit contains b .*

Proof. If $P = \emptyset$, then, since Γ is connected, there exists a minterm that starts with u_1 , whence $y_1 = u_1$. Therefore, it cannot be that $b \prec y_1$, and thus the claim is trivially true. Otherwise, if $P \neq \emptyset$, denote by M_1 the minterm $M_1 = P \cup Y$. Let $X_2 = (M_1 \setminus \{P_{\max}\}) \cup \{b\}$ be the set resulting from replacing $P_{\max}$ with b in M_1 . Since $w(P_{\max}) \leq w(b)$, the set X_2 is authorized (though not necessarily a minterm). Let M_2 be the suffix minterm contained in X_2 (such a minterm exists in view of Lemma 5.1). It must be that $b \in M_2$, since otherwise $M_2 \subseteq Y$, where Y —the canonical complement of P —is a proper subset of a minterm and thus is unauthorized.

Let $A = M_1 \cup M_2 = P \cup \{b\} \cup Y$. We proceed to show that every user in Y is critical for A . This will show that $D(M_1, M_2) \subseteq (M_1 \cup M_2) \setminus Y = P \cup \{b\}$. But since, by Corollary 4.5, the set $D(M_1, M_2)$ is dependent, this will imply that also $P \cup \{b\}$ is dependent. We also observe that it is sufficient to show that $Y_{\min} = y_1$ is critical for A ; this will imply that also all other members of Y , having weight that is no smaller than $w(y_1)$, are also critical for A .

In view of the above, it suffices to show that y_1 is critical for A . Suppose this is not the case; namely, the set $A \setminus \{y_1\}$ is authorized. Since $A \setminus \{y_1\}$ results from M_1 by replacing y_1 by b , where $w(b) \leq w(y_1)$, and since M_1 is a minterm, it must be that $A \setminus \{y_1\}$ is also a minterm. But this is a contradiction to the choice of y_1 as the first element in the canonical complement of P . Hence, all the elements of Y are critical for A , and consequently $P \cup \{b\}$ is dependent.

Since P is part of a minterm, it must be that P is independent. Thus, by

Claim 4.8, the set $P \cup \{b\}$ must contain a unique circuit, and that circuit contains b . $\square$

The next lemma is a generalization of Lemma 5.5. Given a prefix P of some minterm, it gives a sufficient condition for a set $B \subseteq U$ so that $P \cup B$ is dependent in $\mathcal{M}$. It plays an essential role in our study of the characterization of ideal WTASs.

LEMMA 5.6. *Let P be a prefix of some minterm of Γ . Let $Y = \{y_1, \dots, y_t\}$ be the canonical complement of P , and $B = \{b_1, \dots, b_j\}$ be a set such that $P_{\max} \prec B_{\min}$ and $b_j \prec y_j$. Then, the set $P \cup B$ is dependent.*

Proof. The proof is by induction on j . The case $j = 1$ is handled by Lemma 5.5. We assume that the lemma holds for all $i \in [j - 1]$ and proceed to prove it for $i = j$. If $b_i \prec y_i$ for some $i \in [j - 1]$, then the statement of the lemma holds by induction (in fact, in that case we conclude that $P \cup B_{1,i}$ is dependent, which is a stronger claim than what we need to show). Therefore, we may assume hereinafter that $y_i = b_i$ or $y_i \prec b_i$ for all $i \in [j - 1]$.

Assume towards a contradiction that $P \cup B$ is independent. Denote $D = P \cup \{y_1\} \cup B$ and $P' = P \cup \{y_1\}$. The canonical complement of P' is $Y_{2,t}$. On the other hand, since $P'_{\max} = y_1 \preceq b_1 \prec b_2$, and $b_j \prec y_j$, the induction hypothesis, applied to P' and $B_{2,j}$, implies that $P' \cup B_{2,j}$ is dependent. Since $P' \cup B_{2,j} \subseteq D$, the set D is also dependent. Therefore, since we assumed that $P \cup B$ is independent, Claim 4.8 implies that D contains a unique circuit C . The uniqueness of the circuit C in D and the fact that $P' \cup B_{2,j}$ is a dependent subset of D imply that $C \subseteq P' \cup B_{2,j}$. This, in turn, implies that $b_1 \notin C$, unless $y_1 = b_1$. This will allow us to derive a contradiction.

There are three possible cases regarding the position of b_1 with respect to the members of Y : $y_1 = b_1$, $y_1 \prec b_1 \prec y_2$, or $y_2 \preceq b_1$. The first case is trivial: If $y_1 = b_1$, then $P \cup B = P' \cup B_{2,j}$, and thus it is dependent, in contradiction to our assumption.

If $y_1 \prec b_1 \prec y_2$, then by Lemma 5.5, applied to P' and b_1 , the set $P' \cup \{b_1\}$ is dependent and contains a circuit C' that contains b_1 . As $b_1 \in C'$ and $b_1 \notin C$, we conclude that $C \neq C'$. However, as $C' \subseteq D$, this contradicts the uniqueness of the circuit C in D .

The only case left is $y_2 \preceq b_1$. As P' is independent, there must be an index $s \in \{2, \dots, j\}$ such that $b_s \in C$ (for, otherwise, as $b_1 \notin C$, $C \cap B = \emptyset$, and, consequently, $C \subseteq P'$). Consider the set $B^s = B \setminus \{b_s\}$. Since $|B^s| = j - 1$, $P'_{\max} = y_1 \prec b_1 = B_{\min}^s$, and the $(j - 1)$ th element of B^s (which is either b_j , if $s < j$, or b_{j-1}) precedes the $(j - 1)$ th element of the canonical complement of P' (which is y_j), we conclude, by the induction hypothesis, that $P' \cup B^s$ is dependent. Therefore, it contains a circuit C'' that does not contain b_s . Since $b_s \in C$ but $b_s \notin C''$, we infer that $C \neq C''$. However, as $C'' \subseteq D$, this contradicts the uniqueness of C in D . This completes the proof that the set $P \cup B$ is dependent. $\square$

6. WTASs and HTASs. In this section we discuss the family of HTASs, from Definition 3.1, and their relation to WTASs. In section 6.1 we prove certain properties of the matroids associated with such access structures. In section 6.2 we characterize the intersection between HTASs and WTASs. Finally, in section 6.3, we show that if an ideal WTAS has a minterm in the form of a prefix of U , then it is in fact an HTAS.

When discussing an HTAS on some set $U = \{u_1, \dots, u_n\}$, we shall assume that the users in U are ordered according to their position in the hierarchy, from the lowest level to the highest. Namely, that

$$(6.1) \quad L_i = U_{\ell_i, \ell_{i+1}-1} = \{u_{\ell_i}, \dots, u_{\ell_{i+1}-1}\} \quad \forall i \in [m]$$

for some sequence $\ell_1 = 1 < \ell_2 < \dots < \ell_m < \ell_{m+1} = n + 1$. Given a nonempty subset $A \subseteq U$, if $A_{\min} \in L_i$, then A is said to be of level i and is denoted by $L(A) = i$.

6.1. The matroid associated with HTASs. Since any HTAS Γ_H is ideal [6, 35], Theorem 4.1 implies that there exists a matroid $\mathcal{M}$ that is associated with it. We derive herein some properties of such matroids that will be used later in our study of the structure of matroids corresponding to ideal WTASs.

CLAIM 6.1. *Let Γ_H and $\mathcal{M}$ be an HTAS and its associated matroid. Then every circuit of $\mathcal{M}$ not containing u_0 is a union of two distinct minterms.*

Proof. By Corollary 4.4, the circuits of the matroid $\mathcal{M}$ that do not contain u_0 are the union of two minterms of Γ_H , excluding users that are critical to that union. All that needs to be shown is that if M_1, M_2 are two minterms in Γ_H , no user in their union, $u \in M_1 \cup M_2$, is critical. Assume, without loss of generality, that $L(M_1) = i \leq L(M_2)$. Then, as M_1 is a minterm, we conclude that it satisfies the i th threshold condition with an equality; namely, M_1 has k_i users from $\bigcup_{j=i}^m L_j$. Hence, since $M_2 \subseteq \bigcup_{j=i}^m L_j$ and $M_2 \neq \emptyset$, the union $M_1 \cup M_2$ has at least $k_i + 1$ users from $\bigcup_{j=i}^m L_j$. Therefore, we can remove any user from $M_1 \cup M_2$ and still have an authorized set. Hence, no user $u \in M_1 \cup M_2$ is critical for the union. $\square$

CLAIM 6.2. *Let Γ_H and $\mathcal{M}$ be an HTAS and its associated matroid. Then U_{1,k_1+1} is a circuit of $\mathcal{M}$.*

Proof. Consider the two sets U_{1,k_1} and U_{2,k_1+1} . The first one is a minterm of Γ_H . Regarding the second, there are two options: either U_{2,k_1+1} is a minterm (satisfying the k_1 -threshold condition), or it satisfies already the k_2 -threshold condition (this may happen only if $|L_1| = \ell_2 - 1 = k_1 - k_2 + 1$, which is the minimal possible value for the size of that level). In both cases, U_{2,k_1+1} contains a minterm that includes u_{k_1+1} . Hence, U_{1,k_1+1} is a union of two distinct minterms, and therefore, by Corollary 4.5, it is dependent. We claim that it is actually a circuit. If not, then it must contain a circuit C of size smaller than $k_1 + 1$. By Claim 6.1, this circuit is a union of two minterms. Since its size is smaller than $k_1 + 1$, it must be a union of two minterms from levels L_2 and above. However, by Remark 3.2, $|L_1| \geq k_1 - k_2 + 1$, or, equivalently, $|U_{1,k_1+1}| - |L_1| \leq k_2$. This implies that the set U_{1,k_1+1} contains at most k_2 users from levels L_2 and above. Since any minterm from levels L_2 and above must be of size at least k_2 , we infer that U_{1,k_1+1} can contain at most one minterm from those levels. This contradicts our earlier conclusion that it is a union of two minterms from those levels. We therefore conclude that C must be a circuit of $\mathcal{M}$. $\square$

6.2. The intersection of WTASs and HTASs. Let U be a set of users and let Γ be a monotone access structure on U that is both a WTAS and an HTAS. Namely, on one hand, there exist a weight function $w : U \rightarrow \mathbb{N}$ and a threshold $T \in \mathbb{N}$ such that Γ is the corresponding WTAS on U and, on the other hand, there exist a hierarchy in U , where $U = \bigcup_{i=1}^m L_i$, and thresholds $k_1 > k_2 > \dots > k_m$ such that Γ is also the corresponding HTAS on U . Our goal herein is to characterize such access structures that belong to those two classes of access structures.

It should be noted that in the following discussion we cannot assume that the levels of U in the HTAS are nicely organized in a monotonic order as in (6.1).

We proceed with some notation. Let A_i , where $i \in [m - 1]$, denote a subset of $k_i - k_{i+1}$ users of largest weights in L_i , and let A_m be a subset of $k_m - 1$ users of largest weights in L_m . We also let a_i denote a user of minimal weight in L_i , for all $i \in [m]$. Note that, by Remark 3.2, we have that $a_i \in L_i \setminus A_i$ for every $i \in [m]$.

We set $A = \bigcup_{i=1}^m A_i$ and $B = A_m \cup \{a_m\}$. The set A is unauthorized since it fails to satisfy each of the threshold conditions by exactly one user, while B is authorized since it is composed of k_m users of level L_m . Therefore $w(A) < T$ and $w(B) \geq T$. But as $B = A \cup \{a_m\} \setminus (A \setminus A_m)$, we infer that

$$(6.2) \quad w(A \setminus A_m) < w(a_m).$$

We refer to the last level L_m in an HTAS as trivial if $k_m = 1$ (namely, all users of such a level are self-sufficient). We proceed to characterize access structures that are both WTAS and HTAS.

LEMMA 6.3. *If the last level is not trivial, then the number of levels m in the HTAS is at most 2.*

Proof. Assume that $m \geq 3$ and that the last level is not trivial, i.e., $k_m \geq 2$. Let Z_m be a subset of $k_m - 2 \geq 0$ users of largest weight in L_m . Define $Z_{m-1} = A_{m-1} \cup \{a_{m-1}\}$ and $Z_{m-2} = A_{m-2} \cup \{a_{m-2}\}$. Their union $Z = Z_{m-2} \cup Z_{m-1} \cup Z_m$ is authorized since its cardinality is $|Z| = |A_{m-2}| + |A_{m-1}| + k_m = k_{m-2}$, and consequently, it satisfies the $(m-2)$ th threshold condition.

Next, consider the set $B = Z \cup \{a_m\} \setminus (A_{m-1} \cup A_{m-2}) = Z_m \cup \{a_{m-2}, a_{m-1}, a_m\}$. Since, by (6.2), $w(A_{m-1} \cup A_{m-2}) < w(a_m)$, the definition of B implies that $w(B) > w(Z)$. Therefore, as Z is authorized, so is B . However, while B is authorized in the WTAS, it is unauthorized in the HTAS, as implied by the following inequalities: $|B \cap L_m| = |Z_m \cup \{a_m\}| = k_m - 1 < k_m$, $|B \cap (L_{m-1} \cup L_m)| = k_m < k_{m-1}$, and $|B| = k_m + 1 < k_{m-2}$. This contradiction implies that either $m \leq 2$ or the last level is trivial. $\square$

According to Lemma 6.3, access structures that are both WTAS and HTAS and have no self-sufficient users have a very simple hierarchical structure: Either there is one level (in which case the access structure is a simple threshold access structure) or two levels. In the latter case, we show below that if the difference between k_1 and k_2 is larger than 1, the size of the first level is minimal (see Remark 3.2).

LEMMA 6.4. *If the last level is not trivial, $m = 2$, and $k_1 - k_2 > 1$, then $|L_1| = k_1 - k_2 + 1$.*

Proof. Assume towards a contradiction that $|L_1| > k_1 - k_2 + 1$. Let Z_2 be a subset with $k_2 - 2$ users of largest weight in L_2 and $Z_1 = A_1 \cup \{b_1, b_2\}$, where b_1 and b_2 are two users in $L_1 \setminus A_1$ (note that our assumptions imply that Z_1 and Z_2 are well defined). Their union $Z = Z_1 \cup Z_2$ is authorized since $|Z| = k_1$. Next, consider the set $B = Z \cup \{a_2\} \setminus A_1 = Z_2 \cup \{a_2, b_1, b_2\}$. Since, by (6.2), $w(A_1) < w(a_2)$, we conclude that B is also authorized. Hence, it must be also authorized in the HTAS. However, as $|B \cap L_2| = k_2 - 1$ and $|B| = k_2 + 1 < k_1$, the set B is unauthorized in the HTAS. $\square$

Lemmas 6.3 and 6.4 imply that if Γ is an access structure on U that is both a WTAS and an HTAS, and if U has no self-sufficient users (i.e., the last level in the HTAS is not trivial), then either $m = 1$ or $m = 2$, where in the latter case either $k_1 = k_2 + 1$ or $|L_1| = k_1 - k_2 + 1$. If, on the other hand, the access structure has self-sufficient users, i.e., the last level in the HTAS is trivial, then its restriction to the first $m-1$ levels is still a WTAS as well as an HTAS, and, in addition, that restriction has no self-sufficient users. This implies that the structure of that restriction is as described above. This is summarized as follows.

CLAIM 6.5. *Let Γ be both a WTAS and an HTAS. Then the HTAS-parameters of Γ satisfy one of the following conditions:*

1. $m = 1$.

2. $m = 2$ and $k_1 = k_2 + 1$.
3. $m = 2$ and $|L_1| = k_1 - k_2 + 1$.
4. $m \in \{2, 3\}$, the level L_m is trivial, and the restriction of Γ_H to the first $m - 1$ levels is of the form that is described in cases 1–3.

To complete the characterization we proceed to prove the converse. Namely, that any HTAS with parameters as described in Claim 6.5 is also a WTAS. This is shown by constructing the appropriate weight function and threshold in each case.

CLAIM 6.6. *Let Γ_H be an HTAS that satisfies one of the conditions in Claim 6.5. Then there exist a weight function and a threshold such that Γ_H coincides with the corresponding WTAS.*

Proof. Case 1 is a simple threshold, so we can assign each user the weight 1 and set the threshold to k_1 . In case 2, the weight assigned to every user in L_1 is k_2 , the weight assigned to users in L_2 is k_1 , and the threshold is $k_1 \cdot k_2$. In case 3, the weight assigned to users in L_1 and L_2 is 1 and $k_1 - k_2 + 1$, respectively, while the threshold is $k_2(k_1 - k_2 + 1)$. In case 4, we assign weights to the users in the first $m - 1$ levels and set an appropriate threshold according to the condition that is satisfied by the restriction of Γ_H to the first $m - 1$ levels and the rules that were described above for the first three cases; in addition, we assign to every user in the trivial level a weight that equals the threshold. In all four cases it is a straightforward matter to verify that the induced WTAS coincides with the original HTAS. $\square$

6.3. Ideal WTASs with a prefix minterm are HTASs. In this section we make the first step towards proving our main result, Theorem 3.5. Let Γ be an ideal WTAS on a set U of n users, corresponding to a weight function $w : U \rightarrow \mathbb{N}$ and a threshold T . Assume that U possesses a prefix minterm $U_{1,k}$ for some $k \in [n]$ (namely, there exists $k \in [n]$ such that the k users of smallest weights form a minterm). We claim that Γ is an HTAS. We first describe the partition of U into levels and determine the corresponding thresholds. Denoting the resulting HTAS by Γ_H , we proceed to prove that $\Gamma = \Gamma_H$.

The decomposition of U to levels will respect the order of users according to their weights. Namely, each level will be a run of U , and our goal is to determine the transition points between one level and the subsequent one. Since $U_{1,k}$ is a minterm, $U_{1,i}$ is authorized for every $i \in \{k, \dots, n\}$. By Lemma 5.1, for every such i there exists a run-minterm ending at u_i . Let us denote the length of that run-minterm by μ_i . By the nondecreasing monotonicity of the weights, we infer that the sequence of lengths $\boldsymbol{\mu} = (\mu_i)_{k \leq i \leq n}$ is monotonically nonincreasing. Denote by m the number of distinct values assumed by the sequence $\boldsymbol{\mu}$, and let us denote those values by $k_1 > \dots > k_m$. Then the HTAS Γ_H is defined as follows: m is the number of levels, and k_i is the i th threshold. As for the levels, we denote by ℓ_i , where $i \in [m]$, the index of the first user in the first run-minterm of length k_i (e.g., $\ell_1 = 1$ since $U_{1,k}$ is the first run-minterm of length $k = k_1$ and its first user is u_1); then the i th level in the hierarchy is $L_i = U_{\ell_i, \ell_{i+1}-1}$, where $\ell_{m+1} = n + 1$.

In addition, we denote by U_{s_i, t_i} the right-most run-minterm whose length is k_i , where $i \in [m]$, and consider the set $A_i = U_{s_i+1, \ell_{i+1}-1}$. As U_{s_i, t_i} is the last minterm that contains k_i users and U_{ℓ_{i+1}, t_i+1} is the first minterm that contains k_{i+1} users, the set A_i consists of the last $k_i - k_{i+1}$ users in L_i , where $k_{m+1} = 1$. (Note that if u is the last element of the *last* k_i -long minterm and u' is the last element in the *first* k_{i+1} -long minterm, then u and u' are consecutive elements.) An important observation regarding those subsets is that, given $i \in [m]$ and $u_h \in A_i$, there is no run-minterm of the WTAS Γ that starts with u_h ; indeed, if $U_{h,j}$ were a run-minterm, then it would

FIG. 6.1. A WTAS that is also an HTAS.

be a proper subset of the minterm U_{s_i, t_i} if $j \leq t_i$, or a proper superset of the minterm U_{ℓ_{i+1}, t_i+1} if $j \geq t_i + 1$.

An illustration of the construction of the levels of the HTAS appears in Figure 6.1. The example in the illustration is of a WTAS with 14 users of weights 5, 5, 5, 5, 6, 6, 6, 6, 6, 6, 30, 30, 30 and threshold $T = 30$. The vertical dashed lines indicate the three levels in the corresponding HTAS (the third one being a trivial one), and the horizontal lines indicate all of the run-minterms in that access structure.

Next, we prove that the WTAS Γ coincides with the HTAS Γ_H described above.

THEOREM 6.7. *Let Γ be an ideal WTAS on U that has a prefix minterm. Then Γ is an HTAS.*

Proof. Let Γ_H be the HTAS as described above. We will prove that $\Gamma = \Gamma_H$, thus showing that Γ is an HTAS. We start by proving that $\Gamma_H \subseteq \Gamma$. Let $X \in \Gamma_H$. Then for some $i \in [m]$ the set X has at least k_i users from $\bigcup_{j=i}^m L_j$. Letting $B_i = U_{\ell_i, \ell_i + k_i - 1}$ denote the set of the first k_i users from $\bigcup_{j=i}^m L_j$, the nondecreasing monotonicity of the weights implies that $w(X) \geq w(B_i)$. By the construction of levels in Γ_H , the set B_i is a minterm of Γ , whence $w(B_i) \geq T$. Therefore, $w(X) \geq T$ and, consequently, $X \in \Gamma$.

Conversely, assume that $X \notin \Gamma_H$. Then X has at most $k_i - 1$ users from $\bigcup_{j=i}^m L_j$, for every $i \in [m]$. Consider the set $A = \bigcup_{i=1}^m A_i$. By the definition of A , it has exactly $k_i - 1$ users from $\bigcup_{j=i}^m L_j$, for every $i \in [m]$. Moreover, A is the set with the maximal weight among the sets that are unauthorized in the HTAS, and thus $w(X) \leq w(A)$. Therefore, it suffices to show that $A \notin \Gamma$ in order to conclude that $X \notin \Gamma$ and, thus, complete the proof.

To this end, assume that $A \in \Gamma$. Then A contains some minterm $M \in \Gamma$. Assume that M is of level i , $L(M) = i$; namely, i is the lowest level for which $M \cap L_i \neq \emptyset$. Then $M \cap A_i$ is a prefix of M . In order to arrive at a contradiction, we proceed to show that there can be no minterm of Γ that has a prefix which is a subset of A_i for some $i \in [m]$.

Assume, by contradiction, that there are such minterms, and let M' be the lexicographically minimal minterm of Γ of that sort. Let $u_h = M'_{\min}$, and let j be the maximal index such that $M' = U_{h,j} \cup Z$ for some $Z \subset U$. Since $u_h \in A_i$ for some $i \in [m]$, and we observed earlier that no run-minterm of Γ starts in A_i , we conclude that $Z \neq \emptyset$ (and $u_{j+1} \prec Z_{\min}$ because of the maximality of j). We claim that

$j < t_i$. Indeed, if $j \geq t_i$, then M' is a proper superset of $\hat{M} = U_{\ell_{i+1}, t_i} \cup \{Z_{\min}\}$. As $w(\hat{M}) \geq w(U_{\ell_{i+1}, t_i+1}) \geq T$, we conclude that $\hat{M} \in \Gamma$. But then we get a contradiction since a minterm M' cannot be a proper superset of an authorized set $\hat{M}$.

Next, define $Q = M' \cup \{u_{j+1}\} \setminus \{u_j\}$. The set Q is authorized in Γ , and, by Lemma 5.1, it contains a suffix minterm M'' that must contain u_{j+1} , for otherwise it would be a proper subset of M' . Therefore, $M' \cup M'' = M' \cup \{u_{j+1}\} = U_{h,j} \cup \{u_{j+1}\} \cup Z$. We claim that all members of Z are critical for this union. Assume, by contradiction, that $M^* = M' \cup \{u_{j+1}\} \setminus \{z\}$ is authorized, for some $z \in Z$. Since $w(u_{j+1}) \leq w(z)$ and M' was a minterm of Γ , also M^* is a minterm of Γ . But M^* is a minterm of Γ that starts within A_i and $M^* \prec M'$, thus contradicting our choice of M' . Hence, by Corollary 4.5, the set $U_{h,j+1}$ is dependent in $\mathcal{M}$. However, since $s_i < h$ and $j+1 \leq t_i$, this dependent set is properly contained in the minterm U_{s_i, t_i} , leading to a contradiction. Hence, $A \notin \Gamma$, and the proof is thus complete. $\square$

7. Ideal WTASs and TPASs. In the previous section we dealt with the case where the lexicographically minimal minterm of Γ is a prefix; of U . Here, we handle the case where the lexicographically minimal minterm of Γ is a lacunary prefix; namely, it takes the form $M = U_{1,d} \cup U_{d+2,k}$ for some $1 \leq d \leq k-2$ and $k \leq n$. Throughout this section we assume that there is at least one minterm starting with the user u_2 , and that there are no self-sufficient users. If this is not the case, then Γ is a simple composition of access structures, as shown in section 8.2. The section is organized as follows. First we show that $U_{2,k}$ must be a minterm of Γ . Consequently, we show that Γ is one of the two TPASs that were defined in Definition 3.3. Finally, in section 7.1, we design linear ideal secret sharing schemes that realize TPASs.

Consider the set $U_{2,k}$. As $U_{2,k} = M \cup \{u_{d+1}\} \setminus \{u_1\}$ and $w(u_{d+1}) \geq w(u_1)$, the set $U_{2,k}$ is authorized. We proceed to show that it is in fact a minterm of Γ .

CLAIM 7.1. *Let Γ be an ideal WTAS with $M = U_{1,d} \cup U_{d+2,k}$ being its lexicographical minimal minterm for some $1 \leq d \leq k-2$ and $k \leq n$. Then if there exists a minterm that has u_2 as its minimal user, $U_{2,k}$ is a minterm of Γ .*

Proof. Let M' be the lexicographically minimal minterm starting with u_2 . Assume towards a contradiction that the authorized set $U_{2,k}$ is not a minterm. The minterm M' cannot be a run-minterm since $U_{2,k-1}$ is unauthorized (as its weight does not exceed that of $M \setminus \{u_1\}$, which is a proper subset of the minterm M) and $U_{2,k}$ is already an authorized set (since $w(U_{2,k}) \geq w(M)$) that is not a minterm. Let s be the maximal index such that $U_{2,s} \subset M'$. In that case, as M' is not a run-minterm, $M' = U_{2,s} \cup Z$, where $Z \neq \emptyset$ and $u_{s+1} \prec Z_{\min}$. We claim that $s \leq k-2$. Assume, towards a contradiction, that $s \geq k-1$. Then $w(M') \geq w(U_{2,k-1}) + w(Z) \geq w(U_{2,k})$. However, as explained earlier, $U_{2,k}$ is an authorized subset that is not a minterm. Hence, if we remove from $U_{2,k}$ its minimal user— u_2 —we are left with a set that is still authorized. But M' weighs more than $U_{2,k}$ and it also contains u_2 , whence also $M' \setminus \{u_2\}$ is authorized. But this contradicts the fact that M' is a minterm. We conclude that M' —the lexicographically minimal minterm starting with u_2 —takes the form $M' = U_{2,s} \cup Z$, where $s \leq k-2$ and Z is a nonempty set with $Z_{\min} \succ u_{s+1}$.

As Z is the canonical complement of $U_{2,s}$, Lemma 5.5 implies that the set $U_{2,s+1}$ is dependent. Hence, it contains a circuit C_1 of the corresponding matroid $\mathcal{M}$. The circuit C_1 must include the user u_{d+1} (the user that is missing in the minterm M), since, otherwise, as $s+1 \leq k-1$, the circuit C_1 would be a subset of the minterm $M = U_{1,d} \cup U_{d+2,k}$. We claim, and prove in the next paragraph, that $U_{1,d+1}$ is also a circuit of $\mathcal{M}$. Since $u_1 \in U_{1,d+1}$ but $u_1 \notin C_1$, the sets C_1 and $U_{1,d+1}$ are two distinct circuits. In addition, both circuits include u_{d+1} . Therefore, by Lemma 4.6,

the set $C_1 \cup U_{1,d+1} \setminus \{u_{d+1}\}$ is dependent. However, this set is contained in the minterm $M = U_{1,d} \cup U_{d+2,k}$, which is an independent set of the matroid $\mathcal{M}$. This contradiction implies that $U_{2,k}$ is a minterm in Γ .

Hence, we need only to show that $U_{1,d+1}$ is a circuit of $\mathcal{M}$. Let $Y = U_{d+2,k}$, $X = U_{1,d+1}$ and consider $\Gamma_{Y,X}$, namely, the restriction of Γ induced by Y on X . By Lemma 4.11, $\Gamma_{Y,X}$ is an ideal WTAS, and $U_{1,d}$ is a prefix minterm in that access structure. Therefore, by Theorem 6.7, the access structure $\Gamma_{Y,X}$ is an HTAS, and, by Claim 6.2, the set $U_{1,d+1}$ is a circuit in the matroid corresponding to $\Gamma_{Y,X}$. By Lemma 5.5, applied with $P = U_{1,d}$, the set $U_{d+2,k}$ as the canonical complement of P , and $b = u_{d+1}$, the set $P \cup b = U_{1,d+1}$ is dependent in $\mathcal{M}$. Assume, by contradiction that it is not a circuit. Therefore, it possesses a proper subset $C' \subset U_{1,d+1}$ that is a circuit. By Lemma 4.12, the set C' would have to be dependent in the matroid corresponding to $\Gamma_{Y,X}$. But as $U_{1,d+1}$ is a circuit in that matroid, this is impossible. Hence, $U_{1,d+1}$ is also a circuit in $\mathcal{M}$. This completes the proof. $\square$

In view of the above, as we assume herein that there are minterms that start with u_2 , we conclude that $U_{2,k}$ is a minterm. This is a prefix minterm in the restriction of Γ to $U_{2,n}$, denoted hereinafter Γ' . Since Γ' is ideal by Lemma 4.11, and a WTAS by Claim 4.13, and has a prefix minterm, Theorem 6.7 implies that it is also an HTAS. Since we assumed that Γ has no self-sufficient users, then by Claim 6.5, the HTAS Γ' has at most two levels.

We separate our discussion into two cases, according to the number of levels in Γ' . First, we consider the case where Γ' is a simple threshold access structure.

CLAIM 7.2. *If Γ' is an HTAS of one level (i.e., it is a threshold access structure), then a set $X \subseteq U$ is in Γ if and only if $|X| \geq k - 1$ and $|X \cap U_{d+2,n}| \geq k - 1 - d$.*

Proof. Let us begin with sets X that do not include the user u_1 , namely, $X \subseteq U_{2,n}$. For such sets, the second threshold condition ($|X \cap U_{d+2,n}| \geq k - 1 - d$) is implied by the first one ($|X| \geq k - 1$). Since we assumed that Γ' , which is the restriction of Γ to $U_{2,n}$, is a simple threshold access structure, and the value of the threshold equals $|U_{2,k}| = k - 1$, the statement is straightforward in this case.

Next, consider sets X such that $u_1 \in X$. If X satisfies the two conditions in the claim, then its weight is no less than the weight of $M = U_{1,d} \cup U_{d+2,k}$. As $w(M) \geq T$, we conclude that $X \in \Gamma$. Conversely, assume that $X \in \Gamma$ but fails to satisfy one of the two conditions in the claim. Without loss of generality, we may assume that X is a minterm of Γ . Thus, by Lemma 5.3, $|X| = |M| = k - 1$. Therefore, X may violate only the second condition in the claim, namely, $|X \cap U_{d+2,n}| < k - 1 - d$. But then $U_{1,d+1} \subset X$, and that cannot be since then $X \prec M = U_{1,d} \cup U_{d+2,k}$ and M was assumed to be the lexicographically minimal minterm in Γ . $\square$

The access structure that is described in Claim 7.2 is a TPAS of type Δ_1 (see Definition 3.3) with

$$A = U_{1,d+1}, \quad B = U_{d+2,n-1}, \quad C = U_n, \quad m = k - 1, \quad t = 2.$$

It should be noted that a set X belongs to Δ_1 if it satisfies at least one of two threshold conditions. The second condition is $|X \cap C| \geq t$, which, in our case, is an empty condition (as $|C| = 1 < t = 2$). Hence, that access structure is in fact *bipartite*; namely, the question of whether X is authorized or not is determined only by the two numbers $|X \cap A|$ and $|X \cap (B \cup C)|$.

We are left with the case where Γ' is an HTAS of exactly two levels. Assume that $X \in \Gamma'$ if it has at least k_1 users from $U_{2,n}$ or at least k_2 users from $U_{r+1,n}$ for some $3 \leq r \leq n - 2$. As $U_{2,k}$ is a minterm, $k_1 = k - 1$.

CLAIM 7.3. *Under the above assumptions, a set $X \subseteq U$ is in Γ if and only if $|X \cap U_{r+1,n}| \geq k_2$ or both $|X| \geq k_1$ and $|X \cap U_{d+2,n}| \geq k_1 - d$.*

Proof. Assume first that $X \subseteq U$ satisfies one of the above two threshold conditions. If $|X \cap U_{r+1,n}| \geq k_2$, then $X \in \Gamma'$ and thus $X \in \Gamma$. If X satisfies the second condition, then it also belongs to Γ since the set of minimal weight X that satisfies both $|X| \geq k_1$ and $|X \cap U_{d+2,n}| \geq k_1 - d$ is $X = M = U_{1,d} \cup U_{d+2,k}$, and $M \in \Gamma$.

Assume next that $X \in \Gamma$. Without loss of generality, we may assume that X is a minterm and prove that it satisfies one of the two threshold conditions in the claim. We separate the discussion into two cases. If $u_1 \notin X$, then $X \in \Gamma'$. Thus either $|X \cap U_{r+1,n}| \geq k_2$ or $|X| \geq k_1$. If $|X| \geq k_1$, then, as $u_1 \notin X$, it must be that $|X \cap U_{d+2,n}| \geq k_1 - d$. If, on the other hand, $u_1 \in X$, then by Lemma 5.3, we get that $|X| = k_1$. But then, since no minterm contains $U_{1,d+1}$, it must be that $|X \cap U_{d+2,n}| \geq k_1 - d$. $\square$

The access structure Γ , as appears in Claim 7.3, coincides with one of the two TPASs in Definition 3.3. In case $r \geq d+1$, we set $A = U_{1,d+1}$, $B = U_{d+2,r}$, $C = U_{r+1,n}$, and then Γ is of type Δ_1 ,

$$\Gamma = \{X \subseteq U : (|X| \geq k_1 \text{ and } |X \cap (B \cup C)| \geq k_1 - d) \text{ or } |X \cap C| \geq k_2\}.$$

If, on the other hand, $r < d+1$, we claim that Γ is of type Δ_2 . To that end, we set $A = U_{1,r}$, $B = U_{r+1,d+1}$, and $C = U_{d+2,n}$. By Claim 7.3, the structure of Γ is

$$\Gamma = \{X \subseteq U : (|X| \geq k_1 \text{ and } |X \cap C| \geq k_1 - d) \text{ or } |X \cap (B \cup C)| \geq k_2\}.$$

It remains to show that the size of the set B is bounded, in accord with Definition 3.3.

CLAIM 7.4. *If $r < d+1$, then $|B| < d + k_2 - k_1$.*

Proof. The access structure Γ' , the restriction of Γ to $U_{2,n}$, is an HTAS of two levels. A set X is in Γ' if it has at least k_1 users from $U_{2,n}$ or at least k_2 users from $U_{r+1,n}$. Therefore, $U_{2,k} = U_{2,k_1+1}$ is a minterm and so is $U_{r+1,r+k_2}$. Consequently, $r + k_2 > k_1 + 1$ (since otherwise the second minterm would have been a proper subset of the first one). As $|B| = |U_{r+1,d+1}| = d + 1 - r$, we infer that $|B| < d + k_2 - k_1$. $\square$

Example 7.5. Consider the set $U = \{u_1, \dots, u_9\}$, and let Γ be a WTAS where the weights are 16, 16, 17, 18, 19, 24, 24, 24, and 24 and the threshold is 92. First note that there is no prefix minterm as $w(U_{1,5}) = 16 + 16 + 17 + 18 + 19 = 86 < 92$ and $w(U_{2,6}) = 16 + 17 + 18 + 19 + 24 = 94 \geq 92$, and thus $U_{1,6}$ is not a minterm. The lexicographically minimal minterm is $U_{1,3} \cup U_{5,6}$, and so $d = 3$ and $k = 6$. The HTAS structure resulting from the restriction of Γ to $U_{2,9}$ is composed of two levels $U_{2,5}$ and $U_{6,9}$, that is $r = 5$, with thresholds $k_1 = 5$ and $k_2 = 4$. Since $r > d + 1$, the access structure is of type Δ_1 . Setting $A = U_{1,4}$, $B = \{u_5\}$, and $C = U_{6,9}$, a set is authorized if it has at least four users from C , or if it has at least five users, at least two of whom are from $B \cup C$.

We summarize this section in the next theorem.

THEOREM 7.6. *Let Γ be an ideal WTAS with $M = U_{1,d} \cup U_{d+2,k}$ being its lexicographical minimal minterm for some $1 \leq d \leq k - 2$ and $k \leq n$. If there exists a minterm in Γ that has u_2 as its minimal member and Γ has no self-sufficient users, then Γ is a TPAS.*

7.1. Ideal linear secret sharing schemes for TPASs. We now turn to describe ideal linear secret sharing schemes that implement the TPASs Δ_1 and Δ_2 in Definition 3.3. Those schemes extend the ideas of the schemes that were presented

in [25] for bipartite access structures. In fact, if we take $B = \emptyset$, then our schemes coincide with the schemes of [25].

Let us first briefly recall the definition of those access structures. Assume that $|U| = n$ and $U = A \cup B \cup C$, where A , B , and C are disjoint, and $A, C \neq \emptyset$. Let $m, d, t \in \mathbb{N}$ be positive integers such that $m \geq t$. Then

$$\Delta_1 = \{X \subseteq U : (|X| \geq m \text{ and } |X \cap (B \cup C)| \geq m - d) \text{ or } |X \cap C| \geq t\}$$

and

$$\Delta_2 = \{X \subseteq U : (|X| \geq m \text{ and } |X \cap C| \geq m - d) \text{ or } |X \cap (B \cup C)| \geq t\},$$

where in Δ_2 the size of B is restricted to $|B| \leq d + t - m$.

Let $\mathbb{F}$ be a sufficiently large finite field. For a $\lambda \in \mathbb{F}$ and an integer s define the Vandermonde vector $\mathbf{V}_s(\lambda) := (1, \lambda, \lambda^2, \dots, \lambda^{s-1})$ (for clarity, we denote hereinafter all vectors with bold-faced letters). Recall that for any set $A \subseteq \mathbb{F}$ if $|A| \leq s$, then the vectors $\{\mathbf{V}_s(\lambda) : \lambda \in A\}$ are linearly independent. Thus, for any set $A \subseteq \mathbb{F}$ if $|A| \geq s$, the vectors $\{\mathbf{V}_s(\lambda) : \lambda \in A\}$ span the entire space $\mathbb{F}^s$. Let $E = \mathbb{F}^m$ and E_1 and E_2 be subspaces of E of dimensions d and t , respectively, such that if $d + t \geq m$, then $E = E_1 + E_2$; otherwise $E_1 \cap E_2 = \{\vec{0}\}$. Denote $r = \dim(E_1 \cap E_2) = \max(0, d + t - m)$. If $r > 0$, let $\Lambda = \{\lambda_1, \dots, \lambda_r\}$ be a set of elements from $\mathbb{F}$; otherwise $\Lambda = \emptyset$. Let

$$\varphi_1 : \mathbb{F}^d \rightarrow E_1 \quad \text{and} \quad \varphi_2 : \mathbb{F}^t \rightarrow E_2$$

be two isomorphisms such that

$$(7.1) \quad \varphi_1(\mathbf{V}_d(\lambda_i)) = \varphi_2(\mathbf{V}_t(\lambda_i)) \quad \forall \lambda_i \in \Lambda.$$

Finally, we define the functions $\mathbf{a} : \mathbb{F} \rightarrow E_1$ and $\mathbf{b} : \mathbb{F} \rightarrow E_2$ as follows:

$$\mathbf{a}(\lambda) = \varphi_1(\mathbf{V}_d(\lambda)) \quad \text{and} \quad \mathbf{b}(\lambda) = \varphi_2(\mathbf{V}_t(\lambda)) \quad \forall \lambda \in \mathbb{F}.$$

The target vector in the ideal linear secret sharing schemes that we construct below is $\mathbf{b}(\lambda_T)$ for some $\lambda_T \in \mathbb{F} \setminus \Lambda$. Note that the target vector is in $E_2 \setminus E_1$.

Next, we describe the function $\boldsymbol{\eta} : U \rightarrow E$ that assigns vectors from E to users in U , so that the vectors of authorized subsets span the target vector, while the vectors of unauthorized subsets do not; i.e., $\mathbf{b}(\lambda_T) \in \text{span}\{\boldsymbol{\eta}(S)\}$ if and only if $S \in \Gamma$. By Theorem 2.5, this implies that the scheme realizes Γ . The technique we use is similar for both types of access structures, $\Gamma = \Delta_1$ and $\Gamma = \Delta_2$. We assign the vectors to users one at a time and prove correctness by induction. Assume that we already assigned vectors to all users in $U' \subset U$ and that we wish to find a proper assignment of a vector to an additional user $u \in U \setminus U'$. We shall denote this stage in the assignment by $\langle U', u \rangle$. The goal is to find an assignment $\boldsymbol{\eta}(u)$ of a vector so that the following conditions hold:

- C1. If $S \subseteq U'$, $S \notin \Gamma$ but $S' := S \cup \{u\} \in \Gamma$, then $\boldsymbol{\eta}(u)$ should be such that $\mathbf{b}(\lambda_T) \in \text{span}\{\boldsymbol{\eta}(S')\}$.
- C2. If $S \subseteq U'$, $S \notin \Gamma$ and $S' := S \cup \{u\} \notin \Gamma$, then $\boldsymbol{\eta}(u)$ should be such that $\mathbf{b}(\lambda_T) \notin \text{span}\{\boldsymbol{\eta}(S')\}$.

We shall always look for the vector $\boldsymbol{\eta}(u)$ in a single-parameterized family of vectors $\{\boldsymbol{\zeta}(\lambda) \in E : \lambda \in \mathbb{F}\}$ (in the constructions that we present here, $\boldsymbol{\zeta}(\lambda)$ is one of $\mathbf{a}(\lambda)$, $\mathbf{b}(\lambda)$, and $\mathbf{V}_m(\lambda)$). Using Lemma 7.7 below, we shall show that at each stage of the assignment, $\langle U', u \rangle$, and for every $S \subseteq U'$, where $S \notin \Gamma$, there are finitely many bad

FIG. 7.1. The linear spaces in the proof of Lemma 7.7.

choices of the parameter λ that give rise to vectors $\eta(u) = \zeta(\lambda)$ that would violate the relevant condition above. Hence, since $|2^{U'} \setminus \Gamma|$ is bounded, there exists a good choice of λ such that $\eta(u) = \zeta(\lambda)$ satisfies all necessary conditions, provided that the field is sufficiently large. Thus, in the rest of the proof we bound the number of bad values for a specific set S .

Similarly to [25], it can be verified that the size of the field that our schemes require, which is the size of the domain of secrets and shares, is $2^{O(n)}$.

LEMMA 7.7. *Let $X \subseteq \mathbb{F}$ and $Y \subseteq \mathbb{F} \setminus \Lambda$ be such that $|X| < d$ and $|X| + |Y| < m$. Let $V = \text{span}\{\mathbf{a}(x), \mathbf{b}(y) : x \in X, y \in Y\}$. Then $E_1 \setminus V \neq \emptyset$.*

Proof. Hereinafter, let $V_X = \text{span}\{\mathbf{a}(x) : x \in X\}$, $V_Y = \text{span}\{\mathbf{b}(y) : y \in Y\}$, and $E_{1,2} = E_1 \cap E_2$ (see Figure 7.1 for an illustration of those linear spaces). Let us begin with the fairly easy case when $m \geq d + t$. In that case, since $E_1 \cap E_2 = \{\vec{0}\}$, we claim that $V \cap E_1 = V_X$, whence $\dim(E_1 \setminus V) = \dim E_1 - \dim V_X = d - |X| > 0$. Indeed, let $\mathbf{u}$ be an arbitrary vector from $V \cap E_1$. Then, on one hand, $\mathbf{u} = \mathbf{v}_x + \mathbf{v}_y$ for some $\mathbf{v}_x \in V_X$ and $\mathbf{v}_y \in V_Y$, and on the other hand, $\mathbf{u} \in E_1$. Therefore, $\mathbf{v}_y = \mathbf{u} - \mathbf{v}_x \in E_1 - V_X = E_1$. But since $\mathbf{v}_y \in V_Y \subseteq E_2$ and $E_1 \cap E_2 = \{\vec{0}\}$, we infer that $\mathbf{v}_y = \vec{0}$. This implies that $\mathbf{u} = \mathbf{v}_x \in V_X$.

Next, we prove the claim for the case where $r = d + t - m > 0$. Without loss of generality, we may assume that $|Y| = t - k$ for some $0 \leq k \leq r$. Indeed, if $|Y| > t$, it may be reduced to $Y^- \subset Y$ of size $|Y^-| = t$ without affecting V . If, on the other hand, $|Y| < t - r$, it may be extended to a superset $Y^+ \supset Y$ of size $|Y^+| = t - r$. Since $|X| + |Y^+| < d + t - r = m$, we may prove the statement for X and Y^+ and then infer that it also holds for X and Y .

Assume, towards a contradiction, that $E_1 \subseteq V$, whence $\dim(V \cap E_1) = \dim E_1 = d$. We claim that this assumption implies the following two statements:

$$(7.2) \quad \dim(V_Y \cap E_{1,2}) = r - k \quad \text{and} \quad \dim(V_X \cap E_{1,2}) < k.$$

After proving these two statements, we may derive the sought-after contradiction as follows. Since we assumed that $E_1 \subseteq V = V_X + V_Y$, all vectors $e \in E_{1,2}$ may be expressed as $e = x + y$, where $x \in V_X$ and $y \in V_Y$. But since $\dim E_{1,2} = r > \dim(V_X \cap E_{1,2}) + \dim(V_Y \cap E_{1,2})$, as implied by the two statements in (7.2), there exists at least one vector $e \in E_{1,2}$ such that $e = x + y$, for which either $x \in E_1 \setminus E_2$ or $y \in E_2 \setminus E_1$. Without loss of generality, we assume that $x \in E_1 \setminus E_2$. But then $x = e - y \in E_{1,2} + V_Y \subseteq E_2$, as opposed to our assumption that $x \notin E_2$.

Next, we prove the statements in (7.2). Let us begin with the equality in (7.2). The dimension of $E_{1,2} + V_Y$ is t since the $t - k$ base vectors of V_Y , namely $\{\mathbf{b}(y) : y \in Y\}$, may be extended to a full basis of E_2 by any k base vectors of $E_{1,2}$ of the form $\mathbf{b}(\lambda)$, $\lambda \in \Lambda$ (recall that $|\Lambda| = r \geq k$ and that $Y \subset \mathbb{F} \setminus \Lambda$). Therefore,

$$\dim(V_Y \cap E_{1,2}) = \dim V_Y + \dim E_{1,2} - \dim(E_{1,2} + V_Y) = (t - k) + r - t = r - k.$$

In order to prove the inequality in (7.2), we first prove that

$$(7.3) \quad \dim(V_X + E_{1,2}) = d.$$

Since $V_X + E_{1,2} \subseteq E_1$ and $\dim E_1 = d$, all we need to show is that $E_1 \subseteq V_X + E_{1,2}$. We assumed that $E_1 \subseteq V = V_X + V_Y$. Hence, for each $e \in E_1$ there exist $x \in V_X$ and $y \in V_Y$ such that $e = x + y$. But then $y = e - x \in E_1 + V_X = E_1$. Since $y \in V_Y \subset E_2$ we conclude that $y \in E_{1,2}$. This implies that $e \in V_X + E_{1,2}$, whence we arrive at the required conclusion that $E_1 \subseteq V_X + E_{1,2}$. Finally, the inequality in (7.2) is a straightforward consequence of (7.3). Indeed,

$$\dim(V_X \cap E_{1,2}) = \dim V_X + \dim E_{1,2} - \dim(V_X + E_{1,2}) = |X| + r - d;$$

recalling that $|X| < m - |Y| = m - t + k$ and $r = t + d - m$, we infer that $\dim(V_X \cap E_{1,2}) < k$. That concludes the proof. $\square$

7.1.1. Realizing Δ_1 . Here, Γ is an access structure of type Δ_1 . We assign the vectors in three stages. We first describe the assignment $\boldsymbol{\eta}(u)$ for all $u \in C$, then for $u \in A$, and finally for $u \in B$.

Step 1: Assigning vectors to users in C . Let $C = \{c_i\}_{1 \leq i \leq |C|}$, and let γ_i , where $1 \leq i \leq |C|$, be distinct elements of $\mathbb{F} \setminus \Lambda$, all different from λ_T . Then

$$\boldsymbol{\eta}(c_i) = \mathbf{b}(\gamma_i), \quad 1 \leq i \leq |C|.$$

This is essentially the Shamir t -out-of- $|C|$ scheme. Therefore, every t users in C can reconstruct $\mathbf{b}(\lambda_T)$, while no $t - 1$ users can.

Step 2: Assigning vectors to users in A . Let $A = \{a_i\}_{1 \leq i \leq |A|}$. Our claim is that, assuming $\mathbb{F}$ is large enough, we may find $\alpha_i \in \mathbb{F}$, where $1 \leq i \leq |A|$, so that the assignment $\boldsymbol{\eta}(a_i) = \mathbf{a}(\alpha_i)$ is consistent with Γ , restricted to $A \cup C$, and, in addition, for any $S \subseteq A \cup C$, where $S \notin \Gamma$, the following equality holds:

$$(7.4) \quad \dim \text{span}\{\boldsymbol{\eta}(S)\} = |S \cap (B \cup C)| + \min(|S \cap A|, d).$$

(Herein, we could have replaced $S \cap (B \cup C)$ with $S \cap C$, since S does not include users from B .) Namely, whenever we augment an unauthorized set $S \subseteq A \cup C$ with an additional user from A , the dimension of the corresponding subspace that is spanned by the vectors owned by S increases by 1, up to a limit of d users from A (i.e., all users from A beyond the first d ones are redundant). Using (7.4), we guarantee that if $S \in \Gamma$ and $|S \cap C| < t$, then the vectors assigned to S span E , and in particular, span the target vector $\mathbf{b}(\lambda_T)$. We shall prove this claim by induction. Assume that we already assigned vectors to $A_{1,j} := \{a_1, \dots, a_j\}$ for some $0 \leq j < |A|$, so that Γ is respected and (7.4) holds for all $S \in 2^{U'} \setminus \Gamma$, where $U' = A_{1,j} \cup C$. This assumption is obviously true for $j = 0$. We proceed to look for an assignment $\boldsymbol{\eta}(a_{j+1}) = \mathbf{a}(\alpha_{j+1})$ for the next user from A so that conditions C1 and C2 hold for all $S \in 2^{U'} \setminus \Gamma$ (in order to keep respecting Γ), and equality (7.4) holds for all $S \in 2^{U' \cup \{a_{j+1}\}} \setminus \Gamma$. As explained

earlier, it suffices to concentrate on a single set $S \in 2^{U'} \setminus \Gamma$ and bound the number of bad choices of $\alpha_{j+1} \in \mathbb{F}$ for that specific set.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{a_{j+1}\} \in \Gamma$. Since $|S'| = |S| + 1$ but $|S' \cap (B \cup C)| = |S \cap (B \cup C)|$, the fact that $S \notin \Gamma$ and $S' \in \Gamma$ implies that $|S| = m - 1$ and $|S \cap (B \cup C)| \geq m - d$. This, in turn, implies that $|S \cap A_{1,j}| < d$. Therefore, by Lemma 7.7, applied to $X = \{\alpha_i\}_{1 \leq i \leq j}$ and $Y = \{\gamma_i\}_{1 \leq i \leq |C|}$, the vectors owned by S span a subspace of E_1 of dimension $d - 1$ at the most. Hence, for all but at most $d - 1$ values of $\alpha_{j+1} \in \mathbb{F}$, we have $\dim \text{span}\{\boldsymbol{\eta}(S')\} = \dim \text{span}\{\boldsymbol{\eta}(S)\} + 1$. Now, by the induction hypothesis, the set S satisfies (7.4). Therefore, since $|S \cap A| = |S \cap A_{1,j}| < d$, we get that

$$\dim \text{span}\{\boldsymbol{\eta}(S)\} = |S \cap C| + \min(|S \cap A|, d) = |S \cap C| + |S \cap A| = |S| = m - 1.$$

This implies that $\dim \text{span}\{\boldsymbol{\eta}(S')\} = m = \dim E$ so that $\mathbf{b}(\lambda_T) \in \text{span}\{\boldsymbol{\eta}(S')\}$ and C1 holds.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{a_{j+1}\} \notin \Gamma$. If $|S \cap A_{1,j}| \geq d$, then $\text{span}\{\boldsymbol{\eta}(S')\} = \text{span}\{\boldsymbol{\eta}(S)\}$ for any choice of α_{j+1} ; hence, no matter how we chose α_{j+1} in this case, the augmented set S' will remain incapable of spanning the target vector. Also, since any d vectors of the form $\mathbf{a}(\alpha_i)$ span the same subspace E_1 , any choice of α_{j+1} will result with an assignment that keeps respecting (7.4).

Hence, we restrict our attention to subsets $S \in 2^{U'} \setminus \Gamma$ for which $|S \cap A_{1,j}| < d$. We claim that in this case $|S| \leq m - 2$. Assume, by contradiction, that $|S| \geq m - 1$. As $|S \cap A_{1,j}| < d$, we infer that $|S \cap C| \geq m - d$. Since $|S' \cap C| = |S \cap C| \geq m - d$ and $|S'| = |S| + 1 \geq m$, we infer that $S' \in \Gamma$, as opposed to our assumption. Hence, $|S| \leq m - 2$. Our goal is to find α_{j+1} so that the target vector is not in $\text{span}\{\boldsymbol{\eta}(S')\}$ (in order to keep respecting Γ) and that (7.4) still holds for all $S \in 2^{U'} \setminus \Gamma$. Concentrating on the first part of our mission, we want to find α_{j+1} so that $\mathbf{a}(\alpha_{j+1}) \notin \text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$. By Lemma 7.7, for $X = \{\alpha_i\}_{1 \leq i \leq j}$ and $Y = \{\gamma_i\}_{1 \leq i \leq |C|} \cup \{\lambda_T\}$, the space $\text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\} \cap E_1$ is a subspace of E_1 of dimension $d - 1$ at the most. We infer that for all but possibly $d - 1$ values of $\alpha_{j+1} \in \mathbb{F}$, the vector $\mathbf{a}(\alpha_{j+1})$ increases the dimension of $\text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$ by 1. It is easy to see that for all such selections, we get an assignment that will also respect (7.4). This completes the proof that a proper assignment of vectors exists for all users in $A \cup C$. We are ready to proceed to the third and final stage in the assignment.

Step 3: Assigning vectors to users in B. Here we assign vectors to the users in B (note that B may be empty). Let $B = \{b_i\}_{1 \leq i \leq |B|}$. As before, we claim that, provided $\mathbb{F}$ is large enough, there exist $\beta_i \in \mathbb{F}$, where $1 \leq i \leq |B|$, so that the assignment $\boldsymbol{\eta}(b_i) = \mathbf{V}_m(\beta_i)$ is consistent with Γ , and, in addition, for any $S \notin \Gamma$, (7.4) holds. Namely, whenever we augment an unauthorized set S with an additional user from B , the corresponding subspace that is spanned by the vectors owned by S increases by 1. We shall prove this claim by induction. Assume that we already assigned vectors to $B_{1,j} := \{b_1, \dots, b_j\}$ for some $0 \leq j < |B|$, so that Γ is respected and (7.4) holds for all $S \in 2^{U'} \setminus \Gamma$, where $U' = B_{1,j} \cup A \cup C$. This assumption is obviously true for $j = 0$. Next, we look for an assignment for the next user from B , that is, $\boldsymbol{\eta}(b_{j+1}) = \mathbf{V}_m(\beta_{j+1})$, so that conditions C1 and C2 hold for all $S \in 2^{U'} \setminus \Gamma$ (in order to keep respecting Γ), and (7.4) holds for all $S \in 2^{U' \cup \{b_{j+1}\}} \setminus \Gamma$. Again, we concentrate on a single set $S \in 2^{U'} \setminus \Gamma$ and bound the number of bad choices of $\beta_{j+1} \in \mathbb{F}$ for that specific set.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{b_{j+1}\} \in \Gamma$. Since $S \notin \Gamma$ but $S' \in \Gamma$, and the added user b_{j+1} is from B , we conclude that while S fails to satisfy the first of the two

threshold conditions in the definition of Δ_1 , i.e., $|S| < m$ or $|S \cap (B \cup C)| < m - d$, the set S' does satisfy that condition, namely, $|S'| \geq m$ and $|S' \cap (B \cup C)| \geq m - d$. There are two cases to consider here, according to which of the two threshold conditions were violated by S :

1. $|S| = m - 1$.
2. $|S| \geq m$ but $|S \cap (B \cup C)| = m - d - 1$.

In the first case, we claim that $|S \cap A| \leq d$. Indeed, since $|S' \cap (B \cup C)| \geq m - d$ and $|S' \cap (B \cup C)| = |S \cap (B \cup C)| + 1$, we have $|S \cap (B \cup C)| \geq m - d - 1$, whence $|S \cap A| = |S| - |S \cap (B \cup C)| \leq (m - 1) - (m - d - 1) = d$. Applying the induction hypothesis to S , we get by (7.4) that

$$\dim \text{span}\{\boldsymbol{\eta}(S)\} = |S \cap (B \cup C)| + \min(|S \cap A|, d) = |S \cap (B \cup C)| + |S \cap A| = |S| = m - 1.$$

Therefore, for all but $m - 1$ values of β_{j+1} ,

$$\dim \text{span}\{\boldsymbol{\eta}(S')\} = \dim \text{span}\{\boldsymbol{\eta}(S)\} + 1 = m,$$

whence $\mathbf{b}(\lambda_T) \in \text{span}\{\boldsymbol{\eta}(S')\}$.

Next, we show how to reduce the second case to the first case. In the second case $|S \cap A| = |S| - |S \cap (B \cup C)| \geq m - (m - d - 1) = d + 1$. Hence, S includes too many users from A , since for all $a \in A$ the vector $\boldsymbol{\eta}(a)$ is chosen from the d -dimensional space E_1 . Let $a \in S \cap A$, and define $S_1 = S \setminus \{a\}$ and $S'_1 = S_1 \cup \{b_{j+1}\}$. Obviously, $S_1 \notin \Gamma$ and, as can be easily verified, $S'_1 \in \Gamma$. Since $\text{span}\{\boldsymbol{\eta}(S)\} = \text{span}\{\boldsymbol{\eta}(S_1)\}$ and $\text{span}\{\boldsymbol{\eta}(S')\} = \text{span}\{\boldsymbol{\eta}(S'_1)\}$, if β_{j+1} is chosen properly for S_1 , it will also be an appropriate choice for S . Hence, we may repeat this reduction stage until we reach a set S_1 of size $|S_1| = m - 1$, and then apply the arguments of the first case to conclude that all but $m - 1$ values of β_{j+1} are appropriate choices.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{b_{j+1}\} \notin \Gamma$. Arguing along the same lines as above, we may assume, without loss of generality, that $|S \cap A| \leq d$, since any d members of A span E_1 . We claim that $|S| \leq m - 2$. Indeed, if $|S| \geq m - 1$, then $|S \cap (B \cup C)| \geq m - 1 - d$, as $|S \cap A| \leq d$. This implies that $|S' \cap (B \cup C)| \geq m - d$ and $|S'| \geq m$, whence $S' \in \Gamma$, in contradiction to our assumption. Therefore, the dimension of $\text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$ is at most $m - 2 + 1$. Consequently, for all but possibly $m - 1$ values of $\beta_{j+1} \in \mathbb{F}$, we have $\mathbf{V}_m(\beta_{j+1}) \notin \text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$. Hence, for all but possibly $m - 1$ values of $\beta_{j+1} \in \mathbb{F}$, we get that $\mathbf{b}(\lambda_T) \notin \text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{V}_m(\beta_{j+1})\}\}$. Clearly, all such selections yield assignments that respect (7.4).

This concludes the description of the assignment $\boldsymbol{\eta} : U \rightarrow E$ and the proof that it yields an ideal linear sharing scheme that realizes a given access structure Γ of type Δ_1 .

7.1.2. Realizing Δ_2 . Here we propose an ideal linear secret sharing scheme for access structures Γ that are TPASs of type Δ_2 . Recall that, by Definition 3.3, in such access structures $|B| \leq |\Lambda| = r = d + t - m$. We concentrate on cases where $r > 0$ (if $r = 0$, then $B = \emptyset$, and then we get a bipartite access structure).

Step 1: Assigning vectors to users in $B \cup C$. The users in B and C are assigned distinct vectors of the form $\mathbf{b}(\beta_i)$ and $\mathbf{b}(\gamma_i)$, respectively, where $\{\beta_i\}_{1 \leq i \leq |B|} \subset \Lambda$ and $\{\gamma_i\}_{1 \leq i \leq |C|} \subset \mathbb{F} \setminus (\Lambda \cup \{\lambda_T\})$. Clearly, any t users from $B \cup C$ may reconstruct $\mathbf{b}(\lambda_T)$ while no $t - 1$ users can.

Step 2: Assigning vectors to users in A . Let $A = \{a_i\}_{1 \leq i \leq |A|}$. Our claim is that, assuming $\mathbb{F}$ is large enough, we may find $\alpha_i \in \mathbb{F}$, where $1 \leq i \leq |A|$, so that the assignment $\boldsymbol{\eta}(a_i) = \mathbf{a}(\alpha_i)$ is consistent with Γ , and, in addition, for any $S \subseteq U$ where

$S \notin \Gamma$, the following equality holds:

$$(7.5) \quad \dim \text{span}\{\boldsymbol{\eta}(S)\} = |S \cap C| + \min(|S \cap (A \cup B)|, d).$$

We shall prove this claim by induction. Assume that we already assigned vectors to $A_{1,j} := \{a_1, \dots, a_j\}$ for some $0 \leq j < |A|$, so that Γ is respected and (7.5) holds for all $S \in 2^{U'} \setminus \Gamma$, where $U' = A_{1,j} \cup B \cup C$. This assumption is true for $j = 0$ since then, on one hand, $\dim \text{span}\{\boldsymbol{\eta}(S)\} = |S|$, while, on the other hand, $S \cap A = \emptyset$ and $|S \cap B| \leq |B| \leq d+t-m \leq d$. We proceed to look for an assignment $\boldsymbol{\eta}(a_{j+1}) = \mathbf{a}(\alpha_{j+1})$ for the next user from A , so that conditions C1 and C2 hold for all $S \in 2^{U'} \setminus \Gamma$ and (7.5) holds for all $S \in 2^{U' \cup \{a_{j+1}\}} \setminus \Gamma$.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{a_{j+1}\} \in \Gamma$. We infer that $|S| = m - 1$ and $|S \cap C| \geq m - d$. This implies that $|S \cap (A \cup B)| = |S| - |S \cap C| \leq d - 1$. By Lemma 7.7, applied to $X = \{\alpha_i\}_{1 \leq i \leq j} \cup \{\beta_i\}_{1 \leq i \leq |B|}$ and $Y = \{\gamma_i\}_{1 \leq i \leq |C|}$ (here we use the fact that $\beta_i \in \Lambda$ so that, in view of (7.1), $\mathbf{a}(\beta_i) = \mathbf{b}(\beta_i)$), the vectors owned by S span a subspace of E_1 of dimension $d - 1$ at the most. Hence, for all but $d - 1$ values of $\alpha_{j+1} \in \mathbb{F}$, $\dim \text{span}\{\boldsymbol{\eta}(S')\} = \dim \text{span}\{\boldsymbol{\eta}(S)\} + 1$. Now, by the induction hypothesis, the set S satisfies (7.5). Therefore, since $|S \cap (A \cup B)| < d$, we get that

$$\begin{aligned} \dim \text{span}\{\boldsymbol{\eta}(S)\} &= |S \cap C| + \min(|S \cap (A \cup B)|, d) \\ &= |S \cap C| + |S \cap (A \cup B)| = |S| = m - 1. \end{aligned}$$

This implies that $\dim \text{span}\{\boldsymbol{\eta}(S')\} = m$ so that $\mathbf{b}(\lambda_T) \in \text{span}\{\boldsymbol{\eta}(S')\}$.

Let $S \in 2^{U'} \setminus \Gamma$ be such that $S' := S \cup \{a_{j+1}\} \notin \Gamma$. There are two cases to consider here. If $|S \cap (A \cup B)| \geq d$, then any choice of α_{j+1} is good. This is because, in view of (7.1), the vectors given to users in B are $\mathbf{b}(\beta_i) = \mathbf{a}(\beta_i)$, where $\beta_i \in \Lambda$, and consequently, if $|S \cap (A \cup B)| \geq d$, the vectors held by the users of S already span all of E_1 . Hence, for any choice of α_{j+1} , $\text{span}\{\boldsymbol{\eta}(S')\} = \text{span}\{\boldsymbol{\eta}(S)\}$ and S' will still satisfy (7.5).

This leaves us with the case $|S \cap (A \cup B)| < d$. In that case $|S| \leq m - 2$ (since if $|S| \geq m - 1$, then $|S \cap C| = |S| - |S \cap (A \cup B)| \geq m - d$ and $|S'| = |S| + 1 \geq m$, and consequently, S' would have been authorized). Our goal is to find α_{j+1} so that the target vector is not in $\text{span}\{\boldsymbol{\eta}(S')\}$ (in order to keep respecting Γ) and that (7.5) still holds. Concentrating on the first part of our mission, we want to find α_{j+1} so that $\mathbf{a}(\alpha_{j+1}) \notin \text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$. By Lemma 7.7, for $X = \{\alpha_i\}_{1 \leq i \leq j} \cup \{\beta_i\}_{1 \leq i \leq |B|}$ and $Y = \{\gamma_i\}_{1 \leq i \leq |C|} \cup \{\lambda_T\}$, the space $\text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\} \cap E_1$ is a subspace of E_1 of dimension $d - 1$ at the most. Hence, for all but possibly $d - 1$ values of $\alpha_{j+1} \in \mathbb{F}$, the vector $\mathbf{a}(\alpha_{j+1})$ increases the dimension of $\text{span}\{\boldsymbol{\eta}(S) \cup \{\mathbf{b}(\lambda_T)\}\}$ by 1. It is easy to see that for all such selections we get an assignment that will also respect (7.5).

8. A recursive characterization of ideal WTASs by means of composition. In this section we show that if Γ is an ideal WTAS that is not one of the structures that we identified in sections 6.3 and 7, namely, an HTAS or a TPAS, then it is a composition of two ideal WTASs that are defined on smaller sets of users. Such a result provides a recursive characterization of ideal WTASs.

8.1. WTASs and composition of access structures. We begin with the following fundamental lemma that asserts that a composition of two access structures is ideal if and only if those two access structures are ideal.

LEMMA 8.1. *Let U_1 and U_2 be disjoint sets. Let $u_1 \in U_1$, and define $U = U_1 \cup U_2 \setminus \{u_1\}$. Suppose that Γ_1 and Γ_2 are access structures on U_1 and U_2 , respectively,*

such that u_1 is not redundant in Γ_1 and $\Gamma_2 \neq \emptyset$. Furthermore, let Γ be the composition of Γ_1 and Γ_2 via u_1 . Then Γ is ideal if and only if both Γ_1 and Γ_2 are ideal. Moreover, if both Γ_1 and Γ_2 have an ideal linear secret sharing scheme, then Γ has an ideal linear secret sharing scheme.

Proof. Assume that Γ_1 and Γ_2 are ideal. We show that Γ is ideal by describing an ideal secret sharing scheme that realizes it. Given a secret s , we share it among the users of U_1 using an ideal secret sharing scheme for Γ_1 . Then, if s_1 is the share of u_1 in that scheme, we share it among the users of U_2 using an ideal secret sharing scheme for Γ_2 . The resulting scheme is clearly ideal, and its correctness and perfect security stem from the correctness and perfect security of the two schemes for Γ_1 and Γ_2 . It is easy to verify that if both secret sharing schemes for Γ_1 and for Γ_2 are linear, then so is the resulting scheme for Γ .

Conversely, suppose that Γ is ideal. Let $M \subset U$ be a minterm of Γ , and let $M = M_1 \cup M_2$, where $M_1 = M \cap (U_1 \setminus \{u_1\})$ and $M_2 = M \cap U_2$. We choose M for which $M_2 \neq \emptyset$ (since u_1 is not redundant in Γ_1 and $\Gamma_2 \neq \emptyset$ such a minterm exists). By Definition 3.4, $M \in \Gamma$ if and only if $M_1 \cup \{u_1\} \in \Gamma_1$ and $M_2 \in \Gamma_2$. Furthermore,

$$(8.1) \quad \begin{aligned} M_1 \cup M'_2 &\in \Gamma \text{ if and only if } M'_2 \in \Gamma_2 \text{ and} \\ M'_1 \cup M_2 &\in \Gamma \text{ if and only if } M'_1 \cup \{u_1\} \in \Gamma_1. \end{aligned}$$

From the first observation above we conclude that Γ_2 coincides with Γ_{M_1, U_2} —the restriction of Γ that M_1 induces on U_2 . Since by Lemma 4.11 any restriction of an ideal access structure is ideal, we infer that Γ_2 is ideal. As for Γ_1 , let x be an arbitrary element of M_2 , let $U' = U_1 \setminus \{u_1\} \cup \{x\}$, and consider the restriction

$$\Gamma' := \Gamma_{M_2 \setminus \{x\}, U'} = \{Q \subseteq U' : (M_2 \setminus \{x\}) \cup Q \in \Gamma\}.$$

We claim, and prove below, that Γ' is isomorphic to Γ_1 under the natural bijection from 2^{U_1} to $2^{U'}$ (i.e., $A \subseteq U_1$ is mapped to $A' := A \setminus \{u_1\} \cup \{x\} \in U'$ if $u_1 \in A$, and to $A' = A$ otherwise). Therefore, since Γ' is a restriction of Γ , it is ideal, as implied by Lemma 4.11, and, consequently, so is Γ_1 .

We conclude with a proof of the isomorphism. Assume that $A \in \Gamma_1$. If $u_1 \notin A$, then $A \in \Gamma$. Hence, also $A' = A \in \Gamma$ and, in particular, $A' \in \Gamma'$. If $u_1 \in A$, then $(A \setminus \{u_1\}) \cup M_2 \in \Gamma$ (this is implied by the second observation in (8.1)); hence, $A' \cup (M_2 \setminus \{x\}) \in \Gamma$, and therefore $A' \in \Gamma'$. Conversely, assume that $A' \in \Gamma'$, namely, $(M_2 \setminus \{x\}) \cup A' \in \Gamma$. If $x \notin A'$, then $A' \subseteq U_1 \setminus \{u_1\}$. As M_2 is a minterm of Γ_2 (this is implied by the first observation in (8.1)), $M_2 \setminus \{x\} \notin \Gamma_2$. Hence, by Definition 3.4, we conclude that $A' \in \Gamma_1$. But in that case $A = A'$ so that $A \in \Gamma_1$. If $x \in A'$, then $(A' \setminus \{x\}) \cup M_2 \in \Gamma$, from which it follows that $A = (A' \setminus \{x\}) \cup \{u_1\} \in \Gamma_1$. $\square$

The recursive characterization of ideal WTASs will be obtained by distinguishing between two types of users. Specifically, we shall identify a subset of so-called strong users that takes the form of a suffix, $S = U_{k,n}$, where $k \geq 3$, and then the complement subset will be thought of as the subset of weak users, $W = U_{1,k-1}$. A subset of strong users will be called S -cooperative if it is unauthorized, but it may become authorized if we add to it some weak users.

DEFINITION 8.2 (cooperative set). *Given $Y \subseteq S$, if $Y \notin \Gamma$ but $W \cup Y \in \Gamma$, then Y is called an S -cooperative set.*

By Claim 4.13, the access structure $\Gamma_{Y,W}$, the restriction of Γ induced by Y on W , is a WTAS for any partition $U = W \cup S$ and $Y \subseteq S$. We proceed to define a condition on the set S such that if it is satisfied for some suffix $S = U_{k,n}$, where $k \geq 3$,

the access structure Γ is a composition of two ideal WTASs that are defined on sets smaller than U .

DEFINITION 8.3 (strong set). *If for any two S -cooperative sets $Y_1, Y_2 \subseteq S$ the corresponding restrictions of Γ to W coincide, i.e., $\Gamma_{Y_1, W} = \Gamma_{Y_2, W}$, the set S is called a strong set of users.*

If S is a strong set of users, there exists an access structure on W , denoted Γ_W , such that $\Gamma_W = \Gamma_{Y, W}$ for all cooperative subsets $Y \subseteq S$. In that case, every minterm $M \in \Gamma$ is either contained in S or, otherwise, $M \cap W \in \Gamma_{M \cap S, W}$. In the second case we infer that $M \cap S$ is S -cooperative, and since S is strong we get that $M \cap W \in \Gamma_W$. The following theorem shows that if S is a strong set of users, Γ is a composition of two ideal WTASs.

THEOREM 8.4. *Let Γ be an ideal WTAS on U . Suppose that $S = U_{k, n}$, for some $k \geq 3$, is a strong set of users. Then Γ is a composition of two ideal WTASs, each of which is defined on a smaller set than U (one is defined on W , and the other is defined on S supplemented by an additional user).*

Proof. Let Y be an arbitrary S -cooperative set, $Q \subseteq W$ be a minterm of $\Gamma_{Y, W}$, and x be an arbitrary element of Q . Both $\Gamma_{Y, W}$ and $\Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ are restrictions of Γ . Thus, by Lemma 4.11, they are both ideal, and by Claim 4.13, they are both WTASs. Let Δ be the composition of $\Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ and $\Gamma_{Y, W}$ via x . (Since x belongs to the domains of both access structures, W and $S \cup \{x\}$, we may define the composition by first replacing the user x in $\Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ with a copy x' and then compose $\Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ and $\Gamma_{Y, W}$ via x' .) We note that Δ , like Γ , is defined on $U = W \cup S$. We proceed to show that $\Gamma = \Delta$, thus proving the lemma. (Note that $\Gamma_{Y, W}$ is defined on W , whose size is $k - 1 < n$, and Γ' is defined on $S \cup \{x\}$, whose size is $n - k + 2 < n$.)

Let M be a minterm of Γ . Then either $M \subseteq S$ or $M \cap W \neq \emptyset$. If $M \subseteq S$, then $M \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$. Since $x \notin M$ we conclude, by Definition 3.4, that $M \in \Delta$. If, on the other hand, $M \cap W \neq \emptyset$, define $M_W = M \cap W$ and $M_S = M \cap S$. Therefore, M_S is an S -cooperative set. Since S is a strong set of users, we infer that $\Gamma_{M_S, W} = \Gamma_{Y, W}$, whence $M_W \in \Gamma_{Y, W}$. In addition, $Q \in \Gamma_{Y, W} = \Gamma_{M_S, W}$. This implies that $M_S \cup Q \in \Gamma$ and, consequently, that $M_S \cup \{x\} \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$. Therefore, by Definition 3.4, $M = M_W \cup M_S \in \Delta$.

For the other direction, let M be a minterm of Δ , and, as before, $M_S = M \cap S$ and $M_W = M \cap W$. Then either $M_S \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ or both $M_W \in \Gamma_{Y, W}$ and $M_S \cup \{x\} \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$. We separate the discussion into the following two cases.

If $M_S \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$, then $M_S \cup (Q \setminus \{x\}) \in \Gamma$. That means that $Q \setminus \{x\} \in \Gamma_{M_S, W}$. On the other hand, as Q is a minterm of $\Gamma_{Y, W}$, it must hold that $Q \setminus \{x\} \notin \Gamma_{Y, W}$. Hence, $\Gamma_{M_S, W} \neq \Gamma_{Y, W}$. This implies that M_S is not S -cooperative. But since $M_S \cup (Q \setminus \{x\}) \in \Gamma$, the only way M_S is not S -cooperative is if M_S is authorized by itself in Γ . However, $M = M_W \cup M_S$ was a minterm of Δ . Therefore, M_W must be empty, whence $M = M_S$. This brings us to the sought-after conclusion that $M \in \Gamma$.

Now suppose that $M_S \notin \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ but $M_S \cup \{x\} \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ and $M_W \in \Gamma_{Y, W}$. Since $M_S \cup \{x\} \in \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$ we get that $Q \cup M_S \in \Gamma$. On the other hand, $M_S \notin \Gamma_{Q \setminus \{x\}, S \cup \{x\}}$, and thus $M_S \notin \Gamma$. Therefore, M_S is S -cooperative. Since $M_W \in \Gamma_{Y, W}$ and S is a strong set of users, this implies that $M_W \in \Gamma_{M_S, W}$. Therefore $M_W \cup M_S \in \Gamma$, and thus $M \in \Gamma$. $\square$

8.2. Simple compositions. In this section we show that in two simple cases an ideal WTAS is a composition of two ideal WTASs defined on sets smaller than U . The first case is when there are self-sufficient users, and the second is where u_2 starts no minterm of Γ .

FIG. 8.1. Notations for the composition.

Suppose that u_n is a self-sufficient user. Let $\Gamma' = \Gamma_{\emptyset, U_{1,n-1}}$ be the restriction of Γ to $U_{1,n-1}$ (namely, all authorized sets that do not include u_n). By Lemma 4.11, the access structure Γ' is ideal, and by Claim 4.13, it is an ideal WTAS. Let $\Gamma_\vee$ be the simple 1-out-of-2 access structure on the set $\{u', u_n\}$, where u' is an additional dummy user. $\Gamma_\vee$ is clearly an ideal WTAS. It is easy to see that Γ is the composition of Γ' and $\Gamma_\vee$ via u' .

If Γ has no minterm that starts with u_2 , then every minterm that contains u_1 must contain also u_2 (otherwise, we could have replaced u_1 by u_2 in order to get a minterm that starts with u_2). Hence, for every $U_{3,n}$ -cooperative set, $Y \subseteq U_{3,n}$, the access structure that Y induces on $U_{1,2}$ is the same, $\Gamma_{Y, U_{1,2}} = \{U_{1,2}\}$. Therefore, $U_{3,n}$ is a strong set of users in this case. Hence, by Theorem 8.4, the access structure Γ is a composition of two ideal WTASs that are defined on sets smaller than U .

To conclude, we have proved the following lemma.

LEMMA 8.5. *Let Γ be an ideal WTAS on U . If Γ has self-sufficient users, or u_2 starts no minterm of Γ , then Γ is a composition of two ideal WTASs that are defined on sets smaller than U .*

8.3. Identifying composition structures. In this section we show that if Γ is an ideal WTAS, but is not one of the access structures that were characterized in Theorems 6.7 (HTAS) and 7.6 (TPAS), then it is a composition of two ideal WTASs as described in section 8.1. In view of Lemma 8.5, we assume hereinafter that u_2 is the minimal user in some minterm of Γ .

Let M_1 be the lexicographically minimal minterm in Γ . Let u_r be the maximal user in M_1 . Since Γ is neither an HTAS nor a TPAS, then, by Theorems 6.7 and 7.6, there must be at least two users in $U_{1,r-1}$ that are not in M_1 . Let u_ℓ be the *minimal* user in M_1 such that at least two users in $U_{1,\ell-1}$ are missing from M_1 , and let u_d be the *maximal* user in M_1 such that $U_{1,d} \subset M_1$. We denote the users in $M_1 \cap U_{d+1,\ell-1}$, if there are any, by $Y = \{y_1, \dots, y_t\}$. Note that if Y is not empty, then Y is a run of U , and $y_1 = u_{d+2}$. Next, if $Y \neq \emptyset$, we denote the set of users of $U \setminus M_1$ between y_t and u_ℓ (excluding those two users) by $X = \{x_1, \dots, x_s\}$. (Note that $X = U_{d+t+2,\ell-1}$.) Otherwise, we denote the set $U_{d+2,\ell-1}$ as $X = \{x_1, \dots, x_s\}$. Finally, we denote the users of $M_1 \cap U_{\ell,n}$ by $Z = \{z_1, \dots, z_m\}$. Note that the sets X and Z are never empty, and that $z_1 = u_\ell$. The above notations are depicted in Figure 8.1.

We claim that either $U_{\ell,n}$ or $U_{d+2,n}$ is a strong set of users. We start by partitioning U into $W = U_{1,\ell-1}$ and $S = U_{\ell,n}$. We show that if all the S -cooperative sets are of the same size, then $\Gamma_{Y_1, W} = \Gamma_{Y_2, W}$ for every two cooperative sets $Y_1, Y_2 \subseteq S$; namely, S is a set of strong users. If, however, that condition does not hold, we shall show that $U_{d+2,n}$ is a strong set.

An important result in our study is that all S -cooperative sets are at least as large as Z ; namely, their size is at least m .

CLAIM 8.6. *Let $W = U_{1,\ell-1}$, $S = U_{\ell,n}$, and M be a minterm of the access structure Γ . If $M \cap W \neq \emptyset$, then M contains at least m users from S .*

Proof. Assume towards a contradiction that M is a minterm that intersects W such that $|M \cap S| < m$. Recall that every minterm of Γ is an independent set of $\mathcal{M}$, the matroid associated with Γ . Hence, the minterm M_1 is an independent set of size $d + t + m$ of $\mathcal{M}$, and thus, by Claim 4.7, every independent set of $\mathcal{M}$ that is smaller than $d + t + m$ can be expanded to an independent set of size $d + t + m$. Therefore, if $|M| < d + t + m$, the minterm M can be expanded to an independent set I of size $d + t + m$; otherwise, we set $I = M$. By Lemma 5.2, this expansion can be done only by adding to M users that precede $M_{\min}$. As M intersects W , the users in $I \setminus M$ are all from W . Hence, $|I \cap S| = |M \cap S| \leq m - 1$. Therefore, $|I \cap W| = |I| - |I \cap S| \geq d + t + m - (m - 1) = d + t + 1$. Next, we view M_1 as the canonical complement of the empty set (see Definition 5.4). Its $(d + t + 1)$ th element is z_1 . By Lemma 5.6 for $P = \emptyset$, $Y = M_1$, and $j = d + t + 1$, any $d + t + 1$ members of W form a dependent set. Hence I , which was assumed to be independent, contains a dependent set. This contradiction implies that $|M \cap S| \geq m$. $\square$

8.3.1. When all S -cooperative sets are of the same size. Here we show that if all S -cooperative sets are of the same size, namely $|Z| = m$, the set S is a strong set. We accomplish this by showing that all the S -cooperative sets of size m induce the same access structure on W , which is the access structure induced by the S -cooperative set Z . We begin by showing that the weight of every S -cooperative set is at least the weight of Z .

CLAIM 8.7. *Let $V \subseteq S$ be an S -cooperative set. Then $w(V) \geq w(Z)$.*

Proof. Assume towards a contradiction that $w(V) < w(Z)$, and consider the set $W \cup Z$. Since Z is S -cooperative, the set $W \cup Z$ is authorized. Thus, by Lemma 5.1, it must contain a suffix minterm of the form $B \cup Z$, where B is a suffix of W . There are two possible cases: either $B \cup V$ is authorized, or not.

If $B \cup V$ is authorized, then, since $w(V) < w(Z)$, the set $B \cup V$ is a minterm. Hence, as $B \cup V$ and $B \cup Z$ are two minterms that have the same minimal user, $B_{\min}$, Lemma 5.3 implies that $|V| = |Z| = m$. The set $B \cup V$ is independent in $\mathcal{M}$. If $|B \cup V| < d + t + m$, Claim 4.7 implies that $B \cup V$ can be expanded to an independent set I of size $d + t + m$; if $|B \cup V| \geq d + t + m$, we set $I = B \cup V$. By Lemma 5.2, all users in $I \setminus (B \cup V)$ must be from W . Hence, I includes at least $d + t$ users from W . On the other hand, since $|V| = |Z| = m$ and $w(V) < w(Z)$, there must be an index j such that $v_j \prec z_j$. Since M_1 is the canonical complement of the empty set $\emptyset$, we get from Lemma 5.6, applied to $P = \emptyset$, $Y = M_1$, and $B = I_{1,d+t+j}$, that the latter set is dependent. This is impossible since I is independent. Therefore, $B \cup V$ cannot be authorized.

If $B \cup V$ is unauthorized, we let Q be the canonical complement of B . Since $B \cup Z$ is a minterm, we get from Lemma 5.3 that $|Q| = |Z| = m$. On the other hand, by Claim 8.6, since V is S -cooperative, $|V| \geq m$. Since $B \cup V \notin \Gamma$ but $B \cup Q \in \Gamma$, we infer that $w(V) < w(Q)$. Therefore, there must be an index $j \in [m]$ such that $v_j \prec q_j$. Thus, by Lemma 5.6, we get that $B \cup V$ is dependent. On the other hand, since V is S -cooperative and B is a suffix of W , the set $B \cup V$ may be expanded to an authorized superset by adding to it users that precede $B_{\min}$, one by one, until the first time that we get an authorized set. This construction, where in each stage we add a new user that is smaller than all current users in the set, guarantees that we end up with a minterm. But a minterm of Γ cannot contain a dependent set. Therefore, this case is not possible either. We are lead to the conclusion that $w(V) \geq w(Z)$. $\square$

We are now ready to prove that all the cooperative sets of size m induce the same access structure on W .

CLAIM 8.8. *Let V be an S -cooperative set of size m . Then $\Gamma_{V,W} = \Gamma_{Z,W}$.*

Proof. By Claim 8.7, $w(V) \geq w(Z)$. If $w(V) = w(Z)$, the claim is trivial, since Γ is a WTAS. Therefore, we assume that $w(V) > w(Z)$. We first show that $U_{1,d} \cup Y \cup V$ is a minterm of Γ . Since $M_1 = U_{1,d} \cup Y \cup Z$ is authorized, the set $U_{1,d} \cup Y \cup V$ is authorized as well. Assume it is not a minterm. Then, by Lemma 5.1 it contains a suffix minterm of the form $B \cup V$, where B is a suffix of $U_{2,d} \cup Y$. Let Q be the canonical complement of B . Since $B \cup V$ is a minterm, by Lemma 5.3, it must be that $|Q| = |V| = m = |Z|$. Since $B \cup Q$ is authorized and $B \cup Z$ is unauthorized, $w(Z) < w(Q)$. Therefore, there must be an index $j \in [m]$ for which $z_j \prec q_j$. Thus, by Lemma 5.6, the set $B \cup Z$ is dependent. However, this set is contained in $U_{1,d} \cup Y \cup Z$, which is a minterm. This contradiction implies that $U_{1,d} \cup Y \cup V$ is a minterm of Γ . Consequently, since $U_{1,d} \cup Y \cup Z$ is a minterm and $U_{2,d} \cup Y \cup V$ is unauthorized (being a proper subset of a minterm), we infer that $w(Z) + w(u_1) > w(V)$.

We are now ready to prove that $\Gamma_{Z,W} = \Gamma_{V,W}$. Since we deal with the case where $w(Z) < w(V)$, the inclusion $\Gamma_{Z,W} \subseteq \Gamma_{V,W}$ is obvious. For the opposite inclusion, it is sufficient to concentrate on minterms of $\Gamma_{V,W}$. Let M be a minterm of $\Gamma_{V,W}$. Thus, $M \cup V \in \Gamma$, and since $M \cup V \setminus M_{\min} \notin \Gamma$, the set $M \cup V$ is a minterm in Γ . There are two possible cases: If $u_1 \in M$, the minterm $M \cup V$ must be of the same size as M_1 , by Lemma 5.3. Since $|M_1| = d + t + m$ and $|V| = m$, we get that $|M| = d + t$. As $M_1 = U_{1,d} \cup Y \cup Z$ is the minimal minterm in Γ in terms of the precedence order $\prec$, the weight of $U_{1,d} \cup Y$ is minimal among all sets of size $d + t$ that are contained in a minterm. This implies that $w(M) \geq w(U_{1,d} \cup Y)$. This, in turn, implies that $M \cup Z \in \Gamma$ and thus $M \in \Gamma_{Z,W}$.

The second case is when $u_1 \notin M$. Assume, towards a contradiction, that $M \cup Z \notin \Gamma$. Let Q be the canonical complement of M . By Lemma 5.3, $|Q| = |V| = m = |Z|$. Since $M \cup Z \notin \Gamma$ and $M \cup Q \in \Gamma$, $w(Z) < w(Q)$. Therefore, there must be an index $j \in [m]$ such that $z_j \prec q_j$. Thus, by Lemma 5.6, $M \cup Z$ is dependent. However, since $M \cup V \in \Gamma$ and $w(Z) + w(u_1) > w(V)$, we get that $\{u_1\} \cup M \cup Z \in \Gamma$. Moreover, it must be a minterm since any proper subset of $\{u_1\} \cup M \cup Z$ is of weight that does not exceed that of the unauthorized set $M \cup Z$. We have arrived at the absurd situation where the dependent set $M \cup Z$ is contained in a minterm. This contradiction implies that $M \cup Z$ is authorized, so $M \in \Gamma_{Z,W}$. $\square$

Combining Claims 8.6 and 8.8, we arrive at the following corollary.

COROLLARY 8.9. *If there are no S -cooperative sets of size larger than m , then S is a strong set.*

Example 8.10. Consider the set $U = \{u_1, \dots, u_8\}$, and let Γ be a WTAS where the weights are 1, 1, 1, 1, 1, 3, 3, and 3 and the threshold is 6. The lexicographically minimal minterm is $\{u_1, u_2, u_3, u_6\}$, and so there is no prefix minterm and no lacunary minterm. In this example $W = U_{1,5}$ and $S = U_{6,8}$, and the access structure is a composition of a 2-out-of-4 threshold access structure on $S \cup \{u'\}$ and a 3-out-of-5 threshold access structure on the weak side W , where u' is an additional dummy user.

8.3.2. When large S -cooperative sets exist. The conclusion from the previous section is that whenever all S -cooperative sets for $S = U_{\ell,n}$ are of the same size (i.e., $|Z| = m$), the set S is a strong set, and hence, by Theorem 8.4, the access structure Γ is a composition of ideal WTASs that are defined on two smaller sets. Here, we continue to deal with the case where there are S -cooperative sets of size larger than m . In that case we identify another strong set. Specifically, we show that $U_{d+2,n}$ is a strong set of users.

Recall that we assume that there are minterms that start with u_2 . In order to prove that $U_{d+2,n}$ is a strong set we show that for every $U_{d+2,n}$ -cooperative set, V , the access structure that it induces on $U_{1,d+1}$, namely $\Gamma_{V,U_{1,d+1}}$, is a d -out-of- $(d+1)$ threshold access structure. The proof has two stages:

- First we show that if M is a minterm of Γ such that $|M \cap S| > m$, then $M \cap U_{1,d+1} = \emptyset$ (Claim 8.15). This immediately implies that V , being a $U_{d+2,n}$ -cooperative set, intersects S in exactly m users (Corollary 8.16).
- In the second stage, we analyze the restricted access structure that Z induces on W , namely $\Gamma_{Z,W}$, and conclude that $\Gamma_{V,U_{1,d+1}}$ is a d -out-of- $(d+1)$ access structure.

We start with two technical claims. The following claim shows that the weight of z_1 is much larger than the weights of the users preceding it.

CLAIM 8.11. $w(u_{d+1}) + w(x_1) < w(z_1)$.

Proof. Suppose the claim is false and $w(u_{d+1}) + w(x_1) \geq w(z_1)$. Then we can replace z_1 by u_{d+1} and x_1 in the minterm M_1 and get an authorized set M'_1 . By Lemma 5.1, this set contains a suffix minterm. This minterm must intersect W , since Z by itself is unauthorized. But then M'_1 would be a minterm that contains only $m-1$ elements of S , in contradiction to Claim 8.6. $\square$

CLAIM 8.12. *The sets $U_{1,d} \cup Y \cup \{x_1\}$ and $U_{1,d+1}$ are circuits of $\mathcal{M}$ —the matroid that corresponds to Γ .*

Proof. We start with the set $V := U_{1,d} \cup Y \cup \{x_1\}$. Denote by Γ' the restriction $\Gamma_{Z,W \setminus \{u_{d+1}\}}$. By Lemma 4.11 and Claim 4.13, Γ' is an ideal WTAS. Moreover, the set $U_{1,d} \cup Y$ is a prefix minterm of this access structure. Therefore, by Theorem 6.7, Γ' is an HTAS. Thus, by Claim 6.2, V is a circuit of the matroid that corresponds to Γ' , and its size is $|V| = d + t + 1$. As M_1 is the canonic complement of the empty set, z_1 is its $(d+t+1)$ th element, and $x_1 \prec z_1$, we conclude by Lemma 5.6 that V is dependent in $\mathcal{M}$. It must be a circuit in $\mathcal{M}$, for otherwise, by Lemma 4.12, we would get a contradiction to the fact that it is a circuit in the matroid that corresponds to the restriction Γ' .

The proof for $U_{1,d+1}$ is similar. Let $\Gamma'' = \Gamma_{Y \cup Z, U_{1,d+1}}$ be the restriction that $Y \cup Z$ induces on $U_{1,d+1}$. It is an ideal WTAS, and $U_{1,d}$ is a prefix minterm in it. Thus, by Claim 6.2, $U_{1,d+1}$ is a circuit of the matroid that corresponds to Γ'' . As u_{d+1} , which is the $(d+1)$ th user in $U_{1,d+1}$, precedes the $(d+1)$ th user in the canonical complement of the empty set (which is y_1 , or z_1 if $Y = \emptyset$), we infer by Lemma 5.6 that $U_{1,d+1}$ is dependent in $\mathcal{M}$. Finally, by Lemma 4.12, the set $U_{1,d+1}$ must be a circuit of $\mathcal{M}$. $\square$

We now turn to showing that large S -cooperative sets are not contained in minterms that intersect $U_{1,d+1}$. This is done in two steps. First we show that if V is an S -cooperative set of size larger than m , there exists a suffix B of Y such that $B \cup V$ is a minterm. Then, relying upon this result, we show that no minterm of $\Gamma_{V,W}$ intersects $U_{1,d+1}$. This completes the first stage of the proof outlined above.

CLAIM 8.13. *If there exists an S -cooperative set V of size larger than m , there exists a suffix B of Y such that $B \cup V$ is a minterm.*

Proof. Consider the set $A := U_{1,d} \cup Y \cup V$. Since $|V| > |Z|$, the set A cannot be a minterm, as implied by Lemma 5.3. By Claim 8.7, $w(V) \geq w(Z)$. Thus, the set A is authorized and, consequently, it contains a suffix minterm of the form $B \cup V$, where B is a proper suffix of $U_{1,d} \cup Y$.

In order to prove the claim, we need to show that $B \subseteq Y$. Assume, towards a contradiction, that this is not true, namely, that $B_{\min} \in U_{1,d}$. Let $Q = B \setminus \{B_{\min}\} \cup \{x_1\}$. Since $B_{\min} \prec x_1$, the weight of Q is at least the weight of B , and therefore

$Q \cup V$ is an authorized set. Hence, it has a suffix minterm that must contain $\{x_1\} \cup V$. The union of this minterm and the minterm $B \cup V$ is $B \cup \{x_1\} \cup V$. We claim that all the users in V are critical for $B \cup \{x_1\} \cup V$, in the sense of Definition 4.3. Let $v_i \in V$, and assume that it is not critical; i.e., $B \cup \{x_1\} \cup V \setminus \{v_i\} \in \Gamma$. Since $B \cup V \setminus \{B_{\min}\} \notin \Gamma$ (because $B \cup V$ is a minterm), we conclude that $w(B \cup V \setminus \{B_{\min}\}) < w(B \cup \{x_1\} \cup V \setminus \{v_i\})$, whence $w(v_i) < w(B_{\min}) + w(x_1)$. Therefore, as $w(z_1) \leq w(v_i)$ and $w(B_{\min}) \leq w(u_{d+1})$, we arrive at the conclusion that $w(z_1) < w(u_{d+1}) + w(x_1)$, in contradiction to Claim 8.11. This implies that all of the users of V are critical for $B \cup \{x_1\} \cup V$. Thus, by Corollary 4.5, the set $B \cup \{x_1\}$ is dependent. However, $B \cup \{x_1\}$ is properly contained in $U_{1,d} \cup Y \cup \{x_1\}$, which, by Claim 8.12, is a circuit of $\mathcal{M}$. This contradiction implies that B does not intersect $U_{1,d}$ and is therefore a suffix of Y . $\square$

Remark 8.14. If there is an S -cooperative set V of size larger than m , the set Y is not empty. Otherwise, the set B in Claim 8.13 would be empty, whence V is a minterm, in contradiction to our assumption that V is S -cooperative. Therefore, in the rest of this section we assume that Y is not empty.

CLAIM 8.15. *If V is an S -cooperative set of size larger than m and A is a minterm of $\Gamma_{V,W}$, then $A \cap U_{1,d+1} = \emptyset$.*

Proof. Suppose that there is a minterm $A \in \Gamma_{V,W}$ such that $A \cap U_{1,d+1} \neq \emptyset$. We pick a minterm A of that sort having the property that $A \cap (Y \cup X) \preceq M \cap (Y \cup X)$ for all minterms $M \in \Gamma_{V,W}$ such that $M \cap U_{1,d+1} \neq \emptyset$. By Claim 8.13, there is a suffix B of Y such that $B \in \Gamma_{V,W}$. Therefore, as A is a minterm of $\Gamma_{V,W}$, it must be that $Y \not\subseteq A$ (otherwise, if $Y \subseteq A$, the minterm $A \cup V$ would have been a proper superset of the minterm $B \cup V$ since A includes in addition users from $U_{1,d+1}$). Let j be the smallest index such that $y_j \notin A$ (recall that $Y \neq \emptyset$), and consider the set $Q = A \setminus \{A_{\min}\} \cup \{y_j\}$. Since $A_{\min} \in U_{1,d+1}$, we conclude that $w(A_{\min}) \leq w(y_j)$. Thus $Q \cup V$ is authorized in Γ and must contain a suffix minterm M' that contains y_j . The union of $A \cup V$ and M' is $A \cup \{y_j\} \cup V$. The discussion is now separated into two cases: either A is a run of U or it is not.

If A is a run of U , then we first claim that every user of V is critical for $A \cup \{y_j\} \cup V$. Let $v_i \in V$, and assume that it is not critical for $A \cup \{y_j\} \cup V$; i.e., $A \cup \{y_j\} \cup V \setminus \{v_i\} \in \Gamma$. Since $A \cup V \setminus \{A_{\min}\} \notin \Gamma$ (as $A \cup V$ is a minterm), we conclude, by comparing the weights of the two latter sets, that $w(v_i) < w(A_{\min}) + w(y_j)$. However, since $w(z_1) \leq w(v_i)$, $w(y_j) \leq w(x_1)$, and $w(A_{\min}) \leq w(u_{d+1})$, we get that $w(z_1) < w(u_{d+1}) + w(x_1)$, in contradiction to Claim 8.11. Therefore, all users in V are critical for $A \cup \{y_j\} \cup V$. Thus, by Corollary 4.5, the set $A \cup \{y_j\}$ is dependent. Since we are now dealing with the case where A is a run of U , the set $A \cup \{y_j\}$ must be contained in $U_{1,d+1} \cup Y$. Since $A \cup \{y_j\}$ is dependent, it includes a circuit C . That circuit must include the user u_{d+1} , for otherwise C would have been a subset of the independent set $U_{1,d} \cup Y$. Moreover, the circuit C must also contain y_j , for otherwise $C \subseteq A$, while A is contained in a minterm and thus is independent. On the other hand, by Claim 8.12, the set $U_{1,d+1}$ is a circuit of $\mathcal{M}$ that does not contain y_j . Therefore, u_{d+1} is in the intersection of the two distinct circuits $U_{1,d+1}$ and C . Hence, by Lemma 4.6, the set $U_{1,d+1} \cup C \setminus \{u_{d+1}\}$ is dependent. But that latter set is contained in the independent set $U_{1,d} \cup Y$. This contradiction settles the statement whenever A is a run of U .

If A is not a run of U , we claim that every user $a_i \in A$ such that $y_j \prec a_i$ is critical for $A \cup \{y_j\} \cup V$. Otherwise we could replace the user a_i in the minterm $A \cup V$ with the user y_j and still get a minterm that intersects $U_{1,d+1}$. But this would contradict our choice of A as a minterm that is lexicographically minimal in $Y \cup X$. This implies that all users of $A \cup \{y_j\} \cup V$ that have weight greater than or equal to y_j are critical

for that set. In particular, the subset $(A \cap X) \cup V$ consists of only critical users, and consequently, by Claim 4.5, the set $A \setminus X \cup \{y_j\}$ is dependent. Since A is contained in a minterm, this dependent set must contain a circuit C that contains y_j . Since $U_{1,d} \cup Y$ is an independent set of $\mathcal{M}$, it must be that $u_{d+1} \in C$; otherwise C is properly contained in an independent set. However, since $U_{1,d+1}$ is a circuit of $\mathcal{M}$, we get that u_{d+1} is in the intersection of two distinct circuits, C and $U_{1,d+1}$ (note that $y_j \in C$ but $y_j \notin U_{1,d+1}$). Therefore, by Lemma 4.6, the set $C \cup U_{1,d+1} \setminus \{u_{d+1}\}$ is dependent. However, this set is properly contained in $U_{1,d} \cup Y$, which is an independent set of $\mathcal{M}$, and thus we arrive at a similar contradiction as in the previous case. $\square$

COROLLARY 8.16. *Every $U_{d+2,n}$ -cooperative set intersects S in exactly m users.*

Proof. Let B be a $U_{d+2,n}$ -cooperative set. Then there exists a nonempty set $A \subseteq U_{1,d+1}$ such that $M := A \cup B$ is a minterm of Γ . Denote $M_W = M \cap W$ and $M_S = M \cap S$, so that $M = A \cup B = M_W \cup M_S$. As $U_{1,d+1} \subset W$ and $U_{d+2,n} \supset S$, we infer that $M_W \cap U_{1,d+1} = A \neq \emptyset$ and $M_S = B \cap S$.

On the one hand, Claim 8.6 implies that $|M_S| \geq m$, since $M_W \neq \emptyset$. On the other hand, by Claim 8.15, if $|M_S| > m$, then $M_W \cap U_{1,d+1} = \emptyset$. But as $M_W \cap U_{1,d+1} \neq \emptyset$, we conclude that $|M_S| = |B \cap S| = m$. $\square$

We now turn to the second stage of showing that $U_{d+2,n}$ is a strong set. We will show that the existence of large S -cooperative sets and the existence of minterms that start with u_2 imply that $U_{d+2,n}$ is a strong set. By Claim 8.15, every $U_{d+2,n}$ -cooperative set intersects S in exactly m users. By Claim 8.8, if V is an S -cooperative set of size m , then $\Gamma_{V,W} = \Gamma_{Z,W}$. Therefore, it is enough to study the minterms in $\Gamma_{Z,W}$ that intersect $U_{1,d+1}$. Somehow, surprisingly, the existence of a large S -cooperative set affects the structure of $\Gamma_{Z,W}$. The next two claims will serve us in characterizing the structure of $\Gamma_{Z,W}$ in Claim 8.19.

CLAIM 8.17. *If there is an S -cooperative set V of size larger than m , there exists a nonempty suffix B of Y such that $B \cup \{x_1\} \in \Gamma_{Z,W}$.*

Proof. By Claim 8.13, there exists a suffix B of Y such that $B \cup V$ is a minterm of Γ . We next prove that $B \cup \{x_1\} \cup V \setminus \{v_1\} \in \Gamma$. Replacing $B_{\min}$ with x_1 in $B \cup V$, we get an authorized set. Denote by M' the suffix minterm contained in that set, and note that the union of M' and $B \cup V$ is exactly $B \cup \{x_1\} \cup V$. We claim that v_1 cannot be critical for $B \cup \{x_1\} \cup V$. If it was critical, then every user in V would also be critical for that set, and thus, by Corollary 4.5, the set $B \cup \{x_1\}$ would be dependent in $\mathcal{M}$. However, the set $B \cup \{x_1\}$ is properly contained in $U_{1,d} \cup Y \cup \{x_1\}$, which is a circuit by Claim 8.12. Therefore, $B \cup \{x_1\}$ is independent, and thus v_1 cannot be critical for $B \cup \{x_1\} \cup V$. Hence, the set $B \cup \{x_1\} \cup V \setminus \{v_1\}$ is authorized. But since it is obtained from the minterm $B \cup V$ by replacing v_1 with $x_1 \prec v_1$, it must be also a minterm.

We now prove the claim by induction on the size of V . If $|V| = m + 1$, then since $B \cup \{x_1\} \cup V \setminus \{v_1\}$ is a minterm, we conclude that $B \cup \{x_1\}$ is in $\Gamma_{V',W}$, where $V' = V \setminus \{v_1\}$ is an S -cooperative set of size m . But since, in view of Claim 8.8, $\Gamma_{V',W} = \Gamma_{Z,W}$, we arrive at the sought-after conclusion that $B \cup \{x_1\} \in \Gamma_{Z,W}$. If $|V| > m + 1$, then V' is an S -cooperative set of size $|V| - 1$. Hence, we may apply the induction hypothesis to conclude that there exists a suffix B of Y such that $B \cup \{x_1\} \in \Gamma_{Z,W}$. $\square$

The other assumption that affects the structure of $\Gamma_{Z,W}$ is that there are minterms of Γ that start with u_2 .

CLAIM 8.18. *If u_2 is the minimal user in some minterm of Γ , then $U_{2,d+1} \cup Y$ is a minterm of $\Gamma_{Z,W}$.*

Proof. The access structure $\Gamma_{Z,W}$ is an ideal WTAS and its lexicographically

minimal minterm is $U_{1,d} \cup Y$. Let M be a minterm of Γ that starts with u_2 . In particular, M intersects W . By Claims 8.6 and 8.15, the minterm M contains exactly m members of S . Thus, By Claim 8.8, $\Gamma_{M \cap S, W} = \Gamma_{Z, W}$. This implies that $M \cap W$ is a minterm of $\Gamma_{Z, W}$ that starts with u_2 . Recall that, by Remark 8.14, $Y \neq \emptyset$. Hence, Claim 7.1 applies to the access structure $\Gamma_{Z, W}$, and the set $U_{2,d+1} \cup Y$ is a minterm of $\Gamma_{Z, W}$. $\square$

We may now describe the structure of $\Gamma_{Z, W}$. Since we assume that there exists a minterm of Γ that starts with u_2 , the set $U_{2,d+1} \cup Y$ is a minterm of $\Gamma_{Z, W}$, as implied by Claim 8.18. As $U_{2,d+1} \cup Y$ is a run, and it is a prefix in $W \setminus \{u_1\}$, we get that the restriction $\Gamma_{Z, W \setminus \{u_1\}}$ has a prefix minterm. Therefore, by Theorem 6.7, it is an HTAS. The threshold of the first level is $|U_{2,d+1} \cup Y| = d + t$. By Claim 8.17, the run minterm of this HTAS that ends with x_1 starts with an element of Y . Therefore, the transition between the first and the second level in that HTAS (if it exists) occurs within Y . This enables us to prove that $U_{d+2,n}$ is a strong set of users.

CLAIM 8.19. *Suppose that there is an S -cooperative set of size larger than m , and that there is a minterm of Γ that starts with u_2 . Then $U_{d+2,n}$ is a strong set of users.*

Proof. In order to show that $U_{d+2,n}$ is a strong set of users, we show that for any $U_{d+2,n}$ -cooperative set V , the corresponding restriction induced by V on $U_{1,d+1}$, namely $\Gamma_{V, U_{1,d+1}}$, is a d -out-of- $(d+1)$ threshold access structure. Let V be a $U_{d+2,n}$ -cooperative set. Hence, there exists a nonempty set $A \subseteq U_{1,d+1}$ such that $A \cup V$ is a minterm of Γ . Denote $V_W = V \cap W$ and $V_S = V \cap S$. Note that the set V_S is S -cooperative. Moreover, since $A \cup V$ is a minterm of Γ , then $A \cup V_W$ is a minterm of $\Gamma_{V_S, W}$ that intersects $U_{1,d+1}$. Therefore, by Claim 8.15, we conclude that $|V_S| = m$. Thus, by Claim 8.8, $\Gamma_{V_S, W} = \Gamma_{Z, W}$. Consequently, since $A \cup V_W$ is a minterm of $\Gamma_{V_S, W}$, it is also a minterm of $\Gamma_{Z, W}$.

We claim that the size of that minterm is $|A \cup V_W| = d + t$. Indeed, if the minimal user in $A \cup V_W$ is u_1 , then, by Lemma 5.3, $|A \cup V_W \cup V_S| = |M_1| = d + t + m$, and so, as $|V_S| = m$, we get that $|A \cup V_W| = d + t$. Otherwise, $A \cup V_W \subseteq W \setminus \{u_1\}$, and consequently, $A \cup V_W \in \Gamma_{Z, W \setminus \{u_1\}}$. But the latter access structure was shown above to be an HTAS; furthermore, we showed that the first level in that HTAS includes all of $U_{2,d+1}$ and that the corresponding threshold is $d + t$. Since $A \cup V_W$ starts within $U_{2,d+1}$, it is of size $d + t$.

First, we show that for any $D \subseteq U_{1,d+1}$ of size d , $D \cup V \in \Gamma$. Since $w(D) \geq w(U_{1,d})$, we need only to show that $U_{1,d} \cup V \in \Gamma$. We know that $M_1 = U_{1,d} \cup Y \cup Z \in \Gamma$. Since $A \subseteq U_{1,d+1}$ it must be that $|A| \leq d$ (otherwise $A = U_{1,d+1}$, and then $A \cup V$ would be a minterm that precedes M_1 with respect to the lexicographical order). Hence, $|V_W| \geq t$. Since Y consists of the first t users in $U_{d+2,n}$, we conclude that $w(V_W) \geq w(Y)$. Therefore V_W can replace Y in M_1 , and so $U_{1,d} \cup V_W \in \Gamma_{Z, W} = \Gamma_{V_S, W}$. This implies that $U_{1,d} \cup V_W \cup V_S = U_{1,d} \cup V \in \Gamma$, as required. Hence, every subset of d users from $U_{1,d+1}$ completes V to an authorized set.

Finally, we need to show that no smaller subset of $U_{1,d+1}$ completes V to an authorized set. To that end, let B be a minterm of $\Gamma_{V, U_{1,d+1}}$. We proceed to show that $|B| \geq d$. Using the above notation, $B \cup V_W \cup V_S$ is a minterm of Γ , or, equivalently, $B \cup V_W$ is a minterm of $\Gamma_{V_S, W} = \Gamma_{Z, W}$. Arguing along the same lines as we did for $A \cup V_W$, we conclude that $|B \cup V_W| = d + t$. Assume towards a contradiction that $|B| < d$. Then $|V_W| > t$, and consequently, as $V_W \subset U_{d+2,n}$, we get that $w(V_W) \geq w(Y \cup \{x_1\})$. But according to Claim 8.17, $Y \cup \{x_1\} \in \Gamma_{Z, W}$. Hence, since $\Gamma_{Z, W} = \Gamma_{V_S, W}$, we infer that $Y \cup \{x_1\} \cup V_S \in \Gamma$. This implies that also $V_W \cup V_S = V$

is authorized, in a contradiction to our assumption that V is a $U_{d+2,n}$ -cooperative set. That completes the proof. $\square$

8.4. Proof of Theorem 3.5—The characterization theorem. Let Γ be an ideal WTAS defined on a set of users U , and let M_1 be its lexicographically minimal minterm. If either Γ has self-sufficient users or u_2 starts no minterm of Γ , then, by Lemma 8.5, the access structure Γ is a composition of two ideal WTASs on smaller sets of users.

If M_1 is a prefix, then, by Theorem 6.7, the access structure Γ is an HTAS. If M_1 is a lacunary prefix, namely, $M_1 = U_{1,d} \cup U_{d+2,k}$ for some $1 \leq d \leq k-2$ and $k \leq n$, then, by Theorem 7.6, the access structure Γ is a TPAS. Otherwise, by Corollary 8.9 and Claim 8.19, there exists within U a subset of strong users. In this case, we conclude by Theorem 8.4 that the access structure Γ is a composition of two ideal WTASs that are defined on sets smaller than U .

As for the other direction, HTASs are ideal and may be realized by linear secret sharing schemes, as shown in [6, 35]. TPASs are also ideal and may be realized by linear secret sharing schemes, as shown here in section 7.1. Finally, given two ideal access structures, we showed in Lemma 8.1 how to construct an ideal secret sharing scheme for their composition. Hence, the composition is also ideal. Furthermore, by Lemma 8.1, if the secret sharing schemes for the two basic access structures are linear, so is the resulting scheme for the composition of the two access structures. This completes the proof of the characterization theorem. $\square$

ADAPTED LIST COLORING OF GRAPHS AND HYPERGRAPHS*

A. V. KOSTOCHKA[†] AND XUDING ZHU[‡]

Abstract. We introduce and study *adapted list coloring* of graphs and hypergraphs. This is a generalization of ordinary list coloring and adapted coloring, and has more applications than these. We prove that the upper bounds on the adaptable choosability of graphs and uniform hypergraphs in terms of maximum degree are sufficiently stronger than those on the ordinary choosability, while the bounds in terms of degeneracy are the same. We also characterize simple graphs with adaptable choosability 2.

Key words. adapted coloring, list coloring, degree conditions

1. Introduction. Hell and Zhu [6] introduced and studied the notion of *adapted coloring* of graphs.

DEFINITION 1.1. Let H be a multihypergraph (i.e., parallel hyperedges are allowed), and let $F : E(H) \rightarrow \{1, 2, \dots, k\}$ be an edge k -coloring of H (not required to be proper). A vertex k -coloring $c : V \rightarrow \{1, 2, \dots, k\}$ of H is adapted to F if for every color j , the preimage $c^{-1}(j)$ does not contain any hyperedge of color j . In other words, if an edge e of H has color j , then it cannot have all its vertices colored with j .

While the multiplicity of edges does not matter in the ordinary vertex coloring, it does in the adapted coloring. If every (hyper)edge of G has multiplicity k and F colors these edges with all distinct k colors, then any vertex k -coloring of G adapted to this edge coloring is an ordinary proper k -coloring. But choosing different edge colorings yields different problems that have more applications than the ordinary vertex coloring. In particular, adaptable vertex coloring has applications to matrix partitions of graphs, trigraph homomorphisms, and full constraint satisfaction problems [3, 4, 5, 7].

The adaptable chromatic number is defined in a natural way.

DEFINITION 1.2. Let G be a multihypergraph. The adaptable chromatic number $\chi_{ad}(G)$ of G is the minimum integer k such that for every edge k -coloring F of G , there is a vertex k -coloring of G adapted to F .

Hell and Zhu [6] proved that a nonempty graph G has $\chi_{ad}(G) \leq 2$ if and only if G has an edge e such that $G - e$ is bipartite. Thus graphs with $\chi_{ad}(G) \leq 2$ can be determined in polynomial time. However, for $k \geq 3$, it is NP-hard to determine whether a graph G has $\chi_{ad}(G) \leq k$. It was also shown in [6] that for any positive integers k and g , there are graphs G of girth at least g such that $\chi_{ad}(G) = \chi(G) = k$.

In this paper, we introduce and study a logical generalization of the adapted coloring—*adapted list coloring*. We will show a rather general application and derive

several properties of such coloring.

DEFINITION 1.3. *Let H be a multihypergraph and $F : E(H) \rightarrow \mathbf{N}$ be any edge coloring of H (not required to be proper). Let a list assignment $L : V(H) \rightarrow 2^{\mathbf{N}}$ be a function that assigns a list $L(v) \subset \mathbf{N}$ to every vertex v of H . A vertex coloring c of $V(H)$ is an L -coloring adapted to F if for every $v \in V(H)$, $c(v) \in L(v)$, and for every color j , the preimage $c^{-1}(j)$ does not contain any hyperedge of color j . An adapted list coloring of H is an L -coloring of H adapted to F for a list L and an edge coloring F .*

Adapted list coloring can model the following rather general problem. There are jobs $J_1, \dots, J_n$ to be made and people (or machines) $P_1, \dots, P_m$ who can perform these jobs. Some people can do several jobs, but everybody has his/her own limits. For every job J_i , there is the list $L(i)$ of people who can perform this job. For every person P_l , there are inclusion minimal sets $e_{l,1}, \dots, e_{l,k_l}$ such that P_l cannot perform all jobs in the set $e_{l,i}$ at the same time. The question is whether we can assign to each P_l a set $c(l)$ of jobs not containing any of the sets $e_{l,1}, \dots, e_{l,k_l}$ so that each job is assigned to somebody who can perform it. This is exactly a list adapted coloring question: Let H be the hypergraph with $V(H) = \{J_1, \dots, J_n\}$ and $E(H) = \bigcup_{l=1}^m \{e_{l,1}, \dots, e_{l,k_l}\}$. The people are the colors, and each vertex J_i is given a list $L(i)$ of admissible colors. Let F be the edge coloring of H such that $F(e_{l,j}) = l$ for every $l = 1, \dots, m$ and $j = 1, \dots, k_l$. By definition, H has a coloring c adapted to F with $c(J_i) \in L(i)$ exactly when there is a proper job assignment in the original problem.

There are other natural applications of adapted list coloring, but in this paper we will concentrate on the properties of this coloring.

DEFINITION 1.4. *We say that a (multi)hypergraph G is adaptably k -choosable if for every edge coloring F and for every list assignment L with $|L(v)| = k$ for all v , there exists an L -coloring of G adapted to F . The minimum integer k , for which G is adaptably k -choosable, is called the adaptable choosability of G and is denoted by $\text{ch}_{ad}(G)$.*

It follows from the definition that if G has an L -coloring adapted to F , then every subgraph H of G also has an L -coloring adapted to F . Let $\text{ch}(G)$ denote the (ordinary) choosability of G . Then we have $\chi_{ad}(G) \leq \text{ch}_{ad}(G) \leq \text{ch}(G)$.

One may expect that for most graphs, the adaptable choosability is significantly less than the ordinary choosability. This is indeed the case. Moreover, for every multigraph G , $\text{ch}_{ad}(G) \leq \lceil \sqrt{8\Delta(G)} \rceil$. For large $\Delta(G)$ this bound is much better than the Brooks' bound for ordinary coloring. However, the situation with degeneracy is quite different. Our first main result says that there are many d -degenerate graphs G with $\chi_{ad}(G) = d + 1$. Every such graph G must have $\chi(G) = \text{ch}(G) = \text{ch}_{ad}(G) = \chi_{ad}(G)$. Furthermore, all this holds for hypergraphs.

THEOREM 1.5. *For any integers $g \geq 3$, $r \geq 2$, and $d \geq 1$, there is an r -uniform hypergraph H of girth at least g that is d -degenerate and $\text{ch}_{ad}(H) = \chi_{ad}(H) = d + 1$.*

Graphs G with $\text{ch}(G) \leq 2$ were characterized by Erdős, Rubin, and Taylor [2]. Graphs G with $\chi_{ad}(G) \leq 2$ were characterized by Hell and Zhu [6]. Our second main result is a characterization of adaptably 2-choosable simple graphs. Of course, it is enough to describe adaptably 2-choosable multigraphs without vertices of degree 0 and 1.

THEOREM 1.6. *A simple connected graph G with minimum degree at least 2 is adaptably 2-choosable if and only if G consists of two or three internally disjoint paths connecting two distinct vertices of G .*

Theorem 1.6 yields a polynomial time algorithm that decides whether a given graph is adaptably 2-choosable.

We use standard notation. For a vertex x of a multihypergraph G , $E_G(x)$ (or $E(x)$ if G is clear from the context) is the set of hyperedges of G containing x , and $d(x) = |E(x)|$ is the degree of x . By $\Delta(G)$ we denote the maximum degree of G .

For brevity, we will often say “a (k, F) -coloring” instead of “a vertex k -coloring adapted to F ” and “an (L, F) -coloring” instead of “an L -coloring adapted to F .”

In the next section we give upper bounds on adaptable choosability in terms of maximum degree, in section 3 we construct many d -degenerate uniform hypergraphs with adaptable choosability $d + 1$, and in the last section we characterize adaptably 2-choosable graphs.

2. Adaptable choosability and maximum degree. Erdős and Lovász used their famous Local Lemma to prove the following bound.

THEOREM 2.1 (see [1, Theorem 2]). *A $(k + 1)$ -chromatic r -uniform hypergraph contains an edge which is intersected by at least $k^{r-1}/4$ other edges. Thus, the degree of at least one vertex is $> k^{r-1}/4r$.*

Practically repeating their proof word by word for adaptable list coloring, one gets the following result.

PROPOSITION 2.2. *If G is an r -uniform (multi)hypergraph and $\Delta(G) \leq k^r/4r$, then $\text{ch}_{ad}(G) \leq k$. In particular, $\text{ch}_{ad}(G) \leq \lceil \sqrt{8\Delta(G)} \rceil$ for every (multi)graph G .*

For every fixed r , the order of magnitude of this bound is close to the best possible, for example, for complete r -uniform hypergraphs, $K_n^{(r)}$.

PROPOSITION 2.3. *If n is large in comparison with r and*

$$(1) \quad \Delta(K_n^{(r)}) \geq 2r k^r \ln k,$$

then $\text{ch}_{ad}(K_n^{(r)}) \geq \chi_{ad}(K_n^{(r)}) > k$. In particular, $\text{ch}_{ad}(K_n) \geq \chi_{ad}(K_n) > 0.5\sqrt{n/\ln n}$.

Proof. Let $\Delta = \Delta(K_n^{(r)})$. By definition,

$$(2) \quad \Delta = \binom{n-1}{r-1} \leq n^{r-1}/(r-1)!.$$

Let k be the largest integer satisfying (1), and let $m = \lceil n/k \rceil$. Consider a random k -coloring F of the edges of $K_n^{(r)}$, where each of the edges is colored uniformly and independently from all the other edges with one of the colors $1, \dots, k$. Let G_i be the hypergraph formed by the edges of color i , $i = 1, \dots, k$. We will prove that

(3) *with positive probability, the independence number of every G_i is less than m .*

That would imply that for some edge k -coloring F of $K_n^{(r)}$, in any vertex k -coloring of $K_n^{(r)}$ adapted to F , each color can appear at most $m - 1$ times, and hence $K_n^{(r)}$ simply has no such coloring. So, we are now proving (3).

For each i , the probability that G_i has an independent set of size m is at most $\binom{n}{m}(1 - \frac{1}{k})^{\binom{m}{r}}$. Hence, (3) will hold if

$$(4) \quad \binom{n}{m} \left(1 - \frac{1}{k}\right)^{\binom{m}{r}} < \frac{1}{k}.$$

Since $m \geq n/k$, the left-hand side of (4) is at most

$$\left(\frac{ne}{m}\right)^m \exp\left\{\frac{-1}{k} \binom{m}{r}\right\} \leq \exp\left\{m \left(\ln ek - \frac{1}{rk} \binom{m-1}{r-1}\right)\right\}.$$

Therefore, (4) will hold for large n if

$$(5) \quad 0.1 + \ln ek < \frac{1}{rk} \binom{m-1}{r-1}.$$

By (2), for n (and hence m and k) large in comparison with r ,

$$\frac{1}{rk} \binom{m-1}{r-1} \geq 0.9 \frac{1}{rk} \frac{m^{r-1}}{(r-1)!} \geq \frac{0.9}{rk} \frac{n^{r-1}}{(r-1)!k^{r-1}} \geq \frac{0.9}{rk^r} \Delta.$$

Thus (5) will hold for large n if

$$(6) \quad 0.9\Delta > rk^r(0.1 + \ln ek).$$

By the definition of k for large n , $0.1 + \ln ek < 1.1 \ln k$. Hence, to satisfy (6), it is enough that $0.9\Delta > 1.1rk^r \ln k$, which follows from (1). $\square$

For a positive integer k , let $f(k)$ (respectively, $f_m(k)$) be the largest Δ such that $\text{ch}_{ad}(G) \leq k$ for every simple graph (respectively, multigraph) G with maximum degree at most Δ . It follows from Propositions 2.2 and 2.3 that $k^2/8 \leq f_m(k) \leq f(k) \leq 4k^2 \ln k$. It is also interesting to find better estimates of $f_m(k)$ and $f(k)$ for small k . Theorem 1.6 yields $f_m(2) = f(2) = 2$. Theorem 2.4 below provides another upper bound for $\text{ch}_{ad}(G)$ when k is small.

THEOREM 2.4. *If G is a multigraph with maximum degree Δ , then $\text{ch}_{ad}(G) \leq \lceil \Delta/2 \rceil + 1$.*

Proof. Let F be an arbitrary edge coloring of G . We shall prove that if each vertex x of G is given a list $L(x)$ of at least $\lceil d(x)/2 \rceil + 1$ permissible colors, then G has an (L, F) -coloring. (Recall that “ (L, F) -coloring” means “ L -coloring adapted to F ”.) We prove this by induction on the number of edges of G . Without loss of generality, we assume that G is connected. If G has a vertex of degree 1, then $|L(x)| \geq 2$. Therefore, any (L, F) -coloring of $G - x$ can be extended to an (L, F) -coloring of G . If G is a cycle, then the conclusion follows from Theorem 1.6 in section 4. If G has a vertex x of degree 3, then $|L(x)| \geq 3$. Assume $e \in E(x)$ and $F(e) = j$. Remove color j from $L(x)$ to obtain a list assignment L' of $G - e$. By induction hypothesis, $G - e$ has an (L', F) -coloring c . Since $c(x) \neq F(e)$, c is also an (L, F) -coloring of G . Assume that G has a vertex x of degree $d(x) \geq 4$ with $|L(x)| = \lceil d(x)/2 \rceil + 1 < d(x)$. If for some edge $e \in E(x)$, $F(e) \notin L(x)$, then an (L, F) -coloring of $G - e$ is also an (L, F) -coloring of G . Thus we assume that $F(e) \in L(x)$ for all $e \in E(x)$. Then there are two edges $e, e' \in E(x)$ with $F(e) = F(e') = j$. Remove color j from $L(x)$ to obtain a list assignment L' of $G - \{e, e'\}$. By induction hypothesis, $G - \{e, e'\}$ has an (L', F) -coloring c . Since $c(x) \neq F(e) = F(e')$, c is also an (L, F) -coloring of G . $\square$

Theorem 2.4 implies that $f_m(3) \geq 4$. Figure 1 shows an edge 3-colored multigraph G with $\Delta(G) = 5$ that has no vertex 3-coloring adaptable to the given edge coloring. Indeed, assume it has such a 3-coloring c . Then either $c(v) \neq 1$ or $c(v') \neq 1$. By the left-right symmetry, we may assume that $c(v) \neq 1$. Now by the up-down symmetry, we may assume that $c(v) = 2$. Then $c(x) \neq 2$ and $c(y) \neq 2$. Since edge xy has color 1, at least one of x and y (say, x) should be colored with 3. Thus all three vertices

FIG. 1. A multigraph G with $\text{ch}_{ad}(G) \geq 4$.

below x can be colored with only 1 or 2, but the double edges between these vertices forbid any two of them to have the same color.

This example shows that $f_m(3) = 4$. We also have an example showing that $f(3) \leq 5$, but were not able to determine whether $f(3)$ is 4 or 5.

3. Adaptable choosability of d -degenerate graphs. While the upper bounds on adaptable choosability of graphs in terms of maximum degree are significantly better than those on ordinary choosability, this is not the case for bounds in terms of degeneracy. Recall that a multihypergraph G is d -degenerate if each subhypergraph G' of G has a vertex of degree at most d . It is obvious that $\text{ch}(G) \leq d + 1$ for every d -degenerate G . Since $\text{ch}_{ad}(G) \leq \text{ch}(G)$, we have $\text{ch}_{ad}(G) \leq d + 1$. In [6], examples of d -degenerate graphs G with $\chi_{ad}(G) = d + 1$ are given. It is also shown in [6] that for any positive integer d , there are graphs of large girth with $\chi_{ad}(G) = \chi(G) = d + 1$. However, these graphs are far from being d -degenerate. In this section, we prove Theorem 1.5, which is a common strengthening and generalization of these results in [6]. But first we prove a weaker statement.

PROPOSITION 3.1. *For any integers $g \geq 3$, $r \geq 2$, and $k \geq 1$, there is an r -uniform hypergraph G with girth at least g and $\text{ch}_{ad}(G) \geq k$.*

Proof. Let n be large in comparison with g, r , and k . Consider the random r -uniform n -vertex hypergraph $\mathbf{H}(n, r, k)$ with colored edges (and labeled vertices) obtained in the following way: Every r -element subset e of $\{1, \dots, n\}$ independently of all other such r -tuples with probability $1 - (\ln \ln n)/n^{r-1}$ is not in $\mathbf{H}(n, r, k)$, and for each $i = 1, \dots, k$, with probability $\ln \ln n / kn^{r-1}$, e is an edge in $\mathbf{H}(n, r, k)$ colored with color i .

Let F denote the obtained edge coloring, and let H_i be the subhypergraph of $\mathbf{H}(n, r, k)$ induced by the edges of color i , $i = 1, \dots, k$. We will prove using a standard argument that with positive probability both (i) and (ii) below hold:

- (i) there is a set S of at most $n/3$ vertices such that $\mathbf{H}(n, r, k) - S$ has no cycles of length g or less;
- (ii) independence number of every H_i is at most $n/2k$.

If we prove this, then there is a hypergraph H' for which both (i) and (ii) hold. Hence, the hypergraph $H'' = H' - S$ has at least $2n/3$ vertices and in any (k, F) -

coloring of H'' each color can be used for at most $n/2k$ vertices. Thus H'' has no such coloring.

First, consider property (i). For given two vertices v and w , the probability that $\mathbf{H}(n, r, k)$ has at least two edges containing both v and w is at most

$$\sum_{t=2}^{\binom{n-2}{r-2}} \left(\frac{\ln \ln n}{n^{r-1}} \right)^t \binom{\binom{n-2}{r-2}}{t} \leq \sum_{t=2}^{\binom{n-2}{r-2}} \frac{1}{t!} \left(\frac{\ln \ln n}{(r-2)!n} \right)^t \leq \left(\frac{\ln \ln n}{n} \right)^2.$$

Since there are $\binom{n}{2}$ such pairs $\{v, w\}$, the expectation E_2 of the number of the cycles of length two in $\mathbf{H}(n, r, k)$ is at most $0.5(\ln \ln n)^2$. Similarly, for $3 \leq j \leq g$, the expectation E_j of the number of the cycles of length j in $\mathbf{H}(n, r, k)$ is at most $(\ln \ln n)^j/j$. Therefore, the expectation E_0 of the number of the cycles of all lengths from 2 to g in $\mathbf{H}(n, r, k)$ is at most $(\ln \ln n)^g$. Hence for n large, (i) holds with probability at least $1 - 3(\ln \ln n)^g/n > 0.9$.

Similar to the proof of Proposition 2.3, for each $1 \leq i \leq k$, the probability that H_i has an independent set of size $m = \lceil n/2k \rceil$ is at most

$$\binom{n}{m} \left(1 - \frac{\ln \ln n}{kn^{r-1}} \right)^{\binom{m}{r}} \leq \left(\frac{ne}{m} \exp \left\{ -\frac{\ln \ln n}{kn^{r-1}} \binom{m-1}{r-1} / r \right\} \right)^m.$$

For fixed r and k and large n , the m th root of the right-hand side is at most

$$2ke \exp \left\{ -0.5 \frac{\ln \ln n}{kn^{r-1}} \frac{n^{r-1}}{r!k^{r-1}} \right\} \leq 6k \frac{(kr)^r}{\ln n} < \frac{1}{2k}.$$

It follows that with probability at least $0.9 - \frac{k}{2k} = 0.4$, both (i) and (ii) hold for $\mathbf{H}(n, r, k)$. $\square$

Now we are ready to prove Theorem 1.5. For convenience, we restate it here.

THEOREM 1.5. *For any integers $g \geq 3$, $r \geq 2$, and $d \geq 1$, there is an r -uniform d -degenerate hypergraph G with girth at least g and $\text{ch}_{ad}(G) = \chi_{ad}(G) = d + 1$.*

Proof. As observed above, $\chi_{ad}(G) \leq \text{ch}_{ad}(G) \leq \text{ch}(G) \leq d + 1$ for every d -degenerate G . So, it suffices to show that there is an r -uniform d -degenerate hypergraph G' of girth at least g with $\chi_{ad}(G') > d$, i.e., G' has a edge d -coloring F' such that G' has no vertex (d, F') -coloring.

We prove this by induction on d . When $d = 1$, for each r , let G_r be the hypergraph that contains one edge of size r and nothing else. Clearly, $\chi_{ad}(G_r) = 2$.

Assume that the conclusion is true for degeneracy $d - 1$ and all r and g . Given positive integers r and g , let H be an r -uniform $(d - 1)$ -degenerate hypergraph of girth at least g with $\chi_{ad}(H) = d$. Let $n = |V(H)|$ and $r' = n(r - 1)$. By Proposition 3.1, there exists an r' -uniform hypergraph $G = (V, E)$ of girth at least g with $\chi_{ad}(G) \geq d + 1$. Let G' be the hypergraph constructed as follows. For each edge $s = \{v_1, v_2, \dots, v_{r'}\}$ of G , add a disjoint copy of H , called H_s (including the vertices and edges). The vertices of H_s are $\{u_{1,s}, u_{2,s}, \dots, u_{n,s}\}$. Partition these vertices in s into n parts, $X_1, X_2, \dots, X_n$, each of cardinality $r - 1$. Add the edges $\{v_{j,s}\} \cup X_j$ ($j = 1, 2, \dots, n$). We denote the subhypergraph of G' induced by $s \cup V(H_s)$ by G_s (see Figure 2).

Since $\chi_{ad}(H) = d$, there is a $(d - 1)$ -edge coloring F of H such that H has no $(d - 1, F)$ -coloring. Since $\chi_{ad}(G) \geq d + 1$, there is an edge d -coloring Q of G such that G has no (d, Q) -coloring.

Define edge d -coloring F' of G' as follows. Let e be a hyperedge of G' . Then e is contained in G_s for some hyperedge s of G . Assume that $Q(s) = j$. If e is a hyperedge

FIG. 2. The part of G' corresponding to an edge s of G .

of H_s , then let

$$F'(e) = \begin{cases} F(e) & \text{if } F(e) \neq j, \\ d & \text{if } F(e) = j. \end{cases}$$

If e is of the form $\{v_{i,e}\} \cup X_i$, then let $F'(e) = i$. We shall show that G' has no (d, F') -coloring. Assume to the contrary that $c' : V(G') \rightarrow \{1, 2, \dots, d\}$ is such a coloring. Since $\chi_{ad}(G) = d + 1$, there is a hyperedge $s = \{v_1, v_2, \dots, v_{r'}\}$ of G such that $c'(v_1) = c'(v_2) = \dots = c'(v_{r'}) = Q(s)$. If $c(v_{i,s}) = Q(s)$ for any $i \in \{1, 2, \dots, n\}$, then $\{v_{i,s}\} \cup X_i$ is a hyperedge of G' of color $Q(s)$, and all the vertices of this hyperedge are colored by $Q(s)$, which is a contradiction. If $c'(v_{i,s}) \neq Q(s)$ for all $i \in \{1, 2, \dots, n\}$, then the restriction of c' to the copy G_s of G is a $(d - 1, F)$ -coloring, contrary to our assumption.

By construction, G' is d -degenerate and has girth at least g . This proves Theorem 1.5. $\square$

4. Adaptably 2-choosable graphs. The next observation will be quite helpful.

PROPOSITION 4.1. *Let G be a multihypergraph, L be a list assignment for the vertices of G , and F be an edge coloring of G . If G has no (L, F) -coloring, but after deleting any edge or vertex the resulting multihypergraph G' has, then*

- (a) *for every $e \in E(G)$, color $F(e)$ is present in the list of every $v \in e$;*
- (b) *for every $v \in V(G)$, every color in $L(v)$ is a color of some edge containing v .*

Proof. If $F(e)$ is not present in the list of some vertex $v \in e$ and $G - e$ has an (L, F) -coloring, then this coloring is also an (L, F) -coloring of G . If $L(v)$ contains a color α that is not a color of any edge containing v , and $G - v$ has an (L, F) -coloring c , then letting $c(v) = \alpha$ we get an (L, F) -coloring of G . $\square$

Given a coloring F of the edges of a hypergraph G , there is a unique list assignment L such that both (a) and (b) in Proposition 4.1 hold. We will denote this list assignment by $L_{G,F}$ and will say that it *respects* F . Furthermore, instead of “ $(L_{G,F}, F)$ -coloring of G ” we will simply say “ F -coloring of G .” For a vertex x of G , let $F(x) = \{F(e) : e \in E(x)\}$.

LEMMA 4.2. *Let $P = (v_0, v_1, \dots, v_n)$ be a path and F be any edge coloring of P . Then P has no F -coloring.*

Proof. Let $L = L_{P,F}$. For $i = 1, \dots, n$, let $e_i = v_{i-1}v_i$. Assume that c is an F -coloring of P . Then $L(v_0) = \{F(e_1)\}$ and hence $c(v_0) = F(e_1)$. This forces $L(v_1) \neq \{F(e_1)\}$. Since L respects F , we must have $F(e_2) \neq F(e_1)$ and $c(v_1) = F(e_2)$. Repeating this argument, we conclude that $c(v_i) = F(e_{i+1})$ for $i = 0, 1, \dots, n-1$. But $L(v_n) = \{F(e_n)\}$ and hence $c(v_n) = F(e_n) = c(v_{n-1})$, contrary to our assumption that c is an F -coloring of P . $\square$

COROLLARY 4.3. *Let C be a cycle and F be an edge coloring of P . If for some vertex $x \in V(C)$, $|L_{C,F}(x)| = 1$, then C has no F -coloring.*

Proof. Let $L = L_{C,F}$. Split the vertex x of C into two vertices x', x'' with each of x', x'' incident to one edge in $E(x)$, and let $L(x') = L(x'') = L(x)$. The resulting

graph is a path P , and F can be viewed as an edge coloring of P . Any F -coloring of C is also an F -coloring of P . Thus the conclusion follows from Lemma 4.2. $\square$

LEMMA 4.4. *If G is a subdivision of K_4 , then G is not adaptably 2-choosable.*

Proof. Consider first the case that no two adjacent edges are subdivided, i.e., that the subdivided edges form a matching of K_4 . Then the set of nonsubdivided edges of K_4 contains a 4-cycle C_4 . Let F be an edge coloring of G such that the edges of this 4-cycle are colored by color 1. The other edges of G are colored arbitrarily so that each vertex is incident to edges of two distinct colors. For example, the first two graphs in Figure 3 are colored in this way. Let $L = L_{G,F}$. Assume that G has an F -coloring c .

Let the four vertices of the 4-cycle C_4 be v_1, v_2, v_3, v_4 (these four vertices are also the only vertices of G of degree 3) in this order. Then either neither of v_1 and v_3 is colored by color 1, or neither of v_2 and v_4 is colored by 1. Without loss of generality, assume that neither of v_1 and v_3 is colored by 1. Then the restriction of c to the path $P_{1,3}$ of G connecting v_1 and v_3 is an (L', F) -coloring of $P_{1,3}$, where $L' = L_{P_{1,3}, F}$. This contradicts Lemma 4.2.

FIG. 3. Some subdivisions of K_4 .

Next, assume that G has two adjacent edges that are subdivided. Let H be the third graph in Figure 3. Then G is a subdivision of H .

Let F be an edge coloring F of a multigraph Q and $L = L_{G,F}$. We say that F is *difficult* if the following hold:

- (i) $|L(v)| = 2$ for each $v \in V(Q)$.
- (ii) For each color j , the edges of color j induce a tree T_j .
- (iii) Q has no (L, F) -coloring.

The edge coloring F of graph H in Figure 3 is difficult: (i) and (ii) are obvious. To see that (iii) holds, observe that if the top vertex is colored by 1, then the vertex at the center and the leftmost vertex must both be colored by 2, which is a contradiction. If the top vertex is colored by 3, then the rightmost vertex must be colored by 4, which forces both degree 2 vertices of H be colored by 1, which in turn forces the vertex at the center and the leftmost vertex be both colored by 2; which is again a contradiction.

CLAIM 4.1. *Suppose that a multigraph Q has a difficult coloring and Q' is obtained from Q by subdividing one edge. Then Q' has a difficult coloring.*

Proof. Assume Q' is obtained from Q by inserting a vertex w on an edge $e^* = uv$ of Q . In other words, e^* is subdivided into two edges $e' = uw$ and $e'' = wv$. Assume that e^* has color j . Let T_j be the tree induced by the edges of color j . Let T'_j be the tree obtained from T_j by subdividing the edge e^* into $e' = uw$ and $e'' = wv$. Vertex w separates $E(T'_j)$ into two parts, say E_1 (containing e') and E_2 (containing e''). Let j' be a new color (a color not used on any edge of Q). Let F' be the edge coloring of

Q' defined as follows:

$$F'(e) = \begin{cases} j & \text{if } e \in E_1, \\ j' & \text{if } e \in E_2, \\ F(e) & \text{otherwise.} \end{cases}$$

Now we show that F' is a difficult coloring of Q' . It is obvious that (i) and (ii) hold. Assume to the contrary that c' is an $L_{Q', F'}$ -coloring of Q' adaptable to F' . Let c be the L -coloring of Q defined as

$$c(x) = \begin{cases} j & \text{if } c'(x) = j \text{ or } j', \\ c'(x) & \text{otherwise.} \end{cases}$$

Observe that $c'(w) \in \{j, j'\}$, and hence either $c'(u) \neq j$ or $c'(v) \neq j'$. In either case, the ends u and v of the edge e^* cannot both have color j . This implies that c is an (L, F) -coloring of Q , contrary to our assumption that Q is not F -colorable. $\square$

By repeatedly applying Claim 4.1, we derive that each subdivision of H has a difficult edge coloring, and hence is not adaptably 2-choosable. This completes the proof of Lemma 4.4. $\square$

It follows from Lemma 4.4 that adaptably 2-choosable graphs are K_4 -minor free, i.e., series-parallel graphs.

LEMMA 4.5. *If a connected multigraph G has two cycles of length at least 3 that have at most one vertex in common, then G is not adaptably 2-choosable.*

Proof. Assume G has two cycles C_1 and C_2 of length at least 3 that have at most one vertex in common. Let P be a shortest path connecting C_1 and C_2 . Let $\{v\} = V(P) \cap V(C_1)$ and $\{v'\} = V(P) \cap V(C_2)$. This includes the case that $v' = v$.

Let G' be the subgraph of G induced by $V(C_1 \cup C_2 \cup P)$. Let F be an edge coloring of G' such that (1) the two edges of C_1 incident with v are colored with 1, (2) the two edges of C_2 incident with v' are colored with 2, and (3) the remaining edges are colored so that each vertex is incident to edges of two distinct colors (for example, all other edges may have different colors). We shall show that there is no F -coloring of G' . Assume to the contrary that c is such a coloring. If $c(v) = 1$, then the restriction of c to C_1 is an F -coloring of C_1 , contrary to Corollary 4.3. Similarly, if $c(v') = 2$, then the restriction of c to C_2 is an F -coloring of C_2 . If $c(v) \neq 1$ and $c(v') \neq 2$, then the restriction of c to the path P is an F -coloring of P , a contradiction to Lemma 4.2. $\square$

LEMMA 4.6. *If a simple graph G consists of four internally vertex-disjoint paths P_1, P_2, P_3 , and P_4 connecting two vertices u, v , then G is not adaptably 2-choosable.*

Proof. If P is a path not of length 2, then there is a proper edge coloring of P with at most three colors, such that the two end edges (which can be the same edge if P has length 1) are colored with the same color. If P is a path not of length 1, then there is a proper edge coloring of P with at most three colors, such that the two end edges are colored with two given distinct colors.

Case 1. At least two of the paths are not of length 2. Since at most one of $P_1, \dots, P_4$ has length 1, we can renumber our paths so that P_1 and P_2 are not of length 1, and P_3 and P_4 are not of length 2. Color properly the edges of P_1 (respectively, P_2) so that the edge incident to u is colored by 1 (respectively, by 2), and the edge incident to v is colored by 2 (respectively, by 1). Color the edges of P_3 (respectively, P_4) so that both end edges are colored by 1 (respectively, by 2). We have $L(u) = L(v) = \{1, 2\}$. If c is an F -coloring of G , then $c(u), c(v) \in \{1, 2\}$. If $c(u) = c(v) = 1$, then the restriction of c to P_3 is an F -coloring of P_3 , contrary to Lemma 4.2. If $c(u) = c(v) = 2$, then we

get a contradiction by considering path P_4 . If $c(u) = 1$ and $c(v) = 2$, then we obtain a contradiction with the edge coloring of P_1 , and if $c(u) = 2$ and $c(v) = 1$, then we obtain a contradiction with the edge coloring of P_2 .

Case 2. Each of P_1 , P_2 , and P_3 has length 2 and the length of P_4 is not 1. By above we can color the edges of G so that (a) the edges incident to u in P_1 and P_2 are colored with 1, and in P_3 and P_4 are colored with 2; (b) the edges incident to v in P_1 and P_3 are colored with 3, and in P_2 and P_4 are colored with 4. Now $L(u) = \{1, 2\}$ and $L(v) = \{3, 4\}$. Similarly to Case 1, each of the four paths forbids one of the four possibilities $(1, 3)$, $(1, 4)$, $(2, 3)$, and $(2, 4)$ for the pair $(c(u), c(v))$.

Case 3. $|E(P_1)| = |E(P_2)| = |E(P_3)| = 2$ and $|E(P_4)| = 1$. For $1 \leq i \leq 3$, let w_i be the central vertex of the path P_i . We let $F(uv) = F(uw_1) = F(w_2v) = 1$, $F(uw_2) = F(uw_3) = 2$ and $F(w_1v) = F(w_3v) = 3$. It is easy to check that G has no F -coloring for this F . $\square$

Now we are ready to prove Theorem 1.6. For convenience, we restate it here.

THEOREM 1.6. *A simple connected graph G with minimum degree at least 2 is adaptably 2-choosable if and only if G consists of two or three internally disjoint paths connecting two distinct vertices of G .*

Proof. Assume first that a simple connected graph G with minimum degree at least 2 is adaptably 2-choosable. By Lemma 4.4 G is series-parallel. Furthermore, by Lemma 4.5, G is 2-connected and any two cycles of G have at least two vertices in common. This implies that G has two vertices u and v such that for some $k \geq 2$, G consists of k internally vertex disjoint paths connecting u and v . By Lemma 4.6, $k \leq 3$. This proves the “only if” part of the theorem.

Suppose now that the “if” part of the theorem does not hold. Then there is an inclusion minimal subgraph G of a graph G' consisting of three internally disjoint paths connecting some vertices u and v that has no L -coloring adapted to an edge-coloring F , where $|L(w)| = 2$ for every $w \in V(G)$. By Proposition 4.1, G has no isolated or pendant vertices, and it is enough to consider F -colorings.

Let F be an edge coloring of G such that $|F(x)| = 2$ for each vertex x of G . Assume $F(u) = \{a, b\}$ and $F(v) = \{c, d\}$ (where $\{a, b\}$ and $\{c, d\}$ need not be disjoint).

There are four distinct ways to color u and v , namely $(c(u), c(v)) \in \{(a, c), (a, d), (b, c), (b, d)\}$. For each P_i , there is exactly one choice of the pair $(c(u), c(v))$ that cannot be extended to a coloring of P_i adapted to F . Thus, if $2 \leq k \leq 3$, then at least one of the four choices of $(c(u), c(v))$ can be extended to a coloring adapted to F for each of the u, v -paths. $\square$

Remark. Using the proof of the “only if” part of the theorem, one can characterize also all adaptably 2-choosable multigraphs. The remaining argument is a simple case analysis, so we just give a preliminary idea and state the characterization.

We need the following notion: a *double x, y -path* is a multigraph whose underlying simple graph is an x, y -path and in which every edge has multiplicity two. If G has a vertex x with only one neighbor y (does not matter how many edges connect x and y) and $G - x$ is adaptably 2-choosable, then G is also adaptably 2-choosable. Thus it is enough to characterize adaptably 2-choosable multigraphs whose underlying simple graphs have minimum degree at least two. Theorem 1.6 tells us that these underlying graphs have very limited structure.

THEOREM 4.7. *A connected multigraph G whose underlying simple graph G_s has minimum degree at least 2 is adaptably 2-choosable if and only if all of the following holds:*

- (a) G_s consists of two or three internally disjoint paths connecting two distinct vertices x and y of G ;

- (b) all double x, y -paths have the same parity;
- (c) if there are three internally disjoint x, y -paths P_1, P_2 , and P_3 such that P_1 is a double x, y -path of an odd length, then one of P_2 and P_3 has length 1;
- (d) if there are three internally disjoint x, y -paths P_1, P_2 , and P_3 such that P_1 is a double x, y -path of an even length, then at least one of P_2 and P_3 has length 2.

This description is somewhat more sophisticated than Theorem 1.6, but it yields a polynomial-time algorithm for recognition of adaptably 2-choosable multigraphs.

Acknowledgment. We thank a referee for helpful comments.

UNIT CIRCULAR-ARC GRAPH REPRESENTATIONS AND FEASIBLE CIRCULATIONS*

MIN CHIH LIN[†] AND JAYME L. SZWARCFITER[‡]

Abstract. In a recent paper, Durán et al. [*J. Algorithms*, 58 (2006), pp. 67–78] described an algorithm of complexity $O(n^2)$ for recognizing whether a graph G with n vertices and m edges is a unit circular-arc (UCA) graph. Furthermore, the following open questions were posed in the above paper: (i) Is it possible to construct a UCA model for G in polynomial time? (ii) Is it possible to construct a UCA model, whose extremes of the arcs correspond to integers of polynomial size? (iii) If (ii) is true, could such a model be constructed in polynomial time? In the present paper, we describe a characterization of UCA graphs, based on network circulations. The characterization leads to a different recognition algorithm and to answering these questions in the affirmative. We construct a UCA model whose extremes of the arcs correspond to integers of size $O(n)$. The proposed algorithms, for recognizing UCA graphs and constructing UCA models, have complexities $O(n + m)$. Furthermore, the complexities reduce to $O(n)$, if a proper circular-arc (PCA) model of G is already given as the input, provided the extremes of the arcs are ordered. We remark that a PCA model of G can be constructed in $O(n + m)$ time, using the algorithm by Deng, Hell, and Huang [*SIAM J. Comput.*, 25 (1996), pp. 390–403]. Finally, we also describe a linear time algorithm for finding feasible circulations in networks with nonnegative lower capacities and unbounded upper capacities. Such an algorithm is employed in the model construction for UCA graphs.

1. Introduction. In a recent paper, Durán et al. [2] described an algorithm of complexity $O(n^2)$ for recognizing whether a graph G , with n vertices and m edges, is a unit circular-arc (UCA) graph. Furthermore, the following open questions were posed in [2]:

- (i) Is it possible to construct a UCA model for G in polynomial time?
- (ii) Is it possible to construct a UCA model, whose extreme points of the arcs correspond to integers of polynomial size?
- (iii) If (ii) is true, could such a model be constructed in polynomial time?

Problems (ii) and (iii) were also proposed in the book by Spinrad [10]. As for problem (i), the proof of the characterization of UCA graphs in terms of forbidden subgraphs by Tucker [13], actually contains an algorithm for constructing a UCA model. However, due to the possible manipulation of large integers, the complexity of this algorithm is unknown, and so far the construction of a UCA model in polynomial time remains unsolved [2, 10].

In the present paper, we propose a characterization for UCA graphs, which leads to a different recognition algorithm and to answering in affirmative the previous three questions. An extended abstract of the present paper appeared in [7]. The proposed algorithm recognizes UCA graphs and constructs UCA models whose extremes of the arcs correspond to integers of $O(n)$ size, in overall time $O(n + m)$. Furthermore, if the graph G is already given by a proper circular-arc (PCA) model of it, then the complexity of the proposed algorithm reduces to $O(n)$, provided the extremes of the arcs are ordered. Observe that a PCA model for G , when given by its vertices and edges, can be constructed in $O(n + m)$ time, employing the algorithm by Deng, Hell, and Huang [1]. Recall that UCA graphs are PCA graphs.

Our method employs network circulations. We formulate an algorithm finding a feasible circulation in a network with nonnegative lower capacities and unbounded upper capacities. The algorithm has linear time complexity in the size of the network.

Denote by G an undirected graph, with vertex set $V(G)$ and edge set $E(G)$. For an edge $e \in E(G)$, write $e = uv$, where u and v are the *extremes* of e . Denote by $d_G(v)$ for the *degree* of v in G . We may also simply write $d(v)$, instead. Use a similar notation for a digraph D . For a directed edge $e = uv \in E(D)$, say that u is the *start* and v the *end* of e . Write $d_G^-(v)$ and $d_G^+(v)$ for the *indegree* and *outdegree* of vertex v , respectively. Again, also write $d^-(v)$ and $d^+(v)$, simply. Moreover, $E^-(v)$, $E^+(v) \subseteq E(D)$, represent the set of edges of D entering and leaving v , respectively. Also, D is *connected* when its underlying (undirected) graph is connected. Say that D is *strongly connected* when D contains paths from u to v and from v to u , for any $u, v \in V(D)$. Finally, the *bridge* of D is an edge contained in no (directed) cycle of D .

An *out-arborescence* (*in-arborescence*) T of D is a spanning connected subdigraph of D such that there is a distinguished vertex $v^* \in V(T)$, called the *root* of T , satisfying $d_T^-(v^*) = 0$ ($d_T^+(v^*) = 0$), while $d_T^-(v) = 1$ ($d_T^+(v) = 1$) for all of the remaining vertices $v \neq v^*$ of T . Clearly, a strongly connected digraph admits both an out-arborescence and in-arborescence, with root at any arbitrary vertex. When $d_T^+(v) = 0$ ($d_T^-(v) = 0$), call v a *leaf* of T . For $u, v \in V(T)$, if T contains a path from u to v , then u is an *ancestor* of v , and v a *descendant* of u . A *leaf-root ordering* of T is a sequence $v_1, \dots, v_n$ of its vertices, such that $i < j$ implies v_i is not an ancestor (descendant) of v_j in T .

A *network* is a digraph D , having real values b_j, c_j associated to each edge $e_j \in E(D)$. Call b_j the *lower capacity* of e_j , while c_j is the *upper capacity* of e_j . A *circulation* of D is a function W assigning a real number w_j to each edge e_j of D , called the *flow* of e_j . Denote $w^-(v_i) = \sum_{w_j \in E^-(v_i)} w_j$ and $w^+ = \sum_{w_j \in E^+(v_i)} w_j$, for each $v_i \in V(D)$. A circulation is *feasible* when it satisfies

$$w^-(v_i) = w^+(v_i), \text{ for each } v_i \in V(D), \text{ and } b_j \leq w_j \leq c_j, \text{ for each } e_j \in E(D).$$

For our purposes, we only consider networks with finite nonnegative lower capacities and flow values, and unbounded the upper capacities. In this case, the condition $w_j \leq c_j$ is always satisfied.

A *circular-arc* (CA) model for a graph G is a pair $(C, \mathcal{A})$, where C is a circle and $\mathcal{A}$ is a collection of arcs of C , such that each arc $A_i \in \mathcal{A}$ corresponds to a vertex $v_i \in V(G)$, and any A_i, A_j intersects precisely when v_i, v_j are adjacent in G , $1 \leq i, j \leq n$, and $i \neq j$. A CA graph is one admitting a CA model. When no arc of $\mathcal{A}$ properly contains another arc of $\mathcal{A}$ then $(C, \mathcal{A})$ is a PCA model, while if all arcs of $\mathcal{A}$ have the same length, then $(C, \mathcal{A})$ is a UCA model. A PCA (UCA) graph is one admitting a PCA (UCA) model. A *normal* model is a PCA model where no two

(a)

(b)

FIG. 1. A PCA graph and a normal model of it.

arcs cover the circle. Figure 1(a) depicts a PCA graph and a normal model of it is in Figure 1(b). When traversing the circle C , always choose the clockwise direction. If s, t are points of C , then write (s, t) to mean the arc of C defined by traversing the circle from s to t . Call s, t the *extremes* of (s, t) , while s is the *start* and t the *end* of the arc. The *extremes* of $\mathcal{A}$ are the extremes of $A_i \in \mathcal{A}$. For $A_i \in \mathcal{A}$, write $A_i = (s_i, t_i)$. We assume the labelling $A_1, \dots, A_n$ of the arcs is such that the sequence of the start points $s_1, \dots, s_n$ is in the circular ordering of C . For $p, q \in A_i$, if $(s_i, p) \subseteq (s_i, q)$, then p *precedes* q , and q *succeeds* p in A_i . For $p, q, t \in C$, write $\max\{p, q\}_t$ to represent the

point, p or q , which is farthest from t , in the circular ordering of C . If p is an extreme of $\mathcal{A}$, then denote by $PRED(p)$ and $SUC(p)$, the extreme of $\mathcal{A}$, which immediately precedes and succeeds p , in the circular ordering, respectively. We assume that all arcs of C are open, no two extremes of distinct arcs of $\mathcal{A}$ coincide, and no single arc covers C . An arc of C defined by two consecutive extremes of $\mathcal{A}$ is a *segment* of $(C, \mathcal{A})$. Clearly, C is the union of the $2n$ segments of $(C, \mathcal{A})$ and the extreme points. Figure 1(b) shows the ten segments of the corresponding CA model.

The first characterization of CA graphs leading to a polynomial time recognition algorithm is due to Tucker [12, 14]. Subsequently, faster algorithms have been described by Hsu [6] and by Eschen and Spinrad [3]. More recently, a linear time recognition algorithm for CA graphs has been formulated by McConnell [8]. Deng, Hell, and Huang [1] described an algorithm for recognizing PCA graphs in linear time. This algorithm also constructs a corresponding PCA model for the graph. As for UCA graphs, the first polynomial time recognition algorithm is that by Durán et al. [2].

Given a graph G , the algorithm [2] initially employs algorithm [1] to construct a PCA model $(C, \mathcal{A})$ of G , if any. Clearly, G is not UCA if such a model does not exist. Afterwards, this algorithm proceeds with two main phases: The first of them is to transform $(C, \mathcal{A})$ into a normal model. The last phase is the actual algorithm for deciding if G is a UCA graph, employing the normal model constructed in the first phase. The complexities of the algorithms corresponding to these two phases are both $O(n^2)$. The method proposed in the present paper is also composed by similar phases. However, the complexities of the two corresponding algorithms are $O(n)$.

In section 2, we describe the characterizations in which are based the proposed algorithms. The characterization of UCA graphs relates them to circulations in special networks. Section 3 describes the algorithm for finding feasible circulations in general networks, having nonnegative lower capacities and unbounded upper capacities. Section 4 presents the algorithm for constructing normal models. Section 5 contains the actual algorithm for recognizing UCA graphs and constructing UCA models. Further comments form the last section.

2. A characterization for UCA graphs. In this section, we characterize UCA graphs in terms of circulations of a special network. The following two theorems are basic to our purposes.

THEOREM 1 (see Golumbic [4] and Tucker [13]). *Let G be a PCA graph. Then G admits a normal model.*

THEOREM 2 (see Tucker [13]). *Let G be a UCA graph and $(C, \mathcal{A})$ a normal model of it. Then G admits a UCA model, such that its extremes are in the same circular ordering as those of $(C, \mathcal{A})$.*

Let G be a CA graph and $(C, \mathcal{A})$ a CA model of it. Denote by $S_1, \dots, S_{2n}$ the segments of $(C, \mathcal{A})$ in circular ordering, where the start of S_1 and that of A_1 coincide. Denote by l_j the length of S_j . Clearly, any arc $A_i \in \mathcal{A}$ may be decomposed into the segments which form it. The length of A_i equals $\sum_{S_j \subseteq A_i} l_j$. The decomposition allows one to represent relations between lengths of arcs by relations between lengths of the corresponding segments. Consequently, the condition of equality between any two arc lengths required by a UCA model can be expressed by a system of $n - 1$ linear equations q_i , together with $2n$ inequalities, called the *full system* of $(C, \mathcal{A})$:

$$(2.1) \quad q_i : \sum_{S_j \subseteq A_i} l_j = \sum_{S_j \subseteq A_{i+1}} l_j, \quad i = 1, \dots, n - 1,$$

$$(2.2) \quad l_j > 0, \quad j = 1, \dots, 2n.$$

Clearly, equation q_i corresponds to the condition that the length of arc A_i equals that of A_{i+1} . The segment lengths l_j are the variables of such a system of equations. Our aim is to find a solution of the full system, if existing. The values of l_j , obtained from the solution of the system, would define a UCA model for G . In equation q_i , call the term $\sum_{S_j \subseteq A_i} l_j$ the *left side* of q_i , while $\sum_{S_j \subseteq A_{i+1}} l_j$ is its *right side*. Each equation q_i can possibly be simplified if the length l_j of a same segment appears in both the left and right sides of q_i . In this case, subtract l_j from both sides of q_i . The equations so obtained form the *reduced system* of $(C, \mathcal{A})$. The following lemma describes a useful property of these systems.

LEMMA 3. *Let G be a PCA graph, $(C, \mathcal{A})$ a normal model of it, and R the reduced system of $(C, \mathcal{A})$. Then each segment length l_j of $(C, \mathcal{A})$ appears at least once in R , unless S_j is a segment contained in all arcs of $\mathcal{A}$ or in none of them. Furthermore, l_j appears at most twice in R . In the latter situation, the two instances of l_j in R occur in different sides of their equations.*

Proof. Let S_j be any segment of the normal model $(C, \mathcal{A})$. Denote by $\mathcal{A}'$ the set of arcs of $\mathcal{A}$ covering S_j . If $\mathcal{A}' = \emptyset$, then no arc of $\mathcal{A}$ contains S_j , implying that l_j does not appear in R , and the lemma is satisfied. Consider $\mathcal{A}' \neq \emptyset$. We know that $\mathcal{A}'$ does not entirely cover C , otherwise there would be two arcs of $\mathcal{A}$ which would do so, contradicting $(C, \mathcal{A})$ to be normal. Consequently, the circular ordering of the extremes of $(C, \mathcal{A})$, when restricted to the arcs of $\mathcal{A}'$, is a linear ordering. Let A_i and A_k be the first and last arcs of $\mathcal{A}'$, respectively, in the considered linear ordering.

First, let $i \leq k$. Observe that l_j is not on the right side of any of the equations $q_i, \dots, q_k$, of R . Because if l_j is on the right side of q_t , then $k \geq t \geq i$ in the full system. However, l_j is also on the left side of q_t , hence it gets simplified in R . However, l_j is on the right side of q_{i-1} in R provided $i > 1$. Similarly, l_j is not on the left side of any $q_i, \dots, q_{k-1}$ but it is at the left of q_k , provided $k < n$. On the other hand, $i = 1$ and $k = n$ imply that S_j is common to all arcs of $\mathcal{A}$. Consequently, each l_j appears at least once in R , unless S_j is contained in all arcs of $\mathcal{A}$, or in none of them.

Consider the alternative $i > k$. If $i - 1 > k$, then l_j appears on the left of q_{i-1} and on the right of q_k . There are no other occurrences of l_j . Finally, when $i - 1 = k$ it follows that S_j is common to all arcs of $\mathcal{A}$. Again, each l_j always appears at least once in R , except when S_j is contained in all arcs of $\mathcal{A}$. Furthermore, it appears at most twice in R . In the latter situation, l_j occurs on different sides of the corresponding equations. $\square$

Aiming to solve R efficiently, we describe a graph theoretical model for it. Define the *segment digraph* D , as follows. There is a vertex $v_i \in V(D)$ for each equation q_i of R , and one edge e_j for each segment S_j of $(C, \mathcal{A})$. In addition, there is a distinguished vertex $v_0 \in V(D)$. Each edge $e_j \in E(D)$ is directed according to:

- (i) If l_j appears at the left of some equation q_i of R , then e_j starts at v_i ; otherwise it starts at v_0 .
- (ii) If l_j appears at the right of some equation q_k , then e_j ends at v_k ; otherwise it ends at v_0 .

The description of D is complete. Clearly, D has n vertices and $2n$ edges and no loops, except possibly at v_0 .

By adding to each edge $e_j \in E(D)$ a lower capacity $b_j = 1$ and an unbounded upper capacity c_j , we obtain the *segment network* of D .

As an example, the reduced system of the PCA model of Figure 1(b) is illustrated in Figure 2(a), while the corresponding segment digraph is in Figure 2(b). Similarly,

FIG. 2. The reduced system of Figure 1(b) and its segment digraph.

the reduced system and segment digraph corresponding to the PCA model of Figure 3(b) appear in Figures 4(a) and 4(b), respectively.

The following theorem characterizes UCA graphs in terms of feasible circulations.

THEOREM 4. *Let G be a PCA graph, $(C, \mathcal{A})$ a normal model of it, and D its segment network. Then G is a UCA graph if and only if D admits a feasible circulation.*

Proof. Let G be a UCA graph, and $(C, \mathcal{A})$ a normal model of G . By Theorem 2, there exists a UCA model $(C', \mathcal{A}')$ of G such that the endpoints of the arcs of $\mathcal{A}$ and $\mathcal{A}'$ are in the same ordering. That is, $(C, \mathcal{A})$ and $(C', \mathcal{A}')$ differ only by the lengths of the corresponding segments. Let R be the reduced system of $(C, \mathcal{A})$ and D be the segment network. Define a circulation W by assigning a flow w_j to each edge e_j of D , equal to the length l'_j of the segment of $(C', \mathcal{A}')$, corresponding to S_j . We show that such an assignment W is a circulation of D . Let $v_i \in V(D)$, $1 \leq i \leq n-1$, and q_i the corresponding equation in R . Then $w^-(v_i) = \sum_{S_j \subseteq A_i \setminus A_{i+1}} l'_j$. Similarly, $w^+(v_i) = \sum_{S_j \subseteq A_{i+1} \setminus A_i} l'_j$. Because $(C', \mathcal{A}')$ is a UCA model, the lengths of arcs A'_i and A'_{i+1} of $\mathcal{A}'$ are the same, implying that $w^-(v_i) = w^+(v_i)$. It remains to show that this equality also holds for v_0 . This assertion follows from the fact that $\sum_{0 \leq i \leq n-1} w^-(v_i) = \sum_{0 \leq i \leq n-1} w^+(v_i)$, because every edge e_j counts l'_j units both in $\sum_{0 \leq i \leq n-1} w^-(v_i)$ and $\sum_{0 \leq i \leq n-1} w^+(v_i)$. Since $w^-(v_i) = w^+(v_i)$, for each $1 \leq i \leq n-1$, it follows that $w^-(v_0) = w^+(v_0)$. Consequently, W is indeed a feasible circulation of D .

(a)

(b)

FIG. 3. Another PCA graph with its normal model.

Conversely, by hypothesis, D admits a feasible circulation W . We prove that G is UCA by constructing a UCA model $(C', \mathcal{A}')$ for G . First, consider the situation where no segment S_j of $(C, \mathcal{A})$ is contained in all arcs of $\mathcal{A}$ or in none of them. Let w_j be the flow of edge e_j of D . Construct the model $(C', \mathcal{A}')$ of G , by maintaining the endpoints of the arcs of $\mathcal{A}'$ in the same circular ordering as those in $\mathcal{A}$, while possibly modifying the lengths of the segments. The length of C' is defined as $\sum_{e_j \in E(D)} w_j$, while the length of the segment of $(C', \mathcal{A}')$ corresponding to S_j is set to the flow w_j of e_j . We show that the model so constructed is a UCA model.

FIG. 4. The reduced system of Figure 3(b) and its segment digraph.

Let R be the reduced system of $(C, \mathcal{A})$. We show that the assignment $l_j := w_j$ for each segment S_j of $(C, \mathcal{A})$ is a solution to R . Let q_i be an equation of R and v_i the corresponding vertex of D . By the construction of D , the left side of q_i corresponds to the flow values of the edges of D ending at v_i , while the right side of q_i corresponds to the flow values of the edges, starting at v_i . Because D is feasible, $w^-(v_i) = w^+(v_i)$, implying that $\sum_{S_j \subseteq A_i} l_j = \sum_{S_j \subseteq A_{i+1}} l_j$. Moreover, all l_j are positive, because the lower capacities are satisfied. Consequently, W is a solution to R . Clearly, any solution to R is also a solution to the full system. On the other hand, because no segment is contained in all arcs of $\mathcal{A}$ or in none of them, Lemma 3 implies that all segment lengths appearing in the full system also appears in the reduced system, and consequently have been assigned a required value. The latter implies that all arc lengths of $\mathcal{A}'$ are equal, meaning that $(C', \mathcal{A}')$ is a UCA model.

Finally, examine the situation where there is a segment S_j contained in all arcs of $\mathcal{A}$ or in none of them. Construct $(C', \mathcal{A}')$ as above, and assign any positive length to S_j . Clearly, all arc lengths of $\mathcal{A}'$ are equal and $(C', \mathcal{A}')$ is a UCA model. $\square$

The above theorem implies that the problem of recognizing if a given graph G is UCA is equivalent to deciding if the corresponding segment network admits a feasible circulation. We describe a characterization for the existence of circulations in general networks, with arbitrary real nonnegative lower capacities and unbounded upper ca-

capacities. This is a special case of Hoffman's circulation theorem, as below. See [9]. For a subdigraph B of D , write $b^-(B) = \sum_{e_j \in E^-(B)} b_j$ and $c^+(B) = \sum_{e_j \in E^+(B)} c_j$.

THEOREM 5 (see Hoffman [5]). *Let D be a network having an arbitrary real lower capacity b_j and upper capacity c_j , for each edge $e_j \in E(D)$. Then D admits a feasible circulation W if and only if $b^-(B) \leq c^+(B)$, for each subdigraph B of D . Moreover, if b and c are integers, then the flow values can be taken as integers.*

COROLLARY 6. *Let D be a network with real nonnegative lower capacities and unbounded upper capacities. Then D admits a feasible circulation if and only if all bridges of D have lower capacity zero. In this case, a circulation with integer flow values always exists.*

Proof. Suppose D admits a feasible circulation W . To the contrary, assume that D has a bridge e_j with positive lower capacity. Then $e_j \in E^+(B), E^-(B')$ for some distinct strongly connected components B, B' of D . In this situation, we know that $w(E^-(B')) > 0$ and $w(E^+(B')) > 0$. The latter implies that there exists some edge e_k leaving B' and enters a strongly connected component $B'' \neq B, B'$, such that $w_k > 0$. Repeating this argument over and over leads to the contradiction that D is not finite. Consequently, no such e_j may exist.

Conversely, by hypothesis all bridges of D have lower capacity equal to zero. Let B be any strongly connected component of D . Then any proper subdigraph B' of B satisfies $E^-(B'), E^+(B') \neq \emptyset$. Since the upper capacities of D are unbounded and the lower capacities are not, it follows that $b^-(B') < c^+(B')$. Using Theorem 5, we conclude that B admits a feasible circulation, then repeat this argument for the remaining strongly connected components of D . Finally, assign the flow value equal to zero to all bridges of D . We have so obtained a feasible circulation. By simply replacing each lower capacity b_j by the value $\lceil b_j \rceil$, we obtain a feasible circulation with integer flow values. $\square$

As examples, observe that the segment digraph of Figure 2(b) is strongly connected, while that of Figure 4(b) is not. Consequently, the graph of Figure 1(a) is a UCA graph, while that of Figure 3(a) is not.

3. Finding feasible circulations. Let D be a network having finite real nonnegative lower capacities and unbounded upper capacities. We describe an algorithm which finds a feasible circulation W of D , or reports that such circulation does not exist. For each edge e_j of D , let b_j be the given nonnegative lower capacity. The algorithm below computes integer flow values w_j of the feasible circulation W of D .

1. Find the strongly connected components and the bridges of D . If any bridge has a positive lower capacity, then report that no feasible circulation exists and stop. Otherwise, set the flow value $w_j := 0$ for each bridge edge e_j of D . Then perform step 2 for each strongly connected component B of D . At termination, stop.
2. Assign the initial flow values $w_j := \lceil b_j \rceil$, for each edge $e_j \in E(B)$. Then compute $w^-(v_i) = \sum_{e_j \in E^-(v_i)} w_j$ and $w^+(v_i) = \sum_{e_j \in E^+(v_i)} w_j$ for each $v_i \in V(B)$. Finally, run *OUT PROCEDURE* and afterwards run *IN PROCEDURE*.

OUT PROCEDURE. Choose an arbitrary vertex $v^* \in V(B)$ and find an out-arborescence T of B , with root v^* . Repeat the following operations, for each vertex $v \in V(T)$, $v \neq v^*$, in leaf-root ordering: if $w^-(v) < w^+(v)$ then set $w^+(u) := w^+(u) + w^+(v) - w^-(v)$, $w_j := w_j + w^+(v) - w^-(v)$ and $w^-(v) := w^+(v)$, where $e_j = uv$ is the edge of T ending at v .

IN PROCEDURE. Construct an in-arborescence T of B , with the same root v^* , as chosen in the computation of the *OUT PROCEDURE* for B . Repeat the following operations, for each vertex $v \in V(T)$, $v \neq v^*$, in leaf-root ordering: if $w^+(v) < w^-(v)$, then set $w^-(u) := w^+(u) + w^-(v) - w^+(v)$, $w_j := w_j + w^-(v) - w^+(v)$, and $w^+(v) := w^-(v)$, where $e_j = vu$ is the edge of T starting at v .

Next, we assert the correctness of the algorithm.

THEOREM 7. *The above algorithm finds a feasible circulation for D .*

Proof. From Corollary 6, it follows that the algorithm correctly reports the nonexistence of a circulation, whenever there exists a bridge having a positive lower capacity. Otherwise, let B be any strongly connected component of D . We show that the flow values assigned by the algorithm to the edges of B define a feasible circulation for B . Furthermore, since the bridges are assigned a zero flow, the latter implies that the circulation of D so obtained is also feasible.

First, observe that since B is strongly connected it admits both an out-arborescence and an in-arborescence, rooted at the same arbitrary vertex $v^* \in V(B)$. Classify the vertices v_i of D into three types, according to the initial values of $w^-(v_i)$ and $w^+(v_i)$. Say that a vertex v is *in-deficient* when $w^-(v) < w^+(v)$, *out-deficient* when $w^+(v) < w^-(v)$, and *balanced* when $w^-(v) = w^+(v)$.

Consider the computation of *OUT PROCEDURE* and examine the vertices of the chosen out-arborescence T of B , in the ordering chosen by the algorithm. Let $v \neq v^*$ be the vertex next to be visited, in the considered ordering. If v is in-deficient, then the algorithm chooses the edge e_j of T ending at v and modify its weight from w_j to the value $w_j + w^+(v) - w^-(v)$. It is clear that v becomes balanced. Moreover, since T contains exactly one edge e_j entering v , we can assure that v remains balanced until the end of *OUT PROCEDURE*. Consequently, B does not contain in-deficient vertices at the completion of the procedure, except possibly v^* . Similarly, after the completion of *IN PROCEDURE*, B does not contain out-deficient vertices, except possibly v^* . Furthermore, the computation of *IN PROCEDURE* cannot create in-deficient vertices. Consequently, after completing the visits to the second tree, we can assure that all vertices are balanced, except possibly v^* . However, $w_j = 0$, for every bridge e_j of D . Consequently, $\sum_{v \in V(B)} w^-(v) = \sum_{v \in V(B)} w^+(v) = \sum_{e_j \in E(B)} w_j$. That is, $w^-(v^*) = \sum_{v \in V(B)} w^-(v) - \sum_{v \neq v^*} w^-(v) = \sum_{v \in V(B)} w^+(v) - \sum_{v \neq v^*} w^+(v) = w^+(v^*)$, meaning that v^* is automatically balanced. Finally, the vertices of B' outside B are clearly balanced, because all edges entering and leaving them have flow value zero. Therefore W is indeed a feasible circulation. $\square$

It is simple to determine the complexity of the algorithm. Finding strongly connected components can be done in $O(n + m)$ time [11], so as for the initial flow value assignments. The computation of *OUT PROCEDURE* and *IN PROCEDURE* require $O(n)$ time. Consequently, the overall time is $O(n + m)$.

Finally, observe that the flow values of the feasible circulation obtained by the algorithm are all integers of size $w_j < 2 \sum_{e_j \in E(D)} \lceil b_j \rceil$.

4. Constructing normal models. Let G be a PCA graph and $(C, \mathcal{A})$ a PCA model of it. We describe an algorithm for transforming $(C, \mathcal{A})$ into a normal model. The algorithm is based on [2, 4, 13]. For each $A_i \in \mathcal{A}$, the idea is to traverse C , searching for an arc A_j of $\mathcal{A}$ which together with A_i would cover C . If such an arc is found, then the arc A_j is conveniently shrunk with the purpose that A_i, A_j would no longer cover C . Clearly, it has to be assured that the new model so obtained is still a PCA model for G . Recall from Theorem 1 that any PCA graph admits a normal

model.

The proposed method considers the arcs A_i in the circular ordering $A_1, \dots, A_n$. For each i , only a fraction of the arcs of $\mathcal{A}$ would be examined in general, with the above goal of searching for an arc A_j , which together with A_i , cover C . The algorithm consists of the computation of a procedure $NORMAL(i)$, for $i = 1, \dots, n$. Each computation $NORMAL(i)$ examines the extreme points $s'_i, \dots, t'_i \in A_i \cup \{s_i, t_i\}$, consecutive in the circular ordering, where s'_i is the *first point* and t'_i the *last point* of $NORMAL(i)$, respectively. Each iteration inside $NORMAL(i)$ considers one of the extreme points $s'_i, \dots, t'_i$, in circular ordering. Let p be the current point under examination by $NORMAL(i)$. Clearly, p is either a start point or an end point. The following is the action taken, according to these alternatives. If p is a start point, then nothing is done and the examination of p is terminated. Otherwise, $p = t_j$ for some j , and check whether A_i and A_j cover C . In the affirmative case, shrink A_j in such a way that A_i and A_j would no longer cover C , and terminate the examination of p . The actual shrinking operation consists of moving t_j counterclockwise in C , so that it becomes an interior point of the segment $(PRED(s_i), s_i)$. When A_i and A_j do not cover C , then terminate the computation $NORMAL(i)$, disregarding all possible extreme points of $(C, \mathcal{A})$ contained in A_i which lie after $p = t_j$, when traversing A_i in the circular ordering. Consequently, such an extreme point is the last point t'_i of $NORMAL(i)$. The first point s'_i of $NORMAL(i)$ is determined at the moment $NORMAL(i)$ starts, as follows. When $i = 1$, define $s'_1 = s_1$. For $i > 1$, let $s'_i = \max\{s_i, t'_{i-1}\}_{s_{i-1}}$. Similarly as above, the algorithm disregards all extreme points contained in A_i , which lie before s'_i in A_i .

The procedure is formulated below. If p and q are points of C , then denote by $POINT(p, q)$ an arbitrarily chosen point of the (open) arc (p, q) . The external calls are $NORMAL(i)$, for $i = 1, \dots, n$.

procedure $NORMAL(i)$
 if $i = 1$ **then** $p := s_1$ **else** $p := \max\{p, s_i\}_{s_{i-1}}$
 repeat
 if p is an end point t_j **then**
 if $A_i \cup A_j = C$ **then** $t_j := POINT(PRED(s_i), s_i)$
 else return
 $p := SUC(p)$

The following theorem assures that $NORMAL(i)$ terminates, and $(C, \mathcal{A})$ is a normal model after the computation of $NORMAL(n)$.

THEOREM 8. *The algorithm is correct.*

Proof. The algorithm consists of the computation of $NORMAL(i)$, for $i = 1, \dots, n$. We prove that after completing $NORMAL(i)$, no two arcs A_k and A_j cover C , with $1 \leq k \leq i$. Furthermore, we ought to prove that the shrinking operations maintain $(C, \mathcal{A})$ as a PCA model for G .

Clearly, if there is an arc A_j such that A_i and A_j cover C , then $s_j, t_j \in A_i$, and t_j precedes s_j in A_i . Suppose the point $p = t_j$ is reached during $NORMAL(i)$. Then $A_i \cup A_j = C$ implies that t_j will be moved to $POINT(PRED(s_i), s_i)$. Let A_j^* be the new arc A_j , after shrinking. We know that A_i, A_j^* no longer cover C . We show that the configuration of $(C, \mathcal{A})$ still reflects the adjacencies of G . Clearly, A_i and A_j^* still intersect, otherwise A_i, A_j would not cover C . We discuss the intersections between A_j^* and any other arc $A_k \neq A_i$. We can restrict to arcs A_k which intersect A_i and have an extreme point, s_k or t_k , inside (s_i, t_j) , since the intersections of A_j^* and the remaining arcs are not affected by the shrinking of A_j . The following are the possible

alternatives.

- Case 1.* $s_k \in (s_i, t_j)$. If $t_k \in (s_i, t_i)$, then t_k precedes s_k in A_i , otherwise $(C, \mathcal{A})$ is not a PCA model. Consequently, A_k and A_j^* also intersect. When $t_k \notin (s_i, t_i)$ it follows that A_j^* and A_k again intersect, because $s_j \in (s_i, t_i)$.
- Case 2.* $s_k \notin (s_i, t_j)$. By the initial assumption, $t_k \in (s_i, t_j)$. Examine the possibilities for s_k . The situation $s_k \in (s_i, t_j)$ is in Case 1. Let $s_k \notin (s_i, t_j)$. Then $s_k \in (t_j, s_j)$, otherwise A_j contains A_k . Consequently, A_j^* and A_k again intersect.

Consequently, shrinking A_j in the manner $NORMAL(i)$ does actually preserve adjacencies. In what follows, we show that the modified model is still a PCA model. It is sufficient to prove that A_j^* cannot be contained in any other arc of $\mathcal{A}$, except for A_j which has been removed. Suppose the contrary, that is, A_j^* is contained in some arc A_k . In this case, the circular ordering of the considered extreme points must be $t_j^*, s_i, t_k, t_j, s_k, s_j, t_i$; otherwise A_k also contains A_j , or A_k does not contain A_j^* . Consequently, $A_k \cup A_i = C$. Since t_k precedes t_j in A_i , it follows that A_k would have been shrunk before A_j in $NORMAL(i)$. The latter contradicts A_k to contain A_j^* .

It remains to show that any arc A_k , which together with A_i covers C , is detected by the algorithm. Suppose the contrary. That is, $NORMAL(i)$ terminates and does not shrink A_k . Then $t_k \notin (s'_i, t'_i)$. Because $t_k \in (s_i, t_i)$, there are two possibilities.

- Case 1.* $t_k \in (s_i, s'_i)$. Then $s_i \neq s'_i$, which implies $i > 1$ and $t'_{i-1} \in A_i$. We also know that $s'_i \equiv t'_{i-1}$ is an end point t_j satisfying $A_{i-1} \cup A_j \neq C$. Observe that A_{i-1} and A_j may (or may not) coincide. Because $(C, \mathcal{A})$ is a PCA model, the sequence $s_j, s_{i-1}, s_i, t_k, t_j, t_{i-1}, t_i$ is in the circular ordering. Try to locate s_k . Because $A_i \cup A_k = C$, $s_k \in (t_k, t_i)$. However, $s_k \notin (t_k, t_{i-1})$ because A_k and A_{i-1} would also cover C , implying that $NORMAL(i-1)$ would also have moved t_k from the considered position, by an inductive argument. On the other hand, $s_k \notin (t_{i-1}, t_i)$ because in this case $A_{i-1} \cup A_k \neq C$, implying that t_k would have been reached by $NORMAL(i-1)$ before t_j . In the latter situation, $NORMAL(i-1)$ would have terminated at t_k , contradicting the assumption.
- Case 2.* $t_k \in (t'_i, t_i)$. We know there is an arc A_j , such that $t_j = t'_i$ and $A_i \cup A_j \neq C$. Because $A_i \cup A_k = C$, it follows that $s_k \in (t_k, t_i)$. In this situation, A_k contains A_j , contradicting $(C, \mathcal{A})$ to be a PCA model. Hence, Case 2 also does not occur.

Therefore every arc, which together with A_i covers C , is shrunk by the algorithm, completing the proof of correctness. $\square$

THEOREM 9. *The algorithm terminates within $O(n)$ time. Moreover, there are less than $6n$ iterations of the repeat block during the entire process.*

Proof. The number of steps performed by the algorithm corresponds to the number of iterations of the *repeat* block of the described formulation. Such a number is equivalent to the number of assignments of extreme points to p during the entire process. We will prove that the total number of such assignments is less than $6n$. The first value of p is s_1 and the last one, in the worst case, is t_n . We know that p never moves counterclockwise in C . First, assume for a while that p does not stay stationary in two consecutive iterations, and also disregard the shrinking of arcs. Any of the $2n$ extreme points can be assigned to p . If $t_n \notin A_1$, then the assignments would correspond at most to a complete turn around the circle, because the model is PCA. That is, $2n$ assignments. On the other hand, if $t_n \in A_1$, then any extreme lying between s_1 and t_n may be assigned again to p , but at most once more, besides

its assignment in *NORMAL*(1). This corresponds to an additional n units in our account.

Next, examine the case when p stays stationary in two consecutive iterations. Such a situation may only occur, possibly at the first iteration within *NORMAL*(i), when $s'_i = t'_{i-1}$, for $i > 1$. Overall, it counts to additional $n - 1$ units, at most, in the total number of assignments to p .

Finally, examine the shrinking operations. Each time an arc A_j is shrunk, an extreme point t_j^* is placed in a different position of $(C, \mathcal{A})$, offering the possibility to t_j^* itself to be assigned to p . Hence, the shrinking operations may contribute to our account. In fact, if an arc gets shrunk k times during the algorithm, this may represent additional k assignments to p , in the worst case. Furthermore, there might be $O(n)$ distinct arcs, each of them covering C , together with A_j . However, the next assertion assures that even in this case, the number of times A_j gets shrunk is low.

Claim. Any arc of $(C, \mathcal{A})$ may be shrunk at most twice during the entire algorithm.

Proof. Let A_j be an arc of $(C, \mathcal{A})$. Clearly, if A_j together with some other arc does not cover C , then A_j is not shrunk at all. Otherwise, consider the model $(C, \mathcal{A})$ at the beginning of the computation *NORMAL*(k), where A_j gets shrunk for the first time, if any. Denote by $A_{j_1}, \dots, A_{j_l}$ the arcs of $(C, \mathcal{A})$, each of them covers C , together with A_j . This implies that all extreme points of the arcs $A_{j_1}, \dots, A_{j_l}$ belong to (s_j, t_j) . Furthermore, s_{j_k} precedes t_{j_k} in A_j , $1 \leq k \leq l$. Without loss of generality, the starting points $s_{j_1}, \dots, s_{j_l}$ are in the circular ordering. Clearly, the arc of least index among $A_j, A_{j_1}, \dots, A_{j_l}$ corresponds to one of this collection which is first handled by the algorithm. Let $i = \min\{j, j_1, \dots, j_l\}$. The following are the alternatives for i :

- Case 1.* $i = j$. We know that *NORMAL*(j) does not shrink A_j . Furthermore, Theorem 8 implies that *NORMAL*(j) would shrink all arcs $A_{j_1}, \dots, A_{j_l}$. Consequently, A_j never gets shrunk.
- Case 2.* $i = j_1$. Because A_j and A_{j_1} cover C , during *NORMAL*(j_1) the assignment $p := t_j$ necessarily occurs, since Theorem 8 assures that *NORMAL*(j_1) shrinks A_j . Then t_j moves to the position t_j^* , becoming the predecessor of s_1 . The arc A_j^* so obtained does not intersect any of $A_{j_1}, \dots, A_{j_l}$, and consequently, it cannot get shrunk. Consequently, A_j is shrunk only once during the process.
- Case 3.* $i = j_k$, for some $1 < k \leq l$. Then *NORMAL*(j_k) moves t_j to t_j^* , where t_j^* , this time, is the new predecessor of s_{j_k} . Following the circular ordering of $(C, \mathcal{A})$, the first subsequent computation which can possibly shrink A_j is *NORMAL*(j_1). By Case 2, the latter would shrink A_j , exactly once more. Consequently, A_j gets shrunk twice.

The conclusion is that any arc may get shrunk at most twice during the process. $\square$

Consequently, the shrinking operations contribute at most $2n$ units to our account. Therefore the algorithm performs less than $6n$ iterations of the *repeat* block. Each of these iterations requires no more than constant time. That is, the overall complexity is $O(n)$. $\square$

5. Recognition and model construction. In this section, we describe the algorithms for recognizing UCA graphs and for constructing UCA models. Also, we determine the size of the obtained model by showing that its extremes correspond to integers of size $O(n)$.

The algorithm is as follows. Let G be the given graph.

1. Verify if G is a PCA graph, using the algorithm [1]. In the affirmative case, let $(C, \mathcal{A})$ be the PCA model so obtained. In the negative case, G is not UCA.
2. Transform $(C, \mathcal{A})$ into a normal model $(C', \mathcal{A}')$, using the algorithm of section 4.
3. Construct the segment digraph D of $(C', \mathcal{A}')$. Find the connected components of D . Verify if all connected components are strongly connected. In the negative case, report that G is not UCA and stop. Otherwise, report that G is UCA and construct a UCA model $(C'', \mathcal{A}'')$ of it by running Step 4.
4. Construct the segment network of $(C', \mathcal{A}')$ by assigning to each edge $e_j \in E(D)$ a unit lower capacity and an unbounded upper capacity. Then find the flow values of a feasible circulation W of D , using the algorithm of section 3. Let $p'_1, \dots, p'_{2n}$ be the extremes of $(C', \mathcal{A}')$, in circular ordering, with p_1 corresponding to the start point of the first arc of the model. Then construct $(C'', \mathcal{A}'')$ as follows. The length of C'' is $\sum_{e_j \in E(D)} w_j$. The extremes $p''_1, \dots, p''_{2n}$ of $(C'', \mathcal{A}'')$ are defined by the following conditions: p''_1 is an arbitrary point of C'' , and the segment (p''_j, p''_{j+1}) has length w_j , $1 \leq j < 2n$.

The correctness follows basically from Theorems 4, 7, and 8, and Corollary 6. We evaluate the complexity of the recognition algorithm. Step 1 requires $O(n + m)$ time [1]. Step 2 takes $O(n)$ time by Theorem 9. As for Step 3, note that for constructing the segment digraph, we need to construct the full and reduced systems of $(C', \mathcal{A}')$. The first of them is a family of $n - 1$ equations, whose variables are segment lengths. In each side of the equations, the segment lengths are consecutive. Consequently, we need $4n - 4$ indices to represent these equations, overall. On the other hand, in the reduced system, each segment length appears at most twice. That is, it requires at most $4n$ indices. The segment digraph has n vertices and at most $2n$ edges. There is no difficulty to construct D in $O(n)$ time. The connected and strongly connected components can be constructed in linear time [11]. Step 4 also requires linear time in the size of D , according to section 3. Consequently, the overall complexity of algorithm is $O(n + m)$. Furthermore, Steps 2, 3, and 4 require $O(n)$ time, meaning that the complexity of the algorithm reduces to $O(n)$, if the input is a PCA model of G , with ordered extremes of the arcs.

Finally, we verify the size of the UCA model obtained by the algorithm.

COROLLARY 10. *Let $(C, \mathcal{A})$ be a UCA model constructed by the algorithm. Then the extremes of $(C, \mathcal{A})$ correspond to integers of size $< 4n$.*

Proof. Let $p_1, \dots, p_{2n}$ be the extremes of $(C, \mathcal{A})$ in circular ordering. We associate the segment length l_j to the extreme p_{j+1} , $1 \leq j < 2n$. From Step 4 of the algorithm, we know that the length l_j of each segment of $(C, \mathcal{A})$ equals the flow value w_j of the corresponding edge e_j of D . On the other hand, we know from section 3 that $w_j < 2m$. Since $m < 2n$, it follows that $l_j < 4n$. $\square$

6. Conclusion. The proposed algorithms for recognizing UCA graphs and constructing UCA models terminate within $O(n + m)$ time. Furthermore, the complexity reduces to $O(n)$ when the input is a PCA model. It should be noted that the algorithms require the extreme points of the given model to be ordered. If the input is a graph given by its vertices and edges, then there is a preprocessing step, which consists of running the algorithm by Deng, Hell, and Huang [1], for constructing a PCA model of the graph. The algorithm [1] can be implemented so as to construct a PCA model with ordered extreme points within $O(n + m)$ time. On the other hand,

if the input is already a PCA model and its extreme points are not ordered, then we need an additional $O(n \log n)$ steps for ordering.

The UCA model constructed by the proposed algorithm is such that its extreme points correspond to integers of size $O(n)$. Regarding this feature, we leave the four related questions below.

Given a UCA graph G , find a UCA model whose extremes of the arcs correspond to integers, satisfying

- (i) the maximum segment length is minimized.
- (ii) the circle length is minimized.

More generally, for given n , find the least l , such that any UCA graph with n vertices admits a UCA model whose extremes of the arcs correspond to integers, such that

- (iii) the maximum segment length is $\leq l$.
- (iv) the circle length is $\leq l$.

Corollary 10 implies that $l < 4n$ for Question (iii), and that $l < 4n^2$ for Question (iv).

Acknowledgments. We are grateful to Professor Pavol Hell and an anonymous referee for their most valuable suggestions and comments, which lead to improvements in different parts of this paper.

ASYMPTOTIC DETERMINATION OF EDGE-BANDWIDTH OF MULTIDIMENSIONAL GRIDS AND HAMMING GRAPHS*

REZA AKHTAR[†], TAO JIANG[†], AND ZEVI MILLER[†]

Abstract. The edge-bandwidth $B'(G)$ of a graph G is the bandwidth of the line graph of G . More specifically, for any bijection $f : E(G) \rightarrow \{1, 2, \dots, |E(G)|\}$, let $B'(f, G) = \max\{|f(e_1) - f(e_2)| : e_1 \text{ and } e_2 \text{ are incident edges of } G\}$, and let $B'(G) = \min_f B'(f, G)$. We determine asymptotically the edge-bandwidth of d -dimensional grids P_n^d and of the Hamming graph K_n^d , the d -fold Cartesian product of K_n . Our results are as follows. (i) For fixed d and $n \rightarrow \infty$, $B'(P_n^d) = c(d)dn^{d-1} + O(n^{d-\frac{3}{2}})$, where $c(d)$ is a constant depending on d , which we determine explicitly. (ii) For fixed even n and $d \rightarrow \infty$, $B'(K_n^d) = (1 + o(1))\sqrt{\frac{d}{2\pi}}n^d(n-1)$. Our results extend recent results by Balogh, Mubayi, and Pluhár [*Theoret. Comput. Sci.*, 359 (2006), pp. 43–57], who determined $B'(P_n^2)$ asymptotically as a function of n and $B'(K_2^d)$ asymptotically as a function of d .

Key words. bandwidth, edge-bandwidth, Hamming graph, grid, boundary, isoperimetric problem

AMS subject classification. 05C78

DOI. 10.1137/060660291

1. Introduction. Let $G = (V(G), E(G))$ be a simple graph on n vertices. A labeling f is a bijection of $V(G)$ to $\{1, \dots, n\}$. When there is no ambiguity, we will simply write $B(f)$ for $B(f, G)$. The *bandwidth* of f is

$$B(f, G) := \max\{|f(u) - f(v)| : uv \in E(G)\}.$$

The *bandwidth* $B(G)$ of G is

$$B(G) := \min_f \{B(f, G)\}.$$

The notion was introduced by Harper in his influential paper [13], in which he determined the bandwidth of the d -dimensional hypercube by solving the corresponding vertex isoperimetric problem in the hypercube. There are several motivations for studying the bandwidth problem: sparse matrix computations, representing data structures by linear arrays, VLSI layouts, mutual simulations of interconnection networks, and minimizing the effects of noise in the multichannel communication of data (see [10, 11, 24, 7]). The bandwidth problem is NP-hard and is inapproximable by any multiplicative constant even for trees [28]. Bandwidths are known only for a few families of graphs including hypercubes [13], multidimensional grids [8, 22, 23], complete trees [16], and various meshlike graphs (see [16, 17, 20]).

The edge-bandwidth was introduced by Hwang and Lagarias [18]. Here we label the edges instead of the vertices, and the *bandwidth* of an edge-labeling f of a graph

G is

$$B'(f, G) := \max\{|f(uv) - f(vw)| : uv, vw \in E(G)\}.$$

In other words it is the maximum difference of labels between a pair of incident edges. When there is no ambiguity, we will write $B'(f)$ for $B(f, G)$. The edge-bandwidth of a graph G is

$$B'(G) := \min_f B'(f, G).$$

Naturally, $B'(G) = B(L(G))$, where $L(G)$ is the line graph of G . In [19], Jiang et al. reintroduced the notion of edge-bandwidth and studied the relationship between $B(G)$ and $B'(G)$. They determined the edge-bandwidth of caterpillars, the complete graph K_n , and the balanced complete bipartite graph $K_{n,n}$. Gupta [12] pointed out that the inequality $B(T) \leq B'(T) \leq 2B(T)$ for a tree T obtained in [19] together with Unger's inapproximation result [28] for bandwidth imply that determining the edge-bandwidth is also NP-hard.

Recently, there has been an increase of interest in the study of edge-bandwidth. Calamoneri, Massini, and Vrto [9] obtained tight bounds on the edge-bandwidth of complete k -ary trees and bounds on the edge-bandwidth of the hypercube and butterfly graphs. Balogh, Mubayi, and Pluhár [5] subsequently obtained asymptotically tight bounds on the edge-bandwidth of two-dimensional grids and tori, the Cartesian product of two cliques, and the hypercube. Sharpening the result of Balogh, Mubayi, and Pluhár [5] on the two-dimensional grids and tori while confirming a conjecture of Calamoneri, Massini, and Vrto [9], Pikhurko and Wojciechowski [27] showed that the edge-bandwidth of an m by n grid, where $m \geq n$, is $2n - 1$. They also showed that the edge-bandwidth of an m by n torus, where $m \geq n$, is between $4n - 5$ and $4n - 1$. In an unpublished manuscript, Akhtar, Jiang, and Pritikin have independently shown that the edge-bandwidth of an m by n grid, where $m \geq n$, is between $2n - 2$ and $2n - 1$ and that the edge-bandwidth of an m by n torus, where $m \geq n$, is between $4n - 5$ and $4n - 1$.

In this paper, we determine the edge-bandwidth of the d -dimensional grids P_n^d asymptotically when d is fixed and $n \rightarrow \infty$, and we obtain lower and upper bounds on the edge-bandwidth of the Hamming graph K_n^d . When n is a fixed positive even integer and $d \rightarrow \infty$, our lower and upper bounds match asymptotically.

The Cartesian product of graphs G and H , denoted by $G \square H$, is the graph with vertex set $V(G \square H) = \{(u, v) : u \in V(G), v \in V(H)\}$ specified by putting (u, v) adjacent to (u', v') if and only if (i) $u = u'$ and $vv' \in e(H)$ or (ii) $v = v'$ and $uu' \in E(G)$. The d -fold Cartesian product $G \square G \square \cdots \square G$ is denoted by G^d . Let P_n denote a path on n vertices. The d -fold Cartesian product P_n , denoted by P_n^d , is also known as the d -dimensional grid. Equivalently, we can view P_n^d as a graph whose vertices are vectors $\langle u_1, u_2, \dots, u_d \rangle$ of length d where, for all i , $u_i \in \{0, 1, \dots, n-1\}$ and any two vertices $\langle x_1, x_2, \dots, x_d \rangle$ and $\langle y_1, y_2, \dots, y_d \rangle$ are adjacent if and only if there exists $i \in \{1, 2, \dots, d\}$ such that $|x_i - y_i| = 1$ and $x_j = y_j$ for all $j \neq i$. Given a vertex $x = \langle x_1, x_2, \dots, x_d \rangle$, we define the weight of x by $wt(x) = x_1 + x_2 + \cdots + x_d$. For each $r \in \{1, 2, \dots, n\}$, let $L(n, d, r) = \{x \in V(P_n^d) : wt(x) = r\}$. Let $l(n, d, r) = |L(n, d, r)|$ and $l^*(n, d) = \max\{l(n, d, r) : 0 \leq r \leq (n-1)d\}$. We determine $B'(P_n^d)$ asymptotically as a function of n .

THEOREM 1.1. *Let d be a fixed positive integer. We have*

$$B'(P_n^d) = (1 + o(1))dl^*(n, d) = c(d)dn^{d-1} + O(n^{d-\frac{3}{2}}),$$

where $c(d)$ is a constant depending on d , given by $c(d) = \sum_{j=0}^{\lfloor d/2 \rfloor} (-1)^j \binom{d}{j} \frac{(d-2j)^{d-1}}{2^{d-1}(d-1)!}$. Furthermore, $\frac{1}{2\sqrt{d}} \leq c(d) \leq \frac{2\sqrt{11}}{\sqrt{d}}$.

A simple calculation shows that $c(2) = 1$. Hence $B'(P_n^2) = (1+o(1))2n$, which was obtained by Balogh, Mubayi, and Pluhár [5]. For another example, $c(3) = \frac{3}{4}$, yielding $B'(P_n^3) = (1+o(1))\frac{9}{4}n^2$. Theorem 1.1 determines asymptotically the edge-bandwidth of grids of arbitrary dimension.

The d -fold Cartesian product of the complete graph K_n , denoted by K_n^d , is also called the Hamming graph. We obtain lower and upper bounds on $B'(K_n^d)$ for fixed n as a function of d . When n is even, our lower and upper bounds match asymptotically, yielding the following theorem.

THEOREM 1.2. *Let n be a fixed positive even integer. We have*

$$B'(K_n^d) = (1 + o(1)) \frac{\sqrt{d}}{\sqrt{2\pi}} n^d (n-1).$$

Throughout the paper we will use standard enumeration estimates, as found in [25].

2. General bounds. The standard techniques for obtaining lower bounds on bandwidth use isoperimetric inequalities. Many vertex and edge isoperimetric problems have been considered in the literature. Given a graph G and a set $S \subseteq V(G)$, let

$$\partial(S) = \{v \in V(G) - S : \exists u \in S \text{ such that } uv \in E(G)\}.$$

We call $\partial(S)$ the (vertex) *boundary* of S . In other words, $\partial(S) = N_G(S) - S$. Given an optimal numbering f of $V(G)$, let S be the set of vertices receiving labels $1, 2, \dots, k$. Then the highest label assigned to a vertex in $\partial(S)$ is at least $k + |\partial(S)|$. Let v be the vertex with the highest label in $\partial(S)$. It has a neighbor u in S , whose label is at most k . So $|f(v) - f(u)| \geq |\partial(S)|$, which implies $B(G) = B(f, G) \geq |\partial(S)|$. Similarly, consider a vertex x in $\partial(V - S)$ with the smallest label. Its label is at most $k - |\partial(V - S)| + 1$. It has a neighbor y in $V - S$, whose assigned label is at least $k + 1$. So $|f(y) - f(x)| \geq |\partial(V - S)|$. Thus, $B(G) = B(f, G) \geq |\partial(V - S)|$. Therefore, we have $B(G) \geq \max\{|\partial(S)|, |\partial(V - S)|\}$. This yields the following proposition.

PROPOSITION 2.1 (see [13]). *Let G be a graph and k an integer, where $0 \leq k \leq |V(G)|$. Then*

$$B(G) \geq \min_{S \subseteq V(G), |S|=k} \max\{|\partial(S)|, |\partial(V - S)|\}.$$

For each k , let $L_k(G) = \min_{S \subseteq V(G), |S|=k} |\partial(S)|$. By Proposition 2.1, $B(G) \geq L_k(G)$. Since this holds for each k with $0 \leq k \leq |V(G)|$, we have $B(G) \geq \max_k L_k(G)$. This lower bound $\max_k L_k(G)$ for $B(G)$ is often referred to as the *Harper bound*. In general, the Harper bound need not be sharp, and calculating it is difficult (NP-hard).

When the Harper bound is not very useful, it is sometimes useful to consider the iterated boundary (shadow) instead. Given a nonnegative integer q , let

$$\partial^{(\leq q)}(S) = \{v \in V(G) - S : v \text{ is at distance at most } q \text{ from some vertex in } S\}.$$

Hence, in particular, $\partial(S) = \partial^{(\leq 1)}(S)$. Consider an optimal numbering f of $V(G)$. Let S be the set of vertices receiving labels $1, 2, \dots, k$. Let q be any integer such that $1 \leq q \leq n$. Let v be a vertex in $\partial^{(\leq q)}(S)$ with the highest label. Then $f(v) \geq$

$k + |\partial^{\leq q}(S)|$. Vertex v is at distance at most q from some vertex u in S . Note that $f(u) \leq k$. Hence for some edge on a shortest u, v -path, the difference between the f -labels of its two end points is at least $|f(u) - f(v)|/q \geq |\partial^{\leq q}(S)|/q$. This yields the following proposition.

PROPOSITION 2.2. *Let G be a graph and k an integer, where $0 \leq k \leq |V(G)|$. Then*

$$B(G) \geq \min_{S \subseteq V(G), |S|=k} \max_{1 \leq q \leq n} \left| \frac{\partial^{(\leq q)}(S)}{q} \right|.$$

Our discussions above apply similarly to a set of edges. We define the boundary of a set $S' \subseteq E(G)$ of edges in G by

$$\partial(S') = \{e \in E(G) - S' : \exists e' \in S' \text{ such that } e \text{ and } e' \text{ are incident}\}.$$

The iterated boundary for S' is then given, for $q \geq 1$, by

$$\partial^{(\leq q)}(S') = \{e \in E(G) - S' : e \text{ is at distance at most } q \text{ from some edge of } S'\}.$$

We see that $\partial(S') = \partial^{(\leq 1)}(S)$ and $\partial^{(\leq q)}(S') = \partial^{(\leq q-1)}(S) \cup \partial(\partial^{(\leq q-1)}(S'))$. The edge analogues of Propositions 2.1 and 2.2 are then obtained by replacing $B(G)$ by $B'(G)$ and $V(G)$ by $E(G)$.

3. The weight function in multidimensional grids. Recall that $V(P_n^d) = \{\langle x_1, x_2, \dots, x_d \rangle : x_i \in \{0, 1, \dots, n-1\} \text{ for all } i = 1, 2, \dots, d\}$. Two vertices $\langle x_1, x_2, \dots, x_d \rangle$ and $\langle y_1, y_2, \dots, y_d \rangle$ are adjacent if they differ by 1 in one coordinate and agree in all other coordinates. Again, the weight $wt(x)$ of a vertex $x = \langle x_1, x_2, \dots, x_d \rangle$ is defined by $wt(x) = x_1 + x_2 + \dots + x_d$. Given positive integers n, d and an integer r , with $0 \leq r \leq (n-1)d$, let $L(n, d, r) = \{x \in V(P_n^d) : wt(x) = r\}$. Let $l(n, d, r) = |L(n, d, r)|$. Let $l^*(n, d) = \max\{l(n, d, r) : 0 \leq r \leq (n-1)d\}$. It is easy to see that $l(n, d, r)$ is the number of integer solutions to the equation $x_1 + x_2 + \dots + x_d = r$, where $0 \leq x_i \leq n-1$ for each $i \in [d]$. By considering the value of x_1 one can easily derive the following recurrence relation on $l(n, d, r)$, which also appeared in [26].

PROPOSITION 3.1. *Let n, d be positive integers and r an integer. We have $l(n, 1, r) = 1$ if $0 \leq r \leq n-1$ and $l(n, 1, r) = 0$ otherwise. For all d and r with $d \geq 2$ and $0 \leq r \leq d(n-1)$,*

$$l(n, d, r) = \sum_{j=0}^{n-1} l(n, d-1, r-j),$$

and for other values of r we have $l(n, d, r) = 0$.

It is straightforward to derive an exact formula for $l(n, d, r)$ using a generating function. This was done in [26], and we include a short proof for completeness.

PROPOSITION 3.2. *Let n, d, r be positive integers. We have*

$$l(n, d, r) = \sum_{j=0}^{\lfloor \frac{r}{d} \rfloor} (-1)^j \binom{d}{j} \binom{r-jn+d-1}{d-1}.$$

Proof. By prior discussion, $l(n, d, r)$ is the number of integer solutions to $x_1 + x_2 + \dots + x_d = r$, with $0 \leq x_i \leq n-1$ for each $i \in [d]$. For fixed n, d , the generating function for $l(n, d, r)$ is

$$g(x) = (1 + \dots + x^{n-1})^d = \left(\frac{1-x^n}{1-x} \right)^d = (1-x^n)^d \left(\frac{1}{1-x} \right)^d.$$

As $l(n, d, r)$ equals the coefficient of x^r in the above expansion, we have

$$\begin{aligned} l(n, d, r) &= \sum_{j=0}^{\infty} (-1)^j \binom{d}{j} \binom{r - jn + d - 1}{d - 1} \\ &= \sum_{j=0}^{\lfloor \frac{r}{n} \rfloor} (-1)^j \binom{d}{j} \binom{r - jn + d - 1}{d - 1}. \quad \square \end{aligned}$$

The function $l(n, d, r)$ is well-studied in the theory of posets as the *rank number* in the poset of divisors of a number. Consider a positive integer m with prime factorization $m = p_1^{k_1} p_2^{k_2} \dots p_d^{k_d}$, where the p_i are distinct primes and $k_i \geq 1$ for each i . The *rank* of m is $K = k_1 + \dots + k_d$, and $N_r(m)$ is the number of divisors of m of rank r . It is easy to see that, in the case $k_1 = k_2 = \dots = k_d = n - 1$, $N_r(m)$ is precisely $l(n, d, r)$. Chapter 4 of Anderson [3] gives a detailed discussion about the function $N_r(m)$. In particular, we have the following proposition.

PROPOSITION 3.3 (see [3, Chapter 4]). *Let $K = (n - 1)d$. Then the following apply:*

1. $l(n, d, i) = l(n, d, K - i)$ for each i with $0 \leq i \leq K$.
2. For fixed n and d , $l(n, d, i)$ is strictly increasing in i for $i \leq \lfloor \frac{K}{2} \rfloor$ and strictly decreasing in i for $i \geq \lceil \frac{K}{2} \rceil$.

By Proposition 3.3, for fixed n and d , $l(n, d, r)$ is a symmetric and unimodal function of r on $\{0, 1, \dots, (n - 1)d\}$ with maximum value at $r = \lfloor \frac{(n-1)d}{2} \rfloor$ and at $r = \lceil \frac{(n-1)d}{2} \rceil$. Thus, $l^*(n, d) = l(n, d, \lfloor \frac{(n-1)d}{2} \rfloor)$. Setting $r = \lfloor \frac{(n-1)d}{2} \rfloor$ in the formula in Proposition 3.2 for $l(n, d, r)$ then gives us a formula for $l^*(n, d)$. When d is fixed and n tends to infinity, the leading term is a multiple of n^{d-1} whose leading coefficient can be expressed exactly as a sum. We then give a closed form estimate of this leading coefficient using earlier results of Anderson [1, 2] given below.

THEOREM 3.4 (see [2]). *Let $k_1, k_2, \dots, k_d$ be nonnegative integers. Let $K = k_1 + \dots + k_d$. Let s denote the number of integer solutions to the equation*

$$x_1 + x_2 + \dots + x_d = \frac{K}{2}, \text{ where } \forall i \ 0 \leq x_i \leq k_i.$$

Let $A = \frac{1}{3} \sum_{i=1}^d k_i(k_i + 2)$ and $\tau = \prod_{i=1}^d (1 + k_i)$. Then there exist positive constants C_1 and C_2 such that

$$C_1 \frac{\tau}{\sqrt{A}} \leq s \leq C_2 \frac{\tau}{\sqrt{A}}.$$

Furthermore, we can take $C_2 = \sqrt{11}$, and for any small $\epsilon > 0$ we can take $C_1 = \frac{1}{\sqrt{3}} - \epsilon$ when K is sufficiently large.

COROLLARY 3.5. *Let n, d be positive integers, where $n \geq 2$. There exist positive constants C_1 and C_2 such that*

$$C_1 \frac{n^{d-1}}{\sqrt{d}} \leq l^*(n, d) \leq C_2 \frac{n^{d-1}}{\sqrt{d}}.$$

Furthermore, we can take $C_2 = 2\sqrt{11}$, and for any small $\epsilon > 0$ we can take $C_1 = 1 - \epsilon$ when n is sufficiently large.

Proof. By our earlier discussion, $l^*(n, d) = l(n, d, \lfloor \frac{(n-1)d}{2} \rfloor)$ is the number of integer solutions to the equation $x_1 + x_2 + \cdots + x_d = \lfloor \frac{(n-1)d}{2} \rfloor$, where $0 \leq x_i \leq n-1$ for each i . We apply Theorem 3.4. Here $k_i = n-1$ for each $i \in [d]$. So $A = \frac{d}{3}(n^2-1)$ and $\tau = n^d$. Also, $s = l^*(n, d)$. The claim follows. $\square$

We now give the exact formula for $l^*(n, d)$ together with an asymptotic formula for it. There is an exact formula for the coefficient of the leading term in the form of a summation; this coefficient can be bounded using Corollary 3.5. Before we proceed, we need the following routine estimation of binomial coefficients. Recall that if x is a real number and k is an integer, then $\binom{x}{k} := \frac{x(x-1)\cdots(x-k+1)}{k!}$. Also, it is straightforward to check that $e^{-x} \geq 1-x$ for all real x and $1-x \geq e^{-2x}$ for x with $0 < x < \frac{1}{2}$.

LEMMA 3.6. *Let k be a positive integer and N, m nonnegative real numbers such that $N > \max\{2k, mk\}$. Then $\frac{N^k}{k!}(1 - \frac{2k^2}{N}) \leq \binom{N+m}{k} \leq \frac{N^k}{k!}(1 + \frac{2mk}{N})$. So $|\binom{N+m}{k} - \frac{N^k}{k!}| \leq 2(m+2)N^{k-1}$.*

Proof. For the lower bound, we have $\binom{N+m}{k} / \frac{N^k}{k!} > \frac{(N+m-k)^k}{k!} / \frac{N^k}{k!} > \frac{(N-k)^k}{k!} / \frac{N^k}{k!} = (1 - \frac{k}{N})^k$. Since $0 < \frac{k}{N} < \frac{1}{2}$, $(1 - \frac{k}{N})^k \geq e^{-2\frac{k}{N}k} \geq 1 - \frac{2k^2}{N}$.

For the upper bound, we have $\binom{N+m}{k} / \frac{N^k}{k!} < \frac{(N+m)^k}{k!} / \frac{N^k}{k!} = (\frac{N+m}{N})^k = (1 + \frac{m}{N})^k$. Since $(1 + \frac{1}{x})^x < e$ when $x > 0$, we have $(1 + \frac{m}{N})^{\frac{N}{m}} < e$ and hence $(1 + \frac{m}{N})^k < e^{\frac{mk}{N}}$. Since $\frac{mk}{N} < 1$ and $e^x < 1 + 2x$ when $0 < x < 1$, we have $e^{\frac{mk}{N}} < 1 + \frac{2mk}{N}$. Therefore, $\binom{N+m}{k} / \frac{N^k}{k!} < 1 + \frac{2mk}{N}$. The last statement follows readily from the lower and upper bounds. $\square$

THEOREM 3.7. *Let n, d be positive integers. Then*

$$l^*(n, d) = \sum_{j=0}^{\lfloor \frac{d}{2} \rfloor} (-1)^j \binom{d}{j} \binom{\lfloor \frac{(d-2j)n}{2} + \frac{d}{2} \rfloor - 1}{d-1}.$$

We have $l^*(n, 1) = 1, l^*(n, 2) = 2$. For fixed $d \geq 3$, as $n \rightarrow \infty$, we have

$$l^*(n, d) = c(d)n^{d-1} + O(n^{d-2}),$$

where $c(d)$ is a constant depending on d , given by

$$c(d) = \sum_{j=0}^{d/2} (-1)^j \binom{d}{j} \frac{(d-2j)^{d-1}}{2^{d-1}(d-1)!}.$$

Also, $\frac{1}{2\sqrt{d}} \leq c(d) \leq \frac{2\sqrt{11}}{\sqrt{d}}$.

Proof. The exact formula for $l^*(n, d)$ given above is obtained by setting $r = \lfloor \frac{(n-1)d}{2} \rfloor$ in the formula for $l(n, d, r)$ in Proposition 3.2. For fixed d , we derive an asymptotic formula for $l^*(n, d)$ as a function of n . Fix j with $d-2j > 0$. Let $N = \frac{(d-2j)n}{2}$ and $m = (\lfloor \frac{(d-2j)n}{2} + \frac{d}{2} \rfloor - 1) - N$. Then $m \leq d/2$. For sufficiently large n , since d is fixed, we have $N > \max\{2(d-1), m(d-1)\}$. By applying Lemma 3.6, we have

$$\left| \binom{\lfloor \frac{(d-2j)n}{2} + \frac{d}{2} \rfloor - 1}{d-1} - \frac{(d-2j)^{d-1}}{2^{d-1}(d-1)!} \cdot n^{d-1} \right| \leq 2(m+2)n^{d-2} \leq (d+4)n^{d-2}.$$

So

$$\begin{aligned} l^* &= \sum_{j=0}^d (-1)^j \binom{d}{j} \binom{\lfloor \frac{dn-2jn}{2} + \frac{d}{2} \rfloor - 1}{d-1} \\ &= \sum_{j=0}^{\lfloor d/2 \rfloor} (-1)^j \binom{d}{j} \cdot \frac{(d-2j)^{d-1}}{2^{d-1}(d-1)!} \cdot n^{d-1} + O(n^{d-2}). \end{aligned}$$

Let $c(d) = \sum_{j=0}^{\lfloor d/2 \rfloor} (-1)^j \binom{d}{j} \frac{(d-2j)^{d-1}}{2^{d-1}(d-1)!}$. We have $l^*(n, d) = c(d)n^{d-1} + O(n^{d-2})$. Note that $c(d)$ is a constant depending only on d , and, by Corollary 3.5, $\frac{1}{2\sqrt{d}} \leq c(d) \leq \frac{2\sqrt{11}}{\sqrt{d}}$. $\square$

Remark 3.8. When n is fixed and $d \rightarrow \infty$, by using Laplace's method one can show that $l^*(n, d) = \sqrt{\frac{6}{\pi d} \left(\frac{n^2}{n^2-1}\right)} \cdot n^{d-1} + o(n^{d-1})$. See the concluding remarks section for further discussion.

Next, we show that, for all r relatively close to $\lfloor \frac{(n-1)d}{2} \rfloor$ and $\lceil \frac{(n-1)d}{2} \rceil$, $l(n, d, r)$ is close to the maximum value $l^*(n, d)$. This property is important to establishing our lower bound on the edge-bandwidth of P_n^d in the next section.

LEMMA 3.9. *Let n, d, r be integers such that $n, d \geq 2$. If $|r - \lfloor \frac{(n-1)d}{2} \rfloor| = t$, where $0 \leq t \leq \lfloor \frac{n}{2} \rfloor - 1$, then $l(n, d, r) \geq (1 - \frac{t}{n-1})l^*(n, d)$.*

Proof. Let $M = \lfloor \frac{(n-1)d}{2} \rfloor$. By Proposition 3.3, $l^*(n, d) = l(n, d, M)$. For convenience, let $f(j) = l(n, d-1, j)$. By Proposition 3.3, $f(j)$ is symmetric on $[0, (n-1)(d-1)]$, and it is unimodal with peak(s) at $M' = \lfloor \frac{(n-1)(d-1)}{2} \rfloor$ and $M'' = \lceil \frac{(n-1)(d-1)}{2} \rceil$. By Proposition 3.1,

$$l^*(n, d) = l(n, d, M) = \sum_{i=M-(n-1)}^M f(i).$$

Consider the interval of integers $I = [M - (n-1), M]$. Assume first that n is odd. In this case $M' = M'' = \frac{(n-1)(d-1)}{2}$ is the only element at the center of I . The function $f(j)$ is symmetric and unimodal on I with a single peak at $\frac{(n-1)(d-1)}{2}$. Let A denote the sum of $f(j)$ over the first t elements of I , B the sum of $f(j)$ over the last t elements of I , and C the sum of $f(j)$ over the middle $n-2t$ elements of I . The symmetry and unimodality of $f(j)$ imply that $A = B$ and $\frac{C}{A} \geq \frac{n-2t}{t}$. So $l^*(n, d) = A + B + C \geq (2 + \frac{n-2t}{t})A$, which implies $A = B \leq \frac{t}{n} l^*(n, d)$. Now, by Proposition 3.1, $l(n, d, M+t)$ is the sum of $f(j)$ over $I+t$, the translation of I by t . So clearly, $l(n, d, M+t) \geq l(n, d, M) - A \geq (1 - \frac{t}{n})l^*(n, d)$. Similarly, $l(n, d, M-t) \geq l(n, d, M) - B \geq (1 - \frac{t}{n})l^*(n, d)$.

When n is even, we consider the subcases depending on whether d is even or odd. In each subcase, similar analysis shows that $A, B \geq (1 - \frac{t}{n-1})l^*(n, d)$, and hence $l(n, d, M+t) \geq (1 - \frac{t}{n-1})l^*(n, d)$ and $l(n, d, M-t) \geq (1 - \frac{t}{n-1})l^*(n, d)$. $\square$

4. The edge-bandwidth of a multidimensional grid. Bollobás and Leader [8] solved the vertex isoperimetric problem in grids. We will use their result to obtain asymptotically tight bounds on the edge-bandwidth of a multidimensional grids. Our result extends that of Balogh, Mubayi, and Pluhár on two-dimensional grids to grids of any dimension.

DEFINITION 4.1. The simplicial order on $V(P_n^d)$ is defined by $x < y$ if either $wt(x) < wt(y)$ or $wt(x) = wt(y)$ and $x_s > y_s$, where $s = \min\{t : x_t \neq y_t\}$.

Bollobás and Leader [8] showed that for any k , with $0 \leq k \leq |V(P_n^d)|$, the initial segment of length k in the simplicial order has the smallest boundary among all sets of k vertices. For each r with $0 \leq r \leq (n-1)d$, let $B(n, d, r) = \{x \in V(P_n^d) : wt(x) \leq r\}$. In other words, $B(n, d, r) = \bigcup_{j=0}^r L(n, d, j)$. Note that each edge in P_n^d has one end point in $L(n, d, r)$ and the other end point in $L(n, d, r+1)$ for some r .

In the theorem below, let $N(A) = A \cup \partial(A)$, $N(C) = C \cup \partial(C)$, and $N^{(\leq q)}(A) = A \cup \partial^{(\leq q)}(A)$.

THEOREM 4.2 (see [8] (vertex isoperimetric inequality in the grid)). Let $A \subseteq V(P_n^d)$, and let C be the initial segment of length $|A|$ in the simplicial order on $V(P_n^d)$. Then $|N(A)| \geq |N(C)|$. In particular, if $|A| \geq |B(n, d, r)|$, then $|N(A)| \geq |B(n, d, r+1)|$. Also, for all $q \geq 1$ we have $|N^{(\leq q)}(A)| \geq |B(n, d, r+q)|$.

DEFINITION 4.3. Let G be a graph on n vertices. Let $\sigma : x_1 < x_2 < \dots < x_n$ be a linear order on $V(G)$. The labeling f of $V(G)$ satisfying $f(x_i) = i$ is the vertex labeling of $V(G)$ induced by σ .

LEMMA 4.4. Let $G = P_n^d$. Let f be the labeling of $V(G)$ induced by the simplicial order on G . For every $uv \in E(G)$, we have $|f(u) - f(v)| \leq l^*(n, d) + 2l^*(n, d-1) - 1$.

Proof. Without loss of generality, suppose $wt(u) = r$ and $wt(v) = r+1$. Let $A = \{x \in L(n, d, r) : f(x) > f(u)\}$, $B = \{x \in L(n, d, r+1) : f(x) < f(v)\}$, and $C = \{x \in L(n, d, r+1) : f(x) > f(v)\}$. Let $a = |A|$, $b = |B|$, $c = |C|$. Then

$$|f(u) - f(v)| = a + b + 1 \quad \text{and} \quad b + c + 1 = l(n, d, r+1).$$

Suppose $u = \langle u_1, u_2, \dots, u_d \rangle$ and $v = \langle v_1, v_2, \dots, v_d \rangle$. Since $uv \in E(G)$ and $wt(v) = wt(u) + 1$, there exists $j \in [d]$ such that $v_j = u_j + 1$ and $v_i = u_i$ for all $i \in [d] - j$. By our definition of A , vertices in A all have their first coordinate at most u_1 . Let $A_1 = \{x \in A : x_1 = u_1 \text{ or } u_1 - 1\}$, and let $A_2 = \{x \in A : x_1 \leq u_1 - 2\}$. We have $A = A_1 \cup A_2$. Since there are at most $l^*(n, d-1) - 1$ vertices other than u that have u_1 in the first coordinate and there are at most $l^*(n, d-1)$ vertices that have $u_1 - 1$ in the first coordinate, $|A_1| \leq 2l^*(n, d-1) - 1$.

For each $x \in A_2$, let $g(x) = \langle x_1 + 1, x_2, \dots, x_d \rangle$. It is easy to see that g is an injection of A_2 into $L(n, d, r+1)$. Furthermore, for each $x \in A_2$, since $x_1 + 1 < u_1 \leq v_1$, we have $f(g(x)) > f(v)$ by the definition of the simplicial order. So $g(x) \in C$. So g is an injection of A_2 into C . Thus, $|A_2| \leq c$ and $a = |A| = |A_1| + |A_2| \leq 2l^*(n, d-1) - 1 + c$. Now we have

$$\begin{aligned} |f(u) - f(v)| &= a + b + 1 \leq 2l^*(n, d-1) - 1 + c + b + 1 \\ &= 2l^*(n, d-1) - 1 + l(n, d, r+1) \leq l^*(n, d) + 2l^*(n, d-1) - 1. \quad \square \end{aligned}$$

THEOREM 4.5. Let d be a fixed positive integer. For all positive integers n we have

$$B'(P_n^d) \leq d[l^*(n, d) + 2l^*(n, d-1)] = c(d)dn^{d-1} + O(n^{d-2}),$$

where $c(d)$ is defined as in Theorem 3.7.

Proof. First, we define a digraph H from $G = P_n^d$ by orienting each edge xy from x to y if $x < y$ in the simplicial order. For each vertex x , let $E^+(x)$ denote the set of out edges from x . Note that $|E^+(x)| \leq d$ for each x . We define a labeling g of $E(H)$ (and of $E(G)$) using $1, 2, \dots, |E(H)|$ as follows. Suppose the vertices are $u_1, u_2, \dots$, where $u_1 < u_2 < \dots$ in the simplicial order. Starting with 1 we assign the

first $|E^+(u_1)|$ consecutive labels to $E^+(u_1)$, then the next $|E^+(u_2)|$ consecutive labels to $E^+(u_2)$, and so on. Let $e = u_i u_j$ and $e' = u_j u_k$ be two incident edges in G at the vertex u_j . We consider three cases depending on how e and e' are oriented.

Case 1. $i < j < k$ or $i > j > k$. By symmetry, we may assume $i < j < k$. Then we have $wt(u_i) = r - 1, wt(u_j) = r, wt(u_k) = r + 1$ for some r . By Lemma 4.4, $j - i \leq l^*(n, d) + 2l^*(n, d - 1) - 1$. Note that $e \in E^+(u_i)$ and $e' \in E^+(u_j)$. By our definition of g , we have $|g(e') - g(e)| \leq |\bigcup_{t=i}^j E^+(u_t)| \leq d(j - i + 1) \leq d(l^*(n, d) + 2l^*(n, d - 1))$.

Case 2. $i < j$ and $j > k$. In this case, we have $wt(u_i) = wt(u_k) = r - 1$ and $wt(u_j) = r$ for some r . In particular, $|k - i| \leq l(n, d, r - 1) - 1 \leq l^*(n, d) - 1$. Also, $e \in E^+(u_i)$ and $e' \in E^+(u_k)$. Without loss of generality, suppose $i < k$. By our definition of g , we have $|g(e') - g(e)| \leq |\bigcup_{t=i}^k E^+(u_t)| \leq d|k - i + 1| \leq dl^*(n, d) \leq d(l^*(n, d) + 2l^*(n, d - 1))$.

Case 3. $i > j$ and $k > j$. In this case, $e, e' \in E^+(u_j)$, and $|g(e) - g(e')| \leq d < d(l^*(n, d) + 2l^*(n, d - 1))$.

We have shown that $|g(e) - g(e')| \leq d(l^*(n, d) + 2l^*(n, d - 1))$ for every pair of incident edges e and e' in G . This yields $B'(G) \leq B'(g, G) \leq d(l^*(n, d) + 2l^*(n, d - 1))$. By using $l^*(n, d) = c(d)n^{d-1} + O(n^{d-2})$, we get $B'(G) \leq c(d)dn^{d-1} + O(n^{d-2})$. $\square$

We now derive a lower bound on $B'(P_n^d)$ that matches the upper bound in Theorem 4.5 asymptotically when d is fixed and $n \rightarrow \infty$. Our proof is based on the method used by Calamoneri, Massini, and Vrto [9] and Balogh, Mubayi, and Pluhár [5]. We need an easy lemma.

LEMMA 4.6. *Let n and d be positive integers. Let $A \subseteq V(P_n^d)$. Then there are at least $d|A| - dn^{d-1}$ edges incident to A in P_n^d . Also, $|E(P_n^d)| = dn^d - dn^{d-1}$.*

Proof. The graph P_n^d is a spanning subgraph of C_n^d , the d -fold Cartesian product of C_n . We can think of obtaining C_n^d from P_n^d by adding edges of the form uv , where $u = \langle u_1, u_2, \dots, u_d \rangle$ and $v = \langle v_1, v_2, \dots, v_d \rangle$ satisfy that $u_i = 0, v_i = n - 1$ or $u_i = n - 1, v_i = 0$ for some $i \in [d]$ and $u_j = v_j$ for all $j \in [d] - \{i\}$. It is easy to see that there are dn^{d-1} such edges. Since C_n^d is $2d$ -regular, we have $E(P_n^d) = E(C_n^d) - dn^{d-1} = dn^d - dn^{d-1}$.

In C_n^d , since each vertex has degree $2d$, there are at least $2d|A|/2 = d|A|$ edges incident to A . So in P_n^d , there are at least $d|A| - dn^{d-1}$ edges incident to A . $\square$

THEOREM 4.7. *Let $d \geq 2$ be a fixed positive integer. Then we have as $n \rightarrow \infty$*

$$B'(P_n^d) \geq dl^*(n, d)(1 - o(1)) = c(d)dn^{d-1} + \Omega(n^{d-\frac{3}{2}}).$$

Proof. Throughout the proof, whenever necessary, we assume that n is sufficiently large. Let g be an edge labeling of $G = P_n^d$, with $B'(g, G) = B'(G)$. Let S denote the set of edges receiving labels $1, 2, \dots, |E(G)|/2$. We color the edges in S red and the rest of the edges white.

Let us call a vertex *red* if all of its incident edges are red, a vertex *white* if all of its incident edges are white, and a vertex *mixed* if it is incident to both red edges and white edges. Let R denote the set of red vertices, W the set of white vertices, and M the set of mixed vertices. We consider two cases. For convenience, let $l^* = l^*(n, d)$.

Case 1. $|M| \geq 5l^*$. Call a vertex v *bad* if $d(v) \leq 2d - 3$. Let D denote the set of bad vertices in G . If $v = \langle v_1, v_2, \dots, v_d \rangle$ is bad, then it has a 0 or $n - 1$ in at least three of the d coordinates. So $|D| \leq \binom{d}{3} 2^3 n^{d-3} < 2d^3 n^{d-3}$. By Corollary 3.5, when n is sufficiently large, we have $l^* \geq \frac{1}{2\sqrt{d}} n^{d-1} > 2d^3 n^{d-3} > |D|$. Hence, $|M - D| \geq 5l^* - l^* = 4l^*$. Each vertex in $M - D$ has degree at least $2d - 2$. So the total number of edges incident to M is at least $(2d - 2)|M - D|/2 = (d - 1)|M - D| \geq 4(d - 1)l^* \geq 2dl^*$, since $d \geq 2$.

Let $E(M)$ denote the set of edges in G incident to M , and let $E = E(G)$. We have $|E(M)| \geq 2dl^*$. So either $|E(M) \cap (E - S)| \geq dl^*$ or $|E(M) \cap S| \geq dl^*$. Note

that $E(M) \cap (E - S) \subseteq \partial(S)$ and $E(M) \cap S \subseteq \partial(E - S)$. Hence, we have either $|\partial(S)| \geq dl^*$ or $|\partial(E - S)| \geq dl^*$. By Proposition 2.1, we have $B'(g, G) \geq dl^* = c(d)dn^{d-1} + O(n^{d-2})$.

Case 2. $|M| < 5l^*$. We have $|R| + |M| + |W| = n^d$. Hence, either $|R| < n^d/2$ or $|W| < n^d/2$. Without loss of generality, we may assume that $|R| < n^d/2$; otherwise, we switch S with $E - S$ and hence R with W . Let $H = G[R \cup M]$ denote the subgraph of G induced by R and M . Note that $S \subseteq E(H)$. Hence, $|S| \leq |E(H)| \leq 2d(|R| + |M|)/2 = d(|R| + |M|)$. On the other hand, $|S| = |E(G)|/2 \geq (1/2)(dn^d - dn^{d-1})$. So we have

$$d(|R| + |M|) \geq |S| \geq \frac{1}{2}dn^d - \frac{1}{2}dn^{d-1}.$$

From this we get

$$|R| + |M| \geq \frac{1}{2}n^d - \frac{1}{2}n^{d-1}.$$

So

$$|R| \geq \frac{1}{2}n^d - \frac{1}{2}n^{d-1} - |M| \geq \frac{1}{2}n^d - \frac{1}{2}n^{d-1} - 5l^*.$$

By Corollary 3.5, for sufficiently large n we have $l^* \geq \frac{1}{2\sqrt{d}}n^{d-1}$. Hence, $\frac{1}{2}n^{d-1} \leq \sqrt{dl^*}$ and $|R| \geq \frac{1}{2}n^d - \sqrt{dl^*} - 5l^* \geq \frac{1}{2}n^d - (d+5)l^*$. We have

$$(1) \quad \frac{1}{2}n^{d-1} - (d+5)l^* < |R| < \frac{1}{2}n^{d-1}.$$

Since $l(n, d, j)$ is symmetric on $[0, d(n-1)]$ and $\sum_{j=0}^{d(n-1)} l(n, d, j) = |V(G)| = n^d$, we have

$$(2) \quad \sum_{j=0}^{\lfloor \frac{(n-1)d}{2} \rfloor - 1} l(n, d, j) \leq \frac{1}{2}n^d \leq \sum_{j=0}^{\lfloor \frac{(n-1)d}{2} \rfloor} l(n, d, j).$$

For convenience, let $M = \lfloor \frac{(n-1)d}{2} \rfloor$. By Lemma 3.9, $l(n, d, M-t) \geq (1 - \frac{t}{n-1})l^*$ for $t \in [0, \lfloor \frac{n}{2} \rfloor - 1]$. Let n be sufficiently large so that $n > \binom{d+7}{2}$. We have

$$(3) \quad \sum_{t=1}^{d+6} l(n, d, M-t) \geq \sum_{t=1}^{d+6} \left(1 - \frac{t}{n-1}\right) l^* = (d+6)l^* - \frac{\binom{d+7}{2}}{n-1} l^* \geq (d+5)l^*.$$

By (2) and (3), we have $\sum_{j=0}^{M-d-7} l(n, d, j) \leq |R| \leq \sum_{j=0}^M l(n, d, j)$. In other words,

$$(4) \quad |B(n, d, M-d-7)| < |R| < |B(n, d, M+1)|.$$

Therefore, we have $|B(n, d, r)| \leq |R| < |B(n, d, r+1)|$ for some $r \in [M-d-7, M+1]$. Let $q = \lfloor \sqrt{n} \rfloor - 1$. We may assume that n is sufficiently large so that $q \geq d+7$. Let A be a subset of R , with $|A| = |B(n, d, r)|$. By Theorem 4.2, $|N^{(\leq q)}(A)| \geq |B(n, d, r+q)|$. Since $N^{(\leq q)}(A) \subseteq N^{(\leq q)}(R)$, we have $|N^{(\leq q)}(R)| \geq |B(n, d, r+q)|$. Hence,

$$(5) \quad \begin{aligned} |\partial^{(\leq q)}(R)| &= |N^{(\leq q)}(R)| - |R| \geq |B(n, d, r+q)| \\ &\quad - |B(n, d, r+1)| = \sum_{j=2}^q l(n, d, r+j). \end{aligned}$$

For each $j \in [r+2, r+q]$, we have $j \in [M-d-7, M+q+1]$. Since $|j-M| \leq q+1$, by Lemma 3.9,

$$l(n, d, j) \geq \left(1 - \frac{q+1}{n-1}\right) l^* \geq \left(1 - \frac{\lfloor \sqrt{n} \rfloor}{n-1}\right) l^* \geq \left(1 - \frac{2}{\sqrt{n}}\right) l^*.$$

Hence,

$$|\partial^{(\leq q)}(R)| \geq \sum_{j=2}^q l(n, d, r+j) \geq (q-1) \left(1 - \frac{2}{\sqrt{n}}\right) l^*.$$

Let $E(\partial^{(\leq q)}(R))$ denote the set of edges incident to $\partial^{(\leq q)}(R)$. By Lemma 4.6,

$$|E(\partial^{(\leq q)}(R))| \geq d|\partial^{(\leq q)}(R)| - dn^{d-1}.$$

Finally, note that $E(\partial^{(\leq q)}(R)) \subseteq \partial^{(\leq q+1)}(S)$. By applying Proposition 2.2 to the line graph $L(G)$, we have

$$\begin{aligned} B'(g, G) &\geq |\partial^{(\leq q+1)}(S)|/(q+1) \\ &\geq |E(\partial^{(\leq q)}(R))|/(q+1) \\ &\geq (d|\partial^{(\leq q)}(R)| - dn^{d-1})/(q+1) \\ &\geq d \left[(q-1) \left(1 - \frac{2}{\sqrt{n}}\right) \right] l^*/(q+1) - dn^{d-1}/(q+1) \\ &= dl^* \left(\frac{\sqrt{n}-2}{\sqrt{n}} \right) \left(1 - \frac{2}{\sqrt{n}}\right) + O(n^{d-\frac{3}{2}}) \quad (\text{using } q = \sqrt{n} - 1) \\ &= c(d)dn^{d-1} + O(n^{d-\frac{3}{2}}) \quad (\text{by Theorem 3.7}). \quad \square \end{aligned}$$

5. Edge-bandwidth of the Hamming graph I: Upper bound. In this section we derive an upper bound on $B'(K_n^d)$. We view any vertex x in K_n^d as an n -ary d -string $x = \langle x_1, x_2, \dots, x_d \rangle$, where, for all i , $x_i \in \{0, 1, \dots, n-1\}$. Two vertices $x = \langle x_1, x_2, \dots, x_d \rangle$ and $y = \langle y_1, y_2, \dots, y_d \rangle$ are adjacent in K_n^d if and only if the two strings differ in precisely one coordinate. As in section 4, for each $x = \langle x_1, x_2, \dots, x_d \rangle$, we define the *weight* of x as $wt(x) = x_1 + x_2 + \dots + x_d$. Note that, when $n = 2$, K_n^d is just the d -dimensional hypercube Q_d , and, for each vertex x , $wt(x)$ is the number of 1's in the binary string that represents x . The edge-bandwidth $B'(Q_d)$ was asymptotically determined by Balogh, Mubayi, and Pluhár [5], while the vertex bandwidth $B(Q_d)$ was completely determined by Harper in his paper [13]. We will combine the labelings used in these results to design a labeling that yields an upper bound on $B'(K_n^d)$. Let us recall the labelings used in [5, 13].

DEFINITION 5.1. *The vertex-Hales numbering of $V(Q_d)$ is a bijection $h : V(Q_d) \rightarrow \{1, 2, \dots, 2^d\}$ such that $h(x) < h(y)$ if either $wt(x) < wt(y)$ or $wt(x) = wt(y)$ and $x_s > y_s$, where $s = \min\{t : x_t \neq y_t\}$.*

Note that, in section 4, we called a similar ordering on $V(P_n^d)$ the simplicial order. Harper showed that the vertex-Hales numbering achieves the vertex bandwidth for Q_d .

THEOREM 5.2 (see [13]). *Let h be the vertex-Hales numbering of Q_d . Then*

$$B(Q_d) = B(h) = \sum_{k=0}^{d-1} \binom{k}{\lfloor k/2 \rfloor} = (1 + o(1)) \binom{d}{\lfloor d/2 \rfloor}.$$

The last equality used standard estimates of binomial coefficients. Next we describe the labeling used by Balogh, Mubayi, and Pluhár in establishing an asymptotically tight upper bound on $B'(Q_d)$. For convenience, we will call this numbering the *edge-Hales numbering*. Our description of the numbering is equivalent to the one used in [5].

DEFINITION 5.3 (see [5]). *The edge-Hales numbering of Q_d is a bijection $f : E(Q_d) \rightarrow \{1, 2, \dots, d2^{d-1}\}$ such that for any two edges vw and xy , where $wt(w) = wt(v) + 1$ and $wt(y) = wt(x) + 1$, we have $f(vw) < f(xy)$ if either (i) $h(v) < h(x)$ or (ii) $v = x$ and $h(w) < h(y)$.*

THEOREM 5.4 (see [5]). *Let f denote the edge-Hales labeling of Q_d . Then*

$$\left(\frac{d}{2} + o(d)\right) \binom{d}{\lfloor d/2 \rfloor} \leq B'(Q_d) \leq B'(f) \leq \left(\frac{d}{2} + o(d)\right) \binom{d}{\lfloor d/2 \rfloor}.$$

Now we combine the two numberings mentioned above to obtain a total numbering on $V(Q_d) \cup E(Q_d)$, which we will call the *mixed-Hales numbering* of Q_d . This numbering is produced by the following algorithm.

ALGORITHM 5.5 (the mixed-Hales numbering m of Q_d).

Input: The d -dimensional hypercube Q_d .

Output: A bijection $m : V(Q_d) \cup E(Q_d) \rightarrow \{1, 2, \dots, 2^d + d2^{d-1}\}$.

Initialization:

(1) Denote the edges of Q_d by e_i , $1 \leq i \leq d2^{d-1}$, according to the edge-Hales numbering f of Q_d . That is, e_i is the edge e with $f(e) = i$.

(2) Let $m(0^d) = 1$, where 0^d denotes the all-0 string of length d .

(3) For all i , $1 \leq i \leq d2^{d-1}$, let $m(e_i) = i + 1$.

(4) Set $i = 1$.

Iteration:

(5) Suppose $e_i = xy$, where $wt(y) = wt(x) + 1$. If $m(y)$ is not yet defined, then

(5a) let $m(y) = m(e_i) + 1$;

(5b) for all $j > i$, let $m(e_j) = m(e_i) + 1$.

(6) Let $i = i + 1$.

(7) If $i = d2^{d-1} + 1$, terminate; otherwise, go to step (5).

Intuitively speaking, to obtain the mixed-Hales numbering we process the edges one by one in increasing order of edge-Hales label. The algorithm gives a vertex y an m -label at the earliest opportunity, as soon as we process the first edge in the edge-Hales numbering incident to y . See Figure 1 for the mixed-Hales labeling of Q_3 .

Next, we summarize some useful facts about mixed-Hales numbering in the following proposition. In particular, we see that the ordering on $V(Q_d)$ and the ordering on $E(Q_d)$ inherited from the mixed-Hales numbering m of Q_d are precisely the vertex-Hales numbering h and the edge-Hales numbering f of Q_d , respectively.

PROPOSITION 5.6. *Let h, f, m denote the vertex-Hales, edge-Hales, and mixed-Hales numberings of Q_d , respectively. Let 0^d denote the all-0 string of length d and 1^d the all-1 string of length d . For each vertex $x \in V(Q^d) - \{0^d, 1^d\}$, let x^- denote the neighbor of x with the smallest h label and x^+ the neighbor of x with the largest h label. Then the following apply:*

FIG. 1. The mixed-Hales numbering of Q_3 .

1. For each vertex $x \in V(Q_d) - \{0^d, 1^d\}$, the string representing x^- is obtained from the string for x by flipping the rightmost 1 to a 0, and the string representing x^+ is obtained from the string for x by flipping the rightmost 0 to a 1.
2. For each vertex $x \in V(Q_d) - \{0^d, 1^d\}$, among the edges incident to x , xx^- has the smallest m label and xx^+ has the largest m label. Hence, in particular, $m(x) = m(xx^-) + 1$.
3. For any two edges e, e' in Q_d , if $f(e) < f(e')$, then $m(e) < m(e')$.
4. For any two edges vw, xy in Q_d , where $wt(w) = wt(v) + 1$ and $wt(y) = wt(x) + 1$, $m(vw) < m(xy)$ if and only if either $h(v) < h(x)$ or $v = x$ and $h(w) < h(y)$.
5. For any two vertices $x, y \in V(Q_d) - \{0^d, 1^d\}$, if $h(x) < h(y)$, then $h(x^-) \leq h(y^-)$ and $h(x^+) \leq h(y^+)$.
6. For any two vertices, x, y in Q_d , if $h(x) < h(y)$, then $m(x) < m(y)$.

Proof. Part 1 follows immediately from the definition of the vertex-Hales numbering (Definition 5.1). Parts 2 and 3 follow immediately from Algorithm 5.5. Part 4 follows from the definition of the edge-Hales numbering f (Definition 5.3) and part 3.

To prove part 5, suppose $h(x) < h(y)$. Since $h(x) < h(y)$, we have $wt(x) \leq wt(y)$. If $wt(x) < wt(y)$, then $wt(x^-) < wt(y^-)$ and $h(x^-) < h(y^-)$ hold trivially. So we may assume that $wt(x) = wt(y)$. By part 1, the string representing x^- is obtained from the string representing x by flipping the rightmost 1 in x to 0, and the string for y^- is obtained from the string for y by flipping the rightmost 1 in y to 0. Let j denote the smallest coordinate in which x and y differ. Since $h(x) < h(y)$, we have $x_j = 1$ and $y_j = 0$. Since $wt(x) = wt(y)$, if x has k many 1's in coordinates $j+1, j+2, \dots, d$, then y should have exactly $k+1$ many 1's in coordinates $j+1, j+2, \dots, d$. If $k \geq 1$, then clearly $h(x^-) < h(y^-)$. If $k = 0$, then $x^- = y^-$, and hence $h(x^-) = h(y^-)$. By a very similar argument, we have $h(x^+) \leq h(y^+)$.

To prove part 6, we may assume without loss of generality that $x, y \notin \{0^1, 1^d\}$. Suppose $h(x) < h(y)$. Since $m(x) = m(xx^-) + 1$ and $m(y) = m(yy^-) + 1$, to prove $m(x) < m(y)$ it suffices to prove that $m(xx^-) < m(yy^-)$. By part 5, $h(x^-) \leq h(y^-)$. Thus, we have either $h(x^-) < h(y^-)$ or $x^- = y^-$ and $h(x) < h(y)$. By part 4, we have $m(xx^-) < m(yy^-)$. This completes the proof. $\square$

In the next proposition, we bound the number of vertices and the number of edges whose m -labels lie between the m -labels of two incident edges.

PROPOSITION 5.7. *Let h, f, m denote the vertex-Hales, edge-Hales, and mixed-Hales numberings of Q_d , respectively. Let e, e' be two incident edges in Q_d , where $m(e) < m(e')$. Then there are at most $B(h) + 1$ vertices z with $m(e) \leq m(z) \leq m(e')$, and there are at most $B'(f) + 1$ edges e^* with $m(e) \leq m(e^*) \leq m(e')$.*

Proof. By Proposition 5.6 part 2, an edge e^* satisfies $m(e) \leq m(e^*) \leq m(e')$ if and only if $f(e) \leq f(e^*) \leq f(e')$. Hence, since e and e' are incident, there are at most $|f(e') - f(e)| + 1 \leq B'(f) + 1$ such edges e^* . Next, suppose e and e' are both incident to x . Let z be a vertex with $m(e) \leq m(z) \leq m(e')$. If $x = 0^d$ or 1^d , then it is easy to see that there are at most $d < B(h)$ such vertices z . Hence, we may assume that $x \notin \{0^d, 1^d\}$. By Proposition 5.6 part 2, $m(xx^-) \leq m(z) \leq m(xx^+)$. Since $m(x) = m(xx^-) + 1$ and $m(z) > m(xx^-)$, we have $m(z) \geq m(x)$. We show that also $m(z) \leq m(x^+)$. Suppose first that $h(z^-) > h(x)$. Then by Proposition 5.6 part 4, $m(zz^-) > m(xx^+)$, and hence $m(z) = m(zz^-) + 1 > m(xx^+)$, a contradiction. So we must have $h(z^-) \leq h(x)$. By Proposition 5.6 part 5, $h((z^-)^+) \leq h(x^+)$. Since $h(z) \leq h((z^-)^+)$, we have $h(z) \leq h(x^+)$, and thus $m(z) \leq m(x^+)$. So any vertex z satisfying $m(e) \leq m(z) \leq m(e')$ must satisfy $h(x) \leq h(z) \leq h(x^+)$. There are at most $|h(x^+) - h(x)| + 1 \leq B(h) + 1$ such vertices z . $\square$

LEMMA 5.8. *Let p, q, t be positive integers. Let G be a graph obtained from Q_d by replacing each vertex x of Q_d by a t -vertex graph G_x having p edges and each edge xy of Q_d by a set of q cross edges between $V(G_x)$ and $V(G_y)$. Then $B'(G) \leq p(B(h) + 1) + q(B'(f) + 1)$, where h, f denote the vertex-Hales and edge-Hales numberings of Q_d , respectively.*

Proof. Apply Algorithm 5.5 to obtain the mixed-Hales numbering m of Q_d . List elements of $V(Q_d) \cup E(Q_d)$ in the order determined by m , and call this list L . We produce a labeling g of $E(G)$ as follows. Start with label 1. As we scan L , each time we encounter a vertex x , we allocate the next p consecutive labels to the edges of G_x , and each time we encounter an edge $e = xy$, we allocate the next q consecutive labels to the set of q cross edges between $V(G_x)$ and $V(G_y)$.

Consider any pair of incident edges e and e' in G with $g(e) < g(e')$. Suppose both are incident to vertex w , and w lies in G_x . If $x \in \{0^d, 1^d\}$, then it is easy to see that $|g(e) - g(e')| \leq p + dq < p(B(h) + 1) + q(B'(f) + 1)$. Hence we may assume that $x \notin \{0^d, 1^d\}$. By our labeling scheme $|g(e) - g(e')|$ is maximum when e is among the set of q edges of G associated with edge xx^- in Q_d and e' is among the set of q edges of G associated with edge xx^+ in Q_d . By Proposition 5.7 and the definition of g , $|g(e) - g(e')| \leq p(B(h) + 1) + q(B'(f) + 1)$. $\square$

Now we apply Lemma 5.8 to get an upper bound on $B'(K_n^d)$. For convenience, we consider only even n . For odd n , we can upper bound $B'(K_n^d)$ by $B'(K_{n+1}^d)$. We can view K_n^d as being obtained from Q_d by replacing each vertex of Q_d with a copy of $K_{n/2}^d$ and replacing each edge of Q_d by the set of edges between two neighboring copies of $K_{n/2}^d$ in K_n^d . More specifically, for each $x = \langle x_1, \dots, x_d \rangle \in V(Q_d)$, let $O(x)$ denote the subgraph of K_n^d induced by the set of vertices $\{w = \langle w_1, \dots, w_d \rangle : 0 \leq w_i \leq n/2 - 1 \text{ if } x_i = 0, n/2 \leq w_i \leq n - 1 \text{ if } x_i = 1\}$. Then each $O(x)$ is a copy of

$K_{n/2}^d$. For each edge $xy \in E(Q_d)$, let $E(O(x), O(y))$ denote the set of edges in K_n^d having one end point in $O(x)$ and the other end point in $O(y)$. It is easy to see that $|E(O(x), O(y))| = (\frac{n}{2})^2 (\frac{n}{2})^{d-1} = (\frac{n}{2})^{d+1}$ for all $xy \in E(Q_d)$. We denote this quantity by $q(n, d)$. By applying Lemma 5.8 with $p = e(K_{n/2}^d)$ and $q = q(n, d)$, we have the following.

LEMMA 5.9. *Let d be a positive integer and n a positive even integer. We have*

$$B'(K_n^d) \leq e(K_n^d)(B(h) + 1) + q(n, d)(B'(f) + 1).$$

THEOREM 5.10. *Let n be a fixed positive even integer. Let d be a positive integer. We have*

$$B'(K_n^d) \leq (d + o(d)) \binom{d}{\lfloor d/2 \rfloor} \left(\frac{n}{2}\right)^d (n-1) = (1 + o(1)) \frac{\sqrt{d}}{\sqrt{2\pi}} n^d (n-1),$$

as $d \rightarrow \infty$.

Proof. Using Lemma 5.9, Theorems 5.2 and 5.4, $e(K_{n/2}^d) = d(\frac{n}{2})^{d-1} \binom{n/2}{2}$, $q(n, d) = (\frac{n}{2})^{d+1}$, and $\sum_{k=0}^{d-1} \binom{k}{\lfloor k/2 \rfloor} = (1 + o(1)) \binom{d}{\lfloor d/2 \rfloor} = (1 + o(1)) \frac{\sqrt{2}}{\sqrt{\pi d}} \cdot 2^d$, we have

$$\begin{aligned} B'(K_n^d) &\leq \left[d \left(\frac{n}{2}\right)^{d-1} \binom{n/2}{2} \right] \cdot \left[1 + \sum_{k=0}^{d-1} \binom{k}{\lfloor k/2 \rfloor} \right] \\ &\quad + \left(\frac{n}{2}\right)^{d+1} \cdot \left[\left(\frac{d}{2} + o(d)\right) \binom{d}{\lfloor d/2 \rfloor} \right] \\ &= (1 + o(1)) \binom{d}{\lfloor d/2 \rfloor} \left[d \left(\frac{n}{2}\right)^{d-1} \cdot \binom{n/2}{2} \right] \\ &\quad + (1 + o(1)) \cdot \frac{d}{2} \cdot \binom{d}{\lfloor d/2 \rfloor} \cdot \left(\frac{n}{2}\right)^{d+1} \\ &= (1 + o(1)) \binom{d}{\lfloor d/2 \rfloor} \cdot d \cdot \left(\frac{n}{2}\right)^{d-1} \cdot \left(\binom{n/2}{2} + \frac{1}{2} \left(\frac{n}{2}\right)^2 \right) \\ &= (1 + o(1)) \binom{d}{\lfloor d/2 \rfloor} \cdot \left(\frac{1}{2}\right)^{d+1} d n^d (n-1) \\ &= (1 + o(1)) \frac{\sqrt{d}}{\sqrt{2\pi}} n^d (n-1). \quad \square \end{aligned}$$

On a historic note, the idea of blowing up each vertex of Q_d to an “orthant” subgraph $O(x)$ of K_n^d was used by Harper in [15] in his constructive upper bound for $B(K_n^d)$. It was independently discovered by one of us while supervising an M.A. thesis [4]. To develop a constructive upper bound on $B'(K_n^d)$, we used this idea by labeling edges internal to orthants in blocks in the order of the vertex-Hales numbering of Q_d which achieved $B(Q_d)$ [13]. Our next step was to label cross edges between neighboring orthants in blocks in the order of the edge-Hales labeling of Q_d achieving $B'(Q_d)$ asymptotically, described earlier and originating in [5]. In this way both classes of edges, either internal to orthants or crossing between orthants, are labeled. The final step was to merge these two labelings efficiently. The key idea here is to notice that the edge-Hales labeling of Q_d is in some natural sense induced by the vertex-Hales numbering.

6. Edge-bandwidth of the Hamming graph II: Lower bound. In this section we establish a lower bound for $B'(K_n^d)$ which matches the upper bound of the previous section asymptotically when n is even. Our technique employs a theorem of Harper giving a solution to the isoperimetric problem in $[0, 1]^d$.

The approach is to look at K_n^d geometrically as a d -dimensional box having side length 1 and so containing n^d many d -dimensional cells of length $1/n^d$ in each dimension. More specifically, we consider the following mapping from $V(K_n^d)$ to $[0, 1]^d$. For each $i \in \{0, 1, \dots, n-1\}$, let I_i denote the interval $[\frac{i}{n}, \frac{i+1}{n}]$ of real numbers. For each vertex $x = \langle x_1, x_2, \dots, x_d \rangle$ in K_n^d , where each $x_i \in \{0, 1, \dots, n-1\}$, let $g(x) = I_{x_1} \times I_{x_2} \times \dots \times I_{x_d}$. Thus $g(x)$ is a d -dimensional cell of length $1/n^d$ in each dimension. Under this mapping, a subset W of k vertices in $V(K_n^d)$ then corresponds to a collection S of k of these cells. S is a set of measure k/n^d in $[0, 1]^d$, the d -fold product of the unit interval, equipped with the Lebesgue measure.

Given two points $x = \langle x_1, x_2, \dots, x_d \rangle$ and $y = \langle y_1, y_2, \dots, y_d \rangle$ in $[0, 1]^d$, we say that x and y are *neighbors* if there exists $k \in \{1, 2, \dots, d\}$ such that $x_k \neq y_k$ but $x_i = y_i$ for all $i \neq k$. We write $x \leftrightarrow y$ if x and y are neighbors. Given a measurable subset S of $[0, 1]^d$, we define the shadow $\Phi(S)$ to be

$$\Phi(S) = \{y \in [0, 1]^d - S : \exists x \in S \ x \leftrightarrow y\}.$$

We define iterated shadows of S recursively as follows. Let $\Phi^{(1)}(S) = \Phi(S)$, and inductively define $\Phi^{(l+1)}(S) = \Phi(\Phi^{(l)}(S))$.

For a measurable subset S of $[0, 1]^d$, let $|S|$ denote its measure. The following proposition is clear from our definitions and discussions above.

PROPOSITION 6.1. *Let g be the mapping from $V(K_n^d)$ to $[0, 1]^d$ defined above. Let W be a subset of $V(K_n^d)$ and l a positive integer with $1 \leq l \leq d$. We have $g(\partial^{(\leq l)}(W)) = \Phi^{(\leq l)}(g(W))$. Hence, $|\partial^{(\leq l)}(W)| = |\Phi^{(\leq l)}(g(W))| \cdot n^d$.*

To establish a lower bound on $B'(K_n^d)$ we will need to establish a lower bound on $|\partial(W)|$ for any subset W of $V(K_n^d)$ of a given size k . By Proposition 6.1, it suffices to consider the problem of minimizing $|\Phi(S)|$ over all measurable subsets S of $[0, 1]^d$ of a given measure. In [14], Harper showed that the problem of minimizing $|\Phi(S)|$ over all measurable subsets S of $[0, 1]^d$ of a given measure reduces to that of minimizing $|\Phi(S)|$ over all suitably “compressed” such subsets. He then showed by using variational methods that for any given v , $0 \leq v \leq 1$, the smallest value of $|\Phi(S)|$ over all such subsets of measure v is achieved by a “Hamming ball,” which we define as follows.

DEFINITION 6.2. *Let t be real number with $0 \leq t \leq 1$. For any binary d -tuple x of Q_d , let $K(x, t)$ be the subset of $[0, 1]^d$ defined by*

$$K(x, t) = \{y \in [0, 1]^d : 0 \leq y_i \leq t \text{ if } x_i = 1, \text{ and } t < y_i \leq 1 \text{ if } x_i = 0, 1 \leq i \leq d\}.$$

Define the subset $HB(d, k, t)$ of $[0, 1]^d$ called a Hamming ball by

$$HB(d, k, t) = \bigcup_{wt(x) \leq k} K(x, t).$$

Note that if x has weight i , then the measure of $K(x, t)$ is $t^i(1-t)^{d-i}$. So the measure of $HB(d, k, t)$ is $v = v(d, k, t) = \sum_{i=0}^k \binom{d}{i} t^i(1-t)^{d-i}$, and the size of its shadow is $|\Phi(HB(d, k, t))| = \binom{d}{k+1} t^{k+1}(1-t)^{d-k-1}$. For convenience, we use $\alpha(d, m, t)$ to denote $\binom{d}{m} t^m(1-t)^{d-m-1}$. Then $|\Phi(HB(d, k, t))| = \alpha(d, k+1, t)$. We can now state Harper’s theorem.

THEOREM 6.3 (see [14, Theorem 1]). *For any given v with $0 \leq v \leq 1$, the minimum of $|\Phi(S)|$ over all subsets S of $[0, 1]^d$ of measure v is achieved by some $HB(d, k, t)$ for suitable k and t .*

To make effective use of Theorem 6.3, we need to analyze $|\Phi(HB(d, k, t))| = \alpha(d, k + 1, t)$. Observe that if X is a random variable drawn from the binomial distribution $BIN(d, t)$, then $v(d, k, t) = \sum_{i=0}^k \binom{d}{i} t^i (1-t)^{d-i} = \Pr(X \leq k)$ and $\alpha(d, k + 1, t) = \binom{d}{k+1} t^{k+1} (1-t)^{d-k-1} = \Pr(X = k + 1)$.

Our general approach is again the one used in [9, 5], and the proof of Theorem 4.7. Given an optimal edge labeling of $E(K_n^d)$, we consider the set $S' \subseteq E(K_n^d)$ of size about $|E(K_n^d)|/2$ receiving the smallest labels. We then lower bound $|\partial(S')|$ or $|\partial^{(\leq q)}(S')|$ for an adequate q . By an argument similar to the one used in the proof of Theorem 4.7, lower bounding $|\partial(S')|$ is reduced to lower bounding $|\partial(S)|$ for a corresponding set $S \subseteq V(K_n^d)$, with $|S|$ near $\frac{1}{2}n^d$. This then reduces to lower bounding $|\Phi(S)|$, where $S \subseteq [0, 1]^d$, with S having measure near $\frac{1}{2}$. By Theorem 6.3, we need to estimate $|\Phi(HB(d, k, t))| = \alpha(d, k + 1, t)$ when $v(d, k, t)$ is near $\frac{1}{2}$. In light of our earlier observation, this means lower bounding $\Pr(X = k + 1)$ when $\Pr(X \leq k)$ is close to $\frac{1}{2}$, where X is a random variable drawn from $BIN(d, t)$. One could in principle obtain such a lower bound by approximating $BIN(d, t)$ using a normal distribution. But the error analysis in such an approximation is quite involved. Further, when the expected value dt is either too close to 0 or too close to d , a normal distribution approximation becomes infeasible.

Here we use a self-contained and completely combinatorial approach to obtain our estimates. We think our approach is of independent interest. We need a lemma from [21].

LEMMA 6.4 (see [21, Lemma B.7]). *Let n be a positive integer and p a real number such that $0 \leq p \leq 1$. Let X be a random variable drawn from the binomial distribution $B(n, p)$ (where n is the number of independent trials and p is the probability of success of each trial). Then*

$$\Pr(X \leq \lfloor np \rfloor - 1) \leq 1/2 \leq \Pr(X \leq \lceil np \rceil).$$

Lemma 6.4 suggests that if $\Pr(X \leq k)$ is close to $\frac{1}{2}$, then k is close to the expected value np . Thus, we need to lower bound $\Pr(X = k + 1)$ for those k close to np .

LEMMA 6.5. *If z is a real number with $0 < z < \frac{1}{2}$, then $1 - z \geq e^{-2z}$. Let x, y, a be positive real numbers such that $x, y \geq 2a$. Then*

$$\left(1 + \frac{a}{x}\right)^x \left(1 - \frac{a}{y}\right)^y \geq e^{-\frac{a^2}{x} - \frac{a^2}{y}}.$$

Proof. For any real number w , with $0 < w \leq \frac{1}{2}$, we have

$$\begin{aligned} \ln(1 + w) &= w - \frac{w^2}{2} + \frac{w^3}{3} - \frac{w^4}{4} + \cdots \geq w - \frac{w^2}{2} > w - w^2, \\ \ln(1 - w) &= -w - \frac{w^2}{2} - \frac{w^3}{3} - \frac{w^4}{4} - \cdots \geq -w - w^2. \end{aligned}$$

If $0 < z < \frac{1}{2}$, then $\ln(1 - z) \geq -z - z^2 \geq -2z$. So $1 - z \geq e^{-2z}$. Since $x, y \geq 2a$, $0 < \frac{a}{x}, \frac{a}{y} \leq \frac{1}{2}$. Let $K = \left(1 + \frac{a}{x}\right)^x \left(1 - \frac{a}{y}\right)^y$. It suffices to show that $\ln K \geq -\frac{a^2}{x} - \frac{a^2}{y}$. Indeed, we have

$$\ln K = x \ln \left(1 + \frac{a}{x}\right) + y \ln \left(1 - \frac{a}{y}\right) \geq x \left(\frac{a}{x} - \frac{a^2}{x^2}\right) + y \left(-\frac{a}{y} - \frac{a^2}{y^2}\right) = -\frac{a^2}{x} - \frac{a^2}{y}. \quad \square$$

Our next lemma says that if X is a random variable drawn from $BIN(n, p)$, where np is not too small or too large and k is near np , then $Pr(X = k)$ is lower bounded by $\sqrt{\frac{2}{\pi n}}(1 - o(1))$ as $n \rightarrow \infty$. We postpone its somewhat technical proof to the appendix.

LEMMA 6.6. *Let n be a positive integer. Let p be a real number such that $0 < p < 1$. Suppose $5\sqrt{\ln n} \leq np \leq n - 5\sqrt{\ln n}$. Let k be a nonnegative integer. Let X be a random variable drawn from $BIN(n, p)$.*

If $|k - np| \leq \sqrt{\ln n}$, then $Pr(X = k) \geq \sqrt{\frac{2}{\pi n}} \cdot e^{-\frac{1}{\sqrt{n}}}$ when n is sufficiently large.

Now we use Lemma 6.6 to give lower bounds on $|\Phi(S)|$, for subsets S of $[0, 1]^d$ having measure near $\frac{1}{2}$.

THEOREM 6.7. *Let d be a sufficiently large positive integer. Let S be a subset of $[0, 1]^d$ with measure $v = |S|$.*

If $\left| |S| - \frac{1}{2} \right| \leq \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}}$, then $|\Phi(S)| \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}}$.

Proof. By Theorem 6.3, $|\Phi(S)|$ is minimum when S is a Hamming ball. Hence, we may assume $S = HB(d, k, t)$ for some k and t , where k is an integer with $1 \leq k \leq d - 1$ and t is a real number with $0 < t < 1$. We have $|S| = v(d, k, t) = \sum_{i=0}^k \alpha(d, i, t)$ and $|\Phi(S)| = \alpha(d, k + 1, t)$. As observed earlier, if X is a random variable drawn from $BIN(d, t)$, then $|S| = Pr(X \leq k)$ and $|\Phi(S)| = Pr(X = k + 1)$. By our assumption,

$$(6) \quad \left| Pr(X \leq k) - \frac{1}{2} \right| \leq \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}}.$$

By Lemma 6.4,

$$(7) \quad Pr(X \leq \lfloor dt \rfloor - 1) \leq \frac{1}{2} \leq Pr(X \leq \lceil dt \rceil).$$

We consider several cases.

Case 1. $5\sqrt{\ln d} \leq dt \leq d - 5\sqrt{\ln d}$. By Lemma 6.6, for each integer m with $|m - dt| \leq \sqrt{\ln d}$, we have $Pr(X = m) \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}}$, when d is large. Hence, for sufficiently large d , we have

$$\begin{aligned} Pr(X \leq \lceil dt \rceil + \lceil \sqrt{\ln d} - 3 \rceil) &\geq \frac{1}{2} + (\sqrt{\ln d} - 3) \cdot \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}} \\ &\geq \frac{1}{2} + \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \geq Pr(X \leq k), \end{aligned}$$

where the last inequality follows from (6). So $k \leq \lceil dt \rceil + \lceil \sqrt{\ln d} \rceil - 3$. By a similar argument, we have $k \geq \lfloor dt \rfloor - 1 - (\lceil \sqrt{\ln d} \rceil - 3)$. It follows that $|(k + 1) - dt| \leq \sqrt{\ln d}$. Since $5\sqrt{\ln d} \leq dt \leq d - 5\sqrt{\ln d}$, by Lemma 6.6, we have

$$|\Phi(S)| = Pr(X = k + 1) \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}}.$$

Case 2. $dt < 5\sqrt{\ln d}$. In this case, we have $t < \frac{5\sqrt{\ln d}}{d}$. Suppose $t \leq \frac{1}{4d}$. Then

$$Pr(X \leq k) \geq Pr(X = 0) = (1 - t)^d \geq \left(1 - \frac{1}{4d}\right)^d \geq e^{-2 \cdot \frac{1}{4d} \cdot d} \geq e^{-\frac{1}{2}} > 0.6,$$

contradicting (6) for large d . So $t > \frac{1}{4d}$.

If $k > 3dt$, then by Markov's inequality we have $Pr(X > k) \leq \frac{1}{3}$ and hence $Pr(X \leq k) > \frac{2}{3}$, contradicting (6) for large d . So we have $k \leq 3dt \leq 15\sqrt{\ln d}$. Let $m = k + 1$. Then $m \leq 16\sqrt{\ln d}$. We have (recalling that $\frac{1}{4} \leq dt \leq 5\sqrt{\ln d}$)

$$\begin{aligned} |\Phi(S)| &= Pr(X = k + 1) = Pr(X = m) = \binom{d}{m} t^m (1 - t)^{d-m} \\ &\geq \left(\frac{d}{m}\right)^m \cdot t^m \cdot (1 - t)^d \geq \left(\frac{dt}{m}\right)^m \cdot e^{-2td} \geq \left(\frac{1}{4m}\right)^m \cdot e^{-10\sqrt{\ln d}} \\ &= e^{-m \ln 4m - 10\sqrt{\ln d}} \geq e^{-\frac{1}{4} \ln d} \geq \frac{1}{d^{\frac{1}{4}}} \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}} \quad \text{for large } d. \end{aligned}$$

Case 3. $dt > d - 5\sqrt{\ln d}$. In this case, we apply almost identical reasoning as in Case 2 but with $1 - t$ playing the role of t . First we show $1 - t \geq \frac{1}{4d}$. Then we apply Markov's inequality to $d - X$ to show that $d - k \leq 15\sqrt{\ln d}$ and therefore $d - m \leq 16\sqrt{\ln d}$. Then we establish the lower bound on $|\Phi(S)|$ as in Case 2, with $1 - t$ playing the role of t and $d - m$ playing the role of m . We omit the details. $\square$

COROLLARY 6.8. *Let d be a sufficiently large positive integer. Let S be a subset of $[0, 1]^d$ with measure $v = |S|$. Suppose*

$$\frac{1}{2} - \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \leq |S| \leq \frac{1}{2}.$$

Then either

$$|\Phi(S)| \geq 2\sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}}$$

or there exists an integer $l \geq 2$ such that

$$\frac{|\Phi^{(\leq l)}(S) - \Phi(S)|}{l + 1} \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}}.$$

Proof. For each i , let $S_i = \Phi^{(i)}(S)$. Let l denote the smallest m such that $|S_1 \cup S_2 \cup \dots \cup S_m| \geq \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}}$. Let $i \in \{1, \dots, l\}$. Let $S' = S \cup S_1 \cup \dots \cup S_{i-1}$. Then

$$|S'| = |S| + |S_1 \cup \dots \cup S_{i-1}| \leq \frac{1}{2} + \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}}.$$

By Theorem 6.7, we have

$$|S_i| = |\Phi(S')| \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}}.$$

Since this holds for all $i \leq l$, we have

$$|S_1 \cup \dots \cup S_{l-1}| \geq (l - 1) \cdot \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}}.$$

If $l > \sqrt{\ln d} - 3$, then

$$|S_1 \cup \dots \cup S_{l-1}| > (\sqrt{\ln d} - 4) \cdot \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}} > \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}},$$

contradicting our choice of l . So we have $l \leq \sqrt{\ln d} - 3$.

Now, if $|S_1| = |\Phi(S)| \geq 2\sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}}$, then we are done. Otherwise, we have

$$|\Phi^{(\leq l)}(S) - \Phi(S)| = |S_1 \cup \dots \cup S_l| - |S_1| \geq \sqrt{\frac{2}{\pi d}} \cdot (\sqrt{\ln d} - 2) \cdot e^{-\frac{10}{\sqrt{\ln d}}}.$$

Thus since $l + 1 \leq \sqrt{\ln d} - 3$, we get

$$\frac{|\Phi^{(\leq l)}(S) - \Phi(S)|}{l + 1} \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}}. \quad \square$$

The two corollaries which follow are just the equivalents of Theorem 6.7 and Corollary 6.8 for K_n^d , under the correspondence between $[0, 1]^d$ and K_n^d described in Proposition 6.1.

COROLLARY 6.9. *Let n and d be positive integers, where d is sufficiently large. Let S be a subset of $V(K_n^d)$.*

$$\text{If } \left| |S| - \frac{n^d}{2} \right| \leq \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d, \text{ then } |\Phi(S)| \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{1}{\sqrt{d}}} \cdot n^d.$$

COROLLARY 6.10. *Let n and d be positive integers, where d is sufficiently large. Let S be a subset of $V(K_n^d)$. Suppose*

$$\left(\frac{1}{2} - \sqrt{\frac{2}{\pi d}} \cdot \sqrt{\ln d} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \right) \cdot n^d \leq |S| \leq \frac{1}{2} \cdot n^d.$$

Then either

$$|\partial(S)| \geq 2\sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d$$

or there exists an integer $l \geq 2$ such that

$$\frac{|\partial^{(\leq l)}(S) - \partial(S)|}{l + 1} \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d.$$

Corollary 6.9 readily yields the following lower bound on the vertex bandwidth $B(K_n^d)$.

THEOREM 6.11. *Let n be a fixed positive integer. For all positive integers d we have $B(K_n^d) \geq (1 - o(1))\sqrt{\frac{2}{\pi d}} n^d$.*

Proof. Consider a labeling f of $V(K_n^d)$ that achieves the bandwidth. Let S denote the set of vertices receiving labels $1, 2, \dots, \lfloor n^d/2 \rfloor$. By Corollary 6.9, $|\partial(S)| \geq (1 - o(1))\sqrt{\frac{2}{\pi d}} n^d$. Thus, $B(K_n^d) = B(f) \geq |\partial(S)| \geq (1 - o(1))\sqrt{\frac{2}{\pi d}} n^d$. $\square$

In [15], Harper obtained the same lower bound on $B(K_n^d)$ when both n and d go to ∞ . For even n , the lower bound for $B(K_n^d)$ in Theorem 6.11 matches asymptotically the upper bound for $B(K_n^d)$ given in [15] as $d \rightarrow \infty$. Recently, Balogh et al. [6] obtained improved upper and lower bounds on $B(K_n^3)$.

We now establish a lower bound on $B'(K_n^d)$ that asymptotically matches the upper bound given in Theorem 5.10 when n is even. We follow the approach used in [9, 5].

THEOREM 6.12. *Let n be a fixed positive integer. We have*

$$B'(K_n^d) \geq (1 - o(1)) \sqrt{\frac{d}{2\pi}} n^d (n-1) \quad \text{as } d \rightarrow \infty.$$

Proof. Let f be an optimal labeling of $E(K_n^d)$ using labels $1, \dots, \binom{n}{2} dn^{d-1}$. Let S denote the set of edges receiving the first half of the labels. That is, S is the set of the edges receiving labels $1, 2, \dots, \frac{1}{2} \binom{n}{2} dn^{d-1}$. Let us call the edges in S red and the rest of the edges white.

For a vertex $x \in V(K_n^d)$, let $E(x)$ denote the set of edges incident to x . A vertex x is called *red* if all of the edges in $E(x)$ are red and *white* if all of the edges in $E(x)$ are white; otherwise, it is called *mixed*. Let R, W , and M denote the set of red, white, and mixed vertices, respectively.

We have

$$(8) \quad |R| + |W| + |M| = n^d.$$

For $x \in M$, let $r(x)$ denote the number of red edges in $E(x)$. Hence $1 \leq r(x) \leq d(n-1)$. By (double) counting the red edges and the white edges, we have

$$(9) \quad |R| \cdot d(n-1) + \sum_{x \in M} r(x) = \binom{n}{2} dn^{d-1} = |W| \cdot d(n-1) + \sum_{x \in M} (d(n-1) - r(x)).$$

It readily follows from (9) that $|R|, |W| < \frac{1}{2} n^d$. Note that the white edges incident to M belong to $\partial(S)$. Similarly, the red edges incident to M belong to $\partial(E(K_n^d) - S)$. Therefore, we have

$$(10) \quad |\partial(S)| \geq \frac{1}{2} \sum_{x \in M} (d(n-1) - r(x)) \quad \text{and} \quad |\partial(E(K_n^d) - S)| \geq \frac{1}{2} \sum_{x \in M} r(x).$$

By combining these two inequalities we obtain

$$(11) \quad B'(K_n^d) \geq \max\{|\partial(S)|, |\partial(E(K_n^d) - S)|\} \geq \frac{|M| \cdot (n-1)d}{4}.$$

If $|M| \geq 2\sqrt{\frac{2}{\pi d}} \cdot n^d \cdot e^{-\frac{10}{\sqrt{\ln d}}}$, then by (11) we have

$$B'(K_n^d) \geq \frac{|M| \cdot (n-1)d}{4} \geq \sqrt{\frac{d}{2\pi}} n^d (n-1) \cdot e^{-\frac{10}{\sqrt{\ln d}}} = (1 - o(1)) \sqrt{\frac{d}{2\pi}} n^d (n-1),$$

and we are done. Hence, we may assume that

$$(12) \quad |M| < 2\sqrt{\frac{2}{\pi d}} \cdot n^d \cdot e^{-\frac{10}{\sqrt{\ln d}}}.$$

Either

$$\sum_{x \in M} r(x) \leq |M| \cdot d(n-1)/2 \quad \text{or} \quad \sum_{x \in M} (d(n-1) - r(x)) \leq |M| \cdot d(n-1)/2.$$

Without loss of generality, let us assume that the first inequality holds, since otherwise we could switch the roles of red and white vertices. By combining this with (9) and (12), we have

$$(13) \quad \binom{n}{2} dn^{d-1} \leq |R| \cdot d(n-1) + |M| \cdot d(n-1)/2 \leq |R| \cdot d(n-1) + \frac{\sqrt{2}}{\sqrt{\pi d}} n^d \cdot d(n-1).$$

This yields the lower bound

$$\left(\frac{1}{2} - \sqrt{\frac{2}{\pi d}}\right) n^d \leq |R| < \frac{1}{2} n^d.$$

By Corollary 6.10, we have either

$$(14) \quad |\partial(R)| \geq 2 \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d$$

or there exists an integer $l \geq 2$ such that

$$(15) \quad \frac{|\partial^{(\leq l)}(R) - \partial(R)|}{l+1} \geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d.$$

Now clearly $\partial(R) \subseteq M$. So if (14) holds, then we have

$$|M| \geq 2 \sqrt{\frac{2}{\pi d}} \cdot n^d \cdot e^{-\frac{10}{\sqrt{\ln d}}},$$

contradicting (12). Hence, we may assume that (15) holds instead. Let $C = \partial^{(\leq l)}(R) - \partial(R)$. Let $E(C)$ denote the set of edges incident to C . Recalling that S is the set of red edges, we have $E(C) \subseteq \partial^{(\leq l+1)}(S)$. Note that $|E(C)| \geq |C| \cdot d(n-1)/2$. By applying Proposition 2.2 to the line graph $L(K_n^d)$, we have

$$\begin{aligned} B'(K_n^d) &\geq B'(f) \geq \frac{|\partial^{(\leq l+1)}(S)|}{(l+1)} \geq \frac{|E(C)|}{(l+1)} \geq \frac{|C| \cdot d(n-1)}{2(l+1)} \\ &= \frac{|\partial^{(\leq l)}(R) - \partial(R)| \cdot d(n-1)}{2(l+1)} \\ &\geq \sqrt{\frac{2}{\pi d}} \cdot e^{-\frac{10}{\sqrt{\ln d}}} \cdot n^d \cdot \frac{d(n-1)}{2} \quad (\text{by (15)}) \\ &= (1 - o(1)) \sqrt{\frac{d}{2\pi}} \cdot n^d (n-1). \quad \square \end{aligned}$$

7. Concluding remarks. 1. We thank one of the referees for pointing us to the work of Pellegrini [26]. There the weight function $l(n, d, r)$ is expressed as an exponential sum, using the recurrence in Proposition 3.1 and standard results in Fourier series. This led to [26, Proposition 3]

$$l(n, d, r) = \frac{2}{\pi} \int_0^{\frac{\pi}{2}} \cos(x(2r - d(n-1))) \left(\frac{\sin(nx)}{\sin x} \right)^d dx.$$

Recall that $l^*(n, d) = l(n, d, \lfloor \frac{n(d-1)}{2} \rfloor)$. So by letting $r = \lfloor \frac{n(d-1)}{2} \rfloor$ and adapting Pellegrini's application of Laplace's method to estimate this integral for fixed n and $d \rightarrow \infty$, we obtain

$$(16) \quad l^*(n, d) = \sqrt{\frac{6}{\pi d} \left(\frac{n^2}{n^2 - 1} \right)} n^{d-1} + o(n^{d-1}), \quad \text{when } n \text{ is fixed and } d \rightarrow \infty.$$

We note that in Pellegrini's application it is important to have n fixed and $d \rightarrow \infty$. Since we are concerned with the case when d is fixed and $n \rightarrow \infty$, we cannot use (16) in our result. Formula (16) will be useful when one studies $B'(P_n^d)$ when n is fixed and $d \rightarrow \infty$.

2. We have asymptotically determined $B'(K_n^d)$ for fixed even n and $d \rightarrow \infty$, showing that $B' \sim \sqrt{\frac{d}{2\pi}} n^d (n-1)$. In the upper bound labeling, the evenness of n made it possible to partition K_n^d into 2^d many orthants, each isomorphic to $K_{n/2}^d$.

When $n = 2m + 1$ is odd, a similar partition is possible. Here an orthant corresponding to a weight k vertex of Q_d is the Cartesian product of k copies of K_{m+1} and $d - k$ copies of K_m . By applying the same labeling scheme, and noting that a maximum dilation occurs at a pair of cross edges incident to a vertex in an orthant associated with a hypercube node of weight $\lfloor \frac{(m+1)d}{2m+1} \rfloor$, we obtain an upper bound

$$B'(K_n^d) \leq \frac{2m+1}{2m} \sqrt{\frac{m}{m+1}} \sqrt{\frac{d}{2\pi}} n^d (n-1) (1 + o(1)),$$

when $n = 2m + 1$ is fixed and $d \rightarrow \infty$.

This upper bound is within a factor of $\frac{2m+1}{2m} \sqrt{\frac{m}{m+1}}$ from the lower bound in Theorem 6.12. Note that this factor is close to 1 and tends to 1 as $m \rightarrow \infty$. It would be interesting to determine $B'(K_n^d)$ asymptotically when n is odd and $d \rightarrow \infty$. We suspect that the upper bound given here is closer to the truth.

Appendix. Proof of Lemma 6.6.

Proof. We recall Stirling's formula that, for all integers $n \geq 1$, $n! = \sqrt{2\pi n} \cdot (n/e)^n \cdot e^{\frac{\theta}{12n}}$ for some $\theta = \theta(n)$, with $0 < \theta < 1$. We have for some $\theta_1, \theta_2, \theta_3 \in (0, 1)$

$$\begin{aligned} Pr(X = k) &= \binom{n}{k} p^k (1-p)^{n-k} \\ &= \frac{\sqrt{2\pi n} \left(\frac{n}{e}\right)^n}{\sqrt{2\pi k} \left(\frac{k}{e}\right)^k \sqrt{2\pi(n-k)} \left(\frac{n-k}{e}\right)^{n-k}} \cdot p^k \cdot (1-p)^{n-k} \cdot e^{\frac{\theta_1}{12n} - \frac{\theta_2}{12k} - \frac{\theta_3}{12(n-k)}} \\ (17) \quad &\geq \frac{1}{2\pi} \cdot \sqrt{\frac{n}{k(n-k)}} \cdot \left(\frac{np}{k}\right)^k \cdot \left(\frac{n-np}{n-k}\right)^{n-k} \cdot e^{-\frac{1}{12k} - \frac{1}{12(n-k)}}. \end{aligned}$$

Let $a = np - k$. Then $np = k + a$ and $|a| \leq \sqrt{\ln n}$ by our assumption. We have

$$\begin{aligned} (18) \quad \left(\frac{np}{k}\right)^k \cdot \left(\frac{n-np}{n-k}\right)^{n-k} &= \left(1 + \frac{a}{k}\right)^k \left(1 - \frac{a}{n-k}\right)^{n-k} \geq e^{-\frac{a^2}{k} - \frac{a^2}{n-k}} \\ &\geq e^{-\ln n \left(\frac{1}{k} + \frac{1}{n-k}\right)}, \end{aligned}$$

where the first inequality follows from Lemma 6.5. By (17) and (18), we have for large n

$$\begin{aligned} (19) \quad Pr(X = k) &\geq \frac{1}{\sqrt{2\pi}} \cdot \sqrt{\frac{n}{k(n-k)}} \cdot e^{-(\ln n + \frac{1}{12}) \left(\frac{1}{k} + \frac{1}{n-k}\right)} \\ &\geq \frac{1}{\sqrt{2\pi}} \cdot \sqrt{\frac{n}{k(n-k)}} \cdot e^{-2 \ln n \left(\frac{1}{k} + \frac{1}{n-k}\right)}. \end{aligned}$$

Note that $k(n-k)$ is unimodal and is maximized at $k = n/2$. We consider two cases.

Case 1. $k \leq n^{\frac{3}{4}}$ or $n - k \leq n^{\frac{3}{4}}$. In this case, $k(n - k) \leq n^{\frac{3}{4}} \cdot n$. So $\frac{n}{k(n-k)} \geq \frac{1}{n^{\frac{3}{4}}}$. Also, $4\sqrt{n} \leq k \leq d - 4\sqrt{\ln n}$. So $\frac{n}{k(n-k)} \leq \frac{n}{4\sqrt{\ln n}(n-4\sqrt{\ln n})} \leq \frac{1}{\sqrt{\ln n}}$. By (19), we have

$$Pr(X = k) \geq \frac{1}{\sqrt{2\pi}} \cdot \frac{1}{n^{\frac{3}{8}}} \cdot e^{-2 \ln n \cdot \frac{1}{\sqrt{\ln n}}} = \frac{1}{\sqrt{2\pi}} \cdot \frac{1}{n^{\frac{3}{8}}} \cdot \frac{1}{d^{\frac{2}{\sqrt{\ln n}}}} \geq \sqrt{\frac{2}{\pi n}} \cdot e^{-\frac{1}{\sqrt{n}}} \quad \text{for large } n.$$

Case 2. $n^{\frac{3}{4}} \leq k \leq n - n^{\frac{3}{4}}$. In this case, we have $\frac{n}{k(n-k)} \geq \frac{n}{n^2/4} = \frac{4}{n}$ and $\frac{n}{k(n-k)} \leq \frac{n}{n^{\frac{3}{4}}(n-n^{\frac{3}{4}})} \leq \frac{2}{n^{\frac{3}{4}}}$. By (19),

$$Pr(X = k) \geq \frac{1}{\sqrt{2\pi}} \cdot \sqrt{\frac{4}{n}} \cdot e^{-2 \ln n \cdot \frac{2}{n^{\frac{3}{4}}}} \geq \sqrt{\frac{2}{\pi n}} \cdot e^{-\frac{1}{\sqrt{n}}} \quad \text{for large } n. \quad \square$$

POLYCHROMATIC COLORINGS OF SUBCUBES OF THE HYPERCUBE*

DAVID OFFNER†

Abstract. Alon, Krech, and Szabó [*SIAM J. Discrete Math.*, 21 (2007), pp. 66–72] called an edge-coloring of a hypercube with p colors such that every subcube of dimension d contains every color a d -polychromatic p -coloring. Denote by p_d the maximum number of colors with which it is possible to d -polychromatically color *any* hypercube. We find the exact value of p_d for all values of d .

1. Introduction. Denote by Q_n the n -dimensional hypercube, and, for fixed graphs G, H , denote by $\text{ex}(G, H)$ the maximum number of edges in a subgraph of G which does not contain a copy of H . Problems about this quantity are called Turán-type problems, after P. Turán, who gave an exact value for $\text{ex}(G, H)$ when G and H are cliques. There is a rich history of studying Turán-type problems where $G = Q_n$. To cite some well-known examples, Erdős [7] conjectured that $\text{ex}(Q_n, Q_2) = (\frac{1}{2} + o(1))e(Q_n)$. Currently it is known that

$$\frac{1}{2}(n + \sqrt{n})2^{n-1} \leq \text{ex}(Q_n, Q_2) \lesssim .623e(Q_n).$$

The lower bound is due to Brass, Harborth, and Neinborg [4] and the upper bound to Chung [5]. Bialostocki [3] proved that any subgraph of the cube not containing Q_2 as a subgraph and intersecting every Q_2 has cardinality at most $(n + \sqrt{n})2^{n-2}$. As one generalization of Erdős' problem, Erdős [7], Chung [5], Conder [6], and Alon et al. [2] also looked at the size of $\text{ex}(Q_n, C_{2k})$, where C_{2k} is a cycle of even length.

More recently, Alon, Krech, and Szabó [1] asked how large $\text{ex}(Q_n, Q_d)$ is and studied related problems. In particular, they called an edge-coloring of a hypercube with p colors such that every subcube of dimension d contains every color a d -polychromatic p -coloring. Denote by p_d the maximum number of colors with which it is possible to d -polychromatically color *any* hypercube. (Note that the value of p_d gives a lower bound on $\text{ex}(Q_n, Q_d)$; in particular, $e(Q_n)(1 - 1/p_d) \leq \text{ex}(Q_n, Q_d)$.) They proved the following.

THEOREM 1.

$$\binom{d+1}{2} \geq p_d \geq \begin{cases} \frac{(d+1)^2}{4} & \text{if } d \text{ is odd,} \\ \frac{d(d+2)}{4} & \text{if } d \text{ is even.} \end{cases}$$

The lower bound was obtained by construction and the upper bound by a surprising application of Ramsey's theorem, one version of which states that for all r, k there exists an n such that, if the edges of a d -uniform hypergraph on at least n vertices are

†Department of Mathematical Sciences, Carnegie Mellon University, Pittsburgh, PA 15213 (offner@cmu.edu).

colored with k colors, there exists a complete monochromatic subgraph on r vertices. See [8] for a full treatment.

Alon, Krech, and Szabó asked whether it was possible to resolve the behavior of p_d . We will prove that for all d , p_d is equal to the lower bound in Theorem 1, i.e., the following.

THEOREM 2.

$$p_d = \begin{cases} \frac{(d+1)^2}{4} & \text{if } d \text{ is odd,} \\ \frac{d(d+2)}{4} & \text{if } d \text{ is even.} \end{cases}$$

2. Notation. We follow the notation of [1] in denoting vertices, edges, and subcubes: A vertex of Q_n is represented by a vector of n bits. An edge corresponding to two vertices whose vectors differ in one coordinate is represented by a bit vector with a $*$ in that coordinate. A d -dimensional subcube D is represented by a bit vector with d $*$'s, where the vertices of D are those vectors obtained by replacing the $*$'s with any combination of bits.

3. Proof of Theorem 1. For completeness, since the proof of Theorem 2 will use ideas from the proof of Theorem 1 in [1], and since the proof is very nice, we sketch it here.

Proof of Theorem 1 (lower bound). Assume that d is odd. The following $\frac{(d+1)^2}{4}$ -coloring of Q_n is d -polychromatic: Color the edges with elements of $\mathbf{Z}_{\frac{d+1}{2}} \times \mathbf{Z}_{\frac{d+1}{2}}$ as follows: If an edge has a 1's to the left of its $*$, and b 1's to the right of its $*$, assign it the color $(a \pmod{\frac{d+1}{2}}, b \pmod{\frac{d+1}{2}})$. For any subcube Q_d , find the $*$ with exactly $\frac{d-1}{2}$ $*$'s on each side of it. Note that, for this subcube, the set of edges with this $*$ contains all colors. The construction is the same if d is even, except a is taken mod $\frac{d}{2}$ and b is taken mod $\frac{d+2}{2}$, and for any subcube Q_d we consider the edges whose star is the $\frac{d}{2}$ th from the left. $\square$

Proof of Theorem 1 (upper bound). Suppose that we have a d -polychromatic p -coloring c of Q_n , with n huge. We will use Ramsey's theorem for d -uniform hypergraphs with $p^{d^{d-1}}$ colors. We define a $p^{d^{d-1}}$ -coloring of the d -subsets of $[n]$. Fix an arbitrary ordering of the edges of Q_d . For an arbitrary subset S of the indices, define $\text{cube}(S)$ to be the subcube whose $*$ coordinates are at the positions of S and all other coordinates are 0. Let S be a d -subset of $[n]$, and define the color of S to be the vector whose coordinates are the c -values of the edges of the d -dimensional subcube $\text{cube}(S)$ (according to our fixed ordering of the edges of Q_d). By Ramsey's theorem, if n is large enough, there is a set $T \subseteq [n]$ of $d^2 + d - 1$ coordinates such that the color-vector is the same for any d -subset of T . Fix a set S of d particular coordinates from T : those which are the (id) th elements of T for $i = 1, \dots, d$. Any two elements of S have at least $d - 1$ elements of T in between.

Call a hypercube coloring *Ramsey* if the color of an edge is determined by the number of 1's to the left of its $*$ and the number of 1's to the right of its $*$.

LEMMA 3. *The coloring of $\text{cube}(S)$ is Ramsey.*

Proof. Let e_1 and e_2 be two edges of $\text{cube}(S)$ such that they have the same number of 1's to the left of their respective $*$ and the same number of 1's to the right as well. Since there are at least $d - 1$ elements in T in between each coordinate of S , it is possible for us to find a set of d coordinates $S' \subseteq T$ and an edge e_3 of $\text{cube}(S')$ such that

- (i) e_3 is the same edge when restricted to S as e_1 and
- (ii) e_3 occupies the same position in the ordering of edges in $\text{cube}(S')$ as e_2 occupies in $\text{cube}(S)$.

Thus $c(e_1) = c(e_3) = c(e_2)$, and the lemma is proved. $\square$

To finish the proof of the upper bound in Theorem 1, note that there are exactly $1 + 2 + \cdots + d = \binom{d+1}{2}$ ways to separate at most $d - 1$ 1's by a *. By Lemma 3, a d -polychromatic edge-coloring is not possible with more colors. $\square$

4. Proof of Theorem 2.

LEMMA 4. *If a d -polychromatic p -coloring exists for any n , then one of Ramsey-type exists.*

Proof. In the proof of the upper bound of Theorem 1, we showed that, in a sufficiently large hypercube, a Ramsey-colored d -dimensional subcube exists by applying Ramsey's theorem to a $p^{\binom{d+1}{2}}$ -coloring of the d -subsets of the indices of $[n]$. To prove that, for a sufficiently large hypercube, a subcube of any dimension k exists with a Ramsey coloring, simply apply Ramsey's theorem to a $p^{\binom{k+1}{2}}$ -coloring of the k -subsets of $[n]$, defined in an analogous way, and proceed in an identical fashion. Thus for any $p \leq p_d$, one can show the existence of a Ramsey p -colored d -polychromatic hypercube of dimension k by taking any sufficiently large p -colored d -polychromatic hypercube and applying Ramsey's theorem. $\square$

Proof of Theorem 2. Fix d . By Lemma 4, we may consider a Ramsey d -polychromatic p_d -coloring on an arbitrarily large hypercube. Since the coloring is Ramsey, every edge belongs to some color class (a, b) , where there are a 1's to the left of the * and b 1's to the right. It will be convenient to arrange the color classes in a triangular array, with $(0, 0)$ in the first row, $(0, 1)$ and $(1, 0)$ in the second row, and so forth. Define the i th row to be those color classes (a, b) , with $a + b = i$, and the i th diagonal to be those classes of the form (i, j) for any j . Define an $i \times j$ rectangle to be a set of color classes of the following form: $\{(a + \alpha, b + \beta) : 0 \leq \alpha < j, 0 \leq \beta < i\}$, and say a rectangle R is located at the i th diagonal if i is the least diagonal that intersects R . Define a region to be all color classes contained in some consecutive rows and consecutive diagonals.

In this configuration, a d -cube includes the following color classes, from left to right: a $d \times 1$ rectangle, corresponding to the colors of edges using the leftmost *, followed by a $(d - 1) \times 2$ rectangle, corresponding to the colors of edges using the second-leftmost *, etc., until a $1 \times d$ rectangle corresponding to the rightmost *. All of these rectangles cover colors in the same d rows, and they may overlap. They must come in order from left to right, however, since, e.g., if there are a 1's to the left of some *, there are at least a 1's to the left of any * further to the right. Call such a sequence of rectangles a *cube sequence*, and denote them (left to right) by $r_1, r_2, \dots, r_d$. Note that any cube sequence corresponds to color classes covered by at least one cube. See the examples in Figure 1.

Choose a set of d consecutive very long rows. By our assumption that the coloring is d -polychromatic, it is not possible to find a cube sequence in these rows where every rectangle in the sequence lacks a particular color. In particular, imagine picking a color A and scanning the rows from left to right, looking for a copy of r_1 not containing A . If we find one, say, at diagonal d_1 , we note that all copies of r_1 to the left of d_1 contain A . Continuing from left to right, we might then seek a copy of r_2 not containing A , and if the first one we find is at diagonal d_2 , then we note that every copy of r_2 between d_1 and d_2 contains A . By continuing in this manner, we may partition the rows into at most d regions where, in the i th region, every copy of r_i contains A . By repeating this for the other colors, we note that each color partitions the rows into at most d regions, where, in the i th region, each copy of r_i contains the color. By taking the intersections of all of these regions, the rows are partitioned into at most $d \cdot p_d$ regions such that for each region, for every color A , there is a rectangle

FIG. 1. The triangular array of color classes and some cube sequences.

r_A such that every copy of r_A in the region contains A . In particular, since we may choose the rows as long as we like, we can find an arbitrarily long region with this property.

Now consider such a region with m diagonals, where $m \gg d$. For each color A , assign d variables, $\{A_i\}_{i=1}^d$ corresponding to the number of times A appears in the i th row in our region. Note that, if A appears in the top or bottom row, it can be contained in at most one copy of r_A . If it appears in the second or the $d-1$ st row, it can be contained in at most two copies of r_A , and so forth. There are at least $m-d$ copies of r_A in the region, and thus

$$A_1 + 2A_2 + 3A_3 + \cdots + \left\lceil \frac{d}{2} \right\rceil A_{\lceil \frac{d}{2} \rceil} + \cdots + 2A_{d-1} + A_d \geq m - d.$$

Since $A_i + B_i + \cdots = m$, if we add up these equations for each color, we get

$$m + 2m + 3m + \cdots + \left\lceil \frac{d}{2} \right\rceil m + \cdots + 2m + m \geq p_d(m - d).$$

The left-hand side is equal to $\frac{(d+1)^2}{4}m$ if d is odd and $\frac{d(d+2)}{4}m$ if d is even. Divide both sides by m , and note that $(m-d)/m$ can be as close to 1 as desired to obtain the result. $\square$

This method may be used to immediately give other similar results. For instance, say two edges in a subcube belong to the same *layer* if their vector representation contains the same number of 1's. Then, if $q_{d,k}$ ($k \leq d$) is the maximum number such that any Q_n can be edge-colored so that the k th layer of any sub- Q_d contains all colors, then $q_{d,\lceil d/2 \rceil} = \lceil d/2 \rceil$ (e.g., $q_{3,2} = 2$).

Acknowledgments. The author thanks Oleg Pikhurko and Peter Lumsdaine for helpful discussions and Tibor Szabó and an anonymous referee for comments on the paper.

MATROID COMPLEXITY AND NONSUCCINCT DESCRIPTIONS*

DILLON MAYHEW†

Abstract. We investigate an approach to matroid complexity that involves describing a matroid via a list of independent sets, bases, circuits, or some other family of subsets of the ground set. The computational complexity of algorithmic problems under this scheme appears to be highly dependent on the choice of input type. We define an order on the various methods of description, and we show how this order acts upon 10 types of input. We also show that under this approach several natural algorithmic problems are complete in classes thought not to be equal to P.

Key words. matroids, complexity, isomorphism, matroid minors

AMS subject classifications. 05B35, 68Q17

DOI. 10.1137/050640576

1. Introduction. The study of matroid-theoretical algorithmic problems and their complexity has been dominated by two approaches. The first approach was implicitly used by Edmonds [1] and later developed by Hausmann and Korte [4, 5]. It uses the idea of an ordinary Turing machine augmented with an oracle. Suppose that the subject of the computation is a matroid on the ground set E . When queried about a subset, X , of E , the oracle returns in unit time some information about X . That information might be the rank of X , or an answer to the question, “Is X independent?” In this case the oracle is known as the rank or independence oracle, respectively.

The second dominant approach to matroid complexity uses the standard model of a Turing machine but considers as its input only a restricted class of matroids that can be represented by some “succinct” structure, for instance, a graph, or a matrix over a field.

A third approach to the study of matroid complexity would, in some ways, be more natural. A matroid is essentially a finite set with a structured family of subsets (we shall not consider infinite matroids). An obvious way to describe a matroid to a Turing machine is to simply list the subsets that belong to this family. The advantage of this approach is that any matroid could be received as input, and not merely those matroids which belong to some restricted class.

The reason this approach has not received as much attention as the latter two is the concern that the input will be too large. A result of Knuth [8] says that if $f(n)$ is the number of nonisomorphic matroids on a set of size n , then there is a constant c such that

$$\log_2 \log_2 f(n) \geq n - \frac{3}{2} \log_2 n + c \log_2 \log_2 n$$

for sufficiently large values of n . It follows that if Σ is a finite alphabet and $\sigma : \mathcal{M} \rightarrow \Sigma^*$ is an injective encoding scheme that takes the set of all matroids to words in Σ , then there can be no polynomial function p such that $|\sigma(M)|$, the length of the word $\sigma(M)$, is bounded above by $p(|E(M)|)$ for every matroid M . Thus if we wish to use

†Mathematical Institute, University of Oxford, St. Giles, OX1 3LB Oxford, UK, and School of Mathematics, Victoria University of Wellington, P.O. Box 600, Wellington 6140, New Zealand (dillon.mayhew@mcs.vuw.ac.nz).

this type of encoding function we must in some sense abandon the cardinality of the ground set of a matroid as a measure of its “size.” Historically the concern with this type of scheme has been that, because of the large size of the input, the class of problems that can be solved in polynomial time will be artificially inflated, and that therefore, in a trivial way, all algorithmic problems for matroids will be tractable.

In this paper we show that the situation is apparently more subtle than this. We show that several natural matroid problems are complete in classes thought not to be equal to P, even using an encoding scheme that works for all matroids; for instance, the scheme that describes a matroid by listing its independent sets.

A quirk of this approach to matroid complexity is that the difficulty of a computational problem appears to vary widely according to the type of input. A problem may be solvable in polynomial time if the input takes the form of a list of bases, but if the input is a list of circuits, the same problem may be NP-complete.

Before we examine the complexity of matroid-theoretical problems, we define an order on types of input, and we show how this order acts upon a set of 10 natural methods of description. This work is an analogue of that done by Hausmann and Korte [6] and Robinson and Welsh [12]. Both of these works compare different types of oracles.

Our references for basic concepts, notation, and terminology will be Oxley [11] with regards to matroids and Garey and Johnson [2] with regards to complexity theory.

2. Various types of inputs. The 10 types of input that we consider are as follows: RANK, INDEPENDENT SETS, SPANNING SETS, BASES, FLATS, CIRCUITS, HYPERPLANES, NONSPANNING CIRCUITS, DEPENDENT HYPERPLANES, and CYCLIC FLATS.

Of these, some need little explanation. A list of the independent sets, spanning sets, bases, flats, circuits, or hyperplanes of a matroid uniquely specifies that matroid. Thus the corresponding forms of input will consist simply of lists of the appropriate subsets.

The RANK input will list each subset of the ground set, along with its rank. The NONSPANNING CIRCUITS input for a matroid M will specify the rank of M and list all its nonspanning circuits. Dually, the DEPENDENT HYPERPLANES input will specify the rank of M and list its dependent hyperplanes.

A *cyclic flat* is a flat that is also a (possibly empty) union of circuits. It is known that listing the cyclic flats and specifying their ranks completely determines a matroid. Therefore the CYCLIC FLATS input will list each cyclic flat, along with its rank.

(Note that we have not specified how to describe some exceptional cases, such as a matroid M with no nonspanning circuits. In this particular case we will assume that the NONSPANNING CIRCUITS description lists only the rank of M . Other exceptional cases are easily dealt with in a similar way.)

Suppose that f and g are two functions on the positive integers. If there exist constants, c_1 and c_2 , and an integer, N , such that $c_1g(n) \leq f(n) \leq c_2g(n)$ for every positive integer $n \geq N$, then we shall write $f = \Theta(g)$. Equivalently, $f = \Theta(g)$ if and only if $f = O(g)$ and $g = O(f)$.

Suppose that M is a matroid on a ground set of size n , and that INPUT is one of the types of input discussed above. Let (M, INPUT) be a word that describes M via INPUT. We shall assume that a subset of the ground set is specified by its characteristic vector. Thus if the INPUT description involves listing i subsets of $E(M)$, then $|(M, \text{INPUT})| \geq ni$. We shall consider only “reasonable” encoding schemes

(i.e., those that do not allow, for instance, padding of words). It follows easily that $|(M, \text{INPUT})| = \Theta(ni)$.

Obviously there are many other natural ways of describing a matroid, but many are related in a fairly trivial way to one of the methods we have already discussed. For example, a matroid can be described by listing its cocircuits, but the cocircuits are exactly the complements of the hyperplanes.

3. A comparison of inputs. It is natural to ask whether one form of description is intrinsically more compact than another. In this section we attempt to answer that question.

DEFINITION 3.1. *Suppose that INPUT1 and INPUT2 are two methods for describing a matroid. Then $\text{INPUT1} \leq \text{INPUT2}$ if there exists a polynomial-time Turing machine which will produce $(M, \text{INPUT2})$ given $(M, \text{INPUT1})$ for any matroid M .*

Suppose that $\text{INPUT1} \leq \text{INPUT2}$. If a problem is in P for descriptions via INPUT2, then clearly it is in P for INPUT1. Similarly, if a problem is NP-complete for INPUT1, then the same problem is NP-hard for INPUT2.

It is clear that $\leq$ is both reflexive and transitive. The rest of this section will be devoted to proving Theorem 3.2.

THEOREM 3.2. *The 10 types of input listed in section 2 are ordered by $\leq$ according to the Hasse diagram in Figure 1.*

Theorem 3.2 will follow from the subsequent lemmas.

LEMMA 3.3. $\text{RANK} \leq \text{SPANNING SETS}$ and $\text{RANK} \leq \text{INDEPENDENT SETS}$.

Proof. To find $(M, \text{SPANNING SETS})$ given (M, RANK) , a Turing machine need only write onto its output those subsets whose rank equals $r(M)$. Similarly, to produce $(M, \text{INDEPENDENT SETS})$ the machine need only write those subsets of $E(M)$ whose rank is equal to their size. $\square$

LEMMA 3.4. $\text{SPANNING SETS} \leq \text{BASES}$ and $\text{INDEPENDENT SETS} \leq \text{BASES}$.

Proof. The bases of a matroid are exactly the minimal spanning sets and the maximal independent sets, so the result follows easily. $\square$

LEMMA 3.5. $\text{INDEPENDENT SETS} \leq \text{FLATS}$.

Proof. Given the list of independent sets of M , we can create the list of flats by finding, in turn, the closure of each independent set, and then eliminating duplications. To find the closure of the independent set I , we check each set of the form $I \cup e$, where $e \notin I$, to see if it is independent. The element e belongs to $\text{cl}(I)$ if and only if $I \cup e$ is dependent. Since $|(M, \text{INDEPENDENT SETS})| = \Theta(ni)$, where $|E(M)| = n$ and the number of independent sets is i , it is easy to see that this entire procedure can be accomplished in polynomial time. $\square$

FIG. 1. An ordering of input types.

LEMMA 3.6. BASES $\leq$ CIRCUITS.

Proof. If B is a basis of a matroid M and $e \in E(M) - B$, then $B \cup e$ contains a unique circuit $C(e, B)$, known as the *fundamental circuit of e with respect to B* . Since every circuit is a fundamental circuit with respect to some basis, we can construct the list of circuits of M , given the list of bases, by creating the list of fundamental circuits with respect to each of the bases, and then eliminating duplications.

If B is a basis of M , and $e \in E(M) - B$, we find $C(e, B)$ by comparing $(B \cup e) - f$ against the list of bases for each $f \in B$. The element f is in $C(e, B)$ if and only if $(B \cup e) - f$ is a basis. $\square$

The next result follows easily using duality and Lemma 3.6.

LEMMA 3.7. BASES $\leq$ HYPERPLANES.

Let the number of bases and cyclic flats in the matroid M be denoted by $b(M)$ and $z(M)$, respectively.

PROPOSITION 3.8. *Let M be a matroid. Then $z(M) \leq b(M)$.*

Proof. The proof will be by induction on $|E(M)|$. If $|E(M)| = 0$, then $b(M) = z(M) = 1$, so the proposition holds.

Let M be a matroid such that $|E(M)| = n > 0$, and assume that the proposition holds for all matroids on ground sets of $n - 1$ elements. We may assume that there exists an element $e \in E(M)$ such that e is neither a loop nor a coloop, for otherwise $b(M) = z(M) = 1$.

Let $b_e(M)$ be the number of bases of M that contain e , and let $b_{\bar{e}}(M)$ be the number of bases of M that avoid e . Then $b_e(M) = b(M/e)$ and $b_{\bar{e}}(M) = b(M \setminus e)$. Similarly, let $z_e(M)$ be the number of cyclic flats of M that contain e , and let $z_{\bar{e}}(M)$ be the number of cyclic flats that do not contain e . It is easy to see that any cyclic flat that does not contain e is also a cyclic flat of $M \setminus e$, so $z_{\bar{e}}(M) \leq z(M \setminus e)$. Moreover, if Z is a cyclic flat of M , and $e \in Z$, then $Z - e$ is a cyclic flat of M/e . Thus $z_e(M) \leq z(M/e)$, and hence

$$z(M) = z_e(M) + z_{\bar{e}}(M) \leq z(M/e) + z(M \setminus e).$$

By the inductive hypothesis, $z(M/e) \leq b(M/e)$ and $z(M \setminus e) \leq b(M \setminus e)$, so

$$z(M) \leq b(M/e) + b(M \setminus e) = b_e(M) + b_{\bar{e}}(M) = b(M). \quad \square$$

LEMMA 3.9. BASES $\leq$ CYCLIC FLATS.

Proof. Our algorithm for generating the list of cyclic flats, given the list of bases, will start by constructing the closures of all circuits. At each repetition of the loop the algorithm will find the closure of the union of every pair of cyclic flats already on the list.

Suppose that M is a matroid on the ground set E . Note that we can check in polynomial time whether a set is independent by comparing it against the family of bases. Hence if $A \subseteq E$, we can use the greedy algorithm to find a basis I of A . The element $e \notin A$ is in $\text{cl}(A)$ if and only if $I \cup e$ is dependent. It follows that we can find $\text{cl}(A)$ in polynomial time.

From Lemma 3.6 we see that we can find the list of circuits in polynomial time, given the list of bases. Hence we can also construct the list of closures of circuits, add the closure of the empty set, and then eliminate duplications from the list in polynomial time. This completes the preprocessing that the algorithm will do before entering the loop.

Suppose that $Z_1, \dots, Z_t$ is the list of cyclic flats that has been constructed after the loop has been repeated i times. In the next repetition of the loop the algorithm

will take each pair $\{Z_j, Z_k\}$ of cyclic flats and find $\text{cl}(Z_j \cup Z_k)$. At the completion of the loop the algorithm will add these new cyclic flats to the list and then eliminate duplications. By Proposition 3.8 the length of the list at the beginning of the loop will never exceed b , the number of bases. Thus in each repetition of the loop the algorithm must find the closure of at most b^2 unions of flats. It is easy to see that after $r(M)$ repetitions of the loop the algorithm will have found every cyclic flat. Finding the rank of these flats can clearly be accomplished in polynomial time, using the greedy algorithm. Therefore the algorithm can construct $(M, \text{CYCLIC FLATS})$ in polynomial time. $\square$

LEMMA 3.10. $\text{FLATS} \leq \text{HYPERPLANES}$.

Proof. The flat F is a hyperplane of M if and only if there is no flat, F' , such that $F \subset F' \subset E(M)$. This clearly leads to a polynomial-time algorithm. $\square$

LEMMA 3.11. $\text{FLATS} \leq \text{CYCLIC FLATS}$.

Proof. A flat F fails to be a cyclic flat if and only if there is an element $e \in F$ such that $F - e$ is also a flat. This clearly leads to a polynomial-time algorithm. $\square$

LEMMA 3.12. $\text{CIRCUITS} \leq \text{NONSPANNING CIRCUITS}$.

Proof. Given $(M, \text{CIRCUITS})$ a Turing machine can check in polynomial time whether a subset $A \subseteq E(M)$ is independent. Thus such a machine could find a basis of M by using the greedy algorithm. Once the rank of M is known the rest follows easily. $\square$

The next lemma follows easily using duality and Lemma 3.12.

LEMMA 3.13. $\text{HYPERPLANES} \leq \text{DEPENDENT HYPERPLANES}$.

To complete the proof of Theorem 3.2 we must show that if INPUT1 and INPUT2 are two types of input and the preceding results do not imply that $\text{INPUT1} \leq \text{INPUT2}$, then $\text{INPUT1} \not\leq \text{INPUT2}$. It is clear that if $\text{INPUT1} \leq \text{INPUT2}$, then there must exist a polynomial p such that

$$|(M, \text{INPUT2})| \leq p(|(M, \text{INPUT1})|)$$

for any matroid M . Thus if there exists a family of matroids $M_1, M_2, M_3, \dots$ such that $\{|(M_i, \text{INPUT2})|\}_{i \geq 1}$ is not polynomially bounded by $\{|(M_i, \text{INPUT1})|\}_{i \geq 1}$, then $\text{INPUT1} \not\leq \text{INPUT2}$.

The following proposition follows immediately from transitivity.

PROPOSITION 3.14. *Suppose that $\text{INPUT1} \not\leq \text{INPUT2}$. If $\text{INPUT1} \leq \text{INPUT3}$, and $\text{INPUT4} \leq \text{INPUT2}$, then $\text{INPUT3} \not\leq \text{INPUT4}$.*

Using Proposition 3.14, it is a relatively simple matter to check that the proof of Theorem 3.2 will be completed by verifying the following cases:

1. $\text{SPANNING SETS} \not\leq \text{FLATS}$.
2. $\text{INDEPENDENT SETS} \not\leq \text{SPANNING SETS}$.
3. $\text{FLATS} \not\leq \text{NONSPANNING CIRCUITS}$.
4. $\text{CIRCUITS} \not\leq \text{DEPENDENT HYPERPLANES}$.
5. $\text{HYPERPLANES} \not\leq \text{CYCLIC FLATS}$.
6. $\text{CIRCUITS} \not\leq \text{CYCLIC FLATS}$.
7. $\text{NONSPANNING CIRCUITS} \not\leq \text{CIRCUITS}$.
8. $\text{DEPENDENT HYPERPLANES} \not\leq \text{HYPERPLANES}$.
9. $\text{CYCLIC FLATS} \not\leq \text{DEPENDENT HYPERPLANES}$.

LEMMA 3.15 (Case 1). $\text{SPANNING SETS} \not\leq \text{FLATS}$.

Proof. For $n \geq 1$ let M_n be isomorphic to $U_{n-1,n}$, the n -element uniform matroid of rank $n-1$. The number of spanning sets of M_n is $n+1$, whereas the number of flats is $2^n - n$. Thus $|(M_n, \text{SPANNING SETS})| = \Theta(n^2)$, while $|(M_n, \text{FLATS})| = \Theta(n2^n)$. $\square$

LEMMA 3.16 (Case 2). $\text{INDEPENDENT SETS} \not\leq \text{SPANNING SETS}$.

Proof. For $n \geq 1$ let M_n be isomorphic to $U_{1,n}$. The number of independent sets in M_n is $n + 1$, while the number of spanning sets is $2^n - 1$. $\square$

We denote the truncation of the matroid M by $T(M)$. If m is a positive integer, then we define $mU_{r,n}$ to be the matroid obtained by replacing each element in $U_{r,n}$ with a parallel class of size m .

LEMMA 3.17 (Case 3). FLATS $\not\leq$ NONSPANNING CIRCUITS.

Proof. For $n \geq 3$ define M_n to be $T(nU_{n-1,n} \oplus U_{2,2})$. Note that M_n contains $n^2 + 2$ elements. There are $n + 2$ parallel classes in M_n . It follows that the number of flats of M_n is at most 2^{n+2} . However, the number of nonspanning circuits of M_n is exactly $n^n + n \binom{n}{2}$. Thus $|(M_n, \text{FLATS})| = O(n^2 2^{n+2})$. On the other hand $|(M_n, \text{NONSPANNING CIRCUITS})| = \Theta(n^{n+2})$, so the result follows. $\square$

LEMMA 3.18 (Case 4). CIRCUITS $\not\leq$ DEPENDENT HYPERPLANES.

Proof. It is not difficult to see that a polynomial-time algorithm that constructs $(M, \text{DEPENDENT HYPERPLANES})$ from $(M, \text{CIRCUITS})$ for any matroid M can be used to show that $\text{HYPERPLANES} \leq \text{NONSPANNING CIRCUITS}$. This contradicts Proposition 3.14, as $\text{FLATS} \leq \text{HYPERPLANES}$ by Lemma 3.10, and $\text{FLATS} \not\leq \text{NONSPANNING CIRCUITS}$ by Lemma 3.17. $\square$

LEMMA 3.19 (Case 5). HYPERPLANES $\not\leq$ CYCLIC FLATS.

Proof. For $n \geq 3$, let M_n be isomorphic to $2U_{n-1,n}$. The hyperplanes of M_n are exactly the sets of $n - 2$ parallel classes, while any nonempty set of parallel classes is a cyclic flat as long as it does not contain exactly $n - 1$ such classes. Thus the number of hyperplanes is $(n^2 - n)/2$, while the number of cyclic flats is $2^n - n - 1$. $\square$

LEMMA 3.20 (Case 6). CIRCUITS $\not\leq$ CYCLIC FLATS.

Proof. Given $(M, \text{HYPERPLANES})$ we can certainly find $(M^*, \text{CIRCUITS})$ in polynomial time. Also, given $(M^*, \text{CYCLIC FLATS})$ we can find the cyclic flats of M in polynomial time, since the cyclic flats of M^* are the complements of the cyclic flats of M . Moreover, it is easy to see that given $(M^*, \text{CIRCUITS})$ we can find the rank of any subset in M in polynomial time.

Suppose that $\text{CIRCUITS} \leq \text{CYCLIC FLATS}$. The above discussion implies that $\text{HYPERPLANES} \leq \text{CYCLIC FLATS}$, in contradiction to Lemma 3.19. $\square$

LEMMA 3.21 (Case 7). NONSPANNING CIRCUITS $\not\leq$ CIRCUITS.

Proof. If M_n is isomorphic to $U_{n,2n}$, then M_n contains no nonspanning circuits, so by definition $|(M_n, \text{NONSPANNING CIRCUITS})| = O(n)$. On the other hand, the number of circuits is $\binom{2n}{n+1}$, which is exponential in n . $\square$

The next lemma follows using duality and Lemma 3.21.

LEMMA 3.22 (Case 8). DEPENDENT HYPERPLANES $\not\leq$ HYPERPLANES.

LEMMA 3.23 (Case 9). CYCLIC FLATS $\not\leq$ DEPENDENT HYPERPLANES.

Proof of Lemma 3.23. For $n \geq 2$ let M_n be the matroid obtained by adding a single parallel element to a member of the ground set of $U_{n,2n}$. The only cyclic flats of M_n are the empty set, the nontrivial parallel class, and the entire ground set. Thus $|(M_n, \text{CYCLIC FLATS})| = \Theta(n)$. However, any hyperplane that contains the nontrivial parallel class is dependent, so the number of such hyperplanes is $\binom{2n-1}{n-2}$. $\square$

With this lemma we have completed the proof of Theorem 3.2. $\square$

4. Matroid intersection. It is easy to see that given (M, INPUT) , it is possible to determine in polynomial time whether or not a subset of $E(M)$ is independent in M . (Henceforth we assume INPUT to be one of the types of input discussed in section 2.) Hausmann and Korte [6] and Robinson and Welsh [12] show that the standard matroid oracles can be efficiently simulated by an independence oracle. It follows

from these observations that if a computational problem can be solved by an oracle Turing machine in time that is bounded by $p(n)$ for any n -element matroid, where p is a fixed polynomial, then the same problem can be solved in polynomial time by a Turing machine which receives (M, INPUT) as its input.

The converse is not true. Consider the problem of deciding whether a matroid is uniform. Robinson and Welsh [12] note that a Turing machine equipped with an oracle cannot solve this problem in time bounded by a polynomial function of the size of the ground set. In contrast, deciding whether M is uniform given (M, INPUT) is trivial.

However, there do exist matroid-theoretical problems which are probably not solvable in polynomial time, even when the input consists of a list of some family of subsets. One of these is 3-MATROID INTERSECTION.

3-MATROID INTERSECTION.

Instance: An integer k and (M_i, INPUT) for $1 \leq i \leq 3$, where M_1 , M_2 , and M_3 are matroids with a common ground set E .

Question: Does there exist a set $A \subseteq E$ such that $|A| = k$ and A is independent in M_1 , M_2 , and M_3 ?

The fact that this problem is NP-complete was first observed by Lawler [9]. He does not specify a form of matroid input, but he remarks that the problem is NP-complete for partition matroids (direct sums of rank-one uniform matroids). It is clear from his comments that a partition matroid is to be described via the partition of its ground set into connected components. We sketch a modified version of his proof here.

THEOREM 4.1. *If $\text{CIRCUITS} \leq \text{INPUT}$ or if $\text{HYPERPLANES} \leq \text{INPUT}$, then 3-MATROID INTERSECTION is NP-complete. However, if $\text{INPUT} \leq \text{BASES}$, then 3-MATROID INTERSECTION is in P.*

Proof. Obviously the problem is in NP. It suffices to prove NP-completeness only in the case that either $\text{INPUT} = \text{CIRCUITS}$ or $\text{INPUT} = \text{HYPERPLANES}$. We provide a reduction from the following NP-complete problem.

3-DIMENSIONAL MATCHING.

Instance: A set of triples, $M \subseteq X_1 \times X_2 \times X_3$, where X_1 , X_2 , and X_3 are pairwise disjoint sets having the same cardinality.

Question: Does M contain a *matching*? (A subset $M' \subseteq M$, such that every element in $X_1 \cup X_2 \cup X_3$ is contained in exactly one triple in M' .)

Let $M \subseteq X_1 \times X_2 \times X_3$ be an instance of 3-DIMENSIONAL MATCHING, and suppose that $X_i = \{x_1^i, \dots, x_s^i\}$ for $1 \leq i \leq 3$. Suppose that M contains t triples, $p_1, \dots, p_t$. We construct three partition matroids, M_1 , M_2 , and M_3 , on the ground set $E = \{e_1, \dots, e_t\}$. Each matroid M_i contains s connected components, corresponding to the elements of X_i . The connected component corresponding to x_j^i is equal to $\{e_k \mid p_k \text{ contains } x_j^i, 1 \leq k \leq t\}$. It is clear that M contains a matching if and only if M_1 , M_2 , and M_3 contain a common independent set of size s .

It remains to show that $(M_i, \text{CIRCUITS})$ and $(M_i, \text{HYPERPLANES})$ can be constructed in polynomial time. Since the number of circuits or hyperplanes in a partition matroid is at most quadratic in the size of the ground set, this is easily done.

If $\text{INPUT} = \text{BASES}$, then we can find a common independent set of maximum size by considering the intersection of every triple of bases from the three matroids. This can clearly be done in polynomial time, so 3-MATROID INTERSECTION is in P if $\text{INPUT} \leq \text{BASES}$. $\square$

Theorem 4.1 shows that 3-MATROID INTERSECTION is either NP-complete or in P for all but two of the methods of input described in section 2: The status of the problem is open for the case that INPUT = CYCLIC FLATS or INPUT = FLATS.

5. The isomorphism problem. The following computational problem has attracted much attention.

GRAPH ISOMORPHISM.

Instance: Two graphs, G and G' .

Question: Are G and G' isomorphic?

GRAPH ISOMORPHISM is thought to be a good candidate for a problem in NP that is neither NP-complete nor in P (see [2]).

A decision problem that is polynomially equivalent to GRAPH ISOMORPHISM is *isomorphism-complete*. In this section we show that the analogous matroid problem is in general isomorphism-complete.

MATROID ISOMORPHISM.

Instance: (M, INPUT) and (M', INPUT) .

Question: Are M and M' isomorphic?

LEMMA 5.1. MATROID ISOMORPHISM is *polynomially reducible* to GRAPH ISOMORPHISM.

Proof. A proof can be found in [10]; we give an outline here. We must construct a polynomial-time computable transformation that takes descriptions of matroids to graphs in such a way that isomorphism is preserved. There are many ways in which this can be accomplished. The key idea is that a list of characteristic vectors, representing subsets of the ground set, can be seen as the rows of the vertex-adjacency matrix of a bipartite graph.

The rest of the demonstration involves refining the transformation so that, given the unlabeled bipartite graph, it is possible to reconstruct the matroid description, up to relabeling. This guarantees that the transformation preserves isomorphism. Thus we must somehow distinguish the vertices that correspond to subsets of the ground set from the vertices that correspond to elements of the ground set. In the case that INPUT relies upon ranks being assigned to sets, as is the case when INPUT = CYCLIC FLATS, we must find a method of encoding binary representations of integers in the form of graphs. Constructing a transformation that satisfies these criteria, and confirming that it is polynomial-time computable, is an easy exercise. $\square$

Next we develop a polynomial transformation from graphs to matroid descriptions. Suppose that G is a simple graph with n vertices, $\{v_1, \dots, v_n\}$, and m edges, $\{e_1, \dots, e_m\}$. Assume that $n \geq 3$. Let $X = \{x_1, \dots, x_n\}$, $X' = \{x'_1, \dots, x'_n\}$, and $Y = \{y_1, \dots, y_m\}$ be disjoint sets. The matroid $\Phi(G)$ has rank 3, and the ground set of $\Phi(G)$ is $X \cup X' \cup Y$. The nonspanning circuits of $\Phi(G)$ are sets of the form $\{x_i, x'_i\}$, where $i \in \{1, \dots, n\}$, and the sets

$$\{\{z_i, z_j, y_k\} \mid z_i \in \{x_i, x'_i\}, z_j \in \{x_j, x'_j\}, \text{ and } e_k \text{ joins } v_i \text{ to } v_j\}.$$

Thus $\Phi(G)$ can be formed by placing n parallel pairs, corresponding to the n vertices of G , in the plane in general position, and placing elements between parallel pairs that correspond to adjacent vertices, in such a way that no additional dependencies are formed.

Let G be a graph. The *cyclomatic number* of G is $|V(G)| - |E(F)|$, where F is a spanning forest of G . The *bicircular matroid* of a graph, G , denoted by $B(G)$, has the edge set of G as its ground set. The circuits of $B(G)$ are exactly the minimal connected edge sets of G with cyclomatic number two, known as *bicycles*. Thus a set

of edges is independent in $B(G)$ if and only if the subgraph of G it induces contains at most one cycle in every connected component.

Suppose that G is simple and has at least three vertices. Let $G^{\circ\circ}$ be the graph which is obtained by adding two loops at each vertex of G . Then $\Phi(G)$ is isomorphic to the matroid obtained by repeatedly truncating $B(G^{\circ\circ})$ so that its rank is reduced to three.

Suppose that G is a simple graph with $n \geq 3$ vertices and m edges. Then $|\Phi(G)| = 2n + m$. Since $m \leq n^2$, the number of independent sets in $\Phi(G)$ is $O(n^6)$. Thus $(\Phi(G), \text{INPUT})$ can be constructed in polynomial time from a description of G when $\text{INDEPENDENT SETS} \leq \text{INPUT}$.

It is easy to demonstrate that if G and G' are simple graphs on at least three vertices, then G and G' are isomorphic if and only if $\Phi(G)$ and $\Phi(G')$ are isomorphic. Since GRAPH ISOMORPHISM is generally defined in terms of simple graphs, we have proved the following result.

LEMMA 5.2. *If $\text{INDEPENDENT SETS} \leq \text{INPUT}$, then GRAPH ISOMORPHISM is polynomially reducible to $\text{MATROID ISOMORPHISM}$.*

Using duality we see that $(\Phi(G)^*, \text{SPANNING SETS})$ can also be constructed in polynomial time from a description of G , where G is any simple graph with at least three vertices. Since G and G' are isomorphic graphs if and only if $(\Phi(G))^*$ and $(\Phi(G'))^*$ are isomorphic matroids, we have proved the following.

THEOREM 5.3. *If $\text{SPANNING SETS} \leq \text{INPUT}$, or $\text{INDEPENDENT SETS} \leq \text{INPUT}$, then $\text{MATROID ISOMORPHISM}$ is isomorphism-complete.*

6. Detecting minors. It is a well-known observation of Seymour's that an oracle Turing machine cannot decide whether a matroid has a $U_{2,4}$ -minor in time that is polynomially bounded by the size of the ground set [13]. We will show that, in general, deciding whether a matroid contains a minor isomorphic to some fixed matroid can be done in polynomial time, given a list of the independent sets or some similar input. It is routine to verify the following result.

PROPOSITION 6.1. *Suppose that M is a matroid and that X and Y are disjoint subsets of $E(M)$. It is possible to construct $(M/X \setminus Y, \text{INPUT})$ in polynomial time given (M, INPUT) .*

PROPOSITION 6.2. *Let N be a matroid and let t be the number of circuits of N , where $t > 0$. If M is a matroid on the ground set E , and M has a minor isomorphic to N on the set $A \subseteq E$, then there exist circuits, $C_1, \dots, C_t$, of M such that, if $X = (C_1 \cup \dots \cup C_t) - A$ and $Y = E - (A \cup X)$, then $M/X \setminus Y \cong N$.*

Proof. Suppose that $M/X' \setminus Y'$ is isomorphic to N , where (X', Y') is a partition of $E - A$. We may assume that X' is independent. There are exactly t circuits, $C'_1, \dots, C'_t$, in $M/X' \setminus Y'$. For each circuit, C'_i , there exists a circuit C_i of M such that $C_i \subseteq C'_i \cup X'$ and $C'_i = C_i - X'$. Let X be the set $(C_1 \cup \dots \cup C_t) - A$ and let Y be $E - (A \cup X)$. It remains to show that $M/X \setminus Y \cong N$. Note that $X \subseteq X'$. If $X = X'$, then we are done, so suppose that x is an element in $X' - X$. Let $M' = M/(X' - x) \setminus (Y' \cup x)$. To complete the proof it will suffice to show that $M' = M/X' \setminus Y'$. This is elementary. $\square$

Let N be some fixed matroid. It is a consequence of Propositions 6.1 and 6.2 that the following problem is, in general, in P.

DETECTING AN N -MINOR.

Instance: (M, INPUT) .

Question: Does M have a minor isomorphic to N ?

THEOREM 6.3. *If $\text{INPUT} \leq \text{CIRCUITS}$ or $\text{INPUT} \leq \text{HYPERPLANES}$, then $\text{DETECTING AN } N\text{-MINOR}$ is in P for any fixed matroid N .*

Proof. By duality it will suffice to prove the theorem only when INPUT is equal to CIRCUITS. We may assume that we have the list of circuits of N , for we can construct it in constant time.

Suppose that the ground set of M is E , where $|E| = n$, and that M contains c circuits, so that $|(M, \text{CIRCUITS})| = \Theta(nc)$. Suppose also that $|E(N)| = s$, and that N has exactly t circuits. We may assume that $t > 0$, for otherwise the problem is trivially in P.

An algorithm to check whether M has an N -minor could simply work its way through every subset A of E such that $|A| = s$, and every set $\{C_1, \dots, C_t\}$ of t circuits of M . By Proposition 6.1 it is possible to construct $(M/X \setminus Y, \text{CIRCUITS})$, where $X = (C_1 \cup \dots \cup C_t) - A$ and $Y = E - (A \cup X)$, and then check whether $M/X \setminus Y \cong N$ in polynomial time. Proposition 6.2 guarantees that if M does have a minor isomorphic to N , then this procedure will find such a minor. Checking whether an isomorphism exists between N and $M/X \setminus Y$ will take some constant time, so the running time of the algorithm is determined by the number of subsets, $A \subseteq E$, and the number of families of circuits we must check. The first quantity is $\binom{n}{s}$, and the second is $\binom{c}{t}$, so the running time of the algorithm is $O(n^s c^t)$. Since s and t are fixed constants, the algorithm runs in polynomial time. $\square$

In contrast to Theorem 6.3, Hliněný shows that the problem of deciding whether M has a minor isomorphic N for a fixed matroid N is NP-complete when the input consists of a representation of M over the rational numbers [7]. On the other hand, Geelen, Gerards, and Whittle conjecture that the problem is in P when the input consists of a representation of M over a finite field [3].

The exponent in the running time of the algorithm described in Theorem 6.3 depends upon N . It is natural to ask whether there is a *fixed-parameter tractable* (FPT) algorithm for DETECTING AN N -MINOR, that is, an algorithm which runs in time $f(N)|(M, \text{INPUT})|^k$, where f is a function which depends only on N and k is a fixed constant. Certainly such an algorithm exists when INPUT = RANK, for we can simply consider minors of the form $M/X \setminus Y$ for all disjoint sets X and Y , and check by brute force whether any such minor is isomorphic to N . This leads to an FPT algorithm. The existence of such an algorithm when M is described via an input that lies above RANK is an open problem.

We have shown that detecting a fixed minor can be solved in polynomial time, in general. However, the problem of detecting a minor which forms part of the input is, in general, NP-complete.

MINOR ISOMORPHISM.

Instance: (M, INPUT) and (N, INPUT) .

Question: Does M have a minor isomorphic to N ?

THEOREM 6.4. *If INDEPENDENT SETS $\leq$ INPUT or SPANNING SETS $\leq$ INPUT, then MINOR ISOMORPHISM is NP-complete.*

Proof. It is easy to see that MINOR ISOMORPHISM is in NP. The following problem is well known to be NP-complete.

SUBGRAPH ISOMORPHISM.

Instance: Two graphs, G and H .

Question: Does G have a subgraph isomorphic to H ?

Suppose that the graphs G and H correspond to an instance of SUBGRAPH ISOMORPHISM. We may assume that G and H are simple and that both have at least three vertices. Since we can construct either $(\Phi(G), \text{INPUT})$ or $(\Phi(G)^*, \text{INPUT})$ in polynomial time from the description of G (and the same statement applies for H), the proof will be complete if we can demonstrate that G contains a subgraph

isomorphic to H if and only if $\Phi(G)$ contains a minor isomorphic to $\Phi(H)$. This is easily done. $\square$

Suppose that $\mathcal{M}$ is a family of matroids. A natural computational problem is to ask whether a matroid M has a minor isomorphic to a member of $\mathcal{M}$ with specified size. The proof of Theorem 6.4 can be used to show that if $\mathcal{M} = \{\Phi(K_n) \mid n \geq 1\}$, then this problem is, in general, NP-complete. We will conclude by showing that the problem is, in general, also NP-complete when $\mathcal{M} = \{U_{r,n} \mid n \geq r\}$, where r is a fixed constant.

$U_{r,n}$ -MINOR.

Instance: (M, INPUT) and an integer n .

Question: Does M have a minor isomorphic to $U_{r,n}$?

THEOREM 6.5. *If $r > 2$ is a fixed integer and $\text{INDEPENDENT SETS} \leq \text{INPUT}$, then $U_{r,n}$ -MINOR is NP-complete.*

Proof. It is easy to see that $U_{r,n}$ -MINOR is in NP. We construct a reduction from the following NP-complete problem.

INDEPENDENT SET.

Instance: An integer k and a graph G .

Question: Does G contain an independent set of k vertices?

Let $r > 2$ be a fixed integer. Suppose that the integer k and the simple graph G are an instance of INDEPENDENT SET. Let m be the number of edges in G . Let t be $\lceil (r-1)/2 \rceil$, and let tG° be the graph obtained by adding a loop to each vertex of G and then replacing each nonloop edge with a path of length t . The matroid $\Phi_r(G)$ is the bicircular matroid of tG° , repeatedly truncated so that its rank is equal to r .

Checking whether a set of edges of tG° is independent in $B(tG^\circ)$ can certainly be done in polynomial time. Since r is a fixed integer, and no independent set of $\Phi_r(G)$ exceeds r in size, it follows that $(\Phi_r(G), \text{INPUT})$ can be constructed in polynomial time as long as $\text{INDEPENDENT SETS} \leq \text{INPUT}$.

We complete the proof by showing that G has an independent set of k vertices if and only if $\Phi_r(G)$ has a rank- r uniform minor of size $k + mt$.

Every nonloop cycle of tG° contains at least $3t$ edges, so if a bicycle of tG° contains at most one loop, then it has size at least $3t+1$. This quantity is greater than r , as $r \geq 3$. If a bicycle contains two loops, then either it contains exactly $t+2$ elements, or its size is at least $2t+2$. It is straightforward to confirm that $t+2 \leq r$ and that $2t+2 > r$. This shows that the nonspanning circuits of $\Phi_r(G)$ are exactly the sets containing the t edges in a path joining two vertices of G and the two loops incident with those vertices.

Suppose that G contains an independent set of k vertices. These vertices correspond to k loops of tG° . The set containing these loops and all the nonloop edges of tG° cannot contain a nonspanning circuit of $\Phi_r(G)$, by the above discussion. Thus restricting $\Phi_r(G)$ to this set of $k + mt$ elements gives a uniform minor. We may assume that $m \geq 3$, so $k + mt$ is certainly no less than r . Therefore $\Phi_r(G)$ contains a rank- r uniform minor with $k + mt$ elements.

For the converse suppose that $\Phi_r(G)$ has a rank- r uniform minor on the set A , where $|A| = k + mt$, and assume that G has no independent set of k vertices. The number of nonloop edges in A is at most mt . Suppose that A has been chosen so that it contains as many nonloop edges as possible. Now A contains at least k loops, so there must be a pair of loops, l and l' , in A that correspond to adjacent vertices in G . Therefore one of the t edges that join l to l' in tG° does not belong to A . Let us call this edge e . Then $(A - l) \cup e$ contains no nonspanning circuits of $\Phi_r(G)$, and our assumption on A is contradicted. Therefore G has an independent set of k vertices. $\square$

If $r \leq 2$, then $U_{r,n}$ -MINOR is trivially in P. Using duality, we can show that the problem of deciding whether M has a minor isomorphic to $U_{n-r,n}$ is NP-complete for fixed values of $r > 2$ as long as SPANNING SETS $\leq$ INPUT.

7. Open problems. In this summary section we collect some open problems. 3-MATROID INTERSECTION is known to be either in P or NP-complete for all but two of the 10 types of input mentioned in section 2. The status of the problem is open when INPUT is either CYCLIC FLATS or FLATS. MATROID ISOMORPHISM is NP-complete for all forms of input, except possibly RANK. Deciding if MATROID ISOMORPHISM can be solved in polynomial time when the matroids are described via the rank of each of their subsets is an open problem. More generally, it would be interesting to know if there is any “natural” computational problem which is NP-complete for the RANK input.

DETECTING AN N -MINOR is known to be in P for all forms of input except NONSPANNING CIRCUITS, CYCLIC FLATS, and DEPENDENT HYPERPLANES. The status of the problem for these types of input is unknown. The existence or otherwise of an FPT algorithm for MINOR ISOMORPHISM is known only when INPUT = RANK. Otherwise the problem is open.

Acknowledgments. I thank my supervisor, Professor Dominic Welsh, and Professors Colin McDiarmid and James Oxley for very useful advice and discussions. I also thank the referees for their constructive comments. In particular, the question of the existence of FPT algorithms for DETECTING AN N -MINOR was raised by one of the referees.

ON RAMSEY MINIMAL GRAPHS*

V. RÖDL[†] AND M. SIGGERS[‡]

Abstract. A graph G is r -Ramsey-minimal with respect to a graph H if every r -coloring of the edges of G yields a monochromatic copy of H , but the same is not true for any proper subgraph of G . In this paper we show that for any integer $k \geq 3$ and $r \geq 2$, there exists a constant $c > 1$ such that for large enough n , there exist at least c^{n^2} nonisomorphic graphs on at most n vertices, each of which is r -Ramsey-minimal with respect to the complete graph K_k . Furthermore, in the case $r = 2$, we give an asymmetric version of the above result.

1. Introduction. A classical problem of graph theory is determining the Ramsey number for a graph H . This is the minimum number n such that any 2-coloring of the edges of the complete graph K_n on n vertices yields a monochromatic copy of H .

A variation on this problem is to look at coloring the edges of some graph G instead of K_n . Again we are interested in the minimal graphs that yield a monochromatic copy of H when 2-colored.

A graph G is *Ramsey with respect to H* if any 2-coloring of its edges yields a monochromatic copy of H . It is *Ramsey-minimal with respect to H* if it is Ramsey but none of its proper subgraphs are. For results about Ramsey-minimal graphs, see, for example, [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [12], [13], [15], [16], [18], and [19].

In [7], Burr, Erdős, and Lovász showed that for any integer $k \geq 3$ there are infinitely many nonisomorphic graphs that are Ramsey-minimal with respect to the complete graph K_k on k vertices. In [10], this result was strengthened to show that for any integer $k \geq 3$ there exists a constant $c > 1$ such that for all n large enough, there exist at least $c^{n \log n}$ nonisomorphic graphs on at most n vertices that are Ramsey-minimal with respect to K_k .

A graph G is *r -Ramsey with respect to H* if any r -coloring of its edges yields a monochromatic copy of H . It is *r -Ramsey-minimal with respect to H* if it is r -Ramsey but none of its proper subgraphs are.

In this paper we strengthen the result of [10] stated above and extend it to an arbitrary number of colors. Our main result is as follows.

THEOREM 1.1. *For any integers $r \geq 2$ and $k \geq 3$ there exist constants $c = c(r, k) > 1$ and $n_0(r, k)$ such that for all $n \geq n_0(r, k)$, there exist at least c^{n^2} nonisomorphic graphs, on at most n vertices, that are r -Ramsey-minimal with respect to K_k .*

A common generalization for Ramsey-minimal graphs is to the following nonsymmetric definition. A graph G is *Ramsey with respect to H_1 and H_2* if any 2-coloring

yields a monochromatic copy of H_1 in the first color or a monochromatic copy of H_2 in the second color.

At the end of the paper, in section 6, we prove a nonsymmetric version of the result for the case $r = 2$. That is, we observe that with similar quantifications as in Theorem 1.1 there are many graphs that are Ramsey-minimal with respect to K_ℓ and K_k .

Indeed, the results of [7] and [10] above were also proved in this more general setting.

The simplest case of Theorem 1.1 is $k = 3$ and $r = 2$. We prove this case in section 3. In section 4 we prove the theorem for $r = 2$ and all k . Finally, in section 5 we complete the proof. We begin by introducing a preliminary result, the proof of which we put off to section 7.

2. Preliminaries. Throughout the paper, we will identify a graph or hypergraph G with its edgeset $E(G)$. Given an edge e of G we will often write $G - e$ instead of $G - \{e\}$ to mean the (hyper)graph G with the edge e removed. We let $[r]$ denote the set $\{1, \dots, r\}$.

We now introduce signal senders—these are graphs that are very useful in the construction of minimal graphs. They were introduced in [7] and generalized in [10]. We will need them only in the case that $H = K_k$, but since it is not much harder, we prove their existence for a more general graph.

DEFINITION 2.1. *For a graph H , a negative signal sender $S = S^-(r, H, e, f)$ is a graph containing distinguished edges e and f with the following properties:*

- (i) *S is not r -Ramsey with respect to H .*
- (ii) *For every r -coloring of S in which there is no monochromatic copy of H , edges e and f have different colors.*

A positive signal sender $S = S^+(r, H, e, f)$ is the same but we replace the word “different” in property (ii) with “the same.”

In [7] it was proved that there exist positive and negative signal senders for complete graphs when $r = 2$. In [10] a similar proof was used to extend the result to any 3-connected graph H when $r = 2$. We extend the result of [10] to all $r \geq 2$ with the following result.

LEMMA 2.2. *For $r \geq 2$ and any 3-connected graph H there exist*

- (a) *negative signal senders $S^-(r, H, e, f)$,*
- (b) *positive signal senders $S^+(r, H, e, f)$, and*
- (c) *such negative and positive signal sender in which the distance between the edges e and f is arbitrarily large.*

The proof of this lemma is similar to the proof in [10]. We include it in section 7 for completeness. Lemma 2.2, and the constructions in section 3.1, are the main tools that we will use in the proof of Theorem 1.1.

3. Theorem 1.1: The base case. In this section we show that there exist $n_0(2, 3)$ and $c = c(2, 3) > 1$ such that for any $n \geq n_0(2, 3)$ there exist at least c^{n^2} nonisomorphic graphs on at most n vertices that are 2-Ramsey-minimal with respect to the triangle, K_3 . This will be the base case for the inductions we use in the proof of Theorem 1.1.

Let a be an odd integer. For $i = 1, \dots, a$, let $L_i \cup R_i = [a]$ be a partition. Let $\mathcal{P} = (L_i \cup R_i \mid i = 1, \dots, a)$. For each of the 2^{a^2} such choices of $\mathcal{P}$ we will construct a labeled graph $G(\mathcal{P})$ that is 2-Ramsey-minimal with respect to the triangle. We will use this construction in Theorem 3.12 to prove our main result for the case $r = 2$ and $k = 3$.

FIG. 3.1. Edges of E_i and F_i when $j-1, j+1 \in L_i$, and $j \in R_i$.

The graph $G = G(\mathcal{P})$ will be built from three components: $G^*(\mathcal{P})$, $G^\uparrow$, and $G^\downarrow$. $G^*(\mathcal{P})$ is built in section 3.1, and $G^\uparrow$ and $G^\downarrow$ are built in section 3.2. In section 3.3 these graphs are used to construct $G(\mathcal{P})$.

3.1. The graph $G^*(\mathcal{P})$. For odd a and set $\mathcal{P} = \{L_i \cup R_i \mid i = 1, \dots, a\}$ of partitions of $[a]$, we construct the labeled graph $G^*(\mathcal{P})$, as follows. (Recall that we will often identify a graph G with its edgeset $E(G)$.)

CONSTRUCTION 3.1.

(i) Let C_{5a} be a cycle of length $5a$ with vertices $v_1, \dots, v_{5a}$ and edges $\{v_j, v_{j+1}\}$ for all $j = 1, \dots, 5a$ (indices mod $5a$).

(ii) For $i = 1, \dots, a$, let S_i^+ be a copy of the positive signal sender $S^+ = S^+(2, K_3, e, f)$ with distance 3 between edges e and f (cf. Lemma 2.2). Let $\{u_1^i, u_2^i\}$ and $\{u_3^i, u_4^i\}$ be the copies of e and f , respectively, in S_i^+ . Let $U^i = \{u_1^i, u_2^i, u_3^i, u_4^i\}$.

(iii) For $i = 1, \dots, a$, add the edges $\{u_1^i, u_4^i\}$ and $\{u_2^i, u_3^i\}$. Note that this does not introduce any new triangles, because we made the assumption that there is distance 3 between e and f in S^+ . (See Figure 3.1.)

(iv) For vertex sets X and Y , let $K(X, Y)$ denote the complete bipartite graph between X and Y . For each partition $L_i \cup R_i \in \mathcal{P}$, add the following unions of complete bipartite graphs:

$$E_i = \bigcup_{j \in L_i} K(\{u_1^i, u_2^i\}, \{v_{5(j-1)}, \dots, v_{5j+1}\}), \text{ and}$$

$$F_i = \bigcup_{j \in R_i} K(\{u_3^i, u_4^i\}, \{v_{5(j-1)}, \dots, v_{5j+1}\}).$$

(See Figure 3.1.) Let $E = \bigcup_{i=1}^a E_i$ and $F = \bigcup_{i=1}^a F_i$. Observe that for $j \in [a]$ the set $\{v_{5(j-1)}, \dots, v_{5j+1}\}$ contains seven vertices, not just five. Thus the sets $\{v_{5(j-1)}, \dots, v_{5j+1}\}$ and $\{v_{5(j)}, \dots, v_{5(j+1)+1}\}$ overlap in two vertices.

Denote the resulting graph by $G^*(\mathcal{P})$. Thus

$$(3.1) \quad V(G^*(\mathcal{P})) = \{v_1, \dots, v_{5a}\} \cup \bigcup_{i=1}^a V(S_i^+), \text{ and}$$

$$G^*(\mathcal{P}) = C_{5a} \cup E \cup F \cup \bigcup_{i=1}^a S_i^+ \cup \bigcup_{i=1}^a \{\{u_1^i, u_4^i\}, \{u_2^i, u_3^i\}\}.$$

DEFINITION 3.2. We classify the vertices of C_{5a} in $G^*(\mathcal{P})$ with regard to their adjacencies to the graphs S_i^+ .

If one of the indices $j-1$ and j are in L_i , while the other one is in R_i , then the vertices v_{5j} and v_{5j+1} are adjacent to all four vertices of $U^i = \{u_1^i, u_2^i, u_3^i, u_4^i\}$. In this case, we call the vertices v_{5j} and v_{5j+1} external for U^i .

Other vertices of C_{5a} are adjacent to exactly two of the vertices of U^i . We call these vertices internal for U^i .

An edge from $v_j \in C_{5a}$ to U^i is an internal edge if the vertex v_j is internal for U^i . An internal edge of the form $e = \{u_1^i, v_{5j+3}\}$ for $i \in \{1, \dots, a\}$ and $j \in \{0, \dots, a-1\}$ is called a central edge.

LEMMA 3.3. The graph $G^*(\mathcal{P})$ has the following properties:

- (i) $|V(G^*)| = a(5 + |V(S^+)|) < 2a|V(S^+)|$.
- (ii) If $\chi : G^* \rightarrow \{1, 2\}$ is a 2-coloring of the edges of G^* such that χ is monochromatic on C_{5a} and $\chi(\{u_1^i, u_2^i\}) \neq \chi(C_{5a})$ for some $i \in \{1, \dots, a\}$, then χ has a monochromatic triangle.
- (iii) For any central edge e , $G^* - e$ has a triangle-free 2-coloring χ of its edges such that

- (a) χ is monochromatic on C_{5a} , and
- (b) $\chi(\{u_1^i, u_2^i\}) = \chi(C_{5a})$ for all edges $\{u_1^1, u_2^1\}, \dots, \{u_1^a, u_2^a\}$ except one.

Proof. Property (i) follows from (3.1) and the fact that $|V(S^+)| > 5$. The proofs of the other two properties will be considerably longer.

The proof of property (ii) relies on the observation that the only triangle-free 2-colorings χ of the complete graph K_4 on vertices a_1, a_2, b_1 , and b_2 with $\chi(\{a_1, a_2\}) \neq \chi(\{b_1, b_2\})$ have

$$(*) \quad \chi(\{a_1, b_1\}) = \chi(\{a_2, b_2\}) \neq \chi(\{a_1, b_2\}) = \chi(\{a_2, b_1\}).$$

Let χ be a triangle-free 2-coloring of G^* such that χ is monochromatic on C_{5a} , and $\chi(\{u_1^i, u_2^i\}) \neq \chi(C_{5a})$ for some i . We will assume, without loss of generality, that this i is 1, i.e., that

$$\chi(\{u_1^1, u_2^1\}) \neq \chi(C_{5a}).$$

By the properties of S_1^+ , we have that $\chi(\{u_1^1, u_2^1\}) = \chi(\{u_3^1, u_4^1\})$.

The following observations are specific cases of (*):

- (*₁) Edges from any one of the vertices of U^1 to two consecutive vertices v_i and v_{i+1} must get different colors.
- (*₂) Edges from v_i to either u_1^1 and u_2^1 , or u_3^1 and u_4^1 , must get different colors.

Indeed, if, say, u_1^1 were adjacent to both v_i and v_{i+1} , then these vertices and u_2^1 would induce a K_4 , and so observation (*) yields (*₁). Similarly, if v_i is adjacent to, say, u_1^1 and u_2^1 , then so is one of v_{i-1} and v_{i+1} . These vertices then induce a K_4 , and consequently, observation (*) yields (*₂).

The proof of property (ii) of the lemma follows from the following claim.

CLAIM 3.4. If a vertex v_i of C_{5a} is external for U^1 , then $\chi(\{u_1^1, v_i\}) = \chi(\{u_3^1, v_i\})$.

FIG. 3.2. Subgraph of G^* induced by $U^1 \cup \{v_{5j}, v_{5j+1}\}$.

Indeed, assuming this claim, we are done because every v_i in C_{5a} is adjacent to either u_1^1 or u_3^1 , and so by observation $(*_1)$,

$$\chi(\{-, v_1\}) \neq \chi(\{-, v_2\}) \neq \cdots \neq \chi(\{-, v_{5a}\}) \neq \chi(\{-, v_1\}),$$

where “ $-$ ” denotes either u_1^1 or u_3^1 . However, $5a$ is odd, and χ takes on only two values, so this is a contradiction.

To finish the proof of property (ii), we now prove Claim 3.4.

Proof. If the vertex v_i is external for U^1 , then $i = 5j$ or $5j + 1$, where $j \in L_1$ and $j - 1 \in R_1$ (or where $j \in R_1$ and $j - 1 \in L_1$, but the argument for this case is analogous.) In this situation, all possible edges between U^1 and $\{v_{5j}, v_{5j+1}\}$ are in G^* . (See Figure 3.2.) We show that $\chi(\{u_1^1, v_{5j}\}) = \chi(\{u_3^1, v_{5j}\})$. The argument that $\chi(\{u_1^1, v_{5j+1}\}) = \chi(\{u_3^1, v_{5j+1}\})$ is analogous.

Assume without loss of generality, that $\chi(\{u_1^1, v_{5j}\}) = 1$. By $(*_2)$, $\chi(\{u_2^1, v_{5j}\}) = 2$, and then by $(*_1)$, $\chi(\{u_2^1, v_{5j+1}\}) = 1$. We now have two cases as follows:

- If $\chi(\{u_2^1, u_3^1\}) = 2$, then since χ is triangle-free, we have that $\chi(\{u_3^1, v_{5j}\}) = 1$. This is the same as $\chi(\{u_1^1, v_{5j}\})$, as needed.
- If $\chi(\{u_2^1, u_3^1\}) = 1$, then since χ is triangle-free, $\chi(\{u_3^1, v_{5j+1}\}) = 2$. Thus by $(*_1)$, $\chi(\{u_3^1, v_{5j}\}) = 1$. This is the same as $\chi(\{u_1^1, v_{5j}\})$, as needed. $\square$

This completes the proof of the claim and so completes the proof of (ii).

We now prove property (iii) of the lemma. Without loss of generality, we can assume that the central edge e is $\{u_1^1, v_3\}$. Thus $1 \in L_1$, so G^* contains all edges between $\{u_1^1, u_2^1\}$ and $\{v_2, v_3, v_4\}$, and none of the edges between $\{u_3^1, u_4^1\}$ and $\{v_2, v_3, v_4\}$.

We now define a 2-coloring χ of $G^* - e$.

- (a) Let $\chi(f) = 1$ for all edges $f \in C_{5a}$.
 - (b) Let $\chi(\{u_1^1, u_2^1\}) = \chi(\{u_2^1, u_3^1\}) = \chi(\{u_3^1, u_4^1\}) = \chi(\{u_4^1, u_1^1\}) = 2$, and for all $i = 2, \dots, a$, let $\chi(\{u_1^i, u_2^i\}) = \chi(\{u_2^i, u_3^i\}) = \chi(\{u_3^i, u_4^i\}) = \chi(\{u_4^i, u_1^i\}) = 1$.
- Conditions (a) and (b) required by the lemma are thus satisfied. We now have to extend χ to a triangle-free 2-coloring of G^* as follows:

• For all $i \in [a]$ we have $\chi(\{u_1^i, u_2^i\}) = \chi(\{u_3^i, u_4^i\})$, so by the properties of S_i^+ we can (and do) extend χ to a triangle-free 2-coloring of S_i^+ .

• For $i = 2, \dots, a$ let χ have color 2 on all edges between U^i and $V(C_{5a})$.

Observe that so far we have no monochromatic triangles. It remains to extend χ to the edges between $V(C_{5a})$ and U^1 . This is explained below and illustrated in Figures 3.3 and 3.4.

• Relabel v_1 as v_{5a+1} , and v_2 as v_{5a+2} . (This gives v_1 an even index and v_2 an odd index.) With this relabeling in mind, for any edge of the form $f = \{v_i, u_j^1\}$, let $\chi(f) = 1$ if $i + j$ is even, or $\chi(f) = 2$ if $i + j$ is odd.

FIG. 3.3. The coloring χ .FIG. 3.4. The coloring χ when j is odd, $j-1 \in L_1$, and $j \in R_1$.

We now verify that χ is triangle-free on the subgraph of $G^* - \{u_1^1, v_3\}$, that is, induced by $V(C_{5a}) \cup U^1$. This will complete the proof. There are two types of triangles that we must consider as follows:

- We first consider any triangle with an edge induced by U^1 . Such a triangle must contain a vertex $v_i \in V(C_{5a}) - \{v_3\}$. However, the colors of the edges from v_i to any two adjacent vertices of U^1 are different. So such a triangle is not monochromatic.
- We then consider any triangle with an edge induced by $V(C_{5a}) - \{v_3\}$. Such a triangle must also contain a vertex $u_i^1 \in U^1$. However, the colors of the edges from u_i^1 to any two adjacent vertices of $V(C_{5a}) - \{v_3\}$ are different. So such a triangle is not monochromatic.

We have thus shown that there is a triangle-free 2-coloring χ of $G^* - \{u_1^1, v_3\}$, that satisfies properties (a) and (b). This completes the proof of the lemma. $\square$

3.2. The graphs $G^\uparrow$ and $G^\downarrow$. For positive integer $a \geq 3$ we construct $G(5a)^\uparrow$ as follows.

CONSTRUCTION 3.5.

(i) Let C_{5a} be a cycle of length $5a$ with vertices $v_1, \dots, v_{5a}$ and edges $\{v_i, v_{i+1}\}$ for all $i = 1, \dots, 5a$.

FIG. 3.5. $G^\downarrow(a)$.

- (ii) For $i = 1, \dots, 5a$, let $S_i = S^-(2, K_3, e_i, f_i)$ be a copy of the negative signal sender $S^- = S^-(2, K_3, e, f)$ with distance 2 between edges e and f .
- (iii) For $i = 1, \dots, 5a$ identify edge $\{v_i, v_{i+1}\} \in C_{5a}$ (indices mod $5a$) with edge $e_i \in S_i$.
- (iv) Identify the $5a$ edges $f_i \in S_i$ for all $i = 1, \dots, 5a$. Denote the resulting edge by f .

Unless explicitly identified, all vertices in the construction are distinct.

LEMMA 3.6. For integer $a \geq 3$, the graph $G^\uparrow = G^\uparrow(5a)$ has the following properties:

- (i) $|V(G^\uparrow)| < 5a|V(S^-)|$.
- (ii) C_{5a} is monochromatic under any triangle-free 2-coloring of $G^\uparrow$, and such a coloring exists.

Proof. The property that $|V(G^\uparrow)| < 5a|V(S^-)|$ follows from the fact that every vertex of $G^\uparrow$ is in at least one of the $5a$ copies of S^- . We now verify the second property.

Without loss of generality, let $\chi(f) = 2$. Now χ can be extended to a triangle-free coloring of each of the S_i . This done, we necessarily have that all of the edges e_i , for $i = 1, \dots, 5a$, get color 1, i.e., C_{5a} is monochromatic. By the assumption that edges e and f are distance 2 apart the only triangles in $G^\uparrow$ are entirely within one copy of S^- . Thus the coloring χ is a triangle-free coloring of $G^\uparrow$. This gives property (ii), thus completing the proof of the lemma. $\square$

For integer $a \geq 6$, we construct the graph $G^\downarrow(a)$ as follows. (See Figure 3.5.)

CONSTRUCTION 3.7.

- (i) Let B be a set of a pairwise vertex disjoint edges, $B = \{e_1, \dots, e_a\}$. (In Construction 3.9, B will be identified with the set $\{\{u_1^i, u_2^i\} \mid i = 1, \dots, a\}$.)
- (ii) For integer $i = 1, \dots, a$, let S_i be a copy of $S^- = S^-(2, K_3, e, f)$, and let e_i and f_i be the copies of e and f in S_i , respectively.

- (iii) For integer $i = 1, \dots, a-3$, let U_i be a copy of S^- , and let g_i and h_i be the copies of e and f in U_i , respectively.
- (iv) For integer $i = 1, \dots, a-2$, let T_i be a triangle with edges p_i , q_i , and r_i .
- (v) Make the following edge identifications (cf. Figure 3.5).
 - Identify f_1 with p_1 .
 - Identify f_{i+1} with q_i for $i = 1, \dots, a-2$.
 - Identify g_i with r_i for $i = 1, \dots, a-3$.
 - Identify h_i with p_{i+1} for $i = 1, \dots, a-3$.
 - Identify f_a with r_{a-2} .

LEMMA 3.8. For integer $a \geq 3$, the graph $G^\downarrow = G^\downarrow(a)$ has the following properties:

- (i) $|V(G^\downarrow)| < (2a-3)|V(S^-)|$.
- (ii) There is no triangle-free 2-coloring of $G^\downarrow$ that is monochromatic on B .
- (iii) Any 2-coloring χ of B , in which one of the color classes contains a single edge, can be extended to a triangle-free 2-coloring of $G^\downarrow$.

Proof. Property (i) follows from the fact that every vertex of $G^\downarrow$ occurs in at least one of the $2a-3$ copies S_i or U_i of S^- .

To verify property (ii), we must show that every 2-coloring of $G^\downarrow$ which is monochromatic on B must contain a monochromatic triangle.

Let $\chi : G^\downarrow \rightarrow \{1, 2\}$ be a 2-coloring of the edges of $G^\downarrow$ such that $\chi(B) = 1$. Assume that each sender S_i or U_i in $G^\downarrow$ is triangle-free under χ . We show that at least one of the triangles in the set $\mathcal{T} = \{T_1, \dots, T_{a-2}\}$ must be monochromatic by showing that $2|\mathcal{T}| + 1 = 2a-3$ of the $3(a-2)$ edges making up the triangles $\mathcal{T}$ get color 2 under χ .

Since $\chi(B) = \{1\}$, the properties of S^- give us that $\chi(f_i) = 2$ for $i = 1, \dots, a$. These f_i are distinct edges of the triangles $\mathcal{T}$. Furthermore, for each $i = 1, \dots, a-3$, U_i is a negative signal sender under a triangle-free coloring, so either $\chi(g_i) = 2$ or $\chi(h_i) = 2$. Again, these are all distinct edges of the triangles $\mathcal{T}$. Thus $a + (a-3) = 2a-3$ of the edges of the triangles $\mathcal{T}$ are color 2. One of the triangles must therefore be monochromatic, and the property is verified.

For property (iii), assume that χ has color 1 on all edges of B except for the i th one (i.e., the one in S_i). If $1 < i < a$, then χ can be extended to a triangle-free coloring of $G^\downarrow$ such that

- for $j < i-1$, $\chi(p_j) = \chi(q_j) = 2$ and $\chi(r_j) = 1$;
- for $j = i-1$, $\chi(p_j) = \chi(r_j) = 2$ and $\chi(q_j) = 1$; and
- for $j > i-1$, $\chi(p_j) = 1$ and $\chi(q_j) = \chi(r_j) = 2$.

If $i = 1$, then χ can be extended to a triangle-free coloring of $G^\downarrow$ such that for all $j = 1, \dots, a-2$, $\chi(p_j) = 1$ and $\chi(q_j) = \chi(r_j) = 2$.

The case that $i = a$ is symmetric to the case $i = 1$. $\square$

3.3. Construction of $G(\mathcal{P})$. Given a set $\mathcal{P} = \{L_i \cup R_i \mid i = 1, \dots, a\}$ of partitions of the set $\{1, \dots, a\}$, we first define the graph $G'(\mathcal{P})$. The graph $G(\mathcal{P})$ will then be a 2-Ramsey-minimal subgraph of this graph.

We construct $G'(\mathcal{P})$ as follows.

CONSTRUCTION 3.9.

- (i) Let G^* be a copy of $G^*(\mathcal{P})$.
- (ii) Let $G^\uparrow$ be a copy of $G^\uparrow(5a)$.
- (iii) Let $G^\downarrow$ be a copy of $G^\downarrow(a)$.
- (iv) Identify the cycle C_{5a} in G^* with the cycle C_{5a} in $G^\uparrow$. For $i = 1, \dots, a$, set $e_i = \{u_1^i, u_2^i\}$; i.e., identify the set $\{\{u_1^i, u_2^i\} \mid i = 1, \dots, a\}$ of pairwise vertex-disjoint edges in G^* with set $B = \{b_i \mid i = 1, \dots, a\}$ of pairwise vertex-disjoint edges in $G^\downarrow$.

Denote the resulting graph by $G'(\mathcal{P})$.

LEMMA 3.10. *The graph $G' = G'(\mathcal{P})$ has the following properties:*

- (i) *Any 2-coloring of G' has a monochromatic triangle.*
- (ii) *For any central edge e of $G^* \subset G'$ there exists a triangle-free 2-coloring of $G' - e$.*

Proof.

(i) Assume there is a triangle-free 2-coloring of G' . Then by Lemmas 3.6(ii) and 3.8(ii), C_{5a} is monochromatic and B is not. Consequently, by Lemma 3.3(ii), G^* in G' contains a monochromatic triangle.

(ii) Let e be a central edge of G^* . By Lemma 3.3(iii), $G^* - e$ can be colored with C_{5a} monochromatic of color 1, and with B getting color 1 on all edges but one. Thus Lemmas 3.6(ii) and 3.8(iii) guarantee that the rest of $G' - e$ can be colored without any monochromatic triangles. $\square$

Let $G(\mathcal{P})$ be any subgraph of $G'(\mathcal{P})$ that is minimal with respect to property (i) of Lemma 3.10. By property (ii) of Lemma 3.10, $G(\mathcal{P})$ must contain all the central edges of G^* . Thus we have the following.

FACT 3.11. *For distinct sets $\mathcal{P}$ and $\mathcal{P}'$, the labeled graphs $G(\mathcal{P})$ and $G(\mathcal{P}')$ are different.*

Let S^+ be the positive sender $S^+(2, K_3, \ell, r)$ used in the construction of $G^*(\mathcal{P})$, and let S^- be the negative sender $S^-(2, K_3, e, f)$ used in the constructions of $G^\uparrow$ and $G^\downarrow$. Let $s = \max(|V(S^+)|, |V(S^-)|)$. We then have the following $r = 2$, $k = 3$ case of Theorem 1.1.

THEOREM 3.12. *There exists a constant $c = c(2, 3) > 1$ such that for $n \geq n_0 = n_0(2, 3) = 99s$ there exist at least c^{n^2} nonisomorphic graphs, on at most n vertices, that are 2-Ramsey-minimal with respect to the triangle.*

Proof. Let a be the largest odd integer for which $a \leq \frac{n}{9s}$. Since $n \geq 99s$, we have $a \geq \frac{n}{9s} - 2 \geq 11 - 2 = 9$, which yields that

$$a \geq \frac{9}{11} \frac{n}{9s} = \frac{n}{11s}.$$

Now there are 2^{a^2} ways to choose the set $\mathcal{P}$ of a partitions $L_i \cup R_i$ of $\{1, \dots, a\}$. By Fact 3.11, each $\mathcal{P}$ yields a different graph $G(\mathcal{P})$. We therefore have 2^{a^2} different graphs $G(\mathcal{P})$. Using part (i) of Lemmas 3.3, 3.6, and 3.8, we get that each has

$$\begin{aligned} |V(G(\mathcal{P}))| &< |V(G^*(\mathcal{P}))| + |V(G^\uparrow(5a))| + |V(G^\downarrow(a))| \\ &< 2as + 5as + 2as \\ &= 9as \leq n \end{aligned}$$

vertices.

Setting $c_1 = 1/(11s)^2$, there are $2^{a^2} > 2^{c_1 n^2}$ different such labeled graphs. The isomorphism class of any one is at most $n!$, so there are at least

$$\frac{2^{c_1 n^2}}{n!} = 2^{c_1 n^2(1+o(1))} > 2^{c_2 n^2},$$

nonisomorphic graphs, for $c_2 < c_1$, and n is sufficiently large.

This is c^{n^2} , where $c = 2^{c_2}$, so the proof is complete. $\square$

4. Theorem 1.1: Induction on k . We prove Theorem 1.1 for $r = 2$ and all k , by induction on k . The induction will be done by means of the following lemma. The

FIG. 4.1. Construction of G from Lemma 4.1. Note that the two edges f are the same edge.

proof of the lemma takes up the majority of the section. The proof of the induction on k comes only at the very end of the section.

LEMMA 4.1. *Given an integer k there exists a constant $s = s(k)$ such that for a graph G' on n' vertices that is 2-Ramsey-minimal with respect to K_{k-1} , there exists a graph G with the following properties:*

- (i) *The graph G has at most sn' vertices,*
- (ii) *G is 2-Ramsey with respect to K_k , and*
- (iii) *any 2-Ramsey-minimal subgraph of G contains G' as a subgraph.*

Proof. Let $V(G') = \{v_1, \dots, v_{n'}\}$, and construct G as follows. (See Figure 4.1.)

- For $i = 1, \dots, n'$ let $S_i^- = S^-(2, K_k, e_i^-, f_i^-)$ and $S_i^+ = S^+(2, K_k, e_i^+, f_i^+)$ be new copies of the senders $S^-(2, K_k, e, f)$ and $S^+(2, K_k, e, f)$, respectively. Assume that in all of these senders, the copies of e and f are distance at least 2 apart.

- Add new vertices v^- and v^+ . For each $i = 1, \dots, n'$, identify the endpoints of e_i^- with v^- and v_i , and the endpoints of e_i^+ with v^+ and v_i .

- Identify all of the f_i^+ and f_i^- and call this edge f . Let x and y be the endpoints of f .

Set $s = |V(S^-(2, K_k, e, f))| + |V(S^+(2, K_k, e, f))|$. We now verify that the graph G , thus constructed, has all the properties promised by the lemma.

To see property (i) notice that every vertex of G is in at least one of the n' copies of $S^-(2, K_k, e, f)$ or the n' copies of $S^+(2, K_k, e, f)$. Thus

$$|V(G)| < n'(|V(S^-(2, K_k, e, f))| + |V(S^+(2, K_k, e, f))|) = sn'.$$

Property (ii) will be verified in Claim 4.2, and property (iii) follows immediately from Claim 4.4.

CLAIM 4.2. *Any 2-coloring of G yields a monochromatic K_k .*

Proof. Let χ be a 2-coloring of G and assume, without loss of generality, that $\chi(f) = 1$. Then by the properties of the S_i^- , all edges from v^- to G' get color 2, and by the properties of the S_i^+ , all edges from v^+ to G' get color 1. Now χ induces a 2-coloring of G' , which yields a monochromatic copy of K_{k-1} in G' . If this K_{k-1} is color 1, then it makes a monochromatic K_k with v^+ . Otherwise, it makes a monochromatic K_k with v^- . $\square$

The following claim is used in Claim 4.4.

CLAIM 4.3. *Any copy K'_k of K_k in G either intersects G' in at least a K_{k-1} or occurs within S_i^- or S_i^+ for some $i = 1, \dots, n'$.*

Proof. We split the proof of the claim into three cases.

Case 1. $|V(K'_k) \cap V(G')| \geq 2$.

Without loss of generality, let v_1 and v_2 be in $|V(K'_k) \cap V(G')|$. Recall that x and y are the endpoints of f . By the assumption that the edges e and f in $S^-(2, K_k, e, f)$ and $S^+(2, K_k, e, f)$ are distance at least 2 apart, the only neighbors of v_1 are in $V(G') \cup V(S_1^+) \cup V(S_1^-) - \{x, y\}$. (Recall that x and y are the endpoints of f .) Similarly the only neighbors of v_2 are in $V(G') \cup V(S_2^+) \cup V(S_2^-) - \{x, y\}$. Thus the only common neighbors of v_1 and v_2 are in $V(G') \cup \{v^-, v^+\}$. Since the vertices v^+ and v^- are nonadjacent, only one of them belongs to $V(K'_k)$. Consequently, $|V(K'_k) \cap V(G')| \geq k - 1$, i.e., K'_k intersects G' in at least a K_{k-1} .

Case 2. $|V(K'_k) \cap V(G')| = 1$.

Without loss of generality, let $V(K'_k) \cap V(G') = \{v_1\}$. The only neighbors of v_1 are in S_1^- or S_1^+ , but there are no edges between $V(S_1^-)$ and $V(S_1^+)$ except those incident to v_1 . Consequently, K'_k occurs within S_1^- or S_1^+ .

Case 3. $|V(K'_k) \cap V(G')| = 0$.

Since the set $\{v^-, v^+, x, y\}$ induces only the one edge f , at most two of the vertices in this set can be in K'_k . Therefore there is some other vertex v of one of the S_i^- or S_i^+ in K'_k . Without loss of generality, assume that $v \in S_1^-$. All the neighbors of v are in S_1^- . Consequently K'_k occurs within S_1^- . $\square$

It follows from the following claim that any 2-Ramsey-minimal subgraph of G when restricted to $V(G')$ is G' .

CLAIM 4.4. *Removing any edge $e' \in G' \subset G$ we can 2-color G with no monochromatic K_k .*

Proof. Removing edge e' from G' , we can 2-color G' without any monochromatic K_{k-1} . Since the senders can be 2-colored without any monochromatic K_k , Claim 4.3 implies that this gives a 2-coloring of G without any monochromatic K_k . $\square$

This completes the proof of the lemma. $\square$

We now prove the induction on k , thus proving the $r = 2$ case of Theorem 1.1. By section 3, we have the base case, $k = 3$.

Proof. Assume that Theorem 1.1 is true for $r = 2$ and $k - 1$. We must provide integer $n_0(2, k)$ and constant $c(2, k) > 1$ such that for any $n \geq n_0(2, k)$ there exist at least $c(2, k)^{n^2}$ nonisomorphic graphs on at most n vertices, each of which is 2-Ramsey-minimal with respect to K_k .

Letting $s = s(k)$ be from Lemma 4.1, set

$$c(2, k) = c(2, k - 1)^{1/(8s^2)}.$$

Observe that because $c(2, k - 1) > 1$, we have that $c(2, k) > 1$. Let $n_0(2, k)$ be large enough that

$$n_0(2, k) \geq s \cdot n_0(2, k - 1),$$

and that for all $n \geq n_0(2, k)$,

$$(4.1) \quad n! \leq c(2, k)^{n^2}.$$

Given

$$n \geq n_0(2, k) \geq s \cdot n_0(2, k - 1),$$

set $n' = \lfloor \frac{n}{s} \rfloor$. Since $n_0(2, k - 1)$ is an integer, this implies

$$n' \geq n_0(2, k - 1).$$

We can therefore use the induction hypothesis to get at least $c(2, k-1)^{(n')^2}$ labeled graphs on at most n' vertices, each of which is 2-Ramsey-minimal with respect to K_{k-1} . Apply Lemma 4.1 to each of these graphs to get graphs on at most $sn' \leq n$ vertices which are 2-Ramsey with respect to K_k .

Since $n_0(2, k-1) \geq n_0(2, 3) = 99$ by Theorem 3.12, we have that $n \geq n_0(2, k) \geq 99s$, and so

$$n' = \left\lfloor \frac{n}{s} \right\rfloor > \frac{n}{s} - 1 > \frac{n}{2s}.$$

Thus there are at least

$$c(2, k-1)^{(n')^2} > c(2, k-1)^{\frac{n^2}{(2s)^2}} = c(2, k)^{2 \cdot n^2}$$

such graphs. By Lemma 4.1(iii), the 2-Ramsey-minimal subgraphs of these graphs are distinct, though not necessarily nonisomorphic. Dividing by $n!$, which is at most $c(2, k)^{n^2}$ by assumption (4.1), we get at least $c(2, k)^{n^2}$ nonisomorphic 2-Ramsey-minimal graphs for K_k , each on at most n vertices. This completes the proof of Theorem 1.1 for case $r = 2$. $\square$

5. Theorem 1.1: Induction on r . In the previous section we proved the $r = 2$ case of Theorem 1.1 by induction on k . In this section we finish the proof of the theorem by induction on r . We do the induction by means of the following lemma.

LEMMA 5.1. *Given integers r and k there exists a constant $s = s(r, k)$ such that for a graph G' on n' vertices that is $(r-1)$ -Ramsey-minimal with respect to K_k , there exists a graph G with the following properties:*

- (i) *The graph G has at most sn' vertices,*
- (ii) *G is r -Ramsey with respect to K_k , and*
- (iii) *any r -Ramsey-minimal subgraph of G contains G' as a subgraph.*

The induction on r uses Lemma 5.1 in the same way as the induction on ℓ used Lemma 4.1 in the previous section.

Let $c(r, k) = c(r-1, k)^{1/8s^2}$. For large enough n we will find at least $c(r, k)^{n^2}$ graphs on less than n vertices that are r -Ramsey minimal for K_k .

By induction, if $n' = \lfloor n/s \rfloor$ is large enough, there are at least $c(r-1, k)^{n'^2}$ graphs on at most n' vertices that are $(r-1)$ -Ramsey minimal for K_k . Applying Lemma 5.1 to each, we get

$$c(r-1, k)n'^2 > c(r-1, k)^{\frac{n^2}{(2s)^2}} = c(r, k)^{2 \cdot n^2}$$

distinct labeled graphs on at most n vertices that are r -Ramsey-minimal for K_k . Dividing by $n!$ we get at least $c(r, k)^{n^2}$ nonisomorphic graphs on at most n vertices (for n sufficiently large). This completes the induction step.

We thus finish the proof of Theorem 1.1 by proving Lemma 5.1.

Proof of Lemma 5.1. Briefly, G is as follows. Consider G' , a copy of K_{k-2} , and an edge f , which are pairwise vertex disjoint. Add edges between every vertex of G' and every vertex of K_{k-2} . Finally, for all edges e with at least one vertex in $V(K_{k-2})$, connect e to f with positive sender $S^+(r, K_k, e, f)$. (Thus G is constructed with $n' \cdot (k-2) + \binom{k-2}{2}$ copies of $S^+(r, K_k, e, f)$.) In more detail, G is as follows:

- Begin with G' . Let $V(G') = \{v_1, \dots, v_{n'}\}$.
- Add new vertices $w_1, \dots, w_{k-2}$, all edges between them, and one more vertex disjoint edge $f = \{x, y\}$.

- For $i = 1, \dots, n'$ and $j = 1, \dots, k-2$, add edge $e_{ij} = \{v_i, w_j\}$ and let $S_{ij} = S^+(r, K_k, \{v_i, w_j\}, f)$ be a copy of $S^+(r, K_k, e, f)$ in which all vertices are distinct except for v_i, w_j, x , and y . Assume that in all of these senders, the copies of e and f are distance at least 2 apart.

- For each i, j such that $1 \leq i < j \leq k-2$, let $W_{ij} = S^+(r, K_k, \{w_i, w_j\}, f)$ be a copy of $S^+(r, K_k, e, f)$ in which all vertices are distinct except for w_i, w_j, x , and y . Assume again that in all of these senders, the copies of e and f are distance at least 2 apart.

Set $s = 2k|V(S^+(r, K_k, e, f))|$. We now verify that the graph G , constructed above, has all the properties promised by the lemma.

To see property (i) notice that every vertex of G is in at least one of the $n' \cdot (k-2) + \binom{k-2}{2}$ copies of $S^+(r, K_k, e, f)$ in G . Since G' has n' vertices, and is Ramsey for K_k , $n' \geq k$. Thus $\binom{k-2}{2} < n' \cdot k$, and so

$$|V(G)| < n'(2k)|V(S^+(r, K_k, e, f))| = sn'.$$

The following claim verifies property (ii).

CLAIM 5.2. *Any r -coloring of G yields a monochromatic K_k .*

Proof. Let $\chi : V(G) \rightarrow \{1, \dots, r\}$ be an r -coloring of G and assume, without loss of generality, that $\chi(f) = r$. If there is no monochromatic K_k in any of the S_{ij} or W_{ij} , then by the properties of these senders, all edges $\{v_i, w_j\}$ and $\{w_i, w_j\}$ get color r . If any edge in G' gets colored r , then this completes a monochromatic K_k with vertices $w_1, \dots, w_{k-2}$. Thus χ must induce an $(r-1)$ -coloring on G' . But G' is $(r-1)$ -Ramsey with respect to K_k , so G contains a monochromatic K_k . $\square$

Property (iii) follows from Claim 5.4. However, for this, we first need the following claim.

CLAIM 5.3. *For any copy K'_k of K_k in G , either $V(K'_k) \subset V(G') \cup \{w_1, \dots, w_{k-2}\}$ or $V(K'_k) \subset V(S^+)$ for some sender $S^+ = S_{ij}^+$ or W_{ij}^+ .*

Proof. First observe that if there exists $v \in V(K'_k)$ such that

$$(5.1) \quad v \in V(S_{ij}^+) - \{v_i, w_j, x, y\} \quad \text{or} \quad v \in V(W_{ij}^+) - \{w_i, w_j, x, y\},$$

then all the neighbors of v are in S_{ij}^+ or W_{ij}^+ , respectively, and thus $V(K'_k) \subset V(S_{ij}^+)$ (or $V(W_{ij}^+)$), so we are done.

We may thus assume that (5.1) does not hold for any $v \in V(K'_k)$. It follows that $V(K'_k) \subset V(G') \cup \{w_1, \dots, w_{k-2}\} \cup \{x, y\}$. Since x and y have distance at least 2 from $V(G') \cup \{w_1, \dots, w_{k-2}\}$, and $k > 3$, we have that $V(K'_k) \cap \{x, y\} = \emptyset$. Thus $V(K'_k) \subset V(G') \cup \{w_1, \dots, w_{k-2}\}$, which finishes the proof of the claim. $\square$

The following claim implies that any r -Ramsey-minimal subgraph of G contains all the edges of G' , and thus property (iii) of the lemma follows.

CLAIM 5.4. *For any edge e of G' , we can r -color $G - e$ with no monochromatic K_k .*

Proof. Let e be in G' . We can $(r-1)$ -color $G' - e$ with colors $\{1, \dots, r-1\}$ without any monochromatic K_k . We extend this $(r-1)$ -coloring of $G' - e$ to an r -coloring of $G - e$. Let all edges $\{v_i, w_j\}$ and $\{w_i, w_j\}$, and the edge f , get color r . For each positive sender S_{ij}^+ (or W_{ij}^+), the copy $\{v_i, w_j\}$ (respectively, $\{w_i, w_j\}$) of e gets the same color as f , so we can extend our coloring to an r coloring of S_{ij}^+ (or W_{ij}^+) with no monochromatic K_k . By Claim 5.3, this gives a K_k -free r -coloring of $G - e$. $\square$

This completes the proof of Lemma 5.1, and by the comments at the beginning of the section, completes the proof of Theorem 1.1 $\square$

6. The nonsymmetric case. In this section we prove the following nonsymmetric case of our main theorem.

THEOREM 6.1. *For any integers $\ell \geq k \geq 3$ there exist constants $c = c(\ell, k) > 1$ and $n_0(\ell, k)$ such that for all $n \geq n_0(\ell, k)$, there exist at least c^{n^2} nonisomorphic graphs, on at most n vertices, that are Ramsey-minimal with respect to K_ℓ and K_k .*

The proof of this theorem uses the following lemma.

LEMMA 6.2. *Given integers $\ell > k \geq 3$ there exists a constant $s = s(\ell, k)$ such that for a graph G' on n' vertices that is 2-Ramsey-minimal with respect to $K_{\ell-1}$ and K_k , there exists a graph G with the following properties:*

- (i) *The graph G has at most sn' vertices,*
- (ii) *G is 2-Ramsey with respect to K_ℓ and K_k , and*
- (iii) *any 2-Ramsey-minimal subgraph of G contains G' as a subgraph.*

The proof of Theorem 6.1 follows by induction on ℓ using Lemma 6.2 in the same way as the $r = 2$ case of Theorem 1.1 followed by induction on k using Lemma 4.1 in section 4. The base case of the induction, when $\ell = k$, is given by Theorem 1.1. Assuming Lemma 6.2, and that the theorem is proved for $\ell - 1$ and k , the induction step is as follows.

Let $c(\ell, k) = c(\ell - 1, k)^{1/8s^2} > 1$ and $n_0(\ell, k) = s \cdot n_0(\ell - 1, k)$. For $n \geq n_0(\ell, k)$ we will find at least $c(\ell, k)^{n^2}$ graphs on less than n vertices that are 2-Ramsey minimal for K_ℓ and K_k .

Given $n \geq n_0(\ell, k)$, let $n' = \lfloor n/s \rfloor \geq n_0(\ell - 1, k)$. By induction, there are at least $c(\ell - 1, k)^{n'^2}$ graphs that are 2-Ramsey minimal for $K_{\ell-1}$ and K_k on at most n' vertices. Applying Lemma 6.2 to each, we get

$$c(\ell - 1, k)^{n'^2} > c(\ell - 1, k)^{\frac{n^2}{(2s)^2}} = c(\ell, k)^{2 \cdot n^2}$$

distinct labeled graphs on at most n vertices that are 2-Ramsey-minimal for K_ℓ and K_k . Dividing by $n!$ we get at least $c(\ell, k)^{n^2}$ nonisomorphic graphs on at most n vertices (for n sufficiently large). This completes the induction step.

We thus finish the proof of Theorem 6.1 by proving Lemma 6.2. First, we need a result from [10].

DEFINITION 6.3. *Given graphs H_1 and H_2 , a graph $D = D(H_1, H_2, e)$ is an (H_1, H_2) -determiner if*

- (i) *there is a 2-coloring $\chi : D \rightarrow \{1, 2\}$ of D such that there is no copy of H_1 of color 1 and no copy of H_2 of color 2, and*
- (ii) *in any such coloring χ of D , $\chi(e) = 1$.*

Theorem 2.3 of [10] states that for any two integers $\ell > k \geq 3$, there exists a (K_ℓ, K_k) -determiner $D = D(\ell, k, e)$. With this we can prove the lemma.

Proof of Lemma 6.2. Given a graph G' as described in the lemma, let $V(G') = \{v_1, \dots, v_{n'}\}$, and construct G as follows:

- For $i = 1, \dots, n'$, let $D_i = D(\ell, k, e_i)$ be a copy of the (K_ℓ, K_k) -determiner D .
- Add new vertex v_0 . For each $i = 1, \dots, n'$, identify the endpoints of e_i with v_0 and v_i .

The verification that the graph G constructed above has the necessary properties of the lemma is very similar to the proof of Lemma 4.1. $\square$

7. Signal senders. In this section, we give the proof of Lemma 2.2. The proof is a modification of the proof from [10]. Recall that this lemma guarantees, for any 3-connected graph H , and any $r \geq 2$, the existence of

- (a) a negative signal sender $S^-(r, H, e, f)$,
- (b) a positive signal sender $S^+(r, H, e, f)$, and
- (c) such negative and positive signal senders in which the distance between the edges e and f is arbitrarily large.

The section is organized as follows. In subsection 7.1, we introduce a few technical definitions and results that we will use in the proof. In subsection 7.2, we construct a negative signal sender $S^-(r, H, e, f) = S^-(r, H, \{x_0, u\}, \{x_0, u'\})$, in which the vertices u and u' are nonadjacent. This strengthening of part (a) of the lemma will help us in the later parts. In subsection 7.3, we use part (a) to construct a positive signal sender $S^+(r, H, e, f) = S^+(r, H, \{v_0, v_1\}, \{v_0, v_t\})$, in which the vertices v_1 and v_t are nonadjacent. Finally, in subsection 7.4, we use parts (a) and (b) to construct, for any integer $g \geq 2$, positive and negative signal senders $S^+(r, H, \{x_0, x_1\}, \{x_{g+1}, x_{g+2}\})$ and $S^-(r, H, \{x_0, x_1\}, \{x_{g+1}, x_{g+2}\})$ in which the edges $\{x_0, x_1\}$ and $\{x_{g+1}, x_{g+2}\}$ are distance g apart.

7.1. Technical definitions and results. We begin with a couple of definitions.

DEFINITION 7.1. *A circuit of length h in an ℓ -graph $\mathcal{H}$ is a subgraph $\{e_1, \dots, e_h\}$ of $\mathcal{H}$ such that*

$$\left| \bigcup_{i=1}^h e_i \right| \leq (\ell - 1)h.$$

The girth of an ℓ -graph is the length of its shortest circuit.

DEFINITION 7.2. *An ℓ -graph is $(r+1)$ -chromatic if $r+1$ is the minimum number of colors needed to color its vertices such that there is no edge with all vertices having the same color.*

The following is proved probabilistically in [11] and constructively in [14] and [17].

THEOREM 7.3. *For any integers $g, r \geq 2$ and $\ell \geq 3$, there exist $(r+1)$ -chromatic ℓ -graphs $\mathcal{G}$ of girth $> g$.*

We will also need the following technical definitions.

DEFINITION 7.4. *Let $r, \ell \geq 2$ be integers.*

- (i) *An oriented ℓ -graph $\mathcal{H}$ on the vertices $V = V(\mathcal{H})$ is a set of ordered ℓ element subsets, or arcs, of V .*
- (ii) *An (r, ℓ) -pattern is an ℓ -tuple of not necessarily distinct elements from $[r]$, (i.e., an element of $[r]^\ell$.)*
- (iii) *Given a set $\Phi \subseteq [r]^\ell$ of forbidden (r, ℓ) -patterns, an r -coloring $\chi : V(\mathcal{H}) \rightarrow [r]$ of the vertices of $\mathcal{H}$ is Φ -avoiding if*

$$(\chi(v_1), \dots, \chi(v_\ell)) \notin \Phi \text{ for any arc } (v_1, \dots, v_\ell) \in \mathcal{H}.$$

Observe that if $\Phi = \{(i, i, \dots, i) \mid 1 \leq i \leq r\}$ is the set of monochromatic (r, ℓ) -patterns, then a Φ -avoiding r -coloring of an oriented ℓ -graph $\mathcal{H}$ is simply an r -coloring of the vertices of $\mathcal{H}$ in which no arc is monochromatic.

7.2. The negative signal sender $S^-(r, H, \{x_0, u\}, \{x_0, u'\})$. In this subsection we prove a slightly stronger version of part (a) of the lemma by constructing, for any integer $r \geq 2$ and any 3-connected graph H , the negative signal sender $S^-(r, H, \{x_0, u\}, \{x_0, u'\})$ in which the vertices u and u' are nonadjacent.

Let $r \geq 2$ be fixed and H be a 3-connected graph.

The graph F . Let F' be a graph that is r -Ramsey-minimal with respect to H , and let F be obtained from F' by removing an edge $\{x, y\}$. We claim the following:

- (*) Under any H -free r -coloring of the edges of F , x has incident edges of every color.

Indeed, suppose that χ is an H -free r -coloring of F in which x has no incident edges of color i . By setting $\chi(\{x, y\}) = i$, we can extend χ to an r -coloring of F' in which x has only one incident edge of color i . By the r -Ramsey-minimality of F' , F' must then contain a copy of H of color i , in which the vertex x has degree 1. But since H is 3-connected, any vertex has degree at least 3. This is a contradiction.

Indeed, since H is 3-connected, each of its vertices has degree at least 2. So if χ were an H -free r -coloring of F and x had no incident edge of color i , then we could extend χ to an H -free r -coloring of F' by setting $\chi(\{x, y\}) = i$. This would be a contradiction.

The set Φ of forbidden (r, ℓ) -patterns, and the oriented ℓ -graph $\mathcal{H}$. Let F , with vertex x , be the graph constructed in the previous paragraph. Let ℓ be the degree of x in F . Fix an orientation $(x_1, \dots, x_\ell)$ of the neighborhood of x in F . Let Φ be the set of (r, ℓ) -patterns $(r_1, \dots, r_\ell)$ such that the following holds:

The r -coloring χ of the edges $\{x, x_1\}, \dots, \{x, x_\ell\}$ of F defined by $\chi(\{x, x_i\}) = r_i$, for all i , cannot be extended to an H -free r -coloring of the edges of F .

By statement (*), Φ contains all (r, ℓ) -patterns with less than r colors; in particular, it contains the monochromatic pattern $(i, i, \dots, i)$ for $i = 1, \dots, r$. Moreover, because F has an H -free r -coloring, Φ is not the set of all (r, ℓ) -patterns. The following lemma guarantees the existence of an auxiliary oriented ℓ -graph.

LEMMA 7.5. *Given integers $g, r, \ell \geq 2$, let Φ be a proper subset of the set of all (r, ℓ) -patterns, which contains the monochromatic pattern $(i, i, \dots, i)$ for each $i = 1, \dots, r$. Then there exists an oriented ℓ -graph $\mathcal{H} = \mathcal{H}(\Phi, r, \ell, g)$ with girth $> g$, having distinguished vertices u and u' , which satisfies the following:*

- (i) $\mathcal{H}$ has a Φ -avoiding r -coloring.
- (ii) The vertices u and u' do not occur together in any arc of $\mathcal{H}$.
- (iii) Under any Φ -avoiding r -coloring, u and u' get different colors.

The proof of Lemma 7.5 is given at the end of this subsection. Let $\mathcal{H}$ be the oriented ℓ -graph provided by the lemma for the set Φ .

The construction of S^- . We now construct $S^- = S^-(r, H, \{x_0, u\}, \{x_0, u'\})$. (See Figure 7.1.)

CONSTRUCTION 7.6 ($S^- = S^-(r, H, \{x_0, u\}, \{x_0, u'\})$).

(i) For every arc $\mathbf{a} = (v_1, \dots, v_\ell)$ in $\mathcal{H}$ let $F^{\mathbf{a}}$ be a copy of F . The graph S^- is the union of these copies of F . All vertices are distinct unless explicitly identified below. Let $x^{\mathbf{a}}$ and $\{x_1^{\mathbf{a}}, \dots, x_\ell^{\mathbf{a}}\}$ denote the copies of x and its neighborhood $\{x_1, \dots, x_\ell\}$ in $F^{\mathbf{a}}$.

(ii) For every arc $\mathbf{a} = (v_1, \dots, v_\ell)$ in $\mathcal{H}$ and every $i = 1, \dots, \ell$, identify the vertex $x_i^{\mathbf{a}}$ of $F^{\mathbf{a}}$ with v_i of $\mathcal{H}$.

(iii) Identify the vertices $x^{\mathbf{a}}$ for all $\mathbf{a} \in \mathcal{H}$ and call the resulting vertex x_0 . As a result of this identification, we have that $N(x_0) = V(\mathcal{H})$ in S^- .

By property (ii) of Lemma 7.5, the vertices u and u' do not occur together in any arc of $\mathcal{H}$. Thus they are not adjacent in the graph S^- just constructed.

The proof that S^- is a negative signal sender. To finish the proof of part (a) of the lemma, we need to verify that $S^- = S^-(r, H, \{x_0, u\}, \{x_0, u'\})$ is a negative signal

FIG. 7.1. Construction of S^- from F and $\mathcal{H}$.

sender. The proof consists of the following three claims, the first being used to prove the second.

CLAIM 7.7. *Any copy of H in S^- is entirely within F^a for some $a \in \mathcal{H}$.*

Proof. Let H_0 be a copy of H in S^- . For any subgraph $\mathcal{A}$ (i.e., subset of arcs) of $\mathcal{H}$, let $F^{\mathcal{A}}$ be the subgraph of S^- induced by the vertex set $\bigcup_{a \in \mathcal{A}} V(F^a) \subset V(S^-)$. Let $\mathcal{A}^*$ be a minimum subgraph of $\mathcal{H}$ for which $H_0 \subset F^{\mathcal{A}^*}$. We will show that $|\mathcal{A}^*| = 1$. Towards a contradiction, assume that $|\mathcal{A}^*| > 1$. By the minimality of $\mathcal{A}^*$, $|\mathcal{A}^*| \leq |V(H_0)| = g$, so being a subgraph of $\mathcal{H}$, $\mathcal{A}^*$ contains no circuits. This implies that there exists $a_0 \in \mathcal{A}^*$ such that a_0 intersects the rest of $\mathcal{A}^*$ in at most one vertex, i.e., such that $|V(a_0) \cap V(\mathcal{A}^* - a_0)| \leq 1$.

If $V(a_0) \cap V(\mathcal{A}^* - a_0)$ is empty, then removing x_0 (see Construction 7.6(iii)) disconnects F^{a_0} from the rest of $F^{\mathcal{A}^*}$. But by the minimality of $F^{\mathcal{A}^*}$, the intersection of $V(H_0)$ and $V(F^{a_0}) - \{x_0\}$ is nontrivial, so this disconnects H_0 .

On the other hand, if $V(a_0) \cap V(\mathcal{A}^* - a_0)$ contains some vertex y , then y is adjacent to x_0 and the edge $\{x_0, y\}$ is in F^{a_1} for some other $a_1 \in \mathcal{A}^*$. Removing x_0 and y disconnects F^{a_0} from the rest of $F^{\mathcal{A}^*}$, but by the minimality of $\mathcal{A}^*$, the intersection of $V(H_0)$ and $V(F^{a_0}) - \{x_0, y\}$ is nontrivial, so this disconnects H_0 .

Either way we have disconnected H_0 by removing at most two vertices. This contradicts the fact that H_0 is 3-connected. Thus $|\mathcal{A}^*| = 1$ and the claim is proved. $\square$

CLAIM 7.8. *There exists an H -free r -coloring of S^- .*

Proof. Let χ' be a Φ -avoiding r -coloring of the vertices of $\mathcal{H}$. For each vertex v in $\mathcal{H}$, let $\chi(\{x_0, v\}) = \chi'(v)$. For each copy F^a of F this gives a coloring of the edges $(\{x_0, x_1^a\}, \dots, \{x_0, x_\ell^a\})$ which corresponds to a pattern not forbidden by Φ . Thus we can extend the r -coloring χ to the edges of F^a in such a way that there are no monochromatic copies of H in F^a . By Claim 7.7, there are no other copies of H in S^- , and so χ is an H -free r -coloring of S^- . $\square$

CLAIM 7.9. *Under any H -free r -coloring of S^- , the edges $\{x_0, u\}$ and $\{x_0, u'\}$ get different colors.*

Proof. Assume that we are given an H -free r -coloring χ of S^- . This induces an r -coloring χ' of $V(\mathcal{H})$ by $\chi'(v) = \chi(\{x_0, v\})$. For any arc $a = (v_1, \dots, v_\ell)$ in $\mathcal{H}$ this has the coloring

$$(\chi'(v_1), \dots, \chi'(v_\ell)) = (\chi(\{x_0, v_1\}), \dots, \chi(\{x_0, v_\ell\})) = (\chi(\{x_0, x_1^a\}), \dots, \chi(\{x_0, x_\ell^a\})),$$

which corresponds to a pattern not in Φ , since χ is an H -free r -coloring of F^a . Thus χ' is a Φ -avoiding r -coloring of $\mathcal{H}$. But any Φ -avoiding r -coloring χ' of $\mathcal{H}$ has the property that $\chi'(u) \neq \chi'(u')$. Thus $\chi(\{x_0, u\}) \neq \chi(\{x_0, u'\})$. $\square$

We have shown that S^- is a negative signal sender $S^-(r, H, \{x_0, u\}, \{x_0, u'\})$ in which the vertices u and u' are nonadjacent. The proof of part (a) of the lemma will thus be complete with the proof of Lemma 7.5. We give this now.

Proof of Lemma 7.5. Let $\mathcal{G}$ be the $(r+1)$ -chromatic ℓ -graph with girth $> g$, which is guaranteed by Theorem 7.3, and let Φ be as in the statement of the lemma. Since Φ contains all monochromatic (r, ℓ) -patterns, there is no Φ -avoiding r -coloring of the vertices of $\mathcal{G}$ under any orientation of its edges. Let $\mathcal{G}$ be $\mathcal{G}$ with some fixed orientation of the edges. Clearly $\mathcal{G}$ has no Φ -avoiding r -coloring. Let $\mathcal{H}_0$ be a subgraph of $\mathcal{G}$ that is minimal with respect to the fact that it has no Φ -avoiding r -coloring. Since Φ does not contain all (r, ℓ) -patterns there is a Φ -avoiding r -coloring of any graph with just a single arc, so $\mathcal{H}_0$ is nonempty.

We now construct ℓ different graphs $H_1, \dots, H_\ell$ and show that one of them has the properties required of $\mathcal{H}$. Let $(u_1, \dots, u_\ell)$ be an arc of $\mathcal{H}_0$, and let $v_1, \dots, v_\ell$ be new vertices. For $i = 1, \dots, \ell$, form the oriented ℓ -graph $\mathcal{H}_i$ from $\mathcal{H}_0$ by removing the arc $(u_1, \dots, u_\ell)$ and adding the arc $(v_1, \dots, v_i, u_{i+1}, \dots, u_\ell)$. Now $\mathcal{H}_\ell$ clearly has a Φ -avoiding r -coloring, while $\mathcal{H}_0$ does not. Let $i > 0$ be such that $\mathcal{H}_i$ has a Φ -avoiding r -coloring and $\mathcal{H}_{i-1}$ does not. We show that $\mathcal{H} = \mathcal{H}_i$, $u = u_i$, and $u' = v_i$ satisfy the requirements of the lemma. Certainly $\mathcal{H}$ has a Φ -avoiding r -coloring, so we have property (i) of the lemma. Since v_i is in only one arc of $\mathcal{H}$, and this arc does not contain u_i , we have property (ii) of the lemma. For property (iii), we must now show that under any Φ -avoiding r -coloring χ of $\mathcal{H}$, $\chi(u_i) \neq \chi(v_i)$. Assume that $\chi(u_i) = \chi(v_i)$; then χ is a Φ -avoiding r -coloring of $\mathcal{H}_{i-1}$. This is a contradiction, so we are done. $\square$

This completes the proof of Lemma 7.5, and thus the proof of the strengthening of part (a) of Lemma 2.2.

7.3. The proof of part (b) of Lemma 2.2. We first prove the case $H = K_k$ for any $k \geq 3$ by constructing a positive signal sender $S^+ = S^+(r, H, \{v_0, v_1\}, \{v_0, v_{r+1}\})$ which, like in part (a), has the added property that the vertices v_1 and v_{r+1} are not adjacent.

We then sketch the extension of the proof to the case of a general 3-connected graph H by constructing a positive signal sender $S^+ = S^+(r, H, \{v_0, v_1\}, \{v_0, v_t\})$ (t will be determined later), again having the property that the vertices v_1 and v_t are not adjacent.

In both cases, we construct S^+ , show that the vertices v_1 and v_{r+1} (or v_t) are not adjacent, and then prove that S^+ is a positive signal sender by proving analogues of Claims 7.7, 7.8, and 7.9.

The construction of S^+ in the case $H = K_k$. Take the star with root v_0 and leaves $v_1, \dots, v_{r+1}$. For each pair $1 \leq i < j \leq r+1$ except $i = 1$ and $j = r+1$, let $S_{i,j}^- = S^-(r, K_k, \{v_0, v_i\}, \{v_0, v_j\})$ be a copy of $S^-(r, K_k, \{x_0, u\}, \{x_0, u'\})$ in which we identify the copies of x_0, u , and u' with the vertices v_0, v_i , and v_j , respectively. Let the $\binom{r+1}{2} - 1$ copies of $S^-(r, K_k, \{x_0, u\}, \{x_0, u'\})$ be otherwise vertex disjoint, and let S^+ be their union. (See Figure 7.2.)

By the construction, it is clear that the vertices v_1 and v_{r+1} are not adjacent. To finish the proof of part (b) for the case $H = K_k$, we show that S^+ is a positive signal sender. We do this by proving the following claim, the parts of which are analogues to Claims 7.7, 7.8, and 7.9.

FIG. 7.2. A subgraph of S^+ .

CLAIM 7.10. *The graph S^+ has the following properties:*

- (i) *Any copy of K_k in S^+ occurs within $S_{i,j}^-$ for some $1 \leq i < j \leq r+1$.*
- (ii) *There exists a K_k -free r -coloring of S^+ .*
- (iii) *Under any K_k -free r -coloring of S^+ , the edges $\{v_0, v_1\}$ and $\{v_0, v_{r+1}\}$ get the same color.*

Proof. (i) Since each $S_{i,j}^- = S^-(r, K_k, \{v_0, v_i\}, \{v_0, v_j\})$ has the property that the vertices v_i and v_j are nonadjacent, the vertices $v_1, \dots, v_{r+1}$ of S^+ form an independent set. Thus any copy K of K_k in S^+ must contain at least $k-2$ vertices of $V(S^+) - \{v_0, v_1, \dots, v_{r+1}\}$. Let x be one such vertex. Then x is in $V(S_{i,j}^-) - \{v_0, v_i, v_j\}$ for some $1 \leq i < j \leq r+1$. But v_0, v_i, v_j are the only vertices of $S_{i,j}^-$ that have neighbors in S^+ that are outside of $S_{i,j}^-$. Thus $K \subset S_{i,j}^-$.

(ii) Define a K_k -free r -coloring χ of S^+ as follows. Let $\chi(\{v_0, v_{r+1}\}) = 1$ and $\chi(\{v_0, v_i\}) = i$ otherwise. For each of the $S_{i,j}^-$, χ gives different colors to the distinguished edges $\{v_0, v_i\}$ and $\{v_0, v_j\}$, and thus can be extended to a K_k -free r -coloring of $S_{i,j}^-$. By property (i), this yields a K_k -free coloring of S^+ .

(iii) Under any K_k -free r -coloring of S^+ , every pair of edges $\{v_0, v_i\}$ and $\{v_0, v_j\}$, for $1 \leq i < j \leq r+1$, except $\{v_0, v_1\}$ and $\{v_0, v_{r+1}\}$, gets distinct colors. Thus $\{v_0, v_1\}$ and $\{v_0, v_{r+1}\}$ get the same color. $\square$

This concludes the proof of the claim, and thus the proof of part (b) of the lemma in the particular case that $H = K_k$. Observe that this construction can be seen as taking G to be a clique on the vertices $v_1, \dots, v_{r+1}$ with the edge $\{v_1, v_{r+1}\}$ removed and letting S^+ be the “amalgam of copies of S^- along edges of G .” We now extend this proof to the general case by constructing a positive signal sender $S^+ = S^+(r, H, \{v_0, v_1\}, \{v_0, v_t\})$, for any 3-connected graph H , in which the vertices

v_1 and v_t are not adjacent. In extending the proof from the case where $H = K_k$, we have to be more careful to ensure the analogue of Claim 7.10(i). To do this, we let G be an $(r+1)$ -critical graph of large girth with an edge removed, rather than an $(r+1)$ -clique with an edge removed. The construction is otherwise the same.

Construction of S^+ in the case that H is 3-connected. Define the auxiliary graph G as follows. Begin with an $(r+1)$ -critical graph with vertices $\{v_1, \dots, v_t\}$, and having girth greater than $|V(H)|$. Without loss of generality, assume that $\{v_1, v_t\}$ is an edge of this graph, and let G be this graph with the edge $\{v_1, v_t\}$ removed. Notice that under any proper r -coloring ψ of the vertices of G , we have that $\psi(v_1) = \psi(v_t)$.

Construct S^+ as follows. Let v_0 be a vertex not in G . For every edge $\{v_i, v_j\} \in G$, let $S_{i,j}^- = S^-(r, H, \{v_0, v_i\}, \{v_0, v_j\})$ be a copy of $S^-(r, H, \{x_0, u\}, \{x_0, u'\})$. Apart from the vertices $v_0, v_1, \dots, v_t$ let these copies of $S^-(r, H, \{x_0, u\}, \{x_0, u'\})$ be vertex disjoint. That is, let $V(S_{i,j}^-) \cap V(S_{i',j'}^-)$ be $\{v_0\}$ if $i \neq i'$ and $j \neq j'$, $\{v_0, v_i\}$ if $i = i'$ and $j \neq j'$, and $\{v_0, v_j\}$ if $i \neq i'$ and $j = j'$. Let S^+ be the union of these $S_{i,j}^-$.

By the construction, the vertices v_1 and v_t are nonadjacent in S^+ . We thus have only to prove that $S^+ = S^+(r, H, \{v_0, v_1\}, \{v_0, v_t\})$ is a positive signal sender. We do so with the following claim.

CLAIM 7.11. *The graph S^+ has the following properties:*

- (i) *Any copy of H in S^+ occurs within $S_{i,j}^-$ for some $\{v_i, v_j\} \in G$.*
- (ii) *There exists an H -free r -coloring of S^+ .*
- (iii) *Under any H -free r -coloring of S^+ , the edges $\{v_0, v_1\}$ and $\{v_0, v_t\}$ get the same colors.*

Sketch of proof. Property (i) follows from the fact that we started with a graph G' of girth greater than $|V(H)|$, and from the 3-connectedness of H . The proof is a simpler version of the proof of Claim 7.7, and so we omit it.

The proofs of properties (ii) and (iii) are completely analogous to the corresponding properties in the K_k case, so again we omit them. $\square$

This completes the proof of the claim, and thus the proof of part (b) of the lemma.

7.4. The proof of part (c) of Lemma 2.2. Fix an integer $g > 0$. We now prove that there exist a positive signal sender $S^+ = S^+(r, H, \{x_0, x_1\}, \{x_{g+1}, x_{g+2}\})$, and a negative signal sender $S^- = S^-(r, H, \{x_0, x_1\}, \{x_{g+1}, x_{g+2}\})$, such that in each of them, the edges $\{x_0, x_1\}$ and $\{x_{g+1}, x_{g+2}\}$ are distance g apart. Again, the proofs are constructive.

The construction of S^+ . For $i = 0, \dots, g$, let $S_i^+ = S^+(r, H, \{x_i, x_{i+1}\}, \{x_{i+1}, x_{i+2}\})$ be a copy of $S^+(r, H, \{v_0, v_1\}, \{v_0, v_t\})$ from part (b) of the lemma. Let S^+ be the union of these $g+1$ graphs, where all vertices except $x_1, \dots, x_{g+1}$ are distinct. (See Figure 7.3.)

Observe that S^+ contains the path $x_1, \dots, x_{g+1}$ of length g from $\{x_0, x_1\}$ to $\{x_{g+1}, x_{g+2}\}$. Since the vertices x_i and x_{i+2} were not adjacent in S_i^+ , for $i = 0, \dots, g$, and the only edges of S^+ are from the graphs S_i^+ , this is the shortest path between $\{x_0, x_1\}$ and $\{x_{g+1}, x_{g+2}\}$. Thus these edges are distance g apart.

To show that $S^+ = S^+(r, H, \{x_0, x_1\}, \{x_{g+1}, x_{g+2}\})$ is a positive signal sender, we prove the following claim.

CLAIM 7.12. *The graph S^+ has the following properties:*

- (i) *Any copy of H in S^+ occurs within S_i^+ for some $0 \leq i \leq g$.*
- (ii) *There exists an H -free r -coloring of S^+ .*
- (iii) *Under any H -free r -coloring of S^+ , the edges $\{x_0, x_1\}$ and $\{x_{g+1}, x_{g+2}\}$ get the same color.*

FIG. 7.3. S^+ where distinguished edges are distance g apart.

Sketch of proof. The proof of property (i) is very similar to the proof of property (i) of Claim 7.10.

To see that property (ii) is true, observe that any coloring that is constant on the edges $\{v_0, v_1\}, \{v_1, v_2\}, \dots, \{v_{g+1}, v_{g+2}\}$ can be extended to an H -free r -coloring of S^+ .

For property (iii), observe that any H -free r -coloring of S^+ is constant on the edges $\{v_0, v_1\}, \{v_1, v_2\}, \dots, \{v_{g+1}, v_{g+2}\}$. $\square$

The construction of S^- . Use exactly the same construction as for S^+ above, but replace the first positive sender, $S_0^+ = S^+(r, H, \{x_0, x_1\}, \{x_1, x_2\})$, with the negative sender $S^-(r, H, \{x_0, x_1\}, \{x_1, x_2\})$. Let S^- be the resulting graph.

The proof that S^- is a negative signal sender in which the edges $\{x_0, x_1\}$ and $\{x_{g+1}, x_{g+2}\}$ are distance g apart is very similar to the proof above for S^+ .

This completes the proof of the lemma. $\square$

GRAPH-DIFFERENT PERMUTATIONS*

JÁNOS KÖRNER[†], CLAUDIA MALVENUTO[†], AND GÁBOR SIMONYI[‡]

Abstract. For a finite graph G whose vertices are different natural numbers we call two infinite permutations of the natural numbers G -different if they have two adjacent vertices of G somewhere in the same position. The maximum number of pairwise G -different permutations of the naturals is always finite. We study this maximum as a graph invariant and relate it to a problem of the first two authors on colliding permutations. An improvement on the lower bound for the maximum number of pairwise colliding permutations is obtained.

Key words. extremal combinatorics, Shannon capacity of graphs, permutations

AMS subject classifications. 05D05, 05A15

DOI. 10.1137/070692686

1. Introduction. In [1] the first two authors began to investigate the following mathematical puzzle. Call two permutations of $[n] := \{1, \dots, n\}$ *colliding* if, represented by linear orderings of $[n]$, they put two consecutive elements of $[n]$ somewhere in the same position. For the maximum cardinality $\rho(n)$ of a set of pairwise colliding permutations of $[n]$ the following conjecture was formulated.

CONJECTURE 1 (see [1]). *For every $n \in \mathbb{N}$*

$$\rho(n) = \binom{n}{\lfloor \frac{n}{2} \rfloor}.$$

It was observed in [1] that the right-hand-side expression above is actually an upper bound for $\rho(n)$, while the best lower bound given there was a somewhat deceiving

$$(1) \quad 35^{n/7-O(1)} \leq \rho(n).$$

The initial motivation for the present work was to improve on the above lower bound. However, our main purpose in this paper is to study the new graph invariant mentioned in the abstract. We will analyze its possible values for simple classes of graphs and then apply some of the results to obtain a new lower bound for $\rho(n)$.

For brevity's sake let us call a graph *natural* if its vertex set is a finite subset of $\mathbb{N}$, the set of all positive integers, and if the graph is simple (without loops and multiple edges). An infinite permutation of $\mathbb{N}$ is simply a linear ordering of all the elements of $\mathbb{N}$. (Instead of *infinite permutations of $\mathbb{N}$* we will often say simply *infinite permutations* in what follows.) For an arbitrary natural graph $G = (V(G), E(G))$ we will call the infinite permutations $\pi = (\pi(1), \pi(2), \dots, \pi(n), \dots)$ and $\sigma = (\sigma(1), \sigma(2), \dots, \sigma(n), \dots)$ G -different if there is at least one $i \in \mathbb{N}$ for which

$$\{\pi(i), \sigma(i)\} \in E(G).$$

(We will use the same expression for a pair of finite sequences if at some coordinate they contain the two endpoints of an edge of G .) Let $\kappa(G)$ be the maximum cardinality of a set of infinite permutations any two elements of which are G -different. (It is easy to see that the finiteness of G implies that this number is finite as well; see Lemma 1 below.) Clearly, the value of κ is equal for isomorphic natural graphs. In this paper we will analyze this quantity for some elementary graphs and will apply some of the results to the problem of $\rho(n)$. We have been able to determine the value of $\kappa(G)$ only for some very small or simply structured graphs G . Thus, to further simplify matters, we ask questions about the extremal values of κ for graphs with a fixed number of edges (and, eventually, vertices). We define

$$(2) \quad K(\ell) = \max\{\kappa(G) ; |E(G)| = \ell\}$$

and

$$(3) \quad k(\ell) = \min\{\kappa(G) ; |E(G)| = \ell\}$$

as well as

$$(4) \quad K(v, \ell) = \max\{\kappa(G) ; |V(G)| = v, |E(G)| = \ell\}.$$

We also conjecture the following.

CONJECTURE 2. *For every $\ell \in \mathbb{N}$*

$$K(\ell) = 3^\ell.$$

In fact, we will show that $K(\ell)$ lies between 3^ℓ and 4^ℓ for every natural number ℓ . We will also see that $k(\ell)$ is linear in ℓ .

As we will explain, the values of $\kappa(P_r)$, where P_r is the r -vertex path, are relevant when investigating colliding permutations. Giving a lower bound on $\kappa(P_4)$, the lower bound of (1) will be improved to $10^{n/4-O(1)}$.

The concept of graph-different sequences from a fixed alphabet goes back to Shannon's classical paper on zero-error capacity [3]. As explained in the survey [2], a large body of problems in extremal combinatorics can be treated as zero-error problems in information theory. For the relationship of the present problems to zero-error information theory, we refer to [1].

2. Natural graphs and infinite permutations. Let G be a natural graph, and let again $\kappa(G)$ be the maximum cardinality of a set of infinite permutations any two elements of which are G -different, provided that this number is finite. It is easy to see that this is always the case. Let $\chi(G)$ denote the chromatic number of graph G .

LEMMA 1. *For every natural graph*

$$\kappa(G) \leq (\chi(G))^{|V(G)|}$$

holds.

Proof. Let us consider a proper coloring $c : V(G) \rightarrow \{1, \dots, \chi(G)\}$ of G . Let us write $v = |V(G)|$ and denote by $W = [\chi(G)]^{\mathbb{N}}$ the set of infinite sequences over the alphabet $\{1, \dots, \chi(G)\}$. Let μ be the uniform probability measure on W . Let us consider a set C of pairwise G -different permutations. We assign to any $\pi \in C$ the set $W(\pi)$ of all those sequences of W that for all $u \in V(G)$ have the element $c(u)$ in

the position where π contains u . By our hypothesis on C , the sets $W(\pi)$ are pairwise disjoint for the different elements $\pi \in C$, whence

$$1 = \mu(W) \geq \sum_{\pi \in C} \mu(W(\pi)) = \sum_{\pi \in C} \chi(G)^{-v} = |C| \chi(G)^{-v}. \quad \square$$

In the rest of this section we first investigate $K(\ell)$ and $k(\ell)$. Subsequently our new lower bound on $\rho(n)$ will be proved.

Let us denote by $S(G)$ the set of nonisolated vertices of the graph G . We introduce a graph transformation that increases the value of κ .

PROPOSITION 1. *Let F and G be two graphs with G obtained from F upon deleting an arbitrary edge in $E(F)$ followed by the addition of two new vertices to $V(F)$ so that the latter form an additional edge in G . Then*

$$\kappa(F) \leq \kappa(G).$$

Proof. Let us consider the $m = \kappa(F)$ pairwise F -different infinite permutations of an arbitrary optimal configuration for F . Let t be large enough for the initial prefixes of length t of these infinite sequences to be pairwise F -different, and let q be the largest integer appearing in their coordinates. By the finiteness of $\kappa(F)$ such t and q exist. Without restricting generality we can suppose that the new edge of G is $\{c, d\}$ with both c and d being strictly larger than q . We also suppose that the edge that we will delete is $\{a, b\} \in E(F)$. Let us now suffix to each of our length- t sequences a new sequence of the same length t , where the suffix to a sequence $x_1 x_2 \dots x_t$ is obtained from it by substituting every a with c and every b with d while the remaining coordinates are defined in an arbitrary manner but in such a way that the coordinates of the overall sequence of length $2t$ are all different. Clearly, the m new sequences of length $2t$ are G -different. To conclude, we can complete these new sequences to yield infinite permutations any way we like. $\square$

A straightforward consequence of the previous proposition is the following.

COROLLARY 1. $K(\ell) = \kappa(\ell K_2)$. $\square$

Thus we know that $K(\ell)$ is achieved by ℓ independent edges. It seems equally interesting to determine which graphs achieve $k(\ell)$. At first glance one might think that $S(F) \subseteq S(G)$ implies $\kappa(F) \leq \kappa(G)$, but this is false. In particular, complete graphs do not have minimum κ among graphs with the same number of edges. Yet, determining their κ value seems an interesting problem. As we will see, the right answer for what graphs achieve $k(\ell)$ turns out to be stars, at least for ℓ not too small. Below we will study the value of κ for complete graphs, stars, and paths. In particular, path graphs will take us back to the original puzzle about colliding permutations.

PROPOSITION 2. *For the complete graph K_n on n vertices*

$$\frac{(n+1)!}{2} \leq \kappa(K_n).$$

Proof. Consider the set of even permutations of $[n+1]$, and suppose $V(K_n) = [n]$. One can observe that these permutations are K_n -different. Indeed, if two arbitrary permutations of $[n+1]$ are not K_n -different, then they differ only in positions in which for some fixed $i \in [n]$ one has $n+1$ and the other has i . Thus any of these two permutations can be obtained from the other by exchanging the positions of $n+1$ and the corresponding i . But then the two permutations have different parity, and in particular they cannot both be even. In particular, the undesired relation does not

occur between even permutations, and this gives us $\frac{(n+1)!}{2}$ permutations of $[n+1]$ that are K_n -different. Next extend each of these permutations to infinite ones by suffixing the remaining natural numbers in an arbitrary order. $\square$

PROPOSITION 3. *For the graph of ℓ independent edges we have*

$$3^\ell \leq \kappa(\ell K_2) \leq 4^\ell.$$

Proof. Notice that the graph ℓK_2 has chromatic number two, and its number of vertices is 2ℓ , whence our upper bound follows by Lemma 1.

To prove the lower bound, let us denote the edge set of our graph by $E(\ell K_2) = \{\{1, 2\}, \{3, 4\}, \dots, \{2\ell - 1, 2\ell\}\}$. Consider the set of cyclic permutations $C_1 = \{(12\star), (2\star 1), (\star 12)\}$ and for every $1 < i \leq \ell$ the sets C_i obtained from C_1 by replacing 1 with $2i - 1$ and 2 with $2i$. It is clear that for every $i \in [\ell]$ any two of the three ministrings in C_i “differ” in the edge $\{2i - 1, 2i\}$ of our graph ℓK_2 , meaning that they have somewhere in the same position the two different endpoints of this edge. But this means that the 3^ℓ strings in their Cartesian product

$$C = \times_{i=1}^{\ell} C_i$$

are pairwise ℓK_2 -different as requested. Replacing the symbol $\star$ in our strings in an arbitrary order with the different numbers from $[3\ell] - [2\ell]$, we obtain 3^ℓ permutations of $[3\ell]$ that continue to be pairwise ℓK_2 -different. The extension to infinite permutations is as always. $\square$

The only infinite class of graphs for which we are able to determine κ are the stars, i.e., the complete bipartite graphs $K_{1,r}$. We have the following result.

PROPOSITION 4. *For every r*

$$\kappa(K_{1,r}) = 2r + 1.$$

Proof. By Lemma 1 we know that $\kappa(K_{1,r}) < \infty$. Let us denote its value by m . Let us consider the vertices of $K_{1,r}$ to be the elements of $[r + 1]$, and let 1 be the “central” vertex of degree r . It is obvious that in a set of m sequences (infinite permutations) achieving the maximum we are looking for, all the sequences must have the central vertex 1 in a different position. Let us consider our m sequences as vertices of a directed graph T in which $(a, b) \in E(T)$ if the sequence corresponding to a has a $j \in \{2, \dots, r + 1\}$ in the same position where the 1 of the sequence corresponding to b is placed. Then, by definition, the directed graph T must contain a tournament, implying that

$$|E(T)| \geq \binom{m}{2}.$$

On the other hand, every $a \in V(T)$ has at most r outgoing edges. This means that

$$|E(T)| \leq mr.$$

Comparing the last two inequalities, we get

$$m \leq 2r + 1.$$

To prove a matching lower bound, consider the following set of permutations of $[2r + 1]$. For every $i \in [2r + 1]$ let us define the coordinates of the i th sequence

$x_1(i)x_2(i)\dots x_{2r+1}(i)$ by $x_i(i) = 1$ and, in general, $x_{i+j}(i) = j + 1$ for any $0 \leq j \leq r$, where all the coordinate indices are considered modulo $2r + 1$. The remaining coordinates are defined in an arbitrary manner so that the resulting sequences define permutations of $[2r + 1]$. It is easily seen that this is a valid construction. In fact, observe that for any of our sequences the “useful” symbols, those of $[r + 1]$, corresponding to the vertices of the star graph, occupy $r + 1$ “cyclically” consecutive coordinates, forming cyclic intervals. Since $2(r + 1) > 2r + 1$, these intervals are pairwise intersecting, and thus for any two of them there must be a coordinate in the intersection for which the “left end” of one of the intervals is contained in the other. The resulting permutations can be considered as prefixes of infinite permutations in the usual obvious way. $\square$

Now we are ready to return to the problem of determining $k(\ell)$, at least for large enough ℓ . The following easy lemma will be needed.

LEMMA 2. *If a finite graph F contains vertex disjoint subgraphs $F_1, \dots, F_s$, then*

$$\kappa(F) \geq \prod_{i=1}^s \kappa(F_i).$$

Proof. The proof is a straightforward generalization of the construction given in the proof of Proposition 3. Let $\hat{C}_i$ be a set of $\kappa(F_i)$ infinite sequences that are obtained from $\kappa(F_i)$ pairwise F_i -different permutations of $\mathbb{N}$ by substituting all natural numbers $i \notin V(F_i)$ by a $\star$. As the sequences in $\hat{C}_i$ contain only a finite number of elements different from $\star$, we can take some finite initial segment of all these sequences that already contains all elements of $V(F_i)$. Let C_i be the set of these finite sequences. Now consider the set

$$C := \times_{i=1}^s C_i$$

of finite sequences that each contain all vertices in $\bigcup_{i=1}^s V(F_i)$ exactly once and finitely many $\star$'s. These sequences are also pairwise F_i -different for some F_i , and thus they are pairwise F -different. By construction, their number is $\prod_{i=1}^s \kappa(F_i)$. Extending them to infinite permutations of $\mathbb{N}$, the statement is proved. $\square$

It is straightforward from the previous lemma that if $F + G$ denotes the vertex disjoint union of graphs F and G , then $\kappa(F + G) \geq \kappa(F)\kappa(G)$. We do not know any example for strict inequality here. If equality was always true, that would immediately imply Conjecture 2.

Now we use Lemma 2 to prove our main result on $k(\ell)$.

PROPOSITION 5. *Let G be a natural graph with $n := |S(G)| > 20$ and $|E(G)| = \ell$. Then*

$$\kappa(G) \geq 2\ell + 1.$$

The value of $k(\ell)$ is achieved by the graph $K_{1,\ell}$ whenever $\ell > 150$.

Proof. Let G be a graph as in the statement, and let $\nu = \nu(G)$ denote the size of a largest matching in G .

First assume that $\nu \geq n/4$. Then by Proposition 3 and the obvious monotonicity of κ we have

$$\kappa(G) \geq \kappa(\nu K_2) \geq 3^\nu.$$

Since G is simple, we have $\ell \leq \binom{n}{2}$, and thus $k(\ell) \leq \kappa(K_{1, \binom{n}{2}}) = n(n - 1) + 1$. So in this case (when $\nu \geq n/4$) it is enough to prove that

$$3^{\lceil n/4 \rceil} \geq n(n - 1) + 1$$

holds. This is true if $n > 20$.

Next assume that $3 \leq \nu < n/4$. Consider a largest matching of G consisting of edges $\{u_{2i-1}, u_{2i}\}$ with $i = 1, \dots, \nu$. The set $U := \{u_1, \dots, u_{2\nu}\}$ covers all edges of G , and thus $\ell \leq \binom{2\nu}{2} + 2\nu(n - 2\nu)$. So we have

$$k(\ell) \leq \kappa(K_{1,\ell}) \leq 2 \left[\binom{2\nu}{2} + 2\nu(n - 2\nu) \right] + 1$$

in this case. On the other hand, for each vertex $a \in S(G) \setminus U$ there is an edge $\{a, u_i\}$ for some i . We also know that if a and b are two distinct vertices in $S(G) \setminus U$ and one of them is connected to u_{2j-1} (resp., u_{2j}) for some j , then the other one cannot be connected to u_{2j} (resp., u_{2j-1}), since otherwise replacing the matching edge $\{u_{2j-1}, u_{2j}\}$ with the other two edges of the path formed by the vertices a, u_{2j-1}, u_{2j}, b would result in a larger matching, a contradiction. Choosing an edge for each $a \in S(G) \setminus U$ that connects it to a vertex in U , we can form vertex disjoint star subgraphs $K_{1,\ell_1}, \dots, K_{1,\ell_\nu}$ of G , where $\ell_i \geq 1$ for all i and $\sum_{i=1}^\nu \ell_i = n - \nu$. Then by Lemma 2 and Proposition 4 we have $\kappa(G) \geq \prod_{i=1}^\nu (2\ell_i + 1)$. The latter product is minimal (with respect to the conditions on the ℓ_i 's) if one ℓ_i , say ℓ_1 , equals to $n - 2\nu + 1$ and $\ell_2 = \dots = \ell_\nu = 1$. Thus it is enough to prove that

$$3^{\nu-1}(2(n - 2\nu + 1) + 1) > 2 \left[\binom{2\nu}{2} + 2\nu(n - 2\nu) \right] + 1,$$

as the left-hand side is a lower bound on $\kappa(G)$, while the right-hand side is an upper bound on $k(\ell)$. The latter inequality would be implied by

$$3^{\nu-1}(n - 2\nu + 1) > \binom{2\nu}{2} + 2\nu(n - 2\nu) = \nu(2n - 2\nu - 1),$$

which, in turn, is equivalent to

$$\frac{3^{\nu-1}}{\nu} > \frac{2n - 2\nu - 1}{n - 2\nu + 1}.$$

The left-hand side of this last inequality is at least 3 if $\nu \geq 3$, while the right-hand side is strictly less than 3 for $\nu \leq n/4$.

The only case not yet covered is that of $\nu < 3$. For $\nu = 1$ there is nothing to prove, since then G itself is a star. If $\nu = 2$, then let a largest matching be formed by the two edges $\{u_1, u_2\}$ and $\{u_3, u_4\}$, while once again let U denote the union of their vertices. Let $a_1, \dots, a_{n-4}$ be the rest of the nonisolated vertices of G , and note that $n - 4 > 16$. Assume that some a_i is connected to both u_1 and u_2 , yielding a triangle. Then no a_j , $j \neq i$, can be connected to either of u_1 or u_2 ; otherwise we could form a larger matching. For similar reasons, if any a_j is connected to u_3 , then no a_s , $s \neq j$, can be connected to u_4 . (If some a_i forms a triangle with u_1, u_2 and some a_j with u_3 and u_4 , then the remaining vertices a_s must be isolated, implying $n \leq 6$, a contradiction.) Thus if a_i is connected to both u_1 and u_2 , then the rest of the a_j 's form a star centered at either u_3 or u_4 . Thus in this case, using again Lemma 2, Propositions 2 and 4 imply $\kappa(G) \geq 12[2(n - 4) + 1] = 24n - 84$. The foregoing also implies $\ell \leq n + 4$, thus $k(\ell) \leq 2n + 9 < 24n - 84$, whenever $n \geq 5$. Clearly, the situation is similar if we exchange the role of the two matching edges.

Assuming that no triangle is formed, we can again attach each vertex in $S(G) \setminus U$ to one of the edges $\{u_1, u_2\}$ and $\{u_3, u_4\}$, whichever it is connected to. Two vertex disjoint stars can be formed this way, establishing the lower bound $\kappa(G) \geq$

$3(2(n-3)+1) = 6n-15$. For the number of edges we now get $\ell \leq 6+2(n-4) = 2n-2$ since the graph induces at most 6 edges on U . Thus we have $k(\ell) \leq 4n-3$, which is less than $6n-15$ if $n > 6$. This completes the proof of the first statement.

If a simple graph has at most 20 vertices, then its number of edges is at most 190, so the second statement immediately follows from the first one if $\ell > 190$. If the graph contains a K_6 subgraph, then by Proposition 2 we have $\kappa(G) \geq 7!/2 > 381 = \kappa(K_{1,190}) \geq k(\ell)$ if $\ell \leq 190$. Thus we may assume $K_6 \not\subseteq G$, and this implies by Turán's theorem that $\ell \leq 160$ if $n \leq 20$. But $\kappa(K_{1,160}) = 321 \leq 6!/2$, so if the conclusion is not true, we may also assume that G has no K_5 subgraph. Applying Turán's theorem again, this gives $\ell \leq 150$ for $n \leq 20$. Thus the statement is true whenever $\ell > 150$. $\square$

Remark 1. We believe that the statement of Proposition 5 holds without any restriction on n or ℓ . Some improvement on our threshold on ℓ is easy to obtain. It seems to us, however, that proving the statement in full generality either leads to tedious case checkings or needs some new ideas.

The problem of determining κ seems interesting in itself; moreover, it helps to obtain better bounds for the original question on colliding permutations. To explain this, we introduce a notion connecting the two questions. Let $\kappa(G, n)$ be the maximum number of pairwise G -different permutations of $[n]$. Clearly,

$$(5) \quad \kappa(G) = \sup_n \kappa(G, n).$$

Notice that by the finiteness of $\kappa(G)$ the supremum above is always attained, so we could write maximum instead. Further, for the graph P_r , the path on r vertices, we have the following.

LEMMA 3. *For every $n > m > r$ the function ρ satisfies the recursion*

$$\rho(n) \geq \kappa(P_r, m)\rho(n-r).$$

Proof. We will call two arbitrary sequences of integers *colliding* if they have the same length and if somewhere in the same position they feature integers differing by 1. By the definition of $\kappa(P_r, m)$ we can construct this many sequences of length m such that in each of them every vertex of P_r appears exactly once, the other positions are occupied by the “dummy” symbol $\star$, and moreover these sequences are pairwise P_r -different. The latter implies that these sequences are pairwise colliding. Furthermore, we have, also by definition, $\rho(n-r)$ permutations of $[n-r]$ that are pairwise colliding. Let us “shift” these permutations by adding r to all of their coordinates. The new set of permutations of the set $r + [n-r] = [r+1, n]$ maintains the property that its elements are pairwise colliding. Next we execute our basic operation of “substituting” the permutations of the second set into those coordinates of any sequence $\mathbf{x}$ from the first set where the sequence $\mathbf{x}$ has a star. More precisely, consider any sequence $\mathbf{x} = x_1x_2 \dots x_m$ from our first set, and let $S(\mathbf{x}) \in \binom{[m]}{m-r}$ be the set of those coordinates which are occupied by stars. Let further $\mathbf{y} = y_1y_2 \dots y_{n-r}$ be an arbitrary sequence from our second set, i.e., a permutation of $[r+1, n]$. The sequence $\mathbf{z} = \mathbf{y} \rightarrow \mathbf{x}$ is a sequence of length n in which the first m coordinates are defined in the following manner. We have the equality $z_i = x_i$, if $i \leq m$ and $i \notin S(\mathbf{x})$. Suppose further that $S(\mathbf{x}) = \{j_1, j_2, \dots, j_{m-r}\}$. In the j_k th position we replace the symbol $\star$ by y_k . (For $i > m$ we set $z_i = y_{i-r}$.) Clearly, the resulting sequence is a permutation of $[n]$. Further, the so obtained $\kappa(P_r, m)\rho(n-r)$ permutations are pairwise colliding. $\square$

Observe next the following equality.

LEMMA 4.

$$\kappa(P_4, 5) = 10.$$

Remark 2. The existence of 10 permutations of $\{1, \dots, 5\}$ with the requested properties is implicit in [1] since the construction of the 35 colliding permutations of $\{1, \dots, 7\}$ in that paper does contain such a set in some appropriate projection of its coordinates.

Proof. Let us consider the 10 permutations of $\{1, \dots, 5\}$ obtainable by considering the cyclic configurations of $(1, 2)$, $(4, 3)$ and the single element 5. We indeed have 10 different permutations by “cutting” in all the five possible ways both of the two cyclic configurations that three building blocks can define. (So these are 12435, 24351, 43512, 35124, 51243 and similarly the five cyclic shifts of the sequence 43125.) Let us further consider the graph P_4 (or, in fact, $P_4 + K_1$) with vertex set $\{1, \dots, 5\}$ and with edge set $\{\{1, 2\}, \{2, 3\}, \{3, 4\}\}$. In other words, consecutive numbers are adjacent vertices, but 5 is isolated. It is easy to check that the 10 sequences above are P_4 -different for the natural graph we defined.

To see that 10 is an upper bound it is enough to observe that the two even elements of $\{1, \dots, 5\}$ cannot be placed in the same two positions in two permutations belonging to a set of P_4 -different permutations of $\{1, \dots, 5\}$. $\square$

The above construction gives the following improved lower bound for the exponential asymptotics of $\rho(n)$.

PROPOSITION 6.

$$\lim_{n \rightarrow \infty} \rho^{\frac{1}{n}}(n) \geq 10^{\frac{1}{4}}.$$

Proof. A simple combination of our two preceding lemmas implies

$$\rho(n) \geq 10\rho(n-4).$$

An iterated application of this inequality gives the desired result. $\square$

To close this section, let us take another look at Lemma 4. We believe that, in fact, $\kappa(P_4) = \kappa(P_4, 5) = 10$ and more generally,

$$\kappa(P_v) = \kappa(P_v, v+1) = \binom{v+1}{\lfloor \frac{v+1}{2} \rfloor}$$

for even values of v . The original conjecture (see Conjecture 1) for $\rho(v)$ would be an immediate consequence of this conjecture. To see this, suppose first that v is even. Then $\rho(v+1) = \kappa(P_{v+1}, v+1) \geq \kappa(P_v, v+1)$, and this would imply Conjecture 1 for odd values of n right away. Now, since for even n

$$\rho(n) = \kappa(P_n, n) \geq 2\kappa(P_{n-2}, n-1)$$

and likewise,

$$\binom{n}{\frac{n}{2}} = 2 \binom{n-1}{\lfloor \frac{n-1}{2} \rfloor},$$

the last two relations would lead us to settle the conjecture for n even. (The inequality above follows by putting an n to the end of each sequence in an optimal construction

for $\kappa(P_{n-2}, n-1)$ and then doubling each sequence by considering also its variant, which one obtains by exchanging in it $n-1$ and n .)

We also believe that

$$K(v, v-1) = \kappa(P_v).$$

As a combination of the two conjectures above we would arrive at the next statement.

CONJECTURE 3. *For every even $v \in \mathbb{N}$*

$$K(v, v-1) = \binom{v+1}{\lfloor \frac{v+1}{2} \rfloor}.$$

3. Related problems.

3.1. A graph covering problem. We show that determining $K(\ell)$ is equivalent to a graph covering problem introduced below. The following standard definition is needed.

DEFINITION 1. *The (undirected) line graph $L(D)$ of the directed graph $D = (V, A)$ is defined by*

$$\begin{aligned} V(L(D)) &= A, \\ E(L(D)) &= \{(a, b), (c, d)\} : b = c \text{ or } a = d\}. \end{aligned}$$

Let $\mathcal{L}$ denote the family of all finite simple graphs that are isomorphic to the line graph of some directed graph with possibly multiple edges.

Let the minimum number of graphs in $\mathcal{L}$, the edge sets of which together can cover the edges of the complete graph K_n , be denoted by $h(n)$.

PROPOSITION 7. *For any $M \in \mathbb{N}$, the minimum number ℓ for which $K(\ell) \geq M$ is equal to $h(M)$.*

Proof. Consider a construction attaining $K(\ell)$, that is, a graph G with ℓ edges and $K(\ell)$ infinite permutations that are G -different. Let this set of permutations be denoted by W , and let $\{a, b\}$ be one of the edges of G . Define a graph T_{a-b} on W as its vertex set where an edge is put between two permutations if and only if there is a position where one of them has a while the other has b . In other words, the two permutations are G -different by the edge $\{a, b\}$. Consider the graphs T_{a-b} for all edges of G . These all have the same vertex set, while the union of their edge sets clearly covers the complete graph K_M , where $M = K(\ell)$.

Next we show that all the graphs T_{a-b} belong to $\mathcal{L}$. To this end fix an edge $\{a, b\} \in V(G)$ and consider a graph D_{a-b} with its vertex set $V(D_{a-b})$ consisting of those positions where any of the permutations in W have a nonisolated vertex of G . Since G and W are finite, so is $V(D_{a-b})$. For each element of W we define an edge of D_{a-b} . For $\sigma \in W$, let i and j be the two positions where σ contains a and b , respectively. Then let σ be represented by the directed edge (i, j) in D_{a-b} . (If there is another permutation in W with a and b being in the same positions as in σ , then we have another arc (i, j) in D_{a-b} for this other permutation. Thus D_{a-b} is a directed multigraph.) Now it follows directly from the definitions that $T_{a-b} = L(D_{a-b})$, and thus T_{a-b} is indeed the line graph of a digraph. Together with the previous paragraph this proves $h(K(\ell)) \leq \ell$.

For the reverse inequality consider a covering of K_M with $h(M)$ graphs belonging to $\mathcal{L}$. Let the line graphs in this covering be $L_1, \dots, L_{h(M)}$. We may assume that $V(L_i) = [M]$ for all i by extending the smaller vertex sets through the addition of

isolated points. Let $D_1, \dots, D_{h(M)}$ be directed graphs satisfying $L_i = L(D_i)$ for all i . By $E(D_i) = V(L_i) = [M]$ we can consider the edges of all D_i 's labeled by $|E(D_i)|$ elements of $1, \dots, M$. (If L_i had some isolated vertices, then the corresponding labels are not used.) Using these digraphs, we define M permutations $\sigma_1, \dots, \sigma_M$ that are G -different for the graph $G = \ell K_2$ with $\ell = h(M)$. For all i define $t_i = |V(D_i)|$ and identify $V(D_i)$ with $[t_i]$. Consider D_1 . If D_1 has an edge labeled r and this edge is (i, j) , then put a 1 in position i of σ_r and put a 2 in position j of σ_r . Do similarly for all edges of D_1 . Then consider D_2 . If it has an edge labeled r which is (i', j') , then put a 3 in position $t_1 + i'$ of σ_r and put a 4 in position $t_1 + j'$ of σ_r . In general, if D_s has an edge labeled r which is (a, b) , then put a $2s - 1$ in position $(\sum_{k=1}^{s-1} t_k) + a$ and a $2s$ in position $(\sum_{k=1}^{s-1} t_k) + b$ of σ_r . When this is done for all edges of all D_i 's, then extend the obtained partial sequences to infinite permutations of $\mathbb{N}$ in an arbitrary manner. This way one obtains M permutations that are pairwise G -different. To see this consider two of these permutations, say, σ_q and σ_r . Look at the edge $\{q, r\}$ of our graph K_M that was covered by line graphs. Let L_i be the line graph that covered the edge $\{q, r\}$. Then D_i has an edge labeled q and another one labeled r in such a way that the head of the one is the tail of the other. This common point of these two edges defines a position of σ_q and σ_r where one of them has $2i - 1$ while the other has $2i$, making them G -different. $\square$

3.2. Fixed suborders. Here we consider a variant of the problem of the determination of $\kappa(G)$. We restrict attention to complete graphs.

Let $\kappa_{\text{id}}(K_n)$ denote the maximum number of infinite permutations of $\mathbb{N}$ that are K_n -different and contain the first n positive integers (the vertices of K_n) in their natural order.

PROPOSITION 8. *For every $n \in \mathbb{N}$*

$$\kappa_{\text{id}}(K_n) \geq C_n$$

holds, where $C_n = \frac{1}{n+1} \binom{2n}{n}$ is the n th Catalan number.

Proof. For $n = 1, 2$ we have equality: $\kappa_{\text{id}}(K_1) = 1$, $\kappa_{\text{id}}(K_2) = 2$. Set $a_0 = 1$ and $a_n := \kappa_{\text{id}}(K_n)$. It is enough to prove that the numbers a_n satisfy the inequality

$$a_{n+1} \geq \sum_{i=0}^n a_i a_{n-i}$$

that has the well-known recursion of Catalan numbers on its right-hand side (cf. [4]). We will look at our infinite permutations as infinite sequences consisting of infinitely many $\star$'s and one of each of the symbols $1, 2, \dots, n$, where the $\star$'s refer to all other symbols. Clearly, only the positions of the elements of $[n]$ are relevant with respect to the K_n -difference relation. Thus we will define the positions of the elements of $[n]$ and then let the $\star$'s be substituted by the other numbers in any way that will result in infinite permutations of $\mathbb{N}$.

Our construction is inductive. Assume that we already know that $a_k \geq C_k$ holds for $k \leq n$ and thus it suffices to prove it for $n + 1$. Fix a position of our permutations which is “far away,” meaning that it is far enough for having enough earlier positions for the following construction. Call this position j . For each $i = 0, \dots, n$ we construct $a_i a_{n-i}$ sequences having $i + 1$ at their position j . Any two of these sequences that have a different symbol at position j are K_n -different. For those sequences that have $i + 1$ at their position j do the following. Consider a construction of a_i pairwise K_i -different sequences consisting of symbols $1, \dots, i, \star$, where the symbols in $[i]$ are all

used somewhere in the first $j - 1$ positions (this is possible if j is chosen large enough). Take the first $j - 1$ coordinates of all these sequences, a_{n-i} times each, and continue each of them with an $i + 1$ at the j th position. So we have $a_i a_{n-i}$ sequences of length j with $i + 1$ at the j th position, each of these sequences are one of a_i possible types, and we have a_{n-i} copies from each type.

Now consider a_{n-i} sequences with the symbols $1, \dots, n - i, \star$ that are pairwise K_{n-i} -different, and shift each value in these sequences by $i + 1$. (The latter means that we change each value k to $k + i + 1$ in these sequences while $\star$'s remain $\star$'s.) For each type of the previous sequences take its a_{n-i} copies and suffix to each of them one of the current a_{n-i} different sequences. This way one gets $a_i a_{n-i}$ K_{n+1} -different sequences with symbol $i + 1$ at position j . Doing this for all $i = 1, \dots, n$, one obtains $\sum_{i=0}^n a_i a_{n-i}$ K_{n+1} -different sequences, proving the desired inequality. $\square$

Note added in proof. We learned from Graham Brightwell and Marianne Fairthorne that they have improved upon our lower bound in Proposition 6 using a similar approach and independently discovered some of the results (including Lemma 2 and Propositions 2 and 4) presented here.

Acknowledgments. The first author would like to thank Alexandr Kostochka for a stimulating discussion. Thanks also to Riccardo Silvestri for computer help.

REALIZING DEGREE SEQUENCES WITH GRAPHS HAVING NOWHERE-ZERO 3-FLOWS*

RONG LUO[†], RUI XU[‡], WENAN ZANG[§], AND CUN-QUAN ZHANG[¶]

Abstract. The following open problem was proposed by Archdeacon: Characterize all graphical sequences π such that some realization of π admits a nowhere-zero 3-flow. The purpose of this paper is to resolve this problem and present a complete characterization: A graphical sequence $\pi = (d_1, d_2, \dots, d_n)$ with minimum degree at least two has a realization that admits a nowhere-zero 3-flow if and only if $\pi \neq (3^4, 2), (k, 3^k), (k^2, 3^{k-1})$, where k is an odd integer.

Key words. degree sequence, graph, integer flow, characterization

DOI. 10.1137/070687372

1. Introduction. Let $G = (V, E)$ be a graph and let k be a positive integer. An ordered pair (D, ϕ) is called a k -flow of G if $D = (V, A)$ is an orientation of G and $\phi : A \mapsto Z_k$ is an assignment of flows such that, for every vertex v ,

$$\sum_{e \in E^+(v)} \phi(e) \equiv \sum_{e \in E^-(v)} \phi(e) \pmod{k},$$

where Z_k is the set Z/kZ of integers modulo k , and $E^+(v)$ (resp., $E^-(v)$) is the set of all arcs in A with tail v (resp., head v). We say that (D, ϕ) is a *nowhere-zero flow* if $\phi(e) \neq 0$ for any $e \in A$. This concept was introduced by Tutte [19], and the theory of nowhere-zero flows provides an interesting way to generalize theorems about region-coloring planar graphs to general graphs; major open problems in this area are Tutte's celebrated 3-, 4-, and 5-flow conjectures. Interested readers are referred to Jaeger [8] and Seymour [17] for the main ideas of this subject and to Tutte [20] and Zhang [21] for in-depth accounts.

An integer-valued sequence $\pi = (d_1, d_2, \dots, d_n)$ is called *graphical* if there is a *simple* graph G so that the degree sequence of G is exactly the same as π ; such a graph G is called a *realization* of π . For simplicity, we shall also write a graphical sequence in terms of multiplicities, for instance, $(6, 4, 4, 3, 3, 3, 3) = (6, 4^2, 3^4)$. The problem of realizing degree sequences with graphs enjoying certain properties has been a subject of extensive research. Recently a surprising application of graph realization with 4-flows has been found in the design of critical partial Latin squares [5, 15], which leads to the proof [14] of the so-called *simultaneous edge-coloring conjecture*

by Keedwell [10, 11] and Cameron [2]. In this paper we study a closely related open problem proposed by Archdeacon.

PROBLEM 1.1 (see [1]). *Characterize all graphical sequences π such that some realization of π admits a nowhere-zero 3-flow.*

Our objective is to resolve this problem and to present a complete characterization.

THEOREM 1.2. *A graphical sequence $\pi = (d_1, d_2, \dots, d_n)$ with minimum degree at least two has a realization that admits a nowhere-zero 3-flow if and only if $\pi \neq (3^4, 2), (k, 3^k), (k^2, 3^{k-1})$, where k is an odd integer.*

It is worthwhile pointing out that the most striking difference between [14] and the present paper is not the flow number but the proof technique. We say that a graph H is a k -flow contractible configuration if for every graph G containing H as a subgraph, G admits a nowhere-zero k -flow if and only if so does G/H . Actually flow contractible configurations play important roles in both papers: For the 4-flow problem, every circuit of length at most four (cf. Seymour [16] and Catlin [3]) is contractible. The situation, however, becomes much more complicated for the 3-flow problem, and the digon is the only circuit that is 3-flow contractible [16]. So we have to appeal to other 3-flow contractible configurations. To be more precise, a graph $G = (V, E)$ is Z_k -connected [9] if for every $b : V \mapsto Z_k$ with $\sum_{v \in V} b(v) \equiv 0 \pmod{k}$, there exist an orientation $D = (V, A)$ of G and an assignment $\phi : A \mapsto \{1, 2, \dots, k\}$ such that for every vertex v ,

$$\sum_{e \in E^+(v)} \phi(e) - \sum_{e \in E^-(v)} \phi(e) \equiv b(v) \pmod{k}.$$

As shown in [4, 13], Z_3 -connected graphs contain even wheels, triangularly connected graphs with a family of well-described exceptions, etc.; it is Z_3 -connected graphs that will serve as contractible configurations in our proof.

The remainder of this paper is organized as follows. In section 2, we exhibit some basic properties concerning graphical sequences and Z_3 -connectivity. In section 3, we describe some graphical sequences with Z_3 -connected realizations. In section 4, we characterize certain graphical sequences π such that some realization of π admits a nowhere-zero 3-flow and contains nontrivial Z_3 -connected subgraphs. In section 5, we present a proof of the main theorem (Theorem 1.2), which fully characterizes all graphical sequences that can be realized to admit nowhere-zero 3-flows.

We remark that a complete characterization of graphic sequences with Z_3 -connected realizations remains an interesting problem for further study.

2. Preliminaries. Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n$. Throughout we reserve the symbol $\bar{\pi}$ for the sequence $(d_1 - 1, d_2 - 1, \dots, d_{d_n} - 1, d_{d_n+1}, \dots, d_{n-1})$, which is called the *residual sequence* obtained from π by laying off d_n . We shall frequently use the following well-known results in our proof.

LEMMA 2.1. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a sequence. Then*

- (a) $\sum_{i=1}^n d_i$ is even if π is graphical;
- (b) (Hakimi [6, 7]; Kleitman and Wang [12]) π is graphical if and only if so is $\bar{\pi}$.

LEMMA 2.2 (Tutte [18]). *A cubic graph admits a nowhere-zero 3-flow if and only if it is bipartite.*

Lemma 2.2 can be further generalized in the following way.

LEMMA 2.3. *If a graph G admits a nowhere-zero 3-flow, then the subgraph of G induced by all degree-three vertices is bipartite.*

If H is a connected subgraph of a graph G , then G *contracted by* H , denoted by G/H , is the graph obtained from G by deleting all edges in H and then identifying $V(H)$ into a single vertex. The following simple observations follow instantly from the definition of Z_k -connectivity.

LEMMA 2.4 (Jaeger [8]; Seymour [16]). *Every circuit of length at most $k - 1$ is Z_k -connected.*

LEMMA 2.5 (DeVos, Xu, and Yu [4]; Lai, Xu, and Zhang [13]). *Let H be a Z_3 -connected subgraph of a graph G .*

- (a) *If G/H admits a nowhere-zero 3-flow, then so does G .*
- (b) *If G/H is Z_3 -connected, then so is G .*

In our proof these facts enable us to work on a reduced graph after a series of contractions of Z_3 -connected subgraphs. The reduced graphs/graphical sequences often enjoy much nicer properties than the original ones, and therefore are much easier to manipulate.

The following two lemmas are immediate corollaries of Lemmas 2.5 and 2.4.

LEMMA 2.6. *Let G be a Z_3 -connected graph, and let G' be obtained from G by adding a new vertex v and making it adjacent to at least two vertices of G . Then G' is Z_3 -connected.*

LEMMA 2.7. *Let $G = (V, E)$ be a Z_3 -connected graph. Then for any $u, v \in V$ with $uv \notin E$, the graph obtained from G by adding an edge uv is Z_3 -connected.*

Let $G = (V, E)$ be a graph, and let u, v, w be three vertices of G with $uv, uw \in E$. In this paper we shall use $G_{[uv, uw]}$ to stand for the graph $G \cup \{vw\} \setminus \{uv, uw\}$.

LEMMA 2.8. *Let $G = (V, E)$ be a graph, and let u, v, w be three vertices of G with degree $d(u) \geq 4$ and $uv, uw \in E$. If $G_{[uv, uw]}$ is Z_3 -connected, then so is G .*

A graph $G = (V, E)$ is *triangularly connected* if for every $e, f \in E$ there exists a sequence of circuits $C_1, C_2, \dots, C_k$ such that $e \in E(C_1)$, $f \in E(C_k)$, and $|E(C_i)| \leq 3$ for $1 \leq i \leq k$, and $E(C_j) \cap E(C_{j+1}) \neq \emptyset$ for $1 \leq j \leq k - 1$. A *wheel* W_k is the graph obtained from a k -circuit C by adding a vertex v and then making it adjacent to all vertices on C . By convention, we call v the *hub* and C the *rim* of W_k . We also call W_k *odd* if k is odd and *even* otherwise.

The following lemma gives sufficient conditions for a graph to be Z_3 -connected.

LEMMA 2.9 (DeVos, Xu, and Yu [4]). *Let G be a triangularly connected graph. Then G is Z_3 -connected, provided that one of the following conditions is satisfied:*

- (a) *G contains a nontrivial Z_3 -connected subgraph;*
- (b) *the minimum degree of G is at least four;*
- (c) *G is an even wheel W_k , with $k \geq 4$.*

The following lemma establishes the “only if” part of our main theorem (Theorem 1.2).

LEMMA 2.10. *Let k be an odd integer. Then no realization of the graphical sequences $(3^4, 2)$, $(k, 3^k)$, $(k^2, 3^{k-1})$ admits a nowhere-zero 3-flow.*

Proof. Observe the following:

- the only realization G_1 of $(3^4, 2)$ is the graph obtained from K_4 (the complete graph with four vertices) by subdividing an edge precisely once;
- a realization G_2 of $(k, 3^k)$ is *either* an odd wheel *or* several wheels sharing the hub, and at least one of these wheels is odd;
- the only realization G_3 of $(k^2, 3^{k-1})$ is $\frac{k-1}{2}$ copies of K_4 sharing a common edge. (To justify this, let u and v be the two vertices of maximum degree. Then the subgraph obtained from G_3 by deleting u and v is 1-regular.)

By Lemma 2.3, neither G_1 nor G_2 admits a nowhere-zero 3-flow. To prove the statement concerning sequence $(k^2, 3^{k-1})$, let Q_i be a copy of K_4 with vertex

set $\{w_i, x_i, y_i, z_i\}$ for $i = 1, 2, \dots, \frac{k-1}{2}$. As described above, G_3 is obtained from $Q_1, Q_2, \dots, Q_{\frac{k-1}{2}}$ by first identifying all y_i as a single vertex y and all z_i as a single vertex z , and then replacing all edges $y_i z_i$ with a single edge yz . Assume to the contrary that G_3 admits a nowhere-zero 3-flow (D, f) . Then there must exist a 3-flow (D, f_i) of each Q_i such that

- $f(e) = f_i(e)$ for every edge $e \in Q_i - \{yz\}$ (that is, $\text{supp}(f_i) \supseteq E(Q_i) - \{yz\}$) and
- $f = \sum_{i=1}^{\frac{k-1}{2}} f_i$, which implies the existence of a subscript i such that f_i is nowhere-zero on $Q_i (= K_4)$, contradicting Lemma 2.2. $\square$

3. Z_3 -connected realizations. The purpose of this section is to establish the following two theorems, which give some sufficient conditions for Z_3 -connected realizations.

THEOREM 3.1. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n$. If $d_n \geq 3$ and $d_{n-3} \geq 4$, then π has a Z_3 -connected realization.*

THEOREM 3.2. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $n-1 = d_1 \geq d_2 \geq \dots \geq d_n \geq 3$. Then π has a Z_3 -connected realization if and only if $\pi \neq (k, 3^k), (k^2, 3^{k-1})$, where k is odd.*

Let us establish a weaker version of Theorem 3.1 before presenting a proof.

LEMMA 3.3. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n$. If $d_n \geq 3$ and $d_{n-2} \geq 4$, then π has a Z_3 -connected realization.*

Proof. Suppose the contrary: $\pi = (d_1, d_2, \dots, d_n)$ is a counterexample with smallest n . According to the configuration of π , we propose to consider four cases and construct a Z_3 -connected realization of π in each case, thereby reaching a contradiction. Notice that $n \geq 5$ as $n-1 \geq d_1 \geq d_{n-2} \geq 4$.

The lemma is to be proved step by step with the following observations and claims.

(1) $d_1 \geq 5$. Assume the contrary: $d_1 = 4$. Let us consider the following two cases.

Case 1. $d_1 = 4$ and $d_n = 4$. In this case $\pi = (4^n)$, the construction goes as follows: Let C be a circuit with n vertices $v_1, v_2, \dots, v_n$, and let $G^1 = C \cup \bigcup_{i=1}^n \{v_i v_{i+2}\}$, where $v_{n+1} = v_1$ and $v_{n+2} = v_2$. Clearly, G^1 is 4-regular and is triangularly connected. By Lemma 2.9(b), G^1 is Z_3 -connected.

Case 2. $d_1 = 4$ and $d_n = 3$. Since $d_1 = d_{n-2} = 4$ and $d_n = 3$, by Lemma 2.1(a) we have $\pi = (4^{n-2}, 3^2)$. Let G^1 be the graph constructed in Case 1, and let $G^2 = G^1 \setminus \{v_2 v_n\}$. Clearly G^2 is a realization of π . It remains to show that G^2 is Z_3 -connected.

From the construction of G^1 and G^2 , we see that $G^2_{[v_1 v_2, v_1 v_3]}$ is triangularly connected and contains a 2-circuit $v_2 v_3 v_2$. Since any 2-circuit is Z_3 -connected (by Lemma 2.4), Lemma 2.9(a) implies that $G^2_{[v_0 v_1, v_0 v_2]}$ is Z_3 -connected, and hence so is G^2 by Lemma 2.8. Therefore (1) holds.

(2) $d_2 = 4$. Suppose to the contrary that $d_2 \geq 5$. By (1), we have $d_1 \geq 5$ and $d_2 \geq 5$.

Since $n \geq 5$ and $d_{n-2} \geq 4$, we get $d_3 \geq 4$. Hence it can be seen that the residual sequence $\bar{\pi} = (\bar{d}_1, \bar{d}_2, \dots, \bar{d}_{n-1})$, with $\bar{d}_1 \geq \bar{d}_2 \geq \dots \geq \bar{d}_{n-1}$, satisfies $\bar{d}_{n-1} \geq 3$ and $\bar{d}_{n-3} \geq 4$. Thus Lemma 2.1(b) and the assumption on π guarantee the existence of a Z_3 -connected realization $\bar{G}$ of $\bar{\pi}$. We can then get a realization G^3 of π from $\bar{G}$ by adding a new vertex v and d_n edges joining v to the corresponding vertices in $\bar{G}$. By Lemma 2.6, G^3 is Z_3 -connected. This proves (2).

We claim that (3) $d_n = 3$. Otherwise, $d_n = 4$. By (1) and (2), we have $d_1 \geq 5$ and $d_2 = 4$. So $\pi = (d_1, 4, \dots, 4)$. By Lemma 2.1(a), d_1 is even. Thus $d_1 \geq 6$.

Set $k = \frac{d_1-4}{2}$. Let G^1 be the 4-regular triangularly connected graph exhibited in Case 1 of (1). For each $1 \leq i \leq k$, we subdivide the edge $v_{2i+2}v_{2i+3}$ once by a degree-two vertex u_i . Since $n-1 \geq d_1 = 2k+4$, we have $2k+3 \leq n-2$. Now let us identify all u_i with v_1 . Then the resulting graph G^4 is simple and is clearly a realization of π . To show that G^4 is Z_3 -connected, we replace the path $v_{2i+2}v_1v_{2i+3}$ with an edge $v_{2i+2}v_{2i+3}$ for all $1 \leq i \leq k$; the resulting graph is precisely G^1 . Since G^1 is Z_3 -connected, repeated applications of Lemma 2.8 imply that so is G^4 . Thus (3) follows.

By (1), (2), and (3), we have $d_1 \geq 5$, $d_2 = 4$, and $d_n = 3$. So π is either $(d_1, 4, \dots, 4, 3, 3)$ or $(d_1, 4, \dots, 4, 3)$.

If $d_{n-1} = 4$, then the residual sequence $\bar{\pi}$ satisfies the conditions of the theorem, so it admits a Z_3 -connected realization $\bar{G}$, and hence so does G . It remains to consider the case when $d_{n-1} = 3$. Since $d_2 = d_3 = \dots = d_{n-2} = 4$ and $d_{n-1} = d_n = 3$, we see that d_1 is even. So $d_1 \geq 6$. Set $k = \frac{d_1-4}{2}$. Let G^2 be the triangularly connected graph constructed in Case 2 of (1). For each $1 \leq i \leq k$, we subdivide the edge $v_{2i+2}v_{2i+3}$ once by a degree-two vertex u_i . Since $n-1 \geq d_n = 2k+4$, we have $2k+3 \leq n-2$. Now let us identify u_i and v_1 for each $1 \leq i \leq k$. Then the resulting graph G^5 is simple and is clearly a realization of π . To show that G^5 is Z_3 -connected, we replace the path $v_{2i+2}v_1v_{2i+3}$ with an edge $v_{2i+2}v_{2i+3}$ for all $1 \leq i \leq k$; then the resulting graph is precisely G^2 . Since G^2 is Z_3 -connected, by Lemma 2.8 so is G^5 , completing the proof of the lemma. $\square$

Proof of Theorem 3.1. Suppose the contrary: $\pi = (d_1, d_2, \dots, d_n)$ is a counterexample with smallest n . Notice that $n \geq 5$ as $n-1 \geq d_1 \geq d_{n-3} \geq 4$. By Lemma 3.3, we have

(1) $d_{n-2} = 3$.

Let us further make some simple observations.

(2) $d_2 = 4$. Otherwise, $d_2 \geq 5$ for $d_2 \geq d_{n-3} \geq 4$. So the residual sequence $\bar{\pi}$ satisfies the conditions of the theorem, and hence the assumption on π guarantees the existence of a Z_3 -connected realization $\bar{G}$ of $\bar{\pi}$. By Lemma 2.6, we can get a Z_3 -connected realization G of π from $\bar{G}$ by adding a new vertex v and d_n edges joining v to the corresponding vertices in $\bar{G}$. This contradiction implies (2).

Combining (1), (2), and the hypothesis of the theorem, we get

(3) $\pi = (d_1, 4^{n-4}, 3^3)$. So d_1 is odd by Lemma 2.1(a) and hence at least 5.

(4) $n \geq 8$. Suppose to the contrary that $n \leq 7$. Since $d_1 \geq 5$ and is odd by (3), we have $d_1 = 5$ and $n \geq 6$. So $\pi = (5, 4^{n-4}, 3^3)$.

For $n = 6$, let G be the graph obtained from the complete bipartite graph $K_{2,3}$ by adding a new vertex and then making it adjacent to each vertex in the $K_{2,3}$. Clearly each edge of G is contained in a wheel W_4 . Since W_4 is Z_3 -connected by Lemma 2.9(c), so is G by Lemma 2.5(b).

For $n = 7$, let G be the graph obtained from W_4 by adding two adjacent vertices v_1 and v_2 and then making v_1 adjacent to the hub of W_4 and a rim vertex and making v_2 adjacent to two other rim vertices. Since both W_4 and the graph obtained from G by contracting W_4 (which results in a triangle with parallel edges) are Z_3 -connected, so is G by Lemma 2.5(b); this contradiction establishes (4).

Let us distinguish between two cases according to the value of d_1 .

Case 1. $d_1 \geq n-3$. Set $k = \frac{d_1-5}{2} \geq 0$ and $m = \lfloor \frac{n-4}{2} \rfloor$. Take a wheel W_{n-4} with hub w and rim $u_1u_2u_3 \dots u_{n-4}u_1$. Let H be the graph obtained from this wheel by adding k edges u_iu_{i+m} for $i = 1, 2, \dots, k$. Then the degree sequence of H is $(n-4, 4^{2k}, 3^{n-4-2k}) = (n-4, 4^{d_1-5}, 3^{n-d_1+1})$. To get a graph G with n vertices and degree sequence $\pi = (d_1, 4^{n-4}, 3^3)$, we need to add three vertices and

$[d_1 + 4(n - 4) + 9 - (n - 4) - 4(d_1 - 5) - 3(n - d_1 + 1)]/2 = 7$ edges to H . The construction of G goes as follows: We first add a path $P = v_1v_2v_3$ to H , then we connect w and $d_1 - (n - 4)$ vertices on P , and finally add precisely one edge between each of $n - d_1 + 1$ degree-three vertices on H and P , so that there are precisely two edges between each of v_1 and v_3 and H , and there is precisely one edge between v_2 and H .

By (4), $n \geq 8$. Note that if $n = 8$, then $H = W_4$; if $n \geq 9$, then at least one edge is added to W_{n-4} , which implies that H contains an even wheel. So, by Lemma 2.9(c), H contains a Z_3 -connected subgraph (an even wheel) in either case. Clearly, G/H is triangularly connected and contains a 2-circuit. Since a 2-circuit is Z_3 -connected, so is G/H by Lemma 2.9(a). It follows from Lemma 2.5(b) that G is Z_3 -connected, a contradiction.

Case 2. $d_1 \leq n - 4$. By (3), $d_1 \geq 5$. So in this case $n \geq d_1 + 4 \geq 9$. Let us consider the sequence $\sigma = (d_1 - 1, 4^{n-7}, 3^2)$. From the construction of G^2 and G^5 of the proof of Lemma 3.3, we deduce that σ has a Z_3 -connected realization H ; let u_1, u_2, u_3 denote the vertices of H with degree three and degree $d_1 - 1$, respectively. Let G be the graph obtained from H by first adding a complete graph with four vertices v_1, v_2, v_3, v_4 , then deleting edge v_1v_3 , and finally adding a matching of size three between $\{u_1, u_2, u_3\}$ and $\{v_1, v_2, v_3\}$. Clearly, G is a realization of π . Note that G/H is a wheel W_4 with hub v_2 , so by Lemma 2.9(c) it is Z_3 -connected, and hence so is G by Lemma 2.5(b). This contradiction completes the proof of the theorem. $\square$

The proof of Theorem 3.2 is based on the following lemma.

LEMMA 3.4. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n \geq 2$. Then π has a connected realization G that contains an even circuit if and only if $\pi \neq (2^n), (n - 1, 2^{n-1})$, where n is odd.*

Proof. It is easy to see that when n is odd

- the unique connected realization of $\pi = (2^n)$ is an odd circuit;
- the unique connected realization of $\pi = (n - 1, 2^{n-1})$ is $\frac{n-1}{2}$ triangles sharing a common vertex.

Clearly neither of these two graphs contains an even circuit, so the “only if” part is established.

Let us proceed to the “if” part. Assume that $\pi \neq (2^n), (n - 1, 2^{n-1})$, where n is odd, but no connected realization of π contains an even circuit. We further assume that π is chosen with minimum n . Let us make some simple observations.

(1) $n \geq 5$. By the assumption on π , we have $n \neq 3$. Hence $n \geq 4$. If $n = 4$, then $\pi = (2^4)$ or $(3^2, 2^2)$ or (3^4) . In each case π has a connected realization that contains an even circuit. This contradiction yields (1).

(2) $d_n = 2$. Otherwise, $d_n \geq 3$. By (1), the residual sequence $\bar{\pi}$ satisfies the condition of the lemma. Hence it admits a connected realization H that contains an even circuit by the assumption on π . We can then get a desired realization G of π from H by adding a new vertex and making it adjacent to corresponding vertices in H , a contradiction. So (2) holds.

(3) $d_2 \geq 3$. Otherwise, by (2) we have $d_2 = 2$, and so $\pi = (d_1, 2^{n-1})$, where $d_1 = 2k$ for some integer $k \geq 1$. Let H be the graph obtained from k disjoint triangles and then gluing them at a common vertex v . Note that the number of vertices in H is $2k + 1$. According to the assumption on π , we have $n \neq 2k + 1$ and $k \geq 2$. So $2k + 1 \leq n - 1$. Let G be the graph obtained from H by inserting a degree-two vertex into the edge not containing v in the first triangle, and inserting the remaining degree-two vertices (if any) into the edge not containing v in the second triangle. Then G is a connected realization of π that contains an even circuit (of length four), a contradiction. So (3) is proved.

Consider the residual sequence $\bar{\pi}$ of π . By (3), we have $d_1 - 1 \geq d_2 - 1 \geq 2$. If $\bar{\pi}$ satisfies the conditions of the lemma, then the assumption on π guarantees a connected realization H of $\bar{\pi}$ that contains an even circuit. From H we can obviously get a desired realization of π . This contradiction implies that $\bar{\pi} = (2^{n-1})$ or $(n-2, 2^{n-2})$, where $n-1$ is odd and thus n is even.

If $\bar{\pi} = (2^{n-1})$, then $\pi = (3^2, 2^{n-2})$ by (2). We can get a desired realization of π from an n -circuit by adding a chord.

If $\bar{\pi} = (n-2, 2^{n-2})$, then the unique connected realization H of $\bar{\pi}$ is $\frac{n-2}{2}$ triangles sharing a common vertex v . Note that $\pi = (n-1, 3, 2^{n-2})$ by (2). Let G be the graph obtained from H by adding a new vertex and making it adjacent to v and one other vertex. Clearly, G is a connected realization of π and contains an even circuit. This contradiction completes the proof. $\square$

Proof of Theorem 3.2. The “only if” part follows instantly from Lemma 2.10. It remains to show the “if” part.

Consider the sequence $\sigma = (d_2 - 1, d_3 - 1, \dots, d_n - 1)$. Note that $\sigma \neq (2^{n-1})$, $(n-2, 2^{n-2})$, where $n-1$ is odd, for otherwise $\pi = (n-1, 3^{n-1})$ or $((n-1)^2, 3^{n-2})$, contradicting the hypothesis on π . By Lemma 3.4, σ has a connected realization H that contains an even circuit. Let G be the graph obtained from H by adding a new vertex and making it adjacent to each vertex of H . Clearly G is a realization of π . Since G is triangularly connected and contains an even wheel, from Lemma 2.9 we deduce that G is Z_3 -connected. $\square$

4. Partially Z_3 -connected realizations. We propose to establish the following two theorems in this section.

THEOREM 4.1. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n \geq 3$ and $d_3 \geq 5$. Then π has a realization G such that*

- (a) G admits a nowhere-zero 3-flow; and
- (b) G has a Z_3 -connected subgraph H that contains all vertices of G with degree at least four.

THEOREM 4.2. *Let $\pi = (d_1, d_2, 4^{n-k-2}, 3^k)$ be a graphical sequence with $n-2 \geq d_1 \geq d_2 \geq 4$, $d_1 + d_2 \geq 11$, $n-3 \geq k \geq 4$, and $n \geq 9$. Then π has a realization G such that*

- (a) G admits a nowhere-zero 3-flow; and
- (b) G has a Z_3 -connected subgraph H that contains all vertices of G with degree at least four.

Let us introduce three operations before proving these theorems, which will be used frequently in our proofs.

Let H_1 and H_2 be two disjoint graphs. A graph G obtained by adding H_2 onto H_1 via Operation A, B, or C is defined below.

Operation A. Let $u_i v_i$ for $i = 1, 2, \dots, k$ be k edges of H_2 . The graph G is obtained from the union of H_1 and H_2 by first cutting each $u_i v_i$ into two edges $u_i x_i$ and $y_i v_i$ and then identifying each of x_i and y_i with a vertex of H_1 .

Operation B. Let $u_i v_i$ for $i = 1, 2, \dots, k$ be k edges of H_2 . The graph G is obtained from the union of H_1 and H_2 by inserting a degree-two vertex x_i into each $u_i v_i$ and then identifying each x_i with a vertex in H_1 .

Operation C. Let u be a vertex in H_2 with $d(u) = k \geq 2$, and let $u_1, u_2, \dots, u_t$ be t neighbors of u . The graph G is obtained from the union of H_1 and H_2 by splitting u into $t+1$ vertices $u'_1, u'_2, \dots, u'_t, u'$ such that u_i is the only neighbor of u'_i and that $d(u') = d(u) - t$, and then identifying each of those $t+1$ vertices with a vertex in H_1 .

LEMMA 4.3. *Let H_1 be a Z_3 -connected graph, and let H_2 be a cubic bipartite graph with at least four vertices. (H_2 is simple if it has at least six vertices or contains precisely two 2-circuits otherwise.) Then the graph G obtained by adding H_2 onto H_1 via Operation A, B, and/or C admits a nowhere-zero 3-flow.*

Remark. Obviously, the new graph G obtained via Operation C is simple as long as H_1 and H_2 are simple. Let H_3 be the graph obtained from H_2 by cutting all $u_i v_i$. Then the new graph G obtained via Operation A is simple if, first, H_3 and H_1 are simple; second, the edges in H_3 joining the same vertex of H_1 form a matching in H_3 . If G is obtained via Operation B, then G is simple if both H_1 and the graph obtained from H_2 by inserting a new degree-two vertex into each edge $u_i v_i$ are simple and the edges $u_i v_i$ form a matching in H_2 .

Proof. Note that H_1 remains intact in the new graph G , so it is still Z_3 -connected (as a subgraph of G). By Lemma 2.5(a), G admits a nowhere-zero 3-flow if and only if G/H_1 admits a nowhere-zero 3-flow.

Since H_2 is a cubic bipartite graph, by Lemma 2.2, it admits a nowhere-zero 3-flow. Furthermore, $G/H_1 = H_2$ if only Operation C is applied, and if Operation A or B is applied, then G/H_1 can be obtained from H_2 by subdividing some edges once and then identifying the new degree-two vertices as one vertex. Therefore, G/H_1 also admits a nowhere-zero 3-flow. $\square$

LEMMA 4.4. *Let $\pi = (d_1, d_2, 4^{n-4}, 3^2)$ be a sequence with $n - 1 \geq d_1 \geq d_2 \geq 4$ and $n \geq 5$. Then π is graphical, provided that $d_1 + d_2$ is even.*

Proof. Assume the contrary: π is a counterexample with minimum n . Then $n \geq 6$, for otherwise $n = 5$, so $\pi = (4^3, 3^2)$, and thus the graph obtained from K_5 by deleting one edge is a realization of π , a contradiction.

If $d_2 \geq 5$, then the residual sequence $\bar{\pi} = (d_1 - 1, d_2 - 1, 4^{n-5}, 3^2)$. From the assumption on π , we see that $\bar{\pi}$ is graphical and hence so is π , by Lemma 2.1(b); this contradiction yields $d_2 = 4$. Therefore $\pi = (d_1, 4^{n-3}, 3^2)$.

Since $d_1 + d_2 = d_1 + 4$ is even, so is d_1 . It follows that the graph G^2 (resp., G^5) in the proof of Lemma 3.3 is a realization of π if $d_1 = 4$ (resp., $d_1 \geq 6$). $\square$

LEMMA 4.5. *Let $\pi = (d_1, d_2, 5, 4^{n-3-k}, 3^k)$ be a graphical sequence with $n - 2 \geq d_1 \geq d_2 \geq 5$, $n - 3 \geq k \geq 5$, and $n \geq 9$. Then π has a realization G such that*

- (a) G admits a nowhere-zero 3-flow;
- (b) G has a Z_3 -connected subgraph H that contains all vertices of G with degree at least four.

Proof. Let us distinguish between two cases according to the parity of k .

Case 1. k is even. Since $k \geq 5$ and since the degree sum of π is even, in this case we have

- (1) $k \geq 6$, and $d_1 + d_2$ is odd.

We propose to construct a realization G of π with properties (a) and (b) using Lemma 4.3, such that the Z_3 -connected graph H_1 (recall Lemma 4.3) has degree sequence $\pi^* = (d_1^*, d_2^*, 4^{n-2-k}, 3^2)$, where d_1^* and d_2^* are to be determined, and the cubic bipartite graph H_2 has $k - 2$ vertices.

We are to determine d_1^* and d_2^* by letting $A_i = \max\{4, d_i - (k - 2)\}$ and $B_i = \min\{n - k + 1, d_i - 1\}$ for $i = 1, 2$. Then

- (2) $A_i \leq B_i$, and equality holds if and only if $A_i = B_i = 4$. To verify this, note that $4 \leq n - k + 1$ (because $k \leq n - 3$), $d_i - (k - 2) < d_i - 1$ (because $6 \leq k$), $4 \leq d_i - 1$ (because $5 \leq d_i$), and $d_i - (k - 2) < n - k + 1$ (because $d_i \leq n - 2$). Combining these inequalities yields $A_i \leq B_i$ and $d_i - (k - 2) < B_i$. It follows that $A_i = B_i$ if and only if both of them are four. So (2) is true.

Clearly (2) guarantees the existence of d_1^* and d_2^* such that

- $A_i \leq d_i^* \leq B_i$ for $i = 1, 2$;
- $d_1^* + d_2^*$ is even.

By Lemma 4.4, the sequence $\pi^* = (d_1^*, d_2^*, 4^{n-2-k}, 3^2)$ is graphical, and hence by Theorem 3.1 it admits a Z_3 -connected realization H_1 . By the definitions of A_i , B_i , and d_i^* , we have $d_i - (k-2) \leq d_i^* \leq d_i - 1$ for $i = 1, 2$, so

$$(3) \quad 1 \leq d_i - d_i^* \leq k - 2.$$

It follows that $2 \leq (d_1 + d_2) - (d_1^* + d_2^*) \leq 2(k-2)$. Since $d_1 + d_2$ is odd (by (1)) while $d_1^* + d_2^*$ is even, the above inequalities can be strengthened as $3 \leq (d_1 + d_2) - (d_1^* + d_2^*) \leq 2(k-2) - 1$, or equivalently

$$(4) \quad 2 \leq \frac{(d_1 + d_2) - (d_1^* + d_2^*) + 1}{2} \leq k - 2.$$

Using Lemma 4.3, a realization of π can be constructed as follows. Let H_2 be a cubic bipartite graph with $k-2$ (≥ 4) vertices, where H_2 is simple if $k \geq 8$ and contains precisely two disjoint 2-circuits, C_1 and C_2 , if $k = 6$. Then there exist two disjoint perfect matchings M_1, M_2 in H_2 such that $M_i \cap C_i \neq \emptyset$ for $i = 1, 2$ if $k = 6$. Without loss of generality, we assume that $d_1 - d_1^*$ is even. So $d_2 - d_2^*$ is odd. By (3), (4) and the selection of M_i , we can find a subset F_i of M_i such that $|F_1| = \frac{d_1 - d_1^*}{2}$, $|F_2| = \frac{d_2 - d_2^* + 1}{2}$, and $(F_1 \cup F_2) \cap C_i \neq \emptyset$ for $i = 1, 2$ if $k = 6$. Let v_i be the vertex with degree d_i^* in H_1 for $i = 1, 2$, and let ab be a special edge in F_2 . For $i = 1, 2$, let us subdivide each edge in F_i once by a degree-two vertex (let c denote this vertex on the special edge ab), then identifying all these degree-two vertices with v_i . At this stage, the resulting graph has the degree sequence $(d_1, d_2 + 1, 4^{n-2-k}, 3^k)$. Finally, switch the edge ca away from vertex v_2 to a degree-four vertex in $H_1 \setminus \{v_1, v_2\}$. Clearly, the resulting graph G is simple and is a desired realization of the sequence π .

Case 2. k is odd. In this case, we have

- (5) $d_1 + d_2$ is even. According to the value of k , we consider two possibilities.

Subcase 2.1. $k \leq n - 4$. The proof of this subcase goes along the same line as that of Case 1: We propose to construct a realization G of π with properties (a) and (b), using Lemma 4.3, such that the Z_3 -connected graph H_1 (recall Lemma 4.3) has degree sequence $\pi^* = (d_1^*, d_2^*, 4^{n-3-k}, 3^2)$, where d_1^* and d_2^* are to be determined, and the cubic bipartite graph H_2 has $k-1$ vertices.

We are to determine d_1^* and d_2^* by letting $A_i = \max\{4, d_i - (k-1)\}$ and $B_i = \min\{n-k, d_i - 1\}$ for $i = 1, 2$. It is a routine matter to check that

- (6) $A_i \leq B_i$, and equality holds if and only if $A_i = B_i = 4$.

Thus (6) guarantees the existence of d_1^* and d_2^* such that

- $A_i \leq d_i^* \leq B_i$ for $i = 1, 2$;
- $d_1^* + d_2^*$ is even.

By Lemma 4.4, the sequence $\pi^* = (d_1^*, d_2^*, 4^{n-3-k}, 3^2)$ is graphical, and hence by Theorem 3.1 it admits a Z_3 -connected realization H_1 . By the definitions of A_i , B_i , and d_i^* , we have $d_i - (k-1) \leq d_i^* \leq d_i - 1$ for $i = 1, 2$, so

$$(7) \quad 1 \leq d_i - d_i^* \leq k - 1.$$

Let H_2 be a cubic bipartite graph with $k-1$ (≥ 4) vertices, where H_2 is simple if $k \geq 7$, or contains precisely two disjoint 2-circuits, C_1 and C_2 , if $k = 5$. Renaming the subscripts if necessary, we assume that $d_1 - d_1^* \geq d_2 - d_2^*$. Set $t_1 = (d_1 - d_1^*)/2$ and $t_2 = (d_2 - d_2^*)/2$ if $d_1 - d_1^*$ is even, or, set $t_1 = (d_1 - d_1^* + 1)/2$ and $t_2 = (d_2 - d_2^* - 1)/2$ otherwise. Since $d_1 + d_2$ and $d_1^* + d_2^*$ have the same parity, t_1 and t_2 are both integers. Moreover, by (7) we have

- (8) $t_2 \leq t_1 \leq (k-1)/2$, and $t_2 < t_1$ if $d_1 - d_1^*$ is odd.

Let M_1, M_2, M_3 be three disjoint perfect matchings in H_2 . In view of (8), we can find a subset F_i of M_i such that $|F_i| = t_i$ for $i = 1, 2$, $|F_3| = 1$, and $(F_1 \cup F_2 \cup F_3) \cap C_i \neq \emptyset$ for $i = 1, 2$ if $k = 5$. Let v_i be the vertex with degree d_i^* in H_1 for $i = 1, 2$, let ab be a special edge in F_1 such that a is covered by no edge in F_2 if $d_1 - d_1^*$ is odd (such edge is available as $t_2 < t_1$), and let cd be the edge in F_3 . For $i = 1, 2$, let us subdivide each edge in F_i once by a degree-two vertex (let x denote this vertex on the special edge ab) and identify all these degree-two vertices with v_i . At this stage, the resulting graph has the degree sequence $(d_1, d_2, 4^{n-3-k}, 3^{k+1})$ if $d_1 - d_1^*$ is even, or $(d_1 + 1, d_2 - 1, 4^{n-3-k}, 3^{k+1})$ if $d_1 - d_1^*$ is odd. Then switch edge xa away from vertex v_1 to v_2 if $d_1 - d_1^*$ is odd, and finally cut cd ($\in F_3$) into two edges cx and yd and identify x (resp., y) with a degree-four (resp., degree-three) vertex in $H_1 \setminus \{v_1, v_2\}$. Clearly, the resulting graph G is simple and is a desired realization of the sequence π .

Subcase 2.2. $k = n - 3$. In this subcase, by the hypothesis of the theorem we have (9) $\pi = (d_1, d_2, 5, 3^k)$, where $n - 2 \geq d_1 \geq d_2 \geq 5$ and $n \geq 9$.

According to the hypothesis of Case 2, k is odd. From $k = n - 3$ and $n \geq 9$ we deduce that

$$(10) \quad k \geq 7.$$

By Lemma 4.4, the sequence $(4^3, 3^2)$ is graphical and hence, by Theorem 3.1, it admits a Z_3 -connected realization H_1 ; let x_1, x_2, x_3 be the three vertices of degree four in H_1 . Since $k \geq 7$ by (10), we can find a simple cubic bipartite graph H_2 with $k - 1$ vertices. Let u be a vertex of H_2 , let v_1, v_2, v_3 be the neighbors of u in H_2 , and let M_1, M_2, M_3 be three disjoint perfect matchings of H_2 . Renaming the subscripts if necessary, we assume $uv_i \in M_i$ for $i = 1, 2, 3$. Let G^* be the graph obtained from the union of H_1 and H_2 by first splitting u into three vertices $\{u_1, u_2, u_3\}$ (so the three edges incident with u in H_2 become u_1v_1, u_2v_2, u_3v_3) and then identifying u_i with x_i in H_1 for $i = 1, 2, 3$. At this stage, the resulting graph has the degree sequence $(5^3, 3^k)$.

Set $t_1 = (d_1 - 5)/2$ and $t_2 = (d_2 - 5)/2$ if d_1 is odd, and set $t_1 = (d_1 - 4)/2$ and $t_2 = (d_2 - 6)/2$ otherwise. Since $d_1 + d_2$ is even by (5), t_1 and t_2 are both integers. Moreover, since $k = n - 3$ and $n - 2 \geq d_1 \geq d_2 \geq 5$, we have

$$(11) \quad t_2 \leq t_1 \leq (k - 3)/2, \text{ and } t_2 < t_1 \text{ if } d_1 \text{ is even.}$$

Since $M_i - \{uv_i\}$ contains $(k - 3)/2$ edges, we can find a subset F_i of $M_i - \{uv_i\}$ such that $|F_i| = t_i$ for $i = 1, 2$. Let ab be a special edge in F_1 such that a is covered by no edge in F_2 if d_1 is even (such an edge is available as $t_2 < t_1$). We construct a graph from G^* as follows: For $i = 1, 2$, subdivide each edge in F_i once by a degree-two vertex (let c denote this vertex on the special edge ab), then identify all these degree-two vertices with x_i , and finally switch edge ca away from vertex x_1 to x_2 if d_1 is even. Clearly, the resulting graph G is simple and is a desired realization of the sequence π . $\square$

Now we are ready to establish the main results of this section.

Proof of Theorem 4.1. Assume the contrary: π is a counterexample with minimum n . By Theorem 3.1, we have the following:

- (1) $d_n = 3$.
- (2) The residual sequence $\bar{\pi}$ does not satisfy the hypothesis of the theorem.

Otherwise, from the assumption on π we deduce that $\bar{\pi}$ has a realization $\bar{G}$ such that

- $\bar{G}$ admits a nowhere-zero 3-flow;
- $\bar{G}$ has a Z_3 -connected subgraph $\bar{H}$ that contains all vertices of $\bar{G}$ with degree at least four.

Let G be the realization of π obtained from $\bar{G}$ by adding a new vertex v and three edges between v and corresponding vertices in $\bar{G}$ (recall (1)). Let H be the subgraph induced by $V(\bar{H}) \cup \{v\}$ in G . Since $\bar{H}$ contains all vertices of $\bar{G}$ with degree at least four, it also contains all vertices of G with degree at least four as $d_3 \geq 5$ and $d_n = 3$. So the degree of v in H is also three. Hence H is Z_3 -connected by Lemma 2.6. Note that the existence of a nowhere-zero 3-flow is preserved under edge contractions, so $\bar{G}/\bar{H}$ and hence G/H (as $\bar{G}/\bar{H} = G/H$) admits a nowhere-zero 3-flow. It follows from Lemma 2.5(a) that so does G . This contradiction implies (2).

(3) $d_1 \leq n - 2$. Otherwise, $d_1 = n - 1$. Since $d_3 \geq 5$, π has a Z_3 -connected realization by Theorem 3.2, a contradiction. So we get (3).

(4) $d_3 = 5$. Otherwise, $d_3 \geq 6$; combining this with (1), we see that $\bar{\pi}$ satisfies the hypothesis of the theorem, contradicting (2). So (4) holds.

Throughout the proof, let m_k denote the multiplicity of k in π . Then

(5) $m_3 \geq 5$. Otherwise, by Theorem 3.1, we have $m_3 = 4$. Thus precisely three entries of $\bar{\pi}$ are three by (1) and (4). It follows from Theorem 3.1 that $\bar{\pi}$ has a Z_3 -connected realization. Hence so does π by Lemma 2.6. This contradiction yields (5).

(6) $n \geq 9$. Otherwise, $n \leq 8$. From (4) and (5) we deduce that $n = 8$ and $m_3 = 5$. In view of (3), $d_1 \leq 6$. So $\pi = (5^3, 3^5)$ or $(6^2, 5, 3^5)$.

For $\pi = (5^3, 3^5)$, let G be the graph obtained from the disjoint union of a W_4 , with hub v_0 and rim $v_1v_2v_3v_4v_1$, and a path $v_5v_6v_7$ by adding edges $v_5v_1, v_5v_3, v_7v_1, v_7v_3, v_6v_0$. Then G/W_4 is triangularly connected and contains two 2-circuits. Since 2-circuits are Z_3 -connected, so is G/W_4 by Lemma 2.9(a). It follows from Lemmas 2.9(c) and 2.5(b) that G is Z_3 -connected.

For $\pi = (6^2, 5, 3^5)$, we have $\bar{\pi} = (5^2, 4, 3^4)$. Let $\bar{G}$ be the graph obtained from the disjoint union of a W_4 and a W_3 by identifying one rim edge of W_4 with a rim edge of W_3 . Then $\bar{G}$ is a realization of $\bar{\pi}$. Using the same proof employed in the preceding paragraph, we can justify that $\bar{G}$ is Z_3 -connected. Now let G be the graph obtained from $\bar{G}$ by adding a new vertex v and three edges between v and vertices of degree at least four in $\bar{G}$. Clearly, G is a realization of π and is Z_3 -connected by Lemma 2.6. This contradiction proves (6).

From (3), (4), (5), (6), and Lemma 4.5, we deduce the following:

(7) $d_4 = 5$.

(8) $d_2 = 5$. Otherwise, $d_2 \geq 6$. In view of (7), $\bar{\pi}$ satisfies the conditions of the theorem, contradicting (2).

(9) $d_5 \leq 4$. Suppose to the contrary that $d_5 \geq 5$. By (7), we have $d_5 = 5$. It follows that $d_1 = 5$ and $d_6 \leq 4$, for otherwise $\bar{\pi}$ satisfies the conditions of the theorem, contradicting (2). Thus $\pi = (5^5, 4^{m_4}, 3^{m_3})$. Consider the sequence $\pi^* = (4^{m_4+4}, 3^2)$. By Lemma 4.4, π^* is graphical. Thus it has a Z_3 -connected realization H_1 by Theorem 3.1. Note that m_3 is odd since $\pi = (5^5, 4^{m_4}, 3^{m_3})$ (by Lemma 2.1). Let H_2 be a bipartite cubic graph on $m_3 - 1$ (≥ 4) vertices, where H_2 is simple if $m_3 \geq 7$, or contains precisely two 2-circuits, C_1 and C_2 , if $m_3 = 5$. We take three edges e_1, e_2, e_3 in H_2 such that e_1 and e_2 are independent and that $e_i \in C_i$ for $i = 1, 2$ if $m_3 = 5$. Let us construct a graph from the disjoint union of H_1 and H_2 as follows: Cut each of e_1 and e_2 into two edges (let u_1, u_2, u_3, u_4 denote the new vertices), then subdivide e_3 once by a degree-two vertex v , and finally identify u_1, u_2, u_3, u_4 with four degree-four vertices in H_1 , respectively, and v with a degree-three vertex in H_1 . Clearly, G is a realization of π . It follows from Lemma 4.3 that G admits a nowhere-zero 3-flow. This contradiction implies (9).

From the above observations, we conclude

(10) $\pi = (d_1, 5^3, 4^{n-m_3-4}, 3^{m_3})$. So $m_3 \leq n - 4$.

Let us distinguish between two cases according to the parity of d_1 .

Case 1. d_1 is even. In view of (10), we have

(11) m_3 is odd.

We propose to construct a realization G of π with properties (a) and (b), using Lemma 4.3, such that the Z_3 -connected graph H_1 (recall Theorem 3.1) has degree sequence $\pi^* = (d_1^*, 4^{n-m_3-2}, 3^2)$, where d_1^* is to be determined, and the cubic bipartite graph H_2 has $m_3 - 1$ vertices.

In order to determine d_1^* , set $A = \max\{4, d_1 - (m_3 - 1)\}$ and $B = \min\{n - m_3, d_1\}$. By virtue of (3), (5), (10), and (11), it is a routine matter to check that

(12) $A \leq B$ and equality holds if and only if $A = B = 4$.

Thus (12) guarantees the existence of d_1^* such that $A \leq d_1^* \leq B$ and that d_1^* is even. By Lemma 4.4, the sequence $\pi^* = (d_1^*, 4^{n-m_3-2}, 3^2)$ is graphical, and hence by Theorem 3.1 it admits a Z_3 -connected realization H_1 . By the definitions of A , B , and d_1^* , we have $d_1 - (m_3 - 1) \leq d_1^* \leq d_1$, so

(13) $0 \leq d_1 - d_1^* \leq m_3 - 1$, and hence $0 \leq \frac{d_1 - d_1^*}{2} \leq \frac{m_3 - 1}{2}$ (recall Case 1).

Let H_2 be a cubic bipartite graph with $m_3 - 1$ (≥ 4) vertices, where H_2 is simple if $m_3 \geq 7$ and contains precisely two disjoint 2-circuits, C_1 and C_2 , if $m_3 = 5$ (see (11)). By (13), there exist two disjoint matchings M_1, M_2 in H_2 such that $|M_1| = \frac{d_1 - d_1^*}{2}$, $|M_2| = 2$, and $(M_1 \cup M_2) \cap C_i \neq \emptyset$ for $i = 1, 2$ if $m_3 = 5$. Let us first subdivide each edge in M_1 once by a new vertex and identify all these vertices with the vertex of degree d_1^* in H_1 , and then cut each edge in M_2 into two edges (let v_1, v_2, v_3, v_4 be the new vertices) and identify v_1, v_2, v_3 with three degree-four vertices in H_1 , respectively, and v_4 with a degree-three vertex in H_2 . Clearly, the resulting graph G is simple and is a desired realization of the sequence π . By Lemma 4.3, G admits a nowhere-zero 3-flow.

Case 2. d_1 is odd. From (10) we see that

(14) m_3 is even. So $m_3 \geq 6$ by (5).

We propose to construct a realization G of π with properties (a) and (b), using Lemma 4.3, such that the Z_3 -connected graph H_1 (recall Theorem 3.1) has degree sequence $\pi^* = (d_1^*, 4^{n-m_3-1}, 3^2)$, where d_1^* is to be determined, and the cubic bipartite graph H_2 has $m_3 - 2$ vertices.

To this end, set $A = \max\{4, d_1 - (m_3 - 2)\}$ and $B = \min\{n - m_3 + 1, d_1\}$. By virtue of (3), (5), (10), and (14), we get

(15) $A \leq B$ and equality holds if and only if $A = B = 4$.

Thus (15) guarantees the existence of d_1^* such that $A \leq d_1^* \leq B$ and that d_1^* is even. By Lemma 4.4, the sequence $\pi^* = (d_1^*, 4^{n-m_3-1}, 3^2)$ is graphical, and hence by Theorem 3.1 it admits a Z_3 -connected realization H_1 . By the definitions of A , B , and d_1^* , we have $d_1 - (m_3 - 2) \leq d_1^* \leq d_1$, so

(16) $0 \leq d_1 - d_1^* \leq m_3 - 2$, and hence $1 \leq \frac{d_1 - d_1^* + 1}{2} \leq \frac{m_3 - 2}{2}$ (as d_1 and d_1^* have different parities).

Let H_2 be a cubic bipartite graph with $m_3 - 2$ (≥ 4) vertices, where H_2 is simple if $m_3 \geq 8$, or contains precisely two disjoint 2-circuits, C_1 and C_2 , if $m_3 = 6$ (see (14)). By (16), there exist a pair of edge-disjoint matchings M_1, M_2 in H_2 such that $|M_1| = \frac{d_1 - d_1^* + 1}{2}$, $|M_2| = 1$, and $(M_1 \cup M_2) \cap C_i \neq \emptyset$ for $i = 1, 2$ if $m_3 = 6$. Let ab be a special edge in M_1 . We construct a graph from the disjoint union of H_1 and H_2 as follows: First subdivide each edge in M_1 once by a new vertex (let x be the new vertex on the special ab) and identify all these new vertices with the vertex v_1 of degree d_1^* in H_1 , then cut the edge in M_2 into two edges (let y, z be

the new vertices) and identify y, z with two degree-four vertices in H_1 , respectively. At this stage, the resulting graph has the degree sequence $(d_1 + 1, 5^2, 4^{n-m_3-3}, 3^{m_3})$. Finally, switch the edge ax away from v_1 to some degree-four vertex. Clearly, the resulting graph G is simple and is a desired realization of the sequence π (see (10)). By Lemma 4.3, G admits a nowhere-zero 3-flow. This contradiction completes the proof of the theorem. $\square$

Proof of Theorem 4.2. The proof goes along the same line as that of Lemma 4.5, so we give only a sketch here. Let us consider four cases according to the values of k and d_4 : In each case we propose to construct a realization G of π with properties (a) and (b) using Lemma 4.3; the degree sequence π^* of the Z_3 -connected graph H_1 (recall Lemma 4.3) and the number of vertices in the cubic bipartite graph H_2 are given below.

Case 1. k is even and at least six. The number of vertices in H_2 is $k - 2$, and the degree sequence π^* of H_1 is $(d_1^*, d_2^*, 4^{n-2-k}, 3^2)$. In order to determine d_1^* and d_2^* , we

- set $A_i = \max\{4, d_i - (k - 2)\}$ for $i = 1, 2$,
- set $B_1 = \min\{n - k + 1, d_1 - p\}$, where $p = 3$ if $d_2 = 4$ and 2 if $d_2 \geq 5$, and
- set $B_2 = \min\{n - k + 1, d_2 - q\}$, where $q = 0$ if $d_2 = 4$ and 1 if $d_2 \geq 5$.

Case 2. $k = 4$. The number of vertices in H_2 is k , and the degree sequence π^* of H_1 is $(d_1^*, d_2^*, 4^{n-4-k}, 3^2)$. In order to determine d_1^* and d_2^* , we

- set $A_i = \max\{4, d_i - k\}$ for $i = 1, 2$,
- set $B_1 = \min\{n - k - 1, d_1 - p\}$, where $p = 3$ if $d_2 = 4$ and 2 if $d_2 \geq 5$, and
- set $B_2 = \min\{n - k - 1, d_2 - q\}$, where $q = 0$ if $d_2 = 4$ and 1 if $d_2 \geq 5$.

Case 3. k is odd and $d_4 = 4$. The number of vertices in H_2 is $k - 1$, and the degree sequence π^* of H_1 is $(d_1^*, d_2^*, 4^{n-3-k}, 3^2)$. From $d_4 = 4$ it can be seen that $n - 3 - k \geq 1$. In order to determine d_1^* and d_2^* , we

- set $A_i = \max\{4, d_i - (k - 1)\}$ for $i = 1, 2$,
- set $B_1 = \min\{n - k, d_1 - p\}$, where $p = 3$ if $d_2 = 4$ and 2 if $d_2 \geq 5$, and
- set $B_2 = \min\{n - k, d_2 - q\}$, where $q = 0$ if $d_2 = 4$ and 1 if $d_2 \geq 5$.

In each of the above three cases, it is a routine matter to check that $A_i \leq B_i$ and equality holds if and only if $A_i = B_i = 4$. Thus there exist d_1^* and d_2^* such that

- $A_i \leq d_i^* \leq B_i$ for $i = 1, 2$;
- $d_1^* + d_2^*$ is even.

By Lemma 4.4, the sequence π^* is graphical, and hence by Theorem 3.1 it admits a Z_3 -connected realization H_1 . Clearly, we can choose H_2 so that it is simple if it has at least six vertices and contains precisely two disjoint 2-circuits otherwise. Note that H_2 contains three disjoint perfect matchings. By subdividing or cutting a certain number (at least two) of edges in these matchings, we can get a realization G of π , as desired.

Case 4. k is odd and $d_4 = 3$. In this case $n - k - 2 = 1$, so $k = n - 3$. Hence $\pi = (d_1, d_2, 4, 3^k)$, $k \geq 7$, and n is even (recall the hypothesis of the theorem). By Lemma 2.1(a), $d_1 + d_2$ is odd. From $d_1 + d_2 \geq 11$ we further deduce that $n - 3 \geq d_1 \geq 7$ if d_1 is odd.

Let H_1 be a Z_3 -connected realization of $(4^3, 3^2)$ in which vertices x_1, x_2, x_3 are of degree four, and let H_2 be a cubic bipartite graph with $k - 1$ vertices. Let u be a vertex of H_2 , let v_1, v_2, v_3 be the neighbors of u in H_2 , and let M_1, M_2, M_3 be three disjoint perfect matchings of H_2 . Renaming the subscripts if necessary, we assume $uv_i \in M_i$ for $i = 1, 2, 3$. For odd d_1 , let G^* be the graph obtained from the union of H_1 and H_2 by identifying x_1 and u . For even d_1 , let G^* be the graph obtained from the union of H_1 and H_2 by first splitting u into three vertices $\{u_1, u_2, u_3\}$ (so

the three edges incident with u in H_2 become u_1v_1, u_2v_2, u_3v_3) and then identifying u_1, u_2 with x_1 and u_3 with x_2 .

Set $t_1 = (d_1 - 7)/2$ and $t_2 = (d_2 - 4)/2$ if d_1 is odd, and set $t_1 = (d_1 - 6)/2$ and $t_2 = (d_2 - 5)/2$ otherwise. Since $d_1 + d_2$ is odd, t_1 and t_2 are both integers. Moreover, since $k = n - 3$, $n - 2 \geq d_1 \geq d_2 \geq 4$, and $d_1 \leq n - 3$ if d_1 is odd, we have

- $t_1 \leq (k - 1)/2 - 3$ if d_1 is odd and $t_1 \leq (k - 1)/2 - 2$ otherwise, and
- $t_2 \leq (k - 1)/2 - 1$ if d_1 is odd and $t_2 \leq (k - 1)/2 - 1$ otherwise.

For odd d_1 , let F_1 be a subset of M_1 such that F_1 covers none of v_1, v_2, v_3 and $|F_1| = t_1$, and let F_2 be a subset of M_2 such that $uv_2 \notin F_2$ and $|F_2| = t_2$. For even d_1 , let F_1 be a subset of M_1 such that F_1 covers neither v_1 nor v_2 and $|F_1| = t_1$, and let F_2 be a subset of M_3 such that $uv_3 \notin F_2$ and $|F_2| = t_2$. Finally, we construct a graph from G^* as follows: For $i = 1, 2$, subdivide each edge in F_i once by a degree-two vertex, and then identify all these degree-two vertices with x_i . Clearly, the resulting graph G is simple and is a realization of π that admits a nowhere-zero 3-flow, a contradiction. $\square$

5. Realizations with 3-flows. To establish the main theorem of this paper, we shall break the proof into two parts and turn to proving the following two theorems.

THEOREM 5.1. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n \geq 3$. Then π has a realization G that admits a nowhere-zero 3-flow if and only if $\pi \neq (k, 3^k), (k^2, 3^{k-1})$, where k is odd.*

THEOREM 5.2. *Let $\pi = (d_1, d_2, \dots, d_n)$ be a graphical sequence with $d_1 \geq d_2 \geq \dots \geq d_n = 2$. Then π has a realization G that admits a nowhere-zero 3-flow if and only if $\pi \neq (3^4, 2)$.*

The following lemma will be used repeatedly in our proof.

LEMMA 5.3. *Let $k \geq 4$ be an even integer, and let $\pi = (a_1, a_2, a_3, 3^k)$ be a sequence with $0 \leq a_i \leq k$. Then π has a realization that admits a nowhere-zero 3-flow if one of the following holds:*

- (a) a_i is even for $i = 1, 2, 3$, and $a_1 + a_2 + a_3 \geq 4$ if $k = 4$;
- (b) one of a_1, a_2, a_3 is even, and the remaining two are odd and at least three.

Proof. (a) Let H be a cubic bipartite graph with k vertices, where H is simple if $k \geq 6$, or contains precisely two disjoint 2-circuits, C_1 and C_2 , if $k = 4$. Then the edge set of H can be decomposed into three perfect matchings M_1, M_2, M_3 . Since $a_i \leq k$ and since $a_1 + a_2 + a_3 \geq 4$ if $k = 4$, we can find a subset F_i of M_i such that $|F_i| = \frac{a_i}{2}$ for $i = 1, 2, 3$ and that $(F_1 \cup F_2 \cup F_3) \cap C_i \neq \emptyset$ for $i = 1, 2$ if $k = 4$. For $i = 1, 2, 3$, let us subdivide each edge in F_i once by a degree-two vertex and then identify all these degree-two vertices as a single vertex v_i . Then the resulting graph G is a realization of the sequence π . By Lemma 2.2, H admits a nowhere-zero 3-flow, and so does G .

(b) Renaming the subscripts if necessary, we may assume that a_3 is even. By Lemma 2.1, k is even and so $a_i \leq k - 1$ for $i = 1, 2$. Let H be a simple cubic bipartite graph with $k + 2$ vertices, and let M_1, M_2, M_3 be three disjoint perfect matchings of H . Take an arbitrary edge u_1v_1 in M_1 , and take a subset F_i of M_i such that $|F_i| = \frac{a_i - 3}{2}$ for $i = 1, 2$, $|F_3| = \frac{a_3}{2}$, and F_1 (resp., F_2) covers no vertices of $N(u_1)$, the neighborhood of u_1 (resp., $N(v_1)$). Let us now subdivide each edge of F_1 (resp., F_2) once by a degree-two vertex and then identify all these degree-two vertices with u_1 (resp., v_1), and subdivide each edge of F_3 once by a degree-two vertex and then identify all these degree-two vertices. Then the resulting graph G is a realization of the sequence π . By Lemma 2.2, H admits a nowhere-zero 3-flow, and so does G . $\square$

Proof of Theorem 5.1. Since the “only if” part is already established by Lemma 2.10, let us proceed to the “if” part.

Assume the contrary: π is a counterexample with minimum n . By Theorems 3.1, we have

(1) $m_3 \geq 4$.

From Theorem 4.1 it can be seen that

(2) $d_3 \leq 4$.

Let us further make some simple observations.

(3) $4 \leq d_1 \leq n - 2$. The upper bound follows instantly from Theorem 3.2. To justify lower bound, we assume to the contrary that $d_1 = 3$. So $\pi = (3^n)$. Using the upper bound, we have $n \geq 5$. From Lemma 2.1(a) we deduce that n is even and so $n \geq 6$. Thus π can be realized by a bipartite cubic graph, which, by Lemma 2.2, admits a nowhere-zero 3-flow, a contradiction. So (3) holds.

(4) $d_2 \geq 4$. Otherwise, $d_2 = 3$. Thus $\pi = (d_1, 3^{n-1})$. If $n - 1$ is even, then so is d_1 . Set $a_1 = d_1$, $a_2 = a_3 = 0$, and $k = n - 1$. By (3) and Lemma 5.3(a), π has a realization that admits a nowhere-zero 3-flow, a contradiction.

So we assume that $n - 1$ is odd. In this case d_1 is also odd. Write $\pi = (d_1, 3, 3^{n-2})$. Set $a_1 = 0$, $a_2 = d_1$, $a_3 = 3$, and $k = n - 2$. Then, by (3) and Lemma 5.3(b), π has a realization that admits a nowhere-zero 3-flow, a contradiction. This proves (4).

(5) $d_3 = 4$. By (2), $d_3 \leq 4$. We prove by contradiction and assume $d_3 = 3$. Thus $\pi = (d_1, d_2, 3^{n-2})$. Observe that $d_1 + d_2$ is odd, for otherwise (1), (3), and Lemma 5.3 (with $a_i = d_i$ for $i = 1, 2$ and $a_3 = 0$) would guarantee the existence of a realization of π that admits a nowhere-zero 3-flow, a contradiction. It follows that n and exactly one of d_1 and d_2 are odd.

If $d_1 \leq n - 3$, then, by Lemma 5.3(b) (with $a_i = d_i$ for $i = 1, 2$, $a_3 = 3$, and $n - 3 \geq 4$ because n is odd), π has a realization that admits a nowhere-zero 3-flow; this contradiction implies that $d_1 = n - 2$. Hence d_1 is odd and d_2 is even. Now let us take odd wheel W_{n-2} with hub v_0 and rim $v_1 v_2 \dots v_{n-2} v_1$ and take $M = \{v_{2i} v_{2i+1} : 0 \leq i \leq d_2/2 - 1\}$. Clearly, M is a matching of size $d_2/2$. Let us subdivide each edge in M once and identify all the new vertices as a single vertex. Then the resulting graph is a realization of π and admits a nowhere-zero 3-flow (to find it, direct each of edges $v_0 u$, $v_0 v_2$, $v_0 v_3$ from v_0 to the other end, where u is the vertex subdividing $v_0 v_1$; then directions of the remaining edges can be determined accordingly). This contradiction implies (5).

(6) $n \geq 9$. Otherwise, $n \leq 8$. By (5) and (1), we have $d_3 = 4$ and $m_3 \geq 4$. So $n \geq 7$.

If $n = 7$ then, by (3), (5), and Lemma 2.1(a), we have $\pi = (4^3, 3^4)$ or $(5^2, 4, 3^4)$. For $\pi = (4^3, 3^4)$, clearly $K_{3,4}$ is a realization of π that admits a nowhere-zero 3-flow. For $\pi = (5^2, 4, 3^4)$, let G be the graph obtained from the union of W_4 and W_3 by identifying a rim edge of W_4 with a rim edge of W_3 . Then G is a realization of π that, by Lemma 2.9(c) and (a), admits a nowhere-zero 3-flow. So we have $n = 8$.

Since $d_3 = 4$ by (5), we have $m_3 \leq 5$; combining this with (1), we further have $m_3 = 4$ or 5 . Since $d_1 \leq 6$ by (3), one of the following cases must occur:

- $\pi = (6^2, 4^2, 3^4)$,
- $\pi = (6, 4^3, 3^4)$,
- $\pi = (4^4, 3^4)$,
- $\pi = (5^2, 4^2, 3^4)$,
- $\pi = (5, 4^2, 3^5)$, or
- $\pi = (6, 5, 4, 3^5)$.

For each π , we shall exhibit a realization G that admits a nowhere-zero 3-flow, thereby reaching a contradiction.

For $\pi = (6^2, 4^2, 3^4)$, let $\bar{G}$ be the graph obtained from the union of W_4 and W_3 by identifying a rim edge of W_4 with a rim edge of W_3 . Then $\bar{G}$ is the realization of the residual sequence $\bar{\pi}$ and $\bar{G}$ is Z_3 -connected. So it is easy to obtain a realization G of π from $\bar{G}$ such that G admits a nowhere-zero 3-flow, a contradiction.

For $\pi = (6, 4^3, 3^4)$, let G be the graph obtained from W_6 by adding an edge between two nonadjacent vertices, then subdividing two independent edges once each, and finally identifying these new vertices as one vertex. (Since W_6 is Z_3 -connected, so is the graph obtained from W_6 by adding an edge by Lemma 2.7.)

For $\pi = (4^4, 3^4)$, let G be the graph obtained from the cubic bipartite graph with four vertices by subdividing each of the four multiple edges once and then connecting these four degree-two vertices with a 4-circuit. (Note that G can be decomposed into a subdivision of a cubic bipartite graph and a 4-circuit.)

For $\pi = (5^2, 4^2, 3^4)$, let G be the graph obtained from the union of two W_4 's by identifying a rim edge of one W_4 with a rim edge of the other W_4 . (In fact G is Z_3 -connected.)

For $\pi = (5, 4^2, 3^5)$, let G be the graph obtained from a $K_{3,3}$ (with color classes $\{u_1, u_2, u_3\}$ and $\{v_1, v_2, v_3\}$) by subdividing $u_i v_i$ once with a degree-two vertex w_i for $i = 2, 3$, and then adding a triangle $u_1 w_2 w_3 u_1$.

For $\pi = (6, 5, 4, 3^5)$, let G be the graph obtained from W_4 (in which $u_1 u_2$ is a rim edge) by adding a path $v_1 v_3 v_2$ and then adding edges $v_1 u_1, v_1 u_2, v_2 u_1, v_2 u_2, v_3 u_1$. (Note that G is triangularly connected and contains W_4 . So it is Z_3 -connected, by Lemma 2.9(a).)

It is a routine matter to check that G is a realization of π and admits a nowhere-zero 3-flow in each case. This contradiction implies (6).

From (3), (5), (6), and Theorem 4.2, we deduce that

$$(7) \quad d_1 + d_2 \leq 10.$$

Since $d_1 \geq d_2 \geq 4$, we see that (d_1, d_2) is $(6, 4)$, or $(5, 5)$, or $(5, 4)$, or $(4, 4)$. So the following is the complete list of all possible configurations of π :

- $\pi = (6, 4^{m_4}, 3^{m_3})$,
- $\pi = (5^2, 4^{m_4}, 3^{m_3})$,
- $\pi = (5, 4^{m_4}, 3^{m_3})$, and
- $\pi = (4^{m_4}, 3^{m_3})$,

where m_k is the multiplicity of k in π . Let us process these cases one by one: For each π , we shall construct a realization G that admits a nowhere-zero 3-flow, thereby reaching a contradiction.

Case 1. $\pi = (4^{m_4}, 3^{m_3})$. Note that m_3 is even. Depending on the value of m_3 , we consider two subcases.

Subcase 1.1. $m_3 = 4$. Our proof relies on the following statement.

(8) The sequence $(4^k, 2^4)$, with $k \geq 1$, can be realized by a simple connected graph H that admits a nowhere-zero 3-flow. To justify this, we apply induction on k . For $k = 1$, the graph H_1 obtained from two triangles by gluing them at a common vertex is as desired. Suppose that H_k is the desired realization of $(4^k, 2^4)$. Let e, f be two independent edges in H_k , and let H_{k+1} be the graph obtained from H_k by first subdividing each of e, f once with a degree-two vertex and then identifying these degree-two vertices. Clearly, H_{k+1} is a realization of $(4^{k+1}, 2^4)$ and admits a nowhere-zero 2-flow since it is Eulerian. So (8) holds.

By (6), we have $m_4 \geq 5$. In view of (8), we can find a connected realization H of the sequence $(4^{m_4-4}, 2^4)$. Let G be the graph obtained from H by adding a bipartite cubic graph F with four vertices, then subdividing each of the four multiple edges in

F with a degree-two vertex, and finally identifying these four degree-two vertices with the degree-two vertices of H , respectively. Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

Subcase 1.2. $m_3 \geq 6$. For $m_4 \geq 5$, let H_1 be a bipartite cubic simple graph with m_3 vertices, and let H_2 be a Z_3 -connected realization of $(4^{m_4-2}, 3^2)$ (recall Lemmas 4.4 and 3.3). Then we can get a desired realization G of π by cutting one edge of H_1 and then connecting these two half edges to the degree-three vertices of H_2 , respectively. For $3 \leq m_4 \leq 4$, let G be the graph obtained from the union of H_1 and an m_4 -circuit H_3 by subdividing m_4 edges of H_1 once with degree-two vertices and then identifying these new vertices with m_4 vertices of H_3 , respectively. Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

Case 2. $\pi = (5, 4^{m_4}, 3^{m_3})$. Note that m_3 is odd, so $m_3 \geq 5$ by (1). We distinguish two subcases according to the value of m_3 .

Subcase 2.1. $m_3 = 5$. Recall that $n \geq 9$ by (6). For $n = 9$, let H_1 be the graph obtained from W_3 by adding a new vertex and joining it to two vertices of the W_3 . Clearly, H_1 admits a nowhere-zero 3-flow and has degree sequence $(4^2, 3^2, 2)$. For $n \geq 10$, we have $n - m_3 - 2 \geq 3$. By Lemma 4.4, the sequence $(4^{n-m_3-2}, 3^2)$ is graphical and hence, by Lemma 3.3, admits a Z_3 -connected realization F . Let H_1 be the graph obtained from F by subdividing one edge once. Clearly, H_1 admits a nowhere-zero 3-flow and has degree sequence $(4^{n-m_3-2}, 3^2, 2)$. Let H_2 be the cubic bipartite graph on four vertices in which both u_1v_1 and u_2v_2 are of multiplicity two, and let G be the graph obtained from the union of H_1 and H_2 by subdividing u_iv_i once for $i = 1, 2$, and then identifying one new vertex with the degree-two vertex of H_1 and the other new vertex with a degree-three vertex of H_1 . Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

Subcase 2.2. $m_3 \geq 7$. Since $d_3 = 4$ by (5), we have $m_4 \geq 2$. Let H_1 be a realization of $(4^{n-m_3-2}, 3^2, 2)$ as exhibited in the preceding paragraph, and let H_2 be a cubic bipartite simple graph with $m_3 - 1$ vertices. Using H_1 and H_2 and following the same argument as the preceding paragraph, we can obviously get a realization G of π that admits a nowhere-zero 3-flow.

Case 3. $\pi = (6, 4^{m_4}, 3^{m_3})$. Let H be an arbitrary realization of π , and let u be the vertex of degree six in H . Then the configuration of π implies the existence of two nonadjacent neighbors v, w of u in H . Let H' be the graph obtained from H by replacing path $vu w$ with edge vw . Then the degree sequence of H' is $\pi' = (4^{m_4+1}, 3^{m_3})$. By Case 1, π' has a realization G' that admits a nowhere-zero 3-flow. Moreover, if $\pi' = (4^5, 3^4)$, by Subcase 1.1, G' can be chosen such that there is a degree-four vertex x and an edge e such that x is not incident with e and is not adjacent to the end-vertices of e . Let x be a degree-four vertex in G' . Let $X_1 = N(x) \cup \{x\}$ and $X_2 = V(G') \setminus X_1$. Then there must be an edge e not incident with x such that x is not adjacent to the end-vertices of e if $\pi' \neq (4^5, 3^4)$. Otherwise, G' is connected and X_2 is an independent set. Let $[X_1, X_2]$ denote the set of edges with one end in X_1 and the other in X_2 . Then $(n - 5) \times 3 \leq \sum_{u \in X_2} d(u) = |[X_1, X_2]| \leq \sum_{v \in X_1 \setminus \{x\}} (d(v) - 1) \leq 4 \times 3 = 12$. Hence, $n \leq 9$ with equality if and only if X_1 consists of all degree-four vertices and X_2 consists of all degree-three vertices. By (6), we have $n = 9$. Therefore, the degree sequence of G' is $(4^5, 3^4)$, a contradiction to the assumption that $\pi' \neq (4^5, 3^4)$. Therefore, in any case, we can find a degree-four vertex a and an edge e such that a is not incident with e and is not adjacent to the end-vertices of e . Let G be the graph obtained from G' by subdividing e once and then identifying the new vertex with a . Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

Case 4. $\pi = (5^2, 4^{m_4}, 3^{m_3})$. Since π is graphical, using the same argument

employed in the preceding paragraph we deduce that the sequence $(5, 4^{m_4}, 3^{m_3+1})$ is graphical and hence, by Case 2, has a realization H that admits a nowhere-zero 3-flow. Let x be a degree-three vertex. Let $X_1 = N(x) \cup \{x\}$ and $X_2 = V(H) \setminus X_1$. We first show that there exists an edge e such that x is not incident with e and is not adjacent to the end-vertices of e . Otherwise, H is connected and X_2 is independent. Let $[X_1, X_2]$ denote the set of edges with one end in X_1 and the other in X_2 . Since the degree of each vertex in X_2 is at least three and the degree of each vertex in X_1 is at most five, we have $(n-4) \times 3 \leq \sum_{u \in X_2} d(u) = |[X_1, X_2]| \leq \sum_{v \in X_1 \setminus \{x\}} (d(v) - 1) \leq 4 \times 3 = 12$. Therefore, $n \leq 4$, contradicting (6), i.e., that $n \geq 9$. Let e be an edge and x be a degree vertex not incident with e such that x is not adjacent to any end-vertices of e . Let G be the graph obtained from H by subdividing an edge e once and then identifying the new vertex with a degree-three vertex not incident to e . Clearly, G is a realization of π and admits a nowhere-zero 3-flow. This completes the proof of Theorem 5.1. $\square$

Let us make some preparation before presenting the proof of Theorem 5.2.

LEMMA 5.4. *Let k be an integer with $k = 2$ or $k \geq 4$, and let $\pi = (k, 3^k, 2)$ or $(k^2, 3^{k-1}, 2)$. If π is graphical, then it has a realization that admits a nowhere-zero 3-flow.*

Proof. Note that if $k = 2$, then $\pi = (3^2, 2^2)$. Let G be the graph obtained from W_3 by deleting one edge. Clearly, G is a realization of π and admits a nowhere-zero 3-flow. So we assume

(1) $k \geq 4$. According to the configurations of π , we consider two cases.

Case 1. $\pi = (k, 3^k, 2)$. If k is even, then, by Lemma 5.3(a), π has a realization that admits a nowhere-zero 3-flow. It remains to consider the subcase when k is odd. Thus $k \geq 5$ by (1). Let H be a bipartite cubic simple graph with $k+1$ vertices, let u be a vertex of H , and let $\{v_1, v_2, v_3\}$ be the neighbors of u . Then $H \setminus \{u, v_1, v_2\}$ contains a matching M of size $(k-3)/2$. Let G be the graph obtained from H by subdividing each edge in M once, then identifying all the degree-two vertices with u , and finally subdividing one edge uv_3 once. Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

Case 2. $\pi = (k^2, 3^{k-1}, 2)$. In this case k is odd, so $k \geq 5$ by (1). Write $k = 2t+1$. Let H be the graph obtained from the disjoint union of a 4-circuit and $t-1$ triangles by gluing them at a common vertex x . Then H has $2t+2$ vertices and degree sequence $(2t, 2^{2t+1})$. Let G be the graph obtained from H by adding a new vertex y and making it adjacent to all vertices of H except precisely one degree-two vertex in a triangle. Then the degree sequence of G is $((2t+1)^2, 3^{2t}, 2)$, which is exactly π . Since G is triangularly connected and contains W_4 , it is Z_3 -connected by Lemma 2.9 and hence admits a nowhere-zero 3-flow. $\square$

Proof of Theorem 5.2. The “only if” part is already established by Lemma 2.10, so we proceed to the “if” part.

Assume the contrary: π is a counterexample with minimum n . Observe that

(1) $d_2 \geq 3$. Otherwise, $d_2 = d_3 = \dots = d_n = 2$. So d_1 is even. Thus each realization of π admits a nowhere-zero 2-flow; this contradiction leads to (1).

(2) The sequence $\sigma = (d_1, d_2, \dots, d_{n-1})$ is not graphical. Assume to the contrary that σ is graphical. Then $\sigma \neq (3^4, 2), (k, 3^k), (k^2, 3^{k-1})$, where k is an odd integer, for otherwise $\pi = (3^4, 2^2), (k, 3^k, 2)$, or $(k^2, 3^{k-1}, 2)$, so π has a realization that admits a nowhere-zero 3-flow by Lemma 5.3(a) or Lemma 5.4, a contradiction. By Theorem 5.1 and the assumption on π , the sequence σ has a realization H that admits a nowhere-zero 3-flow. Let G be a graph obtained from H by subdividing an edge once. Clearly,

G is a realization of π and admits a nowhere-zero 3-flow; this contradiction implies (2).

(3) Let $\bar{G}$ be an arbitrary realization of the residual sequence $\bar{\pi} = (d_1 - 1, d_2 - 1, d_3, \dots, d_{n-1})$ and let v_i be a vertex of $\bar{G}$ with degree $d_i - 1$ for $i = 1, 2$. Then v_1v_2 is an edge of $\bar{G}$.

Otherwise, v_1 and v_2 are nonadjacent in $\bar{G}$. Thus the graph obtained from $\bar{G}$ by adding edge v_1v_2 is a realization of the sequence $\sigma = (d_1, d_2, \dots, d_{n-1})$, contradicting (1). So (3) holds.

(4) The residual sequence $\bar{\pi}$ is $(3^4, 2)$, $(k, 3^k)$, or $(k^2, 3^{k-1})$, where k is an odd integer.

Otherwise, $\bar{\pi}$ has a realization $\bar{G}$ that admits a nowhere-zero 3-flow. Let v_i be a vertex of $\bar{G}$ with degree $d_i - 1$ for $i = 1, 2$. By (4), v_1v_2 is an edge of $\bar{G}$. Let G be the graph obtained from $\bar{G}$ by adding a new vertex w and making it adjacent to both v_1 and v_2 . Since G contains the triangle wv_1v_2w and since $\bar{G}$ admits a nowhere-zero 3-flow, it is easy to see that so does G . Hence (4) is justified.

From (4) we deduce that one of the following four cases must occur:

- $\pi = (4, 3^4, 2)$,
- $\pi = (4^2, 3^2, 2^2)$,
- $\pi = (k + 1, 4, 3^{k-1}, 2)$ or
- $\pi = ((k + 1)^2, 3^{k-1}, 2)$,

where k is an odd integer. In each case we shall construct a realization of π that admits a nowhere-zero 3-flow, thereby reaching a contradiction.

For $\pi = (4, 3^4, 2)$, π has a realization G obtained by subdividing one edge once of a W_4 . Since W_4 admits a nowhere-zero 3-flow, so does G .

For $\pi = (4^2, 3^2, 2^2)$, let G be the graph obtained from a W_3 by adding a new vertex, making it adjacent to two vertices of the W_3 , and then subdividing an edge. Clearly G is a realization of π . To see that G admits a nowhere-zero 3-flow, let H be the graph obtained from W_3 by duplicating an edge. Then H is triangularly connected and contains a 2-circuit. By Lemma 2.9, H is Z_3 -connected. So G admits a nowhere-zero 3-flow as it is a subdivision of H .

For $\pi = (k + 1, 4, 3^{k-1}, 2)$, let G be a graph obtained from W_k by adding a new vertex and making it adjacent to the hub and a rim vertex. It is easy to see that G is a realization of π and admits a nowhere-zero 3-flow.

For $\pi = ((k + 1)^2, 3^{k-1}, 2)$, let G be the graph obtained from the disjoint union of $\frac{k-1}{2}$ copies of W_3 by gluing all of them along an edge uv , and then adding a new vertex and making it adjacent to both u and v . Clearly, G is a realization of π and admits a nowhere-zero 3-flow.

This completes the proof of Theorem 5.2 and hence of Theorem 1.2. $\square$

HAMILTON CYCLES IN RANDOM LIFTS OF DIRECTED GRAPHS*

PRASAD CHEBOLU[†] AND ALAN FRIEZE[†]

Abstract. An n -lift of a digraph K is a digraph with a vertex set $V(K) \times [n]$, and for each directed edge $(i, j) \in E(K)$ there is a perfect matching between fibers $\{i\} \times [n]$ and $\{j\} \times [n]$, with edges directed from fiber i to fiber j . If these matchings are chosen independently and uniformly at random, then we say that we have a random n -lift. We show that if h is sufficiently large, then a random n -lift of the complete digraph $\vec{K}_h$ is a Hamiltonian **whp**.

Key words. digraph, random, lifts, Hamilton cycle

1. Introduction. For a graph K , an n -lift G of K has a vertex set $V(K) \times [n]$, where for each vertex $v \in V(K)$, $\{v\} \times [n]$ is called the *fiber* above v and will be denoted by F_v . The edge set of an n -lift G consists of a perfect matching between fibers F_u and F_w for each edge $(u, w) \in E(K)$. The set of n -lifts will be denoted $\Lambda_n(K)$. In this paper we discuss random n -lifts, chosen uniformly from $\Lambda_n(K)$. In this case, the matchings between fibers are chosen independently and uniformly at random.

Lifts of graphs were introduced by Amit and Linial in [1], where they proved that if K is a connected, simple graph with minimum degree $\delta \geq 3$, and G is chosen randomly from $\Lambda_n(K)$, then G is δ -connected **whp**, where the asymptotics are for $n \rightarrow \infty$. They continued the study of random lifts in [2], where they proved expansion properties of lifts. Together with Matoušek, they gave bounds on the independence number and chromatic number of random lifts in [3]. Linial and Rozenman [13] give a tight analysis for when a random n -lift has a perfect matching.

Burgin et al. [5] showed that a random n -lift of the complete graph K_h is Hamiltonian, provided h is sufficiently large. In this paper we study a directed version of the question. An n -lift of a digraph K is a digraph with a vertex set $V(K) \times [n]$, and for each directed edge $(i, j) \in E(K)$ there is a perfect matching between fibers $\{i\} \times [n]$ and $\{j\} \times [n]$, with edges directed from fiber i to fiber j .

We use the notation $y \overset{r}{\in} Y$ for “ y is chosen uniformly at random from Y .” We let $\vec{K}_h$ denote the complete digraph on vertex set $[h]$. Note that here there are edges in both directions (u, v) and (v, u) for all $u \neq v \in [h]$.

THEOREM 1. *If h is sufficiently large and $D \overset{r}{\in} \Lambda_n(\vec{K}_h)$, then D is Hamiltonian **whp**.* We will use the 3-phase method used in Cooper and Frieze [6, 7], Cooper, Frieze, and Molloy [8], and Frieze, Karp, and Reed [11].

A *permutation digraph* is a set of vertex disjoint directed cycles that cover all n vertices. Its *size* is the number of cycles.

Phase 1. We show that **whp** the lift D contains a directed permutation digraph of size at most $2 \ln n$.

Phase 2. We increase the minimum cycle length in the permutation digraph to at least

$$n_0 = \left\lceil \frac{100nh^3}{\ln n} \right\rceil.$$

Phase 3. We convert the Phase 2 permutation digraph to a Hamilton cycle.

The main difficulty involved in implementing this strategy comes from Phase 3. This is basically a second moment calculation, but it needs a *trick* to reduce the variance. The idea of the trick is from [6], but implementing the idea has turned out to be quite difficult. This is basically the content of section 4, where we prove a lower bound on the number of Hamilton cycles of a certain type in a digraph of high degree.

We use the following standard inequalities for the tails of the binomial distribution:

$$(1) \quad \Pr(|B(n, p) - np| \geq \epsilon np) \leq 2e^{-\epsilon^2 np/3}, \quad 0 \leq \epsilon \leq 1,$$

$$(2) \quad \Pr(B(n, p) \geq anp) \leq (e/a)^{anp}.$$

2. Phase 1. Making a permutation digraph with at most $2 \log n$ cycles.

LEMMA 1. Suppose that $D \stackrel{r}{\in} \Lambda_n(\vec{K}_h)$. Then **whp** D contains a permutation digraph with at most $2 \ln n$ cycles.

Proof. Let X_0 denote the Hamilton cycle $(1, 2, \dots, h)$ of K_h . Let F_i be the fiber of D corresponding to i . Let $r_{i,j}$ be the permutation defined by the matching $M_{i,j}$ from fiber F_i to fiber F_j in the lift D ; i.e., the edges of $M_{i,j}$ are $\{(i, k), (j, r_{i,j}(k)) : k \in [n]\}$. Let $r = r_{h,1} \circ r_{h-1,h} \circ \dots \circ r_{1,2}$. r defines a permutation of fiber F_1 . The permutation digraph $\{(i, x), (i+1, r_{i,i+1}(x)) : i \in [h], x \in [n]\}$ has as many cycles as the permutation r . The permutation r is a random permutation as it is the composition of random permutations. We know that the number of cycles in a random permutation is at most $2 \ln n$ **whp**; see, for example, Bollobás [4]. $\square$

We partition the cycles of the permutation digraph Σ_0 into sets SMALL and LARGE, containing small cycles C of length $|C| < n_0$ and large cycles $|C| \geq n_0$, respectively.

In a random permutation the expected number of vertices on cycles of length at most n_0 is precisely n_0 [12]. Thus, by the Markov inequality, **whp** Σ_0 contains at most $nh \log \log n / (4 \log n)$ vertices on small cycles.

Thus at the end of Phase 1, we can assume that we have a permutation digraph Σ_0 of size at most $2 \ln n$ which contains at most $nh \log \log n / (4 \log n)$ vertices on cycles of length $\leq n_0$. Let E_0 denote the edges D that are *not* in Σ_0 .

3. Phase 2. Removing small cycles. We now denote the vertices in the lift by $v_{i,k}$, where $i \in [h]$ and $k \in [n]$. We define a near permutation digraph (NPD) to be a digraph obtained from a permutation digraph by removing one edge. Thus an NPD Γ consists of a path $P(\Gamma)$ plus a permutation digraph $PD(\Gamma)$, which covers $([h] \times [n]) \setminus V(P(\Gamma))$.

Each step of the process we are about to describe involves the exposure of an edge $(v_{i,k}, v_{i',k'})$. When an edge is exposed in this way in Phase 2, we say that the two endpoints are *used*. The set of used vertices is denoted by W . Initially, $W = \emptyset$, and we ensure that $|W| \leq n^{3/4}$ throughout. Therefore, at any time the process is conditioned by the knowledge of partial matchings $M'_{i,j}$ between the fibers F_i and F_j

for $i \neq j$. (The matchings $M_{i,i+1}$ have, of course, been completely exposed in Phase 1.) For $j \neq i, i+1$, the unexposed part of $M_{i,j}$ will be a uniform extension of $M'_{i,j}$. So, in particular, when we examine a vertex $v_{i,k} \notin W$, the $M_{i,j}$ edge incident with $v_{i,k}$ is chosen uniformly from a set of size $n - o(n)$.

We now give an informal description of a process which removes a small cycle C from a *current* permutation digraph Σ . We break this process into an *out-phase* and an *in-phase*. We start by choosing an (arbitrary) edge (v_{i,j_0}, v_{i+1,k_0}) of C and delete it to obtain an NPD Γ_0 with $P_0 = P(\Gamma_0) \in \mathcal{P}(v_{i+1,k_0}, v_{i,j_0})$, where $\mathcal{P}(x, y)$ denotes the set of paths from x to y in D . The aim of this process is to produce a *large* set S of NPDs such that for each $\Gamma \in S$, (i) $P(\Gamma)$ has at least n_0 edges and (ii) the small cycles of $PD(\Gamma)$ are a strict subset of the small cycles of Σ . We will show that **whp** the endpoints of one of the $P(\Gamma)$'s can be joined by an edge to create a permutation digraph with (at least) one less small cycle. This completes the informal description.

We now give a fairly formal description, but we leave out some details for later. We produce a sequence $S_0 = \{\Gamma_0\}, S_1, S_2, \dots, S_t, \dots$ of sets of NPDs. Fix $t > 0$ and $\Gamma \in S_{t-1}$, and let v be the terminal endpoint of $P(\Gamma)$. We examine the $h-2$ edges of E_0 leaving v , i.e., the edges going *out* from the end of the path. Let w_j , $1 \leq j \leq h-2$, be the terminal vertices of these edges, and assume that Γ contains edges (x_j, w_j) , $1 \leq j \leq h-2$. Then for $1 \leq j \leq h-2$, $\Gamma_j = \Gamma \cup \{(v, w_j)\} \setminus \{(x_j, w_j)\}$ is added to S_t , assuming that the edge (v, w_j) is *acceptable* w.r.t. Γ . We call this an acceptable *out-step*. An (v, w) is acceptable if the following is true: Suppose that $P(\Gamma) \in \mathcal{P}(\cdot, v)$. Let $\Gamma' = \Gamma \cup \{(v, w)\} \setminus \{(x, w)\}$, where $(x, w) \in E(\Gamma)$. We then say that we *use* w .

- (i) $P(\Gamma')$ contains at least n_0 edges.
- (ii) Any new cycle created (i.e., in Γ' and not in Γ) also has at least n_0 edges.
- (iii) w does not lie on a small cycle of Γ .
- (iv) $P(\Gamma') \in \mathcal{P}(\cdot, x)$, where x has not been used before in Phase 2.

If Γ_j contains no edge (x_j, w_j) , then $w_j = v_{i+1,k_0}$. We accept the edge if $P(\Gamma_j)$ has at least n_0 edges. This would create a permutation digraph (PD) and (prematurely) end an iteration, although it is unlikely to occur.

Each member of S_{t-1} (usually) has $h-2$ descendants in S_t , and in this way we build a tree T_0 of NPDs in a natural breadth-first fashion where each nonleaf Γ at depth t is an element of S_t . By construction, all paths $P(\Gamma)$, $\Gamma \in T_0$, will have the same start vertex, viz. the head v_{i+1,k_0} of the edge deleted from the small cycle C . The construction of T_0 ends when we first have $\nu = \lceil \sqrt{n \log n} \rceil$ leaves. The construction of T_0 constitutes an out-phase of our procedure to eliminate small cycles. Having constructed T_0 we need to do a further in-phase, which is similar to a set of out-phases.

Then **whp** we close at least one of the paths $P(\Gamma)$ to a cycle of length at least n_0 . If this process fails, then we try again with a different independent edge of C in place of (v_{i,j_0}, v_{i+1,k_0}) . If we succeed, then we move on to the next small cycle.

We now fill in the details. We start Phase 2 with a PD Σ_0 , and a general iteration of Phase 2 starts with a PD Σ whose small cycles are a subset of those in Σ_0 . Iterations continue until there are no more small cycles. At the start of an iteration we choose some small cycle C of Σ . There then follows an out-phase in which we construct a tree $T_0 = T_0(\Sigma, C)$ of NPDs as follows: The root of T_0 is Γ_0 which is obtained by deleting an edge (v_{i,j_0}, v_{i+1,k_0}) of C .

We grow T_0 to a depth $O(\log n)$. The set of nodes at depth t will be S_t . $\Gamma \in S_{t-1}$ with $P = P(\Gamma) \in \mathcal{P}(v_{i,j_0}, v)$, $v \in F_i$, has up to $h-2$ descendants in S_t .

LEMMA 2. Let $C \in \text{SMALL}$. Then, where $\nu = \lceil \sqrt{n \log n} \rceil$,

$$\Pr\left(\exists t < \lceil \log_{h/2} \nu + 500 \log \log n \rceil \text{ such that } |S_t| \in [\nu, h\nu]\right) = 1 - O((\log \log n)^3 / \log n).$$

Proof. We assume that we stop construction of T_0 , in midphase if necessary, when $|S_t| \in [\nu, h\nu]$. Let us consider a generic construction in the growth of T_0 .

For an NPD Γ with $P(\Gamma) \in \mathcal{P}(v_{i,j_0}, v)$ we let $Z_j(\Gamma)$ be the 0-1 indicator for the edge (v, w_j) being unacceptable. If $Z_j(v) = 1$, then either (a) w_j lies on $P(\Gamma)$ and is too close to an endpoint—this has probability bounded above by $201h^3 / \log n$ —or (b) the corresponding vertex x_j is in W —this has probability bounded above by $2n^{-1/4}$ —or (c) w_j lies on a small cycle of Γ and hence of Σ_0 ; this has probability bounded above by $\log \log n / 3 \log n$. Then $\Pr(Z_j(\Gamma) = 1) \leq \log \log n / 2 \log n$ regardless of the history of the process to this point.

Let $Z_t = \sum_{\Gamma \in S_{t-1}} \sum_j Z_j(\Gamma)$. Z_t is the sum of possibly dependent random variables, but it is stochastically dominated by the binomial $B((h-2)|S_t|, \log \log n / \log n)$.

We write

$$|S_{t+1}| = (h-2)|S_t| - Z_t.$$

Now let $t_0 = \lceil 1000 \log \log n \rceil$ and $t_1 = \lceil \log_{h/2} \nu + 1000 \log \log n \rceil$.

- (a) $\Pr(\exists t \leq t_0 : |S_t| \leq 500 \log \log n \text{ and } Z_t > 0) = O((\log \log n)^3 / \log n)$.
- (b) $\Pr(\exists t \leq t_1 : |S_t| \geq 500 \log \log n \text{ and } Z_t > h|S_t|/100) \leq (\log n)^{-\Omega(\log \log n)}$.
- (a) $\Pr(Z_t > 0 \mid |S_t| \leq 500 \log \log n) = O((\log \log n)^2 / \log n)$ by the Markov inequality.
- (b) Immediate from (2).

Let $\mathcal{E}_a$ and $\mathcal{E}_b$ be the low probability events described in (a) and (b) above. Assume the occurrence of $\bar{\mathcal{E}}_a \cap \bar{\mathcal{E}}_b$. $\bar{\mathcal{E}}_a$ implies that $|S_t|$ reaches a size of at least $500 \log \log n$ before t reaches t_0 . Once this happens, $\bar{\mathcal{E}}_b$ implies that $|S_t|$ then grows geometrically with t up to time t_1 at a rate of at least $h/2$. The lemma follows. $\square$

The total number of vertices added to W in this way throughout the whole of Phase 2 is $O(\nu |\text{SMALL}|) = o(n^{3/4})$. We try this process once or twice for each $C \in \text{SMALL}$. Let t^* denote the value of t when we stop the growth of T_0 . At this stage we have leaves Γ_k , for $k = 1, \dots, \nu$, each with a path of length at least n_0 (unless we have already successfully made a cycle).

We now execute an in-phase. This involves the construction of trees $T_k, k = 1, 2, \dots, \nu$. The reader may while reading become concerned that in building ν trees of size ν we will need to use too many vertices. This will not be the case. This is a consequence of (3) later. Assume that $P(\Gamma_k) \in \mathcal{P}(v_{i+1,k_0}, v_{i,\ell_k})$. Notice that the start vertex of each of these paths is the same, viz. the head v_{i+1,k_0} of the edge deleted from the small cycle C . We start with Γ_k and build T_k in a similar way to T_0 except that here all paths generated end with v_{i,ℓ_k} . This is done as follows: If a current NPD Γ has $P(\Gamma) \in \mathcal{P}(u, v_{i,\ell_k})$, then we consider adding an edge $(w, u) \in E_0$ and deleting an edge $(w, x) \in \Gamma$. Thus our trees are grown by considering edges directed into the start vertex of each $P(\Gamma)$ rather than directed out of the end vertex. Some technical changes are necessary, however. We consider the construction of our ν trees in two stages. First of all we grow the trees only enforcing (an in-analogue of) condition (iv) of acceptability and thus allow the formation of small cycles and paths. We try to grow them to depth t_1 . The growth of the ν trees can naturally be considered to occur simultaneously. Let $L_{k,\ell}$ denote the set of start vertices of the paths associated

with the nodes at depth ℓ of the k th tree, $k = 1, 2, \dots, \nu$, $\ell = 0, 1, \dots, t_1$. Thus $L_{k,0} = \{v_{i+1,k_0}\}$ for all k . We prove inductively that

$$(3) \quad L_{k,\ell} = L_{1,\ell} \text{ for all } k, \ell.$$

In fact if $L_{k,\ell} = L_{1,\ell}$, then the acceptable E_0 edges have the same set of initial vertices, and since all of the deleted edges are Σ_0 -edges (enforced by (iv)) we have $L_{k,\ell+1} = L_{1,\ell+1}$. Note that the number of nodes in each tree is $O(h^{t_1+1}) = O(n^{3/5})$ if h is sufficiently large. Although we grow many trees, because of (3), the actual number of vertices used in total is $O(n^{3/5})$, and this is why we can claim that **whp** $|W| \leq n^{3/4}$ throughout.

The probability that we succeed in constructing trees $T_1, T_2, \dots, T_\nu$ is, by the analysis of Lemma 3, $1 - O((\log \log n)^3 / \log n)$.

We now consider the fact that in some of the trees some of the leaves may have been constructed in violation of (i)–(iii). We imagine that we prune the trees $T_1, T_2, \dots, T_\nu$ by disallowing any node that was constructed in violation of (i)–(iii). Let a tree be BAD if after pruning it has less than ν leaves and is GOOD otherwise. Now an individually pruned tree has been constructed in the same manner as the tree T_0 obtained in the out-phase. (We have chosen t_1 to obtain ν leaves even at the slowest growth rate of $h/2$ per node as asked for at the end of the proof of Lemma 2.) Thus

$$\Pr(T_1 \text{ is BAD}) = O\left(\frac{(\log \log n)^3}{\log n}\right)$$

and

$$\mathbf{E}(\text{number of BAD trees}) = O\left(\frac{\nu(\log \log n)^3}{\log n}\right)$$

and

$$\Pr(\exists \geq \nu/2 \text{ BAD trees}) = O\left(\frac{(\log \log n)^3}{\log n}\right).$$

Thus

$$\begin{aligned} \Pr(\exists < \nu/2 \text{ GOOD trees after pruning}) \\ \leq \Pr(\text{failure to construct } T_1, T_2, \dots, T_\nu) + \Pr(\exists \geq \nu/2 \text{ BAD trees}) \\ = O\left(\frac{(\log \log n)^3}{\log n}\right). \end{aligned}$$

Thus with probability $1 - O((\log \log n)^3 / \log n)$ we end up with $\nu/2$ sets of ν paths, each of length at least $100nh^3 / \log n$. All paths in one set have the same terminal vertex. Suppose that $v \in F_i$ is the common terminal vertex of one set. If a path in this set begins with a vertex in F_{i+1} , then we attempt to change the fiber of its start vertex to F_k , $k \neq i+1$, by performing an acceptable in-step. We will succeed with probability $1 - o(1)$, given the previous history. Thus assume that we have $\nu/2$ sets of $\nu/2$ paths where if the initial vertex is in fiber F_i , then the terminal vertex is not

in fiber F_{i-1} . Given this,

$$\begin{aligned} \Pr(\text{no } E_0 \text{ edge closes one of these paths}) &\leq \left(1 - \frac{\nu}{2n(1 - o(1))}\right)^{\nu/2} \\ &= O(n^{-1/4}). \end{aligned}$$

Consequently, the probability that we fail to eliminate a particular small cycle C after breaking an edge is $O((\log \log n)^3 / \log n)$. For every $C \in \text{SMALL}$, we have $|C| \geq h$. Therefore, it is possible to try once or twice using independent edges of C , and so the probability that we fail to eliminate a given small cycle C is certainly $O((\log \log n)^6 / (\log n)^2)$ (remember that we calculated all probabilities conditional on previous outcomes and assuming $|W| \leq n^{3/4}$). Hence, since **whp** $|C| = O(\log n)$, we have the following lemma.

LEMMA 3. *The probability that Phase 2 fails to produce a PD with minimal cycle length at least n_0 is $o(1)$.*

At this stage we have shown that if h is sufficiently large, then D almost always contains a PD Σ^* in which the minimum cycle length is at least n_0 .

We shall refer to Σ^* as the *Phase 2 PD*.

Now all the cycles of the PD Σ_0 defined in Phase 1 have lengths divisible by h . Also, as we traverse a cycle the fibers encountered are $F_1, F_2, \dots, F_h, F_1, \dots$. Now Σ^* is obtained from Σ_0 by replacing $O((\log n)^2)$ edges. By considering the unbroken sections of Σ_0 which pass through the fibers in order, we see that for each i , a cycle of length ℓ in Σ^* contains at least $\ell/h - O((\log n)^2)$ edges from fiber F_i to F_{i+1} .

4. Deterministic problem. In this section we give a lower bound to the number of a certain type of Hamilton cycle in a digraph with large minimum in-degree and out-degree.

Let Γ be a digraph with vertex set $[m]$ and minimum in-degree and out-degree at least $.99m$.

For a permutation ρ of $[m]$, let PD_ρ be its associated PD. Let

$$\begin{aligned} T_\Gamma &= \{\rho : PD_\rho \text{ is a subgraph of } \Gamma\}, \\ S_\Gamma &= \{\rho \in T_\Gamma : \rho \text{ is cyclic}\}. \end{aligned}$$

Let ϕ be a fixed *even* permutation of $[m]$. Let

$$R_\Gamma = \{\rho \in S_\Gamma : \phi\rho \text{ is cyclic}\}.$$

The permutations ρ thus correspond to a restricted class of Hamilton cycles in Γ .

In the next few sections we will prove the following theorem.

THEOREM 2. $|R_\Gamma| \geq m!e^{-3m}$.

This will help us resolve a strange technical problem, already met in [6]. It facilitates a second moment calculation.

The proof is quite long and is deferred to a later section, so as not to interrupt the flow of the probabilistic part of the argument.

5. Second moment calculation. Let $C_1, C_2, \dots, C_k$ be the cycles of Σ^* produced by Phase 2, and let $c_i^* = \min_j c_{ij}$, where c_{ij} is the number of *clean* edges in cycle C_i from fiber F_j to F_{j+1} for $j = 1, 2, \dots, h$. An edge is clean if it is not incident with W . Recall that W is the set of vertices v for which Phase 2 exposed an edge incident with v . E_1 will denote the set of clean edges that do not join fibers F_i, F_{i+1} for some i .

The cycles are numbered so that $c_1^* \leq c_2^* \leq \dots \leq c_k^*$ and $c_1^* \geq n_0/h - 2n^{3/4} \geq \frac{99h^2n}{\log n}$. If $k = 1$, there is nothing more to do. Otherwise let $a = \lceil \frac{nh^2}{\log n} \rceil$. We will show that **whp** it is possible to delete a set of edges from each C_i and then replace them so that the resulting structure is a Hamilton cycle. We will use the second moment method to do this.

We select an odd number of edges from each C_i and delete them. The choice of parity is related to the need to keep permutation ϕ (defined next) even. See (4). We will then be able to apply Theorem 2. Continuing, when h is odd, we choose the edges in the following manner. For each C_i , we select a set of $l_i = 2\lfloor \frac{c_i^*}{a} \rfloor + 1$ vertices $v \in C_i \setminus W$ from each fiber F_j , where $j = 1, 2, \dots, h$, and delete the corresponding edges (v, u) in Σ^* . The number of edges deleted from cycle C_i is $m_i = l_i h$, which is odd. Since $v \in C_i \setminus W$, the deleted edge $(v, u) \in \Sigma_0$ is an edge between fibers F_j and F_{j+1} for some j . The above procedure is not acceptable when h is even as we would end up deleting an even number of edges from each cycle. We circumvent this problem by choosing $l_i - 1$ vertices from fiber F_j , where $j \equiv i \pmod{h}$ and l_i from the rest of the fibers for cycle C_i . This ensures that the number of edges deleted from cycle C_i is $m_i = l_i h - 1$, which is odd.

Let $m = \sum_{i=1}^k m_i$. In each cycle C_i choose a vertex x_i which loses a cycle edge directed out of it. Let $v_1 = x_1$ and then go around C_1 defining $v_2, v_3, \dots, v_{m_1}$ in order as the endpoints of the path sections. Then let $v_{m_1+1} = x_2$ and so on. Now relabel the broken edges as $(v_i, u_i), i \in [m]$. We thus have m path sections $P_j \in \mathcal{P}(u_{\phi(j)}, v_j)$ in Σ^* for permutation ϕ , where $\phi(1) = m_1, \phi(2) = 1, \dots, \phi(m_1) = 1, \phi(m_1 + 1) = m_1 + m_2, \phi(m_1 + 2) = m_1 + 1$, etc. (Some path sections could be just a single vertex.)

Note that since ϕ is made up of cycles of odd length,

$$(4) \quad \phi \text{ is an even permutation of } [m].$$

The number of paths starting (ending) at any of the fibers is either $\lfloor \frac{m}{h} \rfloor$ or $\lfloor \frac{m}{h} \rfloor + 1$.

We will attempt to rejoin these paths in a different order so that a Hamilton cycle is constructed. Suppose that path section P starts in fiber $F_\xi(P)$ and ends in fiber $F_\eta(P)$. Because we do not wish to put back edges that we have just deleted: If P immediately precedes Q in some reordering, then we will have $\xi(Q) \neq \eta(P), \eta(P) + 1$. We write $P \rightarrow Q$ if this holds for P, Q .

Fix, for now, a choice of $P_1, P_2, \dots, P_m$, and let Γ be the digraph with vertex set $[m]$ and a directed edge (i, j) whenever $P_i \rightarrow P_j$. We are interested in the number of Hamilton cycles in Γ that satisfy a certain property. Each vertex of Γ has an in-degree and out-degree of at least $m - 2\lfloor \frac{m}{h} \rfloor - 2$. By choosing h to be suitably large, we can assume that $m - 2\lfloor \frac{m}{h} \rfloor - 2 \geq .99m$. Thus, Γ satisfies the conditions of Theorem 2.

Let Ω denote the set of ordered pairs of selections of edges for deletion and cycle rearrangements ρ satisfying the condition that a path ending on fiber F_i is not joined to a path starting on the same fiber or F_{i+1} and such that $\lambda = \phi\rho$ is cyclic. $\omega \in \Omega$ is a *success* if E_1 contains the edges needed for the associated Hamilton cycle.

Let H stand for the union of the PD Σ^* and E_1 . We finish our proof by proving the following lemma.

LEMMA 4. $\mathbf{Pr}(H \text{ does not contain a Hamilton cycle}) = o(1)$.

Proof. Let X be the number of Hamilton cycles in H obtainable by deleting edges as above, rearranging the path sections generated by ϕ , and, if possible, reconnecting all of the sections using edges of E_1 . We can think of this as the sum of indicator

variables indexed by Ω . We will use the well-known inequality

$$(5) \quad \Pr(X > 0) \geq \frac{\mathbf{E}(X)^2}{\mathbf{E}(X^2)}.$$

Probabilities in (5) are thus, with respect to the space of E_1 -choices for edges incident with vertices not in W .

Now the definition of l_i yields that

$$\frac{2nh - |W|h}{a} - (h+1)k \leq m \leq \frac{2nh}{a} + hk$$

and so

$$\frac{1.98}{h} \log n \leq m \leq \frac{2.01}{h} \log n.$$

Also

$$k \leq \log n / 100h^3, \quad l_i \geq 199, \quad \text{and} \quad \frac{c_i^*}{l_i} \geq \frac{a}{2.02}, \quad 1 \leq i \leq k.$$

Now fix a set of m paths and a permutation $\omega \in \Omega$. The probability that the edges exist for a success is at least n^{-m} . For having conditioned on the existence of a set of edges A , the probability that edge (u, v) exists is $1/\mu$, where $\mu \leq n$ is the number of vertices in the fiber containing v which are not incident with an A -edge whose other endpoint is in the same fiber as u . Recall that up to this point all we have done is condition on certain edges being present. The remaining edges form random partial matchings between the fibers. Furthermore, we have only conditioned on the presence of $O(n^{3/4})$ edges in total.

Let $\theta = 1$ if h is even and $\theta_{ij} = \theta \times 1_{i \equiv j \pmod{h}}$.

$$\begin{aligned} \mathbf{E}(X) &= \sum_{\omega \in \Omega} \Pr(\omega \text{ is a success}) \\ &\geq \sum_{\omega \in \Omega} n^{-m} \\ &\geq n^{-m} m! e^{-3m} \prod_{i=1}^k \binom{c_i^*}{l_i - \theta} \prod_{\substack{j=1 \\ j \neq i}}^h \binom{c_i^*}{l_i} \\ &\geq n^{-m} m! e^{-3m} \prod_{i=1}^k \binom{c_i^*}{l_i}^h \left(\frac{l_i}{c_i^*} \right)^\theta, \quad \text{after using Theorem 2,} \\ &\geq e^{-3m} \left(\frac{m}{en} \right)^m \prod_{i=1}^k \left(\left(\frac{c_i^* e^{1-1/12l_i}}{l_i^{1+(1/2l_i)}} \right)^{l_i} \left(\frac{1-2l_i^2/c_i^*}{\sqrt{2\pi}} \right)^h \right) \left(\frac{l_i}{c_i^*} \right)^\theta \\ &\geq e^{-3m} \left(\frac{m}{en} \right)^m \prod_{i=1}^k \left(\frac{e}{1.01} \right)^{l_i h} \left(\frac{c_i^*}{l_i} \right)^{l_i h - \theta} \\ &= e^{-3m} \left(\frac{mea}{(1.01)(2.02)en} \right)^m \\ &\geq e^{-3m} (.9h)^m \\ (6) \quad &\geq n^{\Omega(1)}. \end{aligned}$$

Let M, M' be two sets of selected edges which have been deleted in Σ^* and whose path sections have been rearranged into Hamilton cycles according to ρ, ρ' , respectively. Let N, N' be the corresponding sets of edges which have been added to make the Hamilton cycles. What is the interaction between these two Hamilton cycles?

Let $s = |M \cap M'|$ and $t = |N \cap N'|$. Now $t \leq s$ since if $(v, u) \in N \cap N'$, then there must be a unique $(\tilde{v}, u) \in M \cap M'$ which is the unique Σ^* -edge into u .

We claim that $t = s > 0$ implies $t = s = m$ and $(M, \rho) = (M', \rho')$. (This is why we have restricted our attention to $\rho \in R_\Gamma$.) For the following argument recall that we delete edges (v_i, u_i) , $i \in [m]$, and our path segments go from $u_{\phi(i)}$ to v_i . In our reordering, v_i will be connected to $u_{\phi\rho(i)} = u_{\lambda(p)}$. Suppose then that $t = s > 0$ and $(v_i, u_i) \in M \cap M'$. Now the edge $(v_i, u_{\lambda(i)}) \in N$, and since $t = s$ this edge must also be in N' . But this implies that $(v_{\lambda(i)}, u_{\lambda(i)}) \in M'$ and hence in $M \cap M'$. Repeating the argument we see that $(v_{\lambda^k(i)}, u_{\lambda^k(i)}) \in M \cap M'$ for all $k \geq 0$. But λ is cyclic, and so our claim follows.

We adopt the following notation. Let $\langle s, t \rangle$ denote $|M \cap M'| = s$ and $|N \cap N'| = t$. So

$$\begin{aligned} \mathbf{E}(X^2) &\leq \mathbf{E}(X) + (1 + O(m|W|/n)) \sum_{\omega \in \Omega} n^{-m} \sum_{\omega': N' \cap N = \emptyset} n^{-m} \\ &\quad + (1 + O(m|W|/n)) \sum_{\omega \in \Omega} n^{-m} \sum_{s=2}^m \sum_{t=1}^{s-1} \sum_{\omega': \langle s, t \rangle} n^{t-m} \\ (7) \quad &= \mathbf{E}(X) + (1 + o(1))(A_1 + A_0) \text{ say.} \end{aligned}$$

Clearly

$$(8) \quad A_1 \leq \left(\sum_{\omega \in \Omega} n^{-m} \right)^2 \leq \mathbf{E}(X)^2.$$

For given M, M', ρ , how many ρ' satisfy the condition $\langle s, t \rangle$? We bound it from above by $(m-t)!$ (consider fixing t edges of Λ'). Thus

$$\begin{aligned} A_0 &\leq \sum_{\omega \in \Omega} n^{-m} \sum_{s=2}^m \sum_{t=1}^{s-1} \left[\sum_{\sigma_{11} + \dots + \sigma_{kh} = s} \prod_{i=1}^k \prod_{j=1}^h \binom{l_i - \theta_{ij}}{\sigma_{ij}} \binom{c_i^* - l_i}{l_i - \sigma_{ij}} \right] (m-t)! n^{t-m} \\ &\leq \mathbf{E}(X)^2 \sum_{s=2}^m \sum_{t=1}^{s-1} \binom{s}{t} \left[\sum_{\sigma_{11} + \dots + \sigma_{kh} = s} \prod_{i=1}^k \prod_{j=1}^h \frac{\binom{l_i - \theta_{ij}}{\sigma_{ij}} \binom{c_i^* - l_i}{l_i - \sigma_{ij}}}{\binom{c_i^*}{l_i}} \right] \frac{(m-t)! e^{3m}}{m!} n^t. \end{aligned}$$

Now

$$\frac{\binom{c_i^* - l_i}{l_i - \sigma_{ij}}}{\binom{c_i^*}{l_i}} \leq \frac{\binom{c_i^*}{l_i - \sigma_{ij}}}{\binom{c_i^*}{l_i}} \leq (1 + o(1)) \left(\frac{l_i}{c_i^*} \right)^{\sigma_{ij}} \leq (1 + o(1)) \left(\frac{2.02}{a} \right)^{\sigma_{ij}},$$

where the $o(1)$ term is $O((\log n)^3/n)$. Also

$$\sum_{\sigma_{11} + \dots + \sigma_{kh} = s} \prod_{i=1}^k \prod_{j=1}^h \binom{l_i - \theta_{ij}}{\sigma_{ij}} = \binom{m}{s}.$$

Hence,

$$\begin{aligned}
\frac{A_0}{\mathbf{E}(X)^2} &\leq (1 + o(1)) \sum_{s=2}^m \sum_{t=1}^{s-1} \binom{s}{t} \left(\frac{2.02}{a}\right)^s \binom{m}{s} \frac{(m-t)! e^{3m} n^t}{m!} \\
&\leq n^{.01} \sum_{s=2}^m \sum_{t=1}^{s-1} \binom{s}{t} \left(\frac{2.02}{a}\right)^s \frac{m^{s-t} n^t}{s!}, \quad \text{using } e^{3m} \leq n^{.005} \text{ for } h \text{ large,} \\
&= n^{.01} \sum_{s=2}^m \left(\frac{2.02}{a}\right)^s \frac{m^s}{s!} \sum_{t=1}^{s-1} \binom{s}{t} \left(\frac{n}{m}\right)^t \\
&\leq \frac{2m}{n^{.99}} \sum_{s=2}^m \left(\frac{(2.02)n}{a}\right)^s \frac{1}{s!} \\
&\leq \frac{2m}{n^{.99}} \sum_{s=2}^m \left(\frac{2.02 \log n}{h^2}\right)^s \frac{1}{s!} \\
&\leq \frac{2m}{n^{.99}} n^{2.02/h^2} \\
(9) \quad &= o(1).
\end{aligned}$$

The lemma follows from (5) to (9).

This completes the proof of Theorem 1. $\square$

6. Proof of Theorem 2.

6.1. Lower bound for $|T_\Gamma|$.

LEMMA 5. $|T_\Gamma| \geq m! e^{-5m/2}$.

Proof. Consider a bipartite graph $B = (V_1 \cup V_2, E)$, where V_1, V_2 are disjoint copies of $[m]$. The edge set $E(B) = \{(i, j) : (i, j) \in E(\Gamma)\}$. It follows from the above that the degree of each vertex is at least $\delta_B = .99m$. A perfect matching M in B gives rise to a member ρ of T_Γ , where $j = \rho(i)$ iff $(i, j) \in M$. For a matching M of $K_{m,m}$, let $\nu(M)$ be the number of edges of M which are also in B . Let $\mathcal{M}_k$ denote the set of perfect matchings of $K_{m,m}$ with $\nu(M) = k$, $k = 0, 1, 2, \dots, m$. We first prove that if $\mu_k = |\mathcal{M}_k|$, $k = 0, 1, \dots, m$, and $k \geq .26m + 1$, then

$$(10) \quad \frac{\mu_{k+1}}{\mu_k} \geq \frac{.23m(m-k)}{\binom{m}{2}} \geq \frac{.46(m-k)}{m}.$$

Consider the set $\mathcal{X}$ of ordered pairs (M_1, M_2) , where $M_1 \in \mathcal{M}_k$, $M_2 \in \mathcal{M}_{k+1}$, and the symmetric difference $M_1 \oplus M_2$ is an alternating cycle of length 4. Now each $M \in \mathcal{M}_k$ is in at least

$$(m-k)(2(\delta_B - 1) - (m-1) - (m-k)) \geq .23m(m-k)$$

such cycles.

Explanation. There are $m-k$ choices for an edge $e = (v, w) \in M \setminus E(B)$. Then there are at least $2(\delta_B - 1) - (m-1)$ pairs of vertices (a, b) such that $(a, b) \in M$ and $(v, b) \in E(B)$, $(a, w) \in E(B)$, and at least $2(\delta_B - 1) - (m-1) - (m-k)$ pairs $(a, b) \in M \cap E(B)$, in which case $M' = (M \cup (a, w), (v, b)) \setminus ((v, w), (a, b))$ is a member of $\mathcal{M}_{k+1}$ and $(M, M') \in \mathcal{X}$.

On the other hand, each M is in at most $\binom{m}{2}$ pairs and (10) follows.

Now, if $k \leq .26m$, then

$$(11) \quad \frac{\mu_{k+2}}{\mu_k} \geq \frac{.35m(m-k)}{\binom{m}{2}} \geq \frac{.7(m-k)}{m} \geq \frac{.7(m-k)(m-(k+1))}{m^2}.$$

Explanation. As in the previous case, there are $m-k$ choices for an edge $e = (v, w) \in M \setminus E(B)$. Then there are at least $2(\delta_B - 1) - (m-1)$ pairs of vertices (a, b) such that $(a, b) \in M$ and $(v, b) \in E(B)$, $(a, w) \in E(B)$, and at least $2(\delta_B - 1) - (m-1) - k \geq .72m - 1$ pairs $(a, b) \in M \setminus E(B)$, in which case $M' = (M \cup (a, w), (v, b)) \setminus ((v, w), (a, b))$ is a member of $\mathcal{M}_{k+2}$ and $(M, M') \in \mathcal{X}$. Now, every such pair of edges $\{(v, w), (a, b)\}$ gets counted twice. Hence, the actual number of pairs is at least $.35m$ and (11) follows.

It follows that $\mu_m \geq (.46)^k m^{-k} k! \mu_{m-k}$ for $k \geq 0$ and so

$$m! = \mu_0 + \mu_1 + \cdots + \mu_m \leq \mu_m \sum_{k=0}^m \frac{m^k}{(.46)^k k!} \leq \mu_m e^{m/.46}. \quad \square$$

6.2. Upper bound for $|T_\Gamma|/|S_\Gamma|$. We will now extend an approach of Dyer, Frieze, and Jerrum [9] to directed graphs.

Let $k^* = \lfloor 7 \ln m \rfloor$, and for $1 \leq k \leq m/2$, define $g(k) = m^7 k! (7 \ln m)^{-k}$ and

$$f(k) = \begin{cases} g(k) & \text{if } k \leq k^*, \\ g(k^*) & \text{otherwise.} \end{cases}$$

LEMMA 6. *Let f be the function defined above. Then*

(a) *f is nonincreasing and satisfies*

$$f(k-1) \geq 7k^{-1} f(k) \ln m;$$

(b) *$f(k) \geq 1$ for all k .*

Proof. Observe that g is unimodal and k^* is the value of k minimizing $g(k)$; it follows that f is nonincreasing. When $k \leq k^*$, we have $f(k-1) = g(k-1) = (7 \ln m) k^{-1} g(k) = (7 \ln m) k^{-1} f(k)$. Otherwise, $f(k-1) = g(k^*) = f(k) \geq (7 \ln m) k^{-1} f(k)$. In either case, the inequality in part (a) of the lemma holds.

Part (b) of the lemma follows from the chain of inequalities.

$$\frac{1}{f(k)} \leq \frac{1}{g(k^*)} = \frac{(7 \ln m)^{k^*}}{m^7 k^*!} \leq m^{-7} \sum_{k=0}^{\infty} \frac{(7 \ln m)^k}{k!} = m^{-7} \exp(7 \ln m) = 1.$$

LEMMA 7. $|S_\Gamma| \geq m^{-8} |T_\Gamma|$.

Proof. For $1 \leq k \leq \lfloor m/2 \rfloor$, let Φ_k be the set of all PDs in Γ containing exactly k cycles, and let $\Phi = \cup_k \Phi_k$ be the set of all PDs. Define

$$\Psi = \{(F, F') : F \in \Phi_k, F' \in \Phi_{k-1} \text{ and } F \oplus F' \cong C_0\},$$

where $\oplus$ denotes symmetric difference and C_0 is the directed graph on four vertices with two vertices having in-degree two, out-degree zero, and two vertices having

out-degree two, in-degree zero. Observe that if $(F, F') \in \Psi$, then F' can be obtained from F by deleting two edges and adding two edges; this operation reduces the number of cycles by exactly one.

Our proof strategy is to define a positive weight function on the arc set Ψ such that the total weight of arcs leaving each node (PD) $F \in \Phi \setminus \Phi_1$ is at least one greater than the total weight of arcs entering F . This will imply that the total weight of arcs entering Φ_1 is an upper bound on the number of non-Hamiltonian PDs in Γ and that the maximum total weight of arcs entering a single node in Φ_1 is an upper bound on the ratio $|\Phi \setminus \Phi_1|/|\Phi_1|$.

The weight function $w : \Psi \rightarrow R^+$ is defined as follows: For any arc (F, F') with $F' \in \Phi_k$, if the PD F' is obtained from F by coalescing two cycles of length γ_1 and γ_2 into a single cycle of length $\gamma_1 + \gamma_2$, then $w(F, F') = (\gamma_1^{-1} + \gamma_2^{-1})f(k)$.

Let $F \in \Phi_k$ be a PD with $k > 1$ cycles $C_1, C_2, \dots, C_k$ of lengths $\gamma_1, \gamma_2, \dots, \gamma_k$. Let us try to obtain a lower bound on the weight of the arcs going out of F . Suppose we chose cycle C_i to be one of the two cycles that coalesces with the other to form a new cycle. The number of ways to pick an edge from C_i is γ_i . Having picked an edge (u, v) from C_i , we need to find an edge (s, t) on the remaining cycles such that (u, t) and (s, v) are edges in the digraph Γ . Since the out-degree of u is at least $.99m$, we have at least $.99m - (\gamma_i - 1)$ possible choices for s . Similarly, we have at least $.99m - (\gamma_i - 1)$ possible choices for t . The number of feasible edges (s, t) is

$$\begin{aligned} &\geq .99m - (\gamma_i - 1) + .99m - (\gamma_i - 1) - (m - \gamma_i) \\ &> .98m - \gamma_i \end{aligned}$$

for each edge in C_i . The total number of ways to form a new cycle using C_i is thus at least $\gamma_i(.98m - \gamma_i)$. The weight of any arc leaving F is at least $\gamma_i^{-1}f(k-1)$, which, by Lemma 2, is bounded below by $(7 \ln m)(k\gamma_i)^{-1}f(k)$. We also have to note that every pair $(u, v), (s, t)$ may get counted twice, once from each cycle. Thus, the total weight of arcs leaving F is bounded as follows:

$$\begin{aligned} \sum_{F^+ : (F, F^+) \in \Psi} w(F, F^+) &\geq \frac{1}{2} \sum_{i=1}^k \gamma_i [.98m - \gamma_i] \frac{(7 \ln m)f(k)}{k\gamma_i} \\ &= \frac{1}{2} m [.98k - 1] \frac{(7 \ln m)f(k)}{k} \\ (12) \qquad &\geq 3f(k)m \ln m, \end{aligned}$$

where we have used the fact that $k \geq 2$.

We now give an upper bound to the weight of the arcs $(F^-, F) \in \Psi$ entering F . Suppose once again that F has cycles $C_1, C_2, \dots, C_k$ of lengths $\gamma_1, \gamma_2, \dots, \gamma_k$. A directed arc from F^- to F implies that one of the cycles of F was formed by coalescing two cycles of F^- . Suppose C_i was formed by coalescing two cycles from F^- . By removing the added edges from C_i and putting back the deleted edges, we can generate F^- . Let a and b be the lengths of the corresponding cycles in F^- . Remove one of the added edges from C_i and go around the cycle and remove the edge which is at a distance a . This way we make sure that the deletion of the first of the two added edges uniquely determines the two paths of lengths $a - 1$ and $b - 1$. Since the added edge in F could be any of the γ_i edges, we have at most γ_i choices.

The total weight of arcs entering F can thus be bounded previously as follows:

$$\begin{aligned}
 \sum_{F^-: (F^-, F) \in \Psi} w(F^-, F) &\leq \sum_{i=1}^k \gamma_i f(k) \sum_{\substack{a, b \geq 1 \\ a+b=\gamma_i}} \left(\frac{1}{a} + \frac{1}{b} \right) \\
 &= \sum_{i=1}^k \gamma_i f(k) \sum_{a=1}^{\gamma_i-1} \left(\frac{1}{a} + \frac{1}{\gamma_i-a} \right) \\
 (13) \qquad &\leq 2f(k)mH(m),
 \end{aligned}$$

where $H_m = \sum_{i=1}^m i^{-1} \leq \ln m + 1$ is the m th harmonic number. Combining inequalities (12) and (13), we have

$$\begin{aligned}
 \sum_{F^+: (F, F^+) \in \Psi} w(F, F^+) - \sum_{F^-: (F^-, F) \in \Psi} w(F^-, F) &\geq 3f(k)m \ln m - 2f(k)mH(m) \\
 &\geq f(k)m(\ln m - 2) \\
 &\geq m(\ln m - 2),
 \end{aligned}$$

where the final inequality is by Lemma 6. Thus the total weight of arcs leaving F exceeds the total weight of arcs entering by at least 1, provided $m \geq e^3$. The number of non-Hamiltonian PDs $|\Phi \setminus \Phi_1|$ is bounded above by the total weight of arcs entering Φ_1 , which in turn is bounded, see inequality (13), by $|\Phi_1| \times 2f(1)mH_m \leq m^8 |\Phi_1|/2$. $\square$

6.3. Lower bound on $|R_\Gamma|$. In this section, we will use an argument similar in flavor to the argument of the previous section to give a lower bound on $|R_\Gamma|$. Each $\rho \in S_\Gamma$ yields another permutation $\lambda = \lambda(\rho) = \phi\rho$. Recall that ϕ is considered to be fixed and $\rho \in R_\Gamma$ iff $\lambda = \phi\rho$ is cyclic.

We show next that if $\rho \in S_\Gamma$, then λ has an odd number of cycles. Now ϕ is even, and so λ and ρ have the same sign, $(-1)^{m-1}$. If λ has cycles $C_1, C_2, \dots, C_k$ of sizes $\gamma_1, \gamma_2, \dots, \gamma_k$, then the sign of λ is $(-1)^{\gamma_1-1+\dots+\gamma_k-1} = (-1)^{m-k} = (-1)^{m-1}$.

We let

$$k_0 = 2\lfloor 50001 \ln m \rfloor + 1,$$

and we will consider the following conditions for ρ : (i) λ must have at least k_0 cycles, (ii) the longest cycle in λ has length at most $\leq .8m$, and (iii) the sum of the lengths of the longest two cycles is at most $\leq .92m$.

The λ with less than k_0 cycles will be considered later in this section. Given (i), it is not clear whether or not we can find ρ satisfying conditions (ii) and (iii). Let S_k , k odd be the set of all $\rho \in S_\Gamma$ such that $\lambda(\rho)$ has $k \geq k_0$ cycles. We define a partition $S_k = P_k \cup Q_k \cup R_k$. Let P_k be the set of all ρ which do not satisfy condition (ii), Q_k be the set of those which satisfy condition (ii) but not (iii), and R_k be the set of those which satisfy both conditions (ii) and (iii).

We will first show that a constant fraction satisfying condition (i) also satisfies conditions (ii) and (iii).

6.3.1. $|P_k|/|Q_k \cup R_k| \leq 1/60$. We define $X_k = \{(\rho_1, \rho_2) : \rho_1 \in P_k, \rho_2 \in Q_k \cup R_k \text{ and } \Lambda_1 \oplus \Lambda_2 \cong H_0\}$, where $\Lambda_i = PD_{\lambda(\rho_i)}$, $i = 1, 2$, and $\oplus$ stands for symmetric

difference and H_0 is the directed graph on six vertices as in Figure 1(c). The weight function $w : X_k \rightarrow R^+$ is defined as follows: If Λ_2 is obtained by breaking and patching two cycles of Λ_1 of length γ_1 and γ_2 into two cycles of length γ' and γ'' , then the weight $w(\rho_1, \rho_2) = \gamma_1^{-1} + \gamma_2^{-1}$. We restrict X_k to those (ρ_1, ρ_2) for which $\gamma', \gamma'' \geq m/4$.

Figure 1(a)

Figure 1(b)

Figure 1(c)

FIG. 1.

Suppose $\rho_1 \in P_k$ and $C_1, C_2, \dots, C_k$ are the cycles of Λ_1 in increasing order of size. Let γ_t denote the length of cycle C_t for $t \in [k]$. We will combine C_k with a smaller cycle C_ℓ , $\ell \neq k$, to obtain two cycles (as in Figure 1(b)) such that the new auxiliary graph constructed, say $\Lambda_2 = \Lambda(\rho_2)$, belongs to $Q_k \cup R_k$. The weight of (ρ_1, ρ_2) is $\gamma_k^{-1} + \gamma_\ell^{-1}$. While combining the two cycles, we will have to ensure that ρ_2 is a cyclic permutation.

FIG. 2.

To create $\rho_2 \in Q_k \cup R_k$ we delete edges $(p, \lambda(p))$, $(q, \lambda(q))$, and $(r, \lambda(r))$, from Λ_1 , where p, q, r appear in this order on the Hamilton cycle H_{ρ_1} of Γ , corresponding to ρ_1 ,

and replace them with the edges $(p, \lambda(q))$, $(q, \lambda(r))$, and $(r, \lambda(p))$ as shown in Figure 2 to maintain Hamiltonicity. Vertices q and r are chosen on cycle C_k and vertex p is chosen on C_ℓ , $\ell \neq k$. We will of course have to impose the restriction on p, q , and r in this construction that $(p, \rho(q))$, $(q, \rho(r))$, and $(r, \rho(p))$ are all edges of Γ . There will be other necessary restrictions.

The number of choices for p is γ_ℓ . Given p we rule out at most $m - \gamma_k$ choices for q due to not being on C_k . Recall that C_k is the longest cycle of Λ_1 and it corresponds to $\rho_1 \in P_k$ and so $\gamma_k \geq .8m$. This leaves us with at least $.99m + .8m - m = .79m$ choices. Having chosen q we rule out $m/2$ choices for r within distance $\leq m/4$ from q on C_k . For each such choice, both of the two new cycles replacing C_k, C_ℓ are of size $\geq m/4$, placing ρ_2 in $Q_k \cup R_k$.

Some of these choices are inadmissible because we need to ensure that ρ_2 is a cyclic permutation. First, we will restrict our choice of q to one of the first $m/4$ vertices following p on H_{ρ_1} . We have at least $m/4 - .21m \geq .04m$ such choices. Now we must choose r from the remaining $3m/4$ vertices. We have ruled out $m/2$ already and also rule out further $\leq .02m$ choices of r for which r is not an in-neighbor of $\lambda(p)$ or $\lambda(r)$ is not an out-neighbor of q . This yields at least $(.75 + .8 - .5 - 1 - .02)m = .03m$ choices.

Thus

$$\begin{aligned}
 \sum_{\rho_2: (\rho_1, \rho_2) \in X_k} w(\rho_1, \rho_2) &\geq \sum_{\ell=1}^{k-1} \gamma_\ell [(.04m)(.03m)](\gamma_k^{-1} + \gamma_\ell^{-1}) \\
 &\geq .0012 \sum_{\ell=1}^{k-1} \gamma_\ell m^2 (m^{-1} + \gamma_\ell^{-1}) \\
 &= .0012 \sum_{\ell=1}^{k-1} [\gamma_\ell + m] m \\
 &= .0012 [m - \gamma_k + (k-1)m] m \\
 &\geq .0012 (k-1) m^2 \\
 &\geq 120 m^2 \ln m.
 \end{aligned}
 \tag{14}$$

We now obtain an upper bound on the total weight of pairs containing ρ_2 of $Q_k \cup R_k$. Suppose that $C'_1, C'_2, \dots, C'_k$ are the cycles of Λ_2 in increasing order of length $\gamma'_1 \leq \gamma'_2 \leq \dots \leq \gamma'_k$. Our choices for Λ_1 are restricted as follows: We must choose two cycles C'_r, C'_s such that $\gamma'_r + \gamma'_s = \gamma_k + \gamma_\ell \geq \gamma_k \geq .8m$ and $\gamma'_r, \gamma'_s \geq m/4$. This implies $\{r, s\} = \{k-1, k\}$. Given this, we see that the total weight of edges entering Λ_2 can be bounded as follows: The parameter a is the length of the path from q to r on C_k :

$$\begin{aligned}
 \sum_{\rho_1: (\rho_1, \rho_2) \in X_k} w(\rho_1, \rho_2) &\leq m^2 \max_{M \leq m} \left\{ \sum_{\substack{a+b=M \\ a, b \geq 2}} \left(\frac{1}{a} + \frac{1}{b} \right) \right\} \\
 &\leq m^2 \sum_{a=2}^m \frac{2}{a} \\
 &\leq 2m^2 \ln m.
 \end{aligned}
 \tag{15}$$

It follows that

$$(16) \quad 120m^2|P_k|\ln m \leq \sum_{(\rho_1, \rho_2) \in X_k} w(\rho_1, \rho_2) \leq 2m^2|Q_k \cup R_k|\ln m.$$

We have thus shown that

$$(17) \quad |P_k| \leq |Q_k \cup R_k|/60.$$

6.3.2. $|Q_k|/|R_k| \leq 1/200$. The argument that follows is similar to the one used previously to show that $|Q_k \cup R_k|$ is a constant fraction of $|S_k|$. Now let $Y_k = \{(\rho_1, \rho_2) : \rho_1 \in Q_k, \rho_2 \in R_k \text{ and } \Lambda_1 \oplus \Lambda_2 \cong H_0\}$, where H_0 is the same directed graph on six vertices as in Figure 1(c). The weight function $w : Y_k \rightarrow R^+$ is defined as follows: If Λ_2 is obtained by breaking and patching two cycles of Λ_1 of length γ_i and γ_j into two cycles of length γ' and γ'' , then $w(\rho_1, \rho_2) = \gamma_i^{-1} + \gamma_j^{-1}$. We again restrict our attention to (ρ_1, ρ_2) such that $\gamma', \gamma'' \geq m/10$.

Suppose $\rho_1 \in Q_k$ and $C_1, C_2, \dots, C_k$ are the cycles of Λ_1 in the order of increasing size $\gamma_1 \leq \gamma_2 \leq \dots \leq \gamma_k$, where $\gamma_k \leq .8m$ and $\gamma_k + \gamma_{k-1} > .92m$. We will combine C_k with a smaller cycle C_ℓ , $\ell \notin \{k, k-1\}$, to obtain two cycles (as in Figure 1(b)) such that the new auxiliary graph constructed, Λ_2 , belongs to R_k .

While q and r are chosen from cycle C_k , p is chosen from C_ℓ . The number of choices for p is γ_ℓ . Since $\gamma_k + \gamma_{k-1} \geq .92m$, we have $\gamma_k \geq .46m$. The number of *feasible* choices for q and r is therefore at least $.99m + .46m - m = .45m$. Having chosen q we rule out $.2m$ choices for r within distance $\leq .1m$ from q on C_k . For each such choice, the size of the new largest cycle is at most $\max\{\gamma_{k-1}, \gamma_k + .08m - .1m\}$, and both of the two new cycles replacing C_k, C_ℓ are of size $\geq .1m$, placing Γ_2 in R_k .

Some of these choices are inadmissible because we need to ensure that ρ_2 is a cyclic permutation. First, we will restrict our choice of q so that q is one of the first $.1m$ feasible C_k -vertices following p on H_ρ . Now we must choose r from the remaining $\geq .35m$ feasible C_k -vertices. We have ruled out $.2m$ already and also rule out a further $\leq .02m$ choices of r for which r is not an in-neighbor of $\lambda(p)$ or $\lambda(r)$ is not an out-neighbor of q . This yields at least $.13m$ choices.

Thus,

$$(18) \quad \begin{aligned} \sum_{\rho_2: (\rho_1, \rho_2) \in Y_k} w(\rho_1, \rho_2) &\geq \sum_{\ell=1}^{k-2} \gamma_\ell [(.1m)(.13m)](\gamma_k^{-1} + \gamma_\ell^{-1}) \\ &\geq .013 \sum_{\ell=1}^{k-2} \gamma_\ell m^2 (m^{-1} + \gamma_\ell^{-1}) \\ &= .013 \sum_{\ell=1}^{k-2} [\gamma_\ell + m]m \\ &= .013[m - \gamma_k - \gamma_{k-1} + (k-2)m]m \\ &\geq .013(k-2)m^2 \\ &\geq 1300m^2 \ln m. \end{aligned}$$

We now obtain an upper bound on the total weight of pairs containing a member ρ_2 of R_k . Suppose that $C'_1, C'_2, \dots, C'_k$ are the cycles of Λ_2 in increasing order of length $\gamma'_1 \leq \gamma'_2 \leq \dots \leq \gamma'_k$. Our choices for Λ_1 are restricted as follows: We must choose

two cycles C'_r, C'_s such that $\gamma'_r + \gamma'_s = \gamma_k + \gamma_\ell \geq \gamma_k \geq .46m$ and $\gamma'_r, \gamma'_s \geq .1m$. This implies that $\{r, s\} \subseteq \{k-2, k-1, k\}$. (Those Λ_2 that are paired with Λ_1 have at most 3 cycles of size greater than $.08m$.) Given this, we see that

$$\begin{aligned} \sum_{\rho_1: (\rho_1, \rho_2) \in Y_k} w(\rho_1, \rho_2) &\leq 3m^2 \max_{M \leq m} \left\{ \sum_{\substack{a+b=M \\ a, b \geq 2}} \left(\frac{1}{a} + \frac{1}{b} \right) \right\} \\ &\leq 3m^2 \sum_{a=2}^m \frac{2}{a} \\ &\leq 6m^2 \ln m. \end{aligned}$$

It follows that

$$(19) \quad 1300m^2 |Q_k| \ln m \leq \sum_{(\rho_1, \rho_2) \in Y_k} w(\rho_1, \rho_2) \leq 6m^2 |R_k| \ln m.$$

From (17) and (19), we have

$$(20) \quad |R_k| \geq 9|S_k|/10.$$

6.4. Final estimate. We can now complete our proof of Theorem 2. Fix $k_0 \leq k \leq \lfloor m/2 \rfloor$, and let

$$Z_k = \{(\rho_1, \rho_2) : \rho_1 \in R_k, \rho_2 \in S_{k-2}, \text{ and } \rho_1 \oplus \rho_2 \cong H_1\},$$

where H_1 is the graph shown in Figures 3(c) and 4(c). Here we combine two cases. We take 3 (see Figure 3) or 4 (see Figure 4) cycles from Λ_1 and reduce this number by 2 to create Λ_2 .

Let $\rho_1 \in R_k$ give rise to Λ_1 which has cycles $C_1, C_2, \dots, C_k$ of lengths $\gamma_1, \gamma_2, \dots, \gamma_k$. For $(\rho_1, \rho_2) \in Z_k$ we will delete four edges from Λ_1 and add four new edges to obtain Λ_2 . If Λ_2 is obtained from Λ_1 by breaking and patching cycles of length $\gamma_1, \gamma_2, \dots, \gamma_s$, then $w(\Lambda_1, \Lambda_2) = (\gamma_1^{-1} + \gamma_2^{-1} + \dots + \gamma_s^{-1})$. We will first obtain a lower bound on the total weight of pairs containing ρ_1 .

We choose cycles C_i and C_j from Λ_1 and delete one edge from each $(p, \lambda(p))$ and $(q, \lambda(q))$, respectively. The remaining two edges to be deleted should lie outside the cycles, C_i and C_j . Let the edges deleted from outside the cycles, C_i and C_j , be $(r, \lambda(r))$ and $(s, \lambda(s))$.

We will give a lower bound on the number of sets of four edges that can be deleted from the auxiliary graph. Suppose $(p, \lambda(p))$ and $(q, \lambda(q))$ are chosen from C_i and C_j , respectively. The number of choices for $(p, \lambda(p))$ and $(q, \lambda(q))$ are γ_i and γ_j , respectively. Now, we remove two edges, $(r, \lambda(r))$ and $(s, \lambda(s))$, outside of cycles γ_i and γ_j such that edges of the form $(x, \lambda(y))$ and edges of the form $(y, \lambda(x))$ are edges in Γ for $x \in \{p, q\}$ and $y \in \{r, s\}$. The number of choices for $(r, \lambda(r))$ such that $(p, \lambda(r))$ is an edge in Γ is at least $.99m$. The number of choices for $(r, \lambda(r))$ such that both $(p, \lambda(r))$ and $(q, \lambda(r))$ are edges of in Γ is at least $.99m + .99m - m \geq .98m$. By a similar argument, we have that the number of choices for $(r, \lambda(r))$ such that both $(r, \lambda(p))$ and $(r, \lambda(q))$ are edges of Γ is at least $.98m$. Thus the number of choices for $(r, \lambda(r))$ is at least $.98m + .98m - m \geq .96m$. Since $(r, \lambda(r))$ should lie outside of cycles C_i and C_j , the number of choices for $(r, \lambda(r))$ is $.96m - \gamma_i - \gamma_j$. The same applies

Figure 3(a)

Figure 3(b)

Figure 3(c)

FIG. 3. Figure (a) shows three cycles of Λ_1 and Figure (b) shows the cycle of Λ_2 obtained by coalescing the three cycles of Λ_1 . Figure (c) gives the graph $H_1 = \Lambda_1 \oplus \Lambda_2$.

to $(s, \lambda(s))$. We also add the extra condition that p, q, r, s lie in the order p, q, r, s or p, s, r, q on H_{ρ_1} (see Figure 5), thereby ensuring that ρ_2 is a cyclic permutation. The number of choices for r and s is at least $\binom{(.96m - \gamma_i - \gamma_j)/2}{2}$. The number of choices for p, q, r, s is therefore at least

$$(21) \quad \gamma_i \gamma_j \binom{(.96m - \gamma_i - \gamma_j)/2}{2} \geq .0001 \gamma_i \gamma_j m^2.$$

We can pick the same set of four edges at most 12 times by picking one of the four edges to be the first edge and one of the remaining three to be the second edge from a different cycle. The weight of (Λ_1, Λ_2) is at least $\gamma_i^{-1} + \gamma_j^{-1}$. Consequently, the weight of arcs emanating from $\rho_1 \in R_k$ is

$$(22) \quad \begin{aligned} &\geq \frac{m^2}{12000} \sum_{i=1}^k \sum_{j \neq i} \gamma_i \gamma_j \left(\frac{1}{\gamma_i} + \frac{1}{\gamma_j} \right) \\ &= \frac{m^2}{12000} \sum_{i=1}^k \sum_{j \neq i} (\gamma_i + \gamma_j) \\ &\geq \frac{(k-1)m^3}{12000} \\ &> 8m^3 \ln m. \end{aligned}$$

Figure 4(a)

Figure 4(b)

Figure 4(c)

FIG. 4. Figure (a) shows three cycles of Λ_1 and Figure (b) shows the two cycle of Λ_2 obtained by coalescing the four cycles of Λ_1 . Figure (c) gives the graph $H_1 = \Lambda_1 \oplus \Lambda_2$.

FIG. 5.

Now, we will give an upper bound on the total weight of pairs $(\Lambda_1, \Lambda_2) \in Z_k$ for a fixed $\Lambda_2 \in S_k$. Suppose Λ_2 has cycles $C_1, C_2, \dots, C_k$ of lengths $\gamma_1, \gamma_2, \dots, \gamma_k$. Either one cycle of Λ_2 was formed by coalescing three cycles of Λ_1 or two cycles of Λ_2 were formed by coalescing four cycles of Λ_1 into two.

Case 1. Suppose $C_i \in \Lambda_2$ was formed by coalescing three cycles of lengths a, b , and c from Λ_1 with one edge deleted from the cycles of length a and b and two edges deleted from the cycle of length c , as in Figure 3. There is a choice $1 \leq d \leq c - 1$ for length of the *first* of the paths created from the cycle of length c . Given a, b, c, d ,

there are γ_i choices for p say. Thus the total weight of pairs containing a fixed Λ_2 can be bounded from above in this case by

$$\begin{aligned}
 & \sum_{i=1}^k \gamma_i \sum_{\substack{(a,b,c,d): a,b,c \geq 1 \\ 1 \leq d \leq c-1 \\ a+b+c=\gamma_i}} \left(\frac{1}{a} + \frac{1}{b} + \frac{1}{c} \right) \\
 & \leq m \sum_{i=1}^k \gamma_i \sum_{\substack{(a,b,c): a,b,c \geq 1 \\ a+b+c=\gamma_i}} \left(\frac{1}{a} + \frac{1}{b} + \frac{1}{c} \right) \\
 & \leq 3m \sum_{i=1}^k \gamma_i^2 (\ln \gamma_i + 1) \\
 (23) \quad & \leq 4m^3 \ln m.
 \end{aligned}$$

Case 2. Suppose $C_i, C_j \in \Lambda_2$ were formed by combining four cycles of lengths a, b, c , and d from Λ_1 with one edge deleted from each of the four cycles, as in Figure 4. The total weight of pairs containing a fixed Λ_2 can be bounded from above in this case by

$$\begin{aligned}
 & \sum_{i=1}^k \sum_{j=i+1}^k \gamma_i \gamma_j \sum_{\substack{(a,c): a,c \geq 2 \\ a+c=\gamma_i}} \sum_{\substack{(b,d): b,d \geq 2 \\ b+d=\gamma_j}} \left(\frac{1}{a} + \frac{1}{c} + \frac{1}{b} + \frac{1}{d} \right) \\
 & = \frac{1}{2} \sum_{i=1}^k \sum_{j \neq i} \gamma_i \gamma_j \sum_{a=2}^{\gamma_i-2} \sum_{b=2}^{\gamma_j-2} \left(\frac{1}{a} + \frac{1}{\gamma_i-a} + \frac{1}{b} + \frac{1}{\gamma_j-b} \right) \\
 & \leq \frac{1}{2} \sum_{i=1}^k \sum_{j \neq i} \gamma_i \gamma_j (2\gamma_j \ln \gamma_i + 2\gamma_i \ln \gamma_j) \\
 & \leq \frac{1}{2} \sum_{i=1}^k 4\gamma_i m^2 \ln m \\
 & = 2m^3 \ln m. \\
 (24) \quad &
 \end{aligned}$$

Combining inequalities (22), (23), and (24), we have that for $k \geq k_0$,

$$(6m^3 \ln m) |S_{k-2}| \geq w(Z_k) \geq (8m^3 \ln m) |R_k|,$$

and hence

$$|S_{k-2}| \geq 4|R_k|/3 \geq 6|S_k|/5$$

after using (20). It follows that

$$(25) \quad \sum_{\substack{k \geq k_0 \\ k \text{ odd}}} |S_k| \leq 6|S_{k_0-2}|.$$

Recall that all λ have an odd number of cycles.

We will now consider λ with at most $3 \leq k \leq k_0 - 2$ cycles. We will show that

$$(26) \quad \frac{|S_{k-2}|}{|S_k|} \geq \frac{1}{m^4}$$

which implies

$$|S_k| \leq m^{2(k-1)} |S_1|.$$

Hence,

$$\frac{|R_\Gamma|}{|S_\Gamma|} = \frac{|S_1|}{\sum_{\substack{k \geq 1 \\ k \text{ odd}}} |S_k|} = \Omega(m^{-2k_0}).$$

Therefore we have

$$|R_\Gamma| = e^{-o(m)} |S_\Gamma| \geq e^{-o(m)} |T_\Gamma| \geq m! e^{-(5/2+o(1))m}.$$

It remains to prove (26).

Fix $k \leq k_0 - 2$, and let P_k, Q_k , and R_k partition S_k as before. Suppose $\Lambda \in S_k$ has cycles $C_1, C_2, \dots, C_k$ in increasing order of size $\gamma_1, \gamma_2, \dots, \gamma_k$.

Suppose $\rho \in S_k$. Suppose $(p, \lambda(p)) \in C_i$ and $(q, \lambda(q)) \in C_j$ are deleted where $i \neq j$ and $i, j \in \{1, 2, \dots, k-1\}$. We delete two edges $(r, \lambda(r))$ and $(s, \lambda(s))$ from C_k such that the four paths created can be patched into one cycle, reducing the number of cycles by two. We also ensure that the corresponding ρ' is cyclic. If $\rho \in R_k$, then $\gamma_i + \gamma_j \leq .92m$. If $\rho \in P_k \cup Q_k$, then $\gamma_i + \gamma_j \leq m - \gamma_k \leq .54m$. The binomial term in (21) is thus at least $\binom{(.96m-.92m)/2}{2} > 0$, and this ensures that we have at least one pair of edges in γ_k that can be deleted. Thus there is at least one way to transform $\rho \in S_k$ into $\rho' \in S_{k-2}$. Fix one way for each $\rho \in S_k$. Clearly, each ρ' arises in at most m^4 times in this way.

This verifies (26) and completes our proof of Theorem 2. $\square$

COLORING OF TRIANGLE-FREE GRAPHS ON THE DOUBLE TORUS*

DANIEL KRÁL'[†] AND MATĚJ STEHLÍK[‡]

Abstract. We show that every triangle-free graph on the double torus is 4-colorable. This settles a problem raised by Gimbel and Thomassen [*Trans. Amer. Math. Soc.*, 349 (1997), pp. 4555–4564].

Key words. triangle-free graphs, double torus, graphs on surfaces

AMS subject classifications. 05C15, 05C10

DOI. 10.1137/07067920X

1. Introduction. Colorings of graphs on surfaces permanently attract the attention of researchers in graph theory. The most classical result is the four color theorem [1, 13], which asserts that every planar graph is 4-colorable. Another classical result is Grötzsch's theorem [8], which states that every planar graph with no triangles is 3-colorable; also see [15, 16] for short proofs of this result.

Gimbel and Thomassen [7] generalized Grötzsch's theorem to surfaces of higher genera. While the chromatic number of a graph embedded on a surface of genus g is bounded by $O(g^{1/2})$ [9], the chromatic number of a triangle-free graph that can be embedded on a surface of genus g is bounded by $O((g/\log g)^{1/3})$ [7]. On the other hand, there exist triangle-free graphs embeddable on a surface of genus g that have a chromatic number $\Omega(g^{1/3}/\log g)$ [7].

Let us focus on triangle-free graphs on surfaces of small genera. As we have already mentioned, triangle-free plane graphs are 3-colorable. Every triangle-free graph in the projective plane is 3-degenerate and thus 4-colorable. On the other hand, there are nonbipartite triangle-free projective planar quadrangulations, and each such quadrangulation is 4-chromatic [18]. Kronk and White [11] established that every triangle-free graph on the torus is 4-colorable; as in the case of the projective plane, the bound cannot be improved since there exist triangle-free graphs on the torus that are not 3-colorable (one example is the Cayley graph for the group Z_{13} with generators 1 and 5 [2]). Gimbel and Thomassen [7] asked whether the result of Kronk and White can be extended to the double torus S_2 .

PROBLEM 1 (see [7, Problem 9]). *Is every graph on S_2 of girth four 4-colorable?*

In the present paper, we answer this question in the affirmative way (see Corollary 23). As there are triangle-free graphs on the torus that are not 3-colorable, the bound cannot be improved.

2. Preliminary observations. In this section, we recall standard graph theory notation related to graph colorings and critical graphs. However, we do not provide any detailed introduction to topological graph theory. We refer the reader to a recent

monograph [12] if interested. The only fact that we will need in our further considerations is the following corollary of Euler's formula: The number of edges of a simple triangle-free graph that can be embedded on the surface S_g is at most $2n - 4 + 4g$. In particular, the following lemma holds.

LEMMA 1. *The number of edges of an n -vertex triangle-free graph that can be embedded on the double torus is at most $2n + 4$.*

We also assume that the reader is familiar with basic graph theory concepts such as k -colorability or the chromatic number of graphs. In our investigations, the structure of "extremal" non- $(k-1)$ -colorable graphs will play a crucial role: A graph G is k -critical if it is not $(k-1)$ -colorable but each proper subgraph of G is $(k-1)$ -colorable. Clearly, the minimum degree of a k -critical graph is at least $k-1$. The vertices of a k -critical graph can be partitioned into two groups: *low-degree* vertices of degree $k-1$ and *high-degree* vertices of degree k or more. The subgraph induced by the low-degree vertices of G is denoted by $L_{k-1}(G)$ and that induced by the high-degree vertices by $H_{k-1}(G)$. One of the first results on critical graphs is the following theorem of Gallai that restricts the possible structure of the components of the low-degree subgraph. Recall that a *Gallai tree* is a graph such that each block (maximal 2-connected subgraph) is an odd cycle or a complete graph.

THEOREM 2 (see Gallai [6]). *If G is a k -critical graph, then each component of $L_{k-1}(G)$ is a Gallai tree.*

Gallai [6] also studied which colorings of the high-degree subgraph cannot be extended to the components of low-degree subgraphs. In particular, he showed that if each component of $L_{k-1}(G)$ contains a vertex adjacent to two vertices of $H_{k-1}(G)$ of the same color, then the coloring of $H_{k-1}(G)$ can be extended to all of the components of $L_{k-1}(G)$. This is in fact a special case of a more general phenomenon studied in the area of list colorings [3, 5, 17]. Results obtained in this area allow us to replace the original condition of Gallai by several others. In particular, the following lemma is true.

LEMMA 3. *Let G be a 5-critical graph. Any precoloring of $H_4(G)$ with four colors can be extended to any component of $L_4(G)$ that has*

- *a vertex adjacent to two vertices of $H_4(G)$ of the same color, or*
- *two adjacent vertices v_1 and v_2 of degree two in $L_4(G)$ such that their neighbors in $H_4(G)$ have at least three distinct colors.*

We will also use the following result of Stiebitz [14] that allows us to bound the number of components of the high-degree subgraph by the number of components of the low-degree subgraph.

THEOREM 4 (see Stiebitz [14]). *If G is a k -critical graph that contains a vertex of degree $k-1$, then the number of components of $H_{k-1}(G)$ does not exceed the number of components of $L_{k-1}(G)$.*

Our goal is to show that every triangle-free graph on the double torus is 4-colorable. In order to do so, we show that there are no 5-critical triangle-free graphs that can be embedded on the double torus (Theorem 22). As we have already observed, the minimum degree of a 5-critical graph is four. On the other hand, Lemma 1 implies that the average degree of each triangle-free graph on the double torus is at most slightly above four. Hence the high-degree subgraph of a triangle-free 5-critical graph on the double torus cannot contain too many vertices.

LEMMA 5. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. Let ℓ be the number of vertices of $H_4(G)$ and $d_1, \dots, d_\ell$ their degrees in G . The sum $\sum_{i=1}^{\ell} (d_i - 4)$ is at most eight. In particular, the number of vertices of $H_4(G)$ is at most eight.*

Lemma 5 easily follows from Lemma 1 and the fact that the minimum degree of a 5-critical graph is four, and we leave its detailed proof to the reader.

We finish this section with two results on the minimum number of vertices of a triangle-free graph that is not 3- or 4-colorable. Let us remark that the bounds given in the following two theorems are the best possible.

THEOREM 6 (see Chvátal [4]). *Every triangle-free graph on at most ten vertices is 3-colorable.*

THEOREM 7 (see Jensen and Royle [10]). *Every triangle-free graph on at most 21 vertices is 4-colorable.*

3. Structure of the low-degree subgraph. In this section, we focus on the possible structure of the low-degree subgraph of triangle-free 5-critical graphs on the double torus. We define the *weight* of a component G_0 of $L_4(G)$ to be the number of edges between G_0 and $H_4(G)$. Note that the weight of each component of $L_4(G)$ is even. The next lemma provides us with a simple bound on the total weight of the components of $L_4(G)$ in terms of the number of high-degree vertices and the number of edges of $H_4(G)$.

LEMMA 8. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If $H_4(G)$ has ℓ vertices and m edges, then the total weight of the components of $L_4(G)$ is at most $4\ell + 8 - 2m$.*

Proof. Let $d_1, \dots, d_\ell$ be the degrees of the vertices of $H_4(G)$. By Lemma 5, the sum of the degrees $\sum_{i=1}^{\ell} d_i$ of the vertices of $H_4(G)$ is at most $4\ell + 8$. If the number of edges of $H_4(G)$ is m , then the number of edges between $H_4(G)$ and $L_4(G)$ is at most $4\ell + 8 - 2m$. Hence the total weight of the components of $L_4(G)$ is at most $4\ell + 8 - 2m$. $\square$

By Theorem 2, each component of $L_4(G)$ is a Gallai tree. Let us call a component G_0 of $L_4(G)$ that has no vertices of degree one and that is not an odd cycle a *grunter*. Since each end-block of a grunter must be an odd cycle of length at least five (recall that we are considering triangle-free graphs), the next lemma readily follows from Theorem 2.

LEMMA 9. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus, and let G_0 be a component of $L_4(G)$. If G_0 does not contain a vertex of degree one, then either G_0 is an odd cycle or it is a grunter. In particular, if G_0 does not contain a vertex of degree one, then it contains two adjacent vertices of degree two.*

The simplest components of $L_4(G)$ are trees. A weight of such an n -vertex component is $2n + 2$. In the next lemma, we show that if the weight of an n -vertex component is significantly smaller than $2n + 2$, then n must be quite large. This will allow us to efficiently analyze the structure of components of $L_4(G)$ based on their weights in our further considerations.

LEMMA 10. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If G' is an n -vertex component of $L_4(G)$, then the weight of G' is equal to $2n + 2$ if and only if G' is a tree, and its weight is equal to $2n$ if and only if G' is a cycle or a unicyclic graph. Moreover, if the weight of G' is $2n - 2\ell$, then $n \geq 5 + 4\ell$. In particular, if the weight of G' is less than $2n$, then the weight of G' is at least 16, and if it is less than $2n - 2$, then it is at least 22.*

Specifically, if G' has no vertex of degree one, then its weight is at least $2n \geq 10$, and if G' is a grunter, then its weight is at least 16.

Proof. Observe first that the blocks of G' are odd cycles and edges only since G' is triangle-free. If G' has k blocks that are odd cycles, then the weight of G' is

$2n + 2 - 2k$. Moreover, if G' has k blocks that are odd cycles, the number of vertices of G' is at least $4k + 1$. Hence if the weight of G' is $2n + 2$, then $k = 0$ and G' is a tree. If the weight of G' is $2n$, then $k = 1$ and G' is a cycle or a unicyclic graph.

Assume now that the weight of G' is $2n - 2\ell$. We conclude that G' contains $k = \ell + 1$ blocks that are odd cycles, and thus it contains at least $4k + 1 = 4\ell + 5$ vertices. In particular, if the weight of G' is less than $2n$, i.e., $\ell \geq 1$, then G' has weight of at least

$$2 \cdot (4\ell + 5) - 2\ell = 6\ell + 10 \geq 16.$$

It remains to prove the last part of the lemma. If G' has no vertex of degree one, then $k \geq 1$ and the weight of G' is at least

$$2n + 2 - 2k \geq 2(4k + 1) + 2 - 2k = 6k + 4 \geq 10.$$

If G' is a grunter, then $k \geq 2$ and, consequently, its weight is at least $6k + 4 \geq 16$. The whole lemma has now been established. $\square$

We now aim to utilize our observations on the structure of the low-degree subgraph of a triangle-free 5-critical graph on the double torus. Let us start by showing that the number of components of $L_4(G)$ must be at least two.

LEMMA 11. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The subgraph $L_4(G)$ contains at least two components.*

Proof. By Lemma 5 and Theorem 6, $L_4(G)$ contains at least one component. Assume for the sake of contradiction that $L_4(G)$ has a single component G' . Since G' is a Gallai tree it contains a vertex v of degree at most two. Let w_1 and w_2 be two neighbors of v in $H_4(G)$. Note that the vertices w_1 and w_2 are not adjacent since G is triangle-free. Consider a coloring of $H_4(G)$ with three colors, which exists by Lemma 5 and Theorem 6, and recolor the vertices w_1 and w_2 with the fourth (unused) color. By Lemma 3, the precoloring of the vertices of $H_4(G)$ can be extended to a coloring of G with four colors—a contradiction. $\square$

We finish this section with three lemmas which bound the number of components of $L_4(G)$ under certain assumptions on the total number of vertices and the total weight of the components of $L_4(G)$.

LEMMA 12. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If the total weight of the components of $L_4(G)$ is at most 26 and $L_4(G)$ has at least 15 vertices, then the number of components of $L_4(G)$ does not exceed one.*

Proof. Assume for the sake of contradiction that $L_4(G)$ has at least two components. Since $26 < 2 \cdot 15$, $L_4(G)$ must contain an n_1 -vertex component G_1 of weight at most $2n_1 - 2$.

If the weight of G_1 is exactly $2n_1 - 2$, then $L_4(G)$ must contain another n_2 -vertex component G_2 of weight less than $2n_2$. By Lemma 10, the weight of each of G_1 and G_2 is at least 16. Since the total weight of the components of $L_4(G)$ is at most 26, the component G_2 could not exist. We conclude that the weight of G_1 is at most $2n_1 - 4$.

By Lemma 10, the weight of G_1 is at least 22. Since the total weight of the components of $L_4(G)$ is at most 26, the weight of G_1 is 22 and the weight of the other component of $L_4(G)$ is four. We conclude that G_1 has 13 vertices and the other component of $L_4(G)$ is comprised of a single vertex. Hence $L_4(G)$ has $n_1 + 1 = 13 + 1 = 14$ vertices, which contradicts our assumption that the number of vertices of $L_4(G)$ is at least 15. $\square$

In the next lemma, we show that the number of components of $L_4(G)$ does not exceed two under some weaker assumptions.

LEMMA 13. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If the total weight of the components of $L_4(G)$ is at most 28 and $L_4(G)$ has at least 14 vertices, then the number of components of $L_4(G)$ does not exceed two.*

Proof. Assume for the sake of contradiction that $L_4(G)$ is comprised of three or more components. Since $28/3 < 10$, $L_4(G)$ contains a component that is a tree by Lemma 10. Let G_1 be such a component and n_1 its number of vertices. By Lemma 10, the weight of G_1 is $2n_1 + 2$.

Since the number of vertices of $L_4(G)$ is at least 14 and the total weight of its components is 28, $L_4(G)$ must contain an n_2 -vertex component G_2 of weight at most $2n_2 - 2$. Since the weight of G_2 is at most $28 - 2 \cdot 4 = 20$, the weight of G_2 is $2n_2 - 2$ by Lemma 10. On the other hand, since the sum of the weights of G_1 and G_2 is at least $4 + 16 = 20$, any component of $L_4(G)$ distinct from G_1 and G_2 is a tree by Lemma 10. Hence G_2 is the only component of $L_4(G)$ which is not a tree. We infer from Lemma 10 that the total weight of the components of $L_4(G)$ is at least $2 \cdot 14 + 2 = 30$, which is impossible. This completes the proof. $\square$

Finally, under even weaker assumptions, the number of components of $L_4(G)$ is at most three.

LEMMA 14. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If the total weight of the components of $L_4(G)$ is at most 30 and $L_4(G)$ has at least 14 vertices, then the number of components of $L_4(G)$ does not exceed three.*

Proof. Assume for the sake of contradiction that $L_4(G)$ contains four or more components. Since the average weight of the components of $L_4(G)$ is also at most $30/4 < 10$, one of the components of $L_4(G)$ is a tree, say G_1 . Since the average weight of the components of $L_4(G)$ distinct from G_1 is at most $(30 - 4)/3 < 10$, $L_4(G)$ contains another component G_2 that is a tree. Let n_1 and n_2 be the number of vertices of G_1 and G_2 , respectively. By Lemma 10, the sum of the weights of G_1 and G_2 is $2(n_1 + n_2) + 4$.

Since $L_4(G)$ has 14 vertices and the total sum of the weights of the components of $L_4(G)$ is 30, G must contain an n_3 -vertex component G_3 of weight at most $2n_3 - 2$. Since the weight of G_3 is at most $30 - 3 \cdot 4 = 18$, the weight of G_3 is $2n_3 - 2$ by Lemma 10. Note that the weight of G_3 must also be at least 16. Because the total weight of G_1 , G_2 , and G_3 is at least 24, $L_4(G)$ contains four components and the component G_4 is a tree. Let n_4 be the number of vertices of G_4 . By Lemma 10, the total weight of the components of $L_4(G)$ is $2(n_1 + n_2 + n_3 + n_4) + 4$. Since $n_1 + n_2 + n_3 + n_4 \geq 14$, the total weight of the components of $L_4(G)$ must be at least 32, which is impossible. $\square$

4. Number of edges in the high-degree subgraph. In this section we focus on estimates on the number of edges that could be contained in the high-degree subgraph of a triangle-free 5-critical graph on the double torus. We start by showing a lower bound on the number of such edges.

LEMMA 15. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The subgraph $H_4(G)$ contains at least three edges.*

Proof. Assume to the contrary that there exists a graph G in which $H_4(G)$ contains at most two edges. If $H_4(G)$ has at most one edge or two edges sharing a vertex, we can color the vertices of $H_4(G)$ in such a way that all of the vertices of $H_4(G)$ have the same color except for a single vertex with a different color. Let G' be a component of $L_4(G)$. If G' contains a vertex v of degree one, then v is adjacent to two vertices of $H_4(G)$ of the same color. If G' contains no vertices of degree one, then G' contains two adjacent vertices v_1 and v_2 of degree two by Lemma 9. Since G

is triangle-free, the vertices v_1 and v_2 are adjacent to four different vertices of $H_4(G)$. Hence one of them is adjacent to two vertices of the same color. We conclude that each component of $L_4(G)$ has a vertex adjacent to two vertices of $H_4(G)$ of the same color. Lemma 3 implies that G is 4-colorable, which contradicts our assumption that G is 5-critical.

It remains to consider the case when $H_4(G)$ is formed by two disjoint edges, say x_1x_2 and y_1y_2 , and ℓ isolated vertices, $0 \leq \ell \leq 4$. Let c_{ij} , $i, j = 1, 2$, be the coloring of $H_4(G)$ that assigns the vertices x_i and y_j the same color and all the remaining vertices of $H_4(G)$ another color. Let us consider a component G' of $L_4(G)$. Assume that G' has no vertices of degree one and each vertex of G' is adjacent to vertices of $H_4(G)$ with mutually distinct colors. Since $H_4(G)$ is colored with only two colors, G' has no vertices of degree one. Moreover, each vertex of G' of degree two is adjacent to either x_i or y_j . Since two vertices adjacent in G' cannot both be neighbors of x_i or of y_j , G' is not an odd cycle. Hence Lemma 9 yields that G' is a grunter. Moreover, each vertex of degree two contained in an end-block of the grunter is adjacent to either x_i or y_j (note that the vertices of degree two in an end-block must be adjacent alternately to x_i and y_j).

Let us now distinguish two cases based on the number of grunter components of $L_4(G)$. The number of grunter components of $L_4(G)$ is at most two since each grunter has a weight of at least 16 and the total weight of the components of $L_4(G)$ is at most $40 - 4 = 36$ by Lemma 8.

We first consider the case that $L_4(G)$ has a single grunter component G_1 . If G_1 contains a vertex of degree two adjacent to two vertices in $H_4(G)$ with the same color in the coloring c_{11} or in c_{12} , then the coloring of $H_4(G)$ can be extended to G_1 by Lemma 3. Otherwise, each vertex of degree two is adjacent to two vertices of distinct colors both in the coloring c_{11} and the coloring c_{12} . Hence, the vertices of degree two in the end-blocks of G_1 are adjacent to x_1 and y_1 alternately (because of the coloring c_{11}) and to x_1 and y_2 alternately (because of the coloring c_{12}). Consequently, there is a vertex z of G_1 adjacent to both y_1 and y_2 . We conclude that G contains a triangle y_1y_2z .

It remains to analyze the case that $L_4(G)$ has two grunter components. Let G_1 and G_2 be these two components. Assume that for each of the four colorings c_{ij} , all of the vertices of G_1 or all of the vertices G_2 of degree two are adjacent to vertices of $H_4(G)$ with two different colors. In the previous paragraph, we have shown that G_1 contains a vertex of degree two adjacent to two vertices of $H_4(G)$ with the same color in c_{11} or c_{12} . By symmetry, assume that G_1 contains a vertex of degree two adjacent to two vertices of the same color in c_{12} . Similarly, observe that G_2 contains a vertex of degree two adjacent to two vertices of the same color in c_{12} or c_{22} . Since all vertices of G_2 of degree two must be adjacent to two vertices of distinct colors in c_{12} (otherwise, c_{12} could be extended to both G_1 and G_2), G_2 contains a vertex of degree two adjacent to two vertices of the same color in c_{22} . Along these lines, we conclude that G_1 contains vertices of degree two adjacent to two vertices of $H_4(G)$ of the same color both in c_{12} and c_{21} , and G_2 contains vertices of degree two adjacent to two vertices of the same color both in c_{11} and c_{22} .

Since neither of these four colorings c_{ij} can be extended to both G_1 and G_2 , all vertices of degree two of G_1 are adjacent to two vertices of different colors both in c_{11} and c_{22} , and all vertices of degree two of G_2 are adjacent to two vertices of different colors both in c_{12} and c_{21} . In particular, each vertex of degree two lying in an end-block of G_1 is either adjacent to x_1 and y_2 or to x_2 and y_1 (the other cases

are excluded by our assumption that G is triangle-free). Observe that G_1 has at least four vertices of the former kind and at least four vertices of the latter kind. Similarly, each vertex of degree two lying in an end-block of G_2 is either adjacent to x_1 and y_1 or to x_2 and y_2 , and the number of vertices of each of the two kinds is at least four. We conclude that all of the vertices x_1, x_2, y_1 , and y_2 have at least eight neighbors in G_1 and G_2 . Hence the degree of each of them in G is at least nine, which is impossible by Lemma 5.

We infer from our discussion that for at least one of the colorings $c_{11}, c_{12}, c_{21}, c_{22}$, each component of $L_4(G)$ has a vertex adjacent to two vertices of $H_4(G)$ of the same color: Indeed, we have established this for the components G_1 and G_2 , and for other components, which are not grunterns, this follows from the facts that each other component contains a vertex of degree one and that the vertices of $H_4(G)$ are 2-colored. We can now infer from Lemma 3 that G is 4-colorable, which contradicts our assumption that G is 5-critical. $\square$

We have just established a lower bound on the number of edges of $H_4(G)$. Our next aim is to find an upper bound.

LEMMA 16. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The subgraph $H_4(G)$ contains at most six edges.*

Proof. Assume for the sake of contradiction that $H_4(G)$ has seven or more edges. By Lemma 5 and Theorem 7, $L_4(G)$ has at least 14 vertices, and, by Lemma 11, $L_4(G)$ is comprised of at least two components. By Lemma 8, the total weight of the components of $L_4(G)$ cannot exceed $40 - 14 = 26$. Since $26 < 2 \cdot 14$, $L_4(G)$ has an n_1 -vertex component G_1 of weight less than $2n_1$. On the other hand, the weight of G_1 is at least 16 by Lemma 10. Hence the weight of any other component G_2 of $L_4(G)$ is at most 10. If G_2 were a tree, then $L_4(G)$ would have to contain another component of weight less than twice the number of its vertices, which is impossible. We conclude that G_2 is a cycle of length 5 and its weight is exactly 10. Consequently, the weight of G_1 is 16 and G_1 is a double-5-cycle; i.e., two 5-cycles sharing a vertex. Since the total weight of G_1 and G_2 is 26, the number of vertices of $H_4(G)$ is eight and it contains exactly seven edges. Moreover, the degree of each vertex of $H_4(G)$ in G is five.

Since $H_4(G)$ has eight vertices and seven edges, $H_4(G)$ contains at least four vertices v of degree at most two. Since G is triangle-free, the vertices of G_2 are adjacent to at least five different vertices of $H_4(G)$, and thus there is a vertex v of $H_4(G)$ of degree at most two adjacent to a vertex of G_2 . Since each vertex of $H_4(G)$ can be adjacent to at most two vertices of G_2 (otherwise G would contain a triangle) and the degree of every vertex of $H_4(G)$ in G is five, there exists a vertex v_0 of $H_4(G)$ adjacent to both a vertex of G_1 and a vertex of G_2 . Let v_i be any of the neighbors of v_0 in G_i , $i = 1, 2$. Note that the degree of v_i in G_i is two. Since G_1 is a double-5-cycle, the vertex v_1 has a neighbor v'_1 of degree two in G_1 . Similarly, v_2 has a neighbor v'_2 of degree two in G_2 .

Now color the vertices of $H_4(G)$ with three colors (this is possible by Theorem 6) and recolor the vertex v_0 with the fourth (unused) color. If the vertex v'_1 is not adjacent to two vertices of $H_4(G)$ of the same color, then the neighbors of v_1 and v'_1 in $H_4(G)$ must have at least three distinct colors (two colors appear because of the neighbors of v'_1 and the third color appears because of the vertex v_0 ; note that v_0 is not a neighbor of v'_1 since G is triangle-free). Similarly, if v'_2 is not adjacent to two vertices of $H_4(G)$ of the same color, then the neighbors of v_2 and v'_2 have at least three distinct colors. We infer from Lemma 3 that the precoloring of the vertices of

$H_4(G)$ can be extended to a coloring of all of the vertices of G with four colors—a contradiction. $\square$

Lemmas 15 and 16 now imply the following.

LEMMA 17. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The number of edges of $H_4(G)$ is between three and six.*

5. Structure of the high-degree subgraph. In this section, we further refine our knowledge about the possible structure of high-degree subgraphs of triangle-free 5-critical graphs G on the double torus. Let us start by showing that the number of vertices of $H_4(G)$ must be eight for every such graph G .

LEMMA 18. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The number of vertices of $H_4(G)$ is eight. In particular, the degree of each vertex of $H_4(G)$ is five.*

Proof. Assume first that $H_4(G)$ has at most six vertices. By Lemma 17, $H_4(G)$ contains at least three edges. Hence the total weight of the components of $L_4(G)$ is at most $32 - 6 = 26$ by Lemma 8. By Lemma 11, $L_4(G)$ is comprised of at least two components, and by Theorem 7, $L_4(G)$ has at least $22 - 6 = 16$ vertices, which is impossible by Lemma 12.

It remains to exclude the case when the number of vertices of $H_4(G)$ is seven. By Lemma 17, the number of edges of $H_4(G)$ is between three and six. We first exclude the case when $H_4(G)$ has only three edges. Since $H_4(G)$ has seven vertices, $H_4(G)$ is comprised of at least four components. Hence the number of components of $L_4(G)$ is at least four by Theorem 4. By Lemma 8, the total weight of the components of $L_4(G)$ is $36 - 6 = 30$, and by Theorem 7, the number of vertices of $L_4(G)$ is at least 15. However, such a graph G cannot exist by Lemma 14.

We conclude that $H_4(G)$ has at least four edges. Recall that the number of vertices of $L_4(G)$ is at least 15 by Theorem 7. If $H_4(G)$ has four edges, then Lemma 8 yields that the total weight of the components of $L_4(G)$ is at most $36 - 8 = 28$, and Theorem 4 yields that the number of components of $L_4(G)$ is at least three. Such a graph G cannot exist by Lemma 13. If $H_4(G)$ has five or more edges, then by Lemma 8 the total weight of the components of $L_4(G)$ is at most $36 - 10 = 26$, and Theorem 4 yields that the number of components of $L_4(G)$ is at least two. However, Lemma 12 excludes the existence of such a graph G . We conclude that $H_4(G)$ must have eight vertices. The rest follows from Lemma 5. $\square$

Another fact that we establish in this section is that $H_4(G)$ must be bipartite.

LEMMA 19. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. The subgraph $H_4(G)$ is bipartite.*

Proof. Assume for the sake of contradiction that $H_4(G)$ is not bipartite. By Lemma 18, the number of vertices of $H_4(G)$ is eight. Since the number of edges of $H_4(G)$ does not exceed six by Lemma 17 and G is triangle-free, $H_4(G)$ contains five or six edges. In particular, $H_4(G)$ contains a cycle of length five and possibly one more edge. In the rest, we distinguish two cases based on the number of edges of $H_4(G)$ and eventually obtain contradiction in each of them.

Assume first that $H_4(G)$ contains exactly five edges; i.e., $H_4(G)$ is comprised of a cycle of length five and three isolated vertices. In particular, the number of components of $L_4(G)$ is at least four by Theorem 4. By Lemma 8, the total weight of the components of $L_4(G)$ is at most $40 - 2 \cdot 5 = 30$, and by Theorem 7, the number of vertices of $L_4(G)$ is at least 14. Consequently, Lemma 14 excludes the existence of G .

We have shown that $H_4(G)$ must contain six edges. Consequently, the number

of components of $H_4(G)$ is three. By Lemma 8, the total weight of the components of $L_4(G)$ is $40 - 2 \cdot 6 = 28$, and by Theorem 7, the number of vertices of $L_4(G)$ is at least 14. Theorem 4 and Lemma 13 now exclude the existence of such a graph G . $\square$

6. Bipartite high-degree subgraph with eight vertices. In this section, we utilize our observations to exclude the existence of a 5-chromatic triangle-free graph that can be embedded on the double torus. Let us start by observing that if the high-degree subgraph is bipartite, then at least one of the components of the low-degree subgraph is an odd cycle or a grunter.

LEMMA 20. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If $H_4(G)$ is bipartite, then $L_4(G)$ has a component that is either an odd cycle or a grunter.*

Proof. Assume the contrary, i.e., that each component of $L_4(G)$ has a vertex of degree one by Theorem 4, and consider any 2-coloring of the vertices of $H_4(G)$. Since each component of $L_4(G)$ has a vertex of degree one (which must be adjacent to two vertices of the same color), G is 4-colorable by Lemma 3, contrary to our assumption that G is 5-critical. $\square$

In the proof of the main theorem, we consider 3-colorings of $H_4(G)$ such that one of the colors is assigned to a single vertex. We claim that all such colorings can be extended to all components of $L_4(G)$ of weight at most eight.

LEMMA 21. *Let G be a triangle-free 5-critical graph that can be embedded on the double torus. If the vertices of $H_4(G)$ are precolored with three colors in such a way that one of the three colors is assigned to a single vertex of G , then the precoloring of $H_4(G)$ can be extended to any component of $L_4(G)$ of weight at most 8.*

Proof. Let G' be a component of $L_4(G)$ of weight at most 8. By Lemma 10, G' is a tree. Hence G' is either a single vertex, an edge, or a path comprised of two edges. If G' contains a vertex adjacent to two vertices of $H_4(G)$ of the same color, then the precoloring can be extended to G' by Lemma 3. Hence if the precoloring of $H_4(G)$ cannot be extended to G' , then G' is a path $v_1v_2v_3$ and the vertices v_1 and v_3 are adjacent to vertices of three distinct colors. Since $H_4(G)$ is precolored with three distinct colors, the vertices v_1 and v_3 can be colored with the fourth color. Since the vertex v_2 has degree four, it is adjacent to vertices of at most three distinct colors (its neighbors v_1 and v_3 have the same color), and thus the coloring can also be extended to v_2 as desired. $\square$

We are now ready to prove our main result.

THEOREM 22. *There is no triangle-free 5-critical graph G that can be embedded on the double torus.*

Proof. By Lemmas 18 and 19, $H_4(G)$ is a bipartite graph with eight vertices. By Lemma 17, the number of edges of $H_4(G)$ is between three and six. Hence the total weight of the components of $L_4(G)$ is at most 34 by Lemma 8.

In the rest of the proof, we establish a series of claims that eventually combine to the proof of the theorem.

CLAIM 1. *If $L_4(G)$ contains a component G_1 whose weight is less than twice the number of the vertices of G_1 , then $L_4(G)$ contains another component of weight ten or more.*

Assume the opposite. Let n_1 be the number of vertices of G_1 . Since G_1 is the only component of $L_4(G)$ of weight ten or more, the remaining components of $L_4(G)$ are trees of weight at most eight by Lemma 10. By Lemmas 10 and 20, G_1 is a grunter (G_1 cannot be a cycle since its weight is less than n_1). Consider any 2-coloring c of

$H_4(G)$. If the precoloring c cannot be extended to $L_4(G)$, then each vertex of G_1 of degree two is adjacent to two vertices of $H_4(G)$ of two distinct colors. Let v_1 and v_2 be any two adjacent vertices of degree two in G_1 . Now recolor any vertex of $H_4(G)$ adjacent to v_1 with the third (unused) color. G_1 now contains two adjacent vertices of degree two, namely v_1 and v_2 , such that their neighbors in $H_4(G)$ are colored with three distinct colors. In particular, the precoloring of $H_4(G)$ can be extended to G_1 by Lemma 3. Since the precoloring of $H_4(G)$ can be extended to the remaining component(s) of $L_4(G)$ by Lemma 21, G is 4-colorable, which is impossible.

CLAIM 2. *The subgraph $L_4(G)$ contains no component of weight less than twice the number of its vertices.*

Assume the contrary, i.e., that $L_4(G)$ contains a component G_1 with n_1 vertices of a weight of at most $2n_1 - 2$. Claim 1 yields that $L_4(G)$ contains another component of a weight of ten or more. Let G_2 be this component of $L_4(G)$ and n_2 the number of its vertices. Since the weight of G_1 is at most $2n_1 - 2$, its weight is at least 16 by Lemma 10. Since the total weight of G_1 and G_2 is at least $16 + 10 = 26$, the weight of any component of $L_4(G)$ distinct from G_1 and G_2 is at most eight. Assume that G_1 contains a vertex w of degree one. Hence G_2 is a grunter or a cycle by Lemma 20. In particular, G_2 contains two adjacent vertices of degree two, say v_1 and v_2 . Since G is triangle-free, v_1 and v_2 have four distinct neighbors in H_4 , say $u_1, \dots, u_4$. By symmetry, we can assume that u_1 is not a neighbor of w .

Now consider a coloring of the vertices of $H_4(G)$ with two colors. If G_2 contains a vertex of degree two adjacent to two vertices of $H_4(G)$ of the same color, then the precoloring of the vertices of $H_4(G)$ can be extended to all of the components of $L_4(G)$ by Lemma 3 since each component of $L_4(G)$ has a vertex adjacent to two vertices of $H_4(G)$ of the same color. Otherwise, each vertex of G_2 of degree two is adjacent to two vertices of $H_4(G)$ of distinct colors. Now recolor the vertex u_1 with the third (unused) color. The precoloring of $H_4(G)$ can be extended to G_1 by Lemma 3 since the vertex w is adjacent to two vertices of $H_4(G)$ of the same color, to G_2 since the vertices v_1 and v_2 are adjacent to vertices of $H_4(G)$ of three distinct colors, and to the remaining components of $L_4(G)$ by Lemma 21.

We conclude that G_1 has no vertex of degree one. An analogous argument yields that G_2 also has no vertex of degree one. Since the weight of G_1 is at most $2n_1 - 2$, G_1 is a grunter. If G_2 were also a grunter, then the sum of the weights of G_1 and G_2 would be at least $2 \cdot 16 = 32$ and G_1 and G_2 would be the only components of $L_4(G)$. By Lemma 8, the number of edges of $H_4(G)$ would be at most four, and thus the number of components of $H_4(G)$ would be at least four, which is impossible by Theorem 4. Hence G_2 is an odd cycle.

Let v_1 and v_2 be two adjacent vertices of degree two in G_1 , and let A_1 be the set of their four neighbors in $H_4(G)$. Let A_2 be the set of the neighbors of the vertices of G_2 in $H_4(G)$. Since G is triangle-free, A_2 contains at least five distinct vertices. Hence there is a vertex u contained in both A_1 and A_2 . By symmetry, we can assume that u is a neighbor of v_1 . Let w_1 be a neighbor of u in G_2 and w_2 a vertex of G_2 adjacent to w_1 .

Now consider a coloring of $H_4(G)$ with three distinct colors such that all of the vertices except u are colored with only two colors and u is colored with the third color. By Lemma 21, the coloring can be extended to all of the components of $L_4(G)$ with a possible exception of G_1 and G_2 . If the vertex v_2 is adjacent to two vertices of $H_4(G)$ of the same color, then the precoloring can be extended to G_1 by Lemma 3. Otherwise, the vertices v_1 and v_2 are adjacent to vertices of $H_4(G)$ with three distinct

colors and the precoloring can be extended to G_1 again by Lemma 3. An analogous argument yields that the precoloring can be extended to G_2 . Hence the graph G is 4-colorable, which is impossible. The proof of Claim 2 is now complete.

We have established that the weight of each component of $L_4(G)$ is at least twice the number of its vertices. In particular, all the components of $L_4(G)$ are trees, cycles, and unicyclic graphs. By Lemma 20, at least one of the components is an odd cycle. Let G_1 be this component and n_1 the number of its vertices. In addition, let A_1 be the neighbors of G_1 in $H_4(G)$. Note that $|A_1| \geq 5$.

CLAIM 3. *The subgraph $L_4(G)$ has at least three components of a weight of ten or more.*

First, assume that G_1 is the only component of $L_4(G)$ of a weight of ten or more. Now choose a vertex $w \in A_1$ and color the vertices of $H_4(G)$ with three colors in such a way that all of the vertices of $H_4(G)$ except w are assigned only two colors. Then, the precoloring can be extended to $L_4(G)$ by Lemmas 3 and 21, which is impossible.

Assume next that $L_4(G)$ has two components of a weight of ten or more; let G_2 be such a component distinct from G_1 and let n_2 be the number of its vertices. If G_2 has a vertex v of degree one, then choose $w \in A_1$, that is not a neighbor of v , and proceed as in the previous paragraph. Otherwise, G_2 must be an odd cycle. Since the vertices of G_2 have at least five neighbors in $H_4(G)$, there exists a vertex $w \in A_1$ adjacent to both G_1 and G_2 . Analogously to the preceding cases, the precoloring assigning the vertices of $H_4(G)$ except w two colors and w the third color can be extended to each component of $L_4(G)$.

CLAIM 4. *There is no triangle-free 5-critical graph that can be embedded on the double torus.*

Claim 3 implies that there are at least three components, say G_1 , G_2 , and G_3 , that have a weight of ten or more. If $L_4(G)$ had four components, then their total weight would be at least $3 \cdot 10 + 4 = 34$. Hence $H_4(G)$ would have only three edges by Lemma 8. On the other hand, $H_4(G)$ would have five components, which is impossible by Theorem 4. We conclude that G_1 , G_2 , and G_3 are the only components of $L_4(G)$.

Since $L_4(G)$ is comprised of only three components, $H_4(G)$ has at least five edges by Theorem 4. Hence the total weight of the components of $L_4(G)$ is at most $40 - 5 \cdot 2 = 30$ by Lemma 8. Consequently, the weight of each G_i , $i = 1, 2, 3$, is 10, and $H_4(G)$ is a forest with exactly five edges.

By Lemma 20 and symmetry, we can assume that G_1 is a cycle of length five. If both G_2 and G_3 were trees, then the number of vertices of $L_4(G)$ would be $5 + 4 + 4 = 13$, which is impossible by Theorem 7. We conclude that G_2 is also a cycle of length five. Let A_i , $i = 1, 2$, be the set of vertices of $H_4(G)$ that are adjacent to a vertex of G_i . Note that $|A_i| \geq 5$ for $i = 1, 2$. Moreover, if $|A_i| = 5$, then each vertex of A_i is adjacent to exactly two vertices of G_i .

Now assume that G_3 is a tree, and let v_1 and v_2 be two of its leaves. If $|A_1| > 5$ or $|A_2| > 5$, then there exist three vertices u_1 , u_2 , and u_3 of $H_4(G)$ adjacent to vertices of both G_1 and G_2 . Now consider a 2-coloring of the vertices of $H_4(G)$. If there is a vertex u_i , $i = 1, 2, 3$, not adjacent to v_1 , then recolor u_i with the third (unused) color. The coloring of the vertices of $H_4(G)$ can now be extended to G_1 , G_2 , and G_3 by Lemma 3. Hence the vertices u_1 , u_2 , and u_3 are neighbors of v_1 . By symmetry, we can assume that the colors of u_1 and u_2 are the same. Let us now recolor the vertex u_3 with the third (unused) color. Again, Lemma 3 yields that the precoloring can be extended to the vertices of $L_4(G)$, which is impossible since G is not 4-colorable.

It remains to consider the case when $|A_1| = |A_2| = 5$. Note that each vertex of

A_i is adjacent to exactly two vertices of G_i since G is triangle-free. Since $H_4(G)$ has eight vertices, there exist two vertices u_1 and u_2 adjacent to vertices of both G_1 and G_2 . If u_i is not adjacent to v_1 or v_2 , then we consider a coloring of the vertices of $H_4(G)$ with three colors that assigns the vertex u_i a color different from all of the other vertices of $H_4(G)$ and proceed as in the previous paragraph. Hence both u_1 and u_2 are adjacent to v_1 and v_2 . However, this implies that the degree of u_1 is six, which contradicts our previous deduction that all the vertices of $H_4(G)$ have degree five (see Lemma 18).

We can now conclude that all of the three components G_1 , G_2 , and G_3 are cycles of length five. As in the previous cases, let A_i be the set of neighbors of G_i in $H_4(G)$. If there exists a vertex $u \in A_1 \cap A_2 \cap A_3$, then we color the vertices of $H_4(G)$ with two colors and recolor u with the third (unused) color. We infer from Lemma 3 that the precoloring can be extended to $L_4(G)$, which contradicts our assumption that G is not 4-colorable.

It remains to consider the case when $A_1 \cap A_2 \cap A_3 = \emptyset$. Let u_{12} be a vertex of $A_1 \cap A_2$ and u_{23} a vertex of $A_2 \cap A_3$. Note that such vertices exist since $|A_i| \geq 5$ for every $i = 1, 2, 3$. Now color the vertices of $H_4(G)$ with two colors, recolor u_{12} with the third (unused) color, and u_{23} with the fourth (unused) color. It is straightforward to check that each of the cycles G_1 , G_2 , and G_3 either contains a vertex adjacent to two vertices of the same color or its vertices are adjacent to vertices with at least three distinct colors; thus it has two adjacent vertices of degree two adjacent to vertices of at least three distinct colors in $H_4(G)$. Lemma 3 now yields that the precoloring can be extended to $L_4(G)$, which is impossible since G is not 4-colorable. $\square$

As a corollary of Theorem 22, we can now settle Problem 1.

COROLLARY 23. *Every graph on S_2 of girth four is 4-colorable.*

Acknowledgment. The authors would like to thank both of the anonymous referees for their comments that helped to improved the clarity of the arguments used.

POWER DOMINATION IN PRODUCT GRAPHS*

PAUL DORBEČ†, MICHEL MOLLARD†, SANDI KLAVŽAR‡, AND SIMON ŠPACAPAN§

Abstract. The power system monitoring problem asks for as few as possible measurement devices to be put in an electric power system. The problem has a graph theory model involving power dominating sets in graphs. The power domination number $\gamma_P(G)$ of G is the minimum cardinality of a power dominating set. Dorfling and Henning [*Discrete Appl. Math.*, 154 (2006), pp. 1023–1027] determined the power domination number of the Cartesian product of paths. In this paper the power domination number is determined for all direct products of paths except for the odd component of the direct product of two odd paths. For instance, if n is even and C a connected component of $P_m \times P_n$, where m is odd or $m \geq n$, then $\gamma_P(C) = \lceil n/4 \rceil$. For the strong product we prove that $\gamma_P(P_n \boxtimes P_m) = \max\{\lceil n/3 \rceil, \lceil (n+m-2)/4 \rceil\}$, unless $3m-n-6 \equiv 4 \pmod{8}$. The power domination number is also determined for an arbitrary lexicographic product.

Key words. domination, power domination, electric power monitoring, graph products, paths

DOI. 10.1137/060661879

1. Introduction. Electric power systems need to be continually monitored. One way to fulfill this task is to place phase measurement units at (carefully) selected locations in the system. The power system monitoring problem, as introduced in [2], asks for as few as possible measurement devices to be put in an electric power system.

The power system monitoring problem has been formulated as a graph-theory domination problem by Haynes et al. in [6]. This problem is of somehow different flavor than standard domination type problems, since putting a phase measurement unit into a vertex of a graph can have global effects. For instance, if an electric power system can be modeled by a path, then a single measurement unit suffices to monitor the system no matter how long the path.

For a vertex v of a graph G , let $N(v)$ denote the open neighborhood of v , and for a subset S of $V(G)$ let $N(S) = \cup_{v \in S} N(v) - S$. In the same way, the closed neighborhood $N[S]$ of a subset S is the set $N[S] = N(S) \cup S$.

Let G be a connected graph and S a subset of its vertices. Then we denote the set monitored by S with $M(S)$ and define it algorithmically as follows:

1. (*domination*)

$$M(S) \leftarrow S \cup N(S)$$

2. (*propagation*)

As long as there exists $v \in M(S)$ such that

$$N(v) \cap (V(G) - M(S)) = \{w\}$$

set $M(S) \leftarrow M(S) \cup \{w\}$.

In other words, the set $M(S)$ is obtained from S as follows. First put into $M(S)$ the vertices from the closed neighborhood of S . Then repeatedly add to $M(S)$ vertices w that have a neighbor v in $M(S)$ such that all the other neighbors of v are already in $M(S)$. After no such vertex w exists, the set monitored by S has been constructed.

The set S is called a *power dominating set* of G if $M(S) = V(G)$ and the *power domination number* $\gamma_P(G)$ is the minimum cardinality of a power dominating set.

In [6] these concepts have been introduced in a slightly more complicated way by treating both vertices and edges of a given graph. However, it is easily shown that both approaches are equivalent in the sense that the power dominating sets correspond. In fact, this is also (implicitly) observed in [3].

The power domination number has received considerable attention from the algorithmic point of view. As it turned out, the problem is quite difficult—it is NP-complete even when restricted to bipartite graphs and chordal graphs [6], to planar graphs and circle graphs [4], and to split graphs [4, 11]. On the other hand, the problem has efficient solutions on trees [6] and more generally on graphs with bounded treewidth [10], as well as on interval graphs [11] and block graphs [13]. We also add that the power domination number of block graphs has been further studied in [1], and that in [14] upper bound for the power domination number of general graphs and claw-free graphs are presented.

Dorfling and Henning [3] obtained closed formulas for the power domination numbers of grid graphs. This result is in striking contrast to the fact that a determination of such formulas for the usual domination number of grid graphs is a notorious open problem; see [7, section 2.6.2]. Now, a natural description of a grid is as the Cartesian product of two paths. Besides the Cartesian one, there are three more standard graph products: the strong, the direct, and the lexicographic product [8]. Hence it is natural to ask whether the power domination number can also be determined for these products of paths. In this paper we indeed show this to be the case.

We proceed as follows. In the rest of this section we give definitions used in this paper. In section 2 we determine the power domination number for direct products of paths with the exception of the odd components of products of odd paths. For this case an upper bound is given for which we believe to be optimal. Then, in section 3, we determine the power domination number for the strong product of paths, except that in one of the eight cases the power domination number is only bounded. But also in this case the bounds are almost tight. While it takes quite an effort to obtain the results for the direct and the strong product of paths, it is rather straightforward to deal with the lexicographic product. In fact, in the last section we show that the power domination number can be determined exactly for the lexicographic product of arbitrary graphs in terms of the (total) domination number of the factors.

All of the four standard graph products constructed from graphs G and H have vertex set $V(G) \times V(H)$. Let (g, h) and (g', h') be two vertices in $V(G) \times V(H)$. They are adjacent in the *Cartesian product* $G \square H$ if they are equal in one coordinate and adjacent in the other. They are adjacent in the *direct product* $G \times H$ if they are adjacent in both coordinates. The edge set of the *strong product* $G \boxtimes H$ is $E(G \square H) \cup E(G \times H)$. Finally, (g, h) and (g', h') are adjacent in the *lexicographic product* $G \circ H$ if $gg' \in E(G)$, or if $g = g'$ and $hh' \in E(H)$. All these products are associative; all but the lexicographic product are also commutative. See [8] for more information on all the products.

Let $G * H$ be any of the four standard graph products. Then the subgraph of $G * H$ induced by $\{g\} \times V(H)$ is called an *H-fiber* and denoted ${}^gH$. Similarly, one

defines the G -fiber G^h for a vertex h of H . If $*$ is the Cartesian, the strong, or the lexicographic product, then fibers are isomorphic to the corresponding factors. For the direct product the fibers are discrete, that is, they induce edgeless graphs.

Observe that if one of the factors is the trivial graph, then the direct product is a stable graph, and every other product is isomorphic to the other factor. Therefore, we will assume in the following that both factors are nontrivial.

Finally, for the path P_m we will always assume that $V(P_m) = \{0, \dots, m-1\}$, where vertices are adjacent in the natural way. Moreover, the vertices of $P_m * P_n$ will be denoted by (i, j) , where $0 \leq i < m$ and $0 \leq j < n$.

2. The direct product. For any integers $m, n \geq 2$, the direct product $P_m \times P_n$ is not connected. If m or n is even, $P_m \times P_n$ consists of two isomorphic connected components; otherwise it has two nonisomorphic connected components (see [12]; cf. also [5, 9]). We call the component of $P_m \times P_n$ containing $(0, 0)$ the *even component* and the other component the *odd component*.

In this section we determine the power domination number of the direct product of two paths, except for the odd component of the product of two odd paths. In the first subsection we treat the case when at least one of the paths is even. In this case $\gamma_P(C) = \lceil n/4 \rceil$, where C is a connected component of $P_m \times P_n$ with n even and m odd or $m \geq n$. In the subsequent subsection we follow with products of odd paths proving that for the even component C , $\gamma_P(C) = \lceil (m+n)/6 \rceil$. We close by constructing a power dominating set of the odd component of such products. We conjecture that the construction is optimal.

Let $p_1 : P_m \times P_n \rightarrow P_m$ and $p_2 : P_m \times P_n \rightarrow P_n$ be the natural projections onto the first and the second factor of $P_m \times P_n$, respectively. Then we have the following lemma.

LEMMA 2.1. *Let S be a power dominating set of a connected component C of $P_m \times P_n$. If $m \geq 3$ is odd, then for every subpath $P \subseteq P_n$ of length 3, $p_2(S) \cap P \neq \emptyset$.*

Proof. Suppose to the contrary that there exists a subpath $P = x_1x_2x_3x_4$ of length 3, such that $p_2(S) \cap P = \emptyset$.

Assume C is even and x_1 is even. During the domination step, no vertices of $P_m^{x_3}$ are monitored. Moreover, any neighbor of a vertex from $P_m^{x_3} \cap C$ has two neighbors in $P_m^{x_3}$, not monitored after the domination step. Therefore, no vertex of $P_m^{x_3} \cap C$ may be monitored after the propagation step. Similarly we infer that if x_1 is odd, then no vertices of $P_m^{x_2} \cap C$ may be monitored, a contradiction. Arguments for C being odd are analogous. $\square$

2.1. At least one factor is even. To solve the case when at least one factor is an even path, we begin with two lemmas.

LEMMA 2.2. *Let m and n be even and let S be a power dominating set of a connected component C of $P_m \times P_n$. If there is a subpath $P \subseteq P_m$ of length 3, such that $P \cap p_1(S) = \emptyset$, then for every subpath $Q \subseteq P_n$ of length 3, $Q \cap p_2(S) \neq \emptyset$.*

Proof. We will prove this lemma by contradiction. Let m and n be even, and let S be a power dominating set of a connected component C of $P_m \times P_n$. Both components are isomorphic, so we assume without loss of generality that C is the even component. Suppose that $P = p_1p_2p_3p_4 \subseteq P_m$ and $Q = q_1q_2q_3q_4 \subseteq P_n$ are paths of length 3 with $p_1(S) \cap P = p_2(S) \cap Q = \emptyset$ (see Figure 1). Let

$$F = \{(i, j) \mid i \notin \{p_2, p_3\}, j \notin \{q_2, q_3\}\} \cap C.$$

After the domination step, all the monitored vertices are necessarily in F . Suppose that all the vertices of F are monitored. Suppose (u, v) is a vertex of F such that all

FIG. 1. Proof of Lemma 2.2. Black vertices are in F and gray vertices are in M .

except one neighbor of (u, v) are in F (and thus monitored). Necessarily, (u, v) is on the boundary of $P_m \times P_n$, so $(u, v) \in \{(p_2, 0), (p_2, n-1), (p_3, 0), (p_3, n-1), (0, q_2), (m-1, q_2), (0, q_3), (m-1, q_3)\}$. Since n and m are even, exactly four vertices among these are in the component C . As we can see in Figure 1, when p_1 and q_1 are odd, the set M of the vertices obtained by propagation from F does not contain all the vertices of C . Therefore, S may not power dominate C . The cases for other parities of p_1 and q_1 are similar. $\square$

LEMMA 2.3. *Let m be even and let C be a connected component of $P_m \times P_n$. If all the vertices from $(P_m^u \cup P_m^v) \cap C$ are monitored, where u and v are adjacent vertices of P_n , then C is power dominated.*

Proof. Since m is even, both $P_m^u \cap C$ and $P_m^v \cap C$ contain a vertex that has exactly one neighbor not in $(P_m^u \cup P_m^v) \cap C$. It follows easily that the two neighboring fibers (or the neighboring fiber if there is only one such) are monitored. Induction completes the argument. $\square$

THEOREM 2.4. *Let n be even and C be a connected component of $P_m \times P_n$. If m is odd or $m \geq n$, then $\gamma_P(C) = \lceil n/4 \rceil$.*

Proof. Let n be an even integer, and let C be a connected component of $P_m \times P_n$. Since both components are isomorphic, we assume without loss of generality that C is the even component. We will first prove the lower bound, then give a construction that reaches it and thus prove the upper bound.

We first consider the case when m is odd. All the vertices in $P_m^1 \cap C$ have two neighbors in $P_m^0 \cap C$, so any power dominating set $S \subseteq C$ has nonempty intersection with the fiber P_m^0 or P_m^1 .

By Lemma 2.1 a power dominating set S of C has the property that for any subpath $P \subseteq P_n$ of length 3, $P \cap p_2(S) \neq \emptyset$. Without loss of generality assume that $P_m^1 \cap S$ is nonempty. Since the fiber P_m^0 as well as the fibers P_m^{n-2} and P_m^{n-1} (but not P_m^{n-3}) might have empty intersection with S and at least every fourth fiber has nonempty intersection with S , we find that $|S| \geq |\{1, 1+4, \dots, 1+4 \lceil (n-4)/4 \rceil\}| = \lceil n/4 \rceil$. Hence $\gamma_P(G) \geq \lceil n/4 \rceil$.

FIG. 2. An optimal power dominating set of $P_m \times P_n$ is shown on the left. The maximal set of monitored vertices is marked with broken line on the right.

Now let m be even, $m \geq n$. Let S be a power dominating set of $P_m \times P_n$. By Lemma 2.2, there is either no subpath of P_m of length 3 disjoint with $p_1(S)$ or there is no subpath of P_n of length 3 disjoint with $p_2(S)$. Hence $|S| \geq \lceil n/4 \rceil$. This is the desired lower bound if $n = 4k$.

If $n = 4k + 2$ and $|S| = k$, then either there is a subpath $P \subseteq P_n$ of length 3 disjoint with $p_2(S)$, or the first three or the last three P_m -fibers (that is, P_m^0, P_m^1 , and P_m^2 or P_m^{n-3}, P_m^{n-2} , and P_m^{n-1}) have empty intersection with $p_2(S)$. In the first case there is no subpath of P_m of length 3 disjoint with $p_1(S)$; therefore in this case $m = n$. But this means that S is disjoint with fibers ${}^0P_n, {}^1P_n$, and ${}^2P_n$ (or ${}^{m-3}P_n, {}^{m-2}P_n$, and ${}^{m-1}P_n$). Therefore, using the right-hand side of Figure 2, we verify that ${}^0P_n$ is not monitored, a contradiction. The second case is when P_m^0, P_m^1 , and P_m^2 have empty intersection with $p_2(S)$. If also ${}^0P_n, {}^1P_n$, and ${}^2P_n$ have empty intersection with $p_1(S)$, then ${}^0P_n$ and P_m^0 are not monitored. Otherwise there is a subpath of P_m of length 3 disjoint with $p_1(S)$. This case leads to a contradiction as shown in Figure 2. Thus if $n = 4k + 2$ and $|S| = k$, then S cannot be a power dominating set. Hence in either of the cases $|S| \geq \lceil n/4 \rceil$.

To prove the reverse inequality we need to construct a power dominating set S of C with $|S| = \lceil n/4 \rceil$. Let

$$(1) \quad S = \{(1, 1 + 4\alpha) \mid \alpha = 0, \dots, \lceil n/4 \rceil - 1\}.$$

Observe that all the vertices from ${}^0P_n$ are monitored since for every vertex from ${}^0P_n$ there is a neighboring vertex from S which dominates it; see the left-hand side of Figure 2. Next observe that also all the vertices from ${}^1P_n$ are monitored, since for every vertex from ${}^1P_n$ there is a vertex from ${}^0P_n$ with all but one vertices in S . Since the consecutive fibers ${}^0P_n$ and ${}^1P_n$ are monitored and n is even, Lemma 2.3 implies that S is a power dominating set of C . This completes the proof. $\square$

Note that Theorem 2.4 holds also for $n = 2$. Indeed, a connected component of $P_m \times P_2$ is isomorphic to P_m whence its power domination number is 1.

2.2. Both factors are odd. We continue with the odd times odd case. For this case we introduce the following concept on a grid $P_m \square P_n$.

Consider an initial set S of vertices. Let D be initialized by $D = S$. As long as there is a vertex v in $V \setminus D$ such that v has at least two neighbors in D , add v to D . If at the end of the process $D = V(P_m \square P_n)$, then we call the set S a *life winning (LWS) set* of $P_m \square P_n$. Let us call this concept the *life-like game*.

THEOREM 2.5. *For any positive integers m, n , there exists a LWS set of $P_m \square P_n$ of cardinality $\lceil \frac{m+n}{2} \rceil$ and it is a minimum LWS of $P_m \square P_n$.*

Proof. Let

$$\begin{aligned} S = & \left\{ (2i, 0) \mid 0 \leq i \leq \frac{m-1}{2} \right\} \\ & \cup \left\{ (m-1, 2j + \mathcal{E}) \mid 0 \leq j \leq \frac{n-2}{2}, \mathcal{E} = 1 \text{ if } m \text{ is even, } 0 \text{ otherwise} \right\} \\ & \cup \{(m-1, n-1)\}. \end{aligned}$$

For example, if m and n are odd, S consists of vertices $(0, 0), (2, 0), \dots, (m-1, 0), (m-1, 2), (m-1, 4), \dots, (m-1, n-1)$. It is straightforward to verify that S is an LWS set of the desired cardinality.

Let us prove that S is minimum. For $X \subseteq V(P_m \square P_n)$ let $\Pi(X)$ be the *perimeter* of X , that is, $\Pi(X) = \sum_{v \in X} (4 - |N(v) \cap X|)$. If D' is a subset of $V(P_m \square P_n)$ obtained by propagation from D , then $\Pi(D') \leq \Pi(D)$. Indeed, any vertex added to D decreases $\Pi(D)$ by at least 2 and adds at most 2 to $\Pi(D)$. At the end of the propagation, $\Pi(D) = 2(m+n)$. At the beginning, $\Pi(S) \leq 4|S|$. Hence, $|S| \geq (m+n)/2$. $\square$

The above theorem might be of independent interest, but for our purposes it is important that during the propagation process the perimeter of the monitored set does not increase.

In the following we will consider the direct product $P_m \times P_n$ and at the same time the Cartesian product $P_m \square P_n$, where the vertex sets of both products are the same.

LEMMA 2.6. *Let m, n be odd integers and P a power dominating set of the even component of $P_m \times P_n$. Let S be the set monitored by P after the domination step of the algorithm. Then S is a LWS of $P_m \square P_n$.*

Proof. We first remark that all the vertices of the even component either have both their coordinates odd or both even. We will call them odd and even vertices, respectively. Since both m and n are odd, the set of even vertices is a LWS of $P_m \square P_n$.

Let M and D , initialized to S , be the sets that are propagating for power domination and life-like game, respectively. We will prove by induction that any even vertex in M is in D . From the choice $M = D = S$, this condition is initially true.

Suppose an even vertex w is added to M . Then, it is monitored by propagation from an odd vertex v . Any odd vertex has four neighbors, all even. So all the three other neighbors of v are monitored and belong to D . In Figure 3, we show how w is thus also put in D by the rule of the life-like game. $\square$

THEOREM 2.7. *Let $m \leq n$ be odd and C the even component of $P_m \times P_n$. Then*

$$\gamma_P(C) = \max \left\{ \left\lceil \frac{n}{4} \right\rceil, \left\lceil \frac{m+n}{6} \right\rceil \right\}.$$

Proof. Since any power dominating set of C contains a vertex from P_m^0 or P_m^1 , and a vertex from P_m^{n-2} or P_m^{n-1} , Lemma 2.1 implies that $\gamma_P(C) \geq n/4$.

FIG. 3. Propagation from an odd vertex to an even.

Let P be a power dominating set of $P_m \times P_n$. Let S be the set monitored after the domination step. Let us consider the life-like game starting on S . Every vertex from P contributes at most five vertices to S which propagate to a 3×3 box in the grid. Denoting the obtained set S' we infer that every vertex in P contributes at most 12 to $\Pi(S')$. The set S' is a LWS of the grid, so $12|P| \geq 2(m+n)$. (Here we have used the fact that during the propagation process the perimeter of the monitored set does not increase.) Therefore $|P| \geq \lceil (m+n)/6 \rceil$.

To establish the upper bound we construct a corresponding power dominating set P of C as follows. Suppose first that $m \leq n \leq 2m$ and set

$$S_1 = \{(1+2i, 1+4i) \mid 0 \leq i \leq (2n-m-3)/6\},$$

$$S_2 = \{((2n-m)/3+4j, (4n-2m-3)/3+2j) \mid 1 \leq j \leq (2m-n-3)/6\}.$$

Suppose that $n+m \equiv 0 \pmod{6}$ (the perfect case). Then set $P = S_1 \cup S_2$. Otherwise, construct P from a maximal perfect case contained in $P_m \times P_n$ by adding the vertex $(m-2, n-2)$ to it. It is straightforward to verify that in all cases P is a power dominating set. Moreover, $((2n-m-3)/6+1) + (2m-n-3)/6 = (m+n)/6$, hence $|P| = \lceil (m+n)/6 \rceil$.

Let $n > 2m$. Then set

$$S_1 = \{(1+2i, 1+4i) \mid 0 \leq i \leq (m-3)/2\},$$

$$S_2 = \{(1, 1+4j) \mid (m-3)/2 < j \leq (n-3)/4\}.$$

Now the perfect case is when $n \equiv 3 \pmod{4}$, in which case we set $P = S_1 \cup S_2$. Otherwise, proceed as above by adding $(m-2, n-2)$ to the power dominating set of a maximal perfect case contained in $P_m \times P_n$. Since $(m-3)/2 + 1 + ((n-3)/4 - (m-3)/2) = (n+1)/4$, in this case $|P| = \lceil n/4 \rceil$. $\square$

The construction for the first case from the previous proof is illustrated in Figure 4 with black dots. Moreover, another optimal power dominating set is presented with black squares in order to illustrate that such a set can be unusual.

THEOREM 2.8. *Let $m \leq n$ be odd and C the odd component of $P_m \times P_n$. Then*

$$\gamma_P(C) \leq \max \left\{ \left\lceil \frac{n-2}{4} \right\rceil, \left\lceil \frac{m+n-2}{6} \right\rceil \right\}.$$

Proof. We give a construction of a power dominating set of the given cardinality. Suppose $m \leq n \leq 2m+2$ and $m+n-2 \equiv 0 \pmod{6}$ (the perfect case); then the construction is as follows. Let

$$S_1 = \{(3+2i, 4i) \mid 1 \leq i \leq (2n-m-7)/6\} \text{ and}$$

$$S_2 = \{((2n-m-1)/3+4j, (4n-2m-11)/3+2j) \mid 1 \leq j \leq (2m-n-7)/6\}.$$

FIG. 4. Two optimal power dominating sets of the even component of $P_{17} \times P_{19}$.

Then $P = S_1 \cup S_2 \cup \{(2, 1), (m - 2, n - 3)\}$ is a power dominating set of C . Since $(2n - m - 7)/6 + (2m - n - 7)/6 + 2 = (m + n - 2)/6$, this construction has the claimed cardinality.

In the nonperfect case, construct S_1 and S_2 for a minimal perfect case containing $P_m \times P_n$. Add to these sets the vertices $(2, 1)$ and $(m - 2, n - 3)$ (thus, only this last vertex differs). This set clearly has the cardinality $\lceil (m + n - 2)/6 \rceil$.

If $n > 2m + 2$ and $n \equiv 1 \pmod{4}$, then let

$$S_1 = \{(1 + 2i, 2 + 4i) \mid 0 \leq i \leq (m - 3)/2\} \text{ and} \\ S_2 = \{(1, 2 + 4j) \mid (m - 3)/2 \leq j \leq (n - 5)/4\}.$$

In the nonperfect case ($n \equiv 3 \pmod{4}$), construct S_1 and S_2 for $P_m \times P_{n+2}$ and it will form a PDS of $P_m \times P_n$. Since $(m - 3)/2 + 1 + ((n - 5)/4 - (m - 3)/2) = (n - 1)/4$, in this case $|P| = \lceil (n - 2)/4 \rceil$. $\square$

We think that the upper bound of Theorem 2.8 is optimal. However, proving that this is the case seems harder than it was for the even component.

3. The strong product. In this section we prove the following theorem.

THEOREM 3.1. Let $n \geq m \geq 2$. Then

$$\gamma_P(P_n \boxtimes P_m) = \max \left\{ \left\lceil \frac{n}{3} \right\rceil, \left\lceil \frac{n + m - 2}{4} \right\rceil \right\}$$

unless $3m - n - 6 \equiv 4 \pmod{8}$, in which case

$$\max \left\{ \left\lceil \frac{n}{3} \right\rceil, \left\lceil \frac{n + m - 2}{4} \right\rceil \right\} \leq \gamma_P(P_m \boxtimes P_n) \leq \max \left\{ \left\lceil \frac{n}{3} \right\rceil, \left\lceil \frac{n + m - 2}{4} \right\rceil + 1 \right\}.$$

FIG. 5. Propagation from the border.

In the first subsection we prove the lower bounds, while in the subsequent two subsections corresponding power dominating sets are constructed. It is easily verified that the result holds if $n < 4$ and $m < 4$. Hence in the rest of this section we assume that $n \geq m \geq 4$.

3.1. Proof of the lower bound.

LEMMA 3.2. $\gamma_P(P_m \boxtimes P_n) \geq \lceil \frac{n}{3} \rceil$.

Proof. Let S be a power dominating set of $P_m \boxtimes P_n$. Suppose there is a P_m -fiber that does not contain any vertex of $N[S]$. Then, the vertices of this P_m -fiber have to be monitored during the propagation step. Consider the first vertex w of this P_m -fiber that is monitored, and let v be the vertex that monitors w . The vertex v has at least one other neighbor in the same P_m -fiber as w . This neighbor is not yet monitored, so the propagation cannot happen. Thus S must dominate at least one vertex of each P_m -fiber, which implies that $\gamma_P(P_m \boxtimes P_n) \geq \lceil n/3 \rceil$. $\square$

LEMMA 3.3. $\gamma_P(P_m \boxtimes P_n) \geq \frac{n+m-2}{4}$.

Proof. Let S be a minimum power dominating set of $P_m \boxtimes P_n$. We can suppose that S contains no vertices on the boundary (that is, the vertices of $P_m \boxtimes P_n$ of degree 3 or 5), since any closed neighborhood of a vertex on the boundary is contained in the closed neighborhood of a vertex not on the boundary.

Let M be the set of monitored vertices of $P_m \boxtimes P_n$ during a propagation step of the algorithm. Let $B(M)$ be the set of vertices of M that have less than eight neighbors in M . We claim that during the propagation step, $|B(M)|$ cannot increase.

Suppose that during the propagation step we monitor a new vertex w , where w is the only neighbor not in M of some vertex v from M . Then w may now be added to $B(M)$. We distinguish two cases.

Case 1. The degree of v is 8. Then v now has all its eight neighbors in M , so v is removed from $B(M)$. Some other vertices may be removed from $B(M)$, if w was their eighth neighbor to enter M , but none other may be added. So $|B(M)|$ cannot be increasing.

Case 2. The degree of v is less than 8. In this case we check that w could have been monitored with a propagation from a vertex not on the boundary. The cases to be considered are shown in Figure 5, where $\bullet$ are vertices monitored, $\circ$ are vertices not monitored, and $\cdot$ may or may not be monitored.

In case (a) of the figure, the vertex u (in a box) has all its neighbors except w monitored, so we can suppose the propagation comes from this vertex. Cases (b), (e), and (f) cannot occur: the vertex v in a circle cannot have been monitored during the domination step, so it must have been monitored with some propagation. But any neighbor of v also has another neighbor not in $M(S)$, a contradiction. In cases (c) and (d), the two vertices in circles are monitored. By our assumption that no vertices of S are on the boundary, they must have been monitored by propagation (otherwise u would be monitored). But none of them may have been monitored before the other, since all their neighbors are either neighbor of both, or also neighbor of u . The case of a propagation from a corner is induced by cases e and f . This proves the claim.

Hence $|B(M)|$ cannot increase during a propagation step of the algorithm. After the domination step of the algorithm, $|B(M)|$ is not greater than $8|S|$. Moreover, at the end of the algorithm, when all the vertices are monitored, $|B(M)|$ is equal to $2n + 2m - 4$. So we must have $|S| \geq (n + m - 2)/4$. $\square$

3.2. A construction for $n \geq 3m - 6$. In this subsection we construct power dominating sets for the case when one path is much longer than the other, more precisely, when $n \geq 3m - 6$. Then

$$\left\lceil \frac{n}{3} \right\rceil \geq \left\lceil \frac{3n}{12} + \frac{3m-6}{12} \right\rceil = \left\lceil \frac{n+m-2}{4} \right\rceil,$$

hence the power domination number depends only of the size of the longer path. Thus we need to construct a power dominating set S of cardinality $\lceil n/3 \rceil$. We do this as follows. Set $S = S_1 \cup S_2$, where

$$S_1 = \{(1+i, 1+3i) \mid 0 \leq i \leq m-3\}$$

and

$$S_2 = \begin{cases} \{(1, 3m-9+3j) \mid 1 \leq j \leq \lceil (n-3m+6)/3 \rceil\}, & n \equiv 1 \pmod{3}, \\ \{(1, 3m-8+3j) \mid 1 \leq j \leq \lceil (n-3m+6)/3 \rceil\}, & \text{otherwise.} \end{cases}$$

The construction is illustrated in Figure 6.

It is easy to check that the set S will power dominate the whole strong product. Moreover, $|S| = |S_1| + |S_2| = m-2 + \lceil (n-3m+6)/3 \rceil = \lceil n/3 \rceil$.

3.3. A construction for $n \leq 3m - 6$. In this case m and n are comparable. Since $\lceil n/3 \rceil \leq \lceil (n+m-2)/4 \rceil$ we need to construct power dominating sets S of cardinality $\lceil (n+m-2)/4 \rceil$. We start with the case when 8 divides $3m-n-6$, and modify it in all the other cases.

Case 1. $3m-n-6 \equiv 0 \pmod{8}$. Set $S = S_1 \cup S_2$, where

$$\begin{aligned} S_1 &= \{(1+3i, 1+i) \mid 0 \leq i \leq (3m-n-6)/8\} \\ S_2 &= \{(1+3(3m-n-6)/8+j, 1+(3m-n-6)/8+3j) \mid \\ &\quad 1 \leq j \leq (n+m-6)/4 - (3m-n-6)/8\}. \end{aligned}$$

The construction is illustrated in Figure 7.

For coherence of the above construction we should remark that

- $\frac{3m-n-6}{8}$ and $\frac{n+m-6}{4} = m-3 - \frac{3m-n-6}{4}$ are integers.
- $\frac{n+m-6}{4} - \frac{3m-n-6}{8} = \frac{3n-m-6}{8}$ is positive since $n \geq m$ and $n \geq 4$.
- The coordinates of the last vertex which is furthest up and right are $(m-2, n-2)$, so all the vertices are in the graph.

FIG. 6. Optimal power dominating sets when one path is relatively long.

- The set S does not contain any vertex on the border of the grid. (This remark will be very useful in the following.)

The set S contains $(n + m - 2)/4$ vertices and is therefore optimal.

Case 2. $3m - n - 6 \equiv 1 \pmod{8}$. In this case $3m - (n + 1) - 6 \equiv 0 \pmod{8}$. Then we construct the power dominating set S of $P_m \boxtimes P_{n+1}$ from Case 1. Removing the fiber P_m^0 from $P_m \boxtimes P_{n+1}$ we get a graph $G = P_m \boxtimes P_n$. Since S does not contain any border vertex, the set S restricting to G does not change. Consequently, $|S| = (n + 1 + m - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

Case 3. $3m - n - 6 \equiv 2 \pmod{8}$. Then $3m - (n + 2) - 6 \equiv 0 \pmod{8}$, hence construct the power dominating set S of $P_m \boxtimes P_{n+2}$ as in Case 1 and restrict it to the graph $P_m \boxtimes P_{n+2}$ with the fibers P_m^0 and P_m^{n+1} removed. Now $|S| = (n + 2 + m - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

Case 4. $3m - n - 6 \equiv 3 \pmod{8}$. Since $3(m + 2) - (n + 1) - 6 \equiv 0 \pmod{8}$ we take the power dominating set S of $P_{m+2} \boxtimes P_{n+1}$ and remove the fibers ${}^0P_n$, ${}^{m+1}P_n$, and P_m^0 . Then $|S| = (n + 1 + m + 2 - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

Case 5. $3m - n - 6 \equiv 4 \pmod{8}$. As $3(m + 2) - (n + 2) - 6 \equiv 0 \pmod{8}$ we proceed as before, removing the fibers ${}^0P_n$, ${}^{m+1}P_n$, P_m^0 , and P_m^{n+1} . Then $|S| = (n + 2 + m + 2 - 2)/4 = \lceil (n + m - 2)/4 \rceil + 1$. Note that in this special case we miss the lower bound by 1.

Case 6. $3m - n - 6 \equiv 5 \pmod{8}$. Then $3(m + 1) - n - 6 \equiv 0 \pmod{8}$ so we construct the power dominating set S of $P_{m+1} \boxtimes P_n$ and remove the fiber ${}^0P_n$. Then $|S| = (n + m + 1 - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

Case 7. $3m - n - 6 \equiv 6 \pmod{8}$. Then $3(m + 1) - (n + 1) - 6 \equiv 0 \pmod{8}$ and we start from the power dominating set S of $P_{m+1} \boxtimes P_{n+1}$, and remove the fibers ${}^0P_n$ and P_m^0 . Now $|S| = (n + 1 + m + 1 - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

FIG. 7. Power dominating sets of products of path of similar length.

Case 8. $3m - n - 6 \equiv 7 \pmod{8}$. Then $3(m + 1) - (n + 2) - 6 \equiv 0 \pmod{8}$. Take the power dominating set S in $P_{m+1} \boxtimes P_{n+2}$ and remove the fibers ${}^0P_n$, P_m^0 , and P_m^{n+1} . We have $|S| = (n + 2 + m + 1 - 2)/4 = \lceil (n + m - 2)/4 \rceil$.

4. The lexicographic product. The remaining standard graph product to consider is the lexicographic one. For it, the power domination problem is much easier. In fact we will determine the power domination number for any lexicographic product in terms of the domination number and the total domination number of its factors.

Recall that for a graph $G = (V, E)$, a set $S \subseteq V$ is a *dominating set* if each vertex in $V \setminus S$ is adjacent to at least one vertex of S . If in addition each vertex of S has a neighbor in S , then S is called a *total dominating set*. The *domination* (resp., *total domination*) *number* $\gamma(G)$ (resp., $\gamma_t(G)$) of G is the minimum cardinality of a dominating (resp., total dominating) set. Then we have the next theorem.

THEOREM 4.1. *Let G be a nontrivial graph without isolated vertices. Then for any nontrivial graph H ,*

$$\gamma_P(G \circ H) = \begin{cases} \gamma(G); & \gamma_P(H) = 1, \\ \gamma_t(G); & \gamma_P(H) > 1. \end{cases}$$

Proof. Suppose $\gamma_P(H) = 1$. Let $\{v\}$ be a power dominating set of H and D a dominating set of G . Then $D \times \{v\}$ is a power dominating set of $G \circ H$. Indeed, for any vertex u of G , if $u \notin D$, any vertex of ${}^uH$ is in the neighborhood of (u', v) , for

some $u' \in D$ with $uu' \in E(G)$, so it is monitored. If $u \in D$, any neighbor of a vertex of ${}^uH$ not in ${}^uH$ is monitored, and $\{(u, v)\} \cup N(u, v)$ is monitored. So since $\{v\}$ is a power dominating set of H , the fiber is monitored. Therefore $\gamma_P(G \circ H) \leq \gamma(G)$.

Assume that there is a power dominating set S of $G \circ H$ that contains less than $\gamma(G)$ vertices. Then there is an H -fiber ${}^uH$ that contains no vertex of $S \cup N(S)$. So the vertices of ${}^uH$ are monitored by the propagation. Consider the first propagation that occurs to a vertex (u, v) of ${}^uH$. The vertex (u, v) must be the only neighbor not monitored of some vertex not in ${}^uH$. But this other vertex is also adjacent to all the other vertices of ${}^uH$, which are not monitored yet. Since H has more than one vertex, this implies that there can be no propagation on ${}^uH$. Hence $\gamma_P(G \circ H) \geq \gamma(G)$.

Suppose now $\gamma_P(H) > 1$. Let D be a total dominating set of G . Then for any vertex v of H , $D \times \{v\}$ is a dominating set of $G \circ H$ and so a power dominating set of H of cardinality $|D| = \gamma_t(G)$. Thus $\gamma_P(G \circ H) \leq \gamma_t(G)$.

Let S be a minimum power dominating set of $G \circ H$. Suppose there is an H -fiber ${}^uH$ that contains at least two vertices of S . Let S' be obtained by removing from S all vertices of ${}^uH$ but one and adding an arbitrary vertex of a neighboring H -fiber (if there is none yet). Then $N[S] \subseteq N[S']$, so S' is a power dominating set of $G \circ H$, with $|S'| \leq |S|$. Repeating this process if necessary, we may now assume that every H -fiber of $G \circ H$ contains at most one vertex in S .

Suppose that there exists an H -fiber ${}^uH$ such that for any neighbor v of u in G , ${}^vH \cap S$ is empty. So the vertices monitored by P in ${}^uH$ are exactly the vertices monitored by $S \cap {}^uH$. Since there is no power dominating set of H of cardinality 1, $S \cap {}^uH$ contains at least two vertices, a contradiction. Thus, any vertex $u \in V(G)$ has a neighbor v in G such that the H -fiber ${}^vH$ contains a vertex of S . So the set $\{v \in V(G) \mid {}^vH \cap S \neq \emptyset\}$ is a total dominating set of G and we conclude that $\gamma_P(G \circ H) = |S| \geq \gamma_t(G)$. $\square$

In Theorem 4.1 we have assumed that G has no isolated vertices. In the case that G contains r isolated vertices, let G' be the subgraph of G induced by nonisolated vertices. Then $G = G' \cup rK_1$ and $G \circ H$ is the disjoint union of $G' \circ H$ and k copies of H . Consequently, $\gamma_P(G \circ H) = \gamma_P(G' \circ H) + r\gamma_P(H)$.

Acknowledgments. We thank Sylvain Gravier for introducing us to the concept of the power domination and for useful conversations. We are also grateful to one of the referees for a careful reading of the manuscript.

PLANAR GRAPHS OF ODD-GIRTH AT LEAST 9 ARE HOMOMORPHIC TO THE PETERSEN GRAPH*

Z. DVOŘÁK†, R. ŠKREKOVSKI‡, AND T. VALLA†

Abstract. Let G be a graph and let $c : V(G) \rightarrow \binom{1, \dots, 5}{2}$ be an assignment of 2-element subsets of the set $1, \dots, 5$ to the vertices of G such that for every edge vw , the sets $c(v)$ and $c(w)$ are disjoint. We call such an assignment a $(5, 2)$ -coloring. A graph is $(5, 2)$ -colorable if and only if it has a homomorphism to the Petersen graph. The *odd-girth* of a graph G is the length of the shortest odd cycle in G (∞ if G is bipartite). We prove that every planar graph of odd-girth at least 9 is $(5, 2)$ -colorable, and thus it is homomorphic to the Petersen graph. Also, this implies that such graphs have a fractional chromatic number at most $\frac{5}{2}$. As a special case, this result holds for planar graphs of girth at least 8.

1. Introduction. One of the most natural generalizations of the usual graph coloring is the k -tuple coloring. We assign to each vertex a set of k distinct colors, instead of just one color, and require that the adjacent vertices obtain disjoint sets of colors. Such an assignment is called a k -tuple coloring, or a k -tuple n -coloring if n colors are used (where $k \leq n$). To be brief, we use the term (n, k) -coloring instead. Obviously, an $(n, 1)$ -coloring is just the usual n -coloring.

It is easy to see that these multicolorings are homomorphisms to Kneser graphs. The *Kneser graph* $K(n, k)$ (where $2k \leq n$) is a graph with a vertex set consisting of all k -element subsets of $\{1, 2, \dots, n\}$ and with two vertices adjacent if and only if the subsets are disjoint. An (n, k) -coloring of G also can be viewed as a homomorphism of G to $K(n, k)$. Let us note that $K(5, 2)$ is isomorphic to the Petersen graph.

The *fractional chromatic number* of G , denoted $\chi_f(G)$, is the infimum of the fractions n/k such that G admits an (n, k) -coloring. The notion can also be alternatively defined using the linear relaxation of the integer programming formulation of the graph coloring problem. For a fixed k , the minimum n such that G admits an (n, k) -coloring is called the k -tuple chromatic number of G and it is denoted by $\chi^k(G)$. Therefore, $\chi_f(G) = \inf \chi^k(G)/k$. More details about this coloring can be found in the monograph of Scheinerman and Ullman [6].

Pirnazar and Ullman [5] showed that the fractional chromatic number of a planar graph with girth at least $8n - 4$ is at most $2 + \frac{1}{n}$, in particular, that planar graphs with girth 12 have a fractional chromatic number at most $\frac{5}{2}$. We improve this result by showing that every planar graph of odd-girth at least 9 (and thus also every

planar graph of girth 8) is $(5, 2)$ -colorable, and hence it has a fractional chromatic number at most $\frac{5}{2}$. Another interpretation of this result is that such graphs have a homomorphism to the Petersen graph. Regarding the lower bounds, Pirnazar and Ullman [5] show that there exists a planar graph of girth 5 with fractional chromatic number $\frac{13}{5}$. This implies that our result cannot be improved to odd-girth 5. We leave the case of odd-girth 7 as an open problem.

Our result also has connections to several important conjectures regarding flows and circular chromatic number. Let C be a circle of (Euclidean) length r . An r -circular coloring of a graph G is a mapping c which assigns to each vertex v of G an open unit length arc $c(v)$ of C , such that for every edge $xy \in E(G)$, $c(x) \cap c(y) = \emptyset$. We say a graph G is r -circular colorable if there is an r -circular coloring of G . The circular chromatic number of a graph, denoted by $\chi_c(G)$, is defined as

$$\chi_c(G) = \inf\{r \mid G \text{ is } r\text{-circular colorable}\}.$$

The following well-known inequalities hold for each graph G :

$$\chi(G) - 1 < \chi_c(G) \leq \chi(G) \quad \text{and} \quad \chi_f(G) \leq \chi_c(G) \leq \chi(G).$$

It is also well known that the circular chromatic number is always a rational number. For more details on the circular chromatic number see [10].

The concept of (n/k) -circular colorings is closely related to the concept of (n, k) -flows. Let G be a graph and D an orientation of G . For positive integers k and $n \geq 2k$, an (n, k) -flow f of D is a mapping that assigns to each edge e of D an integer $f(e) \in \{k, k+1, \dots, n-k\}$ such that $\sum_{e \in E^+(v)} f(e) = \sum_{e \in E^-(v)} f(e)$ for every vertex v ; Here $E^+(v)$ is the set of edges incident to v that are directed away from v , and $E^-(v)$ is the set of edges incident to v that are directed towards v in D . A graph G is said to admit an (n, k) -flow if G has an orientation D that admits an (n, k) -flow.

Notice that $(n, 1)$ -flows are precisely nowhere-zero integer n -flows introduced by Tutte [7, 8]. One can find more about flows in the monograph of Zhang [9] and the survey of Jaeger [2]. The following well-known conjecture was proposed by Jaeger [3].

CONJECTURE 1 (circular-flow conjecture). *For any integer $k \geq 1$, every $4k$ -edge-connected graph admits a $(2k+1, k)$ -flow.*

Note that the circular-flow conjecture for $k = 1$ and $k = 2$ implies the famous 3-flow conjecture and 5-flow conjecture of Tutte, respectively. For planar graphs, the flow problem can be dualized to the circular coloring problem. More precisely, an (n/k) -circular coloring of a planar graph G corresponds to an (n, k) -flow of the dual graph of G . Therefore, the restriction of Jaeger's conjecture to planar graphs is equivalent to the following.

CONJECTURE 2. *Every planar graph G of girth at least $4k$ has a circular chromatic number at most $2 + \frac{1}{k}$.*

The odd-edge connectivity of a graph G is the size of the smallest odd edge-cut of G . The dual of odd-edge connectivity is an odd-girth. The odd-girth of a graph G is the length of the shortest odd cycle in G (∞ if G is bipartite). Klostermeyer and Zhang [4] proposed a strengthening of Conjecture 2, where the edge-connectivity condition is replaced by an odd edge-connectivity condition as follows.

CONJECTURE 3. *Every planar graph G of odd-girth at least $4k+1$ has a circular chromatic number at most $2 + \frac{1}{k}$.*

Regarding Conjecture 3, Zhu [11] proved that for every $k \geq 2$, planar graphs of odd-girth at least $8k-3$ have a circular chromatic number at most $2 + \frac{1}{k}$. Later Borodin et al. [1] proved that a planar graph with girth at least $\frac{20k-2}{3}$ has a circular

chromatic number at most $2 + \frac{1}{t}$. Both results imply that planar graphs of girth at least 13 are $(5, 2)$ -colorable.

Conjecture 3 for $k = 2$ implies that the fractional chromatic of each planar graph of odd-girth at least 9 is at most $\frac{5}{2}$. Our result shows that this conclusion is indeed true.

2. Main theorem. The following theorem is the main result presented in this paper.

THEOREM 1. *Every planar graph of odd-girth at least 9 is $(5, 2)$ -colorable.*

To prove this theorem, we first show that we may restrict our attention to graphs without any short cycles. To deal with short faces, we use the following lemma proved by Klostermeyer and Zhang [4].

LEMMA 2 (folding lemma). *Let G be a planar graph with odd-girth $g > 3$. If $C = v_0v_1 \dots v_{r-1}$ is a facial circuit of G with $r \neq g$, then there is an integer $i \in \{0, \dots, r-1\}$ such that the graph G' obtained from G by identifying v_{i-1} and v_{i+1} (where indices are taken modulo r) is also of odd-girth g .*

To handle short cycles that are not faces, we show that under some assumptions, a coloring of the exterior of such a cycle can be extended to its interior as follows.

THEOREM 3. *Let H be a 2-connected planar graph such that H does not contain a cycle of length smaller than 9, except possibly for its outer face O_H whose length is at least 4. The graph H is $(5, 2)$ -colorable. Furthermore, if the length of O_H is at most 8, then any proper $(5, 2)$ -coloring of O_H can be extended to a proper coloring of H .*

Assuming that Theorem 3 holds, we can prove Theorem 1 easily. Given a plane graph G and a cycle C , let $\text{Int}_G(C)$ be the subgraph of G consisting of vertices and edges that lie on C or inside C , and let $\text{Out}_G(C)$ be the subgraph of G consisting of vertices and edges that lie on C or outside C . Thus, $\text{Int}_G(C)$ and $\text{Out}_G(C)$ share only the vertices and edges of C .

Proof of Theorem 1. For the sake of contradiction, let us assume that Theorem 1 is false and let G be a counterexample with minimum number of vertices. Obviously, G is connected. We may also assume that G is 2-connected; otherwise we can color each block separately and permute the colors so that the colorings agree on the cut-vertices.

Let us show that each face of G has size at least 9. Let $g \geq 9$ be the odd-girth of G . Assume that G contains a face of length different from g . By Lemma 2, there exist vertices v_1 and v_2 on that face such that the graph G' obtained from G by identifying v_1 and v_2 is a planar graph of odd-girth g . Note that the vertices v_1 and v_2 are not adjacent because of the restriction on the odd-girth of G . By the minimality of G , the graph G' is $(5, 2)$ -colorable. However, since v_1 and v_2 are not adjacent, this also gives a proper $(5, 2)$ -coloring of G , which is a contradiction.

If G does not contain any cycle of length less than 9, then G is $(5, 2)$ -colorable by Theorem 3. Therefore, assume that G contains a short cycle. Let C be a cycle in G of length at most 8 such that the number of vertices of $\text{Int}_G(C)$ is minimal. Since G does not contain any face of length less than 9, the graph $\text{Out}_G(C)$ has less vertices than G . By the minimality of G , there exists a proper $(5, 2)$ -coloring c of $\text{Out}_G(C)$. The graph $\text{Int}_G(C)$ does not contain any cycle shorter than 9, and thus the coloring c can be extended to the vertices of $\text{Int}_G(C)$ by Theorem 3. This shows that G can be $(5, 2)$ -colored, which is a contradiction. $\square$

It remains to prove Theorem 3. We proceed by the discharging method. Let us assume that H is a minimal counterexample to the theorem throughout the rest of the paper, and let O_H be its outer face. We first assign charge to vertices and

faces of H in such a way that the total amount of charge is negative. The bound on the length of faces ensures that the charge of each face is nonnegative, and we never change the charge of faces, and hence we know that at each moment the total charge of vertices is negative. The initial distribution of the charge is described in section 4. We then redistribute the charge, and assuming that H is a minimal counterexample to Theorem 3, we show that the final charge of each vertex is nonnegative. Since the amount of charge does not change during its redistribution, we obtain a contradiction. This will establish Theorem 3.

In section 3, we describe some subgraphs that cannot appear in H ; we call such subgraphs (configurations) *reducible*. The proof of reducibility of a configuration C usually proceeds in the following way. By the minimality of H , we know that $H - C$ can be properly colored. We then show that an arbitrary coloring of $H - C$ can be extended to C , thus showing that H is (5,2)-colorable and obtaining a contradiction.

The discharging proceeds in two phases. Let us call vertices of degree at least 3 *important*. In the first phase (section 5), we consider vertices of degree 2 in H and make their charge nonnegative by moving charge from adjacent important vertices. We then analyze the charge of important vertices and show that the subgraph H' induced by the important vertices with negative or small positive charge has a very special structure—in particular, it has maximum degree at most 3, and only vertices of degree at most 2 may have negative charge.

In section 7, we study the reducible configurations in H' . This enables us to restrict the structure of H' . Finally, we run the second phase of discharging over H' , moving the charge from vertices of degree three to vertices of smaller degree in H' , and show that one of 3-vertices is contained in a reducible configuration (section 8).

Throughout the proof, we need to handle the precolored outer face O_H . We would run into problems if a vertex v of a reducible configuration C were precolored, since we would be unable to prove that the coloring of $H - C$ can be extended in a way that is consistent with the color of v . To avoid this problem, we add an extra charge to the vertices of O_H while still preserving the fact that the total amount of charge is negative. This extra charge ensures that the charge of the vertices of O_H is large enough, and thus they do not appear in any configuration we consider—only configurations whose total charge is negative are important in the discharging method.

3. Reducible configurations. We say that a configuration (a subgraph) is *reducible* if it cannot appear in the minimal counterexample H , except possibly if some of its vertices are precolored. To use the discharging method we first need to prove that some configurations are reducible. We start with the following lemma that enables us to handle vertices of degree 2 in H .

LEMMA 4. *The following claims hold:*

- (1) *Let $P = v_1v_2v_3$ be a path of H such that $d(v_2) = 2$ and v_2 is not a precolored vertex of the outer face. If c is a coloring of $H - v_2$ such that $c(v_1) \cap c(v_3) \neq \emptyset$, then c can be extended to a proper coloring of H .*
- (2) *Let $P = v_1v_2v_3v_4$ be a path of H such that $d(v_2) = d(v_3) = 2$ and neither v_2 nor v_3 is precolored. If c is a coloring of $H - \{v_2, v_3\}$ such that $c(v_1) \neq c(v_4)$, then the coloring c can be extended to a proper coloring of H .*
- (3) *If P is a path $v_1v_2v_3v_4v_5$ in H such that $d(v_2) = d(v_3) = d(v_4) = 2$ and neither of v_2, v_3 , and v_4 is precolored, then P is reducible.*

Proof. Let us prove each claim separately:

- (1) Let $X = \{1, \dots, 5\} \setminus [c(v_1) \cup c(v_2)]$. The size of X is at least two, and thus we can choose $c(v_2) \subseteq X$.

- (2) If $c(v_1) \cap c(v_4) = \emptyset$, then set $c(v_2) = c(v_4)$ and $c(v_3) = c(v_1)$. Otherwise $c(v_1) = \{a, b_1\}$ and $c(v_4) = \{a, b_2\}$ have exactly one common element a . Let $\{b_3, b_4\} = \{1, \dots, 5\} \setminus \{a, b_1, b_2\}$. We set $c(v_2) = \{b_2, b_3\}$ and $c(v_3) = \{b_1, b_4\}$.
- (3) Suppose that this configuration appears in H . There exists a coloring c of $H - \{v_2, v_3, v_4\}$ by the minimality of H . Let $c(v_2)$ be a color-pair disjoint with $c(v_1)$ and distinct from $c(v_5)$ and use the second claim of this lemma to color v_3 and v_4 . In this way, we extend the coloring to H , thus obtaining a contradiction. $\square$

We need to show that many subgraphs are reducible. For each such subgraph C , we consider the coloring of $H - C$ and extend it to C . We usually use counting arguments of the following type: If a vertex v of C is adjacent to exactly one vertex u of $H - C$, the vertex v can be colored by one of three colors that are not forbidden by the color of u . If we determine the numbers of available colors for each vertex of C in a similar way, and show that C can be colored from all possible lists of colors of the given length, then we prove that C is reducible. To make the statements and the proofs of the theorems simpler, we introduce a notion closely related to the list coloring.

Let $\mathcal{P} = \binom{\{1, \dots, 5\}}{2}$ be the set of all unordered pairs of the elements of $\{1, \dots, 5\}$ and let us call the elements of $\mathcal{P}$ *color-pairs*. A *list* is a subset of $\mathcal{P}$, and if its size is k , then we call it a *k-list*. Lists are used to specify which color-pairs can be used at vertices in the considered configurations. For a given $X \subseteq \{1, \dots, 5\}$, let $\text{ss}(X) = \{p \in \mathcal{P}; p \subseteq X\}$ be the list of all 2-element subsets of X . Let $\text{int}(X) = \{p \in \mathcal{P}; p \cap X \neq \emptyset\}$ be the list of all color-pairs that intersect X .

A *type* is a set of lists. Types are used to express properties of the possible colorings of the considered configurations. For example, if we know that a vertex v has one neighbor precolored with a color-pair p , then the color-pairs that can be used to color v must be disjoint with p , and the list of such color-pairs belongs to the type $\mathcal{N}_3$ defined below. Let us point out the following special types:

- $\mathcal{P}_{\text{all}} = \mathcal{P}$ is the set of all lists, and $\mathcal{P}_k$ is the set of all k -lists. Thus, $\mathcal{P}_{10} = \{\mathcal{P}\}$.
- $\mathcal{N}_4 \subset \mathcal{P}_4$ is the set of all 4-lists such that no color belongs to all color-pairs in the list. For example, the list $L = \{\{1, 2\}, \{1, 3\}, \{1, 4\}, \{1, 5\}\}$ does not belong to $\mathcal{N}_4$.
- $\mathcal{N}_3 \subset \mathcal{P}_3$ is the type of all 3-lists that can be expressed as $\text{ss}(X)$ for some 3-element subset X of $\{1, \dots, 5\}$.
- $\mathcal{N}_7 \subset \mathcal{P}_7$ is the set of all 7-lists, whose complements belong to $\mathcal{N}_3$. In other words, $\mathcal{N}_7$ is the type of all lists that can be expressed as $\text{int}(X)$ for some 2-element subset X of $\{1, \dots, 5\}$.

If $\mathcal{A}$ and $\mathcal{B}$ are two types, we write $\mathcal{B} \geq \mathcal{A}$ if every list in $\mathcal{B}$ has a (not necessarily proper) subset that belongs to $\mathcal{A}$. That is, the lists in $\mathcal{B}$ are “greater” than the lists in $\mathcal{A}$. In particular, if $\mathcal{B} \geq \mathcal{A}$ and a coloring can be extended to a vertex whose list of available colors belongs to $\mathcal{A}$, then the coloring can also be extended to the same vertex with a list from $\mathcal{B}$. Obviously, if $\mathcal{B} \subseteq \mathcal{A}$, then $\mathcal{B} \geq \mathcal{A}$. Also, $\mathcal{P}_m \geq \mathcal{P}_n$ for $m \geq n$.

LEMMA 5. *The following relations hold:*

- (1) $\mathcal{P}_7 \geq \mathcal{N}_3$, and
- (2) $\mathcal{P}_9 \geq \mathcal{N}_7$.

Proof. Consider the first claim. We may assume that there exists a set X of seven color-pairs that does not contain a subset in $\mathcal{N}_3$. Each of the color-pairs has two elements; therefore, there must be a color that belongs to at least three color-pairs

in X . We may assume that these color-pairs are $\{1, 2\}$, $\{1, 3\}$, and $\{1, 4\}$. Hence, the color-pairs $\{2, 3\}$, $\{2, 4\}$, and $\{3, 4\}$ cannot belong to X . By the size of X , all remaining color-pairs must belong to X . In particular, $\{1, 5\}$ and $\{2, 5\}$ belong to X and together with $\{1, 2\}$ they form a list from $\mathcal{N}_3$, which is a contradiction.

Let us now prove the second claim. Let X be an arbitrary list in $\mathcal{P}_9$, i.e., $X = \mathcal{P} \setminus \{p\}$ for a color-pair p . Let Y be any 2-element subset of $\{1, \dots, 5\} \setminus p$. The set $\text{int}(Y) \in \mathcal{N}_7$ is a subset of X , witnessing that $\mathcal{P}_9 \geq \mathcal{N}_7$. $\square$

We say that a color-pair p_1 *forbids* a color-pair p_2 if p_1 and p_2 are not disjoint, and that a list L *forbids* a color-pair p if every color-pair in L forbids p . This means that if vertices u and v are adjacent and the color of u belongs to L , then the color of v cannot be p ; conversely, if the color of v is p , then we cannot color u from the list L . We often use a counting argument—if we determine that less than 10 color-pairs can be forbidden at a vertex v by a coloring of some of its neighbors, such a coloring can be extended to the vertex v . A color-pair that is not forbidden is called *free*.

So far, we were using the terms “configuration” and “reducible” intuitively. Let us now define them formally using the concept of types. A *configuration* C is a graph $G_C = (V_C, E_C)$ together with a function $\text{type}_C : V_C \rightarrow \wp(\mathcal{P}_{\text{all}})$ that assigns a type to each vertex of C . Let us remark that we only consider configurations that do not contain precolored vertices of the face O_H . The configuration represents an induced subgraph of H whose reducibility we study. We want to show that any precoloring of the vertices of $V(H) \setminus V_C$ can be extended to a $(5, 2)$ -coloring of the whole H . The types of the vertices of the configuration reflect the constraints imposed by colors of vertices of $V(H) \setminus V_C$ —each proper $(5, 2)$ -coloring of $V(H) \setminus V_C$ gives us a list of free colors at each vertex v of C , and the type of v in the configuration consists of all such lists.

An *instance* Q of the configuration C is a function from V_C to $\mathcal{P}_{\text{all}}$ such that $Q(v) \in \text{type}_C(v)$ for each vertex v . The instance Q is *colorable* if there exists a proper coloring c of G_C such that $c(v) \in Q(v)$ for each vertex of C . The configuration C is *reducible* if each instance of C is colorable.

Note that if $\mathcal{X}$ and $\mathcal{Y}$ are types with $\mathcal{X} \geq \mathcal{Y}$ and we change the type of a vertex in a reducible configuration from $\mathcal{Y}$ to $\mathcal{X}$, then the new configuration is reducible as well. We use the following notation to simplify the descriptions of configurations. If $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_k$ are types, then $\text{path}(\mathcal{X}_1 \mathcal{X}_2 \dots \mathcal{X}_n)$ is a path $v_1 v_2 \dots v_n$ on n vertices with $\text{type}(v_i) = \mathcal{X}_i$ for each i . Similarly, $\text{cycle}(\mathcal{X}_1 \mathcal{X}_2 \dots \mathcal{X}_n)$ is a cycle $v_1 v_2 \dots v_n$ on n vertices with $\text{type}(v_i) = \mathcal{X}_i$.

LEMMA 6. *The following configurations are reducible:*

- (1) $\text{path}(\mathcal{P}_1 \mathcal{P}_8)$,
- (2) $\text{path}(\mathcal{P}_2 \mathcal{P}_6)$,
- (3) $\text{path}(\mathcal{P}_3 \mathcal{P}_5)$, and
- (4) $\text{path}(\mathcal{N}_4 \mathcal{P}_4)$.

Proof. Observe that a configuration $\text{path}(\mathcal{X} \mathcal{P}_n)$ is reducible if and only if every list in $\mathcal{X}$ forbids at most $n - 1$ color-pairs. In the rest of this proof, let a, b, c, d , and e be mutually distinct elements of $\{1, \dots, 5\}$. Let us consider the configurations separately as follows:

- (1) A single color-pair $\{a, b\}$ forbids exactly the seven color-pairs of $\text{int}(\{a, b\})$; therefore, $\text{path}(\mathcal{P}_1 \mathcal{P}_8)$ is reducible.
- (2) If the two color-pairs are disjoint, say $\{a, b\}$ and $\{c, d\}$, then they forbid four color-pairs $\{a, c\}$, $\{a, d\}$, $\{b, c\}$, and $\{b, d\}$. Otherwise they share a common element, say, the pairs are $\{a, b\}$ and $\{a, c\}$; then they forbid five color-pairs—the four color-pairs that contain a and the color-pair $\{b, c\}$. Therefore, $\text{path}(\mathcal{P}_2 \mathcal{P}_6)$ is reducible.

(3) Without loss of generality, there are the following four possibilities for three color-pairs:

- $\{a, b\}$, $\{a, c\}$, and $\{a, d\}$, forbidding the four color-pairs that contain a .
- $\{a, b\}$, $\{a, c\}$, and $\{b, c\}$, forbidding three color-pairs $\{a, b\}$, $\{a, c\}$, and $\{b, c\}$.
- $\{a, b\}$, $\{a, c\}$, and $\{b, d\}$, forbidding three color-pairs $\{a, b\}$, $\{a, d\}$, and $\{b, c\}$.
- $\{a, b\}$, $\{a, c\}$, and $\{d, e\}$, forbidding two color-pairs $\{a, d\}$ and $\{a, e\}$.

Therefore, $\text{path}(\mathcal{P}_3 \mathcal{P}_5)$ is reducible.

(4) Note that if a list X is a subset of a list Y and X forbids n color-pairs, then Y forbids at most n color-pairs. If L is any list from $\mathcal{N}_4$, then there is a list $L' \subset L$ of size three such that the intersection of elements of L' is empty. But such a list L' forbids at most three color-pairs, as follows from the proof of the previous claim of this lemma. Therefore, L also forbids at most three color-pairs, and hence $\text{path}(\mathcal{N}_4 \mathcal{P}_4)$ is reducible. $\square$

Before we proceed with the next lemma, let us introduce the following convention: We use $\mathcal{X}^*$ inside a path or a cycle description of a configuration for an arbitrarily long (possibly empty) chain of vertices of type $\mathcal{X}$. For example, $\text{path}(\mathcal{P}_2 \mathcal{P}_7^* \mathcal{P}_9)$ may be any of $\text{path}(\mathcal{P}_2 \mathcal{P}_9)$, $\text{path}(\mathcal{P}_2 \mathcal{P}_7 \mathcal{P}_9)$, $\text{path}(\mathcal{P}_2 \mathcal{P}_7 \mathcal{P}_7 \mathcal{P}_9)$, etc.

Note that a chain of vertices of type $\mathcal{P}_7$ “propagates” the type of the vertex adjacent to it. For example, let $uv_1v_2 \dots v_kw$ be a path, let the type of u be $\mathcal{P}_6$ (or any other type $\mathcal{X} \geq \mathcal{P}_6$), and let the type of each v_i ($1 \leq i \leq k$) be $\mathcal{P}_7$. Let Q be an instance of this configuration. The list $Q(u)$ forbids at most one color-pair q , because $\text{path}(\mathcal{P}_6 \mathcal{P}_2)$ is reducible by Lemma 6(2). Let $Q_1 = Q(v_1) \setminus \{q\}$ be the list of v_1 without the forbidden color-pair. The size of Q_1 is at least six, and thus it also forbids at most one color-pair q_1 in the list of v_2 . Similarly the list $Q_2 = Q(v_2) \setminus \{q_1\}$ forbids at most one color-pair in the list of v_3 , etc. Finally, the nonforbidden part of $Q(v_k)$ forbids at most one color-pair in $Q(w)$. This in particular means that if $|Q(w)| > 1$, we may color the vertex w by a remaining color and then choose a free color for $v_k, v_{k-1}, \dots, v_1$, and u . Thus, we can say that $\text{path}(\mathcal{P}_6 \mathcal{P}_7^*)$ behaves as $\text{path}(\mathcal{P}_6)$. Similarly, since a list in $\mathcal{P}_5$ forbids at most two color-pairs by Lemma 6(3), $\text{path}(\mathcal{P}_5 \mathcal{P}_7^*)$ behaves as $\text{path}(\mathcal{P}_5)$, and since a list in $\mathcal{P}_2$ forbids five color-pairs by Lemma 6(2), $\text{path}(\mathcal{P}_2 \mathcal{P}_7^*)$ behaves as $\text{path}(\mathcal{P}_2)$. The lists in types $\mathcal{P}_4$ and $\mathcal{P}_3$ may forbid four color-pairs by Lemma 6(3), so $\text{path}(\mathcal{P}_4 \mathcal{P}_7^*)$ and $\text{path}(\mathcal{P}_3 \mathcal{P}_7^*)$ behave as $\text{path}(\mathcal{P}_3)$.

LEMMA 7. *The following configurations are reducible:*

- (1) $\text{path}(\mathcal{P}_2 \mathcal{P}_8 \mathcal{P}_5)$,
- (2) $\text{path}(\mathcal{P}_2 \mathcal{P}_7^* \mathcal{P}_{10} \mathcal{P}_7^* \mathcal{P}_2)$, and
- (3) $\text{path}(\mathcal{P}_2 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_3)$.

Proof. Let us prove the reducibility of each of the configurations separately.

- (1) The reducibility of the configuration $\text{path}(\mathcal{P}_2 \mathcal{P}_8 \mathcal{P}_5)$ is a simple consequence of Lemma 6(2), (3). A vertex with a list from type $\mathcal{P}_2$ forbids at most five color-pairs. A vertex with a list from type $\mathcal{P}_5$ forbids at most two color-pairs. Therefore, there is at least one free color-pair in the list of the vertex of type $\mathcal{P}_8$.
- (2) Since the type of vertices propagates through the chain of vertices of type $\mathcal{P}_7$, it is sufficient to show that $\text{path}(\mathcal{P}_2 \mathcal{P}_{10} \mathcal{P}_2)$ is reducible. Let $v_1v_2v_3$ be the configuration and let Q be an instance of the configuration. A vertex of type $\mathcal{P}_2$ forbids at most five color-pairs. If either $Q(v_1)$ or $Q(v_3)$ forbids less than five color-pairs at v_2 , then the instance is colorable. By the proof of Lemma 6(2), a list $L \in \mathcal{P}_2$ can forbid five color-pairs only if the color-pairs in

L intersect each other. Suppose that both $Q(v_1)$ and $Q(v_3)$ forbid five color-pairs. Let a be the intersection of color-pairs in $Q(v_1)$ and b the intersection of color-pairs in $Q(v_3)$. If $a \neq b$, then let $p = \{a, b\}$; otherwise let p be any color-pair that contains a . Observe that p is forbidden by both $Q(v_1)$ and $Q(v_3)$. This means that the total number of forbidden color-pairs in $Q(v_2)$ is at most nine; hence the instance is colorable.

- (3) We argue similarly to the previous claim that it suffices to show that $\text{path}(\mathcal{P}_2 \mathcal{P}_9 \mathcal{P}_3)$ is reducible. We use an argument similar to the previous case. Let $v_1 v_2 v_3$ be the configuration and let Q be an instance of the configuration. A vertex of type $\mathcal{P}_2$ forbids at most five color-pairs and a vertex of type $\mathcal{P}_3$ forbids at most four color-pairs. Therefore, if the instance is not colorable, $Q(v_1)$ must forbid precisely five color-pairs and $Q(v_3)$ must forbid precisely four color-pairs. The proofs of Lemma 6(2), (3) show that this may happen only if both $\bigcap_{p \in Q(v_1)} p \neq \emptyset$ and $\bigcap_{p \in Q(v_3)} p \neq \emptyset$. Let a be the element of intersection of $Q(v_1)$ and b the element of intersection of $Q(v_3)$. If $a \neq b$, then let $p = \{a, b\}$; otherwise let p be any color-pair that contains a . Observe that p is forbidden by both $Q(v_1)$ and $Q(v_3)$. This means that the total number of forbidden color-pairs in $Q(v_2)$ is at most eight, which shows that the instance is colorable. $\square$

LEMMA 8. *The configurations $\text{path}(\mathcal{P}_2 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_8 \mathcal{P}_7^* \mathcal{P}_2)$ are reducible.*

Proof. Let $v_1 v_2 \dots v_n$ be one of the configurations described by the statement of this lemma, and let Q be its instance. Since $\mathcal{P}_2$ propagates over a chain of vertices of type $\mathcal{P}_7^*$, it suffices to consider the case when v_2 has type $\mathcal{P}_9$ and v_{n-1} has type $\mathcal{P}_8$.

By Lemma 7(3), the configuration $\text{path}(\mathcal{P}_2 \mathcal{P}_9)$ on $v_1 v_2$ forbids at most two color-pairs at v_3 . If $n = 4$, then v_3 is of type $\mathcal{P}_8$, and hence $Q(v_3)$ contains at least six free color-pairs. This instance of the configuration $\text{path}(\mathcal{P}_6 \mathcal{P}_2)$ on $v_3 v_4$ is colorable by Lemma 6(2). If $n > 4$, then the type of v_3 is $\mathcal{P}_7$ and $Q(v_3)$ contains at least five free color-pairs. Since the type $\mathcal{P}_5$ propagates over chain of vertices of type $\mathcal{P}_7$, it suffices to show that the configuration $\text{path}(\mathcal{P}_5 \mathcal{P}_8 \mathcal{P}_2)$ is reducible. This follows by Lemma 7(1). $\square$

LEMMA 9. *The cyclic configurations $\text{cycle}(\mathcal{N}_3 X \mathcal{N}_3 \mathcal{P}_{10} \mathcal{P}_{10})$, where X is an arbitrary path consisting of one vertex of type $\mathcal{P}_9$ and at least three vertices of type $\mathcal{N}_7$, are reducible.*

Proof. Let $v_1 v_2 \dots v_k$ be one of these configurations, where v_1 and v_{k-2} are the vertices of type $\mathcal{N}_3$ and v_{k-1} and v_k have type $\mathcal{P}_{10}$. By symmetry, we may assume that the types of v_2 and v_3 are $\mathcal{N}_7$. Let Q be an instance of this configuration. We may assume that $Q(v_1) = \text{ss}(\{1, 2, 3\})$. By Lemma 4(2), any coloring of the vertices v_1 and v_{k-2} by distinct color-pairs can be extended to v_{k-1} and v_k .

Suppose first that $Q(v_{k-2}) \neq Q(v_1)$, and thus $|Q(v_{k-2}) \cap Q(v_1)| \leq 1$. Now restrict the configuration to the vertices $v_1, \dots, v_{k-2}$ and create an instance Q' such that $Q'(v_1) = Q(v_1) \setminus Q(v_{k-2})$ (i.e., a list that consists of at least two color-pairs) and $Q'(v_i) = Q(v_i)$ for $i > 1$. Every coloring of Q' can be extended to a coloring of Q by Lemma 4(2), and the instance Q' is colorable by Lemma 7(3). Hence, Q is colorable as well.

In the rest of the lemma, we assume that $Q(v_{k-2}) = Q(v_1)$. We know that $Q(v_2) = \text{int}(p)$, where p is some color-pair. Let us now consider the case that $p \notin Q(v_1)$. Without loss of generality, we may assume that either $p = \{1, 4\}$ or $p = \{4, 5\}$. Restrict the configuration to vertices $v_2, \dots, v_{k-2}$ and create an instance Q' such that $Q'(v_2) = \{\{1, 4\}, \{1, 5\}, \{4, 5\}\} \subset Q(v_2)$, $Q'(v_{k-2}) = \{\{1, 2\}, \{1, 3\}\}$ and $Q'(v_i) =$

$Q(v_i)$ for $2 < i < k - 2$. It is easy to check that any coloring of Q' can be extended to a coloring of Q , since for each color-pair in $Q'(v_2)$ we may color v_1 with $\{2, 3\}$. The instance Q' is colorable by Lemma 7(3). Thus, Q is colorable as well.

Now we consider the case $p \in Q(v_1)$. Without loss of generality, we may assume $p = \{1, 2\}$ and $Q(v_3) = \text{int}(q)$, where q is one of the following color-pairs: $\{1, 2\}$, $\{1, 3\}$, $\{1, 5\}$, $\{3, 5\}$, or $\{4, 5\}$. Let us fix $c(v_1) = \{1, 3\}$; then, the free color-pairs at v_2 are $\{2, 4\}$ and $\{2, 5\}$. Consider the configuration restricted to vertices $v_3, \dots, v_{k-2}$. Let Q' be the instance such that $Q'(v_{k-2}) = \{\{1, 2\}, \{2, 3\}\}$, $Q'(v_i) = Q(v_i)$ for $4 < i < k - 2$ and $Q'(v_3)$ is the list of color-pairs that are not forbidden by the free color-pairs $\{\{2, 4\}, \{2, 5\}\}$ of v_2 . That is,

- if $1 \in q$, then $\{\{1, 3\}, \{1, 4\}, \{1, 5\}\} \subseteq Q'(v_3)$.
- if $q = \{3, 5\}$ or $q = \{4, 5\}$, then $\{\{1, 5\}, \{3, 4\}, \{3, 5\}\} \subseteq Q'(v_3)$.

The instance Q' is colorable by Lemma 7(3). We have chosen the list of v_3 such that the color $c(v_3)$ forbids at most one color-pair at v_2 ; thus we can color v_2 by $\{2, 4\}$ or $\{2, 5\}$. Since $c(v_1) \neq c(v_{k-2})$, this coloring can be extended by Lemma 4(2) to the coloring of the whole configuration; thus finishing the proof of this lemma. $\square$

We define the following operations on types:

- $\text{cut}_1(\mathcal{X}) = \{X'; (\exists X \in \mathcal{X}) X' \subseteq X, |X \setminus X'| \leq 1\}$, i.e., the lists in this set can be obtained from those in $\mathcal{X}$ by removing at most one color-pair.
- $\text{cut}_3(\mathcal{X}) = \{X'; (\exists X \in \mathcal{X}) (\exists p \in \mathcal{P}) X' = X \cap \text{int}(p)\}$, i.e., the lists in this set can be obtained from those in $\mathcal{X}$ by removing color-pairs that are disjoint with a color-pair p .
- $\text{cut}_7(\mathcal{X}) = \{X'; (\exists X \in \mathcal{X}) (\exists p \in \mathcal{P}) X' = X \setminus \text{int}(p)\}$, i.e., the lists in this set can be obtained from those in $\mathcal{X}$ by removing color-pairs that intersect a color-pair p .

Let us write cut_a^k for applying k times the operation cut_a ; in particular, cut_a^0 is the identity. These operations are used to reflect the effect of precoloring a vertex of a configuration to the lists of remaining vertices—for example, if a list of a vertex v belongs to type $\mathcal{X}$ and we color a neighbor of v , the list of color-pairs that are not forbidden by this precoloring belongs to type $\text{cut}_7(\mathcal{X})$. Note that the operations commute with each other; i.e., $\text{cut}_a(\text{cut}_b(\mathcal{X})) = \text{cut}_b(\text{cut}_a(\mathcal{X}))$ for each $a, b \in \{1, 3, 7\}$. The index of the cut operator describes the number of colors removed from the lists; i.e., at most a colors are removed from each list of $\mathcal{X}$ in $\text{cut}_a(\mathcal{X})$ for $a \in \{1, 3, 7\}$.

LEMMA 10. *The following relations hold:*

- (1) $\text{cut}_1(\mathcal{P}_n) \geq \mathcal{P}_{n-1}$,
- (2) $\text{cut}_3(\mathcal{P}_{10}) = \mathcal{N}_7$,
- (3) $\text{cut}_7(\mathcal{P}_{10}) = \mathcal{N}_3$, and
- (4) $\text{cut}_3^2(\mathcal{P}_{10}) \geq \mathcal{N}_4$.

Proof. The first three claims are trivial. Let us consider the fourth one. Let $L \in \text{cut}_3^2(\mathcal{P}_{10})$. Note that $|L| \geq 4$. If $|L| \geq 5$, then L obviously contains four color-pairs whose intersection is empty. Thus, we need only consider the case when $|L| = 4$. This happens only when the color-pairs p_1 and p_2 used to obtain L from $\mathcal{P}_{10}$ by cut_3 operations are disjoint. We may assume that $p_1 = \{1, 2\}$ and $p_2 = \{3, 4\}$. The list $L = \{\{1, 3\}, \{1, 4\}, \{2, 3\}, \{2, 4\}\}$ belongs to $\mathcal{N}_4$, thus proving the fourth relation. $\square$

A vertex is called *important* if its degree is at least 3, and an edge is called *important* if both of its vertices are important. Let us call a path with k inner vertices of degree 2 connecting two important vertices a k -link. In particular, an important edge is a 0-link. Links with $k > 0$ are called *proper*. By Lemma 4(3), only 0-, 1-, and 2-links may appear in H .

Let G be a fixed subgraph and v an important vertex belonging to G . We say that G is *closed* with respect to v if all links incident to v are either completely contained in G (including the other important vertex of the link) or share only the vertex v with G . For such a vertex v , let $U(v)$ be the set of important vertices that do not belong to G and that are joined with v by a link, and let $U^*(v)$ be the set consisting of v vertices in $U(v)$ and the vertices of the links connecting v to vertices of $U(v)$. Suppose that v is joined by n_k k -links to vertices in $U(v)$ for $0 \leq k \leq 2$. Let $\mathcal{U}_v = \text{cut}_7^{n_0}(\text{cut}_3^{n_1}(\text{cut}_1^{n_2}(\mathcal{P}_{10})))$. We say that G is closed if it is closed with respect to all important vertices in G .

The following lemma shows how we can determine the type of a vertex v in a configuration C from the links through that v is connected to vertices that do not belong to C . This lemma basically restates Lemma 4 and tells us that links to vertices of C can be eliminated and replaced by setting the types of vertices of the configuration using the appropriate cut operations.

LEMMA 11. *Let v be an important vertex of a subgraph G such that G is closed with respect to v . Let c be a proper coloring of the graph induced by $U(v)$. If L is the list of color-pairs p such that $c(v) = p$ for some extension of c to the subgraph induced by $U^*(v)$, then $L \in \mathcal{U}_v$.*

Proof. If $u \in U(v)$ is adjacent to v , then the color-pair $c(u)$ forbids all color-pairs that intersect $c(u)$ at v . By Lemma 4, if u is joined to v by a 1-link, then the color-pair $c(u)$ forbids all color-pairs that are disjoint with $c(u)$. Finally, if u is joined to v by a 2-link, then the color-pair $c(u)$ forbids the color-pair $c(u)$ at v . The operations cut_7 , cut_3 , and cut_1 modify the lists in the type they are applied to in the same way, and since the lists for all possible choices of the colors assigned to the vertices of $U(v)$ are included in $\mathcal{U}_v$, we infer that $L \in \mathcal{U}_v$. $\square$

If we determine the types of important vertices of an induced subgraph of H using Lemma 11 and the resulting configuration is reducible, then we obtain a contradiction with the fact that H is a counterexample to Theorem 3, as the following lemma shows. This provides us with a powerful tool for determining the subgraphs that cannot appear in H .

LEMMA 12. *Let G be a closed subgraph without precolored vertices. Let C be the configuration on G , where the type of each important vertex v of C is $\mathcal{U}_v$ and the type of each 2-vertex is $\mathcal{P}_{10}$. If the configuration C is reducible, then G cannot appear in H .*

Proof. Suppose for the sake of contradiction that G appears in H . Let $W = V_C \cup \bigcup_{v \in V_C} (U^*(v) \setminus U(v))$ be the set consisting of V_C and vertices of degree 2 contained in proper links that share only one vertex with C . Let $V' = V(H) \setminus W$. By the minimality of H , the subgraph induced by V' has a proper $(5, 2)$ -coloring c_1 .

Let v be an important vertex of C . Let F_v be the list of color-pairs that

- intersect the color-pair $c_1(u)$ for some neighbor u of v belonging to V' , or
- are disjoint with the color-pair $c_1(u)$ for some $u \in V'$ that is connected with v by a 1-link, or
- are equal to the color-pair $c_1(u)$ for some $u \in V'$ that is connected with v by a 2-link.

Let $L_v = \mathcal{P} \setminus F_v$. By Lemma 11, $L_v \in \mathcal{U}_v$. Let Q be the instance of C such that $Q(v) = L_v$ for each important vertex $v \in V(C)$ and $Q(v) = \mathcal{P}$ for each 2-vertex v of C . Since C is reducible, the instance Q is colorable. Let c_2 be a proper coloring c_2 of this instance.

Note that for two adjacent important vertices $u \in V'$ and $v \in C$, the color-pairs $c_1(u)$ and $c_2(v)$ are disjoint. Let $W' = W \setminus V_C$ be the set of 2-vertices that belong

to the links joining C with V' . Note that the vertices of W' do not belong to the precolored outer face of H , since the vertices of G do not belong to it either. Observe that we have chosen the lists L_v in such a way that the union of the colorings c_1 and c_2 can be extended to W' , using Lemma 4(1), (2). This yields a proper $(5, 2)$ -coloring of H , which is a contradiction. $\square$

4. Initial charge. We assign a charge to vertices and faces of H . For every $v \in V(H)$, we define the initial vertex charge $\text{ch}_0(v)$ as

$$\text{ch}_0(v) = \frac{7}{3}d(v) - 6,$$

where $d(v)$ denotes the degree of v in the graph H . Let $F(H)$ be the set of faces of the graph H . For every face $f \in F(H)$, distinct from O_H , we define the initial face charge $\text{ch}_0(f)$ as

$$\text{ch}_0(f) = \frac{2}{3}r(f) - 6,$$

where $r(f)$ denotes the length of f . The charge of the outer face O_H is set to $\frac{2}{3}r(O_H) + \frac{11}{2}$. By Euler's formula, the total amount of charge is

$$\begin{aligned} \sum_{v \in V(H)} \text{ch}_0(v) + \sum_{f \in F(H)} \text{ch}_0(f) &= \left(\frac{14}{3}|E(H)| - 6|V(H)| \right) \\ &\quad + \left(\frac{4}{3}|E(H)| - 6|F(H)| \right) + \frac{23}{2} \\ &= 6(|E(H)| - |V(H)| - |F(H)|) + \frac{23}{2} \\ &= -\frac{1}{2}. \end{aligned}$$

Here we see the charge assigned to the vertices of small degrees:

$d(v)$	2	3	4	5	6
$\text{ch}_0(v)$	$-\frac{4}{3}$	1	$\frac{10}{3}$	$\frac{17}{3}$	8

Note that the charge of each face f distinct from O_H is at least $\frac{2}{3}r(f) - 6 \geq 0$, since $r(f) \geq 9$. We redistribute the charge of the vertices in two phases such that the total amount of charge does not change. However, we show that in the minimal counterexample H , the final charge of each vertex and face is nonnegative, thus contradicting the existence of the minimal counterexample and proving Theorem 3.

5. First phase of discharging. In the first phase, we ensure that all 2-vertices have a nonnegative charge. We use the following redistribution rules to move a charge from the important vertices to links:

- (R1) If xyz is a 1-link in H such that x has degree 3, 4, or 5 and y is not precolored, then x sends $\frac{2}{3}$ to y .
- (R2) If $xyzv$ is a 2-link in H such that x has degree 3, 4, or 5 and y is not precolored, then x sends $\frac{4}{3}$ to y .
- (R3) If x is a vertex of degree at least 6 adjacent to a 2-vertex y , and y is not precolored, then x sends $\frac{4}{3}$ to y .
- (R4) If the length r of O_H is at most 8, the face O_H sends $\frac{4}{3}$ to each vertex incident to it.

FIG. 1. Reducible 3-vertex subgraphs.

The charge after the first phase is denoted by ch_1 . The charge of 2-vertices becomes nonnegative after the first phase. Furthermore, note that the charge of a vertex w of degree at least 6 is nonnegative:

$$\text{ch}_1(w) \geq \frac{7}{3}d(w) - 6 - \frac{4}{3}d(w) = d(w) - 6 \geq 0.$$

If the face O_H is precolored, then each vertex w of O_H has at least two neighbors to that it does not send any charge, and hence its charge is at least

$$(5.1) \quad \text{ch}_1(w) \geq \frac{7}{3}d(w) - 6 - \frac{4}{3}(d(w) - 2) + \frac{4}{3} = d(w) - 2 \geq 0.$$

The charge of inner faces does not change, and thus it is still nonnegative. The charge of O_H changes only if its length r is at most 8, and then the final charge of O_H is at least $(\frac{2}{3}r + \frac{11}{2}) - \frac{4}{3}r \geq \frac{1}{6}$. Therefore, the charge of each face after the first phase of discharging is nonnegative, and hence the sum of the charges of vertices is negative. In the rest of the paper, we only take into account the charge of vertices.

Let us now analyze the possible neighborhoods of important vertices of H . We first consider neighborhoods of 3-vertices.

LEMMA 13. *Subgraphs (a) and (b) in Figure 1 cannot appear in H unless the 3-vertex is precolored.*

Proof. Consider first the subgraph (a). Using Lemma 12, the type of x after the links are eliminated is $\text{cut}_3^3(\mathcal{P}_{10}) \geq \mathcal{P}_1$. Since a configuration consisting of a single vertex of type $\mathcal{P}_1$ is reducible, this subgraph cannot appear in H .

Now consider the subgraph (b). Let v_1, v_3 , and v_4 be the vertices adjacent to x_1, x_3 , and x_4 outside of the subgraph, respectively. Let c be a coloring of $H - \{x_1, x_2\}$. Note that $c(v_3) \neq c(v_4)$ because of the vertices x_3 and x_4 . The set of colors p such that the coloring c' defined by $c'(v_3) = c(v_3)$, $c'(v_4) = c(v_4)$, and $c'(x_3) = p$ is proper and can be extended to x_4 is $\text{int}(c(v_4)) \setminus \text{int}(c(v_3))$, and since $c(v_3) \neq c(v_4)$, this set has size at least two. Hence, we can change colors of x_3 and x_4 so that $c(x_3) \neq c(v_1)$. We extend the coloring c to vertices x_1 and x_2 using Lemma 4. Since H is not $(5, 2)$ -colorable, the subgraph (b) cannot appear in H . $\square$

The complete list of possible subgraphs in the neighborhood of a nonprecolored 3-vertex that do not contain one of these two reducible subgraphs is given in Figure 2. The final charge and the type of the central vertex when all incident proper links are eliminated (as in Lemma 11) are also shown in the figure. The edges of 1-links and 2-links are drawn thin and the important edges are drawn thick.

Let us now consider neighborhoods of 4-vertices.

FIG. 2. 3-vertex neighborhoods.

FIG. 3. A reducible 4-vertex subgraph.

LEMMA 14. If A_1 , A_2 , and A_3 are three subsets of $\{1, \dots, 5\}$ of size three, then there exists a color-pair that is a subset of two of the sets A_1 , A_2 , and A_3 . Consequently, $\text{cut}_3^3(\mathcal{P}_{10}) \geq \mathcal{P}_2$.

Proof. We may assume that $A_1 = \{1, 2, 3\}$. No two of the sets A_1 , A_2 , and A_3 may be disjoint, and thus we assume that $|A_1 \cap A_2| = |A_1 \cap A_3| = 1$. But then $\{4, 5\} \subset A_2, A_3$. $\square$

LEMMA 15. The subgraph B0 in Figure 3 cannot appear in H unless the 4-vertex is precolored.

Proof. By Lemma 14, $\mathcal{X} = \text{cut}_3^3(\mathcal{P}_{10}) \geq \mathcal{P}_2$. The type of the important vertex of the configuration is $\text{cut}_1(\mathcal{X}) \geq \mathcal{P}_1$, and the subgraph cannot appear in H by Lemma 12. $\square$

The complete list of possible subgraphs in the neighborhood of a nonprecolored 4-vertex that do not contain B0 is given in Figure 4. Next, we study neighborhoods of nonprecolored 5-vertices.

LEMMA 16. The subgraph C0 in Figure 5 cannot appear in H unless the 5-vertex is precolored.

Proof. The type of the important vertex of the configuration is $\text{cut}_1^3(\text{cut}_3^2(\mathcal{P}_{10})) \geq \mathcal{P}_1$, and the subgraph cannot appear in H by Lemma 12. $\square$

Let $d_{\text{imp}}(v)$ be the number of important neighbors of a vertex v of H . We show that vertices of large degree have a charge of at least $\frac{2d_{\text{imp}}(v)}{3}$, which will provide enough charge to distribute in the second phase of discharging.

LEMMA 17. If v is a 5-vertex in H such that $\text{ch}_1(v) < \frac{2d_{\text{imp}}(v)}{3}$, then v belongs to the subgraph C1 depicted in Figure 6.

Proof. If $d_{\text{imp}}(v) = 0$, then v would be incident to at most two 2-links by Lemma 16, and hence $\text{ch}_1(v) \geq \frac{17}{3} - 2 \cdot \frac{4}{3} - 3 \cdot \frac{2}{3} = 1$. If $d_{\text{imp}}(v) \geq 2$, then $\text{ch}_1(v) \geq \frac{17}{3} - (5 - d_{\text{imp}}(v))\frac{4}{3} = \frac{4d_{\text{imp}}(v)}{3} - 1 \geq \frac{2d_{\text{imp}}(v)}{3} + \frac{1}{3}$.

FIG. 4. 4-vertex neighborhoods.

FIG. 5. A reducible 5-vertex subgraph.

FIG. 6. Another 5-vertex subgraph.

Now we may assume that $d_{\text{imp}}(v) = 1$. If v is incident to a 1-link, then $\text{ch}_1(v) \geq \frac{17}{3} - 3 \cdot \frac{4}{3} - \frac{2}{3} = 1 > \frac{2}{3}$. Therefore, v is incident to four 2-links and belongs to the configuration C1. $\square$

Finally, we consider vertices of degree at least 6.

LEMMA 18. *Every vertex v of H of degree $d \geq 6$ has charge $\text{ch}_1(v) \geq \frac{2d_{\text{imp}}(v)}{3}$.*

Proof. The charge of v is at least

$$\frac{7}{3}d - 6 - (d - d_{\text{imp}}(v))\frac{4}{3} = d - 6 + \frac{4}{3}d_{\text{imp}}(v) \geq \frac{2d_{\text{imp}}(v)}{3}. \quad \square$$

6. Vertex classes and graph H' . After the first phase of discharging, some of the vertices still have a negative charge. In the second phase, we want to make the charge of all vertices nonnegative by moving the charge over the important edges. It turns out that it is always sufficient to move the charge at most $\frac{2}{3}$ over each edge, and thus we need only consider configurations consisting of vertices whose charge is smaller than $\frac{2}{3}d_{\text{imp}}$. We may classify the important vertices by type and charge after the first phase as follows:

- A. A 4-vertex v incident to one important edge and three 2-links (B2 in Figure 4). Its charge after the first stage is $-\frac{2}{3}$. By Lemma 11, when we consider reducibility of a configuration C containing v , and none of the three important vertices to that v is connected through the 2-links belongs to C , we may assume that the type of v is $\mathcal{P}_7$. For brevity we omit the references to Lemma 11 in the rest of the enumeration.
- B. A 3-vertex incident to one important edge and two 1-links (A1 in Figure 2). Its charge is $-\frac{1}{3}$, and when the 1-links are omitted, its type is $\mathcal{N}_4$.
- C. A 4-vertex incident to one important edge, one 1-link, and two 2-links (B3 in Figure 4), or a 5-vertex incident to one important edge and four 2-links (C1 in Figure 6). The charge of such a vertex is at least 0 and when the proper links are omitted, its type is $\geq \mathcal{P}_5$.
- D. A 3-vertex incident to two important edges and one 2-link (A2 in Figure 2). Its charge is $-\frac{1}{3}$ and when the 2-link is omitted, its type is $\mathcal{P}_9$.
- E. A 3-vertex incident to two important edges and one 1-link (A3 in Figure 2). Its charge is $\frac{1}{3}$ and when the 1-link is omitted, its type is $\mathcal{N}_7$.
- F. A 4-vertex incident to two important edges and two 2-links (B6 in Figure 4). Its charge is $\frac{2}{3}$ and when the 2-links are omitted, its type is $\mathcal{P}_8$.
- G. A 3-vertex incident to three important edges (A4 in Figure 2). Its charge is 1.
- H. A vertex incident to d important edges and with charge at least $\frac{2d}{3}$.

To distinguish the items in this classification from “types” introduced earlier, we say that the vertex described in the item $\mathcal{X}$ of this classification has *class* $\mathcal{X}$. If $\mathcal{X}$ and $\mathcal{Y}$ are classes, let us say that a vertex v is of class $(\mathcal{X}\mathcal{Y})$ if v is of class $\mathcal{X}$ or $\mathcal{Y}$.

We now want to restrict our attention to only the subgraphs of H that do not have enough charge. In order to do this, we create a new planar multigraph H in that we replace the parts of the graph H that have enough charge by vertices of class $\mathcal{H}$, which turn out to be easy to handle. More precisely, we obtain H' from H by iterating the following operation as long as possible: If there is an induced closed connected subgraph G with at least two important vertices such that G is joined to the rest of the graph by d important edges and the total charge of vertices in G is $c \geq \frac{2d}{3}$, then we contract this subgraph to a single vertex v . We keep the parallel edges that might arise during this operation, but we remove loops. We let the charge of v be c and its class $\mathcal{H}$. This operation does not change the total charge of the vertices, and thus it

is enough to prove that the total charge of vertices of H' is nonnegative in order to obtain a contradiction. Note that the construction does not necessarily determine H' uniquely, but it ensures that any closed connected subgraph of H' with at least two important vertices has a charge of at most $\frac{2}{3}$ per outgoing edge.

The following crucial observation enables us to work with the graph H' instead of H in the rest of the paper: The configurations whose reducibility we are going to consider do not contain vertices of class $\mathcal{H}$. We also never pose any assumptions on whether the vertices adjacent to the configurations we consider are distinct or not in the following proofs; in particular, decontracting the vertices of class $\mathcal{H}$ does not affect the reducibility of the configurations. Therefore, if we find a reducible configuration in H' , the corresponding configuration in H is reducible as well, thus obtaining a contradiction with the minimality of H .

If the outer face O_H is precolored, we contract it to a vertex of class $\mathcal{H}$ as the first step in the construction of H' : The degree of the created vertex is $\sum_{v \in O_H} (d(v) - 2)$, and each vertex v of the face has a charge of at least $d(v) - 2$ by the analysis we performed in section 5 (inequality (5.1)). Additionally, note that any cycle in H' of length less than 9 contains a vertex of class $\mathcal{H}$, and all parallel edges must be incident with at least one vertex of class $\mathcal{H}$.

7. Further reducible configurations. In this section we focus on the reducibility of the configurations in H' that have a negative charge. A *string* is a path or a cycle (if it matters, we use the terms *path string* and *cycle string* to distinguish between these two possibilities) in H' whose edges are all important and whose vertices do not have class $(\mathcal{GH})$. Vertices of class $(\mathcal{ABC})$ may, of course, be only the end vertices of a path string, while the inner vertices of a string must be of class $(\mathcal{DEF})$. A path string that contains a vertex of class $(\mathcal{ABC})$ is called a *leaf string*. Note that we do not impose any restrictions on where the proper links from the vertices of the string lead to (i.e., they may connect vertices inside the string). We call a string *spanned* in case there exists a proper link such that both of its important vertices belong to the string. The *charge* of a string is the sum of the charges of its vertices.

We use the notation $\text{path}(T_1 \dots T_k)$ and $\text{cycle}(T_1 \dots T_k)$ for the strings whose vertices have classes $T_1, \dots, T_k$, in the order of their occurrence on the path or the cycle. We let $\mathcal{X}^k$ stand for a path of k vertices of class $\mathcal{X}$. We also use the following notation for describing the inner vertices of strings: We let $(\mathcal{D}, \mathcal{EF})^{m,n}$ mean a string that consists of m vertices of class $\mathcal{D}$ and n vertices of class $(\mathcal{EF})$, in any order. We write $(\mathcal{D}, \mathcal{EF})^{\leq m,n}$ for a string that consists of at most m vertices of class $\mathcal{D}$ and exactly n vertices of class $(\mathcal{EF})$, in any order, and similarly for other possible combinations of numbers and $\geq$ or $\leq$. We sometimes use this notation inside $\text{path}(\dots)$ or $\text{cycle}(\dots)$ to denote a substring in this form. For example, $\text{path}((\mathcal{D}, \mathcal{EF})^{2,1})$ is one of the strings $\text{path}(\mathcal{D}^2 \mathcal{E})$, $\text{path}(\mathcal{D}^2 \mathcal{F})$, $\text{path}(\mathcal{D} \mathcal{E} \mathcal{D})$, $\text{path}(\mathcal{D} \mathcal{F} \mathcal{D})$, $\text{path}(\mathcal{E} \mathcal{D}^2)$, and $\text{path}(\mathcal{F} \mathcal{D}^2)$. For consistency, we also sometimes use $(\mathcal{D}, \mathcal{EF})^{0,n}$ for strings that consist entirely of vertices of class $(\mathcal{EF})$, and $(\mathcal{D}, \mathcal{EF})^{n,0}$ for strings that consist of only vertices of class $\mathcal{D}$.

In the following lemmas, we describe the strings in H' that are not reducible. Lemmas 19–21 deal with the leaf strings that contain a vertex of class $\mathcal{A}$, $\mathcal{B}$, or $\mathcal{C}$. Lemma 22 considers the nonleaf path strings. Finally, Lemma 23 shows that H' does not contain any cycle strings with negative charge (and thus no cycle strings at all, by construction of H').

LEMMA 19. *The strings in H' that are not reducible and that contain a vertex of class $\mathcal{A}$ are of the form $\text{path}(\mathcal{A}(\mathcal{D}, \mathcal{EF})^{0,\leq 3})$. Moreover, these strings are not spanned.*

Proof. Let s be a string in H' that contains a vertex of class $\mathcal{A}$. Note that if s is one of the strings from the statement of the lemma, s cannot be spanned, since every cycle in H' of length less than 9 contains a vertex of class $\mathcal{H}$.

Suppose now that s is not one of the strings described in the statement. The string s cannot contain more than three vertices of class $(\mathcal{EF})$ in a row; otherwise the charge of the substring formed by the vertices of class $(\mathcal{EF})$ would be at least $\frac{4}{3}$ and this substring would become a vertex of class $\mathcal{H}$ during the construction of the graph H' . Therefore, s must contain a substring s' of form $\text{path}(\mathcal{A}(\mathcal{D}, \mathcal{EF})^{0, \leq 3} \mathcal{X})$, where the class $\mathcal{X}$ is different from $(\mathcal{EF})$ (i.e., $\mathcal{X}$ is one of $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$, or $\mathcal{D}$).

Since H' does not contain a cycle of length less than 9 without a vertex of class $\mathcal{H}$, the string s' cannot be spanned. Therefore, s' is a closed subgraph of H' , and we may apply Lemma 11. Let us show that regardless of the choice of $\mathcal{X}$, the configuration C obtained from s' by the procedure described in statement of Lemma 11 is reducible. Let v be the vertex of s' with class $\mathcal{X}$.

According to the analysis we performed in section 6, the vertex of class $\mathcal{A}$ has type $\mathcal{P}_7$, and the vertices of class $(\mathcal{EF})$ have type at least $\mathcal{P}_7$. Similarly, if the class of v is $(\mathcal{ABC})$, its type is at least $\mathcal{P}_4$. If the class of v is $\mathcal{D}$, then v is incident to one edge and one 2-link outside of C , and thus its type is $\text{cut}_1(\text{cut}_7(\mathcal{P}_{10})) \geq \mathcal{P}_2$.

Therefore, it suffices to show that the configuration $\text{path}(\mathcal{P}_7^* \mathcal{P}_2)$ is reducible. By Lemma 6(2) and the fact that the type $\mathcal{P}_2$ propagates over vertices of type $\mathcal{P}_7$, this is indeed the case. It follows that s' cannot appear in H' . $\square$

LEMMA 20. *The strings in H' that are not reducible and that contain a vertex of class $\mathcal{B}$ are of the form $\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{0, \leq 2})$ or $\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{1, \leq 3})$. Moreover, these strings are not spanned.*

Proof. The string cannot contain a vertex of class $\mathcal{A}$ by Lemma 19. Let us consider several cases regarding the string of vertices of class $(\mathcal{DEF})$ adjacent to the vertex of class $\mathcal{B}$. Note that the string cannot contain more vertices of class $(\mathcal{EF})$ than specified in each of the cases; otherwise it would contain a subgraph with a charge of at least $\frac{2}{3}$ per outgoing important edge. None of the strings may be spanned; otherwise H' would contain a cycle of length at most 8 not containing a vertex of class $\mathcal{H}$.

$\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{0, \leq 1} \mathcal{B})$: By Lemma 11, it suffices to show that configurations $\text{path}(\mathcal{N}_4 \mathcal{N}_4)$ and $\text{path}(\mathcal{N}_4 \mathcal{P}_7 \mathcal{N}_4)$ are reducible. For the former one, this follows from Lemma 6(4). For the latter one, by Lemma 6(4), a list from $\mathcal{N}_4$ forbids at most three color-pairs, and hence we may always choose a color-pair that is not forbidden for the middle vertex.

$\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{\leq 1, \leq 1} \mathcal{C})$: The corresponding configuration $\text{path}(\mathcal{N}_4 \mathcal{P}_7^* \mathcal{P}_5)$ is reducible, as $\mathcal{P}_5$ is propagated over a chain of $\mathcal{P}_7$'s and the final configuration $\text{path}(\mathcal{N}_4 \mathcal{P}_5)$ is reducible by Lemma 6(4).

$\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{1, \leq 2} \mathcal{B})$: The corresponding configurations $\text{path}(\mathcal{N}_4 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{N}_4)$ are reducible by Lemma 7(3), since $\mathcal{N}_4 \geq \mathcal{P}_3$.

$\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{1, \leq 3})$: This is one of the configurations described in the statement of the lemma.

A string with prefix $\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{1, \leq 3} \mathcal{D})$: Let s be this prefix. Note that s cannot be spanned: In order to avoid a cycle of length at most 8, the link would have to be a 2-link between the end-vertices of the path. However, a vertex of class $\mathcal{B}$ is incident only to 1-links. Consequently, the string $\text{path}(\mathcal{B}(\mathcal{D}, \mathcal{EF})^{1, \leq 3} \mathcal{D})$ corresponds to a configuration $\text{path}(\mathcal{N}_4 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_2)$ —the type $\mathcal{P}_2$ of the last vertex of the path is obtained from $\mathcal{P}_9$ (the type of vertex of class $\mathcal{D}$) by applying operation cut_7 , to take into account the important vertex adjacent to it outside of the configuration. This configuration is reducible by Lemma 7(3).

This shows that indeed the only such strings in H' that are not reducible are the nonspanned strings described in the claim of this lemma. $\square$

LEMMA 21. *The strings in H' that are not reducible and that contain a vertex of class $\mathcal{C}$ are of the form $\text{path}(\mathcal{C}(\mathcal{D}, \mathcal{EF})^{0, \leq 1})$ or $\text{path}(\mathcal{C}(\mathcal{D}, \mathcal{EF})^{1, \leq 2})$. Moreover, these strings are not spanned.*

Proof. Let s be a string in H' that contains a vertex of class $\mathcal{C}$. By Lemmas 19 and 20, the string s cannot contain a vertex of class $(\mathcal{AB})$. We distinguish several cases. Note that in each of the cases the considered string cannot contain more vertices of class $(\mathcal{EF})$ than specified; otherwise s would contain a subgraph with charge at least $\frac{2}{3}$ per outgoing important edge and this subgraph would be eliminated during the construction of H' . The considered strings also cannot be spanned, since the length of the cycle would be less than 9. If s contains at least two vertices of class $\mathcal{D}$, then s has a prefix $\text{path}(\mathcal{C}(\mathcal{D}, \mathcal{EF})^{1, \leq 2} \mathcal{D})$. However, the corresponding configuration $\text{path}(\mathcal{P}_5 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_2)$ is reducible by Lemma 7(3). Otherwise, if s contains two vertices of class $\mathcal{C}$, then s is $\text{path}(\mathcal{C}(\mathcal{D}, \mathcal{EF})^{\leq 1, 0} \mathcal{C})$, but the corresponding configurations $\text{path}(\mathcal{P}_5 \mathcal{P}_5)$ and $\text{path}(\mathcal{P}_5 \mathcal{P}_9 \mathcal{P}_5)$ are reducible by Lemmas 6(3) and 7(3). Therefore, the only possible strings are indeed those described in the statement of this lemma. $\square$

Finally, there is a classification of path strings that are composed from vertices of class $(\mathcal{DEF})$ only. To simplify the arguments we characterize only the strings whose charge is negative.

LEMMA 22. *The path strings in H' that are not reducible, contain only vertices of class $(\mathcal{DEF})$, and have negative charge are nonspanned strings of one of the following forms: $\text{path}(\mathcal{D})$, $\text{path}((\mathcal{D}, \mathcal{EF})^{2, \leq 1})$, or $\text{path}((\mathcal{D}, \mathcal{EF})^{3, \leq 2})$.*

Proof. A string with m vertices of class $\mathcal{D}$ may contain at most $m - 1$ vertices of class $(\mathcal{EF})$ in order for it to have a negative charge. The strings described in the statement of this lemma are nonspanned, because the length of the cycle that a spanning link would create is at most 7.

Let us assume that $s = v_1 \dots v_k$ is a string in H' with a negative charge that consists of only vertices of class $(\mathcal{DEF})$ and that contains at least four vertices of class $\mathcal{D}$. We want to show that s is reducible. We may assume that s is minimal; i.e., it does not contain a substring with more than three vertices of class $\mathcal{D}$ and negative charge.

By the minimality of s , its substring $s' = v_2 \dots v_k$ either has nonnegative charge or contains at most three vertices of class $\mathcal{D}$. Since the charge of vertices of classes $(\mathcal{EF})$ is positive, this means that v_1 is of class $\mathcal{D}$. Similarly, the class of v_k is $\mathcal{D}$. Furthermore, if s contains more than four vertices of class $\mathcal{D}$, then v_2 and v_{k-1} must also be of class $\mathcal{D}$; otherwise we can remove the first (or the last) two vertices from s .

Since the charge of a vertex of class $\mathcal{D}$ is $-\frac{1}{3}$, if the charge of s is less than $-\frac{1}{3}$, the string s must contain exactly four vertices of class $\mathcal{D}$; otherwise we can remove the first vertex from s . In case the charge of s is exactly $-\frac{1}{3}$, the string s contains at most six vertices of class $\mathcal{D}$ —if there are at least 7 vertices of class $\mathcal{D}$, let s_1 be the shortest prefix of s that contains four vertices of class $\mathcal{D}$, and let s_2 be the suffix of s that starts at the last vertex of class $\mathcal{D}$ that belongs to s_1 . Obviously s_1 and s_2 both contain at least four vertices of class $\mathcal{D}$. Let c be the charge of s and c_i be the charge of s_i for $i = 1, 2$. The strings s_1 and s_2 share exactly one vertex of class $\mathcal{D}$, and hence $c = c_1 + c_2 + \frac{1}{3}$. Therefore, at least one of c_1 and c_2 must be negative, contradicting the minimality of s .

The string s must be spanned; otherwise by Lemma 8, the configuration $\text{path}(\mathcal{P}_2 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_9 \mathcal{P}_7^* \mathcal{P}_2)$ corresponding to s is reducible. It follows that there

are no minimal strings with a charge less than $-\frac{1}{3}$, since such strings consist of four vertices of class $\mathcal{D}$ and at most two vertices of class $(\mathcal{EF})$, and such strings cannot be spanned, as H' does not contain a cycle of length at most 8 without a vertex of class $\mathcal{H}$. Thus, we may assume that the charge of s is $-\frac{1}{3}$.

Let us first consider the case that s contains exactly four vertices of class $\mathcal{D}$. Such a string must contain three vertices of class $\mathcal{E}$ in order to be spanned, and there must be a 2-link between v_1 and v_7 . But the resulting configuration is reducible by Lemma 9.

If s contains five vertices of class $\mathcal{D}$, we consider several possibilities:

- *The string s contains four vertices of class $\mathcal{E}$.* The path $v_1 \dots v_8$ is a substring of s with four vertices of class $\mathcal{D}$ and four vertices of class $\mathcal{E}$. Let us recall that v_1, v_2 , and v_8 are vertices of class $\mathcal{D}$. The vertices of the configuration cannot be joined by a 1-link, because the vertices of class $\mathcal{D}$ are incident only to 2-links and the vertices of class $\mathcal{E}$ are too close to each other. As the vertices of class $\mathcal{E}$ are not incident with 2-links, there must be a 2-link joining two vertices of class $\mathcal{D}$. Let v_i and v_j ($i < j$) be two vertices joined by a 2-link such that $j - i$ is the smallest possible. The difference $j - i$ must be at least 6, and at least one of $v_{i+1}, \dots, v_{j-1}$ must be of class $\mathcal{D}$, since there are only four vertices of class $\mathcal{E}$. Therefore, the configuration $v_i \dots v_j$ together with the 2-link is reducible by Lemma 9.
- *The string s contains two vertices of class $\mathcal{E}$ and one vertex of class $\mathcal{F}$.* Let v_a be the vertex of s of class $\mathcal{D}$ different from v_1, v_2, v_7 , and v_8 , and let v_b be the vertex of class $\mathcal{F}$. By symmetry, we may assume that $a < b$. The vertices of class $(\mathcal{EF})$ cannot be all consecutive in s , since they would form a substring with charge $\frac{4}{3}$ that would be replaced by a vertex of class $\mathcal{H}$ during the construction of H' , and hence $a > 3$. Consider the substring $v_a \dots v_8$. The vertices v_a and v_8 are of class $\mathcal{D}$, and there is one more vertex of class $\mathcal{D}$ and a vertex of class $\mathcal{F}$ inside the substring. This substring is too short to be spanned and it is reducible by Lemma 8.
- *The string s contains two vertices of class $\mathcal{F}$.* We consider the substring on vertices $v_1 \dots v_6$. This substring cannot be spanned and it contains four vertices of class $\mathcal{D}$, and thus it is reducible by Lemma 8.

Finally, consider the case that s contains six vertices of class $\mathcal{D}$ and at most five vertices of class $(\mathcal{EF})$. We know that classes of v_1 and v_2 are $\mathcal{D}$. If classes of v_3 and v_4 are both $(\mathcal{EF})$, the substring on vertices $v_4 \dots v_k$ has negative charge, contradicting the minimality of s . Similarly, it is not possible for v_3 to have class $\mathcal{F}$. Since the string $\text{path}(\mathcal{D}^4)$ is reducible by Lemma 8, s cannot contain four consecutive vertices of class $\mathcal{D}$, and thus exactly one of v_3 and v_4 has class $\mathcal{D}$. Similarly, exactly one of v_{k-3} and v_{k-2} is of class $\mathcal{D}$. Since s has charge $-\frac{1}{3}$, it contains either five vertices of class $\mathcal{E}$, three vertices of class $\mathcal{E}$, and one of class $\mathcal{F}$, or one vertex of class $\mathcal{E}$ and two of class $\mathcal{F}$.

If s contains five vertices of class $\mathcal{E}$, considering that s cannot contain four consecutive vertices of class $\mathcal{E}$ by the construction of H' , it follows that s is equal to $s_1 = \text{path}(\mathcal{D}^2 \mathcal{E} \mathcal{D} \mathcal{E}^3 \mathcal{D} \mathcal{E} \mathcal{D}^2)$. If s contains three vertices of class $\mathcal{E}$ and one of class $\mathcal{F}$, it similarly follows that s is equal to $s_2 = \text{path}(\mathcal{D}^2 \mathcal{E} \mathcal{D} \mathcal{E} \mathcal{F} \mathcal{D} \mathcal{E} \mathcal{D}^2)$. In case s contains one vertex of class $\mathcal{E}$ and two of class $\mathcal{F}$, the classes of v_3 and v_7 cannot be $\mathcal{F}$ by the minimality of s . However, the two vertices of class $\mathcal{F}$ would then have to be adjacent in s . This is not possible, as their total charge is $\frac{4}{3}$ and they would be eliminated during the construction of H' .

The string s_1 contains a substring $s'_1 = \text{path}(\mathcal{D}^2 \mathcal{E} \mathcal{D} \mathcal{E}^3 \mathcal{D})$. If s'_1 is nonspanned, then it is reducible by Lemma 8. There may be a 2-link between two vertices of

class $\mathcal{D}$, but in that case s_1 together with the link is reducible by Lemma 9. The string s_2 contains a substring $\text{path}(\mathcal{D}\mathcal{E}\mathcal{D}\mathcal{E}\mathcal{F}\mathcal{D})$ that cannot be spanned, and hence is reducible by Lemma 8.

Therefore, the only nonleaf path strings with negative charge in H' are those listed in the statement of this lemma. $\square$

Let us now show that no cycle strings appear in H' .

LEMMA 23. *H' does not contain a cycle string.*

Proof. A cycle string consists of a vertices of class $(\mathcal{D}\mathcal{E}\mathcal{F})$, and thus its length must be at least 9. If its charge is negative, then it contains a substring of length 6 with a negative charge. Such a string cannot be spanned and it is reducible by Lemma 22. A cycle string has no outgoing important edges and it forms a closed subgraph, and hence if its charge is nonnegative, then it would be replaced by a vertex of class $\mathcal{H}$ during the construction of H' . Therefore, H' does not contain any cycle strings. $\square$

Let us note that strings in H' do not have large negative charge.

LEMMA 24. *Each leaf string in H' has a charge of at least $-\frac{2}{3}$, and each nonleaf path string has a charge of at least -1 .*

Proof. Let us inspect all possible strings. By Lemma 19, the leaf strings that contain a vertex of class $\mathcal{A}$ are of form $\text{path}(\mathcal{A}(\mathcal{D}, \mathcal{E}\mathcal{F})^{0, \leq 3})$, and thus their charge is at least $-\frac{2}{3}$.

By Lemma 20, the leaf strings that contain a vertex of class $\mathcal{B}$ contain only one such vertex and at most one vertex of class $\mathcal{D}$, and hence their charge is at least $-\frac{2}{3}$.

By Lemma 21, the leaf strings that contain a vertex of class $\mathcal{C}$ contain at most one vertex of class $\mathcal{D}$, and hence their charge is at least $-\frac{1}{3}$.

By Lemma 22, a nonleaf path string with a negative charge contains at most three vertices of class $\mathcal{D}$, and thus its charge is at least -1 . $\square$

8. Second phase of discharging. Now we are ready to perform the second phase of discharging in the graph H' . Note that all vertices whose charge after the first phase is negative are inside strings. A path string $s = v_1v_2 \dots v_k$ is *adjacent* to a vertex v of class $(\mathcal{GH})$ if v and v_1 are adjacent. A string is *maximal* if it is not a proper substring of another string in H' . In this phase, the vertices of classes $(\mathcal{GH})$ send a charge to the adjacent maximal strings, thus making the charge of the vertices in the strings nonnegative. We then argue that the vertices of class $\mathcal{G}$ with negative charge must belong to reducible configurations. The rules for discharging are the following:

- (R5) A vertex of class $\mathcal{H}$ sends a charge of $\frac{2}{3}$ to each adjacent maximal string.
- (R6) A vertex of class $\mathcal{G}$ adjacent to a maximal leaf string of charge $c < 0$ sends a charge of $-c$ to the string.
- (R7) A vertex of class $\mathcal{G}$ adjacent to a maximal nonleaf string of charge $c < 0$ sends $-\frac{c}{2}$ to the string.

Each vertex of class $\mathcal{H}$ sends a charge of at most $\frac{2}{3}$ per important edge by (R5), and thus its final charge is nonnegative. By Lemma 24, each leaf string in H' has a charge of at least $-\frac{2}{3}$ and each nonleaf path string has a charge of at least -1 . Therefore, each maximal leaf or path string with charge $c < 0$ receives a charge of at least $-c$ from the adjacent vertices of class $(\mathcal{GH})$ and its final charge is nonnegative. By Lemma 23, the cycle strings do not appear in H' . It remains to show that also the charge of vertices of class $\mathcal{G}$ is nonnegative. Let us start with some definitions and lemmas.

By the classification of the strings presented in the previous section, the maximal path strings with negative charge in H' are nonspanned, and we can divide them into the following sets according to the charge they receive from the adjacent vertices of $\mathcal{G}$:

- $C_{\frac{2}{3}}$ is the set of strings to which vertices of class $\mathcal{G}$ send $\frac{2}{3}$, i.e., $\text{path}(\mathcal{A})$ and $\text{path}(\mathcal{D}\mathcal{B})$.
- $C_{\frac{1}{2}}$ is the set containing a single string $\text{path}(\mathcal{D}^3)$ to which vertices of class $\mathcal{G}$ send $\frac{1}{2}$.
- $C_{\frac{1}{3}}$ is the set of strings to which vertices of class $\mathcal{G}$ send $\frac{1}{3}$, consisting of $\text{path}(\mathcal{E}\mathcal{A})$, $\text{path}(\mathcal{B})$, $\text{path}(\mathcal{E}\mathcal{D}\mathcal{B})$, $\text{path}(\mathcal{D}\mathcal{E}\mathcal{B})$, $\text{path}(\mathcal{D}\mathcal{C})$, $\text{path}(\mathcal{D}^2)$, and all path strings that consist of three vertices of class $\mathcal{D}$ and one of class $\mathcal{E}$.
- $C_{\frac{1}{6}}$ is the set of strings to which vertices of class $\mathcal{G}$ send $\frac{1}{6}$, consisting of all path strings with n_d vertices of class $\mathcal{D}$, n_e vertices of class $\mathcal{E}$, and n_f vertices of class $\mathcal{F}$, where the triple (n_d, n_e, n_f) is one of $(1, 0, 0)$, $(2, 1, 0)$, $(3, 0, 1)$, or $(3, 2, 0)$.

Let $C_{\text{all}} = C_{\frac{2}{3}} \cup C_{\frac{1}{2}} \cup C_{\frac{1}{3}} \cup C_{\frac{1}{6}}$. We are going to consider configurations formed by strings in C_{all} adjacent to a vertex of $\mathcal{G}$. The main problem is dealing with the spanned configurations. Since some of these strings are quite long, it is impossible to directly use the girth restriction to show that the configurations cannot be spanned. To solve this problem, we restrict our attention to prefixes of these strings that are short enough so that the girth argument is applicable. The following lemma claims that we can replace each string in C_{all} by a single vertex of type $\mathcal{P}_2$ when considering the reducibility of a subgraph of H' . We recommend that the reader recalls Lemma 12 and the related definitions at this point.

LEMMA 25. *Let G be a closed subgraph of H' and let s be a path string $v_1v_2 \dots v_k$ in G belonging to C_{all} such that the important vertex adjacent to v_1 distinct from v_2 also belongs to G , but (in case s is a nonleaf string) the important vertex adjacent to v_k distinct from v_{k-1} does not belong to G . Let K' be a configuration obtained from G by removing the vertices $v_2, \dots, v_k$ and the 2-vertices of the proper links incident with them and letting the type of each important vertex v of K' be $\mathcal{U}_v$. We create a configuration K from K' by changing the type of v_1 to $\mathcal{P}_2$. If K is reducible, then G is reducible as well.*

Proof. We proceed similarly as in the proof of Lemma 12. We consider G as a subgraph of H . Depending on s , we select a suitable number m ($2 \leq m \leq k+1$) as described below. Let W be the set consisting of $V(K)$, the vertices $v_2, v_3, \dots, v_{m-1}$, and the 2-vertices of the proper links incident to them, and $V' = V(H) \setminus W$. By the minimality of H , there exists a coloring c'_1 of the subgraph of H induced by V' . As we demonstrate below, it is possible to extend the coloring c'_1 to vertices $v_2, \dots, v_{m-1}$ in such a way that there are at least two free color-pairs a and b at v_1 , thus obtaining a partial coloring c_1 . We define the lists $L_v \in \mathcal{U}_v$ for each important vertex v in the same way as we did in the proof of Lemma 12. We now create an instance Q of K by setting $Q(v) = L_v$ for each important vertex v of K except for v_1 , and by setting $Q(v_1) = \{a, b\}$ and $Q(v) = \mathcal{P}$ for each 2-vertex of K . Since K is reducible, its instance Q has a coloring c_2 . As in the proof of Lemma 12, we observe that the union of the colorings c_1 and c_2 can be extended to a proper $(5, 2)$ -coloring of H . This will show the reducibility of G . It remains to show how to determine m and how to extend c'_1 to c_1 . We discuss several cases that cover all strings in C_{all} .

If $k = 1$ or the class of v_1 is $\mathcal{D}$, we set $m = 2$ and $c_1 = c'_1$. In this case, the class of v_1 is $(\mathcal{A}\mathcal{B}\mathcal{D})$, and $\mathcal{U}_v \geq \mathcal{P}_2$. This implies that for any coloring c_1 , the list L_v contains at least two color-pairs a and b as required.

If the class of v_1 is $\mathcal{E}$ and the class of v_2 is $(\mathcal{A}\mathcal{D})$, then we set $m = 3$. Similarly to the previous case, with respect to the coloring c'_1 , L_{v_2} contains at least two color-pairs a_1 and a_2 , and $L_{v_1} \in \mathcal{N}_7$. Suppose that $L_{v_1} = \text{int}(p)$. At least one of a_1 or a_2 (say a_1)

is distinct from p . Thus, a_1 forbids at most five color-pairs in L_{v_1} . We set $c_1(v_2) = a_1$ and $\{a, b\} \subseteq \text{int}(p) \setminus \text{int}(a_1)$.

If the class of v_1 and v_2 is $\mathcal{E}$ and the class of v_3 is $\mathcal{D}$, then we set $m = 4$. Similarly as in the previous case, there are at least two free colors at v_3 and we may choose a color for v_3 such that it keeps two free colors at v_2 . Repeating the same argument, we color v_2 in such a way that there are at least two free color-pairs at v_1 .

The remaining case is that the class of v_1 is $\mathcal{F}$ and the class of v_2 is $\mathcal{D}$. In this case we set $m = 3$. There are at least two free colors a_1 and a_2 at v_2 . Let L be a subset of L_{v_1} (where L_{v_1} is defined with respect to c'_1) that contains exactly eight color-pairs. It cannot be the case that both $\text{int}(a_1)$ and $\text{int}(a_2)$ are subsets of L , since $|\text{int}(a_1) \cup \text{int}(a_2)| \geq 9$. We may assume that $\text{int}(a_1) \not\subseteq L$, and hence $|L \setminus \text{int}(a_1)| \geq 2$. We color v_2 with the color-pair a_1 , which leaves at least two free color-pairs at v_1 . $\square$

A string in $C_{\frac{1}{3}} \cup C_{\frac{1}{2}}$ contains one of the following substrings adjacent to v : $\text{path}(\mathcal{E}\mathcal{D}^2)$, $\text{path}(\mathcal{E}\mathcal{D}\mathcal{B})$, $\text{path}(\mathcal{D}\mathcal{E}\mathcal{B})$, $\text{path}(\mathcal{D}\mathcal{E}\mathcal{D})$, $\text{path}(\mathcal{D}^2)$, $\text{path}(\mathcal{D}\mathcal{C})$, $\text{path}(\mathcal{E}\mathcal{A})$, or $\text{path}(\mathcal{B})$. Let $C_{\#}$ be the set consisting of these strings. We show that each of these strings forbids only a few color-pairs. Note that unlike in Lemma 25, here we must assume that there are no links from such a string to the rest of the configuration.

LEMMA 26. *Suppose that $s = v_1 \dots v_k \in C_{\#}$, and let us consider a closed configuration that includes s and a vertex v of class $\mathcal{G}$ adjacent to s , but contains neither any of the proper links incident to s nor (in case s is not a leaf string) the important vertex adjacent to v_k distinct from v_{k-1} . The string s forbids at most two color-pairs at v , with the exception of $\text{path}(\mathcal{B})$ which forbids at most three color-pairs.*

Proof. Let us consider the elements of $C_{\#}$ separately.

If $s = \text{path}(\mathcal{E}\mathcal{D}^2)$ or $s = \text{path}(\mathcal{E}\mathcal{D}\mathcal{B})$, then the type of v_1 is $\mathcal{N}_7$, the type of v_2 is $\mathcal{P}_9$, and the type of v_3 is $\geq \mathcal{P}_2$, by Lemma 12. By Lemma 7(3), the configuration $\text{path}(\mathcal{P}_3\mathcal{P}_7\mathcal{P}_9\mathcal{P}_2)$ is reducible, and thus the string s forbids at most two color-pairs at v .

Similarly, if $s = \text{path}(\mathcal{D}\mathcal{E}\mathcal{D})$ or $s = \text{path}(\mathcal{D}\mathcal{E}\mathcal{B})$, the type of v_1 is $\mathcal{P}_9$, the type of v_2 is $\mathcal{P}_7$, and the type of v_3 is $\geq \mathcal{P}_2$. Again by Lemma 7(3), the configuration $\text{path}(\mathcal{P}_3\mathcal{P}_9\mathcal{P}_7\mathcal{P}_2)$ is reducible and s forbids at most two color-pairs at v .

If $s = \text{path}(\mathcal{D}^2)$ or $s = \text{path}(\mathcal{D}\mathcal{C})$, then the type of v_1 is $\mathcal{P}_9$ and the type of v_2 is $\geq \mathcal{P}_2$. Since the configuration $\text{path}(\mathcal{P}_3\mathcal{P}_9\mathcal{P}_2)$ is reducible by Lemma 7(3), s forbids at most two color-pairs at v .

If $s = \text{path}(\mathcal{E}\mathcal{A})$, then the type of v_1 is $\mathcal{N}_7$ and the type of v_2 is $\mathcal{P}_7$. The vertex v_2 forbids at most one color-pair at v_1 , and v_1 then forbids at most one color-pair at v , by Lemma 6(2).

Finally, if $s = \text{path}(\mathcal{B})$, then the type of v_1 is $\mathcal{N}_4$, and it forbids at most three color-pairs at v by Lemma 6(4). $\square$

The strings in $C_{\frac{2}{3}} \cup C_{\frac{1}{2}}$ forbid even fewer color-pairs.

LEMMA 27. *Suppose that $s = v_1 \dots v_k \in C_{\frac{2}{3}} \cup C_{\frac{1}{2}}$, and let K be a configuration that includes s and a vertex v of class $\mathcal{G}$ adjacent to s , but contains neither any of the proper links incident to s nor (in case s is not a leaf string) the important vertex adjacent to v_k distinct from v_{k-1} . The string s forbids at most one color-pair at v .*

Proof. Let us consider each possible string separately.

If $s = \text{path}(\mathcal{A})$, then the type of v_1 is $\mathcal{P}_7$. By Lemma 6(2), the configuration $\text{path}(\mathcal{P}_2\mathcal{P}_7)$ is reducible, and thus s forbids at most one color-pair at v .

If $s = \text{path}(\mathcal{D}\mathcal{B})$, then the type of v_1 is $\mathcal{P}_9$ and the type of v_2 is $\mathcal{N}_4$. By Lemma 7(3), the configuration $\text{path}(\mathcal{P}_2\mathcal{P}_9\mathcal{N}_4)$ is reducible, thus showing that s forbids at most one color-pair at v .

Finally, if $s = \text{path}(\mathcal{D}^3)$, then the type of v_1 and v_2 is $\mathcal{P}_9$ and the type of v_3 is $\mathcal{P}_2$. By Lemma 8, the configuration $\text{path}(\mathcal{P}_2 \mathcal{P}_9 \mathcal{P}_9 \mathcal{P}_2)$ is reducible, thus also in this case, s forbids at most one color-pair at v . $\square$

We are now ready to show that the final charge of vertices of class $\mathcal{G}$ is nonnegative.

THEOREM 28. *The charge of each vertex of classes $(\mathcal{G})$ after the second phase of discharging is nonnegative.*

Proof. Let v be a vertex of class $\mathcal{G}$. The charge of v before the second phase is 1. We prove that if the charge of the vertex v would become negative after applying the rules (R5)–(R7), then the configuration in the neighborhood of v is reducible. If v is adjacent to at most one maximal string with a negative charge, then v sends at most one unit of charge by Lemma 24, and hence the final charge of v is nonnegative. The vertex v cannot be joined to a single string with negative charge through more than one edge; otherwise the string together with v forms a cycle of length less than 9. Let s_1 , s_2 , and s_3 be the strings adjacent to v . There are the following cases in that the charge of v after the second phase is negative (up to symmetry):

- s_1 belongs to $C_{\frac{2}{3}}$ and s_2 belong to $C_{\frac{2}{3}} \cup C_{\frac{1}{2}}$. The configuration formed by s_1 , v , and s_2 cannot be spanned by the girth constraints. By Lemma 27, each of s_1 and s_2 forbids at most one color-pair at v . The precoloring of s_3 forbids at most seven color-pairs at v . Since there is at least one free color-pair at v , the configuration is reducible.
- $s_1 \in C_{\frac{2}{3}}$, $s_2 \in C_{\frac{1}{3}}$, and $s_3 \in C_{\frac{1}{3}} \cup C_{\frac{1}{6}}$. Consider the configuration formed by v , s_1 , the prefix substring of s_2 contained in $C_{\#}$, and a single vertex of type $\mathcal{P}_2$ that replaces s_3 using Lemma 25. This configuration cannot be spanned. By Lemmas 27, 26, and 6(2), the strings forbid at most 1, 3, and 5 color-pairs at v , respectively. Therefore, there is a free color-pair at v and the configuration is reducible.
- $s_1, s_2 \in C_{\frac{1}{2}}$, and $s_3 \in C_{\frac{1}{6}} \cup C_{\frac{1}{3}} \cup C_{\frac{1}{2}}$. We consider the configuration formed by v , the substrings $\text{path}(\mathcal{D}^2) \in C_{\#}$ of s_1 and s_2 , and a vertex of type $\mathcal{P}_2$ that replaces the string s_3 using Lemma 25. This configuration cannot be spanned by the girth constraints. By Lemmas 26 and 6(2), the strings forbid at most two, two, and five color-pairs at v , respectively, and hence the configuration is reducible.
- $s_1 \in C_{\frac{1}{2}}$ and $s_2, s_3 \in C_{\frac{1}{3}}$. We consider the configuration formed by v , $s_1 = \text{path}(\mathcal{D}^3)$, the prefix substring s'_2 of s_2 that belongs to $C_{\#}$, and a vertex of type $\mathcal{P}_2$ that replaces s_3 . Consider first the case that the configuration is not spanned. By Lemmas 27, 26, and 6(2), the numbers of color-pairs forbidden by the strings at v are at most 1, 3, and 5, respectively, and hence the configuration is reducible.

Let us now consider the case that the configuration is spanned. By the girth restrictions, this can happen only if there is a 2-link from the last vertex of s_1 to s'_2 . The girth restrictions also exclude the case $s'_2 = \text{path}(\mathcal{B})$, and thus s'_2 forbids at most two color-pairs, by Lemma 26. We shorten s_1 to its substring $\text{path}(\mathcal{D}^2) \in C_{\#}$ in the configuration. The new configuration cannot be spanned, and by Lemmas 26 and 6(2), the numbers of forbidden color-pairs at v are at most two, two, and five, respectively. Therefore, this smaller configuration is reducible.

This shows that the charge of v is nonnegative after the second phase of discharging. $\square$

This is the last piece needed in order to finish the proof of our main result.

Proof of Theorem 3. We proceed by contradiction. We assume that H is a minimal counterexample to this theorem. We assign a charge to the vertices and faces of H as described in section 4 such that the total amount of charge is negative. We run the first phase of discharging over H as described in section 5, arguing that the charge of all faces and 2-vertices is nonnegative after this phase. We construct the graph H' described in section 6 such that the sum of the charges of vertices of H' is negative. Finally, we run the second phase of discharging as described in section 8. The final charge of each vertex of class $(\mathcal{GH})$ and of each string is nonnegative, which is a contradiction. $\square$

9. Conclusion. An immediate consequence of Theorem 1 is the following.

COROLLARY 29. *Every planar graph of girth at least 8 is $(5, 2)$ -colorable.*

From R. Naseraser we learned that no planar graph of odd-girth 7 is known that does not map to the Petersen graph. This motivates the following question.

PROBLEM 1. *Is there a planar graph of odd-girth 7 with fractional chromatic number greater than $\frac{5}{2}$? Or is there at least one that does not map to the Petersen graph?*

HAT GUESSING GAMES*

STEVE BUTLER[†], MOHAMMAD T. HAJIAGHAYI[‡], ROBERT D. KLEINBERG[§], AND
TOM LEIGHTON[¶]

Abstract. Hat problems have become a popular topic in recreational mathematics. In a typical hat problem, each of n players tries to guess the color of the hat he or she is wearing by looking at the colors of the hats worn by some of the other players. In this paper we consider several variants of the problem, united by the common theme that the guessing strategies are required to be deterministic and the objective is to maximize the number of correct answers in the worst case. We also summarize what is currently known about the worst-case analysis of deterministic hat guessing problems with a finite number of players.

Key words. hat game, deterministic strategies, sight graph, Tutte–Berge formula, hypercube

DOI. 10.1137/060652774

1. Introduction. Consider the following game. There are n distinguishable players and one adversary. The adversary will place on the heads of the players hats of k different colors, at which point players are allowed to see all hats but their own. No communication is allowed. Each player then makes a private guess as to what color of hat he or she is wearing. The goal of the players is to maximize the number of correct guesses.

To help players maximize their correct guesses, the players are allowed to meet before the hats are placed on their heads and to determine a public deterministic strategy (public in that everyone, including the adversary, knows the strategy, and deterministic in that the guesses are determined completely by the hat placement). What is the maximum number of correct guesses that can be guaranteed, and what strategy should be implemented to achieve the maximum?

These questions have been answered in [3, 9]. Here we will present the answers and consider some variations on the game, showing that they lead to some surprisingly subtle combinatorial and algorithmic problems and theorems. We proceed as follows. In the remainder of the introduction we answer these questions for the game as stated. In section 2 we consider what happens when players are not able to see everyone, which might be applicable as an abstraction of the problem of guessing information globally in a market or a decentralized computing system, in which each person (or software

agent) has only partial/local knowledge. In section 3 we give a hypercube interpretation of the game which gives insight into the nature of optimal strategies, and we explore a version of the hats game where the adversary has a restricted hat supply.

Hat guessing games have long been a popular source of problems in recreational mathematics, and variations of hat guessing games have recently attracted increasing attention [6], partly because of their connections with coding theory (particularly Hamming codes). As another example, Aggarwal et al. [1] have used hat problems in the design of deterministic auction mechanisms. When constructing truthful auction mechanisms, a mechanism designer must devise a procedure for assigning a price to each bidder based only on the bids of other players (or else she may have an incentive to lie about her bid), with the goal of charging many bidders a price which is close to their own bidders. Note the formal similarity to hat problems, in which the goal is to devise a procedure for assigning a guess to each player based only on the hat colors of other players, with the goal of assigning to many players a guess which matches their own hat colors. By exploiting this similarity between the two problems, Aggarwal et al. used hat guessing strategies for a variant of the balanced hat problem (discussed in section 3.1) to provide a generic procedure for converting a randomized auction into a deterministic auction with approximately the same revenue, in markets with single-parameter bidders and no supply constraints.

Finally, it is worth mentioning that the fact that we are considering deterministic strategies instead of randomized ones is very important in this paper. The main reason is that these deterministic strategies focus on the worst-case scenarios instead of average or even almost-all scenarios. As a result, for several problems in this paper obtaining a randomized algorithm which guesses a constant fraction of the desired hat colors on average is easy, though we cannot even guess one hat color or a constant number of hat colors deterministically (see sections 2.3 and 2.4).

1.1. A winning approach to the hat guessing game.

Example 1. Consider the case where there are 2 players and 2 colors of hats. Then a winning strategy for these players is to have the first player guess what the second player is wearing and the second player to guess the color opposite of what the first player is wearing. If they are wearing hats of the same color, then the first player guesses correctly. If they are wearing different colors, then the second player guesses correctly. In any case there is one correct guess (and one incorrect guess).

It is interesting to note that in this example the expected number of correct guesses is one, which is the same as if they had guessed randomly. What their strategy has done is eliminate the variance involved in the guessing. The other thing to note is that neither player has any idea who guessed correctly, but they do know collectively that one of them did. These two properties will hold in general.

We have the following general result, first proved for 2 colors by Winkler [9] and later generalized to k colors by Feige [3].

THEOREM 2. *If there are n players and hats of k different colors, then there exists a strategy guaranteeing at least $\lfloor n/k \rfloor$ correct guesses. No strategy can improve on this.*

Proof. We first demonstrate a strategy. Number the players 1 to n and the colors of the hats 1 to k . The i th player will guess as if the sum of all the hats (including his/her own) is congruent to $i \bmod k$. At least $\lfloor n/k \rfloor$ of the players will be acting correctly and will therefore guess correctly.

To see that this cannot be improved upon we use an averaging argument. If a player sees a particular placement of hats, then this player is in one of k situations

and will guess correctly in exactly one of these situations. Since there are k^{n-1} ways to place the hats on the remaining players, we see that each player will make k^{n-1} correct guesses over all possible placements of hats. Since there are n players and k^n ways to place the hats, then on average we have $nk^{n-1}/k^n = n/k$ correct guesses. It follows that the adversary can find some placement of hats with at most $\lfloor n/k \rfloor$ correct guesses. $\square$

2. Restricting our vision in the game. In the original version of the game every player can see every other player. In an actual implementation of the game with a large group of people this might be difficult to achieve. So we now consider a variation where each player sees some subset of the other players.

To do this we introduce another layer to the game. We consider the “sight graph” where the vertices are the players and we have a directed edge from $a \rightarrow b$ if player a can see player b . As an example, in the original version of the game the graph was the complete graph on n vertices. For a given sight graph G we will let $H(G)$ denote the maximum number of correct guesses that the players can guarantee using an optimal strategy when there are 2 colors of hats.

In this section we will first consider the undirected case, i.e., the case in which every directed edge (u, v) is accompanied by the reverse edge (v, u) . For this case, an exact answer to $H(G)$ is known. In the directed case no exact answer for $H(G)$ is known but simple lower and upper bounds do exist. Finally, we consider the case when there are more than 2 colors of hats, for which little is known.

2.1. The undirected case. When we have an undirected graph the obvious strategy is to have players pair up as best as possible. Then in each pair we can implement the strategy in Example 1. This shows that we can guarantee at least $|M|$ correct guesses, where M is a maximum matching of G . The next result shows that this cannot be improved upon.

THEOREM 3. *Let G be an undirected graph with M a maximum matching of G . Then $H(G) = |M|$.*

Proof. It remains to show that $H(G) \leq |M|$. To do this we use the Tutte–Berge formula [2, 8], which says that there is a subset U of the vertices such that

$$|M| = \frac{|V| + |U| - o(G - U)}{2},$$

where $o(G - U)$ is the number of connected components of the induced subgraph $G - U$ which have an odd number of vertices. For $j = o(G - U)$ let $W_1, \dots, W_j$ be the connected components of $G - U$, which have an odd number of vertices, and let Y be the union of all the connected components of $G - U$ which have an even number of vertices.

Given any strategy we place hats as follows. First, place hats on U arbitrarily. Having fixed the hat placement on U , the guess of each player in W_i is now completely determined by the hat placement on W_i (since the only other players that can be seen are U which have already been placed). Applying the arguments from Theorem 2 we see that there is some placement of hats on each W_i with at most $(|W_i| - 1)/2$ correct guesses. Similarly we can place hats on Y so that there are at most $|Y|/2$ correct guesses. Therefore the total number of correct guesses is bounded above by

$$|U| + \frac{|Y|}{2} + \frac{|W_1| - 1}{2} + \dots + \frac{|W_j| - 1}{2} = \frac{|V| + |U| - j}{2} = |M|.$$

This concludes the proof. $\square$

2.2. The directed case. For the directed case there is no obvious strategy to adopt, and no sharp bound for $H(G)$ is known. However, there exist simple upper and lower bounds, as shown in the following.

LEMMA 4. *Given a directed graph G let $c(G)$ denote the maximal number of vertex disjoint cycles in G , and let $F(G)$ denote the minimum number of vertices whose removal from G makes the graph acyclic. Then $c(G) \leq H(G) \leq F(G)$.*

Proof. The lower bound follows by noting that for every cycle we can guarantee one correct guess. For example, if we have a cycle $a_1 \rightarrow a_2 \rightarrow \cdots \rightarrow a_k \rightarrow a_1$, then by having players $a_1, \dots, a_{k-1}$ guess the opposite color of the next player and a_k guess the color of the hat that a_1 is wearing, we guarantee at least one correct guess.

For the upper bound we note that we can arrange the vertices in order so that the removal of $v_1, \dots, v_{F(G)}$ leaves the graph acyclic and the remaining vertices $v_{F(G)+1}, \dots, v_n$ are such that if $i > F(G)$ and there is an edge from v_i to v_j , then $j < i$. In other words for the last $n - F(G)$ vertices, all outgoing edges point to the left. We place hats on the first $F(G)$ players arbitrarily and then we can place hats on players $F(G) + 1$ to n in turn, choosing each of the last $n - F(G)$ hat colors so as to force the corresponding player to guess incorrectly, given the colors of the preceding players. $\square$

By a theorem of Reed et al. [4], formerly known as Younger's conjecture (namely, for every integer $k \geq 0$ there exists an integer $t \geq 0$ such that every digraph G has k vertex disjoint directed cycles, or G can be made acyclic by deleting at most t vertices), this implies a criterion for determining whether a family of directed graphs has an unbounded "hat number."

COROLLARY 5. *Let $\mathcal{G}$ be a set of finite directed graphs. The set $\{H(G) : G \in \mathcal{G}\}$ is unbounded if and only if the set $\{F(G) : G \in \mathcal{G}\}$ is unbounded.*

Neither bound in Lemma 4 is sharp. For the upper bound, the undirected triangle has $F(G) = 2$, but we know from Theorem 2 that $H(G) = 1$. An example showing that the lower bound is not sharp is a little more involved and is given below.

Example 6. Let G consist of a directed four cycle $a \rightarrow b \rightarrow c \rightarrow d \rightarrow a$ with a fifth node e joined to the other four by bidirected edges. This graph, shown in Figure 1, has $c(G) = 1$ and $H(G) = 2$.

To describe a strategy we will let A, B, C, D, E denote the actual colors of hats placed on players a, b, c, d, e respectively, while g_a, g_b, g_c, g_d, g_e denote their guesses. We can describe their strategy in mod 2 arithmetic as follows:

$$g_a = B + E; \quad g_b = C + E; \quad g_c = D + E; \quad g_d = A + E + 1;$$

$$g_e = \begin{cases} 1 & \text{if } (A + B, B + C, C + D, A + D + 1) \text{ has Hamming weight 1;} \\ 0 & \text{if } (A + B, B + C, C + D, A + D + 1) \text{ has Hamming weight 3.} \end{cases}$$

What happens is that the players a, b, c, d will make either one or three correct guesses, depending on what e is wearing. So e guesses as though his/her hat would force one correct guess among the other four players. Thus, either e guesses incorrectly and

FIG. 1.

there are three correct guesses among a, b, c, d ; or e guesses correctly and there is one correct guess among a, b, c, d for a total of two correct guesses.

Question. For an undirected graph G how do we calculate $H(G)$? The obvious algorithm for deciding if $H(G) \geq h$ requires nondeterministic exponential time nondeterministically comes up with a guessing strategy for the players, and then spends exponential time verifying that this strategy produces at least h correct answers on every input. We do not know if there is a more efficient algorithm for deciding if $H(G) \geq h$.

We note that in answering this question for directed graphs it suffices to consider graphs G which are strongly connected. In particular, $H(G) = \sum_k H(G_k)$ where G_k are the strongly connected components of G . The proof of this is similar to the argument of the upper bound in Lemma 4. Namely, we can order the strongly connected components so that there is an edge from G_i to G_j only if $i > j$. Then the adversary acts optimally on each of the connected components in turn.

A related question concerns the complexity of optimal guessing strategies. Define a guessing strategy with sight graph G to be *optimal* if it achieves at least $H(G)$ correct answers on every input. We saw in the proof of Theorem 3 that when G is undirected, there is always an optimal guessing strategy in which each player's guess is computed by evaluating a linear function (over the field with two elements) whose inputs are the other players' hat colors together with the constant 1. For directed graphs this is not the case. The sight graph in Example 6 has $H(G) = 2$, but the reader may verify by a simple case analysis that for every linear guessing strategy, there exists an input on which fewer than 2 players answer correctly.

Question. Is it true that for every directed graph G , there is an optimal guessing strategy in which every player's guess is computed by inserting the other players' hat colors into a Boolean circuit of size polynomial in $|G|$?

Note that an affirmative answer to this question would imply that the problem of deciding if $H(G) \geq h$ belongs to the complexity class Σ_2^P , providing a partial answer to the preceding question.

2.3. More than 2 colors of hats. Considerably less is known when there are more than 2 colors involved in the game. Let $H_k(G)$ denote the maximum number of correct guesses that the players can guarantee using an optimal strategy when there are k colors of hats. From the proof of Theorem 2, we know that $H_k(G) = 1$ when G is an undirected k -clique, and therefore $H_k(G) \geq \ell$ whenever G contains ℓ disjoint undirected k -cliques. However, it is possible to avoid k -cliques altogether and still guarantee at least one correct guess, as shown below.

THEOREM 7. *For every number k , there exists a bipartite graph G with $H_k(G) > 0$.*

Proof. Let G be a complete bipartite graph with $n = k - 1$ vertices on the left side and $m = k^{k^n}$ vertices on the right side. Let C denote the set of all k -colorings of the left side of G . Note that $|C| = k^n$ and $m = k^{|C|}$; hence m is equal to the number of mappings from C to $\{1, 2, \dots, k\}$. Pick a one-to-one correspondence between the vertices on the right side of G and the mappings from C to $\{1, 2, \dots, k\}$, and let each vertex on the right side of G guess its color using the corresponding mapping.

We will need the following claim.

Claim. Let c_R denote a fixed coloring of the right side of G , and let C' denote the set of all colorings c_L of the left side of G such that the combined coloring (c_L, c_R) causes every vertex on the right side to guess its color incorrectly. Then $|C'| < k$.

Now it's time to define the guessing strategies used by the vertices on the left side of G . Given the coloring of the right side, the set C' defined in the lemma above has

at most $n = k - 1$ elements. So let $c_1, c_2, \dots, c_n$ be a list of colorings which contains every element of C' . For $i = 1, 2, \dots, n$, vertex i on the left guesses that its color is $c_i(i)$. This guessing strategy (combined with the guessing strategy for the vertices on the right side as defined above) guarantees at least one correct answer. This is because the above claim guarantees that at least one vertex on the right side guesses correctly unless the coloring of the left side belongs to C' . But if the coloring of the left side belongs to C' , then it is equal to c_i for some i in $1, 2, \dots, n$, in which case vertex i on the left guesses its color correctly.

It remains to prove the claim. The proof follows from noting that if C' contains k distinct elements $c_1, c_2, \dots, c_k$, then there exists a function f from C to $\{1, 2, \dots, k\}$ which assumes k distinct values on the set $\{c_1, \dots, c_k\}$. Let v denote the vertex on the right side of G corresponding to f . Since the set $\{f(c_1), f(c_2), \dots, f(c_k)\}$ contains all k colors, we must have $f(c_i) = c_R(v)$ for some i in $1, 2, \dots, k$. Thus, the combined coloring (c_i, c_R) causes vertex v to guess its color correctly, contradicting our assumption that c_i belongs to C' , ending the proof. $\square$

Question. Is there a bipartite graph G satisfying $H_k(G) > 0$ whose size is polynomial in k ? What if, instead of bipartite, we consider k -clique-free graphs?

Question. Call an undirected sight graph G “edge-critical for the hats game with k colors” if G has the property that there exists a guessing strategy which guarantees at least one correct answer for the hats game with k colors, but no proper subgraph of G has this property. For $k = 2$, the only edge-critical graph is a 2-clique. For $k > 2$, there are at least two (undirected) edge-critical graphs, namely a k -clique and a subgraph of the complete bipartite $(k - 1)$ -by- (k^{k-1}) graph. For $k > 2$, are there infinitely many graphs which are edge-critical for the hats game with k colors?

We close this section by proving that $H_k(G) = 0$ whenever $k > 2$ and G is an undirected tree. This fact is a consequence of the following more general lemma.

LEMMA 8. *Suppose we are given an undirected tree T ; a guessing strategy Γ for the hat k -coloring problem on T ; a node v in T ; and a pair of colors c_1, c_2 . Then there exists a k -coloring ($k \geq 3$) of T such that every node guesses its color incorrectly, and the color of node v is either c_1 or c_2 .*
